Figure 5. CNN results tracking mIoU during training for the 80/10/10 split (left) and robot scanning split (right). Blue represents training data and green represents validation data.

Table 1. Network Evaluation Metrics

Dataset	Split	CCE	mIoU
80/10/10	Train	0.0182	76.0%
	Val.	0.0163	72.7%
	Test	0.0169	74.5%
Robotic Scanning Split	Train	0.0166	71.1%
	Val.	0.0560	79.5%
Pascal VOC 2012	Benchmark	n/a	77.3% [8]

The results measured by CCE and mIoU show the network achieves comparable results for delamination assessment when compared to its performance on benchmark datasets. However, numbers cannot be compared to existing delamination assessment methods, as no fully automated methods exist on a similar infrared image dataset. To review the quality of the method, the output of the network was assessed on its

ability to predict delaminations for a typical inspection. Figure 6 shows delamination locations predicted by the network. The first three examples show results on images of bridge deck soffits that contain a various number of delaminated locations. The results show that the proposed methodology is capable of detecting nearly all delaminations, while avoiding false positives.

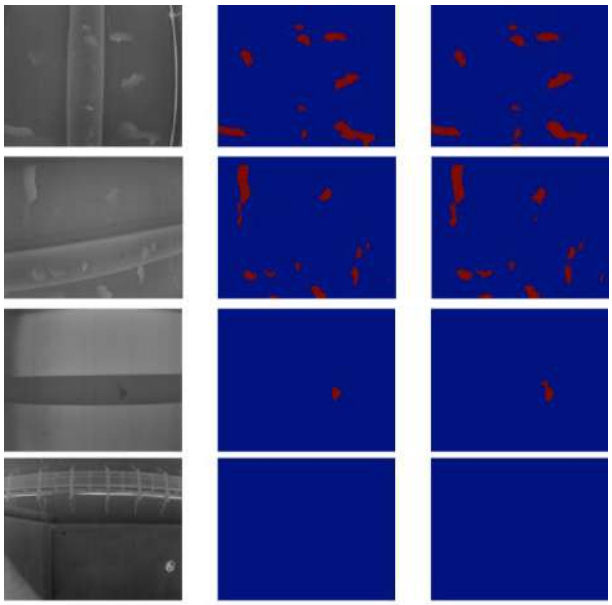

Figure 6. CNN example prediction results. Image (left), prediction (middle), true label (right).

The main source of error in these examples is the fine details. The edges of delaminations in the prediction are more rounded compared to the label, and small or thin delaminations are not well detected. This is a limitation based on the number of parameters used in the network and can be solved by adding more trainable parameters in the network. However, this limitation is not of great concern for concrete bridge inspection since precise knowledge of the delamination borders is not a requirement for bridge inspection. As discussed earlier, real-time visualization of the delamination assessment results is more valuable. In addition, traditional inspection procedures such as chain dragging and hammer sounding are not capable of precisely detecting edges and therefore this methodology is already a major improvement over current practice.

The fourth example in Figure 6 shows an example where there are a few potential areas that the network could falsely predict as a delamination. There is a scaffolding structure underneath the bridge, a small dark area and a small white area. In this case, the network successfully avoids false positives, showing that it has successfully learned some characteristics of a delamination and is not easily misled by similar artifacts.

It is also worth noting that the validation set of the robotic scanning split achieved the highest mIoU rating. This is most likely because the images taken by the robotic scan contained a large number of fairly clear delaminations. This is evidence that the quality of the image can influence the ability of the network to predict delamination locations.

5 Conclusion and Future Work

This work presents a novel automated concrete delamination assessment methodology using infrared imagery, robotics, and CNNs. A versatile pixel-wise defect labeler was first developed specifically for concrete bridge defects and was shown to help expedite the pixel-wise labelled image dataset creation. MobileNetV2 (Deeplab V3 implementation) was used to perform pixel-wise segmentation on infrared images of reinforced concrete bridges. This method was able to achieve high performance when evaluated on a data set of 500 infrared images by accurately detecting and locating delaminations under varying bridge environments. Quantitatively, the mIoU score for delamination assessment was shown to be comparable to what this network achieved on the Pascal VOC 2012 benchmark dataset. Qualitatively, the network was shown to predict delaminated areas correctly and avoid areas that have high potential to be classified as a false positive. The majority of the errors lowering the mIoU score are due to fine details around the edges of the delaminations which is of little concern to bridge inspections.

The network was also shown to be able to combine with a mobile ground robot (or any other unmanned mobile robotic platform). 62 images of a concrete bridge soffit and girder were taken by an upward facing compact infrared camera mounted on the robot and delaminated areas were predicted by the network. This test achieved high mIoU, which illustrates the ability of the delamination assessment network to integrate with robotic inspection. This is highly beneficial, as different unmanned robots can be used to accommodate specific accessibility limitations. Overall, this methodology presents significant improvements over state-of-the-art bridge inspection.

Future work will involve collecting a larger dataset to improve results, but a more complex network is likely not necessary as finer details are redundant for delamination assessment. In addition to more data, a quantitative comparison will be performed between the automated robotic assessment results and results from traditional sounding methods. Lastly, this methodology will be extended to other concrete bridge defects such as spalls, cracks, corrosion stains, and exposed reinforcing bar in visible spectrum images.

Abstract –

An essential component of effective safety management systems is the identification and proactive mitigation of hazards through the completion of job hazard assessment (JHA). Aimed at identifying potential hazards and subsequently implementing controls that reduce the likelihood or severity of incidents, JHA is a manual process influenced by the experiences, specific expertise, and biases of safety practitioners, rendering the development of standard mitigation strategies difficult in practice. Due to factors including ineffective information storage and dissemination systems, knowledge management of JHA data remains a challenge in the industry. To overcome these limitations, this paper proposes and describes the development and application of a web-based JHA system designed to enhance JHA management efficiency by facilitating accessibility, interfacing, connectivity, and information-sharing between users during the completion of JHAs. By increasing and facilitating access to information, the proposed system can enhance the consistency of JHAs generated throughout the organization, while also ensuring that potential safety risks are not overlooked by less experienced or otherwise biased personnel. Project and safety managers validated the functionality of the proposed system; they indicated that the proposed system could enhance the efficiency and consistency with which JHAs were generated, resulting in the improvement of real practice. The proposed system's importance is described, and its approach is detailed.

Safety; Job Hazard Assessment; Web-Based; Knowledge Management

1 Introduction

The construction phase of many projects has multiple potential hazards associated with various activities and tasks [1]. Many researchers have aimed to understand, identify, and analyze the root cause of construction-site incidents with the goal of reducing or preventing occupational hazards. These research efforts can be divided into two categories, namely: pre-hazard (proactive) analysis, and post-hazard (reactive) analysis [2]. Whereas reactive analysis research focuses on mitigating future reoccurrence by analyzing incidents that have occurred , proactive analysis research focuses on preventing incidents through advanced construction planning by analyzing factors that may result in potential hazards (e.g., equipment, height, or space requirements) [2]. Planning for safety typically involves the identification of all potential hazards and the selection of corresponding safety measures through a pre-hazard analysis process [3]. Effective safety planning can prevent incidents and the injury of construction personnel, in turn reducing associated project costs and delays [3].

Job hazard analysis (JHA) is one of the most widespread safety management practices for proactive safety planning in construction [2]. The Occupational Safety and Health Administration (OSHA) recommends conducting JHAs to address hazards in the workplace, and to reduce injuries and illnesses [4]. By identifying all potential task-related hazards and suggesting the means to reduce or avoid them, JHAs can be an effective tool for examining workplace operations, establishing proper job procedures, and ensuring that all employees are properly trained [4]. If effectively performed, JHAs can result in fewer worker injuries and illnesses, safer and more effective work methods, reduced workers' compensation costs, and increased productivity [4].

As with many construction practices, efficient management of JHA data is critical for preventing errors

from reoccurring,[5] particularly when construction personnel lack sufficient experience, or are biased by the occurrence of prior incidents. A lack of safety knowledge has been reported as one of the main reasons for high incident rates in the construction industry [6]. In many circumstances, worksite fatalities are associated with the insufficient sharing and communication of required information [7]. The role of knowledge management in improving the performance of occupational health and safety systems has been analyzed in the academic literature [8][9], where sharing safety knowledge and experience has been found to improve safety performance. The traditional JHA process requires construction personnel to perform several tasks, including reviewing historical documentation and applying findings to activities on new construction projects [10][11]. While several research studies aimed at enhancing JHA practices have been conducted, none has addressed the inherent problem of knowledge-management in traditional construction JHA practice.

Due to varying site conditions, job constraints, and work environments, no construction project is truly identical to any other. JHAs must be continuously recompiled or re-performed [2][12][10]. While JHA knowledge from previous activities may be revisited for guidance, reviewing previous JHAs can be time-consuming, especially when the number of activities, their steps, and their associated hazards are significant [2]. Additionally, construction personnel creating JHAs must often review fragmented information across various references, such as safety regulations, incident records, best practices, and personal experiences [11]. As a result, the completion of JHAs is an error-prone, time-consuming task [13][10]. Furthermore, the inconsistent use of terminology, lack of detailed information, and inappropriate storage of data may result in knowledge being inadvertently omitted during the development of future JHAs, potentially even creating a false sense of security in documentation.

This paper proposes the design of a web-based system capable of addressing the knowledge management problem inherent to traditional JHA practice. This system uses a dual database approach that allows practitioners to quickly and easily combine pre-defined, task-level JHAs to best suit the specific needs of a project. Implemented as a web-based system, the proposed approach is capable of efficiently managing historical data, unifying JHA knowledge of various experts, facilitating the creation of new JHAs, and easily sharing JHA knowledge between workers.

2 Literature Review

The process of conducting JHAs (reviewed in [2], [4], [13], [14], and [15]) consists of three main stages, as detailed in Figure 1 and detailed as follows:

1. *Identification*: The identification of hazards is performed for a specific job or activity by segmenting the activity into a sequence of stages, resulting in the identification of all possible hazards that may occur during the work. Currently, construction personnel conducting JHAs rely on brainstorming sessions to identify steps within different construction jobs and to identify associated hazards [14].
2. *Assessment*: The assessment is carried out by evaluating the severity level and probability of all identified hazards.
3. *Mitigation and Control*: Strategies for mitigating or controlling hazards are identified and proposed.

Before beginning the job onsite, JHAs are typically read and explained to workers in a pre-task work meeting. To ensure that each worker is familiar with the hazards associated with each task as well as the proposed mitigation strategies, each participant may be required to acknowledge its content by signing a form [10]. Notably, JHAs may also be used by certain project teams or owners for legal purposes [10].

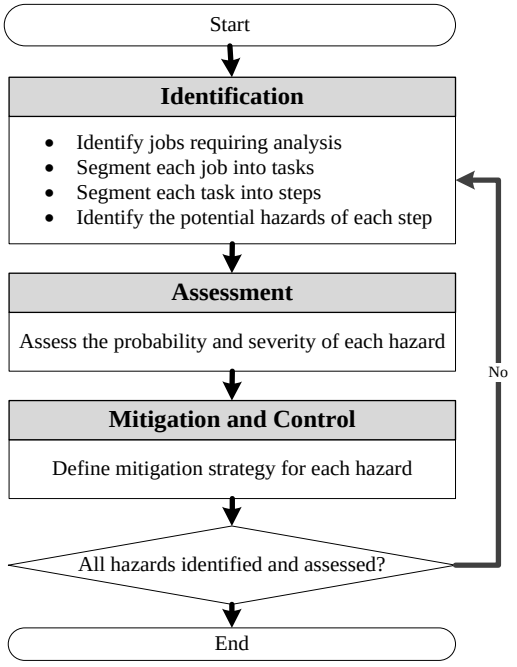

Figure 1. Traditional JHA process

2.1 Enhancing JHA Practices in Construction

Several studies have focused on automating the generation of JHAs. Chi et al. [12] presented a text-classification-based approach that analyzes construction safety documents and extracts safety approaches to automate the 'mitigation and control' step of JHAs. In a

separate study, Chi et al. [1] applied an ontology-based text classification to automate the matching of safe approaches identified from existing resources with unsafe scenarios to enhance the development of JHAs. Zhang et al. [10][13] used an ontological approach to capture, model, and connect safety management knowledge to building information models (BIM), enabling automated hazard analysis and safety task scheduling. An ontological approach was proposed by Wang et al. [2] for structuring knowledge regarding activities, job steps, and hazards to enhance access to safety information. Their approach includes an ontological reasoning mechanism for automatically identifying and selecting safety rules that apply to given activities.

Automated prediction of incident sites and activities associated with increased incident likelihood has been the focus of other studies. By linking the information between the CPM schedule and safety-recommendation databases, Bansal [3] introduced a geographic information system (GIS)-based, navigable 3D animation of safety planning for identifying sites and activities with an increased potential for incidents. A structured tool has also been developed for Construction Job Safety Analysis (CJSA) focusing on the identification of potential loss-of-control events for detailed staging of construction activities [15].The goal of this tool is predicting fluctuating safety risk levels and supporting safety-conscious planning and management.

Notably, while previous studies have attempted to automate the identification of hazards, none has focused on developing systems that enhance knowledge management in traditional JHA practice.

2.2 Management of Safety Knowledge

The importance of knowledge management in construction project safety has been extensively reported. By analyzing safety knowledge-sharing through social networks, Fang et al. [6] have examined how construction employees selected their social relations on the basis of safety knowledge. Finding that safety knowledge-sharing through social networks was a significant source of knowledge transfer, the authors concluded that safety education was more critical than tenure during the safety knowledge sharing process. Observing an influence of knowledge exchange systems on safety compliance, Gressgård [5] suggested that knowledge management and exchange systems are central for enhancing safety behavior, particularly in cases involving shift changes, varying working times, high-level subcontracting, and other factors that lead to nonsynchronous knowledge sharing.

Technologies focused on enhancing knowledge-sharing have also been proposed. Li et al. [7] investigated the ability of various technologies to share construction safety knowledge, finding that mobile apps, the Internet of Things (IoT), and Web 2.0 could provide promising solutions for the distribution of knowledge on construction sites. A conceptual, web-based safety knowledge management system designed to improve safety performance and productivity has been discussed by Kamardeen [9]. Similarly, Elzarka et al. [16] proposed a knowledge-based management system capable of integrating safety and schedule information to facilitate the inclusion of safety as an integral part of project planning and control. As an extension of this, a knowledge management tool for small and medium enterprises that allows users to easily aggregate and capitalize on information from various sources has also been developed [17]. Sherehiy and Karwowski [8] have proposed a knowledge management model for effective OSHE (occupational safety, health, and ergonomics) management, establishing knowledge as the central resource.

Although the studies mentioned above share similar objectives with this study (i.e., facilitating safety knowledge development and accessibility), none of these studies has formalized the traditional JHA in a way that can support efficient development, storage, and sharing of the JHAs in construction. A system designed to enhance knowledge management in JHA practice has yet to be developed.

3 System Design and Development

The proposed system is built on the concept of segmenting construction activities (which vary considerably from project-to-project) into a subset of repetitive tasks that can be combined to suit the specific requirements and needs of a particular construction job. Using this system, job-level JHAs are built by combining multiple segments, each containing various combinations of recurring task-level hazard assessments to suit the specific requirements of a project. This approach is expected to reduce the time and effort required to develop JHAs, decrease errors, and increase the consistency of JHAs throughout the organization.

An innovative feature of the system is its dual database design, which allows for the customization of JHAs in one database while ensuring existing knowledge is not lost during the customization process. Specifically, the *Template Database* generated by safety experts contains the entire table of tasks and associated steps, hazards, assessments, tools, and personal protective equipment (PPE), as well as all associated expert knowledge and experience. In contrast, the *JHA Database* contains modified JHAs specific for each project. Safety supervisors search the template database for the required job and pull the job to the JHA database,

where the JHA is adapted and modified for the specific conditions of the new project. Since the template database is anticipated to contain all information related to a task, modifications would simply involve the removal of unnecessary safety considerations (e.g., removal of grading considerations if work is to be completed on a flat surface).

3.1 System Architecture

An overview of the proposed JHA process is illustrated in Figure 2. The system's architecture is built using *Django* [18] and a *React & Redux* framework [19]. The system is built on a cloud-based *MySQL* database, which provides a centralized, reliable means of sharing and storing JHA knowledge that is accessible to users from various locations. JHA knowledge is stored on a server, and a standard web browser is used as a gateway to exchange JHA knowledge.

The web-based JHA system is implemented using an architecture composed of the following four logical layers: a user layer, an interface layer, an application layer, and a repository layer. Figure 3 depicts the system architecture and describes the various functional activities that are carried out within the JHA extranet.

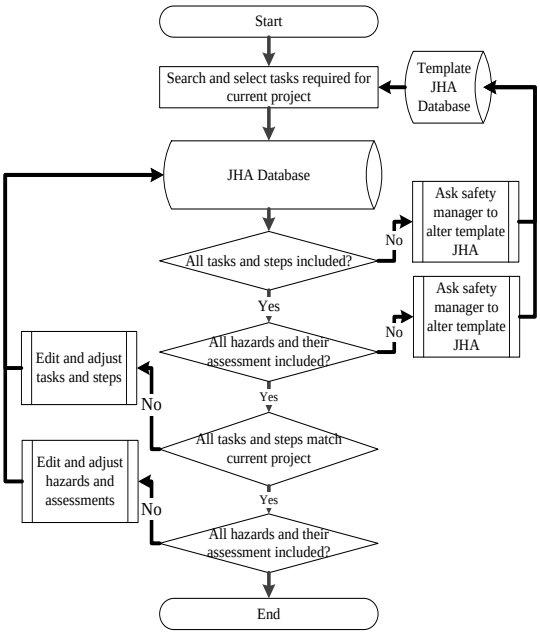

Figure 2. Proposed JHA process

The *user layer* (layer one) is installed on the user's machine and is connected to the server through the *interface layer* (layer two). The interface layer is, in turn, connected to the *repository layer* (layer four), with access to and control over the *information layer* (layer three) within the *MySQL* database, subject to access restrictions. The *interface layer* (layer two) lists the processes available to each user depending on their assigned access level. In the developed system, the following three access-levels are as follows: (1) a safety manager level, which has full access to the system; (2) a safety supervisor level, which can create, edit, view, and download a JHA but is unable to alter the template database; and (3) a worker level, which is limited to viewing and downloading existing JHAs in the system. In summary, the JHA safety knowledge is represented in the form of a relational model using *MySQL*. The relational model [20] defines a set of relations, describes the relationships between entities, and determines how these stored data interact.

3.2 System Development

The main development tools of the system include *React & Redux* [19], a *Django* REST framework (*D*RF) [18], and *MySQL*. The *D*RF connects to the database, which uses *Python* as the programming language. The database is initialized on *MySQL*. *React & Redux* uses *JavaScript* as a programming language. While *React & Redux* acts as the user interface, a cascading style sheet (CSS) layout is used to perform certain formatting functions of the user interface. *React & Redux* uses a built-in tool to connect the system's front end and back end, allowing a front end user to fetch data from the back end, and to push data to the back end.

4 Practical Application of the System

A simple, illustrative example is used to demonstrate the practical application of the proposed system. Involving the operation of an excavator on a construction site, the job is associated with the following three tasks: pre-operation, operation, and post-operation. To build a new JHA, a user logs into the system using the login interface (Figure 4). Once logged in, the user accesses the main dashboard of the system, which varies in appearance based on the user's access level (i.e., visibility of the various components will be affected by the user's access level). For example, the dashboard of a safety manager level user contains the (1) template database, which encompasses the tasks, steps, hazards, tools, and PPE tables; (2) JHA database, which contains all the JHAs of the various projects; and (3) the create button, which initiates the creation of a new JHA (Figure 5). The JHA database in the dashboard of a worker-level user, contrastingly, contains only the means to view and download existing JHAs.

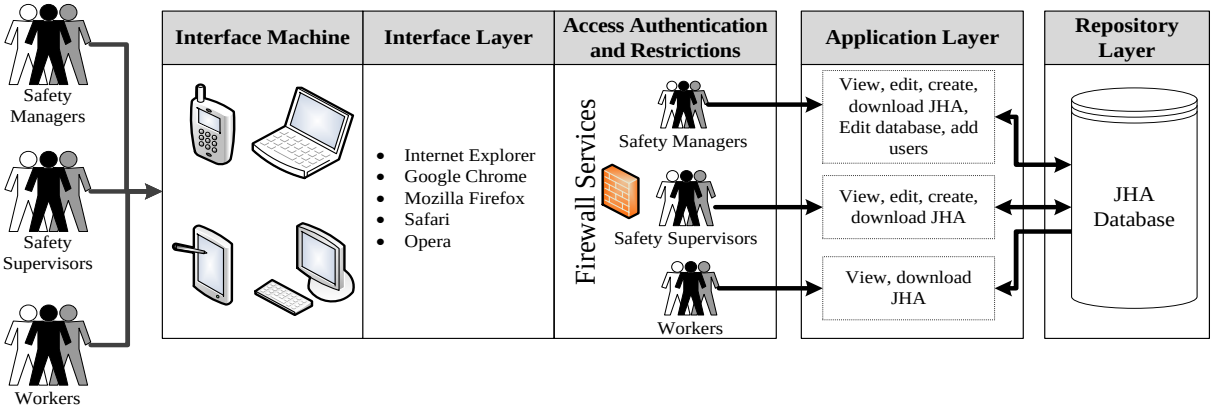

Figure 3. Structure of the JHA system

To initiate the creation of a new JHA, users click on the create button, which triggers the opening of a new window (Figure 6, *top*). This window contains eight tabs: general information, creators, editors, prerequisites, tasks, crew review, and approval tabs, which mimic the layout of a traditional JHA. Tasks are added to a job using the "Tasks" tab (Figure 6, *bottom*); importantly, only predefined tasks contained within the template database can be added to a job, ensuring that all JHAs are first populated with existing, standardized knowledge. Once the predefined tasks have been selected and imported from the template database into the JHA database, subcomponents can be adjusted according to the context of the current project (Figure 7). After all eight of the tabs have been finalized, the new JHA is created and stored in the database where it can be viewed, edited, and downloaded.

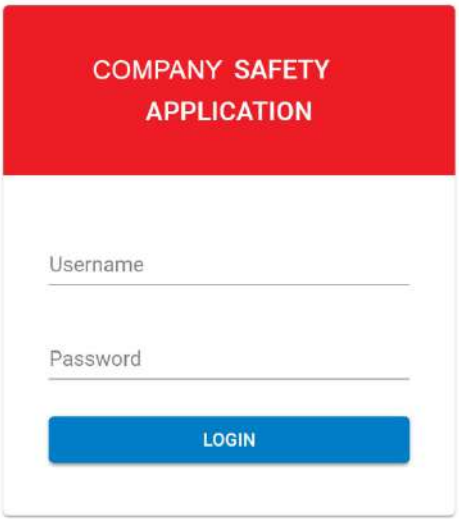

Figure 4. System login

5 System Evaluation

Subject matter experts assessed functionality and determined whether or not the proposed system had the potential to enhance JHA practices. A demonstration of the software was presented to safety managers who were then asked to provide feedback in an interview format. Specifically, they were asked (C1) if they found the system easy to use, (C2) if they thought the system would improve accuracy of generated JHAs, (C3) if the system would allow timelier access JHA knowledge, and (C4) if access to information was improved. All experts interviewed were pleased with the system functionality, indicating that it was straightforward, easy-to-use, and had the potential for improving current practices. Suggested improvements included adding a visualization component that could provide more intuitive insight regarding the number and severity of project-associated risks. In order to quantitatively assess the functionality of the system, the three experts (E1, E2, and E3) were asked to evaluate the system on Likert scale (1-5) where 1 means very low, 2 means low, 3 means medium, 4 means high, and 5 means very high. They were asked to evaluate the system based on the criteria listed above. Experts are not fully satisfied with the initial stage of the system. Future work will increase efficiency.

Table 1. Quantitative Evaluation of Expert Opinion

Criteria	E1	E2	E3	Average	Avg. %
C1	4	5	5	4.67	93.4%
C2	4	4	3	3.67	73.4%
C3	3	4	4	3.67	73.4%
C4	4	5	4	4.33	86.7%

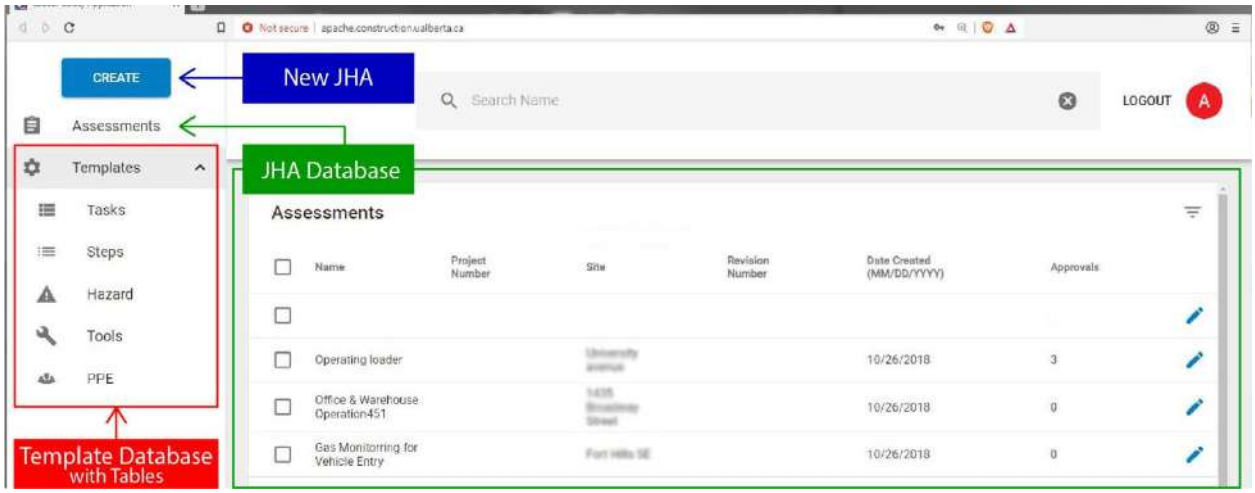

Figure 5. Main dashboard of the system

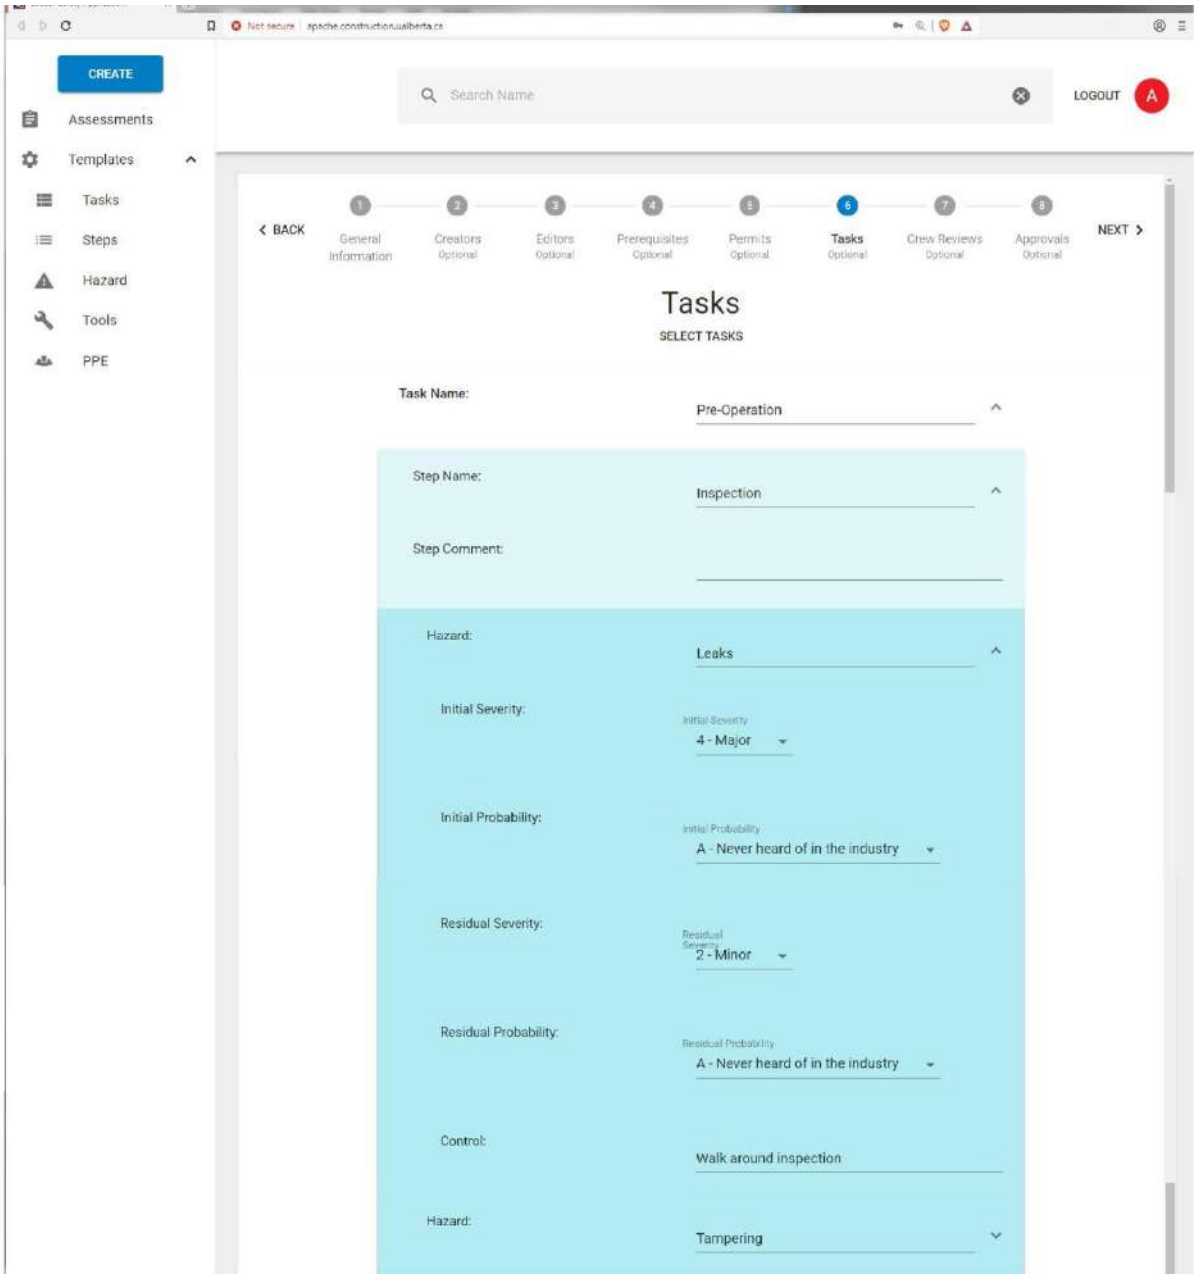

Figure 7. Hazard steps

6 Conclusion

JHA is a routine component of many proactive safety management systems in construction. Reliance on inconsistently-formatted and often fragmented information motivated the development of a web-based system. Using a dual database approach, the proposed system facilitates JHA creation, storage, and sharing. Subject matter experts found the preliminary version of the system capable of improving current practice. Future work may include the addition of graphics depicting the number and severity level of hazards, integration of the system with the project schedule to visualize the day-to-day hazard-levels, or development of text-mining algorithms. Currently, safety personnel have to search the template database to identify and assess hazards and their severity. Automation of these processes is suggested for future research. Automating the identification process is planned by applying some artificial intelligence techniques (such as case-based reasoning) to help the safety personnel easily identify and evaluate potential hazards based on current context

and historical information. Real project data will later be used to quantitatively evaluate the functionality, accuracy, and efficacy of the system.

Abstract –

Proactive approaches designed to prevent incidents before they occur are essential for achieving effective safety management. Emerging as an important component of proactive safety management, leading indicators are used to assess and control safety performance. With the aim of reducing the number or severity of worksite accidents, methods capable of predicting future safety performance using leading safety indicators have been developed. However, these methods have been developed for a specific set of leading indicators. This has substantially limited their application in practice, as leading indicators with the greatest impact on safety performance vary considerably between organizations and projects. An approach for predicting accident occurrence on construction sites that can be applied to any combination of leading indicators is proposed to address these limitations. Data used to develop the proposed approach were collected by a construction company from eight construction projects over a period of two years. Feature selection techniques were used to filter the original factors into the most critical subset, which were then used as inputs. Various supervised learning algorithms, namely support vector machine (SVM), logistic regression, and random forest, were then tested to determine which algorithm(s) yielded the highest prediction accuracy. The results demonstrate that the proposed procedure can be used for early recognition of potentially hazardous project characteristics and site conditions regardless of the number or type of leading indicators available within an organization. Research in this area is expected to facilitate the implementation of targeted safety management controls and to improve safety performance.

Keywords –

Safety Leading Indicators; Safety Management; Safety Performance; Machine Learning

1 Introduction

Safety leading indicators are an essential component of proactive safety management, providing valuable information regarding organizational safety performance [1]. Leading indicators, defined by Grabowski et al. [2], Hinze et al. [3], and Kjellén [4], are conditions, events, or measures antecedent to undesirable events that can be used to predict the occurrence of accidents, near misses, or any undesirable safety state. Measuring leading indicators allows practitioners to define a threshold value for metrics below which corrective actions should be taken, with the aim of reinstating the performance above the required level [5]. Accordingly, leading safety indicators have emerged as a more effective alternative than traditional lagging indicators, which are measured after the occurrence of an accident [5].

Safety professionals have contended that the careful selection, measurement, and mitigation of leading indicators can result in real improvements in practice [3]. Practical improvements are attributed to the ability of leading indicators to be linked causally and proactively with safety outcomes in terms of accidents [6]. Criteria for selecting useful leading indicators have been defined [7] and include validity, reliability, sensitivity, representativeness, openness to bias, and cost-effectiveness. Øien et al. [8] have expanded on this, indicating that successful safety indicators should also be measurable on a numerical scale, updated regularly, and reflect selected determinants of overall safety.

Because of the potential interactive effect associated with combining and analyzing various leading indicators, a comprehensive set of leading indicators is believed to provide the best predictive result [9]. Indeed, many researchers, including Garza et al. [10] and Hinze et al. [9], recommend that companies should use a combination of leading indicators to assess safety performance rather than depending on a single indicator. Furthermore, companies should consider indicators outside of the safety department that have been found to reliably predict safety performance, such as those

associated with project performance. While construction companies collect a liberal amount of project-performance data to track the overall performance of their projects, they struggle to make use of these data for safety performance assessment purposes.

A number of leading indicator-based methods capable of predicting safety performance have been reported in the literature. However, these methods have been developed using only a specific set of leading indicators. Accordingly, many of these methods are dependent on certain dataset types or formats, making it difficult for practitioners to generalize the application of these methods in practice.

This study proposes an approach capable of proactively assessing safety performance regardless of the number or type of leading indicators available to a specific construction organization or project. The first part of this work is published in [11] where the authors showed that project performance data collected by different departments can be used as inputs for creating machine learning algorithms for safety leading indicators. Using a machine-learning approach, the proposed methodology can be applied to any dataset. In this particular case, the dataset is collected for non-safety associated purposes (e.g., cost, quality, and schedule) to predict the occurrence (i.e., yes/no) of an accident. The proposed approach was used to assess the safety performance of an organization based on data collected from eight projects over a period of two years., Various measures not traditionally associated with safety performance (i.e., quality, cost, and schedule) were included in the analysis to demonstrate the adaptability of the proposed approach. The various machine-learning algorithms were compared.

2 Literature Review

While several theoretical safety leading indicator studies have been conducted [3, 5, 12], few construction companies have successfully implemented programs capable of monitoring safety leading indicators in practice. In cases where companies have implemented such systems, there is little information available in the literature detailing which specific leading indicators have been applied by these companies [9]. Several factors identified by the Construction Industry Institute (CII) and other academic researchers may explain why successful leading-indicator monitoring programs have yet to be widely used in practice (i.e., knowledge gaps).

2.1 Predictive Models in the Safety Domain

Previous investigators have suggested that personal protective equipment (PPE) and proactive detection-based strategies are not sufficient for facilitating a zero injury state [13] and that predictive models of safety performance may play a key role in bridging this gap [14]. Predicting and understanding anticipated changes in safety performance can assist organizations in developing accident mitigation strategies more efficiently and effectively. Indeed, Schultz [13] has demonstrated the ability of one company to reduce injury rates through the application of advanced and predictive analytics together with a growing safety dataset. A number of predictive models have been developed with the aim of proactively forecasting where and when workplace injuries will occur. Ghodrati et al. [14] built various models to predict construction safety outcomes at the macro level. They demonstrated that the number of companies in any liable earnings category predicted safety outcome as well as the number of claims and entitlement claims in all constructed models. They also found a positive and significant relationship between the number of companies in various liable earnings categories and the severity of associated occupational injuries. In another study, Esmaeili et al. [15] used principal component analysis and a linear prediction model to test the validity of risk attributes for predicting safety outcomes. Although their method was able to predict safety outcomes effectively, it was limited to small-scale projects. A Bayesian-network hybrid model has been proposed by Xia et al. [16], to holistically explore safety risk factors in construction projects and predict the probabilities of project safety states.

2.1.1 Machine Learning-Based Models

Machine-learning algorithms function by learning from historical data in a manner that easily complements expert opinion. Although machine learning has been used widely in construction research for more than two decades, its application in the field of construction safety remains limited [17]. Poh et al. [18] presented a machine-learning approach to develop leading indicators that classify construction sites by their safety risk. A machine-learning approach using occupational accident data was also used by Sarkar et al. [19] to predict occupational accident outcomes, such as injuries, near misses, and property damage. Although the results of the studies mentioned above demonstrate considerable promise, the specificity of the datasets that the researchers used to develop these methods renders the widespread application of these methods difficult in practice for organizations with dissimilar data; in particular, generalization is difficult for datasets related to project performance rather than safety performance.

3 Research Methodology

Figure 1illustrates the research methodology. This methodology is a standard data mining process, as

Table 1. Collected variables

Performance Category	Variable/Feature
General	Project ID, Contract Type, Report Date, Contract Change Order (CCO), Outstanding CCO, CCO Submitted to Date, Request for Information (RFI), RFI Submitted to Date, Open RFI
Cost	Original Budget, Re-Baseline Budget, Approved Changes, Revised Contract Value, Pending Changes, Forecast at Completion, Earned Value, Incurred Value, Outstanding Change %, Work Order CPI
Schedule	Work Order % Complete, Work Order SPI, Work Order HPI
Quality	Non-Conformance Report (NCR), Open NCR, Field Surveillance Report (FSR), FSR Submitted to Date, Open FSR.
Safety	(0-1) Years of Experience Direct Hours, (1-2) Years of Experience Direct Hours, (2-3) Years of Experience Direct Hours, (3-4) Years of Experience Direct Hours, +4 Years of Experience Direct Hours, Foreman Hours, Shift Hours, Exposure Hours, Accident

defined by Witten et al. [20]. First, data are collected and studied to determine if the dataset is suitable for further processing. Second, raw data are cleaned and prepared (i.e., removal of missing data and outliers) for input into machine-learning algorithms. Data cleaning and preparation attempts to address any empty fields in records, data entry errors, and instances where data have been collected in an ad hoc manner [21]. This step ensures that the machine-learning algorithms produce an ideal model with improved performance. Finally, various prediction models are developed, and their performances are evaluated.

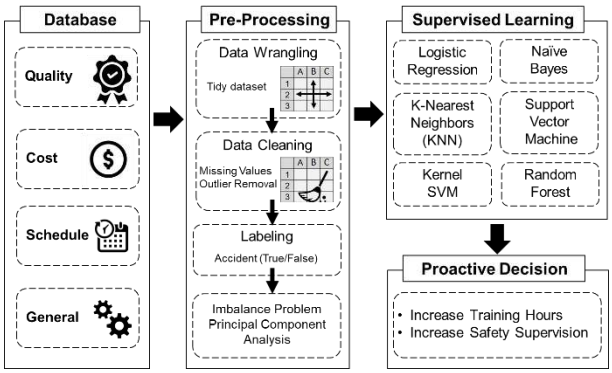

Figure 1. Research methodology

3.1 Data Collection

The dataset used in this research was obtained from a large construction company in Alberta, Canada, with a broad range of construction expertise including building, industrial, and infrastructure projects. The dataset, which encompassed eight industrial projects completed over two consecutive years (2016 to 2017), initially contained 123 biweekly records of each project's performance- (e.g., cost, schedule, and quality performance) and safety-related data (e.g., direct worker hours, foreman hours, shift hours, and accident occurrence). Biweekly accident records were associated with biweekly project performance- and safety-related data. More details about the definition of each of these features and integration of data from different departments is provided in [11]. A description of the variables collected is presented in Table 1.

3.2 Data Cleaning and Preparation

Features and variables that were not useful for this work were first removed. For example, three variables related to the budget and contract value (i.e., original budget, re-baseline budget, revised contract value) all provided similar information. Here, only one variable (re-baseline budget) was considered and kept. Second, missing values were removed or substituted by values that allowed for the development of the model while, at the same time, not adversely affecting model performance [20]. In this particular dataset, the value "Years of Experience Direct Hours" was missing in over 50% of the total records. Due to the limited number of data points, associated columns were removed. The features listed in Table 1 were filtered, resulting in a dataset of 23 features.

3.2.1 Data Labeling

Two labels were selected: (1) True, indicating an accident occurred in the worksite or (2) False, indicating no accident occurred.

3.2.2 Class Imbalance Problem

Machine-learning algorithms perform best when the number of observations is approximately equal in each class [20]. After data cleaning and feature selection, a total of 79 "no accident" and 23 "accident" cases were recorded. Random over-sampling techniques [22] were used to overcome the class imbalance and to reduce the negative impact this may have on algorithm performance.

3.2.3 Principal Component Analysis (PCA)

In machine learning, Principal Component Analysis (PCA) is useful for dimension reduction when analyzing high-dimensional datasets, reducing the number and increasing the independence of predictors [23]. Each principal component is a normalized principal component or linear combination of original variables. Based on the concept that principal components are orthogonal to each other (and correlation coefficients are all zero), PCA allows for the removal of multicollinearity in the features. In PCA, the first principal component is the one that captures the maximum variance of the data set. In other words, it determines the direction of the highest variability in the data.

Scatter plots and correlations between the independent variables are depicted in Figure 2. Of note, the highest correlation observed was between Shift Hours and Foreman Hours, (r=0.93; Figure 2). The results of PCA showed that PC1 explained 59% of the variability in the data set and that the first four principal components explained 90% of the variability in the dataset.

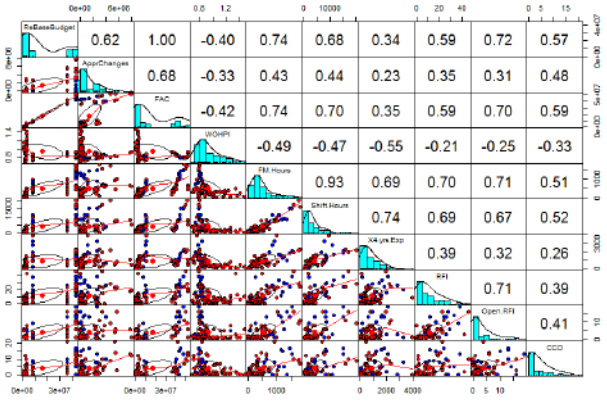

Figure 2. Correlation between independent variables

3.3 Model Generation

After the dataset was cleaned, various machine-learning models were generated and tested. In the current study, classification models were developed using the statistical package *R* [22]. While a large variety of classification models are available in the literature, this study selected models that (1) are widely used for investigating construction problems; (2) have been used in previous studies to predict safety performance and accident occurrence; and/or (3) are useful for modeling complex relationships. The models chosen include k-nearest neighbours (k-NN), logistic regression (LR), random forest (RF), support vector machine (SVM), Kernel support vector machine (KSVM), and Naïve Bayes.

4 Results

Model error is estimated using cross-validation or split validation, and often repeated several times [20]. In this study, the classification models were trained and validated using a 70/30 split validation approach, where the dataset was randomly divided into two parts used for (70%) training and (30%) testing purposes.

Models were evaluated and chosen based on several performance metrics derived from the confusion matrix (Table 2)[24]. These metrics include the following: *Recall*, which describes the probability of correctly predicting "True" relative to the total number of actual "True" and "False False" (FF) in the dataset [Eq. (1)]; *Precision* [Eq. (2)]; and *Accuracy*, which describe the probability correct predictions relative to the total number of predictions [Eq. (3)] [20]. These measures are commonly applied as performance indicators by researchers due to their straightforward interpretation.

Table 2. Description of confusion matrix

	Predicted False	Predicted True
Actual False	True False (TF)	False True (FT)
Actual True	False False (FF)	True True (TT)

$$Recall = TT/(TT + FF) \quad (1)$$

$$Precision = TT/(TT + FT) \quad (2)$$

$$Accuracy = (TT + TF)/(TT + FT + FF + TF) \quad (3)$$

Table 3. Summary of performance metrics of models

Table 3. Model performance

Model	Recall (%)	Accuracy (%)	Precision (%)
LR	71.4	93.5	100
KNN	85.7	87.0	66.6
SVM	57.1	87.0	80.0
Kernel SVM	28.5	80.6	66.6
NB	85.7	87.0	66.6
RF	57.1	87.0	80.0

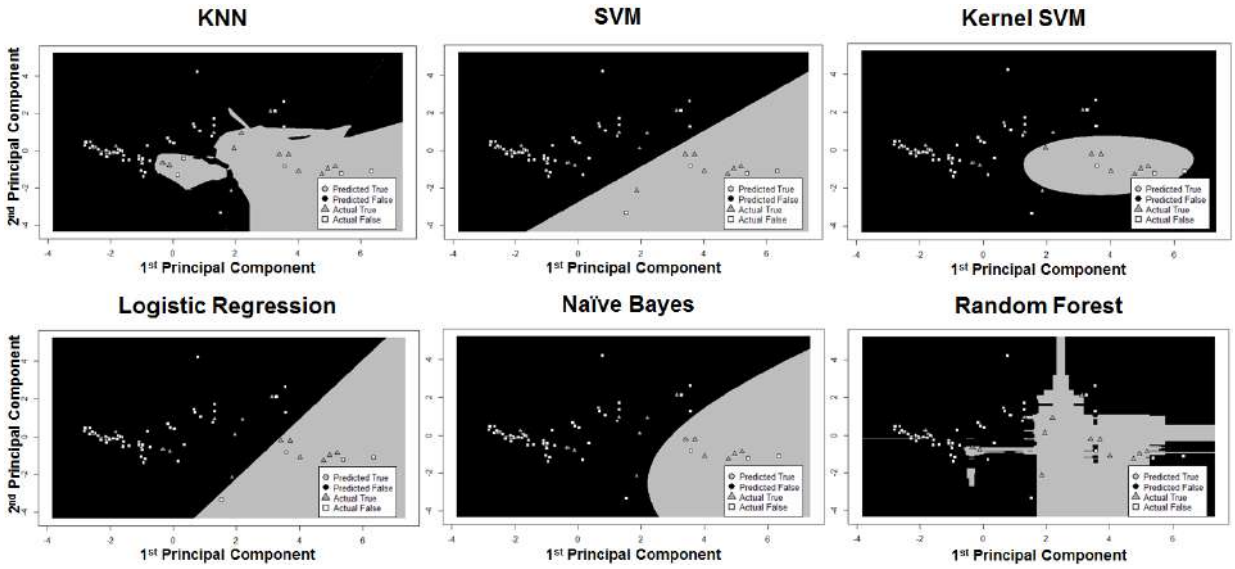

Figure 3. Hyperplanes and decision boundaries of different classifiers

Although *Accuracy* offers a simple measure of the overall performance of a model, it (1) does not consider the type of prediction errors being made and (2) does not consider the distribution (i.e., relative frequencies) of the classes.

Recall is considered the most suitable metric for selecting a model when there is a high cost associated with True/ False. For instance, in accident prediction, if an accident (True True) is predicted as no accident (True False), the consequence can lead to enormous costs for the company. For this reason, *Recall* is used to identify the best model in this study. Both KNN and Naïve Bayes classifiers were associated with the greatest *Recall*, indicating that these models were able to best predict the low-frequency class (in this case, accident occurrence).

Figure 3 visualizes the decision boundaries and the performance of the mentioned classification methods on a randomly selected subset of data. A dimension reduction algorithm (PCA) was applied to reduce the dimensions of the feature vector to two dimensions. As mentioned, the first PCA captures the highest amount of variance in the feature vector, and the second PCA is a component orthogonal to the first one. In Figure 3, as indicated in the legend, the gray and black areas represent proportions predicted by the classifier to be True (i.e., accident) or False (i.e., no accident), respectively. Gray triangles and white squares represent data points that are actually True or False, respectively.

5 Conclusion

While many research studies have been conducted investigating the impact of safety leading indicators on safety performance of construction sites, their use remains limited by certain practical challenges. Due to the approach in which the models were designed in particular, the implementation of prediction methods is often limited to a specific set of leading indicators.

This research study used a machine-learning approach to develop a model that can forecast safety performance from leading indicators regardless of the number or type of leading indicators available. First, the dataset is cleaned and pre-processed. Then, feature selection techniques are applied to reduce the dimensionality of the dataset and to identify the important features affecting safety performance. Finally, machine-learning algorithms are applied for training and validating purposes.

The method was tested using a dataset provided by a large construction company in North America. Out of 23 features, only 10 were found to have a notable influence on safety performance. After evaluation, Naïve Bayes (NB) and K-Nearest Neighbours (KNN) were found to be the best performing algorithms, achieving a *Recall* of 0.857.

Unlike previous studies, which have used theoretical or statistical approaches, this study has used a machine-learning approache to develop a safety performance prediction metric. The results of this study can be used by safety practitioners to (1) improve safety practices or (2) guide the allocation of resources towards monitoring indicators with the most influence on safety performance, saving organizations time and money. For future research, the authors suggest further segmenting the variables of safety (safety hours) with respect to weather conditions, overtime, or other impacting factors.

Abstract
Media age has seen a huge amount of data flowing in from all directions, be it online news sources, social media, technical documents, and many more. There is a huge scope of these data sources for utilization in the transportation sector that can potentially improve the current practice of transportation infrastructure planning. In order to effectively capture, analyze, and utilize the information from various sources, ontologies are useful tools as they can provide clear and structured knowledge in the transportation domain. Majority of the existing transportation-related ontologies focus on traffic management and route planning. The objective of this paper is to initiate the development of an integrated ontology that can help with long-term planning and decision-making of transportation infrastructure by proposing a preliminary taxonomy in this domain. To this end, 20 transportation planning visionary documents published by government agencies were collected and analyzed using topic modelling techniques. Specifically, two topic modeling methods: Latent Dirichlet Allocation (LDA) and Non-negative Matrix Factorization (NMF) models were used to extract important and emerging concepts related to transportation infrastructure planning. Leveraging the important and emerging concepts, a preliminary taxonomy of transportation infrastructure planning was then developed and presented.
Keywords –
Smart Transportation infrastructure planning; Ontology; Taxonomy; LDA; NMF

1 Introduction

Ontology is a systematic description of entities with regards to their properties, relationship, and constraints expressed by axioms [1]. Due to its ability in promoting sharing of knowledge bases, knowledge organization, and interoperability among systems, ontologies have been used extensively in many domains and studies (e.g., disaster management, business modelling, disease management) [2-5].

The transportation research domain has long been benefitting from the application of ontologies. Ontologies are particularly fitting to handle the challenges arising from the large volume and variety of transportation related data (e.g., survey, sensor data) [6-7]. Majority of the ontologies developed in transportation research domain focus on trip planning [1, 8], trip disruption [9], traffic management [10-11], service monitoring [12], and urban freight transport problems [13, 14]. Despite the extensive use of ontologies in transportation research, to the best of the authors' knowledge, there is no scholarly work available in literature that directly focuses on an integrated ontology for transportation infrastructure planning. In many of the existing studies, transportation infrastructure planning had been considered as an auxiliary element towards other functions of transportation (e.g., see [15]). An assumption had been made in many of these studies that a desirable level of transportation infrastructure quality was already achieved for other transportation planning purposes such as trip planning, traffic management, and service monitoring. However, infrastructure is the foundation for realizing transportation functions. With the help of an integrated transportation infrastructure planning ontology, transportation infrastructure can be planned and managed in a more holistic way. Thus, transportation infrastructures can be better equipped to serve traffic demand, public safety, and social needs.

Transportation infrastructure planning can be defined as the process of making decisions concerning the potential changes required for transportation related infrastructures to improve the quality of life. Transportation infrastructure planning is a complex process. Without a structured ontology for information and knowledge management, there are major challenges in transportation infrastructure planning. First, transportation infrastructure planning documents and

publications from different sources may have different focus and use different structures and terminologies. For example, different agencies may have different definitions and metrics to assess transportation infrastructure performance. Therefore, it will be difficult to compare or integrate transportation infrastructure performance data and establish uniform baselines across different agencies. Second, a robust transportation infrastructure planning requires information from varied sources such as online news, social media, technical reports, and many more [5]. There is no way to effectively extract, analyze, and utilize the information from heterogeneous sources without a formal structure.

To address these challenges, the objective of this study is to initiate the development of an integrated ontology for transportation infrastructure planning. Such integrated ontology could help: (1) increase interoperability across different transportation infrastructure plans published by different governmental and non-governmental agencies at different levels; (2) facilitate the collection and analysis of data from various sources including social media (e.g., Twitter). Essentially, the ontology would help to build an integrated framework for smart transportation planning by incorporating data from different sources into a smart knowledge management and decision making system. It ultimately helps decision makers and planners to have a holistic approach to plan, build, and manage our transportation infrastructures.

As a first step in developing the ontology, a preliminary taxonomy for transportation infrastructure planning is proposed in this study via two topic modelling techniques: Latent Dirichlet Allocation (LDA) and Non-negative Matrix Factorization (NMF). The models have been used to extract important and emerging concepts related to transportation planning from 20 transportation planning documents. These concepts are then appropriately analysed and categorized to create a hierarchical taxonomy for transportation infrastructure planning.

2 Methodology

The methodology used to develop the preliminary taxonomy includes six steps. As shown in Figure 1, the first step was document collection, in which transportation planning related documents were collected.

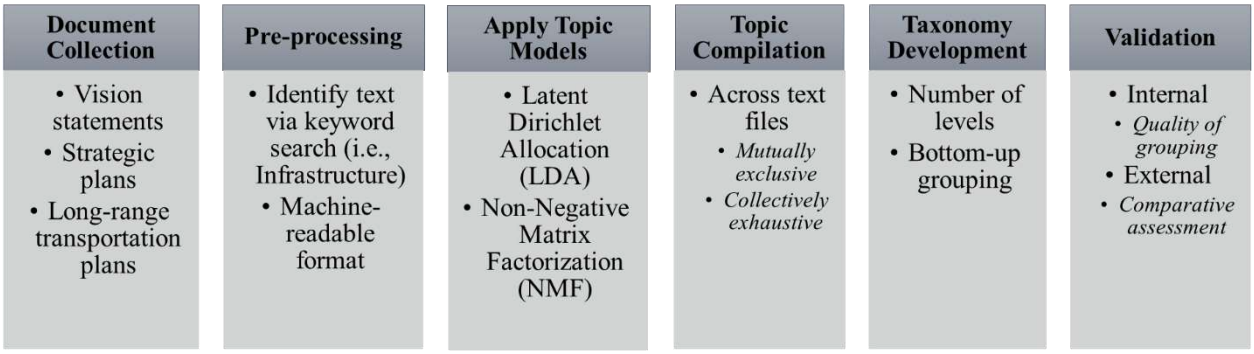

Figure 1. Taxonomy development steps

In the second step, useful texts were extracted from the collected documents and processed into a format that could be readily used for topic modelling. In the topic modelling step, two modeling techniques, i.e., LDA and NMF, were implemented on data extracted from each document to generate relevant topics. Then, different topics identified across all the documents were compiled and summarized in step four, i.e., topic compilation. The fifth step was taxonomy development, in which the structure of a preliminary transportation infrastructure planning ontology were developed. Finally, in step six, the proposed taxonomy was validated. Details of each of the steps in the proposed methodology are provided below.

2.1 Document Collection

As a first step, transportation planning documents were collected via a standard google search using key words such as transportation planning vision, transportation long-term plan, strategic transportation plan, etc. In total, 20 documents were identified through this process. These documents include transportation vision statements [13], long-range transportation plans [14], long-term regional transportation and land use plans [16-17], and many more. Majority of these documents were developed by state DOTs, while some were developed by legislative bodies at the city level. In some cases external consultants were assigned to provide support to develop such documents.

2.2 Pre-processing

Since transportation planning is such a broad term and covers many different aspects, the collected

documents in the first step are often times long-winded and hence, contain a variety of information that may not be directly pertinent to transportation infrastructure planning. Hence, data pre-processing was conducted by searching the keyword *"infrastructure"* within each document. Paragraphs with the keyword "*infrastructure*" in them were extracted from each document under the assumption that such texts were more apposite to the focus of this study. Separate text files were created for each document. These text files were then further processed to eliminate the possibility of encoding errors when they were read via *Python* for topic modelling. For example, all the apostrophe characters were removed from the text files before topic models were applied.

Table 1. A sample output of the application of topic models

Topic Model	Topic Example	Contexts (from "Invest in Transit 2018-2023 Regional Strategic Plan" [21])
Non-negative Matrix Factorization (NMF)	Funding, agencies, projects, state, local	• The agencies are ready to deliver more improvement projects, but more funding is required to do that. • The agencies have filled some of the funding gaps with short term fixes and by working with local governments and agencies. • If supported by a diversity of state, federal, and local funding commitments, it would empower agencies to improve the systems. • Agencies will be specific and transparent about funding needs and usage of funds. • RTAs Project Management Oversight office monitors the implementation of capital projects and found in its most recent report that 95 of state bond funded projects were tracking on time and 100 were on budget notwithstanding delays related to state funding. • Diversify and increase transit capital funding sources through state and local funding commitments of new revenue sources or expansions of existing revenues (e.g. gas tax). • The region will continue to seek federal funding and apply it to regionally and nationally significant projects. • The agencies have a track record of delivering on large capital project commitments.

2.3 Apply Topic Models

The processed data was then analyzed using topic modelling. Topic modelling is essentially a form of text mining that utilizes either unsupervised or supervised statistical machine learning techniques to identify patterns in structured or unstructured text [18]. It employs the process of similarity by clustering the words and identifying topics. Two topic modelling techniques: LDA and NMF were implemented in this study. LDA and NMF are two widely used topic modelling techniques. LDA is based on probabilistic graphical modelling while NMF relies on linear algebra [19-20]. While LDA and NMF have significantly different mathematical underpinnings, both techniques are capable of returning the most pertinent topics in a document. In this study, we used both techniques for analysis to ensure we capture all the important topics for transportation infrastructure planning. Before delving into detail about the mechanisms of LDA and NMF, it is important to clarify that in this study we ran topic models for each text files individually. Therefore, each text file generated is considered as a collection of *documents*. Here, *document* means a complete sentence (shown as one line in text files). The topic modeling results generated for each text file by both LDA and NMF were essentially based on the analysis of the collection of *documents* in each file. For better representation, from now on *document* in the text files will be referred to as "Single Line Source (SLS)" throughout this paper.

The mechanisms and implementation procedures of LDA and NMF are provided below. Machine learning library Scikit-learn was used in conjunction with Python to implement both LDA and NMF for identifying topics and their respective contexts [21].

2.3.1 Latent Dirichlet Allocation (LDA)

Let us suppose there are D SLSs in a text file with W words. Assuming K topics to discover, LDA was implemented as

Step 1: Randomly assign each word in $d \in D$ to one of the $k \in K$ topics

Step 2: Identify topic representations of all the SLSs and word distributions of all the topics.

Step 3: For each SLS $d \in D$:

- Go through each word $w \in W$
  - For each topic $k \in K$:
    - Compute the proportion of words in SLS $d \in D$ that are currently assigned to topic $k \in K = p(k|d)$
    - Compute the proportion of assignments to topic $k \in K$ over all SLSs that come from the word $w \in W = p(w|k)$
  - Reassign $w \in W$ to a new topic based on the probability $p(k|d) * p(w|k)$

Step 4: Repeat step 3 a large number of times to reach a steady state solution.

2.3.2 Non-negative Matrix Factorization (NMF)

Let us consider a nonnegative data matrix where each column of X corresponds to a SLS $d \in D$ and each row to a word $w \in W$. Each entry (m, n) in data matrix X represents the number of times the mth word appears in the nth SLS. Given such a matrix X with rank r, it can be factorized into two matrices V and H such that

$$X(:, n) \approx \sum_{k=1}^{r} V(:, k)\, H(k, n) \quad with\, V, H \geq 0$$

The goal is to find the best possible factorized matrixes that minimizes the following objective function

$$\underset{V,H\geq 0}{minimize} ||X - VH||^2$$

Since the weights in the linear combinations are nonnegative (i.e., $H \geq 0$), only the union of the sets of words defined by the columns of V can be used to reconstruct the original SLSs. Hence, the columns of V can be interpreted as topics.

The primary output of both LDA and NMF is a set of topics, each of which consists of a cluster of words. However, with only words in a topic, it is sometimes challenging to interpret or determine what each topic is about. This is non-trivial especially in ontology or taxonomy development as understanding of the context of each topic is crucial for better representation of the categories, properties, and relations among the data, concepts, and entities. Hence, in this study, not only the topics but also the context of each topic (i.e., SLSs that are the origins of each topic) are extracted and evaluated. A sample output of the topic models is provided in Table 1. This example shows one of the topics extracted from "Invest in Transit 2018-2023 Regional Strategic Plan" that provides a regional transit strategic plan for Chicago and Northeastern Illinois using NMF [22]. This topic covers a set of 5 words and the 8 SLSs. With the help of the contexts, it is evident that this topic is about the funding of transportation infrastructure projects. More specifically, the diversity of funding sources and transparent use of funding are the two focuses of this topic.

2.4 Topic Compilation

Due to the varying nature of collected files, a vast array of topics were generated. In this step, first, topics generated via LDA and NMF from each text file were compared and compiled. Then, topics identified across different text files were complied. Two criteria were used for topic compilation: mutually exclusive and collectively exhaustive. Mutually exclusive ensures that no topics were repeatedly counted and collectively exhaustive ensures that all the important topics identified were included.

2.5 Taxonomy Development

Taxonomy development step provides a preliminary solution about what concepts and/or factors impact and should be considered in smart transportation infrastructure planning. Moreover, successful implementation of this step can provide a hierarchical structure to organize different concepts and/or factors. A bottom-up approach was used in this step to develop the taxonomy using topic information generated in the previous step. For example, different hazards such as tornado, wildfire, and heatwave were included in the contexts of topics related to natural hazards and their impacts on transportation infrastructure. Therefore, these specific hazards were identified as the bottom-level entities and were grouped together at a higher level of the taxonomy under *natural risk*. Since there were other topics identified extensively discussing man-made hazards and their impacts on transportation infrastructure, "*natural risks*" and "*man-made risks*" were identified as two parallel concepts and grouped together under "*risk*" category in the taxonomy (see Figure 2 for details). In this study, four levels (i.e., level 0, level 1, level 2, level 3) in total were identified in the taxonomy to organize all the important information and concepts in a structured way. Level 3 is the lowest level with the finest level of granularity, followed by level 2, level 1, and finally level 0. It should be noted that caution needs to be taken in this step, as subjective judgement is required for appropriate grouping.

2.6 Validation

As the last step, both internal and external validation of the preliminary taxonomy were conducted. First, internal validation was conducted by the authors to ensure the quality of topic modelling and taxonomy development. The topics identified as well as the concept grouping structure were cross checked. Second, external validation was conducted by comparing the taxonomy with other existing studies. For example: *mobility* was a key topic captured across multiple documents and thus was identified as a concept related to service performance of transportation infrastructure in the proposed taxonomy.

In related transportation literature [23], *mobility* is used as one indicator of service quality of transportation infrastructure as well. Therefore, it was validated that *mobility* was properly grouped with other concepts that are relevant to *service quality* of transportation infrastructure under the *performance* domain in the proposed taxonomy.

3 Proposed Taxonomy

This section presents the preliminary transportation infrastructure planning taxonomy developed in this study. Figure 2 shows the first three levels in the taxonomy. Level 3 is not shown in Figure 2 due to the large magnitude of information. A sample representation of all the levels is demonstrated in Table 2 using the example of *risk* domain. The details of the proposed preliminary taxonomy are explained as follows, organized by the seven categories of concepts in Level 1:

Risk

A few documents explored the potential of *natural* and *man-made hazards* on transportation infrastructure and risks associated with them. Among the man-made hazards, traffic crashes were considered to be the most important source and hence, were investigated in detail. Apart from traffic crashes; hazmat spills, cyber-attacks, terrorism, etc. were also explored in several documents as potential man-made hazards that could have a detrimental effect on transportation infrastructure.

It was observed that natural hazards and their associated risks were given more importance compared to man-made hazards. A variety of natural hazards, such as wildfire, drought, heatwave, flooding, landslides, avalanches, storm surges, and earthquakes were extensively discussed and investigated for their threats to the transportation infrastructure (e.g., prolonged heat waves could increase the premature deterioration of infrastructure).

Utilization

Utilization refers to the utilization of transportation infrastructure in terms of the type and weight of vehicles using the infrastructure, and the usage frequency of infrastructures. The information of utilization has significant impacts on current and future transportation infrastructure planning. For example: in Georgia's statewide transportation plan [24], it highly emphasized that flow of freight in terms of weight, the type of vehicle most commonly used for freight transportation, and the usage of roads could provide useful insights into the infrastructure needs. Hence, *vehicle type*, *road usage*, and *vehicle weight* need to be carefully monitored. *Vehicle type* can refer to different classes of vehicles specified by The Federal Highway Administration (FHWA), *road usage* can refer to estimating Average Annualize Daily Traffic (AADT), and *vehicle weight* can refer to the maximum allowable weight that each class of vehicle can carry. *Vehicle type*, *road usage*, and *vehicle weight* can holistically provide useful information to maintenance requirement and frequency, as well as future needs of transportation infrastructures.

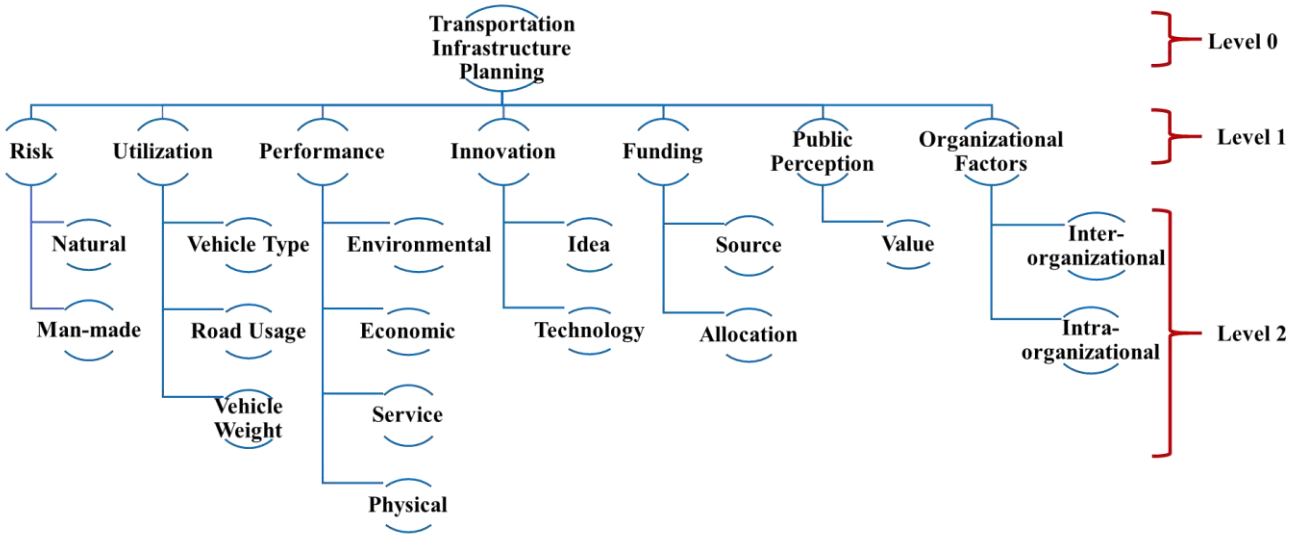

Figure 2. Illustrating the proposed transportation infrastructure planning taxonomy

Performance

Performance refers to the capability of current transportation infrastructures to fulfill the user needs.

Performance has been categorized into four classes in the proposed taxonomy, i.e., *environmental, economic, service*, and *physical*. In terms of *environmental* performance, different state DOTs or local legislative bodies provided different benchmarks such as air quality, water quality, greenhouse gas/carbon emission, and preservation of open space. Among them, greenhouse gas/carbon emission had been the focal point in majority of the documents that discussed the environmental performance of transportation infrastructures. With regards to *economic* performance, employment growth, supply chain and logistics reliability, inter-industry economic competition, etc. were identified as the major indicators for transportation infrastructure. *Service* performance is arguably the predominant measure of transportation infrastructure performance that was emphasized in almost all the documents. There were a number of transit service performance measures that had been discussed in detail such as ride quality, vehicle mobility, accessibility, intermodal coordination, transit security, connectivity, flexibility, and quality of transit fare system. On the other hand, service measures in terms of personal mobility such as walkability were also highlighted in a few documents. There were a few additional service measures that were not associated with transit but with quality of transportation infrastructure in general. For example, quality of road signs, quality of lightings, and coverage of emergency service patrol were discussed as indicators of transportation infrastructure quality in many documents. Finally, *physical* performance measures refer to the physical conditions of transportation infrastructures. *Physical* performance measures refer to the condition of transportation infrastructures such as bridge, culvert, airport, parking lots, rapid transit, heavy rail, and urban rail. The physical performance measures indicators can range from visual inspection ratings to complex performance index (e.g., pavement condition index (PCI)).

Innovation

Innovation has brought a lot of changes to today's transportation infrastructure. In the proposed taxonomy, innovation has been identified as an important concept in Level 1 and can be represented by two classes, i.e., *idea* and *technology*. *Idea* refers to new lines of thoughts to improve the quality of transportation system. For example, complete streets (i.e., streets that are designed and maintained to enable convenient and safe travel and access for all users regardless of modal choice) and greenway corridors (i.e., corridors that are specifically designed for recreational or pedestrian use ensuring environmental, wildlife habitat, and water resources benefits) are new and innovative ideas that were introduced in many of the documents to future-proof transportation infrastructure [17].

In terms of *technology*, it was found that automated and connected vehicles, novel data management framework, alternative fuel, alternative energy (e.g. solar power) etc. had been gaining attention and adopted widely across USA and hence, need to be exhaustively investigated regarding their impacts on transportation infrastructure planning and development. For example, with more electric vehicle on the road, there is a need to integrate the electric charging infrastructure development into transportation planning.

Funding

Funding was identified to be a critical factor in transportation planning. It is often challenging to acquire adequate funding to maintain and improve the existing transportation infrastructure, as well as to develop new infrastructure. Leveraging the information from topic modelling results, there are two level-2 concepts under funding: *source* and *allocation. Source* refers to the authorities and financial entities that provide money for transportation infrastructure related ventures. Three types of major sources were found from the documents, i.e., public, private, and public-private partnerships. *Allocation* refers to allocating the monetary funds to different areas or activities. For example, allocation of funding can be based on different levels of transportation development and improvement needs in different areas (e.g., rural, urban, or sub-urban). Allocation of funding could also be based on types and urgency of activities (e.g., preservation, modernization, or expansion). Different funding allocation rules might be applied to make sure the money is used in a most effective way to the most needed areas and activities.

Public Perception

Public perceptions and opinions are influencing transportation infrastructure more and more. One example found in the topic modelling result from this study is that, people (especially the younger generation) are becoming more conscious of the transportation choices they have and how these choices affect not only their lives but also the environment and society. They are becoming more aware of the detrimental effects of auto-dependency and want a transportation system that promote healthy living. Moreover, there is a growing consensus among the people that reducing auto-dependency help preserve the environment in many ways as well. Hence, it was observed from multiple documents that there had been a growing demand in recent years for developing and improving biking, hiking, and walking infrastructures. This phenomenon has been termed as *value* in the proposed taxonomy under public perception category. There are other types of public perceptions such as complaints that might affect transportation infrastructure planning, which were not captured in the

20 documents analysed in the current study. More documents will be included in the analysis to further develop the concept of public perception and its impacts on transportation infrastructure planning in future work.

Organizational Factors

Organizational factors relate to the culture of the transportation planning agencies (e.g., DOT) towards better management practices. These organizational factors greatly affect the adoption and implementation of any transportation planning policies and decision-making process behind. There are two major classes of organizational factors: *intra-organizational* and *inter-organizational* factors. *Intra-organizational* factors include an agency's commitment to not only improve internal communications and engagement processes, but also ensure that plans, programs, and projects are in line with its long term strategic goals. For example, San Francisco Municipal Transportation Agency's strategic plan emphasize that all agency plans, programs, and projects of the agency must be adjusted accordingly to fit the scope of the strategic plan [25].

On the other hand, *inter-organizational* factors refer to the collaboration and coordination attitude of transportation planning agencies with other transportation partners. A high level of coordination and collaboration among state government leaders, congressional delegation, land use planning governing bodies, industry stakeholders, tribes, non-profit organizations, and the general public were found to be significant in ensuring robust transportation infrastructure [e.g., 26].

Table 2. Sample construction of transportation planning taxonomy

Level 0	Level 1	Level 2	Level 3
Transportation infrastructure planning	Risk	Natural	Wildfire, drought, heatwave, flooding, landslides, avalanches, storm surges, earthquakes
		Man-made	Hazmat spills, cyber-attacks, terrorism, traffic crash

4 Conclusions

In order to develop an integrated ontology for transportation infrastructure planning, a taxonomy was proposed in this study as the first step. The transportation infrastructure planning taxonomy was developed using topic modelling techniques based on textual information from 20 transportation planning documents published by government agencies. The taxonomy and the ontology that will be built could potentially address the interoperability challenge of transportation plans at various levels and across different regions. In addition, they could provide a formalized structure to collect, organize, analyse, and utilize information from different sources to help transportation infrastructure planning. The ultimate goal of this study is to create a smart transportation infrastructure planning platform that can help planners to make informed infrastructure planning and management decisions using information and knowledge effectively with the help of the ontology.

The current study has several limitations. First, both the number and scope of documents included in the topic modelling analysis in this study are limited. For future study, the authors will collect more data from more sources, including online social media data to implement topic modelling and identify emerging concepts related to transportation infrastructure planning. The taxonomy will be further developed based on new concepts and information captured. Second, in order to grow the taxonomy proposed into an integrated ontology, more elements including attributes, relationships, rules, and restrictions of concepts will need to be investigated extensively in future studies.

Automated Detection of Urban Flooding from News

F. Zarei[a], and M. Nik-Bakht[a]

Abstract –
Although minor overflows do not cause a huge amount of loss; as the number of such overflows increases, the amount of water wasted, and the compound consequent challenges become considerable. Therefore, detecting overflows, investigating their cause root and resolving them in a timely manner are among new needs for infrastructure managers. This paper suggests a new method for detecting distributed water overflows by extracting the flood information (such as the date and location of the incident) from the news. As a case study, we crawled Montreal newspaper and news websites to detect the related news to urban flooding and their detailed information. We trained several classifiers to identify news relevant to flood. Our experiments illustrate that by applying mutual information method for feature selection and employing support vector machine (SVM) architecture as the classifier, relevant news can be detected with an accuracy (F-measure) of above 80%. Such actionable information can help infrastructure managers with a wide range of decisions from repair and maintenance of existing systems, to capacity evaluation for new designs.

Keywords –
Classification; Montreal newspaper; Urban Flooding; Water overflows

1 Introduction and background

Nowadays, anthropogenic climate change alters weather patterns with significant shifts in climate normal and extremes [1]. On the one hand, having more extreme events such as heavy rainfalls could lead to an increase in the risk of urban flooding. On the other hand, the aging infrastructure, encroachment on drainage canals, and reduced natural drainage introduce additional risk factors. Heavier rainfalls in aging infrastructure may generate urban flooding [2]. This is particularly increasing the frequency and magnitude of distributed incidence which is also known as compound effect.

At the same time, 'responsible citizenship' is an emerging phenomenon with several benefits such as citizen engagement, detecting public service performance and citizens 'priorities via feedbacks [3]. Reporting the civic complains in the media in recent years is supporting in this regard. In fact, it is a belief that citizens are inherently capable to solve their own problems at a higher level, collectively and collaboratively.

The citizens are enabled by resolving the urban issues to monitor, record and report the social problems together [4]. Several social media platforms such as Twitter, Instagram and complaint boards provide channels for the citizens to get engaged in different levels of problem solving and decision making. Using these platforms, citizens can take a photo from a civic phenomenon, add a comment, geotag, and share it. In fact, it is argued that citizens gain more awareness by the aid of these platforms and they can help the authorities to learn about the issues faster and more efficient. In [5], the authors use Deep Belief Network (DBN) and Long Short-Term Memory (LSTM) for detecting traffic accidents from social media data, specifically Twitter, and compared their results with the data of 15,000 loop detectors. It is concluded in this research that around 66% of the tweets which are relevant to the accidents are consistent with the facts about the accidents.

By using tweets, the authorities can gain a better understanding of the number of involved citizens with the issues and the intensity of problems [6]. In this regard, after the emergence of smart cities, it is attempted to apply new technologies and ideas to improve social, political and economic systems. It is aimed that such technologies could help the citizens to increase their level of participation in civic issues.

In [7], the authors provided a platform named "Citicafe". This platform has an exchangeable based interface to improve the citizen engagement by allowing direct messaging. It can help citizens to gather information related to their neighborhoods and report their problems. As another example, Indian government authorities collaborated with Twitter to launch "Twitter Seva" [8] whose goal is the enhancement of public service engagement by providing a platform for following complaints in a real-time manner. In this platform, the citizen interactions are limited to one

whose communicated since there are no chat interfaces.

Considering board range of events reported in social media, one of the high-level goals of our research work is to automatically detect the overflow incidents from people's inputs and also to communicate warning alarms. We need to study the source of any observed and reported on-the-ground water to know whether it is related to flood, overflows or pipe leakages.

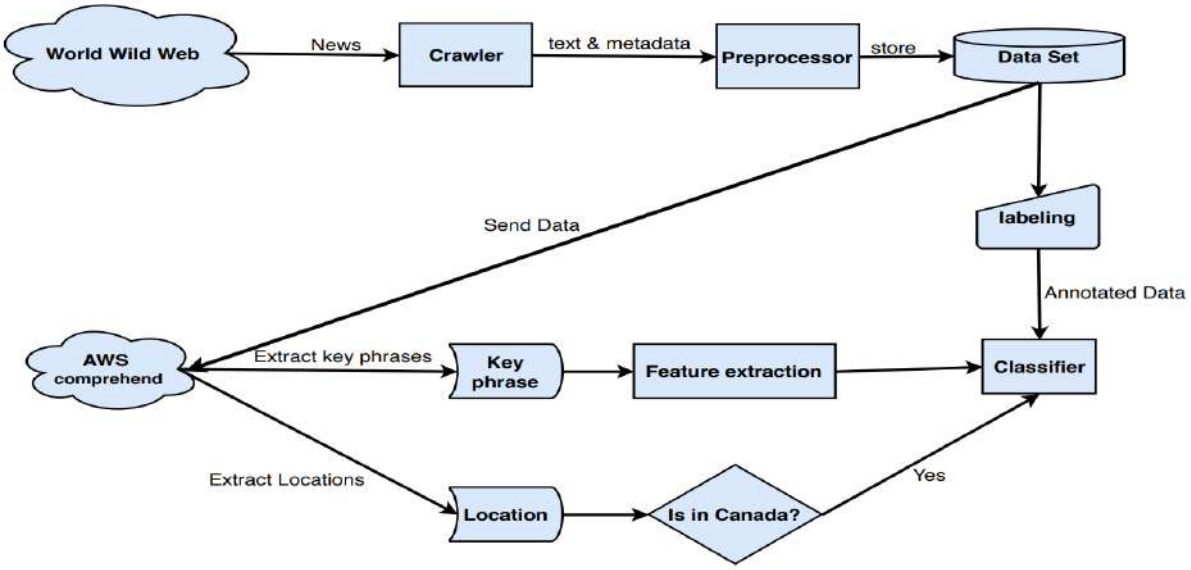

Figure 1. The architecture of the proposed method

In this regards, a binary classifier is required to categorize floods in a more specific context; from a nice rainy day to some serious failures. In the ideal case, not only we should be able to automatically detect flood spots in the city, but also we must detect the source and type of flood. In fact, we must be able to realize whether, with a high chance, it is a natural phenomenon or related to an infrastructure shortcoming.

With this aim, we collected and annotated news, and went through their content to find more related words. Considering co-occurrence of terms, we need to exclude the news which are not about water but include the terms which are normally used in discussing articles. On the first step, by searching the term "flood" on flood newspaper websites, we let the website's search engine to screen the news. Then, the obtained news was passed to Comprehend, which is Software as a Service (SaaS) provided by the amazon web services (AWS) [9]. Comprehend helped us to extract entities and key phrases from the news sentences. On the next step and after generating the relevant features manually, the required features for classification were selected by applying a mutual information method [10]. Having the features, Bayesian classifier (Naïve Bayes) [11], Meta algorithm (AdaBoost) [12], Decision tree (Id3) [13], Neural network (Multi-layer perceptron (MLP)) [14], Kernel estimation (KNN) [15] and Support vector machine (SVM) [16] classifiers were tested to label the news as relevant and irrelevant to the flood. Finally, the accuracy of the classifiers was evaluated in the sense of F-measures.

The remainder of this paper is organized as follows. The overall process flowchart of the proposed method is discussed in Section 2. Section 3 provides a discussion about the approach of crawling and also the data collection process. Applied feature extraction and feature selection approaches are explained in Section 4. In Section 5 the method of classification is provided. Section 6 presents the simulation and the obtained results, and finally, concluding remarks are provided at the end of the paper.

2 Proposed method

In this section, the entire flowchart of the proposed method will be discussed. As mentioned before, the main purpose of this work is detecting flood events in city of Montreal. In this regard, we concentrate on the flood-related news reported in Montreal newspapers. After gathering such news, the topic of each news article, which is a sentence, is considered as the input of the system. By using the Application Programming Interface (API) of the AWS, the existing name-entities and the key-phrases of the sentence are extracted. The news is considered irrelevant to our research if its extracted location is outside Canada. In such cases, the system goes to the next sentence. Otherwise, each word of the news article is searched in the provided word-list. If that word exists in the *i-th* place of the word-list, the

i-th element of the feature vector becomes 1 and remains zero otherwise. Next, the feature generator provides an appropriate matrix of data with their features for the classifier. Finally, the classifier decides whether the news is related to the flood. This procedure is represented in Figure 1.

3 Data extraction

3.1 Data collection

The applied dataset was selected from the most popular Montreal local English newspaper, "Montreal Gazette" [17]. In this regard, with the aid of search engine of this website, we filtered the news archive and selected the ones which contain the word "flood". On the next step and after such filtering, all the related news gathered into our database by building a crawler for this website in python.

3.2 Corpus construction

Once we crawled all the news form the mentioned newspaper, we had to reorganize the collected data in a format which is easy to use for our research purposes. The data of the gathered collection consist of 6 attributes including title, the body of the news, the category of the news, the date, the link, and the link of images.

3.3 Data annotation

In the next step, we assign a number to each sentence manually, which indicates the relevance of the news article. The news was divided into two categories named as relevant and irrelevant. The relevant news examples to the flood were labeled as '+1' and the irrelevant ones labeled as '-1'. "Leaky pipe floods Van Horne Ave., creates Sunday traffic woes" and "More than a year after floods, family of 7 will soon be homeless" are two examples for each group, respectively.

4 Feature extraction and feature selection

Feature extraction and feature selection are two important processes which should be done prior to classification to improve its accuracy and decrease its computational complexity. Therefore, feature selection has a considerable importance in the scope of this paper. The methodology of feature selection applied in this work can be explained in two main steps: keywords extraction, and filtering.

4.1 Keyword extraction

The main aim of this step is extracting the 'name entities' such as the locations and extracting key-phrases of each news article. The location of a news is important in this research since our goal is finding the place of flooding. We applied AWS Comprehend service to extract the locations mentioned in the news as well as their key phrases. Amazon Comprehend is a natural language processing (NLP) service that uses deep learning to find the meaning and insights in texts. The topic of news was the input of the Comprehend service and the output was the location and key phrases of the news. We consider these keywords as the features for the classification. However, not all the extracted keywords can be beneficial for the classification. Firstly, the features applied in classification must be able to discriminate the data. Moreover, some of the extracted features are redundant and can deteriorate the classifier. Therefore, the features need to be filtered prior to the classification. The way of filtering of the features is described in the next section.

4.2 Manual selection of related and unrelated key-phrases

In this step, we calculate the occurrence of each feature in our dataset. Then, those features which are not very common in our corpus are deleted from the list of features. These features are the ones whose occurrence is less than 5 times in sentences. After this reduction, we still need to reduce the features to the ones related to flooding. Hence, we were through the list and deleted the irrelevant features. Finally, an automatic feature selection method was applied to the list of remaining features to make the features ready for classification.

4.3 Automatic feature selection by applying mutual information

There are many different approaches for feature selection. In this work, we focus on the information-theory-based approach. This method has attracted the most attention since it can detect nonlinear correlations among the features. Mutual information is an important concept in information theory. It can evaluate the relevance between two random variables X and Y. In this paper, the mutual information of two variables $word\ (w)$ and $topic\ (t)$ is defined as below:

$$\boldsymbol{MI(w,t) = \log\big(P(w|t)\big) - \log\big(P(w)\big)}. \quad (1)$$

Here,

$$P(w|t) = \frac{\text{NDTW}}{Total\ number\ of\ Docs\ with\ the\ topic\ t}$$

$$P(w) = \frac{NDW}{Total\ number\ of\ Docs}$$

Here, NDTW stands for the number of documents with the topic t containing the word w and NDW stands for the number of documents containing the word w. We apply this method to select a subset of highly discriminant features. Hence, the features which have the capability of discriminating the data of different classes are selected.

5 Classification

In a typical supervised classification problem, the main goal is to train a classifier by using a dataset $U = \{(X^1, t^1), \dots, (X^n, t^n)\}$ of n labeled instances where each instance x^i is characterized by d features, i.e. $X = (X_1, \dots, X_d)$, and a label which indicates the class that it belongs to.

In this section, the main goal is to classify the news into 'related to the flood' and 'nonrelated to the flood'. Different applied classification methods are Naïve-Bayes classifier, AdaBoost, Id3, MLP and SVM. In the next section, the results of these classifiers are compared.

In order to evaluate the classifiers diagnostic tests were performed and three metrics were considered: precision, recall and F-measure.

$$precision = \frac{tp}{tp + fp}$$

$$Recall = \frac{tp}{tp + fn}$$

$$F_measure = 2.\frac{precision.recall}{precision + recall}$$

Here, *tp* is the number of data samples with the real label of positive which are labeled as positive by the machine. Furthermore, *tn* is the number of data samples with the real label of negative which are labeled as negative by the classifier. Similarly, *fp* is the number of data samples with the real label of negative which are labeled as positive by the machine. Finally, *fn* is the number of data samples with the real label of positive which are labeled as negative by the classifier.

6 Result and Evaluation

After search in "Montreal Gazette" newspaper data, the term "flood", 957 news items were found, started from September 16, 2009. This extracted news was manually labeled: 528 of them are labeled as relevant and 429 as irreverent.

By applying the feature extraction through Comprehend service and omitting the irrelevant features, the number of selected features for the classification was reduced to 98. In the next step and by applying the mutual information method, the number of features reduced to 50.

These features were passed to the classification agents whose results are reported in Table 1. For the evaluation, 10-fold cross validation was applied and precision, recall, and F-measure were calculated.

Table 1. Results of the classifiers

Classifiers	Precision	Recall	F-measure
Naïve Bayes	0.741	0.887	0.807
AdaBoost	0.711	0.932	0.805
Id3	0.707	0.887	0.787
MLP	0.697	0.870	0.774
KNN	0.751	0.859	0.801
SVM	0.762	0.832	0.824

The importance of precision and recall depends on the application. In some cases, having a higher precision is critical and in some other cases the recall has such importance. However, generally it is desired to consider both of them and evaluate the F-measure. Comparing the accuracy of the classifiers, it is seen that the SVM classifier classified the data more accurately. This is due to the characteristic of the SVM classifier that makes it a good choice for providing an adequate discrimination boundary for double class classification problems.

7 Demonstration of the results

After extracting the locations and finding the relevant news, results were encoded as colors and were visualized. Figure 2 presents number of news mentioned flooding in "Montreal Gazette" from 2009 to 2018. As seen, the number of sections in which flood is reported is increasing through the time. Also, the colors are getting more saturated which indicates the higher number of flood report in that area.

8 Conclusion

Detecting the small water overflows and finding their resources are important especially when the cause of water overflows is a malfunction of the infrastructure. In this work, we attempted to detect news about the flood as either a natural or a man-made phenomenon, reported in Montreal newspaper. In this regard, 4 classifiers were trained and the results were compared. In the end, we reached more than 80% accuracy in terms of the F-measure score, which belongs to the SVM classifier by applying mutual information method

for feature selection. The results of this research are useful for infrastructure managers who make decision about the maintenance of different infrastructure.

One of the main limitations of this work is that our corpus is quite small for the learning process since we just applied the text of one newspaper. Hence, more data sets should be applied to improve the performance of this work.

Following this work, we can use more properties from the website contents such as images of the news. In this work, we just classified the topic of the news. However, most of the news in the newspapers have images. Hence, by applying some image processing techniques, we can understand whether the news is related to the flood or not. By combing this results with the classifier results, we can increase the accuracy of the classification.

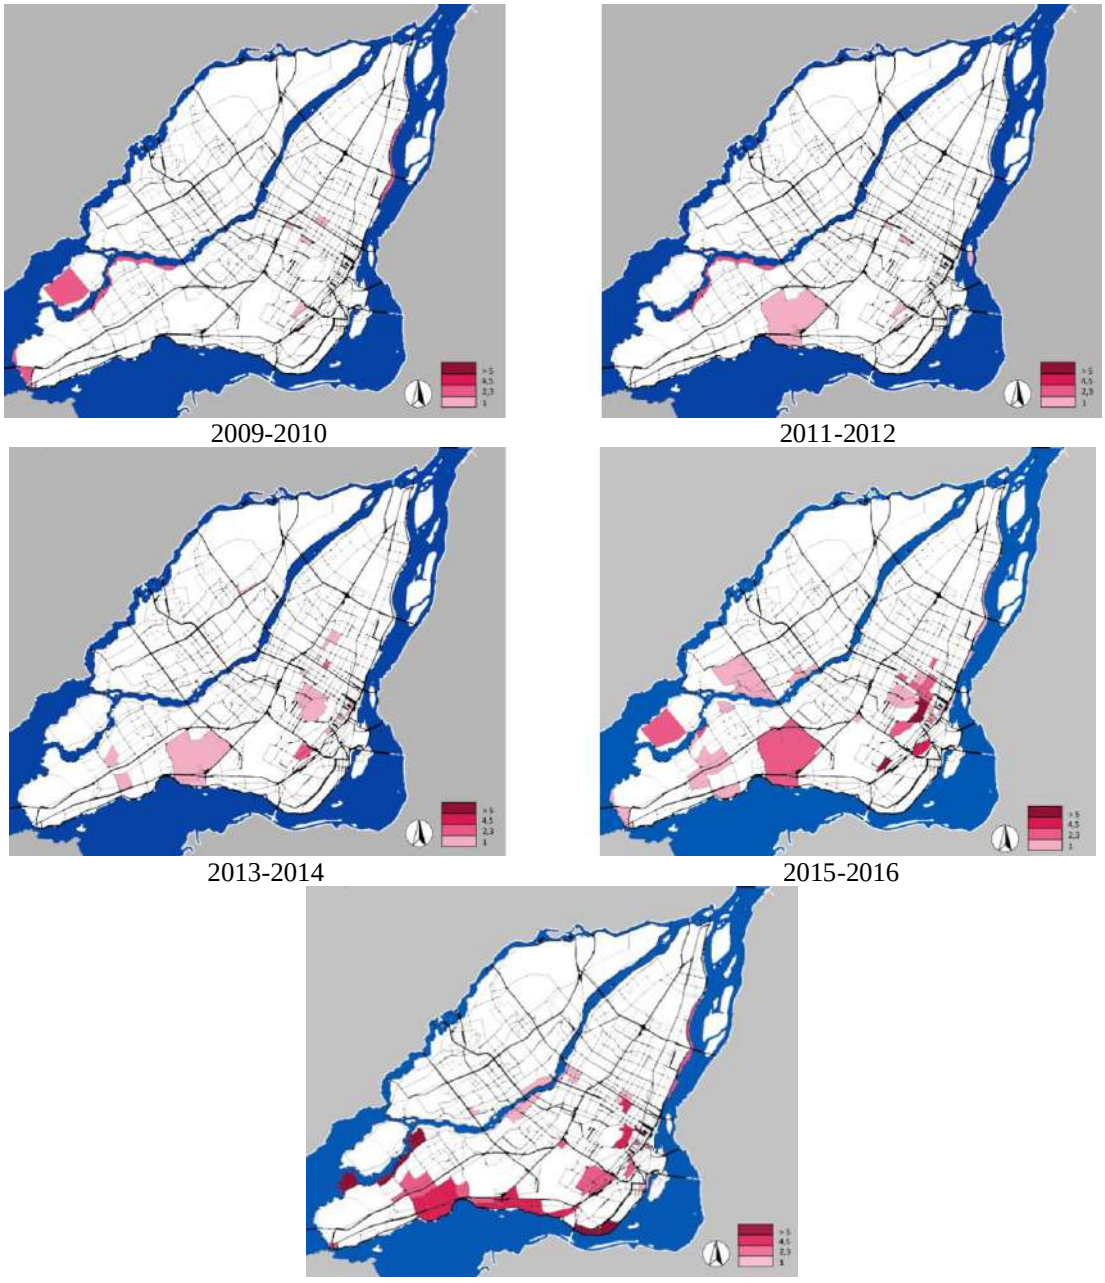

Figure 2. Number of flood reported in “Montreal Gazette” in different parts of Montreal

Adaptive Automation Strategies for Robotic Prefabrication of Parametrized Mass Timber Building Components

O. D. Krieg[a] and O. Lang[a]

[a] Intelligent City Inc., Canada
E-mail: odk@intelligent-city.com

Abstract –

This paper presents applied research into automated and adaptive robotic prefabrication strategies for a generative platform design enabling mass customized, mass timber modular construction. The development is part of an ongoing effort by the company to bring a holistic approach of design-driven modular mass timber housing and advanced prefabrication techniques into the market of urban densification. The presented work is currently developed for the delivery of two mass timber housing projects with four and 12 storeys, the latter acting as a case study in this paper. In the first part, the paper explains the possibilities and challenges of large-scale robotic fabrication in timber construction as well as strategies for embedding robotics within a digital design workflow. The focus will be on the required change in the industry's design thinking for automation strategies to be effective. In the second part the development of an adaptable construction system suitable for robotic automation will be presented. We argue that while automation of conventional assembly steps might be suitable in some cases, the construction system, and ultimately the individual building parts, must be developed in reciprocity with the capabilities, or the design space, of the machine. The authors share their experience of the application of such an integrated process and its requirements towards the collaboration between, and the automation of, design, construction, engineering, and manufacturing. In its conclusion, the authors argue that a long overdue paradigm change in the architecture and building industry can only be achieved through the complete convergence of all disciplines.

1 Introduction

Throughout human history wood has almost always played a dominant role as a building material. Its wide-spread availability in most climate zones, combined with the relative ease of shaping and processing the material allowed humans to develop and refine resourceful, resilient and adaptive construction techniques over thousands of years. In fact, many hundred-year old buildings in China, Japan and Europe are still standing today and prime examples of the creative and intricate constructions made from mostly linear elements.

The required labour and material knowledge for harvesting and processing trees led to a wide-spread but locally differentiated culture of timber fabrication. The interdependency of available materials, tools and culture is evident in the differences between structural systems and buildings throughout the world [1].

However, as the Industrial Revolution took hold of the building industry in the 19th century, it led to a shift from local knowledge and local fabrication to industrialized and globalized mass production, which also brought a shift from value-added products to value-engineered and standardized components [2]. The replacement of manual but customized processes with automated but standardized manufacturing also resulted in standardized construction systems still applied in various forms today. Although standardization brought the advantages of higher quality control and the economies of scale, standardized construction systems lacked geometric flexibility and therefore the ability to adapt to different internal and external conditions. With a dramatic increase in available energy, the focus shifted away from wood and towards the mass production of steel and concrete, which became the primary building material of an industrialized world.

Given the environmental challenges we are facing today, and the struggle for sustainable living and urban densification, it is clear that the future of building construction needs to be energy-efficient, adaptable, lightweight, multifunctional and prefabricated in factory environments. Although wood is one of the oldest

building materials, new engineered wood products such as Cross Laminated Timber (CLT) are answering to all of these criteria. Although wood in its natural occurrence exhibits a great range of variation in material characteristics [3], engineered timber has a high and controllable structural strength, a positive carbon footprint [4], and a very low embodied energy compared to other building materials [5, 6]. Moreover, its mostly localized availability makes the material particularly suitable for the development of sustainable construction methods with short transportation routes [7]. Lastly, its accessibility as a renewable resource makes wood a prime candidate for new design and manufacturing developments, and it comes to no surprise that the general interest in mid-rise and high-rise timber construction has grown significantly over the last decade. On the example of robotically prefabricated mass timber building components, the paper presents an approach to a new paradigm of a sustainable and digitally designed architecture.

2 Context

2.1 Systemic Innovation and Digital Design

The Industrialization initiated a paradigm change in the building industry that, although advantageous at first, proved to be a barrier in our post-industrialized world [8]. During the 19th and 20th century, design, engineering, manufacturing and construction became fragmented and compartmentalized into highly specialized and disconnected disciplines [9]. The result was a highly hierarchical model with specialized organizations that soon developed individual interests opposing each other, ultimately limiting the free movement of knowledge and slowing down innovation. This is particularly detrimental as innovation in architecture is highly dependent on many different disciplines. Research on innovation explains this interdependency with the term "systemic innovation", where multiple and interdependent industries need to change all their processes in order for innovation to take place [10]. Systemic innovation diffuses slowly in project-based industries such as the construction sector. When multiple organizations must act together in order to implement change, innovation is dependent on an interorganizational network [11].

The industry's ongoing resistance to innovation becomes evident in its spending on research and development. In Canada, construction accounted for 8.8% of the nation's 2014 Gross Domestic Product (GDP) while its R&D spending was at 0.06% of the GDP. By contrast, the manufacturing sector comprised 13% of the GDP while its R&D spending was at 3.91% of the GDP [12]. Productivity has lagged accordingly: in the U.S., construction labour productivity has barely gained 10% over the past 70 years, versus a 760% productivity increase in overall economic productivity during the same period. Even worse, for the past 50 years construction productivity has actually declined [8].

A good example for this slow change is the adaption of digital planning processes such as Building Information Modelling (BIM), which requires a multitude of organizations distributed across all hierarchies of the construction industry to employ the technology. And although BIM is slowly being implemented by companies and municipalities today, the rise of digital planning processes has been almost independent from developments of digital fabrication. While both industries have slowly been digitalized in the past decades, they are still within the same hierarchical and fragmented model with limited information exchange and flexibility [9].

While digitalized planning processes may allow for more complex shapes and potentially more adapted and performative buildings, they are still characterized by a traditional top-down design method, leaving questions of producibility and materiality for a later stage [13]. Designers and architects are usually uninformed about manufacturing capabilities, leading them to either overestimate or underestimate the possibilities [14]. This lack of information exchange not only causes higher planning costs through late changes in the design, but it also requires more time and effort for manufacturers [15]. Ultimately, design decisions can not be based on transparency and idea generation but are instead driven by assumed cost efficiencies and risk mitigation.

We argue that in order to truly advance architecture and the building industry, systemic innovation throughout the fields of design, material science, manufacturing and construction is necessary, ultimately leading to a reconceptualization of how architecture is designed, made and delivered, while avoiding the friction inherent in the conventional building industry of today. This is the basis of production immanent planning [16] where reciprocities between fabrication possibilities, materiality and the design process are enabled through interactive digital tools [17]. Only through the convergence of design and manufacturing, and a constant feedback between the disciplines, the true potentials of technological innovation, namely affordability, precision, quality and sustainability will be unlocked.

2.2 Robotics in Timber Construction

The renewed interest in timber construction goes hand in hand with digital fabrication tools such as CNC machines having become well established in the industry. But although most wood processing machines are speeding up typical processing steps, they are task-specific and reinforce the use of already known fabrication methods and construction systems.

Meanwhile, the automobile industry witnessed the introduction of industrial robots in the 1980s, which came together with new manufacturing paradigms such as mass customization [18]. During the 1990s, early exploration of large-scale robotics for automated on-site construction were carried out in Japan [19]. Although technical challenges of building-sized machines on construction sites, and the decline of the building economy proofed to be too big of a hurdle, robotics has again been explored in architectural research more recently [20]. To some extend, this renewed interest is due to the concept of the industrial robot constituting a very different approach. The main difference when compared to process-specific CNC machines is that industrial robots were designed as mass-produced, affordable, high quality and flexible machines. They serve as a generic platform on which different tools and functions can be attached. Their controls are easy to access and can be directly implemented with an adaptive, digital design and manufacturing process.

The potential of industrial robots in timber construction ultimately derives from their extended kinematic range and their adaptability to new fabrication processes, allowing for the development of more complex and differentiated building components [21]. This introduces a shift from machines being made for specific processes towards the building or component being viewed as a product. Following the pattern of innovation consequences during the Industrialization in the 19th and 20th century, technical innovation such as the implementation of industrial robots can have a large impact on the development of architectural design.

Ultimately, innovation in manufacturing techniques for architecture has to go hand in hand with a rethinking of how building systems are conceived. In order to take full advantage of the industrial robot's flexibility, the main focus has to lie in the development of a comprehensive, digital design-to-fabrication workflow with a direct transfer of machine data.

2.3 Potentials of Applied Research

Research in advanced robotic fabrication in timber construction has shown promising results in the reciprocal development of manufacturing processes, construction systems and architectural potentials. The fundamental difference to typical innovation in the construction industry lies in the bottom-up research methodology.

The roof of the Arch_Tec_Lab at ETH Zurich is an example for automation of complex assembly processes that would not be feasible with manual labour (fig. 1). The precise spatial positioning of wooden components requires a new kind of manufacturing process with high precision and without any additional formwork [22]. The roof was designed and developed by the Gramazio Kohler Research group in collaboration with a larger planning team. The roof is made from large wooden trusses that consist of small timber slats stacked together in an alternating manner [23]. Instead of continuous top and bottom cords the trusses are entirely made from short slats nailed together at different angles. The type of nailed connection, the position and order of assembly were all developed in conjunction with a new robotic manufacturing technology that is able to cut, position, attach and photograph in one sequence. The design space derived from this process was explored through the undulation of the roof, which ultimately changed the angle and nailing position of each of the over 94,000 connections.

Figure 1. Robotic assembly of large timber trusses for the ETH Zürich Arch_Tec_Lab. Source: ETH Zürich, Apolinarska 2016 [21]

The Institute for Computational Design and Construction at the University of Stuttgart is leading research for robotic fabrication methods for segmented timber shells. Here, the manufacturing technology is developed in conjunction with a computational design method to generate and control the geometry of each segment of a larger shell structure and output the required manufacturing data [24]. For the development of a construction system made from double-layered, hollow cassettes, the researchers employed industrial robots to precisely assemble and then format each component in a multi-step manufacturing process (fig. 2). The complexity of the manufacturing process and the customized shapes of each building element necessitates a digital design-to-fabrication method and is ultimately only possible because of the adaptability of the developed manufacturing system. This approach allowed the researchers to design extremely lightweight and efficient shell structures [24].

2.4 Project Aim and Application

Although industrial robots have size and weight restrictions that originally related to car manufacturing, the above examples show their potential application for the prefabrication of medium-scale building components for large-scale structures. They also show how adaptability can play an important role when developing a completely digital workflow in relation to the available machines and tools.

While traditional processing steps and construction systems have been developed in relation to human strength and size [1], so are newly available machines related to the size and weight of building elements, as well as to the dexterity required for assembly or processing. It can therefore be argued that the machine setup defines the design space of the manufacturing process as much as the material.

The authors have applied the approach of production-immanent planning in the development of a mass timber building system. The aim of this development is the careful application of innovative manufacturing techniques, and therefore bridging the gap between academia and practice. In this process, industrial robots are applied for additive processes in order to allow for the assembly of heavy, medium-sized elements into larger panels. The task of formatting those elements stays within the realm of standard CNC machines but is implemented within the digital design-to-fabrication workflow in order to allow for a direct output of machine data. This holistic approach to design and manufacturing not only streamlines the entire process but, more importantly, allows for an inherent flexibility and adaptability without additional complexities. In its application, the developed processes can combine the consistency and quality control of mass production with the variability and individuality of cultural and societal responses to the built environment. Only then can quality, performance, scalability and differentiation replace repetition and manual construction.

3 Methods

The development presented in this paper is situated within the context of the architecture and building industry's need for affordable, sustainable, customizable and qualitative urban living. Through an integration of design, architecture, manufacturing and off-site prefabrication, the authors are introducing a new paradigm in the construction industry: empowering people to live better and more sustainably with the help of highly digitalized design and fabrication processes.

While the manufacturing development is based on robotically assisted, complex assembly processes, it is also connected to a larger development effort of parametric design methods that allow for a product-design approach in architecture, incorporating the entire value chain from design to delivery of innovative buildings. The main motivation is not to build shapes that were otherwise not possible, but to develop the ability for a variable response on a consistent platform.

3.1 Platform-Based Design

In the context of manufacturing automation, the concept of platform-based design is one of the key factors for allowing architecture to embrace a product-oriented design approach incorporating fabrication, material, engineering and functionality. Platform-based design is an integration-oriented design approach for the systematic use of an underlying logic, system, or platform, for the development of complex products that share compatible hardware or software [25]. This allows to establish a general knowledge base on which variant forms of the same solution can be realised. It also directs the development of the design process towards a class of products that can have a variety of design solutions for customized requirements within a common framework [26]. While platform-based design has been an established and decade-old concept in many other industries such as car manufacturing, its application in the highly individualized construction industry has not yet been explored to a level that would satisfy the need for customization in relation to a building's context, owner and tenants. By developing a platform within a computational design framework, the focus lies on a high degree of variability in the design process.

The platform is based on the modularised or panelised prefabrication of mass timber building components that can be shipped and assembled on site. The main structural components are defined by their relationship to the modular framework, and their geometry is derived from a parametrically defined logic further explained in chapter 2.3. For the explanation of the building system and its robotic assembly the authors will focus on the floor panels, which can also be assembled into volumetric modules at a later stage in the process.

The platform can be described as a four-sided but not necessarily rectangular, panel made from two layers of smaller Cross Laminated Timber (CLT) panels that are interconnected with smaller Laminated Veneer Lumber (LVL) beams. This panel is later connected to a varying number of columns on site, which are placed on the axis of the panels' borders and intersect with the panels in a way that allows steel connectors to connect and ensure a continuous force-flow. The panels are further connected between each other with thin strips along their edges to form a structurally continuous slab and allow for lateral force transer. Connections to concrete cores or CLT shear walls are special cases for which specific details have been developed. While smaller CLT panels are chosen as the main structural element due to their global availability, the width of a panel is not necessarily constrained by shipping container dimensions as they can be transported vertically on trucks.

The exact arrangement of CLT panels within one floor panel, their width and length, and the number of columns to be connected to a specific panel is parametrically defined and derived from a 3D model that incorporates design intent and structural requirements (fig. 3). The panels and their shapes are generated in an algorithm taking into account all connection details that will lead to certain penetrations or cuts within the panels. Following the geometry of a boundary condition from a preceding digital design process, the design space is ultimately defined by transportation constraints, but generally between 25 ft and 53ft in length, and between 10 ft and 40 ft in width (fig. 4). This allows to accommodate studios as well as up to 3BR and double-storey apartments.

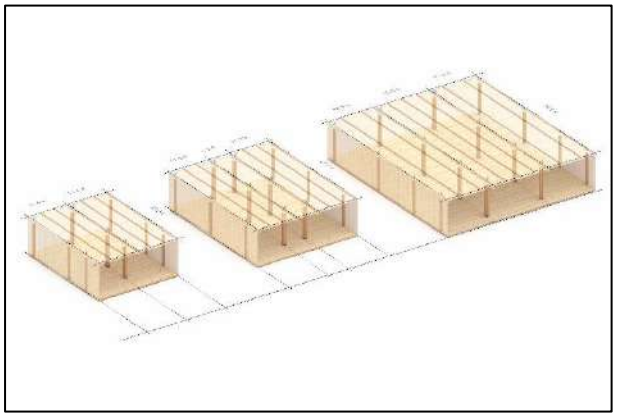

Figure 3. Visualisation of the parametric model adapting to the design space. The individual building elements populate the available space and obtain certain connection details through locators

3.2 Integrated Robotic Assembly

Timber is a great fit for modular construction due to its machinability and relatively low weight, meaning it can be more easily transported and assembled on site when compared to steel or concrete. Mass timber specifically, however, regardless of its structural and fire safety advantages compared to lightweight timber frame, is leaving the realm of human-scale building elements due to its weight and size, and therefore emphasizing the need for advanced manufacturing techniques. While many building materials and construction systems have been developed for the human scale and manual assembly, focusing on robotic processes allows for a reconceptualization of building element dimensions and weights. Most medium-sized mass timber elements are within the size and weight range of common industrial robots and therefore ideal for the introduction of automated and adaptive manufacturing. As a result, intersection points between human labour and robotic processes need to be carefully integrated.

The presented digital design process is developed in conjunction with appropriate manufacturing techniques and their possibilities: The arrangement of CLT panels and their connections were developed to be executed by similar but adapted robotic processing steps with offline programming. Contrary to traditional CAD/CAM processes where the geometry of the building element is imported into special software for machine code generation, the digital design-to-fabrication workflow developed by the authors generates machine code directly with the geometry. This seemingly complex digital connection between manufacturing and design is in fact easier as the geometry and meta-data of every building element is already parametrically generated, and all information can be further processed to generate the required machine code within one program.

The main development goal was to automate the process from CNC formatting to the assembly of the main structural components visualised in the previous chapter. Not only would this allow for an expedited assembly process but also reduce the complexity of manually measuring and laying out heavy timber elements. Instead, previously CNC-formatted timber elements are being handled by industrial robots, put into a measurably correct position and joined together. Robots are positioned on tracks parallel to either side of the panels in order to pick and place material as well as to connect elements with screws and nails (fig. 4). The size of the elements and the dimensions of the robotic manufacturing cell was developed in relation to the required design space. The manufacturing process is currently being implemented at the company's factory. First prototypes will be produced in the first half of 2019 and full manufacturing capacity will be expected by the end of the year.

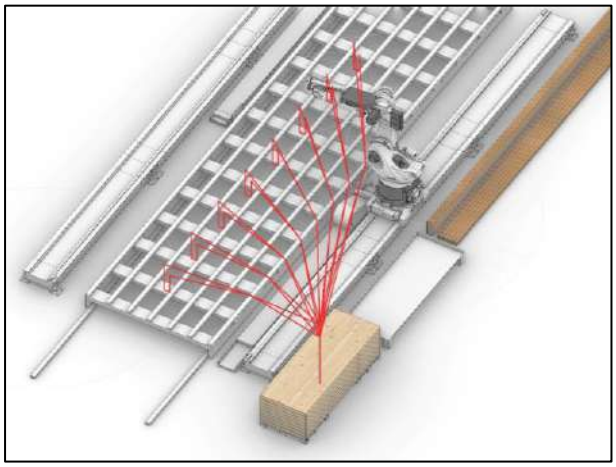

Figure 4: Diagrammatic overview of the robotic assembly process with the highlighted tool path of a robot for handling a stack of CLT panels during assembly

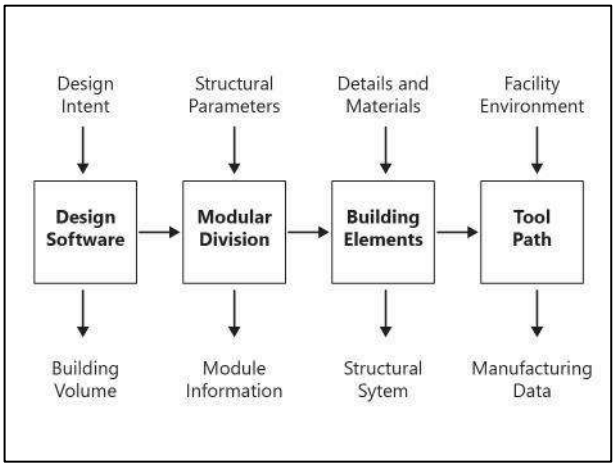

Figure 5. Flow chart of the design process towards the fabrication model. The early design model gets transferred to a modular division, its building elements and finally machine data

3.3 Parametric Design Process

The automatic generation of building components and manufacturing data is preceded by a digital design process that allows the exploration of different building designs within the design space of the construction system. In a digital design process, larger building volumes with up to 18 storeys are subdivided based on the requirements of the modular or panelised construction. After the subdivision, several structural parameters can be inserted in order to control the position of columns and concrete cores if necessary. The modular subdivision will adjust pass on the geometric information together with structural information in the form of locators. Each building group essentially acts as a data container, continuing to collect information as the digital process continues (fig. 5). When populated with all structural elements described in chapter 2.1, each element is already connected to information regarding its robotic assembly. In the case of the CLT panels, the assembly process can be stored depending on the overall size of a floor panel and the position of the CLT panel within it. Hence, each CLT panel has a certain number of geometric locations in its data model, along which the industrial robot will pick and place it in relation to the facility environment. These locations are previously defined and will result in tool path instructions for the robot. In the algorithm, all building elements of one building group will be processed simultaneously in order to export one file for the manufacturing process. A similar process is also created for the generation of CNC machining data before the assembly. The geometry of each building element is directly transferred into the necessary machining steps in order to cut the boundaries and penetrations of each CLT panel.

4 Result: High-Rise Modular Buildings

The platform-based design and manufacturing process has been developed to serve a multitude of urban infill developments ranging from 4 to 18 storeys, with sites ranging from 33 to 400 ft in width. To date, the platform has been tested on a dozen project proposals, six of which are currently in the design process. Among one of the first to showcase the platform in a real-life, large-scale application is a project called Corvette Landing (fig. 6)

Corvette Landing is a 12-storey mixed-use development designed to transition the still low-density single- and multi-family Township of Esquimalt BC, adjacent to Victoria. Planned and developed as an industry-first panelized and prefabricated mass-timber hybrid building, it seeks to combine the low carbon footprint with a high level of livability and expedited construction. The building is an affordable housing project to be Passive Haus certified in order to act as an example for adaptable, repeatable, scalable and sustainable condominium buildings.

Mass timber construction based on the building system described in this paper is applied from the second floor up. Around 150 panels will be prefabricated in the company's manufacturing facility specifically developed for this kind of application. On site, the panels and columns will connect to so-called concrete micro-cores necessary for lateral stability in this high seismic zone. As the elevators and stair cases are in an external, open courtyard, the concrete cores are only as big as a bedroom in this project.

The project received rezoning and development permit approval from the Township of Esquimalt due to its innovative character, green building strategy, and the

broken-up and terraced building volume. It passed the Review Board for Site Specific Regulation by the BC Housing Ministry's Building Safety Standard Branch in 2018 and will be one of the first mass timber high-rise housing projects in Canada. Start of construction is scheduled for 2019.

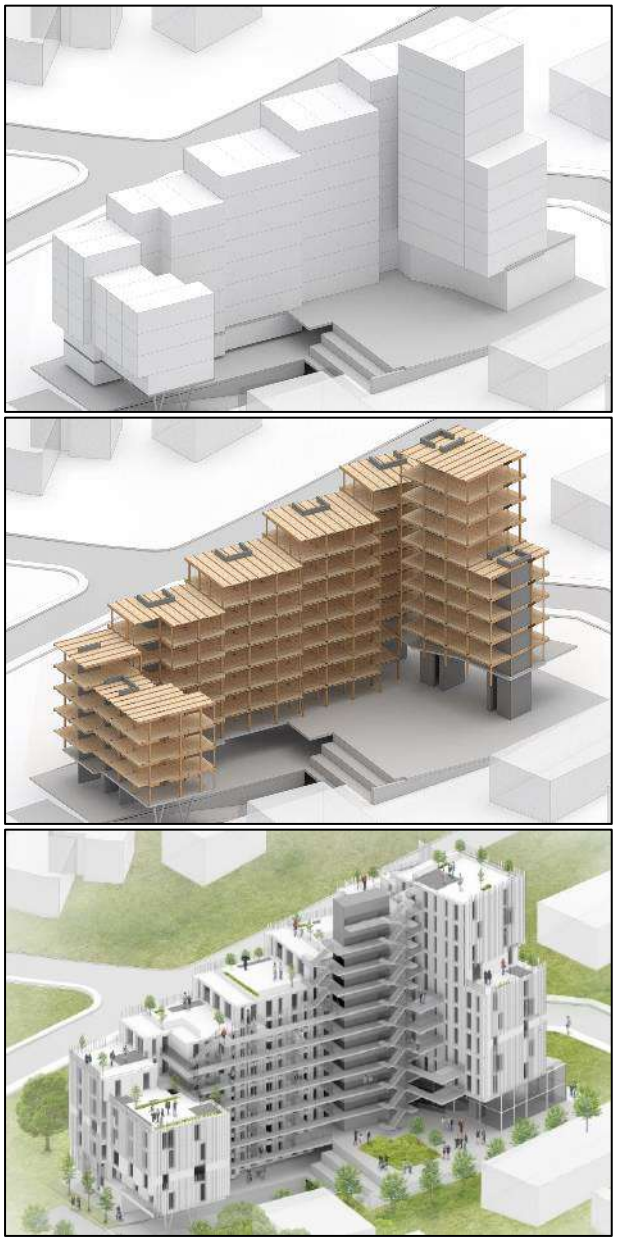

Figure 6. Visualisation of the modular layout (top) and the resulting construction system (bottom) for Corvette Landing. Each panel has a different geometry due to the setbacks, column positions and concrete cores

5 Conclusion

The development presented in this paper is a manifestation of a new paradigm in architecture and construction, converging design, material, structure and manufacturing. It enables the urgently needed transformative change of the urban housing sector towards a resilient urban densification and sustainable and livable future.

Mass timber construction most notably provides the opportunity to develop more adaptive and geometrically differentiated construction systems while still being realized with a certain economic efficiency. However, in order to adapt a construction system and its building parts to specific structural or architectural situations, a parametric design process and a direct and automated fabrication data generation is required.

We argue that in order for a paradigm shift to take place in the architecture and construction industry, already existing knowledge needs to be combined, calibrated and exchanged. A wholesale shift towards prefabricated buildings with mass timber components is challenging but possible. Collaboration across the spectrum of industry players will be necessary. The barriers to innovation run deep and cannot be solved by one actor alone.

6 Acknowledgements

The authors would like to thank their colleagues at LWPAC and Intelligent City as well as their consulting partners for their support in the development of the methods and results described in this paper. Part of this research and development was funded by the Industrial Research Assistance Program (IRAP) of the National Research Council Canada.

Abstract –

Reusing knowledge from past projects is a critical task in construction, given the increasing complexity in such projects: numerous stakeholders, a multi-disciplinary domain, and multi-objectives besides the traditional ones such as cost and schedule. Unstructured data, such as progress reports and minutes, is a rich source of knowledge that can be revisited in projects as the contextual nature of documents permits describing the nuances of the interrelations and uniqueness of each project. However, texts are difficult to formalize in a way that the process of retrieval and analysis of relevant knowledge be automated using computers. In this paper, we present an innovative approach that encompasses formalization, retrieval, analysis, and reuse of knowledge from case studies of past construction projects. Assuming that energy is an objective, the cases are represented as a network of common concepts found in every project. The nodes are the concepts, and the links between them are established whenever there is an association between two concepts that affects the energy use in construction. Conversely, the comments of team members of a current project can also be captured and represented using the same standardized set of concepts. Using network analysis, we can retrieve the most relevant cases, which are similar to the current project, study the most important concepts, extract clusters of concepts, and capture the nuances of the cases in a more objective way. A concept map based on the literature and three case studies of past oil and gas projects are developed to undertake this approach. We evaluate the method by simulating the collaborative environment of one of the cases through the participation of ten volunteers in Green 2.0, an online media to discuss construction projects. At the end of the test, we perform a correlation between the networks of the test and the case study.

Knowledge retrieval and representation; Unstructured data; Network analysis; Blockmodeling; Construction management; Energy use

1 Introduction

The primary objective of this work is to utilize network theory to help formalize and consistently process unstructured data (mainly text) in construction management. The aim is to support capturing, retrieving and coordinating knowledge reuse during project deliberations. Documents and reports developed based on the input or deliberations of project stakeholders are a fundamental container and widely used means to capture construction knowledge. This fact is primarily due to the subjectivity of the domain. In general, planning and managing construction projects depend on the reuse of implicit knowledge and expertise gained in previous projects. The challenge is how we can capture and reuse knowledge contained in unstructured data developed by project stakeholders. How can one externalize the tacit knowledge contained in them? Doing so in an efficient manner has been increasingly becoming important due to the growing complexity of projects. First, due to the increase in the number of stakeholders who have to participate in decision making. Second, the increase in the number and diversity of decision criteria. For example, in addition to the traditional cost and schedule, project decision makers have now to consider additional issues such as environmental impacts as well as energy consumption. Third, compounding the challenges, many of the issues are contested—for example: how to identify and measure impacts on communities and sustainability.

Foundational approaches, such as rule-based expert systems and knowledge bases, have significant limitations in this milieu [1]. These limitations are due to the contextual nature of projects. Each project has

unique composition/attributes and boundary conditions, which influence the relevance and interpretation of rules as well as the ability to adapt them to the needs of the project context. Semantic models of knowledge, such as ontologies, provide a very suitable approach to handle such subjective and unstructured nature of knowledge [2]. However, the static nature of ontology has shortcomings [3]. This constraint, again, is due to the contextual nature of construction knowledge. More importantly, knowledge constructs (models) are "relativistic" as they depend on the judgment of stakeholders: it is typically quite difficult to achieve full (standardized) agreements between stakeholders.

Unstructured data, such as online discussions, minutes of meetings, e-mails, progress reports, and case studies have recently gained the attention of knowledge management (KM) practitioners [4,5]. This remark is because such corpus represents subjective knowledge in semantic forms. They are also, by default, context-sensitive. However, possibly, the most important advantage of using project text corpus as a source of knowledge is that they are the results of intense and critical dialogue between experts. Meetings transcripts, online discussions, e-mail threads, final reports and project case studies represent venues for knowledge exchange, conflict resolution, innovation, and consensus creation. Hence, it is not surprising that unstructured data are more informative than other sources.

Given that a good deal of the knowledge in the domain is textual, can using semantic network analysis be helpful? Instead of free text, typically used in case studies, can we build networks of project concepts and benefit from the traditional network analysis measures in enhancing the formality and objectivity of analyzing project knowledge? For example, what can we learn about a project if we study the centrality of, say, safety in its concept network? If two concepts, for instance, safety and excavation, are not linked in the concept network, does this reflect incomplete analysis?

In other words, the specific problem that this research project aims to address is that pure textual representation of project knowledge in the case studies may not be an optimal solution. First, the retrieval of such cases for future use can be inefficient. Typically, this would be done through a set of keywords recorded by the case developers or suggested by a content analysis algorithm. The automatically generated topics are suggested based on word frequencies and associations. This procedure, however, does not necessarily capture coherent or essential topics from a text corpus. While human tags (the manual categorization of the text in meaningful topics) are more superior, their standalone nature does not allow for capturing the interrelationships of case concepts. Furthermore, such tags are never optimal (they cannot cover all possible future needs). Second, it is difficult for upper management to conduct any formalized analytics using just a set of documents. Beyond the benefits of case reuse to guide new projects, cross-case analysis can detect trends, suggest and emphasize concept relationships (for a more detailed review of works published in this field, please see [6]).

Compared to other stages of the project life cycle, the construction phase has received the least attention from researchers [7]. This fact is mainly because of its limited contribution to the overall energy consumption of a project but, more importantly, it is the unique challenges of the construction stage. While the energy use in construction has been a topic of constant debate in academia [8,9], this scope falls much more under the umbrella of the construction knowledge management domain than energy efficiency or life cycle assessment. Hence, this research is not an energy assessment or a quantitative estimate of the energy use of the construction phase.

For such a subjective domain, learning from historical project cases can be very helpful. They map prior project conditions and their relationships to project performance (about energy); and document pitfalls, solutions, and lessons learned. The textual nature of these cases allows the user to contextualize the options and challenges of the project and gain a deeper understanding of the relevance of the listed best practices to a new project.

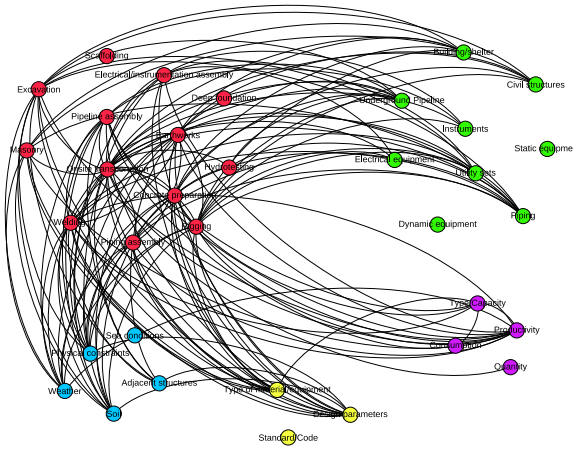

Figure 1. The concept network for one of the case studies developed in the research

The main objective of this research is to realize a system to use network theory to help formalize text corpus of project cases and, possibly, other documents to facilitate the externalization of tacit knowledge in an objective and reusable manner. The main contribution of this research is the creation of an approach that

formalizes the knowledge of projects embedded in unstructured data through transferring text into a network of concepts. In more specific terms, by using the formalized networks of concepts, the method can capture and reuse the knowledge from previous project cases to support the deliberations of the decision-making team during the construction planning of future projects.

The proposed system will permit stakeholders to collaborate, investigate, formalize, and capture the knowledge embedded in unstructured data to manage energy use in the construction phase of O&G projects.

2 Methodology

The proposed approach relies on the following scenario: using manual or automated means, the network of concepts of a current project is established. The network can be developed through semantic analysis of project documents or a summary report of a project, hopefully, developed by a group of collaborators. At the same time, during a retrieval process, the project team was able to find relevant cases that are similar to the current project. Figure 1 shows an example of the graph of a network of concepts of one of these case studies. The team then is interested in discovering (or externalizing) the most relevant knowledge constructs of this case. The goal is to help them sift through the complexity of the network: what are the concepts that have significant interaction within the current project. Alternatively, help them externalize and discover some of their implicit knowledge that the network captured for them. For that, they use a prior generic network built on the common sense knowledge of a group of experts. Blockmodeling, in this case, is used to rearrange this generic network into meaningful blocks that are easier to visualize and to interpret. A manager can work on comparing the blocks of several cases, the current project, and the generic network to study differences of patterns.

The main steps of the methodology are as follows:

a) Based on the literature review, we present a concept map, which is a simplified taxonomy of concepts associated with the energy use in construction. The proposed concept map guarantees the networks are always represented on the same base of concepts Figure 2.

b) We develop three case studies of past oil and gas projects in Brazil. In-depth semi-structured interviews of project team members are the main source of evidence of each case. A minimum number of participants should be interviewed until the authors reach the saturation of information, in which the information provided by the interviewees begin to repeat and therefore no additional interview is necessary [10]. The participants respond open-ended questions about the challenges, best practices, opportunities, and risks that affects or could affect the energy use during the construction phase. A profile of responses is generated for each interview. In each profile, the research team identifies keywords or expressions that semantically resembles the concepts from the base taxonomy (letter “a”). A relation or a link is established whenever there is a semantic association between two concepts that affects the energy use in the construction phase. These relations are transferred to an adjacency matrix, and a network of concepts is represented for each case study, such as the one in Figure 1. The procedure above permits to represent any case study as a network of concepts. Dealing with case studies as a formalized network of pre-established concepts allows us to apply several metrics and indexes to study them by using network analysis. For example, if the discussions or social interactions of members of a current project, such as an online discussion tool, are captured using the same procedure discussed in letter “b”, a QAP analysis [11] of the current and case networks offers an interesting retrieving method of similar past projects.

Supposing that the three case networks presented in this article were retrieved from a repository of cases using such alternative, now we want to compare the retrieved cases with a generic network, which does not reflect any specific project. Exploring the differences between project-driven cases and a general network can shed light on what relevant knowledge the past project has to offer so that it should be taken into consideration in the new project.

c) To collect the data for the generic network, we conduct an expert survey [6]. As opposed to the project-related cases, the survey is conducted to collect the common knowledge of the participants without any project in mind. To do so, we transform the 573 possible relations of the concept map in close-ended questions, divided them into fourteen online surveys and submit them to experts in the O&G field in Brazil. The questions are multiple choice, in which the answers follow an intensity rating scale: no effect/low effect/moderate effect/high effect, with each answer having a score from 1 to 4, respectively. As a criterion to create the relations in the generic network, we establish a link or tie between two concepts whenever the average of all responses for each question was greater than 2.5. Three examples of questions are listed below.

- Does excavation affect the energy use during the construction of utility systems?
- Does welding affect the energy use during the assembly of piping?
- Does weather affect the energy use of earthworks?

d) Once the data collection phase is concluded, we represent the survey answers as a three-mode generic network, in which the ties between the nodes of the same category are disregarded.

e) The steps below allow us to contrast the knowledge constructs between each case and the generic network, by using a three-mode generalized blockmodeling approach [12] to create a baseline (a blockmodel) from the generic network as follows:

- We pre-define the clusters of the construction activities based on their typical function in construction sites and our prior knowledge of the cases. This assumption increases the chance to find substantive blocks using the blockmodeling method.
- As an input for the blockmodeling, we define the number of clusters and the type of blocks allowed to form during the optimization. With the clusters of the activities and the constraints established beforehand, the algorithm attempts to reorder the remaining concepts in such a way that it fulfills the defined requirements.
- After running the blockmodeling with the constraints defined above for the generic network, we select the solution that provides the best interpretation. The status of generic network is assigned to the best solution.
- The adjacency matrix of the case networks are rearranged to fit the blockmodel obtained from the previous procedure. In this case, the interest is in the different blocks. The different blocks and their inter-relations are interpreted and compared with the baseline in the light of the case studies, and then these findings are reported.
- We introduce a block analogy index that quantitatively assesses the overall and the block-to-block similarities of the case-based networks. The less similar the case network is to the baseline, the more case-specific, contextual the project is.

Construction Activities		Systems		Factors

Figure 2. The proposed concept map (taxonomy) of energy concepts

3 Results and Discussions

The results are presented in the following sections for the concept networks of projects A, B, and C, and the combined case. More details of the case studies can be found in [6]. The combined case is a Boolean sum of the three networks of cases, and is an attempt to produce a network that generically represents the three cases. Three analyses are presented: similarity, centrality-level, and blockmodeling. Detailed information for each analysis can also be found in [6].

3.1 Similarity of Networks

We used the concept of dissimilarity to develop a retrieving process. Two nodes have a dissimilarity equal to 1 (one) if they do not share any one of their neighbors. In contrast, they are structurally equivalent (or 100% similar) if the dissimilarity is 0 (zero) or, in other words, they share all their ties.

Using UCINET, we used the Quadratic Assignment Procedure (QAP) regression analysis to calculate the correlation coefficient and its respective p-value for each pair of networks. In the dissimilarity matrices, each cell of the matrix is the dissimilarity calculated for each pair of nodes of the original studied matrix). The dissimilarity is zero for the elements of the diagonal of the matrix, since each node is 100% similar to itself.

Table 1. Correlation coefficient of the dissimilarity matrices using QAP regression of the three case studies and two combined case networks

	Project A	Project B	Project C	Combined case 1	Combined case 2
Project A	1	0.516	0.309	0.720	0.695
Project B	0.516	1	0.333	0.690	0.728
Project C	0.309	0.333	1	0.502	0.433
Combined case 1	0.720	0.690	0.502	1	0.659
Combined case 2	0.695	0.728	0.433	0.659	1

Table 2 P-values of the similarity matrices using QAP regression

	Project A	Project B	Project C	Combined case 1	Combined case 2
Project A	0	0.0003	0.0003	0.0003	0.0017
Project B	0.0003	0	0.0003	0.0003	0.1310
Project C	0.0003	0.0003	0	0.0003	0.1060
Combined case 1	0.0003	0.0003	0.0003	0	0.0017
Combined case 2	0.0017	0.1310	0.1060	0.0017	0

Table 1. presents the correlation coefficient for each pair of the similarity matrices using the QAP regression

on UCINET. Each concept network has a similarity matrix. Since the correlation coefficient can assume any value between -1 and 1, the values in the diagonal are one because, indeed, the correlation between each matrix and itself is perfect. Nevertheless, the results of Table 1 must be carefully cross-checked with the p-values in Table 2. To be confident that a strong correlation exists between the structure of two networks, assuming a 95% confidence interval, the p-values in should be lower than 5% or 0.05, meaning that such correlation coefficient is statistically significant.

By analyzing the results, it is observed that the network of Project A correlates better with Project B when compared to Project C (0.516 against 0.309). This correlation probably exists because, although Project A and B have different logistics and environments, both construction projects are characterized by having a high volume of piping, static equipment, electrical/automation, and utility works. The correlations between the case studies are not so little that one can affirm the networks are not part of the same domain, but they are not high enough to be considered useless in dealing with different cases whose network representations are the same.

Regarding the combined cases, each one being an attempt to represent the three case studies generically, the results of Table 1 for the correlation coefficient were considered relatively satisfactory with some limitations [6].

3.2 Centrality Measures

Centrality measures are used to identify the most prominent nodes in the network. The structure of the concept networks suggests that the choice of the most suitable measure depends on the category of node. As the concept networks are directed, we opted to calculate the out-degree, which just considers the number of outward ties. The construction activities are in the intermediate layer of the network, and they serve as a bridge connecting the factors and the physical system; thus, betweenness is more appropriate to detect the more important construction activities. Regarding the systems, we considered not only the nodes with the highest degree, but also the degree of the nodes each node is connected to. In this sense, the in-eigenvector centrality is more indicated [10].

Table 3 presents the out-degree, betweenness, and in-eigenvector centralities for Project A. The table is truncated for the sake of saving space. Concerning the 13 construction activities, rigging (or material handling), onsite transportation, and scaffolding are the most central activities considering the betweenness centrality. These activities were cited several times by the respondents during the interview phase. However, no participant directly indicated the importance of these construction activities as being the most influential for the energy expenditure during construction. This fact could be better investigate by looking at their betweenness centrality. As a brownfield located in an existing industrial plant in full operation, the performance of this project was highly influenced by the numerous restrictions regarding access control, limited layout, and existing equipment or buried structures. These limitations ended up shaping the logistics of the construction, which is formed by the transportation of materials and workforce, material handling, and assembly/disassembly of scaffolds due to work at higher heights. Using the betweenness centrality permitted the research to elicit other influential activities other than the obvious energy-intensive ones, such as welding, excavation, deep foundation, and more.

Table 3. Out-degree, in-degree, betweenness, and in-eigenvector centralities for the network of Project A. The values are presented in descending order to highlight the most central activities/factors

Activities/factors	Out-degree	Betweenness	In-Eigenvector
Construction activities			
Rigging	9	73.261	0.363
Onsite transportation	8	28.152	0.246
Scaffolding	7	19.894	0.297
Welding	4	8.753	0.363
Masonry	9	6.673	0.066
Excavation	8	6.651	0.066
Physical systems			
Piping	0	0.000	1.000
Static equipment	0	0.000	0.964
Civil structures	0	0.000	0.938
Utility sets	0	0.000	0.860
Electrical equipment	0	0.000	0.654
Instruments	0	0.000	0.654
Design factors			
Design parameters	12	16.012	0.000
Type of material/equipment	9	0.000	0.000
Standard/Code	5	0.000	0.000
Site characteristics			
Geographical location	15	0.000	0.000
Adjacent structures	13	0.000	0.000
Soil	5	0.000	0.000
Resources factors			
Productivity	11	49.012	0.117

Type/Capacity	6	51.975	0.206
Consumption	6	4.000	0.117
Quantity	1	0.000	0.000

The out-degree of site characteristics, design and resources factors is the most appropriate centrality to highlight the most prominent factors. The schedule of this project was highly challenging, and the volume of activities provided by the design (scope) had a critical role: the larger the scope is, the higher the energy use. As such, the centrality analysis revealed that the node "design parameters" has the highest out-degree in the design category. Regarding site characteristics, the geographical location and adjacency structures have the highest out-degree. These two factors are closely related to the causes that affected the construction activities mentioned above (access control, limited layout, and the presence of buried structures).

Looking at the in-eigenvector measures of the physical systems, it was found that piping, static equipment, and civil structures were the most impacted systems concerning energy use. As a matter of fact, these four systems encompassed most of the scope of the project. In this regard, static equipment is a proxy for the five atmospheric storage tanks, which required large volumes of rigging, onsite transportation, scaffolding, and welding. Piping and utility systems are portrayed here because of the amount of piping assembly, which also involves welding and energy-intensive logistics. Finally, civil structures received a high in-eigenvector degree because of the works regarding excavation and deep foundation services for the tanks and other pieces of equipment.

3.3 Blockmodeling

To find a meaningful blockmodel for the generic network that can be compared with the networks of the case studies, four subgroups of activities are created according to a functional classification: logistics, heavy-duty equipment, structural civil works, and electro-mechanical assembly. Onsite transportation, rigging, and scaffolding are the three activities that best represent the logistics in construction sites. Excavation, earthworks, and pipeline assembly are characterized by demanding pieces of heavy-duty equipment, such as excavators, dozers, graders, and pipelayers. Structural civil works encompass deep foundation, concrete preparation, and masonry works. Finally, electro-mechanical assembly, which significantly differs oil and gas projects from other installations, is comprised of electrical/instrument assembly, piping, welding, and hydrotesting. In the optimization blockmodeling process, these four subcategories of activities are four pre-established clusters. Hence, the blockmodeling algorithm attempts to create blocks by permuting systems and factors to match the pre-specified clusters of activities, the required of blocks types and the constraints. Since the logistics, heavy-duty equipment, structural civil works, and electro-mechanical services have different characteristics, it is expected that the final optimized blocks capture clusters of meaningful knowledge constructs that are representative of the generic network.

Figure 3 brings the adjacency matrix of the generic network before and after the generalized blockmodeling. We can visualize the participants' perception with regards to the region of the factors vs. activities blocks (area "1"), as well as the "activities x systems" blocks (area "2"). Most importantly, through the figure, we observe how blockmodeling rearranged the nodes in a way that it is easier to interpret and simplify the network.

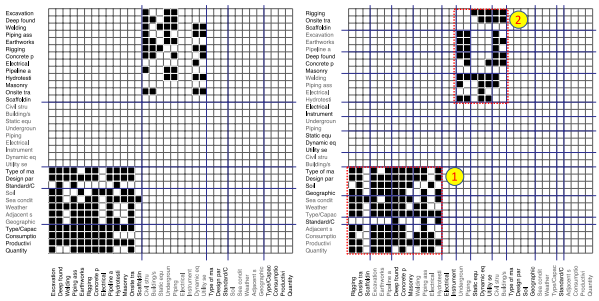

Figure 3. The three-mode adjacency matrix of the generic network before (left) and after (right) a generalized blockmodeling with twelve clusters [13]

Figure 4 (see [13] for enlarged pictures) brings the blockmodel in the form of the adjacency matrix for both the generic network of the survey and Project B. The results suggest Projects A and B have several features in common because many of their blocks diverge equally from the generic network. They have similarities even though the former is an industrial facility and the latter is an offshore LNG terminal.

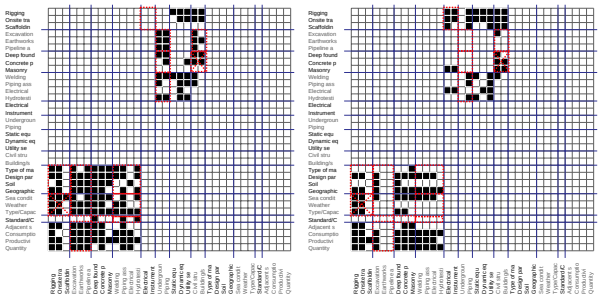

Figure 4. The three-mode adjacency matrix of the blockmodel of the baseline (left) and the rearranged Project B network (right) [13]

The main objective of the survey was to capture the general knowledge of the participants with no specific project in mind, which means that one should not expect the generic network to represent unusual relations and blocks that can potentially aggregate a meaningful knowledge. Conversely, comparing the differences between blocks can pinpoint what is so singular in the case study, and this information, along with the related context of the project, can be used in future projects.

The proposed method also includes the calculation of the average block analogy index $\bar{k}$ for each case-based network with the blockmodel obtained above as a baseline [6,13]. The smaller $\bar{k}$, the more the case-based network moves away from the baseline blockmodels, and therefore the more one can learn from the differences and the context of the past project embedded in a case network.

3.4 The Evaluation Approach

Since we introduced a new collaborative approach for energy-related processes in the construction phase, the best way to assess this research is through evaluation, not validation. Validation checks if a proposed model complies with internal specifications and if the results collected from the samples can be statistically generalized to the population. The validation would require a significant number of projects and a corresponding extensive database to conclude, which is out of the scope of this research.

To undertake the evaluation phase of this research, we conducted a test using Green 2.0, an online discussion media to discuss energy in construction [14]. We simulated the discussion environment of one of the cases studied in this research: Project A. Ten volunteers participated in the test: undergraduate and master's civil engineering students, construction managers, and a design engineer. The participants were educated in the case and asked to tag their comments based on the 34 concepts of the concept map. For each comment, the participants needed to choose the systems associated with their ideas, and, for each system, the factors that would influence the energy use of the corresponding construction activities. At least a triple of tags should be selected for each comment: one factor that influences at least one activity that is associated in turn to at least one system.

Since the test and Project A are based on the same case study, it is expected that both concept networks are similar. A correlation analysis between both networks can provide an internal validation for the proposed methodology to represent the network of the cases. We performed a QAP analysis and calculated the block analogy index $\bar{k}$ for the networks (the closer $\bar{k}$ is to 1, the more similar the networks are). The correlation factor found was 0.45 with a level of significance of 0.0002 (0.02%), and $\bar{k}$ was 0.51. Some of the factors that may have limited the results are the hypothetical nature of the test, the lack of experience of the students with O&G projects, and the time of the test.

Right after the test, we submitted an online questionnaire and conducted a focus group with the participants. In both evaluation methods, the participants assessed the concept map, the process of collaboration, the outcome of the test, and Green 2.0 as the interface. Overall, all the participants reported a high level of satisfaction with the four criteria. However, many commented on the difficulty of dealing with a limited number of tags. The issue of dealing with the tags may also have prevented from obtaining a better correlation/similarity between the networks.

4 Conclusion

Using unstructured data in a KM system has always been a problem in the construction domain. The industry struggles to deal even with intrinsic processes, such as documenting, historical productivity metrics, and benchmarking. In this sense, knowledge retrieval and representation methods such as lessons learned, case studies, and ontology have been widely used to improve the performance of projects. Nevertheless, these solutions have limitations regarding adaptability, applicability (capturing what is right for each project), documentation, and operation/maintenance (case studies and ontologies).

This research proposes a collaborative knowledge-based method to improve the use and management of unstructured data sources. It can be applied to the decision-making and planning processes related to energy management during the construction phase. Fundamentally, the proposed approach transfers text corpus into concept networks. A simplified taxonomy of factors, systems, and construction activities is used to capture the central concepts (to be used by the networks). The networks has edges (or links) set between the concepts (or nodes) that significantly affect energy use during the construction phase of a project.

The proposed method, as well as the system, can support the DM with better assumptions while providing a collaborative environment in which project teams can debate and co-investigate the best means to improve energy consumption during the construction phase.

Capturing knowledge from interviews, surveys and case analysis (the primary tools used in this work) is dependent on human interpretation, which may be subject to errors during the phases of profiling the answers and interpreting/collecting the relations. Despite its intrinsic disadvantages, the human interpretation allows for the exploration and detection of subtle relations in the participants' answers that are often difficult to perceive through other methods, such as surveys or questionnaires

[15,16]. The methodology to detect the relations cited above leads to semantically rich and contextualized knowledge, and the human interpretation is very effective in producing such outcomes.

Despite following a scientific procedure, detecting the relations from the case studies manually may be prone to errors. Future works can attempt to integrate automated knowledge retrieval tools to collect and represent the concept networks directly from the unstructured data generated in project environments.

Generalized blockmodeling has a significant number of parameters and constraints that influence the number of solutions. Although the number of inconsistencies in each solution is one of the most crucial parameters, each solution has to be manually interpreted before the one with the most substantive sense can be identified. Depending on the number of possibilities and solutions, this trial-and-error process may be overwhelmingly time-consuming. Therefore, the method to obtain blocks should be meticulously adapted to the needs of the study. For example, instead of using the four suggested clusters of activities, one can obtain a blockmodel from the three subcategories of factors of the concept map.

The analysis focused on the different types of blocks and the inconsistencies of each block to obtain valuable information regarding the case studies. Nevertheless, an alternative (and perhaps complementary) interpretation may be given to the opposite approach: What are the inconsistencies that have prevented blocks of the same type from being ideally equal? In addition, future works can attempt to implement semi-automated knowledge retrieval and representation tools to generate the cases and the networks.

Digital Fabrication and Crafting for Flexible Building Wall Components: Design and Development of Prototypes

N.F. Naqeshbandi[a] and P. Mendonça[a]

[a]Department of Architecture, University of Minho, Portugal
E-mail: nzarbandi@gmail.com, mendonca@arquitectura.uminho.pt

Abstract –

This research aims to explore and reflect the links between form, function, material and fabrication to develop and assemble more adjustable and flexible building walls. The interconnection of these main aspects of creation is particularly driven by the raising prominence of digital and computational tools in the context of design and fabrication. The new trends in digital fabrication and construction industry have fundamentally impacted building envelope components design with a shift in emphasis from flexible structures to envelope and from form to performance. The objective of this research is to develop new prototypes for more lightweight, dynamic, possibly interactive body envelope with the contribution of digital crafting. The first wall prototype was designed and assembled in the laboratories of University of Minho using CAD and subtractive machining to produce the parts and apply physical tests to the wall. Based to that experiment the second prototype is digitally developed and generated with additive manufacturing; presenting the development process; as an attempt to build an entire envelope from printed components.

Keywords –

Digital design; Digital fabrication; Crafting; Building wall components; Component design; Rapid Prototyping

1 Introduction

Innovations in material, design, and fabrication processes are currently thoroughly researched and applied in various areas. Digital technology and digitally driven fabrication are now the norm of turning architects, designers and researchers towards new concepts of design thinking and manufacturing that subsequently lead to more advanced architecture. Digital fabrication with crafting techniques can evolve the creation of physical prototypes; evaluate the constructability, material behaviour and selection as well as aesthetic qualities. There is a strengthened and more correspondent relation between the development and fabrication process combined with a higher flexibility considering the geometry, process, and material driven design; not only in the phase of design and manufacturing but also in the final step (Lu B., Li D., Tian X. 2015).

Wide range fabrication technologies and composite materials have been developed and started to impact architecture for their high performance characteristics. The intelligent control and automation of processes break up the strong limitation of variation in material, structure and form in the traditional industrial production. Students and professionals design with three-dimensional digital tools and, through this technology, design and construction are inextricably woven together in a continuous feedback loop. Based on the principles of open source, computer numerical controlled CNC production data is distributed and further developed via the Internet and new knowledge regarding materialization is being shared. Ideally, production knowledge is shared using Creative Commons licenses and a global network of mini factories is created with these networked digital production methods.

In the realm of building components, the walls are providing primary site of innovative research and physical tests. Building partition and envelope wall components are among the elements in a building that can be improved for better performance and more integrated with the other building systems. The wall component prototype is related with the geometry, the function and the materials made up to perform the required design. One of the key innovations in the field of building construction and building physics has been the emergence of high-performance materials (Aksamija A., Snapp T., Hodge M., Tang M.2012). The criteria to estimate the potential of the technologies for their application in the wall are weight, rigidity, and load-bearing capability of the parts.

The advancements in Additive Manufacturing AM technology is proceeding towards customizing products in design, production and material selection; have hugely impacted the way 3D printing is viewed and relied upon by engineers, designers and manufacturers and lead increasingly construction evolutions. 3D

printers are nowadays substantial for experimenting prototypes and approaching the end-use production parts in hundreds of plastic, metals and other printing materials (Hager I., Golonka, A., Putanowicz, R. ICEBMP 2016).

2 Prototype Design: Digital Design and Crafting

Building designs and prototypes are not born out only digitally, but they can be realized digitally and to come to exist in faster time and with more accuracy. With the aid of computer aided design (CAD) and computer-aided manufacturing (CAM) technologies rapid developments have broad in building design, construction practices and rapid prototyping. Digital design is the early step of the work that provides CAD mother model. Digital processes starts with analyzing the information data structurally for all parts of the prototype to prepare them for CAM software, the second step is translating the analyzed information to command the fabrication machines to produce the physical modeling either on-site or in the factory; this workflow is known as "File to Factory". The focus of the technology descriptions will lay on the methods to produce components from different materials that contribute to a wall partition.

The fabricating processes due to the manufacturing methodology can be categorized as: subtractive manufacturing (CNC) and additive manufacturing (3d printing). Both are considered active tools for Rapid prototyping.

2.1 Subtractive Manufacturing

Subtractive manufacturing also known as CNC machining, involves the process of removing a specified surface or volume of material from solids and also milling axially; by using cutting devices; either by electro-, chemically- or mechanically-reductive also advanced CNC (multi-axis milling).

In axially constrained devices, the piece of material that is milled has one axis of rotational motion such as lathes. There are millings of three-dimensional solids that have the ability to raise or lower the drill-bit, to move it along X, Y and Z axis, removing materials volumetrically. There are also four- and five-axis machines when milling special shapes.

From the advantages of subtractive processes, can include a wide selection of end-use materials; offer a variety of surface finishes, good dimensional control and fast with a high degree of repeatability suitable for end-use manufacture. The disadvantages are related to some material waste, and geometry restrictions; certain geometries such as a sphere as well as complex geometries Additive are still the choice.

2.2 Additive Manufacturing

The term Additive Manufacturing also referred to nowadays as synonym 'layering manufacturing' and '3d printing', a process by which digital 3D design data is used to build up geometry in layers by depositing and bonding materials one layer at a time. The AM build the geometry by depositing with the benefits of robotically controlled and free-form manufacturing. The size and speed of the adding nozzle and the design size directly affects the build time, therefore, design, size, geometry, function, material and application of the component are substantial for selecting the right technology and material for the prototype. Materials available with 3D printing technologies range in heat deflection, chemical resistance and durability and material viability greatly depends on design, application and desired product life. To determine the material and 3D printing process which will best support one application, the most appropriate materials and technologies should be considered, as mentioned on Table 1 Adapted from: https://www.protolabs.com/resources/white-papers/rapid-prototyping-processes/

Table 1. Interaction between materials and techniques on digital fabrication

Rocess	Description	Finish	Example Materials
CNC	Machined using CNC mills and lathes	Subtractive machined	Most commodity and engineering-grade thermoplastics and metals
LASER	Machined using Laser head	Subtractive machined	Wood derivatives, Cardboards, PMMA and metal plates
SLA	Laser-cured photopolymer	Additive layers of 0.05-0.15mm (typical)	Thermoplastic-like photopolymers
SLS	Laser-sintered powder	Additive layers of 0.10mm (typical)	Nylon, TPU
DMLS	Laser-sintered metal powder	Additive layers of 0.02-0.03mm (typical)	Stainless steel, titanium, chrome, aluminum, Inconel

FDM	Fused extrusions	Additive layers of 0.15-0.35mm (typical)	ABS, PLA, PC, PC/ABS, PPSU
MJF	Inkjet array selectively fusing across bed of nylon powder	Additive layers of 0.10-0.20mm (typical)	Black Nylon 12
PJET	UV-cured jetted photopolymer	Additive layers of 0.015-0.030mm (typical)	Acrylic-based photopolymers, elastomeric photopolymers
DDM	Direct extrusion	Additive layers (variable)	Concrete, clay, plaster
IM	Injection-molded typically using aluminum tooling	Molded smooth (or with selected texture)	Most commodity and engineering-grade thermoplastics, metal, and liquid silicone rubber

The selection criteria among the described technologies will be on the basis of product delivery, material ,tolerance ,cost ,quantity of product, and desired needs of product whether its speed, function or a specific material (Yadav, K., Sharma, K. R., and Anand, D. JMSME, 2015).

2.3 Digital Crafting and Material Selection

Although both Additive and Subtractive have similar workflow method but still there are notable differences. The connection of digital design and digital manufacturing can be resumed as 'Digital Crafting', which describes the combination of work techniques typical of craftsmen with computer-supported processes. The way of honoring material and its strong – but ever changing – relation to manufacturing processes leads not only to new design aesthetics but also to a new, crafting oriented way of design thinking.

The principles of digital design and manufacturing processes are rather linked to a way of craft production than industrial processes as they emphasize the qualities of the materials used and provide higher flexibility during the development and production process.

Smart materials have been applied in architecture, but rarely so that the responses give a global effect on the performance of the entire building. The materials as well as the technical equipment for AM technologies have been continuously developed since. A new market opened up that is still growing today. Choosing the right materials and techniques is substantial for creating highly customized building components.

Material-technology partnerships expanding more nowadays as material chemistry explored more as well as mechanical properties can be evaluated very precisely. As stated in the differences between additive and subtractive manufacturing, materials are defined by the technology. 3D printing transforms materials through either external heat, light, lasers or other directed energies depending on the printer type. The ability of a material's mechanical composition to react positively to a certain directed energy marries that material to a technology which can deliver the desired change.

The new trends in advancing technologies encourage products made from more environmental friendly material. The performance of materials varies and to fabrication technologies and processes the material needs to be efficient in terms of mechanical properties and design capabilities. For AM developments, materials correspond with developments in methods and machines; as the workflow also improves to achieve more benefits from materials, therefore, material selections expanded to include ecological and less harmful materials.

Smart materials have been applied in fabrication as they can just replace conventional materials been used with the advanced machines, whilst smart properties can perform additional benefits. An example of this is 3d painting with nano-particles of titanium oxide, which not only protect the surface but also reduce pollution in the surrounding environment through photo catalytic behavior.

Emerging digital processes are beginning to impact the profession of architecture in a manner similar to what has occurred in other creative/design disciplines providing new methods to evolve the practice of architectural design. The study presented two models to demonstrate the technical process used to translate digital designed models to manufacture descriptions and physical assembly.

3 Smart Building Component Design Using Subtractive Techniques

The first case study presents the research process of an innovative solution for partitions, designated as AdjustMembrane, developed within a Portuguese Foundation for Science and Technology funded research project. The proposed system is a modular non-loadbearing wall, tensioned between the pavements and ceiling slabs, which are used as anchoring elements. It allows several advantages, related with the weight reduction to achieve good sustainable indicators, such as

the reduction of construction costs, energy, and materials. It is easy to recycle and reuse, allowing easy assembling and disassembling [Mendonça, Macieira and Ramos, 2014].

This solution of non-structural partition wall is characterized by a structure in tensioned belts that serve as support for the two-stage assembly of panels with a core in fibrous material, as showed in Figure 1.

Figure 1. Component design with MDF (Laser cutter)

The core may include a grid (Figure 2) - with modules that can be subtracted or added to allow the panels to adapt to the dimensional requirements of the space to be partitioned and which at the same time serve to reinforce and give rigidity to the panel.

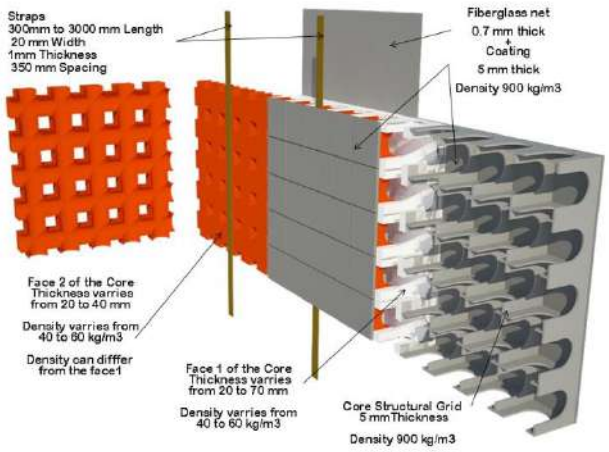

Figure 2. Prototype design and system assembly

The core of the panel solution is characterized by having vertical grooves in the interior allowing the integration of water, gas and electricity networks; the core shall consist of a material fibrous / porous so as to function at the same time as thermal and acoustic insulation of the facilities and between the various compartments.

The typological suitability required that there were a translucent variant of the study material for the partition wall. To do this, the prototype must be carried out with the application of a translucent material and performed acoustic and light transmission tests.

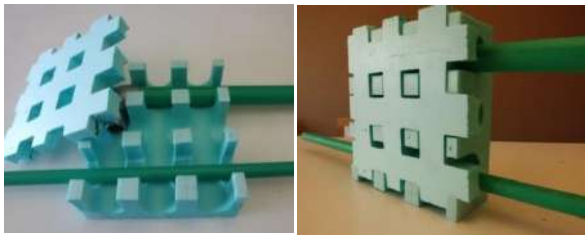

Figure 3. Component manufactured XPS (CNC hotwire cutter 2D)

4 Smart Building Component Design: Digital Fabrication and 3D Printing

The research objective is to build and develop components by conceptualizing the component assemblage and bringing it to the physical modeling with the use of 3d printing. The concept of the development is another advantage of digital fabrication when extending the future possibilities to the real scale. Although the components generated here are physically small, the study concern is how to build assembly descriptions based on real-world construction.

The most popular 3D printing manufacturing technologies can be found as PolyJet, Stereolithography (SL), Laser Sintering (LS), Fused Deposition Modeling (FDM) and Direct Metal Laser Sintering (DMLS) and more. For the study Polyjet was used for printing the component.

The aim of this case study design is to undergo the considerations of developing printing and developing the prototype through the following:

4.1 Prototype Development Process

As the study is to propose prototype development for a digitally driven fabrication framework, an exploratory model on the usability of a prototyping-process is designed. The analytical data have continued with the objectives of the first case, more flexible and manual assembling building envelopes, therefore, the

development process is considered a design to manufacturing process with Additive (Fig 3).

4.1.1 Data Preparation for Prototype By Additive Manufacturing

Data preparation is identical to other AM processes, with an exception to a supplemental post- processing step which is optimizing the generated printing path of the precipitation head so as to decrease the time of printing in addition to possible overprint of materials because of orifice proration that is on and off, by diminishing the non-printed motions of the precipitation head. A 3D MAX model was designed for the printing component, transformed as an SLT document format, slicing is performed using a coveted layer depth, a printing track is produced for each layer, and for the printing a G-Code document is manufactured.

4.1.2 Application Process

Many materials which are printed by 3D system provide biocompatible features, abilities for sterilization, licensing from FDA for skin exposure, toxicity, fire retard, heat fume, and resistance to chemical agents or other credentials that might be serious for your plan. When a material and 3D printing process is selected for the design, it will be mandatory to guarantee that your substance is capable of delivery upon these credentials.

4.1.3 Function

Stringent investigations are performed for 3 D printing substances for answering the stress types it can tolerate and the grade of the terrible environment the substance will surpass in. The fact that the material is able to act in a desirable employment depends partially on layout.

4.1.4 Geometry

As it is previously stated, substances which are printed by the 3 D technology cannot be isolated from their concordant technology. Moreover, every technology regardless of its kind (Like FDM, stereo lithography or Laser Sintering) is proficient in presenting specific geometrical fulfillments. While selecting the technology of substance and 3 D printing, dimensional tolerances, minimum feature fulfillment as well as thickness of the wall of the layout should be taken in to consideration.

The Geometry development process of the building wall component design Consider the dimensional tolerances, minimum feature execution and wall thicknesses of your design when choosing a material and 3D printing technology. The thickness for this component was 100mm.

Figure 4. The Geometry development process of the building component design

Printed designs can result in fine surface finish products with the right post-processing. Some materials may be better suited to certain post-processing methods than others – heat treating stainless steel versus post-curing a photopolymer, for example.

During the design process flexibility and sustainability of applying composite envelope configuration were assessed through Digital designing and optimization tools that can help to identify assembly and disassembly tolerances and analysis of performance objectives.

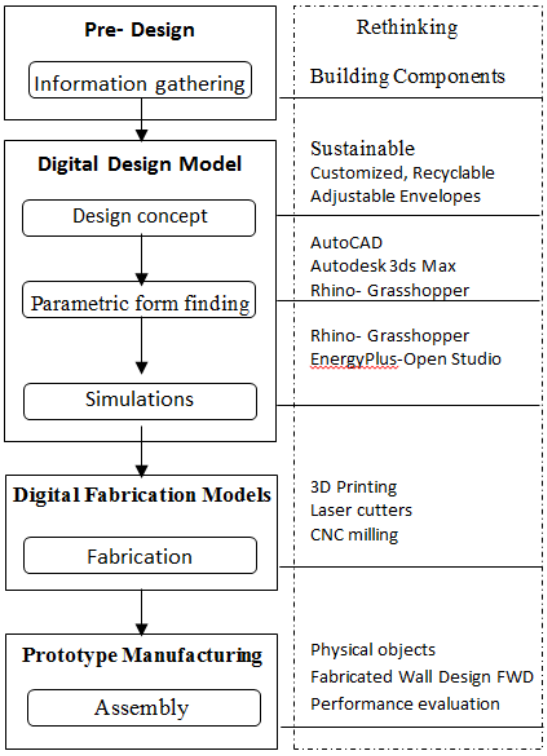

Figure 5. The development process of the building component design. Adapted from "Re-Skinning: Performance-Based Design and Fabrication of Building Facade Components" (PERKINSWILL, 2012 / VOL 04.01)

4.2 Assembly Description

The printed parts can be manually attached to become a base unit easily to connect with the printed tube bars. When combining more units, they formulate a panel, with repeating the process then a standing wall structure ready to assemble the electrical plugs and wires and also the mechanical piping. Then the system will be ready to apply panels to.

Figure 6. 3D printed component prepared for assembly

The 3D printing components will be subjected to rigorous testing in order to answer the kinds of stresses it can endure and for more future developments the components can be coded and marked with the nodes of intersection with adjacent layers of structure.

The units are designed to be fastened to each other and the final structure will be completely self-supporting and will not require secondary scaffolding. The final product is the scale of a room and is composed of 600 3D printed parts.

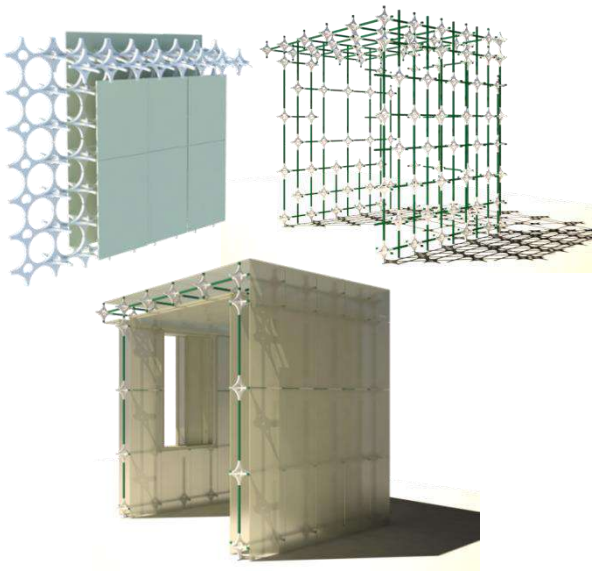

Figure 7. The FWS to be assembled, the Designed and rendered with 3cDs Max

4.3 Digital Fabrication and Performance Design

The partition wall system Adjust Membrane presents ease integration of facilities, good mechanical principles, and good acoustic properties and modularity. Experimental prototypes were executed to test the mechanical properties, the access to the placement of installations as well as the integration of the structural grid and the way of installing the partition wall. The assembly process has been tested allowing to define the expected to adjustments, in particular with regard to the connection to the structural straps.

The mechanical properties to be tested for a printed sample of a panel consisting of 3 attaching units and to determine the physical test in the Construction and Technology laboratories of Uminho, Structural links have to be more detailed and investigated, with trials and simulations. The connection between panels should be tested in prototype as well as possible coating application.

5 Conclusion

The study demonstrates the potential of digital design and fabrication, and crafting techniques to develop building envelope components to become more adjustable, flexible and sustainable. Digital design tools offer guidance in analyzing the manufacturability of the building components. The principles of digital design and manufacturing processes are rather linked to a way of craft production rather than industrial processes as they emphasize the qualities of the materials used and provide higher flexibility during the development and production process.

New developments in advanced computational tools and methods are offering unprecedented ways for design exploration and evaluations. Performance-based design that integrates simulations and environmental analysis in the design process has an advantage over traditional design methods, because it allows a certain design iteration to be evaluated against different solutions. Also, digital fabrication techniques allow for creation of physical prototypes, which can be used to evaluate constructability, material behavior and selection as well as aesthetic qualities.

Contribution of digital crafting in the generation of design and building assemblies is an integral approach in improving design process, with the direct connection to practice and research. The innovative products can be developed rapidly with digital design and fabrication of numerous representation tools and production software. Such uses of technology strengthen the ties between design and craftsmanship and motivates to a continual evolution of the field of architecture with construction

companies and universities supporting such innovative trends of research and design.

The study on typological suitability, functional and structural performance in both wall solutions presented in this paper will be subjected to more analytics, performance simulations and later experimental testing. There is a strengthened and more correspondent relation between the development and fabrication processes combined with a higher flexibility considering the geometry: in the phase of design and manufacturing but also in the final shape.

Acknowledgments

Abstract –

The characteristics of dynamic construction sites increase the difficulty of collecting the high-quality geometric data necessary to achieve construction management activities. This paper introduces a new autonomous framework for 3D geometric data collection in a dynamic cluttered environment using an unmanned ground vehicle (UGV) and an unmanned aerial vehicle (UAV). This method first deploys UAV to collect photo images of a site and builds a point cloud of the 3D terrain of the site, including obstacle information. A mesh grid is then created from the UAV-generated point cloud, and simulation for laser-scan planning is conducted to determine the stationary laser-scan positions at which a mobile robot can collect data with less occluded views while capturing all crucial geometric information. Finally, optimal paths for the UGV to navigate among the estimated scan positions are generated. Promising test results regarding data accuracy and collection time show that the proposed collaborative UAV-UGV approach can significantly reduce human intervention and provide technologies for enabling construction site to be frequently monitored, updated, and analyzed for timely decision-making.

1 Introduction

Collecting accurate and complete geometric data from construction sites is essential but challenging. It is particularly crucial to obtain timely, complete, and accurate spatial information for decision-making in construction projects since inaccurate, missing, or insufficiently detailed data can lead to uncertainty in decision-making. However, the dynamic and complex properties of construction sites not only require various 3D geometric data but also increase the difficulty of efficiently and effectively collecting spatial data [1], [2]. It is also necessary to ensure that data collection activities have a minimal influence on other construction activities; interference between data collection and construction activities can cause project delays and low data quality, which results in poor decision-making and further delays [3].

Currently, the quality of 3D spatial data acquisition depends solely on the intuition or experience of the data collector. This experience-based data collection may not be practical or efficient due to the complexity of the process, which involves 3D spatial domain and the physical target placing for registration. Also, feedback is limited during the data acquisition, and registration process since the completeness of site scan is unknown until the full registration is completed. Furthermore, low-quality 3D spatial data can negatively impact effective decision-making, and duplicated data caused by largely overlapping scan ranges can result in extensive time and computational burdens for data processing. Further, it is possible that unnecessarily high-quality data may be collected for unimportant features at a job site while other geometric data necessary for making critical decisions may be missing. Therefore, a strong need exists to smoothly integrate automated jobsite inspection into the daily or weekly work cycle. If the jobsite inspection is automated, quality control measurements can be taken and reported to stakeholders automatically as well. To increase the efficiency of daily as-is data collection in the field, this study proposes a framework of the unmanned aerial vehicle (UAV)-assisted laser-scan location and path planning for an autonomous mobile robot, or unmanned ground vehicle (UGV).

2 Related Work

2.1 3D Reconstructions from UAV Images and Cooperation with UGV

Extracting 3D geometric data from the scene of interest [4] is very valuable for activities such as monitoring construction progress [5], [6] and defect analysis [7], [8]. The 3D reconstruction process has advanced dramatically due to recently developed computer vision-based technologies. One method for producing a 3D sitemap is photogrammetry. Photographs provide useful information about the construction progress that can be automatically processed and converted to 3D point clouds using Structure from Motion [7]-[9]. Due to stability and payload issues, UAVs typically use a photo camera to capture scenes and build a 3D point cloud with photogrammetry. Since a ground robot can be more easily stabilized with higher payloads than an aerial robot, it can collect a higher quality of 3D geometry data.

As a means of collecting 3D geospatial information, UAVs and mobile robots share the advantage of being able to collect geospatial information without exposing surveyors or device operators to hazardous areas. However, both technologies also have distinct disadvantages caused by their measuring positions. The ground-based measurement methods used by mobile robots have blind spots behind vertical obstacles and cannot capture horizontal surface data located higher than the robots. In contrast, UAVs generate blind spots under horizontal obstacles (e.g., roof). Furthermore, the overall accuracy of the point cloud generated by UAVs is lower than that of the ground-based generated point cloud even though UAVs possess operational advantages over the ground-based approaches regarding navigation.

2.2 Scan Planning and Autonomous Scanning

A widely used technology in many field applications, Light Detection and Ranging (LiDAR) can measure a wide area with higher resolution and accuracy compared to photographs and is generally not limited by surrounding lighting and weather conditions during its operation. However, multiple scans from different locations must be taken and registered because of limited data capture coverage and occlusions. To register multiple scans in one coordinate system, many physical targets or markers are typically pre-installed in the overlapping scan area, which requires substantial cost, labor, and time [9]. A well-designed scanning plan minimizes data collection time while capturing all required geometric information. Latimer et al. [10] have used the concept of "sensor configuration space" to automate laser-scan planning. The configuration space is a 3D volume in which specific geometric features, or "information goals," are displayed on an imaging sensor. Their algorithm clusters information goals and generates configuration spaces for each cluster. It then selects sensing locations and plans the "minimum-time" path for moving the scanner to this location. Some studies have shown that the laser-scan planning problem can be solved using as-designed models [11], [12]. However, current practices still manually collect and process the 3D point clouds of large-scale environments, which requires many scans and often results in high labor and time costs, human errors, and inconsistent data quality. Automating some or all of the data collection and registration processes can mitigate these problems.

Automatic scanning has recently gained strong interest among academics and industry technology developers. Various sizes and types of LiDAR have been equipped to vehicles and mobile or aerial robots, and the simultaneous localization and mapping (SLAM) technique has been utilized in their approaches in generating dynamic point clouds[13], [14]. In robotics, SLAM is a popular method for enabling a robot to estimate its current position and orientation from a map of the environment created by LiDAR or cameras. The problem with this approach is that most SLAM systems are commanded manually; humans must decide where to go and how to perform complete scanning of a large site [15], [16]

3 Objective

The objective of this study is to explore a methodology that carries out multiple automation including robot navigation, laser scanning, and registration of multiple point clouds collected by 3D laser scanners mounted on UGV. To achieve the research objective, the following primary tasks are proposed. First, UAV is deployed to obtain an initial 3D map of the cluttered site. Second, optimal scan locations are estimated by simulation, using a mesh grid applied to the UAV-generated map and an occupancy map generated based on the gradient value of the terrain. Finally, the optimal navigation path is determined from among the simulated scan locations. The overall framework of the proposed approach is shown in Figure 1.

4 Methodology

4.1.1 System Architecture

In this study, a UAV (DJI Mavic Pro) equipped with a 1/2.3" complementary metal-oxide semiconductor sensor and a hybrid LiDAR system mounted on the Ground Robot for Mapping Infrastructure (GRoMI) are used, as shown in Figure 2. The two major parts of GRoMI are a laser scanning system and a mobile

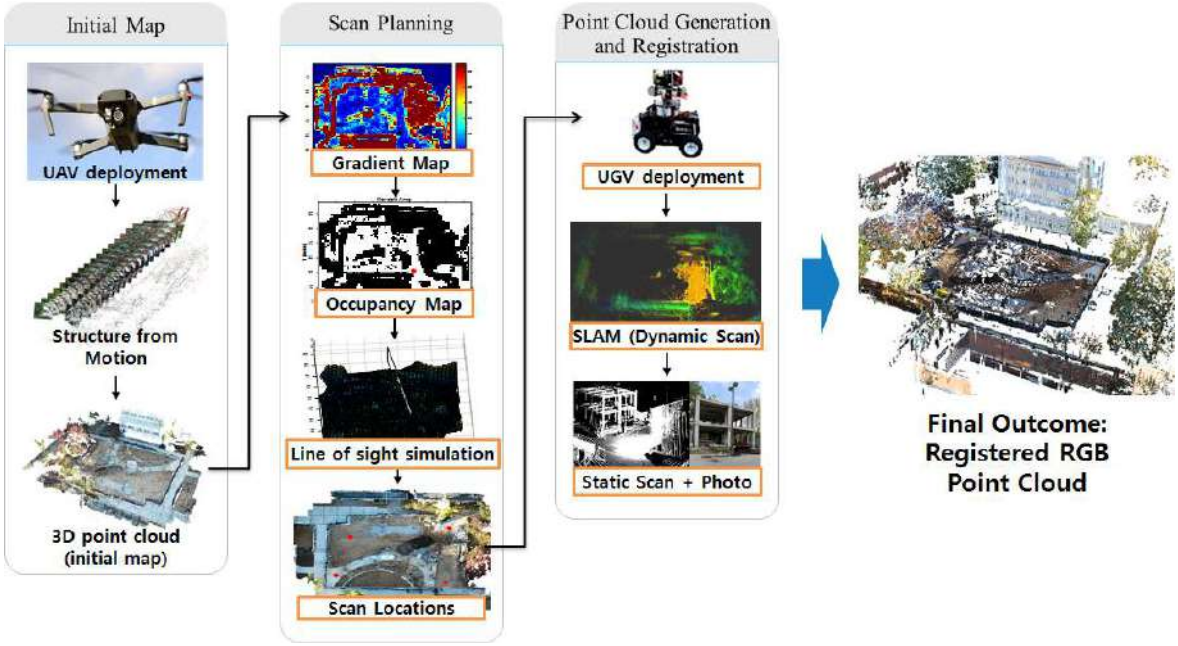

Figure 1. The overall framework of the collaborative UAV-UGV data collection and visualization

platform. The upper laser scanning system includes four vertically mounted 2D SICK line laser scanners to collect 3D mapping information. A horizontally mounted 2D line laser scanner is to estimate the robot's location and pose information on a 2D plane and a regular digital camera to obtain the RGB data of the scenes. The lower mobile platform system, used primarily for navigation, has object avoidance sensors, an IMU, and a navigation camera. The robotic system offers the following functionalities: 1) point-cloud data acquisition while the robot is moving; 2) RGB data collection through a DSLR camera, and 3) autonomous navigation.

The proposed framework allows the robot to automatically collect the geometry data for construction progress monitoring and analysis through LiDAR-based SLAM and automatic point cloud registration methods. To avoid the potential of interfering with construction workers and other activities, the data collection has been done after daily work is completed. In addition, collecting scan data during construction work is not meaningful because the site geometry is rapidly changing and blocked by moving objects (e.g., workers and equipment). In this study, the tested environment is limited to the outdoor construction site since this approach is using UAV-generated map data as prior information for UGV's scan and path planning.

4.1.2 UAV Scan

The factors affecting the performance of the photogrammetry created from UAV include 1) ground control points (GCPs); 2) ground sampling distance (GSD); 3) overlapping ratio; and 4) image processing methods.

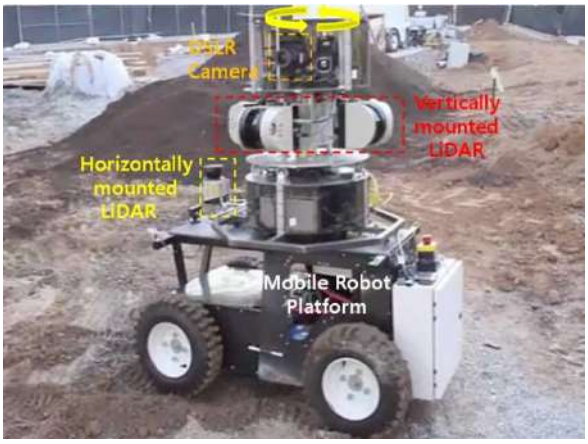

Figure 2. UAV (top) and ground robot systems (below)

Because this study is intended for autonomous 3D as-is data collection in which there is no human intervention, and GCPs were not considered. Referring to the number of pixels per unit length, GSD is a factor related to the flight level, focal length, and resolution of the camera. The GSD can be written as the following Equation (1):

$$\text{GSD} = \frac{H}{f}\,\mu \tag{1}$$

Where H is flight height above ground level (m), f is a focal length (mm), and μ is pixel size (μm). Since the GSD value directly affects the results of the photogrammetry, it is important to determine the flight altitude. The overlapping ratio also affects the accuracy of the photogrammetry. Both GSD and overlapping ratio should be determined when the flight plan is made. In this study, flight altitude was set to 30 m above ground level to determine the GSD to be 1 cm. Using the images obtained from the UAV, this study processed photogrammetric data to generate a point cloud, as shown in Figure 3.

Figure 3. UAV-generated 3D point cloud map of the construction site using image data

4.1.3 Scan-Spot Selection for the Mobile Robot

The scan planning method proposed by this study is to locate satisfactory stationary scanning locations for GRoMI by evaluating the candidate scan locations with a line-of-sight simulation of a 3D laser scanner. Considerations for selecting these locations include 1) the surface point with a large field-of-view of the surroundings with minimal obstructions; 2) the minimal overlapped area between scans; and 3) the most complete possible scan areas for the entire site. Evaluation criteria include a quantity of point data and the amount of occlusion, which differ depending on each scan location. Based on these criteria, a number of scans and data collection time can be reduced while maintaining satisfactory area coverage and level of detail. The scan-spot selection process is accomplished through the following four steps:

1) Divide the job site into cells (1 m by 1 m each) and compute the gradient between neighbor cells for each cell,
2) Create a 2D gradient map and an occupancy map to find the movable area at a site,
3) Run a line-of-sight simulation for every candidate scan location cell and count how many points and how few occlusions can be achieved, and
4) Find candidate scan locations where more point-cloud data and less occlusion can be obtained.

These four steps are described in detail below.

A. Gradient Map Generation

The first stage of the scan planning process requires obtaining an initial 3D terrain model of the target site. In general, it is difficult to use existing or as-designed 3D data because as-is site conditions are generally different from the existing information. Therefore, the UAV-generated point cloud is used as a guidance map to compute the scan locations and to generate a navigation path for GRoMI. The gradient-based map is used to simulate a series of scan views for the robotic scanning system at all scan locations before GRoMI conducts any data acquisition tasks. At first, the UAV-generated point cloud of the construction site is divided into 1 m by 1 m cells. Gradients between neighbor cells are then computed. Figure 4 demonstrates the gradient map of a test site. It can visualize which cells are flattened, tilted or occupied by obstacles. The blue color area is relatively flat with a small gradient value where the mobile robot can be better balanced horizontally for laser scanning, and the red color area is relatively inclined with a more considerable gradient value where the mobile robot should avoid.

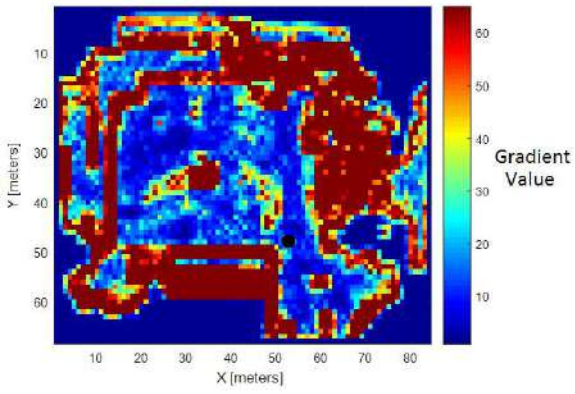

Figure 4. Gradient map of a test site

B. Occupancy Map for Candidate Scan Locations

Based on the generated gradient map, the movable and flat areas in the site are defined by setting a specific gradient threshold value. The movable area is the place where GRoMI can move around because the area has a relatively small gradient value, and it is used for path planning for GRoMI. A reference point is required for selecting optimal locations. This study uses the starting position of GRoMI as the reference point. Figure 5 shows the occupancy map of the movable areas, while GRoMI's initial location is shown as a small red dot in the target site. Occupancy means whether the obstacle is present at each cell.

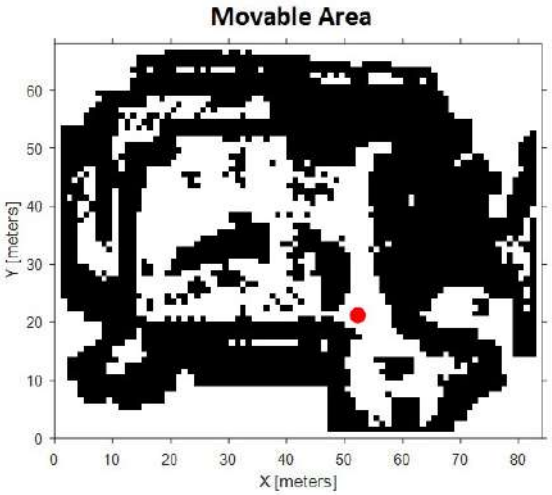

Figure 5. Occupancy map for the movable area

C. Line-of-Site Simulation

The next step is to compute the visibility of each candidate scan location. The ray tracing algorithm [17] is used to calculate the line-of-sight visibility. At first, the mesh grid is created from the UAV-generated point cloud. The 3D ray tracing for each laser line is then simulated. It is possible to find the cross points between laser lines and contour of the terrain. These points can be classified into two groups. The first is the simulated laser points, which are the minimum distance points from the specific scan location, has one point per laser line. The others are occluded points. This simulation lists the scan locations with the maximum number of points from the laser scanner and the minimum number of occlusion points. In addition, the greedy cover algorithm [18] is utilized to select an approximation for the optimal number of scan locations necessary to cover the entire site. It chooses the scan location that can see the largest amount of the boundary and then continues selecting the scan locations to cover the remaining area from the potential viewpoints. This process repeats until either the entire site has been covered or the iteration reaches the approximation for the optimal number of scans.

D. Find Satisfactory Scan Locations

The scan planning simulation calculates the number of laser points and occlusion points during the previous steps. Among these locations, removing some of the scan locations within a specific distance is required to minimize the overlapped area caused by the redundancy. The specific distance differs depending on the size of the target site; a 10 m distance is used for our test bed. After the simulation, four of the optimized scan locations were estimated as shown in red dots in Figure 6.

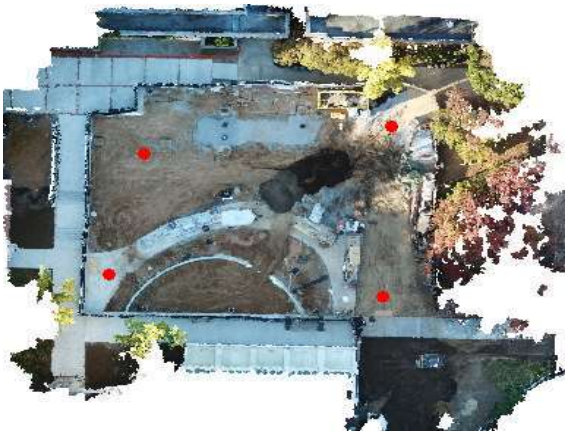

Figure 6. Identified scan locations from the scan planning simulation with UAV's point cloud (top view)

4.1.4 Automatic Registration of Scans

The laser-scan data from the horizontal LiDAR is used by the Hector SLAM algorithm to estimate the position and orientation of GRoMI on the horizontal plane. The Hector SLAM algorithm, developed by Kohlbrecher et al. [19], is employed in this study to perform laser-scan matching between the laser scans and progressively built maps to estimate the robot's postures and planar maps of the environment. In addition, the SLAM-driven localization approach is used to automatically register the point clouds obtained from each stationary scan location [20].

5 Results

In this study, a real-world construction site at the Georgia Tech campus was selected as a cluttered environment for the test. Three devices, UAV, GRoMI, and a commercial laser scanner, were used to build 3D point clouds of the site. To generate a 3D point cloud,

UAV used the photogrammetry technique, and a commercial laser scanner used sphere targets for point

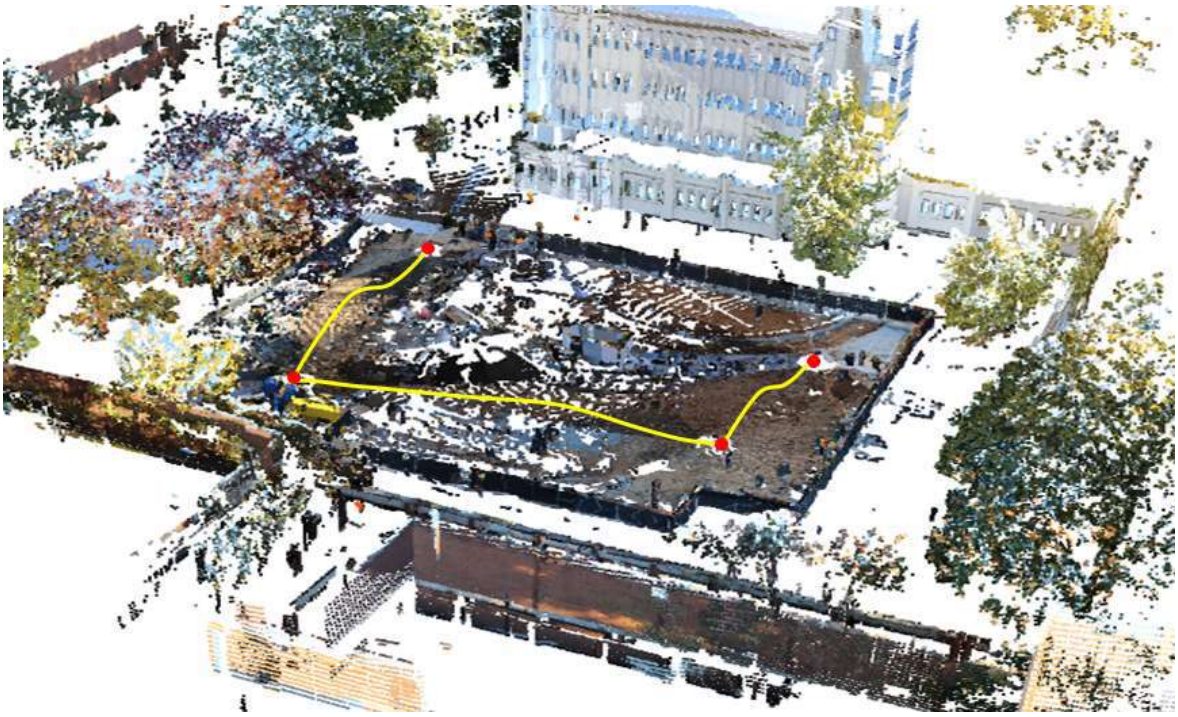

Figure 7. Registered 3D point cloud of the test site and GRoMI's scan and moving paths

cloud registration. As previously described, GRoMI conducted the SLAM-based automatic registration. Figure 7 shows the automatically registered RGB point clouds of the target site made by GRoMI.

Table 1. Error assessment

	GRoMI
Mean absolute error (MAE)	1.97 cm
Root mean square error (RMSE)	2.31 cm

Table 2. Required time from data collection to registration

	GRoMI	Commercial laser scanner
Pre-processing	35 min	10 min
Operation	30 min	40 min
Post-processing	0 min	40 min

In this study, the commercial laser scanner is considered the ground truth to measure the registration error of the registered point cloud collected by GRoMI since the terrestrial laser scanner has the highest accuracy of ±3 mm. As shown in Table 1, the mean absolute error (MAE) between the GRoMI and commercial laser scanner point clouds is 1.97 cm, and the root mean square error (RMSE) is 2.31 cm; MAE is an average distance between two point cloud sets, and RMSE is a standard deviation between two data sets.

Table 2 shows the required time to build a 3D registered point cloud with each device. The pre-processing includes the UAV's scanning time and path-planning processes for GRoMI and a target placing and laser preparation time for the commercial laser scanner. Operation refers to the data collection process with each device, and post-processing is the point-cloud registration process. During the 35 min of pre-processing for GRoMI, 10 min of UAV operation, 20 min of point-cloud generation, and 5 min of scan planning are included. The clear advantage of using GRoMI with UAV is the shortened processing and operation time. A commercial laser scanner has slightly higher accuracy but requires significantly more time than GRoMI for the target relocation and manual point clouds registration. Also, it cannot guarantee the complete scan of the job site since selecting scan locations is based on human intuition. Conversely, the advantage of using GRoMI is the planning scan locations and paths created by using a UAV-generated point cloud. Thus, it can realize more favorable results. Also, it does not need post-processing (registration) because it is registered automatically using the robot localization data (i.e., SLAM). Therefore, the proposed aerial mobile robot-based autonomous data acquisition approach resulted in higher time and cost efficiencies compared with the traditional terrestrial LiDAR-based data acquisition method.

6 Discussion and Conclusion

In general, effective mobile robot path planning for unknown and clustered environments is challenging because no a priori information of site conditions exists. To overcome these problems, this paper introduces an autonomous method for 3D point-cloud generation through the collaboration between UAV and UGV. From the test results, both commercial laser scanner and UGV yielded satisfactory accuracy. However, the proposed method, with UGV (GRoMI), is more effective in post-processing for point-cloud registration using the SLAM-driven robot localization data. The advantages of using the proposed approach over traditional methods include (1) to automate the point-cloud acquisition process by finding the robot's preferred scan locations and planning navigation paths with the aid of UAV's site map; (2) to remove redundant scans and reduce time and cost for data collection; (3) to reduce missing areas of the target site; and (4) to automatically register multiple scans.

The proposed framework enables mobile robots to robustly and effectively collect high-quality site data, thereby enhancing site inspection and monitoring capabilities and reducing necessary time and cost. Since the robot can frequently update the geometric information of a site, it can be used for several construction management applications including virtual site access from remote places, progress monitoring, defect management, safety, legal dispute, supply chain management, as-built BIM, and more.

However, the implementation of the proposed method is still limited by its dependence on UAV's generated map data. As such, pre-processing for the proposed approach requires more time than the traditional 3D scanning process. For future study, the current robotic approach should be further investigated for cases when UAV data is not available (e.g., indoor construction). In this case, the robot must be able to itself estimate preferred scan locations.

Abstract –

Deep learning and neural networks have empowered many tasks including semantic segmentation and image classification. Recently, novel neural networks were proposed that could directly process three-dimensional (3D) point clouds. In this paper, we present a software tool incorporating a variety of measuring tools to analyze and validate raw point cloud data while enabling an interactive segmentation of point clouds using deep learning. One of the primary advantages of implementing deep learning for point cloud segmentation is that it enables feature extraction to be learned through neural networks based on a large amount of data. Our software tool allows users to visualize 3D point cloud data sets containing millions of points in standard web browsers and process 3D point clouds using deep segmentation with deep neural networks. The interaction tool can assist with distinguishing structural buildings elements from non-structural objects in a given dataset.

Keywords –

Point cloud; Deep learning; Web-based interaction

1 Introduction

Point clouds are three-dimensional (3D) models that consist of points compared with other 3D model representations, such as meshes, volumetric models, and depth maps. Point clouds are obtained by scanning the real world using an 3D imaging method such as laser scanning (light detection and ranging, lidar) or photogrammetry. Point cloud data can be transformed into other 3D model representations and products by further processing, modeling, and analysis.

Point cloud data can be utilized in a variety of applications, such as construction progress monitoring, building structural analysis, and generation of 3D models. In addition, point clouds are also widely used in real-time perception applications such as the use of lidar perception in autonomous driving vehicles or robotic SLAM (simultaneous localization and mapping) systems. For most of these applications, point clouds are typically treated as raw data, which requires it to be processed and analyzed to extract useful information.

Building Information Modeling (BIM) is a process involving the generation and management of digital representations called "Building information models" (BIMs), which are files which can be extracted, exchanged or networked to support decision-making regarding a building or other built asset. It is also enabling its users to share and compare their models seamlessly throughout the whole lifecycle of their project, from planning to demolition. It offers a variety of benefits including prevention of data loss from one phase to another, as well as improved visualization and coordination between different trades involved in a project. BIM implementation in the construction industry has increased exponentially in the last decade. Scan-to-BIM is a process of 3D laser scanning a physical space or site to create an accurate digital representation through BIM. This representation can be used for design, progress tracking or project evaluation. The data collection in Scan-to-BIM helps eliminate human error that may occur otherwise when using traditional surveying methods and it enables collection of a high volume of data over a short amount of time. Next, the scanning data (i.e. point cloud) need to be shared with the project team; this is done most commonly by importing the data into the project's common data environment (CDE), which enables the team members to analyze, visualize and model the point cloud. This end-to-end approach delivers more detailed and accurate information about a project and enables one to verify the progress of the work in an objective manner.

Different applications usually employ different approaches to extract features from point clouds. Point features often encode certain statistical properties of the points, are designed to be invariant to certain transformations, and can be classified as intrinsic or extrinsic parameters. They can also be categorized as local features and global features. For a specific task, it is nontrivial to find the optimal feature combination. Deep learning can provide end-to-end training which automates the feature extraction process by learning from existing point cloud data, and could significantly reduce

data complexity for modeling and data analysis in an automated Scan-to-BIM framework.

In the big data era, WebGL and server framework over web browsers has become increasingly popular. Such architectures are supported over a standard browser, and enables developers, artists, companies, researchers to share their data with a wider audience and access their work on any device in any place without the need of installing additional software.

Furthermore, the widespread use of neural networks demands high-performance computational resources, (e.g., multi-core CPUs and GPUs), especially when users are required to work remotely without powerful computing resources. Web-based client-to-server communication architecture and the application of deep learning on the server side allow users to work remotely with massive 3D data regardless of the device they use. Currently, several web-based services, such as Sketchfab and Potree allow users to upload, share and view content without any knowledge about the underlying 3D modeling and geometry mechanics. But to our knowledge no deep learning service have existed.

This paper introduces a prototype web-based end-to-end point cloud processing toolbox that is capable of loading and viewing point cloud data. Furthermore, it is capable of applying neural network semantic scene segmentation and annotating point clouds. This work is expected to be a basic building block to a complete Scan-to-BIM framework.

2 Related Work

2.1 Web-based Massive Point Cloud rendering

Potree [15], a web-based renderer for large point clouds, allows users to view data sets with billions of points, obtained from sources such as lidar or photogrammetry, in real time in standard web browsers. The focus of Potree is on large point clouds, and its measuring tools allow users to visualize, analyze and validate raw point cloud data without the need for a time-intensive and potentially costly meshing step.

PointCloudViz server [19] and the corresponding web client are commercial services by Mirage Technologies, which complement their free desktop lidar viewer.

The streaming and rendering of billions of points in web browsers, without the need to load large amounts of data in advance, is achieved with a hierarchical structure that stores subsamples of the original data at different resolutions. A low-resolution version is stored in the root node and with each level, the resolution gradually increases. The structure enables Potree to neglect regions outside the view frustum, and to render distant regions at a lower level of detail.

ShareLIDAR [16] is a multi-resolution point cloud renderer with hosting service. Its notable features include illumination through normals, an orthographic top view, a sectioning (height-profile) tool and the adjustment of point sizes. However, it loads data in smaller tiles that do not cover the whole data set, which results in a large empty space within the display while the user waits for the data to stream in.

2.2 Point Cloud Feature Extraction

3D point clouds are typically processed using point cloud features that are customized for specific tasks. Point features often encode certain statistical properties of points that are usually classified as intrinsic or extrinsic parameters of transformations, or they are categorized as local and global features.

2.3 Deep Learning for Processing Large Scale Point Clouds

Deep learning is a recent technique used for point cloud processing. Previous research on 3D Convolutional Neural Networks (CNN) convert 3D point clouds to 2D images or 3D volumetric grids. Qi et al. [18] and Hang et al. [9] developed methods that project 3D point clouds or shapes into several 2D images, and then apply 2D CNN for classification. Although these approaches have achieved great results for shape classification and retrieval tasks, they cannot be extended for high-resolution scene segmentation tasks. [22, 9, and 6] presented approaches that voxelize point clouds into volumetric grids by quantization and then apply 3D CNN. These approaches are constrained by the volumetric resolution of the 3D point cloud; further, the computational cost of 3D convolutions is a significant disadvantage, especially when processing very large point clouds. [11] improves the resolution significantly by using a set of unbalanced octrees where each leaf node stores a pooled feature representation. Kd-networks [4] compute the representations in a feed-forward bottom-up fashion on a Kd-tree with a certain size. In a Kd-network, the input number of points in the point cloud needs to be the same during training and testing, which unfortunately does not hold for many tasks.

In [8], an effective feature learning method called PointNet is introduced that directly applies the raw data without preprocessing the point clouds. Point clouds are simple and unified structures and are easier to learn from compared to meshes or other types of 3D models.

2.3.1 Building Information Modeling

Building Information Modeling (BIM) is both a technology and a process that results in easer collaboration between involved parties by using a virtual

3D model of a structure. From the technology perspective, BIM is an object-oriented database that hosts both geometric and non-geometric information such as material types, costs, and scheduling. BIM has been adopted at a growing rate in the construction industry. It is used for a variety of tasks including design coordination (commonly known as clash coordination/detection), constructability analysis, and 3D/4D analysis, amongst others.

Both geometric and non-geometric data stored in BIM should be well defined when developing the BIM model. BIM data is typically stored online on a data cloud to manage and share information among members of a team working on the same project as well as to avoid the potential complications that may arise from the use of models that are not up-to-date.

One of the objectives of the system proposed in this paper is to ensure that it can assist users with model visualization and data management, which are essential for data collaboration and vital to the success of BIM.

2.3.2 System Design

To overcome the weaknesses inherent in previous point cloud processing and visualization approaches, this study aims to provide an efficient data management and visualization solution with a user-friendly interface.

Figure 1 illustrates the major nodes for achieving the goal with their individual function.

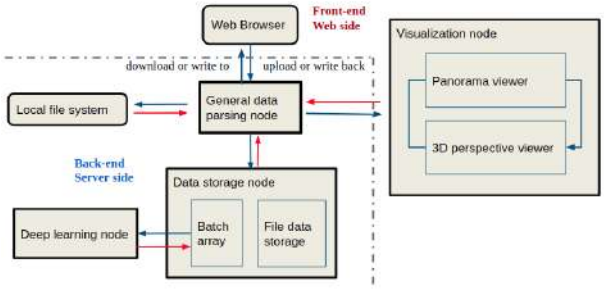

Figure 1. Data flow in the major functionality module of the proposed system

The system can be divided into the front-end and the back-end. The front-end provides the user interaction interface and enables visualization of point clouds using three different approaches. The front-end interaction interface performs several operations, including storing and parsing data into the designated format, which are sent to the back-end. Data parsing is automatically determined by the "General Data Parsing Node". Figure 1 shows that files can be uploaded into the system online or directly by the administrator in the server's file system. After the data processing is complete, the user can download the results or the data that have been processed (such as an intermediate file that is parsed in a different format, a semantic segmentation result, or a 2D panoramic image).

The general data parsing node is one of the core modules of the proposed system. It enables to use different file formats for the input file.

The use of an intermediate file makes sure that for each function module, the input format requirement is not the main hindrance to data flow through the system. This also enables all modules to use the most appropriate file format in order to decrease possible programming difficulties and compatible language problems. The intermediate file communication method ensures the system focuses on the portability and reusability and achieves low coupling, which is convenient for further development and reusing of the code.

After the data been parsed by the "General Data Parsing Node", the formed data will be stored in the data storage node. The data herein has been parsed into two structures. The first structure is in 2D array panorama form, which lists the point cloud information in a 2D array structure following a 2D panorama image sequence that can be traced back to each of the scanners that is used to acquire data. The second structure is in a batch array format, from which we can directly transfer to the neural network in order to train the network for further improvement or simply calculate the semantic segmentation result with the point cloud data from a single scan by going through the forward propagation. We will discuss how data are formed in all these intermediate files in detail in the next section.

The highlight of this system is our "Deep Learning Node", which is an abstract interface that can trigger deep learning related algorithms and trained neural networks obtained in a run. In our extendable system, the neural network model can be changed when desired. Researchers can replace or upgrade the model when they want to have a different model architecture of a network in order to improve the performance, or have a new model that can work on a different task.

Another highlighted feature in this system is the "Visualization Node", which provides a method to visualize the raw data and the analyzed result applies on the raw data views. The panorama viewer and the 3D perspective viewer provide two different ways for users to visualize the point cloud data and task results. The Panorama viewer provides the ability to show the raw data as a panoramic image with original color or by the instance segmentation result processed by the Norvana [2] algorithm. It provides several useful tools that can assist with the organization of the point cloud data and enables users to perform annotation operations on panorama image directly through a canvas. The 3D perspective viewer provides the basic visualization window for viewing the point cloud model in 3D from different perspectives.

2.3.3 Deep Semantic Segmentation of Point Clouds

In this work, the PointNet [8] architecture is utilized in the deep learning function node (Figure 2). The structured batch array, which contains the information per point in an indoor point cloud scene, will be fed to the proposed network. Each point has 9 attributes, including X, Y, Z, R, G, B, and 3D normalized location with respect to the room (from 0 to 1).

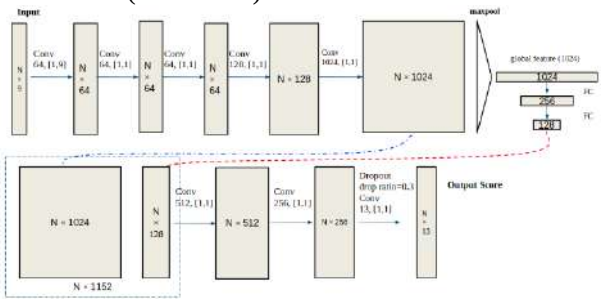

Figure 2. The network architecture based on PointNet baseline structure

The architecture contains 3 consecutive, multiple layer perceptions (MLP). In our implementation, we use an equivalent form of convolutional filters with a size of 1×1 instead.

After the feature learning, resulting in 1024 new point features, we apply a max-pooling layer to down-sample and aggregate these point features into global features. We then make the global features pass through a fully connected (FC) layer to aggregate to 128 features. These 128 features, which are tiled to the same dimension as the number of points, are then concatenated with the previous N×1024 features. After the next several convolutional layers that are similar to previous operations, we obtain the output score of a 13-dimensional array after the softmax layer.

2.3.4 Showcase and Functionality Introduction

The operation with user friendly interaction will lead user to go through the whole pipeline that finish their task step by step.

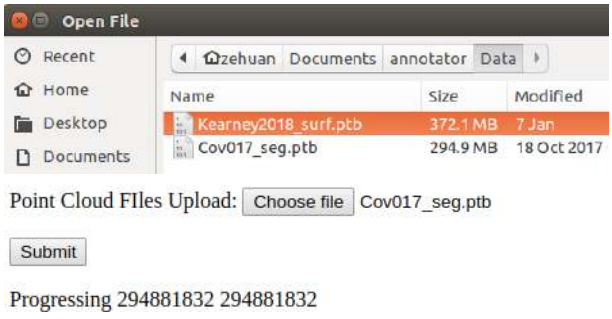

Figure 3. File select (top) and file upload (bottom) interfaces

Figure 3 explains the very first step where a user uploads a data file to the server, and then internally the file parsing node on server side will reformat the data.

After data has been reformatted, the panorama image viewer will pop up and show a panoramic image with original color and with three buttons to allow the following operations: image rotation operations, "show instance segmentation," and "show semantic segmentation."

Figure 4. Panoramic image view

The result of the instance segmentation will show up and generate the canvas overlay on the original color image. The instance segmentation results were generated according to the algorithm [2] using test data collected from a building (Covell Hall) at Oregon State University main campus. This panoramic image is shown with photographic color in different image fuse ratio (opacity). The interface also includes the panel to show which color block indicates which class ID. In that case, people can easily access the classification result directly from the algorithm and perform manual annotation, or refine the result. The user can further improve the automated results of the algorithm or annotate the dataset with a real ground truth classification result and feed it into deep neural network.

Figure 5. Panoramic image view with colormap overlay representing the instance segmentation results obtained using Norvana algorithm

2.3.5 Instance Segmentation

The classification and segmentation algorithm are the

core operation module in our system. Norvana, introduced in [2] is a highly efficient and novel approach to segment point clouds. Segmentation is a common procedure of post-processing to group the point cloud into a number of clusters to simplify the data for the sequential modelling and analysis needed for most applications. Norvana rapidly segments laser scan data based on edge detection and region growing. The algorithm computes incidence angles and then performs normal variation analysis to separate silhouette edges and intersection edges smooth surfaces. A modified region growing algorithm groups the points lying on the same smooth surface. The proposed method efficiently exploits the gridded scan pattern utilized during acquisition of laser scanning data from most sensors and takes advantage of parallel programming to process approximately 1 million points per second. Moreover, the proposed segmentation does directly not require estimation of the normal at each point, which limits the errors in normal estimation propagating to segmentation. Figure 6 shows an example scan segmented by Norvana.

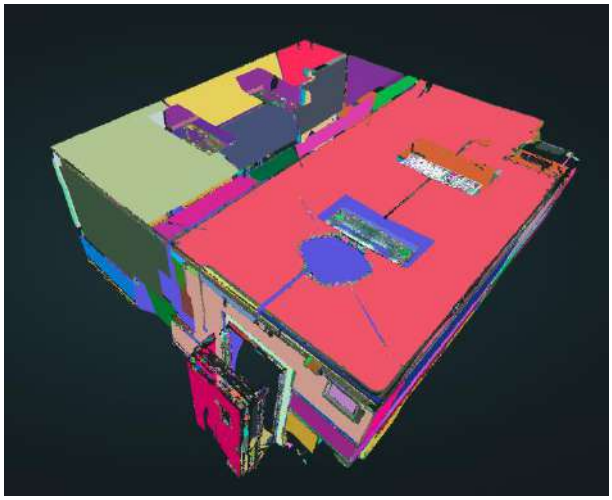

Figure 6. Norvana segmentation results in 3D perspective view via Potree

Along with the appearance of the 2D panorama with instance segmentation overlay and tools, the 3D viewer of the instance segmentation result is also shown (Figure 6). Orbit navigation with mouse and keyboard are supported. This viewer is powered by a Nested octree data structure. Points are rendered in hierarchal order to minimize the use of computational resources and avoid crashing the browser.

Table 1. Indoor object classes

Structural classes		Non-structural classes	
Column	Wall	Door	Window
Ceiling	Floor	Bookcase	Board
Beam		Chair	Sofa
		Table	Clutters

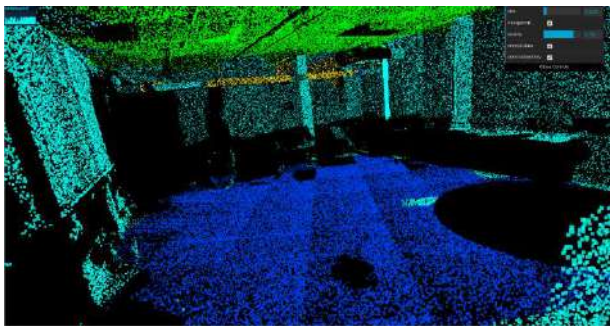

Figure 8. The scene after the semantic filter application to remove the non-construction class objects in the point cloud

3 Experiment

This section details the experiment conducted on the S3DIS (3D Semantic Parsing of Large-Scale Indoor Spaces) dataset that is visualized on the 3D viewer and segmented using deep neural network [1].

The S3DIS dataset (Figure 9) is composed of five large-scale indoor areas from three different buildings, each covering approximately 1900, 450, 1700, 870 and 1100 square meters (total of 6020 square meters). These areas show diverse properties in architectural style and appearance, including office areas, educational and exhibition spaces, conference rooms, personal offices, restrooms, open spaces, lobbies, stairways, and hallways.

One of the areas includes multiple floors, while all the other areas include only one floor. All the point clouds are automatically generated without any manual intervention using the Matterport scanner.

The dataset contains 3D scans of six different areas including 271 rooms. Each point in the scan is annotated manually with one of the semantic labels from the 13 categories (chair, table, floor, wall, etc., and clutter). We can further distinguish these 13 classes as a structural object (e.g., floor, ceiling wall, etc.) or a non-structural object (e.g., table, sofa, door, etc.). With the tag of different classes, we can visualize the two main clusters

(structural vs. non-structural, Figure 7) or view individual classes (or combination) via checking each class of interest (Figure 8).

The training data points are split room by room, and the rooms were split into blocks with 1m x 1m area. Then the segmentation algorithm in PointNet was trained to predict point classes of each block. Each point is represented by a 9-dimensional vector of XYZ, RGB and normalized location as to the room (from 0 to 1). For training, 4096 points were randomly selected from each block on-the-fly. After training, all the points in the testing dataset are tested on.

The precision-recall curve of the segmentation is calculated for both construction structure and non-construction structure points (Figure 9). This result is transferred from original 13-class semantic segmentation for each point into binary classification.

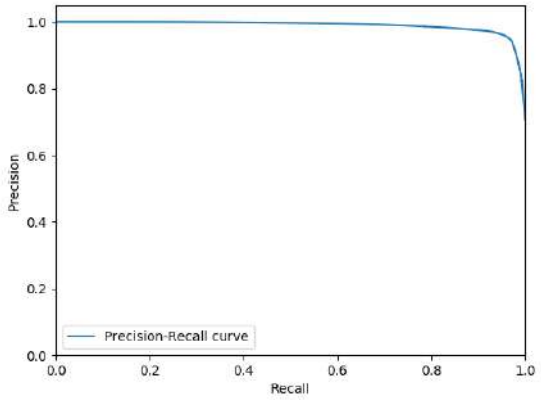

Figure 9. Precision-Recall curve for structural and non-structural objects classification in the S3DIS dataset

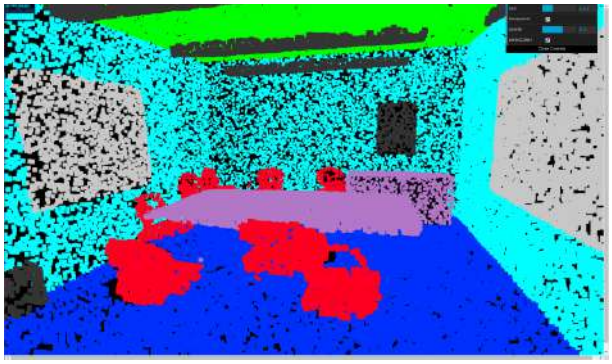

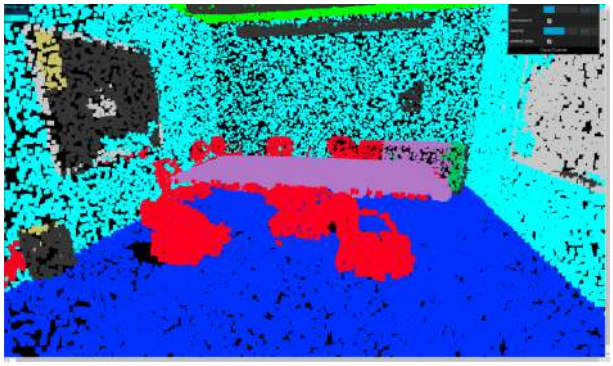

Figure 10. Conference room scene in S3DIS dataset. The ground truth semantic labelling result (top), and the prediction result (bottom) in 3D perspective viewer.

Figures 10-12 present three different point clouds of indoor scenes, selected from the S3DIS dataset. Each figure contains ground truth semantic labeling and the prediction results showing different classes.

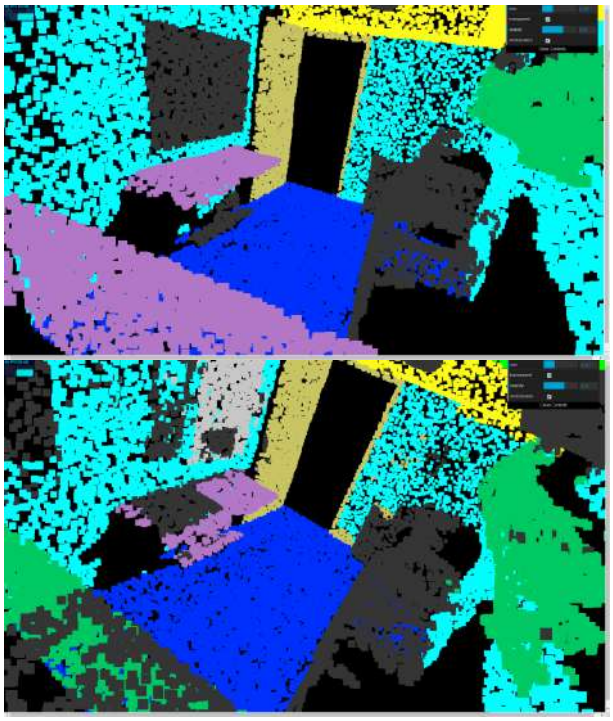

Figure 11. Copy room scene in S3DIS dataset. Top view shows the ground truth, and the bottom view shows the prediction labelling result

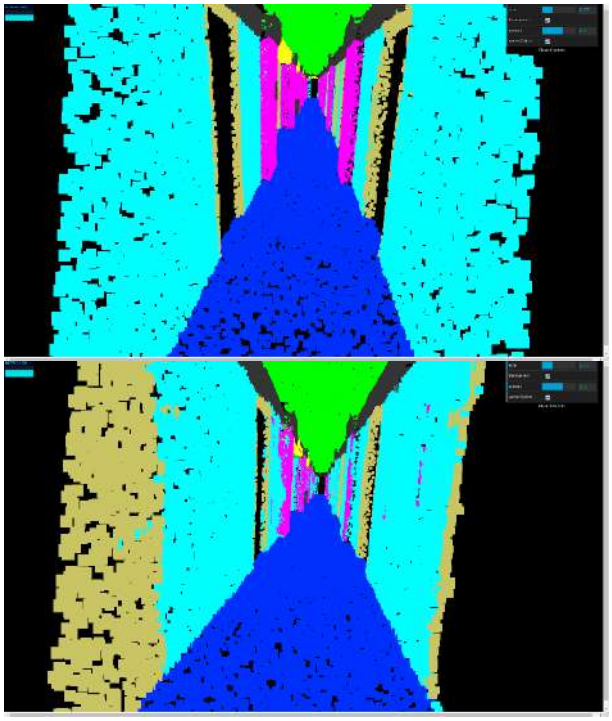

Figure 12. The ground truth (top), prediction result (bottom)

In Figure 10, the board and the clutter were slightly mismatched since the white board and the paint (belong to clutter class) could not be differentiated by the segmentation algorithm. However, tables and chairs were classified correctly with very little mismatch using PointNet.

In Figure 11, in the copy room scene, semantic labeling was performed with high accuracy. However, there were still some mismatches. For example, the table was mismatched with the part of ceiling on the bottom-left corner of the figure.

In Figure 12, a hallway scene is presented. This scene does not contain many corners or small objects. Thus, the segmentation of walls, floor and ceiling were done successfully. The figure also demonstrates that the segmentation prediction result is very close to the ground truth.

4 Conclusion and Future work

This paper presented a system that is capable of rendering 3D point clouds with millions of points real time in standard web browsers. It uses intermediate data storage format and data stream parsing to ensure that the proposed system is compatible with different file formats. In other words, it can process data regardless of the input file format and the neural network architecture. Furthermore, utilization of asynchronous mechanism and recall function during the front-end step dramatically reduces the total data download / visualization time and improve the runtime speed. The general file storage node and multiple view approach enable the system to render raw point cloud data in different representations, including panoramic and 3D viewer. To achieve a better visual quality, methods such as a multi-layer canvas interaction interface was implemented in order to increase the computing efficiency and to enable visualization and input interaction process in parallel.

Deep semantic segmentation results obtained from indoor scene point cloud data obtained from the S3DIS dataset are also presented, where each point in the dataset was labeled as structural and non-structural classes.

In future work, the point cloud rendering efficiency of the system will be improved, and other interaction tools including the synchronous correspondence of two viewers will be added. Furthermore, point cloud selection tools should be added to the 3D perspective viewer. Another issue that needs to be addressed in future work has to do with filling the empty spaces, i.e. “holes”, after filtering out the non-construction objects. More efficient point cloud semantic segmentation algorithms and network architecture could also be applied to the more recent PointConv [22] architecture.

Abstract –

Well-coordinated construction site logistics are important for the efficient assembly of large-scale plants. Delays in logistics have a negative impact on assembly processes and vice versa. Incorrect storage or improper transport can lead to damage to the sensitive plant components. All relevant logistical constraints must therefore be systematically analyzed, assessed and evaluated during the planning of construction site and assembly processes. For this purpose, precise knowledge of the logistical requirements of each individual component is very important. Nowadays this information is not available in digital form and must be elaborately compiled and evaluated manually. The logistical requirements are also essential for the planning of processes. So-called 4D models are already being created and used in plant construction, but storage and transport processes on the construction site are only rudimentarily taken into account. In general, the 4D models only describe the construction process. In order to better investigate and plan construction site logistics using 4D models, the logistical requirements must be identified, classified, generated for each plant component and made available digitally. Therefore, an ontology for the description of logistic boundary conditions and requirements is presented in this paper. The focus is on large-scale plant engineering and the special storage and transport conditions of the various components. The ontology is also a knowledge base to identify which information is required for the planning of construction site logistics and which may need to be added. Then, for example, semi-automatic allocation of storage space can be calculated, an analysis of the utilization of transport equipment can be carried out or the impact on the assembly processes can be determined.

Logistics requirements; Ontology; 4D BIM; Site layout planning; Plant construction

1 Introduction

A precisely coordinated logistics system is important for the efficient and cost-effective handling of projects in large-scale plant construction. This is particularly important as very sensitive and large components are usually transported and stored in plant construction. Planning includes the selection, design, dimensioning and optimization of processes, material flows and resources. Depending on the complexity of the large-scale plant, many different boundary conditions must be considered in the project-specific planning of construction site logistics. The planning and control of construction site logistics for such large-scale projects are not sufficiently supported by digital planning tools. Nowadays, this requires extensive project experience. If transport and storage conditions are not correctly analyzed and adhered to, this not only leads to delays in assembly, but also to damage to the sensitive system components. In the worst case, elaborate rework or complete disassembly is necessary.

Digital models have also been used for several years in large-scale plant construction for the planning and prefabrication of plant components. However, the digital models are hardly used on site. Even if system components are visualized on the construction site with the help of mobile devices, there is currently no IT-based support for planning and controlling the logistical processes on the construction site in detail. On-site transport, storage and detailed intermediate steps cannot be analyzed, checked and visualized with existing concepts and solutions. Certain information for the precise planning and control of logistics is already available based on the digital model. However, the information available is insufficient and must be systematically supplemented.

In our approach, we examine the required logistics information and describe it formally and evaluably in the Web Ontology Language (OWL) format. This ontology is linked to the information of a 3D Building Information Model (BIM) to generate logistics information for the specific component or assembly task.

2 Related Work

The planning of construction projects is generally associated with uncertainties, because the customer-specific engineering and construction of large-scale plants fundamentally differ from stationary series production. In addition to technical and structural limits, organizational project specifications, such as production steps, construction phases or resource disposition as well as logistical boundary conditions in particular are relevant aspects. Gutfeld et al. (2014) [1] describe the problems and deficits of project management in plant construction and present a method for simulation-based and logistically integrated project management in plant construction. Nowadays, the construction schedule is manually created by project managers based on their experience. The assumptions they made during the planning phase can prove to be disadvantageous in the actual construction process. This is not only due to delays in the delivery of materials, but may also be due to difficulties during assembly. A number of aspects can affect project plans, such as weather, lack of storage spaces or limited resources [2]. Therefore, a subsequent, continuous review and, if necessary, adjustment of the schedules is required. Until now, the focus of the project managers has been on the delivery dates and the duration of the assembly processes. Logistics on the construction site itself has received little attention so far. Usually, logistics processes are regulated spontaneously on site. This leads to unnecessary delays due to lack of suitable storage areas and continuous material search.

The construction industry is currently experiencing a change to a digital construction planning process mainly with the help of BIM. The BIM method is used to provide necessary information of a specific building project starting from the planning phase up to facility maintenance with the help of an intelligent 3D-Model. This is achieved by expanding the geometrical information (3D) of the model with additional information. A BIM-model can be used for visualization, fabrication drawings, code reviews, forensic analysis, facilities management, cost estimating, conflict, interference and collision detection and construction sequencing. During the whole construction process, an up-to-date as-built BIM-model helps keep an overview of the construction site and to avoid incorrect planning that may cause interferences of different trades. These interferences generally cost time, which leads to higher costs due to additional wage costs or contractual fines because of delay [3]. The Industry Foundation Classes (IFC) provide a comprehensive and standardized data model for the vendor-neutral exchange of digital building models. A significant advantage of IFC is that digital model objects can be dynamically extended by any additional information [4].

To implement an integrated digital planning, the site layout also needs to be integrated into BIM-models. A BIM-based site layout planning not only provides 3D models of site equipment, where 2D site layout plans can easily be derived from, but also considers scheduling information. The linking of building elements or construction equipment with activities of a time schedule is called a 4D model. The main purpose is the visualization and analysis of the construction processes and the temporally variable construction site equipment [5]. The use of 4D-BIM promotes communication and enables a uniform understanding between all project participants. Variant assessment tests provide support in procurement with material lists and material calculations. The planned progress can be represented at any time during the construction project and delays can be seen by comparison with an as-built model. This also supports the analysis of work processes.

An essential aspect of BIM is the linking of building elements with other external information for a certain application. Which information is linked or added under which conditions can be defined using a higher-level ontology. An ontology describes a hierarchy of concepts (class and subclass) linked by relationships, adding appropriate axioms to express relationships between concepts and limit their interpretation. Furthermore, ontologies can be used to describe a common vocabulary of terms and the specification of their meaning for the knowledge area [6]. Special ontologies have already been developed in various research approaches in the construction industry. Zhang and Issa (2012) use an ontology to extract specific information from a BIM-model [7]. El-Gohary et al. (2010) show a concept of a domain ontology for supporting knowledge-enabled process management and coordination across various stakeholders, disciplines, and projects [8]. Kim et al. (2009) use an ontological consistency checking for design coordination in BIM [9]. Lee et al. (2015) create an ontology model for supporting information handling of off-site automatic prefabrication and on-site assembly [10]. In order to achieve the target of just-in-time (JIT) production and lean construction, Xiong et al. (2018) use the Process Specification Language (PSL) based ontology to unify the process information from multiple planning software applications [11]. Pedro et al. (2017) use an ontology for linking and sharing Job Hazard Analyses (JSA), safety rules and training contents for construction safety [12]. For the controlling of construction site logistics, it is important to have (near) real-time data to confirm the planned schedule. Therefore, Isaac (2016) reviewed existing scheduling methods and compared their outputs with the data provided by automated monitoring technologies. He proposes ways in which scheduling methods can be enriched in order to better support real-time monitoring and control processes [13]. One of the key integration gateways between BIM and ontology is represented by the ifcOWL and ifcWoD [14]. These ontologies allow the publication

of IFC-based building models using the Resource Description Framework (RDF) data model.

3 Methodology

An essential requirement for planning and control in large-scale plant construction is the systematical description of all logistical constraints according to the specific project. There are different requirements for different plant components and parts. Certain components must be specially stored and transported. Suitable storage areas and transport aids have to be available for this purpose. This information must be systematically recorded, documented and made available digitally in advance. In our concept describes below, the logistical requirements are described flexibly and they are reusable with the help of an ontology. In large-scale plant construction, the focus lies on sensitive and costly plant components. The components are usually prefabricated and partly pre-assembled. Afterwards, the components are transported to the construction site. The next step is often an intermediate storage. On international construction sites, most problems arise during this intermediate storage and corresponding transport.

For typical plant components and projects in large-scale plant construction, our ontology covers all essential logistical boundary conditions. Complex dependencies between the components, means of transport and logistic influencing variables are modelled. The ontology is thus a formally ordered representation of a set of concepts and the relationships between them. The ontology is used to provide expert knowledge on logistic processes on construction sites in a digitized and formal form for planning and control. Furthermore, ontologies contain inference and integrity rules, i.e. rules on conclusions and on ensuring compliance.

We worked out company-specific requirements by analyzing the results of surveys on the topic of logistics and assembly planning for small medium-sized (SME) companies by means of expert interviews and case study analyzes. Here, other companies were also involved in individual discussions in order to record project and product-specific boundary conditions regarding organization, technology, personnel, quality and safety measures and country-specific regulations to be observed. In addition, requirements regarding the content of a digital planning and management of the construction logistics are included. At the same time, it is being examined how and to what extent product-specific restrictions must be formulated.

It is assumed that a digital model of the plant and the site equipment as well as associated and linked assembly processes for the individual components are available (see Figure 1). The existing digital models (4D-BIM including construction site layout) are imported and evaluated. This means that the components, storage areas, transport aids, processes and other boundary conditions are extracted. The ontology is used to classify the various objects and to conclude the associated logistical requirements. Therefore, every object needs to provide the standard properties, inter alia, family, type, identifier and dimensions. With the help of manual inputs via a user interface, logistics information, respectively logistics requirements per component, can be edited as well as extended and later used for planning and controlling on-site logistics.

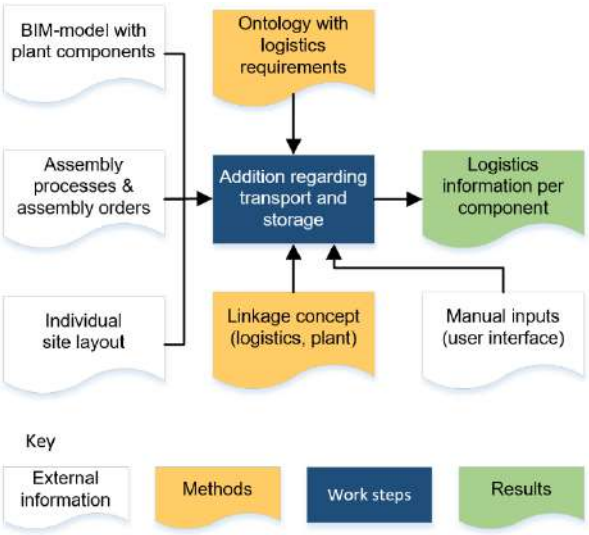

Figure 1. Methodology overview

4 Ontology for Logistics Requirements

When planning onsite-logistics, it is important to consider the specific requirements of the plant components. For space and cost reasons, not all components can be stored in secure areas. Therefore, the use of different types of storage areas is appropriate. Secure areas should be provided for very sensitive or very valuable components. Such components are typically present particularly in large-scale plant construction. Components that cannot be mounted directly after delivery (e.g. due to delays in the assembly of previous components) must be secured accordingly. Other components, which are sensitive to environmental influences such as dust, sunlight, cold or moisture, must be stored in closed storage areas. However, if components are to be protected from rain and direct sunlight only, a covered area will be a sufficient storage location.

If components react very sensitively to external influences, they will be specially packaged. The disadvantage

of packaging is that often special transport aids are requires and more waste is produced. In this case, the disposal areas must be enlarged or reorganized accordingly. The construction site layout must also be analysed and taken into account in detail. For example, it must be determined which transport routes and areas are available. Figure 2 shows a typical layout of a construction site in large-scale plant construction.

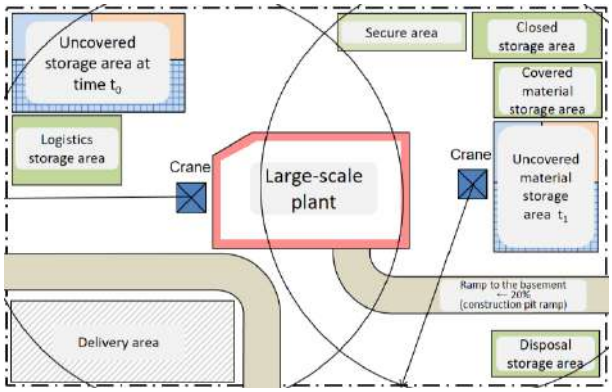

Figure 2. Construction site layout with typical logistical elements

In connection with the storage location, the logistical requirements of the components must also consider that they can be reached and equipped in a time-effective manner (e.g., only components of the same type may be stacked). The range of the cranes must also be taken into account. It should be noted, for example, that a direct crane operation from the truck to the covered storage areas might not be possible due to the roofing. For the affected components, lift trucks, or forklifts must be available on delivery, as well as suitably qualified personnel. In some cases, roof elements of the storage areas must also be removed for the delivery of large, heavy equipment requiring appropriate storage. JIT delivery should be preferred for such components.

During transport and storage of components on the construction site, the following information must be observed:

- package size (number of components per package),
- weight,
- packaging dimensions,
- permissible temperature range,
- permissible (air) humidity range,
- shock sensitivity,
- permitted change of position,
- stackability,
- fragility,
- legal requirements,
- hazardous content,
- just-in-time priority,
- assembly order.

For a valid planning of logistics processes, it is important to have the necessary project-relevant information available. This information can also be used to optimize logistics processes on the construction site. The logistical requirements should therefore be known at an early stage. The exact definition of the logistics processes (transport and storage at the construction site) depends not only on the components of the large-scale plant, but also on the delivery dates, assembly processes and other conditions at the construction site. In order to optimize assembly and logistics processes, planners must be provided with project-relevant information in the right quality at the right time. BIM is a suitable method for storing

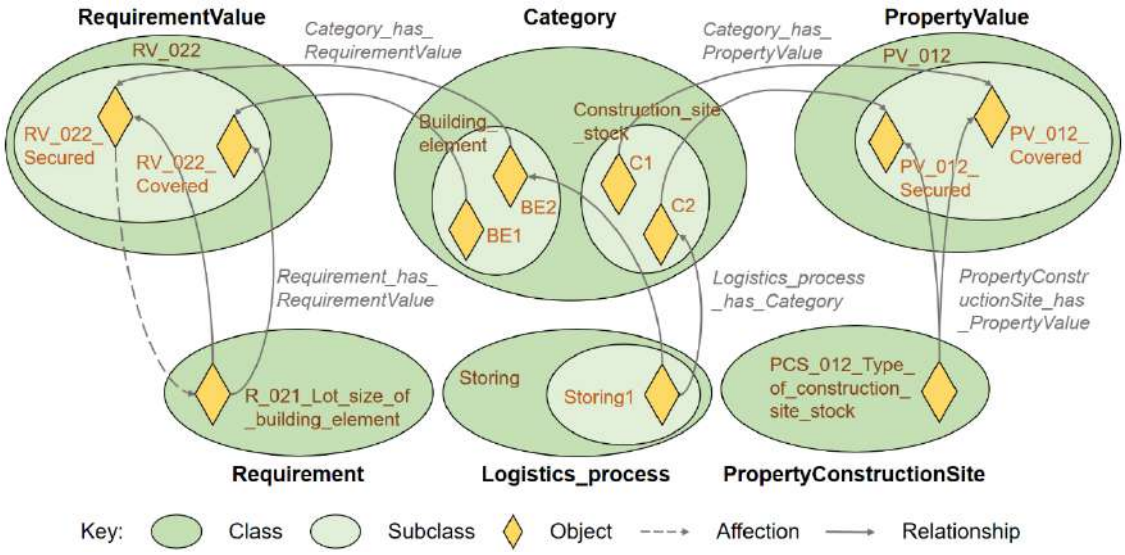

Figure 3. Detail of the basic structure of the developed ontology

this information and making it available to all parties involved. For the planning of logistics processes in large-scale plant construction, requirements for components, construction site equipment, etc. were examined and confirmed with the help of an interview study.

The ontology is mainly designed to support the planning of construction site logistics. For this purpose, existing information in the form of BIM-models of the objects of the plant to be built, the necessary assembly processes and scheduled resources are analyzed based on the ontology and are supplemented by necessary logistical information. The ontology provides a basis for summarizing requirements for the planning of logistics processes on the construction site in large-scale plant construction. In its semantic structure, the planning-relevant information on requirements, prerequisites for site equipment and planning objects (see Figure 3, class *Category* with *Construction_site_stock*, *Building_element* etc.) can be linked, represented and saved. The class *Requirement* contains a list of possible logistical requirements.

Currently ca. 20 pre-defined requirements are available. The characteristics of these requirements are described in the *RequirementValue* class. The individual components relevant to planning (such as *Assembly_group*, *Assisting_tool*, *Building_element*, *Construction_site_stock*, *Control*, *Data*, *Means_of_transport*, *Staff*, *Structure*, *and Working_environment*) are described in the *Category* class. The processes to be planned (*Assembly_process* and *Logistics_process* with *Search*, *Storing* and *Transport* subclasses) are defined in the *Process* class. They are assigned to certain properties in relation to the construction site facilities (*PropertyConstructionSite*), whereby the values of these properties are also assigned in a class called *PropertyValue* is defined. The list *PropertyConstructionSite* with the properties and their characteristics can also be extended. To compare the requirements with a digital model, the class *Sources* is defined with subclasses *BIM* and *Calculations*.

The ontology editor *Protégé 5.2* [15] was used to develop the ontology. The hierarchy of the ontology is shown in Figure 4. The *RequirementValue* and *PropertyValue* classes were created to group the possible characteristics of the properties and requirements. They group the values into individual numbered types (subclasses) and display their possible values in the form of objects (see Figure 4).

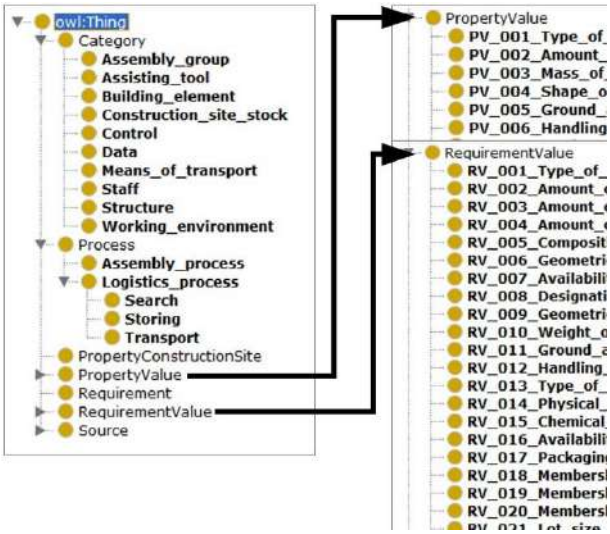

Figure 4. Classes *RequirementValue* and *PropertyValue*

With the help of the proposed ontology, the information relevant for planning can be linked and visualized in the *Protégé* editor with the help of *OntoGraf* (see Figure 5). This visualization helps to understand and verify the ontology.

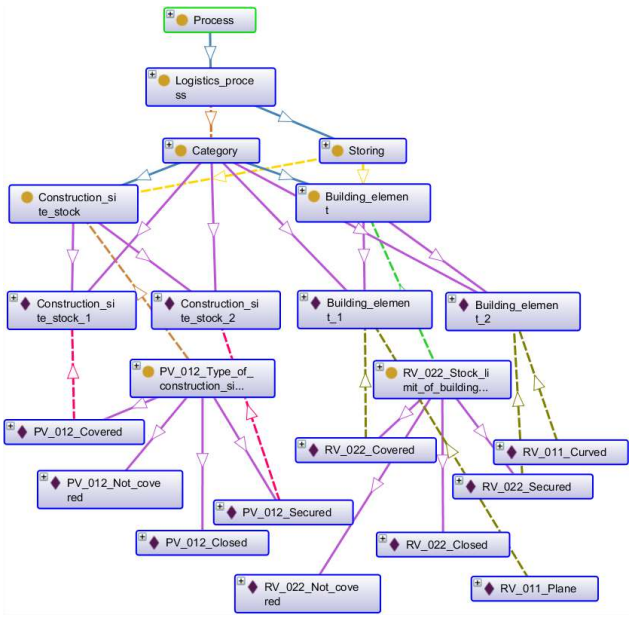

Figure 5. Graphical representation of the ontology in OntoGraf

Figure 6 shows how the limitations of a component (to be stored only in a covered place) influence the storage process. The associated storage process can therefore only be planned considering this requirement. For this purpose, the conditions on the construction site must be examined with regard to a covered storage area and the storage of the component in such a storage area must be planned. Afterwards, the corresponding relationship is set according to this relationship.

Figure 6. Classes *Requirement* and *PropertyConstructionSite*

5 Evaluation of the Ontology

The proposed ontology can be used in the BIM-based planning of site logistics processes to share knowledge about site logistics. This ontology will assist project participants in two areas. First, it will help to identify and classify the requirements for planning individual processes, as the user may not have enough logistics knowledge to fully incorporate this information into BIM-models. Second, it will help to analyze the information from a BIM-model in relation to logistics planning and assign it to the processes to be planned. These two cases are explained in the following sections using the proposed ontology. The queries are created with the *Protégé 5.2* tool.

5.1 Case 1 - Ontology to Read the Requirements for Planning the Individual Processes

When creating BIM-models, these requirements can be incorporated into the model in the form of planning-relevant information. For this purpose, a checklist can be created using the ontology in order to check such planning-relevant information in the model.

Simple ontology queries can be performed in *Protégé 5.2* using either a DL query or a SPARQL query. SPARQL is a query language for RDF, i.e. a query language for databases capable of retrieving and editing data stored in RDF format [16]. Table 2 shows an extract of the result of the SPARQL query shown in Table 1 that retrieves *Requirements* relevant to logistics planning. This list of planning-relevant information can be used as a checklist.

Table 1. SPARQL query for requirements

```
PREFIX bimlog: <http://www.semantic-web.org/user/ontologies/2018/12/bimlog#>
SELECT ?Requirement
WHERE { ?Requirement a bimlog:Requirement}
order by asc(str(?Requirement))
```

Table 2. Results of SPARQL query for requirements

Requirement
R_001_Type_of_assembly_group
…
R_008_Designation_of_building_element
…
R_010_Weight_of_building_element
…
R_039_Transmission_speed
…
R_051_Priority_of_task
…
R_060_Lot_size_of_building_element
…

5.2 Case 2 - Analysis of Information from BIM-Models in Relation to logistics Planning

If the information on the individual category classes (e.g. *Building_element*) from BIM-models is integrated into the ontology, the missing information can be analyzed and supplemented.

Table 3 shows the SPARQL query where components are retrieved, their requirement values are queried and restricted to the referring requirements of warehouse or transport restrictions (see Table 4).

Table 3. SPARQL query for Building_element and RequirementValue

```
PREFIX bimlog: <http://www.semantic-web.org/user/ontologies/2018/12/bimlog#>
SELECT ?Building_element ?Stock_limit
WHERE {
?Building_element a bimlog:Building_element.
?Building_element bimlog:Category_has_requirementValue ?Stock_limit.
?Stock_limit a bimlog:RV_022_Stock_limit_of_building_element}
```

Table 4. Results of SPARQL query for Building_element and RequirementValue

Building_element	Stock_limit
Building_element_2	RV_022_Secured
Building_element_1	RV_022_Covered

Queries can be carried out to obtain further information on transport and storage on the construction site, to find out where the construction elements are stored on the construction site and by which means of transport they can be transported. It is also possible to add new recommendations to the requirements according to use. For example, it is also possible to define automatic recommendations to support the decisions of project planners.

In our approach, we used the 4D-BIM software ceapoint desiteMD to import an IFC-format building model. As shown in Figure 7 information based on the developed ontology can help to visualize specific elements for the logistics planning.

Figure 7 shows two states of the visualization. In the upper screenshot, the entire plant is shown at the time t_1, in the lower screenshot, however, the object properties are used to highlight and to show only all the components in question. In this sample model, these are the bolts, queried by their amount and *Weight_of_building_element*. The advantage of the visualization in this example is the quick recognition of a possible storage position for short transportation paths of these small but numerous elements. Furthermore, possible logistical problems or potentially vulnerable components can be identified. For each element, IFC 3D Models only provide standard properties e.g. name, dimensions, material and identifier, while the ontology database only provides general logistics information, independent of individual elements.

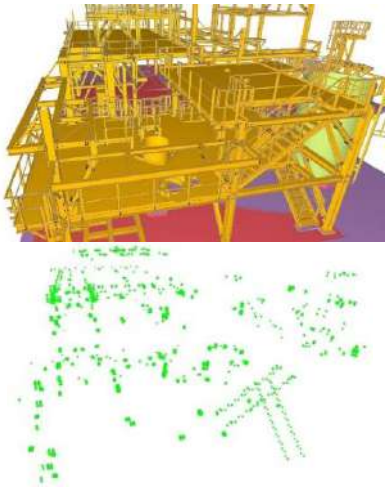

Figure 7. Highlighted consumable building components

To receive the specific logistics information for each element the information of the ontology database and the IFC 3D-model need to be linked as shown in Figure 8.

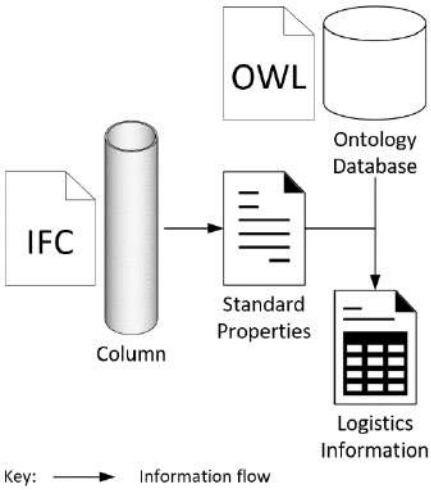

Figure 8. Receiving and linking logistics information

The link between the IFC and the OWL format may be established e.g. with the software *ceapoint desiteMD* via JavaScript and the help of the *Apache Jena RDF API* (Application Programming Interface).

6 Conclusion & Outlook

The definition of the specific requirements and the development of the ontology with the support of the surveyed companies creates the methodical prerequisite for semantically combining logistics, assembly and product descriptions to ensure a standardization and transferability of the results. This approach enables companies to

identify gaps in their planning to ensure smoother operation, to improve processes to reduce costs and save time on the job site.

Today, there are no commercial solutions on the market or scientific approaches available to implement a BIM-based logistics model. Therefore, new ground is broken with the conceptual work carried out in our approach. Based on the results of this work, software solutions can be developed for the coupling of IFC models and OWL ontologies. Based on our methodology, comprehensive databases can be created and will support project managers and planners to plan their construction schedules and to ensure a smoother progress of the projects. These databases can be continually supplemented, so that these knowledge bases grow gradually and require only fewer adjustments in future projects. Furthermore, the component information could also be extended by empirical values for the assembly time, thus ultimately enabling semi-automatic scheduling, taking into account all logistical requirements on the construction site.

Acknowledgements

The results presented in this paper originated in the joint research project "BIMLog - BIM-Based Logistics Planning and Control in Large-Scale Plant Construction" of the University of Kassel and the Ruhr University Bochum. The Industrial Collective Research (IGF) Operation (19720 N) of the Bundesvereinigung Logistik e.V. (BVL) was funded via the Industrial Research Associations (AiF) under the program for the promotion of the IGF by the German Federal Ministry for Economic Affairs and Energy (BMWi) based on a resolution by the German Bundestag.

Abstract –

The Triple Bottom Line (TBL) framework defined by Elkington in 1998 [1] proposed three aspects of sustainability: economical, environmental and social. However, several researchers have observed that further studies are needed to guide people and companies on how to achieve sustainable development. Specifically, many gaps are found in trying to implement social sustainability in processes within companies. This study aims to contribute to the integration of social sustainability in processes, with a specific focus on companies that fabricate and deliver post-disaster temporary housing. Our study is based on Value Stream Mapping (VSM) methodology, which previous research studies have identified as one of the main lean methodologies to analyze and identify waste in processes. Existing approaches based on VSM only attempted to integrate social sustainability of internal stakeholders into it. The research described in this paper aims to extend previous studies by integrating social sustainability of external stakeholders in companies' processes using VSM methodology. The analyzed system is the fabrication and delivery of panelized post-disaster temporary housing solutions where the post-disaster context is used to identify processes as well as internal and external stakeholders. Subsequently stakeholders' expectations and indexes that relate them with the outcomes of companies' processes are defined using existing research studies on social impact and on disaster management. Then, a model is proposed to integrate social sustainability of external stakeholders on VSM methodology. Finally, the proposed model is tested within an existing NGO that fabricates and delivers panelized post-disaster temporary housing in Chile.

Keywords –

Social sustainability; Value stream mapping; Lean and Sustainability; Post-disaster temporary housing; Panelized housing

1 Introduction

In 1987, the World Commission on Environment and Development (WCED) established by United Nations, proposed the most accepted definition of sustainable development: "sustainable development is development that meets the needs of the present without compromising the ability of future generations to meet their own" [2]. However, as several researchers have stated, further studies are needed to guide people and companies on how to achieve sustainable development [3-10]. Then, in order to propose guidance on achieving sustainable development, Elkington in 1998 [1] proposed the Triple Bottom Line (TBL) framework defining three trends on sustainability: economic, environmental and social. Where economic sustainability aims for long-term business profits (including costs of products, services, programs, etc.); environmental sustainability aims for the preservation of natural ecosystems [1] and social sustainability aims for supporting and fostering long-term human and society´s well-being [1].

The research described in this paper aims to contribute to the integration of social sustainability in processes of fabrication and delivery of panelized post-disaster temporary housing. Therefore, only the social sustainability aspect of TBL will be analysed within the disaster management context.

Most of the existing studies on social sustainability focus on supporting strategic decisions within companies, and limited research studies have focused on guiding processes' managers in process design towards social sustainability. Also, limited studies considered social sustainability within disaster management context, specifically for activities, such as fabrication and delivery of post-disaster temporary housing. The main objective of the research described in this paper is to contribute to the evaluation of existing fabrication and delivery processes of panelized post-disaster housing from social sustainability perspective. To achieve that objective, the research team focused on integrating social sustainability

into the Value Stream Mapping tool (VSM), which a well-known methodology to analyse processes is.

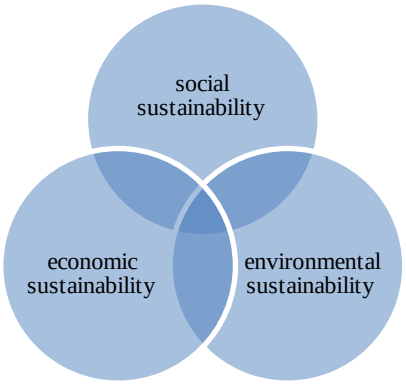

Figure 1. TBL diagram based on Elkington, 1998

2 Research Methodology

As it was stated before, the research presented in this paper aims to integrate social sustainability in the processes of fabrication and delivery of panelized post-disaster temporary housing using Value Stream Mapping methodology. This research builds on and extends prior studies on social impact, value stream mapping and post-disaster activities. In order to propose a plausible model for the integration of social sustainability, the post-disaster temporary housing context is used to define the system, participant stakeholders, as well as relevant indexes towards social sustainability. Finally, the proposed model was tested in a real scenario, the 2017 fire that affected Chile where 305 post-disaster temporary houses were built by the NGO Fundación Vivienda [11]. The results of the proposed model in the case study are shown and analysed in this paper.

3 State of the Art

Previous researchers have identified several interest topics in social sustainability. These topics are based on Elkington' social sustainability definition and aim to simplify and focus social sustainability analysis (see Colantonio 2009 research [4] for further social sustainability topics analysis). This research focuses only on Well-being of people and Basic needs (such as housing and food) topics. Therefore, the following sections summarize the state of the art of research studies that are relevant for these topics and this research.

3.1 Social Sustainability and Social Impact

Social sustainability has been studied in several fields, however, most of the developed methodologies have focused on the social impact of projects, programs and policies, hence they have not aimed to measure social sustainability contribution of processes [12-14]. Most of these methodologies aim for development agencies and NGOs, such as the Social Life Cycle Assessment methodology (S-LCA), defined in the "Guidelines for Social Life Cycle Assessment of Products" published by the United Nations Environment Programme (UNEP) in 2009 [15-16]. This is one of the most accepted social impact methodologies, it is based on the structure of the Environmental Life Cycle Assessment methodology defined on the ISO 14044 and aims to provide a roadmap for social impact assessment of products.

Several previous studies have summarized and compared social impact methodologies and/or performed case studies. For example, Costa & Pesci (2016) [17] reviewed 12 different social impact models used by academics and practitioners. They focused on identifying stakeholders and defining metrics, and concluded that metrics have to be based on the relationship between stakeholders and the analyzed organization. Moreover, the research team stated that stakeholders' point of views have to be considered to define social impact metrics. In another study Dubois-Iorgulescu (2018) [18] performed 33 case studies to understand how a system's boundaries were defined in different situations. They found that most of the case studies assessed social impact at top management level and only few of them (three) assessed social impact at process level. Dubois-Iorgulescu (2018) [18] study also focused on identifying a cut-off criteria to dismiss unconnected elements in product chains. They detected that almost half of the analyzed case studies did not present clear definitions to include or exclude elements in particular systems.

Few studies have developed approaches to integrate social impact on processes. For example, Baumann et al. (2013) [19] examined the production of airbag systems and concluded that is better to adapt Environmental Life Cycle Assessment methodology (E-LCA) instead of S-LCA methodology to measure social impact of processes. The research team argued that social indexes and categories defined in S-LCA are unclear along the life-cycle, therefore they cannot be used in different life cycle stages [19]. In another study, Feschet et al. (2013) [20] studied how changes in the banana industry of Cameroon affected GDP and life expectancy using the Preston curve, which defines a relationship between GDP and life expectancy. This study concluded that multi-criteria analysis with several impact categories and stakeholders is needed to draw more accurate and stronger social impact conclusions [20]. In another study, Jorgensen et al. (2010) [21] attempted to analyze the social impact of particular choices among processes. In order to do it, the study defined two different scenarios: a baseline scenario, and a test scenario with changes incorporating some implemented management decisions. Although this study is an starting point, the research team only focused on the

social impact on the workers of the company and did not include external stakeholders in the analysis [21].

3.2 Social Sustainability in Value Stream Mapping

Several previous studies have identified synergies between lean and sustainable practices [15, 22-30]. However, most of the approaches have focused on the environmental part of sustainability and only few have focused on the social part. Moreover, as stated in the study done by Martínez-Jurado & Moyano-Fuentes (2014) [30], within which they reviewed 58 articles from 1990 to 2013 approaches targeting their lean and social sustainability integration have been developed only during the last few years [29-30].

Since VSM has been identified as one of the main lean methodologies to analyze processes [15][30], most of the previous approaches that integrate lean and social sustainability are based on VSM methodology. For example, the study done by Helleno, de Moraes, & Simon (2017) [31] aimed to integrate VSM with social and environmental sustainability in manufacturing processes in Brazil. They identified social and environmental indexes through a comprehensive literature review and tested them in three factories: a cosmetic products mill, a thermoplastic products mill and an alumninium appliances mill. Although the study integrated social sustainability in manufacturing processes using VSM, the impact on the community was only assessed using the domestic rate of production against the total products available in the market. Therefore, no other stakeholder expectations were included to assess social sustainability of the processes.

Another example is found in Faulkner & Badurdeen (2014) [28] study, within which the research team developed the sustainable value stream mapping methodology (Sus-VSM) to integrate social sustainability in VSM. They started reviewing methods that aimed to integrate sustainability in processes but found that none of the nine reviewed methods included specific social sustainability metrics. As in Helleno, de Moraes & Simon (2017) [31] study, they also recognized that different metrics are needed for different industries, therefore their focus was on defining generic social metrics that can be applied in several specific industries. However, the proposed social metrics only addressed physical work within processes and work environment inside the mills. Hence, only internal stakeholders were considered and no social sustainaibility assessment was done for external stakeholders.

In further studies related to Sus-VSM, Brown, Amundson, & Badurdeen (2014) applied Sus-VSM on three manufacturing contexts with different products and production volumes. They identified that several challenges arise when different system descriptions and boundaries are considered. Hence, they concluded that case studies from different industries are needed to define comparable parameters and generalize metrics. Although this study provided insights about the applicability of Sus-VSM, it did not extend the social sustainability metrics defined by Faulkner & Badurdeen (2014) [28].

3.3 Social Sustainability in Post-Disaster

As it was identified at the beging of this section, one of the social sustainability topics is people's basic needs. In a post-disaster context, the most accepted minimum standard for basic needs was defined by the Sphere Handbook, a standard that is meant to by used during disaster response and was developed by the International Red Cross and a group of NGOs involved in humanitarian aid [37]. This standard identifies the following basic needs areas: water supply, sanitation and hygiene, food security, nutrition, shelter and settlement and health [37]. Since this research is based on the post-disaster temporary housing context, only studies focusing on shelter and settlement assessment after a disaster are considered. However few literature exist in this context and only two studies were found, the first of them is Johnson (2007) [32] research that analyzed particular temporary housing projects after the 1999 earthquakes in Turkey. In this post-disaster situation, the Turkish government gave rental stipends to some of the affected people, but also built 40,621 emergency housing on 136 settlements nearby the affected cities. Johnson's analysis was done at the project level and his study provided the analysis of four projects: two of them lead by the government and two lead by NGOs. The analyses were done using the Logical Framework Analysis approach (logframe), an approach promoted by the US Agency for International Development (USAID) to define stakeholders' roles and to plan activities to achieve defined goals or impacts [12]. Although Johnson's (2007) study [32] identified the impacts of projects' objectives, the analysis was done at a project-level and no process was included. Furthermore, the study did not identify all of the stakeholders who participated in the project and hence did not analyze the impacts of the projects to all of the stakeholders. For example, in one of the projects the NGO Action by Churches Together was in charge, but their objectives specific processes objectives, such as construction times or local materials used, were not included in the study.

Another study that focused on post-disaster temporary housing is Mora & Akinci (2018) research [11], which is the starting point of the research described in this paper. This study focused on measuring the social impact of innovation in processes of fabrication and delivery of post-disaster temporary housing. The research team adapted S-LCA methodology to identify the system, participating stakeholders and their objectives, and to identify processes. Through a case study based on data

from NGO Fundación Vivienda in the post-disaster situation generated by 2017 fire in Chile, the research team identified social impacts that can be influenced by the processes of fabrication and delivery of post-disaster temporary housing. Then, they analyzed the innovations done in the case study and proposed indexes to measure the social impacts. However, the research team only used S-LCA definitions to define the indexes and they did not include any other social sustainability or impact methodology.

4 Integrating Social Sustainability in VSM in Post-Disaster Temporary Housing Context

4.1 System Definition

There are several examples of temporary housing approaches around the world, Wagemann (2012) [33] identified 53 different types of temporary housing for post-disaster contexts implemented only from 2001 to 2011 [33]. These designs have been proposed by several architects and organizations and one of the first identified approaches was proposed in 1944 by Jean Prouvé to support temporary housing for refugees [33-34]. More recent architects have been working in this topic, like Shigeru Ban that have successfully implemented emergency housing since 1995 in diverse post-disaster contexts [35]. Other proposals and designs are from the governmental side, for example in Chile temporary housing is regulated by the National Office of Emergency (ONEMI). This governmental office defined the minimum surface, insulation and fire-resistance rating for the envelope, as well as transportation and installation requirements for the temporary housing used in Chile [36].

Although sometimes the terms shelter and temporary housing are interchanged, there is a clear distinction between them. The most accepted definitions of these terms were provided by Quarantelli in 1995 [38]:

- *Emergency shelter:* Refers to short period accommodation (most of the times only overnight) outside its own home immediately after the occurrence of a disaster. For example, a friend´s house can be considered as an emergency shelter.
- *Temporary shelter:* Refers to short period accommodation (days to months) during post-disaster. For example, a tent or a rented apartment can be considered as a temporary shelter.
- *Temporary housing:* Refers to long period accommodation (months or years) used until people can return to a permanent house. For example FEMA trailers used after Katrina 2005 in New Orleans can be considered in this category [39].
- *Permanent housing:* Refers to permanent accommodation (years). It can be a repaired house or a new one.

All of these approaches aim to resume normal life after a disaster [37], the former two accommodations aim for short time periods after a disaster, while the latter two accommodations aim for long periods [38]. Documented examples of post-disaster accommodations are found in Johnson (2007) [32] study, where people first moved to tents (temporary shelter), then to temporary housing and then to permanent housing. In another documented example, after the 8.5 Richter scale earthquake in Chile people moved directly from emergency shelters to temporary housing and then to permanent housing [40].

The research described in this paper focuses on temporary housing and external stakeholders, therefore only activities and external stakeholders involved in the fabrication and delivery of temporary housing are studied. Moreover, the temporary housing system analyzed in this research is a sub-area of disaster management, which aims to reduce the impact of disaster on communities and encompasses the management of pre-disaster and post-disaster stages [41]. Additionally, four stages can be identified in any disaster management strategy: mitigation, preparedness, response and recovery [41-44]. Preparedness and mitigation are pre-disaster activities, and response and recovery are post-disaster activities [37]. This research narrows the analyzed system to the fabrication and delivery of post-disaster temporary housing in response and recovery stages.

Several stakeholders, such as governments, local and international NGOs, private contractors, communities and final users are involved in each one of the disaster management activities. Although their final goal for disaster management is the same, specific objectives can vary amongst them. For example, private companies could aim to provide standardized low-cost solutions while NGOs could aim to provide community-based solutions [45]. Moreover, several strategies exist to implement post-disaster housing reconstruction. According to Barenstein (2006) [46], who analyzed reconstruction approaches after the earthquake of Gujarat, India, the differences between post-disaster housing strategies are: location (of the new house), funding (for materials and labor), fabrication (of the new house), delivery (of the new house) and on-site construction. For example, in an owner-driven strategy, affected families can be in charge of financing a solution, while in a subsidiary or a contractor-driven approach externals, such as NGOs or governments, provide financial assistance to the affected families [46].

The research described in this paper is based on a subsdiary approach, hence, the housing solution is financed, fabricated, delivered and built on-site by externals, who are not families that are affected by a disaster. This research also considers that new housing solutions are installed where houses were prior disaster.

4.2 Identification of Stakeholders

While previous studies narrowed the integration of social sustainability in VSM to internal stakeholders, the research presented in this paper aims to include external stakeholders when integrating social sustainability in VSM. However, the internal or external classification of the stakeholders is not straightforward and depends on the analyzed system. In the context of post-disaster temporary housing construction, previous studies identified the following participating stakeholders during response and recovery: affected families; NGOs and donor agencies; local and national governmental agencies; housing suppliers and housing on-site builders [32] [37] [47]. Therefore, since this research only focuses on the fabrication and delivery processes of panelized post-disaster housing, internal stakeholders are those in charge of the fabrication and delivery processes of the housing, while external stakeholders are the ones that receive the outcome (post-disaster temporary housing) including intermediates and final user.

Then, since this study is based on a subsidiary approach, we considered as external stakeholder the stakeholders that are funding labor and materials as well as the stakeholders in charge of on-site construction (including those that coordinate on-site construction) and final user of the housing solution. For example, in a governmental subsidiary approach, government funds labor and materials while fabrication, delivery and on-site construction can be performed by private contractors or NGOs.

4.3 Identification of Relevant Social Sustainability Indexes

As it has been described in previous sections, most of previous studies proposed social sustainability indexes for internal stakeholders. Only Helleno, de Moraes & Simon (2017) [31] proposed social sustainability indexes to assess an external community. However, the indexes proposed by them are not applicable to the system defined in this research since their indexes were defined for mass consumption products in a regular context. Then, in order to propose suitable indexes to assess social sustainability for external stakeholders in a post-disaster temporary housing context, several methodologies that have aimed to assess social sustainability were studied and summarized in Table 1.

Table 1. Summary of social sustainability indexes from social impact methodologies and studies

Methodology or study	Stakeholder	Qty. of indexes
Social Life Cycle Assessment [48]	- Workers - Consumer - Local Community - Society - Value chain	No indexes were proposed
Global Reporting Initiative (GRI) [49]	- Workers - Consumer - Local Community - Society - Value chain	58 21 18 11 54
Social Vulnerability index [50]	- Local Community	11
Fontes et al. (2018) [51]	- Workers - Consumers - Local Community	No indexes were proposed
Jorgensen et al. (2010) [21]	- Local community	4
Lagarde & Macombe (2014) [52]	- Local community	6
Feschet et al. (2013) [20]	- Society	1
Baumann et al. (2013) [19]	- Society	8
Handbook for emergencies [53]	-Consumer	7

Although several social sustainability indexes were identified in this research, not all of them allow social sustainability assessment of external stakeholders in the defined post-disaster temporary housing system. Moreover, from all the identified indexes, only the following indexes can be estimated using information from the processes of fabrication and delivery of post-disaster temporary housing and provide information to guide processes' managers in process design towards social sustainability.

1. *Percentage of products and services assessed for improvement:* This index is from Global Reporting Initiative (GRI) [49] and it enables the assessment of the ratio of processes that have been re-designed towards social sustainability. Therefore, it assesses internal processes and provides information to processes' managers.
2. *Total number of incidents for noncompliance of regulations:* This index is also from GRI [49] and it allows the assessment of how many stakeholder requirements have not been fulfilled towards social sustainability. Therefore, it assesses internal processes and provides information to processes' managers.
3. *Content of substances that can cause environmental or social impact:* This index is also from GRI [49] and it enables the identification of products that can negatively impact social sustainability of external stakeholder. Therefore, it assesses internal processes and provides information to processes' managers.
4. *Demand fulfillment:* This index is based on the Handbook for emergencies [53] and Mora & Akinci' study [11] and it enables the assessment of the speed

of the delivery of the solution towards social sustainability. Therefore, it assesses internal processes and provides information about external stakeholders that oversee on-site construction, on-site coordination and final users to processes' managers.

5. *On-time arrivals:* This index is based on [53] and [11] studies and allows the assessment of the arrival expectation of the stakeholders. Therefore, it assesses internal processes and provides information about external stakeholders that oversee on-site construction, on-site coordination and final users to processes' managers.

4.4 Integrating System, Stakeholder and Social Sustainability Indexes to VSM

Value stream are the processes or actions required in a plant or company to produce a product from raw material and deliver it to a customer [54]. Therefore, Value Stream Mapping (VSM) is a plot of all of the processes and information flows to fabricate a product within a given company or plant. This plot allows decision-makers to analyse the current state of the production and to define a "future state" (or desired state) of the flow and processes [54]. In the research described in this paper, we modelled only processes and information flows that relate fabrication and delivery of post-disaster temporary housing with the identified external stakeholders and that can be assessed by the proposed indexes.

Based on the stated definitions of system, stakeholders and indexes, Figure 2 shows a generic model developed to integrate social sustainability for external in VSM for the subsidiary approach of post-disaster temporary housing. The arrows between the stakeholders indicate there is a relationship between them, however, these relationships can change among different scenarios, therefore the direction of the double-headed arrows must be defined in the analyzed scenario.

The main difference between the proposed model and the regular VSM model and also with Sus-VSM model proposed by Faulkner & Badurdeen (2014) [28] is that the proposed model considers multiple external stakeholder receiving the product while previous models considered only one external stakeholder receiving the product. This modification enables the identification of all the participant external stakeholders as well as their expectations on the outcome. In the context of the research presented in this paper, this modification aims to represent all the participant external stakeholders and their expectations towards social sustainability in the subsidiary approach of the fabrication and delivery of post-disaster temporary housing.

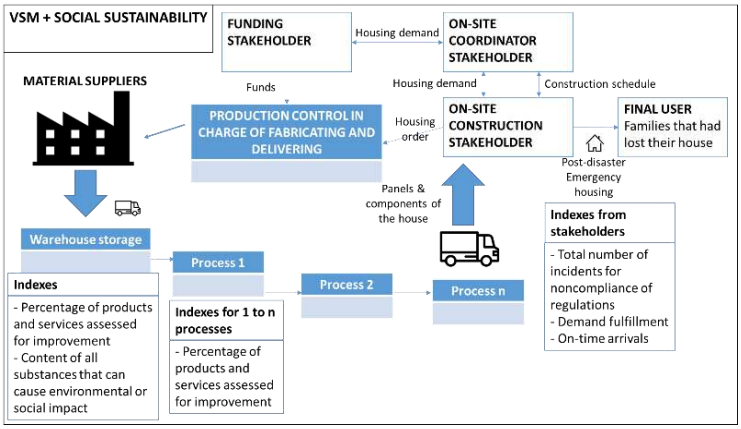

Figure 2. Generic model for social sustainability integration of external stakeholders in VSM

5 Case Study: Panelized Post-Disaster Temporary Housing Processes at Fundación Vivienda, Chile

The proposed model was tested with the NGO Fundación Vivienda in Chile. Specifically, data from the 2017 Fire in Chile from Mora & Akinci (2018) study (11) and on-site interviews were used to feed and test the model. In this event, Fundación Vivienda was in charge of fabricating and delivering the houses and the external stakeholders were:

6. *Funding:* NGO TECHO-Chile (data from interviews with NGO's director of operation)
7. *On-site coordination:* Local governments [11]
8. *On-site construction:* NGO TECHO-Chile [11]
9. *Final user:* Families who had lost their house [11]

Based on the identified external stakeholders and the identified process within Fundación Vivienda, Figure 3 shows our proposed model applied to this case study. Additionally, changes to the fabrication and delivery processes were documented in Mora & Akinci (2018) study [11], therefore the proposed indexes can be calculated for an initial state (before the changes were applied) and for a future state (Figure 3). The calculated indexes are shown in Table 3 and they enabled the comparison between the initial and the final state of the system.

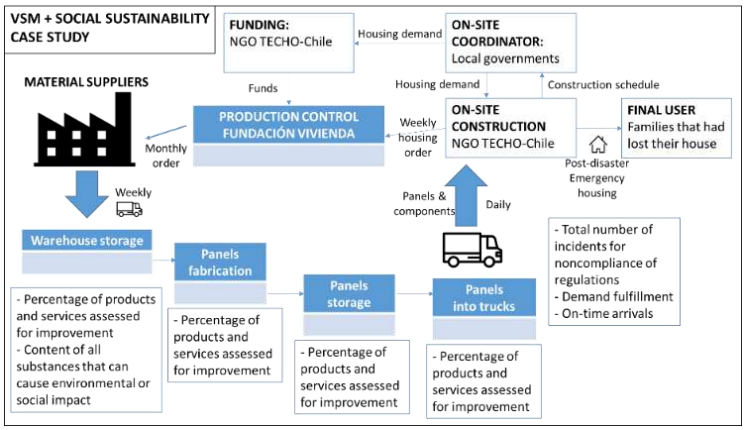

Figure 3. Proposed model to integrate social sustainability in VSM applied in 2017 Fire in Chile case study

Table 3. Summary of indexes of initial and final state of the processes and information flow in the case study

Index	Initial state	Final state
Percentage of products and services assessed for improvement	0%	100%
Total number of incidents for noncompliance of regulations	0%	9.8%
Content of substances that can cause environmental or social impact	0	0
Demand fulfillment	75%	84%
On-time arrivals	66%	92%

6 Case Study Discussion

The case study demonstrated that the model proposed in this research can enable social sustainability assessment of external stakeholders in VSM. As it has been stated, this was not possible in previous VSM approaches because they only considered one final user of the outcome, but the model proposed in this research enabled the representation of the several stakeholders that exist between the factory (that is fabricating and delivering the outcome) and the final user. For example, in this case study, NGO TECHO-Chile was an external stakeholder although it was not the final user of the outcome.

Moreover, when changes were done to the processes, the indexes proposed in the model enabled social sustainability assessment of external stakeholders. This is important to processes' managers because the comparison between the indexes of an initial and final state enables the social sustainability evaluation of the changes. Also, the proposed indexes enabled internal processes evaluation towards social sustainability of external stakeholders. For example, the index "percentage of products and services assessed for improvements" indicates whether the company is improving products and services towards maximizing its social sustainability contribution to external stakeholders. Another proposed index is "total number of incidents for noncompliance of regulations" which can assess whether changes done impacted the compliance of the outcome according to the external stakeholders' requirements. In this case study the changes done increased this index, which means that some of the changes negatively impacted the social sustainability expectations of the external stakeholders.

Another proposed index that assessed company' processes towards social sustainability is the "content of substances that can cause environmental or social impact" index. In this case study, the company was not using harmful substances or products in its process flow, therefore this index is 0, and must be supported.

Finally, "demand fulfillment" and "on-time arrivals" indexes represent the social sustainability expectation about the outcome of the NGO TECHO-Chile and affected families. A 100% index means that changes done to the fabrication and delivery processes were fulfilling social sustainability expectation of these external stakeholders. In this case, when comparing initial and final states, a positive change in the indexes is noticeable, which means that the changes done to the processes maximized social sustainability of external stakeholders.

It is important to mention that the model proposed in this research is based on a subsidiary reconstruction approach to build post-disaster temporary housing, therefore housing solutions were financed, fabricated, delivered and built on-site by people or companies that are not the families affected by a disaster. Then, further studies are needed to validate the model with other reconstruction approaches, such as the owner-driven approach.

7 Conclusions

The model proposed in this research aims to contribute to the integration of social sustainability assessment of external stakeholders in VSM in a post-disaster temporary housing context. In order to do it, the proposed model enables the evaluation of existing processes towards integrating social sustainability perspective of external stakeholders into processes. Moreover, the proposed model enables the integration of additional external stakeholders and not only the final user of the outcome. This external stakeholder's integration enables the addition of different stakeholders' expectations on the outcome, towards social sustainability in VSM. Also, in order to integrate these expectations, the research presented in this paper defined specific indexes that were tested in a case study and demonstrated their suitability to

integrate social sustainability's point of view into processes.

Moreover, the case study used to test the model demonstrated that the proposed model with the proposed indexes can be applied in a subsidiary approach to fabricate and delivery post-disaster emergency housing. The case study also demonstrated that the proposed indexes enabled the integration of external stakeholders' social sustainability point of view within existing processes of fabrication and delivery of the housing solutions. Finally, the calculated indexes also enabled the assessment of changes done to processes towards social sustainability. Therefore, the model and indexes proposed in this research are valuable to processes' managers for process design towards social sustainability of external stakeholders.

8 Perspectives

This study was useful to understand what social sustainability indexes are useful in a post-disaster temporary housing system and how they can be included in VSM. However, only stakeholders that received the outcome of the processes were considered, hence other stakeholders have to be studied in detail as well. Moreover, surveys with statistical validity must be done to evaluate social sustainability indexes' relevance to its associated stakeholders.

Abstract –

Building Information Modeling (BIM) is a methodology to digitally represent all the physical and functional characteristics of a building. Importantly, in smart buildings smart components that are enabled with sensing and actuation need to be modeled accurately within the BIM model. This data representation needs to include multiple status of the smart component based on their performance to guide the design and construction process. However, currently there is not a clear methodology or guideline on how to embed smart components in the BIM model. Visualization techniques have been developed based on CAD technology to integrate smart components in the building model but these techniques have not been applied to BIM environment. To accurately model smart components, the component must be more than a single status representation and must contain complete and accurate dynamic data of the smart component. In this research, data properties, visualization techniques, and categorization of smart components is investigated. Then, through an experimental investigation, nine smart components across five building disciplines are modeled and embedded in a BIM model of a smart space. The model includes parameters that facilitate the data representation of the smart components. Data properties, data organization, and simulation of the smart component within the building model is explained. Challenges and future research is discussed.

Smart components; BIM; Smart buildings; Sensors; Actuators

1 Introduction

Smart buildings are buildings that consist of several types of interconnected smart technologies and smart components that enable the building to run based on the data collected by the smart components. This data can enable the increased sustainability, occupant experience, financial performance, operational efficiency, and prestige of smart buildings [1]. To enable the design of smart buildings, development of the 3D model of the building and planning for context-aware design of such smart environment is critical for designers [2].

On the other hand, Building Information Modeling (BIM) is a methodology that utilizes a set of software tools and processes for facilitating the creation and use of the digital representation of the physical and functional characteristics of a building. BIM models are intelligent data-rich sources of building data that can be used through the lifecycle of a building to analyze buildings and inform design, construction, and maintenance decisions [3]. In fact, smart technologies can be embedded in building spaces and components, using smart objects to enhance the performance of the building. However, there is a lack of studies on how BIM can accurately represent smart objects and the data within the design and construction of smart buildings. There is no clear guideline on how to model smart components, how to accurately embed the required data within the BIM model, and how to organize the data associated with the smart components within the BIM model. There is a need to develop BIM use cases to indicate how smart objects can be modeled and embedded within the BIM model [4].

Importantly, smart technologies and components need to be integrated with BIM to accurately model and analyze smart components within smart buildings [4]. BIM can help the design and construction process with the opportunity to integrate smart components from the design phase as well as the post-construction and operation of the building while providing a data repository for the users and for its for maintenance [2,4]. Therefore, this research investigates how BIM can be used in the development of smart buildings during the

design process and how smart objects can be embedded with organized data in the BIM model to guide the process of design and construction of smart buildings. The objective of this study is to investigate how data properties of smart objects can be integrated in BIM models embedding sensing and actuation data. This paper will first study the ways smart component properties can be captured. Next, existing visualization techniques and simulation strategies for smart components is discussed. Then, the study investigates the different categories of smart components and within an experiment, the study develops BIM models of multiple building disciplines of a given space in a use case scenario to discuss how smart components with required data can be embedded in the BIM model.

2 Smart Components Data Properties

Smart environments operate through a sensing and actuating paradigm. A smart environment requires sensors to collect data and to communicate with smart components. The microprocessors analyze the data received from the sensors and command the actuators to respond accordingly. The actuator then uses the sensor data to complete their actions. Recently this paradigm has shifted from a wired sensing and actuating connection to an Internet of Things (IoT) approach. Internet of Things is a technology to create a network of interconnected objects that do not require human interference to perform tasks. These tasks can fall into the three main categories of sensing, analytics, and visualization [5]. There has been studies on how to embed smart objects in the BIM model of a smart building. Zhang et al. [4] embedded smart components in a Revit model to later work with a facility management tool they developed for energy management functions. They specifically integrated the smart components so that they can be exported to Industry Foundation Classes (IFC) to enable interoperability through open BIM standard. Their approach uses (1) Revit's IFC shared parameter specifying IFCSensorType to indicate the sensor type within an IFC entity (2) element property in the smart component family for the actuator, for the type of smart object, and for the mark tag of an individual smart object. Their work provides a data exchange interface for their developed facility software through mapping the smart object's family property parameters to IFC text, then, to their facility software interface and also, the smart device through using three main data as output, input and control [4]. Their study does not specify the structure of the object properties in the family level and it does not contain types of smart components other than smart objects for energy management systems. Also, their framework relies on the IFC within EXPRESS technology and P21 encoding (STEP-file) which parses the IFC files, it created a disconnected environment [6] with the source of data in the BIM model that relies on exporting and importing files. The work by Dave et al. [7] has developed a web based solution called Otaniemi3D that can integrate smart devices with the BIM data to provide information about energy usage, occupancy, and user comfort. They have exported the BIM model to a static IFC file essentially for the data regarding spaces in the building. They do not add the smart component and all the required properties of the smart component to the original BIM model (in Revit). Instead, they remodel the Revit file to add sensor data through IFC shared parameters using IfcSensorType to specify the type of sensor (e.g. TEMPRETURESENSOR). Then, they load the IFC file into IFCOpenShell to visualize the model then translate it to the final web formats to be transferred to Otaniemi3D environment running on a web browser. They also mentioned that during the data translation process, IfcSensorType and IfcSpaces data are either missing or incorrectly mapped which is not fully fixed and automated as they describe [7]. There is currently a lack in knowledge of how to model smart components integrating required data properties through the design and construction process and how to visualize smart components data in the BIM model, especially pertaining to data regarding sensors, actuators, microprocessors and components with more than one status.

3 Visualization of Smart Components

Crigliano [8] developed a QCAD extension as a systematic approach to appropriately allocate and install sensor nodes in an indoor environment. These sensor nodes are essential to smart environments to ensure that smart components receive data upon which to act. The 2D modeled environment allows the layout of sensor nodes to be adequately visualized.

Su and Huang [2] proposed a Visualization System of Context-aware Application Scenario Planning (VS-CaSP) and developed a visualization tool for non-technology users. VS-CaSP allows designers to quickly plan and construct 3D environments through rule-based and 3D visualization techniques. While the system is functional and claimed to be easy-to-use, it is based on CAD and its functionalities need to be extended to fulfill the needs of a BIM Model. Additionally, the rule expressions need to be evaluated to ensure the representation of more complex requirements in smart buildings. In this study some of the recommendations in the study by Su and Huang [2] is used and extended to BIM modeling and smart component parameters in the use case development.

3.1 Simulation Techniques

Agent-Based Modeling (ABM) is a simulation approach to model complex, interacting systems of

agents. Components are modeled agent by agent or interaction by interaction. ABM is distinguishable by its emphasis on modeling the agent's heterogeneity and the emergence of self-organization. It has a bottom-up approach, thus the system's behavior emerges from how individual heterogeneous agents interact with each other and their environment based on defined rules. These features offer a way to model systems with agents, who can learn and adapt from other agents [9], to assess how their interactions affect the system.

Discrete Event Simulation (DES) is another simulation approach that mimics system behavior. DES tracks the system's state during a length of time using a collection of state variables. The system's state can only change instantaneously and these changes are referred to as events [10]. ABM and DES can be useful as they can reflect the dynamic nature of smart components and capture complicated behavior, dependencies and interrelationships [11, 12]. Although a simulation approach can be an effective technique, this is only possible if the simulation tool is integrated with the BIM authoring tool.

4 Categorization of Smart Components

Smart objects function based on sensing and actuation and they consist of sensors, microprocessors and actuators in order to connect with the surrounded environment in the building so that they can react accordingly [13, 14]. Sensors read the real-time status of the environment and pass the input as a signal through a network for processing [15]. Sensors and actuators each act as a node in a Wireless Sensor Network (WSN) which can have the ability to work with other systems and devices such as the occupancy feedback system. Table 1 shows the different criteria which can be used for the categorization of smart objects.

Sensors can be categorized based on various criteria, many researchers [16,17] have classified sensors based on their type and parameter they read from the outside environment (e.g. vibration, humidity, pressure etc.). However, a lot of other factors such the environment needs and complexities, [17], the phase of the project lifecycle [18, 19], and area of usage in buildings [16, 18] affect the criteria for categorization of sensors. As sensors receive information from their surroundings, they send the data as an electronic signal to the actuators, and actuators take action accordingly [14]. This makes the interaction and sequence of data transfer between sensors and actuators critical in the way they respond to the changes in their surrounded environment. As Liu et al. [19] have demonstrated, the sequence and type of data transfer can lead to different networks and systems, in addition, the type of output data from each sensor defines how the smart object would respond to the environment.

Table 1. Criteria for categorization of smart components

Categorization Criteria	Example Categories
Sensor Type	Thermal Humidity Acoustic RFID Motion Light Vibration Pollution Pressure Flow Rate Plug Load Devices Fire Smoke
Speed Needs	Static Mobile Embedded
Building Phase	Construction Plan and Design Construction Safety Management Site Facility and Material Management Site Environment Construction Process Management Structural Inspection Re- Structure & Expansion
Areas of Usage in Building	HVAC System Information and transformation (e.g. sensing floors, high rise elevators) Safety and Security (e.g. biometric authentication access) Maintenance and Facility Management Modeling Building Occupancy IT Equipment Openings (window, door) Status
Component Type	Blinds Door Windows Electrical Devices Lights Fan Heater Boiler Urinals Water closet Facade
Building Discipline	Architectural Mechanical Electrical Structural
Connection & Data Exchange	Periodic Conditional Timeout Interrupt
Output Data	Booleans Binary (e.g. Yes/No, Occupy/Empty) Continuous Range of Values

A threshold is defined for smart objects which they

respond accordingly to that predefined value. According to Weng and Agarwal [16], these conditions contains a broad range of variables such as binary statements, Booleans, as well as continuous range of values. This study specifically investigates the BIM modeling in the design and construction phase with regard to capturing these conditions within the data properties of the smart components.

5 An Approach to Information Modeling of Smart Components

This study focuses on integrating smart components within BIM models and it was undertaken in two phases as explained below.

5.1 Study Phase

This research informed decisions on how to represent smart components and the data that the smart components would need to contain through the study of the current status of the modeling of smart components, previous work on smart components and smart technology. Then, to categorize smart components and parameters, all investigated smart components as well as their parameters and modeling requirements were listed and then went through a selection process to determine which smart components would be modeled in the experiment. The overarching study process is depicted in Figure 1.

Figure 1. Overarching study process

5.2 Modeling Phase

For the next step, to integrate smart components with the BIM model an experiment was designed for this empirical study and a use case was developed to represent the BIM model of the building in the experiment. A prototype was developed as the use case to integrate selected smart components. The model will be explained in more details in the following sections.

For the development of smart components and embedding them in the BIM model, the study first investigated several smart technologies as well as capabilities of the selected space within the use case. Then, nine smart components from five building disciplines were selected to be modeled and integrated in the BIM model. As mentioned in section 4, among categorization criteria for smart components, this study uses "Building Discipline" criteria to categorize and arrange the information regarding the smart components. Then, data properties were added to the developed smart components to represent the capabilities and data inputs and outputs received by the smart components. The data properties are provided for both sensing and actuating. Table 2 shows the list of selected smart components in this study and their object properties based on sensor parameters and actuator parameters.

Table 2. List of Modeled Smart Components and Their Object Parameters

Category	Smart Object Name	Sensor Parameters	Actuator Parameters
Architectural	Door	Occupant's Presence Temperature	Position Angle
	Window	Humidity Luminance Occupancy Temperature	Opening Distance
Electrical	Security Alarm	Surveillance Status Security Code Occupancy Windows Doors Lights	Alarm Status
	Smart Plug	Timer Load	Status
Mechanical	Duct Static Pressure Sensor	Resistance	Status
	Air Handling Unit	Temperature Humidity Occupancy	Status
Structural	Structural Deflection Monitoring	Strain	Compression Force Tension Force
Fire Protection	Fire Detection Sensor	Smoke Detection CO2 Detection Temperature	Resident Notification Fire Department Notification Sprinkler Activation
	Sprinkler	Sprinkler Sensor	Status

For all of these smart components there are two additional properties as the "sensor type" and "actuator type" that is integrated as well. These smart components are used in the buildings with the means of providing occupant comfort, reducing energy consumption, and providing safety [1]. For example, fire protection is considered as one of the most important safety issues in

the buildings as it can lead to damage and fatality, therefore it is of vital importance to have an immediate notification system for the occupants. Many researchers [20,21] have used sensors capable of detecting any high rising amount of smoke, heat, or CO2 gas in the environment. Once the sensor detects any abnormal presence of these parameters in the environment, the input from sensors then goes to the actuator. Depending on the system design, the actuator parameter can be simple alarm system for notifying the occupants and the fire department all the way to activating sprinklers for preventing the fire from spreading [21]. Smart plug is another object integrated in this study. Shutting down any unnecessary or unused electronic is considered as one of the methods to reduce the electricity consumption of the building. In light of this subject, Weng and Agarwal [16] have suggested tracking the plug load of electronic devices, using this method, systems such as lighting and IT equipment which are not being used by occupants can be easily spotted and be turned off. For places such as offices or schools, where the occupant's system usage is predictable and follows a certain schedule, one can use timer sensors to turn off equipment in a specific time [22]. For the structural discipline in this study, a Structural Deflection Monitoring (SDM) system in embedded for monitoring dynamic deflection of columns and beams. In this system, the Long-gauge fiber Bragg grating (LG-FBG) sensors can measure average strain over a certain length [23] and accordingly when needed, the actuator will apply compression or tension force measured in kips.

The next step is digital development of building using BIM authoring tools. In this study we use Autodesk Revit. A medical waiting room was developed as the use case. In this research, the use case was selected within a commercial building. This part of the study allows a space to be developed with the integration of smart components into the building performance. By limiting the use case to one space within the building, the focus is on the smart components and their parameters as opposed to general building performance. This also allows for the ability to generalize the study findings upon completion of this one scenario. In fact, the prototype used for this study is a one story steel structure, 1300 square foot commercial waiting room facility with a front desk space. Each building disciple was housed in a separate model before being linked together using Revit linked features. Modeled building disciplines included architectural, structural, mechanical, electrical, and fire protection.

Next, is embedding smart components in the building. The BIM model was created considering the following sub-models: architectural, structural, mechanical, electrical, and fire protection. Each smart component categorized in Table 2 was embedded in the building model of its corresponding discipline as shown in Figure 2. Figure 3, 4 and 5 illustrate the BIM model data set developed as the prototype in this study.

6 Results

One of the challenges regarding the integration of smart components with the BIM model of the smart building is the static nature of current BIM authoring tool which limits the data representation of smart components with multiple status in a dynamic environment. In this study, nine smart components across the five different building disciplines were modeled. Component parameters were developed based on the literature study in the initial study phase. In order to represent the parametric behavior of the smart components and most importantly to capture multiple status of the smart components to inform the design and construction process, experimental equations were used to represent the interrelations of the sensor and actuator. Experimental equations for the parameters of the nine smart component are shown in Table 3.

For each smart component a parametric object is modeled and all the parameters and equations are embedded in the model. For instance, for the automatic door a parametric one panel door was modeled. Standard attributes such as height, width, and thickness were used to model the door. Other parameters involving the integrated smart technology including sensor type, actuator type, and opening angle were assigned to the door. To enable the data representation of the automatic door capabilities, parameters were added for presence and temperature. The presence parameter was assigned an integer of 0 or 1, where 0 designates no presence detected and 1 designates presence detected. Similarly, the temperature parameter was assigned an integer of 0 or 1, where 0 designates the temperature is within the specified range and 1 designates the temperature is outside of the specified range. An experimental equation was developed such that the opening angle of the door was controlled by the presence and temperature parameters, Angle = (Presence x 45 degrees) + (Temperature x 45 degrees). Based on inter-related sensor-actuator rules [2] this methodology has enabled the data representation of automatic door data in the BIM model to inform the design and construction process with multiple status of the smart object.

Table 3. Simulation equations for smart components

Component - Actuator	Equation	Sensor Numerical Associations	Conditions
Door - Angle	= (Presence * 45) + (Temperature * 45)	**Presence:** 0 = no presence detected, 1 = presence detected **Temperature:** 0 = below or at temperature, 1 = above temperature	
Window - Opening Distance	= (Humidity + Luminance + Temperature) x Occupancy	**Humidity:** 0 – outside of threshold 1 – within threshold **Luminance:** 0 – outside of threshold 1 – within threshold **Occupancy:** 0 – no occupants detected 1 – occupants detected **Temperature:** 0 – outside of threshold 1 – within threshold	**Opening Distance:** 0 – window is closed 1+ – window is open
Security Alarm – Alarm Status	if Surveillance Status = 1, (Occupancy + Windows + Doors + Lights) x Security Code	**Surveillance Status:** 0 – inactive 1 – active **Occupancy:** 0 – no occupants detected 1 – occupants detected **Windows:** 0 – windows closed 1 – windows open **Doors:** 0 – doors closed 1 – doors open **Lights:** 0 – lights off 1 – lights on **Security Code:** 0 – code entered 1 – code not entered	**Alarm Status:** 0 – alarm is inactivated 1+ alarm activated
Smart Plug - Status	= Timer x Load	**Timer:** 0 – inactive 1 – active **Load:** 0 – inactive 1 – active	**Smart Plug Status:** 0 – off 1 - on
Duct Static Pressure Sensor - Duct Status	= Resistance	**Resistance:** 0 – outside of threshold 1 – within threshold	**Duct Status:** 0 – duct is not in use 1 – duct is in use
Air Handling Unit - Status	= (Temperature + Humidity) x Occupancy	**Temperature:** 0 – outside of threshold 1 – within threshold **Humidity:** 0 – outside of threshold 1 – within threshold **Occupancy:** 0 – no occupants detected 1 – occupants detected	**Air Conditioner Status:** 0 – off 1+ – on
Structural Deflection Monitoring- Compression Force	= Strain	**Strain:** 0 – outside of threshold 1 – within threshold	**Compression Force:** 0 – force applied 1 – force not applied
Fire Detection Sensor – Resident Notification	= Smoke Detection + CO2 Detection	**Smoke Detection:** 0 - smoke under threshold 1 - smoke over threshold **CO2 Detection:** 0 - CO2 under threshold 1 - CO2 over threshold	**Resident Notification:** 0 – not activated 1+ – activated.
Fire Detection Sensor – Fire Department Notification	= Smoke Detection + CO2 Detection	**Smoke Detection:** 0 - smoke under threshold 1 - smoke over threshold **CO2 Detection:** 0 - CO2 under threshold, 1 - CO2 over threshold	**Fire Department Notification:** ≤1 – not activated 2+ - activated
Fire Detection Sensor - Sprinkler Activation	= Smoke Detection + CO2 Detection	**Smoke Detection:** 0 - smoke under threshold 1 - smoke over threshold **CO2 Detection:** 0 - CO2 under threshold 1 - CO2 over threshold	**Sprinkler Activation:** ≤1 – not activated 2+ - activated
Sprinkler - Status	= Sensor Activation	**Sensor Activation:** 0 - no/off 1 - yes/on	**Sprinkler Status:** 0 – sprinklers are off, 1 – sprinklers are on

Also, an air handling unit was modeled in the way that its parameters such as temperature, humidity, and occupancy were added to the component. The temperature parameter was assigned an integer of 0 or 1, where 0 designates the temperature is within the specified range and 1 designates the temperature is outside of the specified range. The humidity parameter was assigned an integer of 0 or 1, where 0 designates the humidity is

within the specified range and 1 designates the humidity is outside of the specified range. The occupancy parameter was assigned an integer of 0 or 1, where 0 designates no occupancy detected and 1 designates occupancy detected. An experimental equation was developed such that the on/off status of the air handling unit was controlled by the temperature, humidity, and occupancy parameters while Status = (Temperature + Humidity) x Occupancy thus can inform the design and construction process. Figure 6 shows the family parameters modeled in Revit for the smart air handling unit developed in this study.

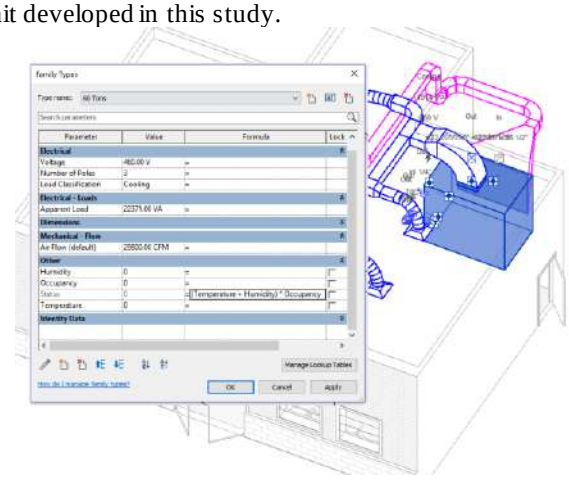

Figure 6. Family parameters for the smart air handling unit

Once the parameters and equations have been established for each of the components in the model (see Table 3), these can be integrated into a simulation model. The simulation model takes two types of input information. The first type of input is the components' parameters obtained from the smart components data properties. The second type of input is the value range of a parameter, which depicts the status from the low-start point of the first event to the last-finish point of the last event in the process. To represent the behavior of the system, the simulation model considers the components (with its parameters) as agents and model these to capture their interactions and dependencies. The model may also adjust probability distributions to the parameters of the smart components, which defines the status of the component. By modelling agents, the simulation phase aims to predict the smart components' values that will serve as inputs for the actuator. The input to the simulation phase includes the probability distributions of the components' values (with the maximal status for each parameter), which allow generating multiple scenarios using random numbers drawn from the probability distributions. Additionally, the model can also estimate the parameters by fitting probability distributions. Fitting methods allow selecting the parameters that produce the best fit to the collected data. With this fitted distributions, it is possible to replicate the components' values.

The results from the simulation model can then be integrated to the BIM authoring tool to digitally represent the smart components and better manage information to guide the process of design and construction of smart buildings. With the information collated from the simulation model into the BIM tool, it is expected that a rich data file can be produced for optimizing the facilities management process. The reader is referred to [24] for a detailed description on how to integrate information and create COBie (Construction Operations Building Information Exchange) data for the facilities management process. COBie data comes directly from the building information. This information is collected, stored and linked (using COBie) and COBie deliverables become the monitor and decision support documents to be updated and managed.

7 Discussion and Conclusion

This study investigated the data properties of smart components with the purpose to be embedded in the BIM model while capturing smart components conditions with required sensing and actuation to inform the design and construction process. Future research will study data flow and interaction of smart components in the BIM model and smart devices. In this study, several smart components were modeled with their corresponding parameters to enable their accurate representation and data capabilities. While these smart components can hold relevant data, this data must be embedded manually for each component individually as parameters are not identical among the components. Future research should evaluate the effectiveness of the smart component data representations created in this study.

Other modeling challenges pertained to visualization. While the opening angle of a door can easily be seen as the inputted data changes, actuations such as air handling unit status are harder, if not impossible, to visualize. Instead, one must look at the data parameters to determine the component's status in a dynamic smart environment. Similarly, developing equations that simulated the components' actuations proved challenging. As several sources of sensor data affect the component's actuations, the interrelations of the data needs to be captured while creating the data representation. Future research should evaluate simulation equations to more accurately represent the interconnected inputs and behaviors of the various smart components. To accomplish this, future work may look toward integrating computational solutions and if/then rule principles into the BIM smart framework. BIM software systems such as Revit are currently a static methodology that does not lend itself to depicting smart components that constantly read, evaluate, and respond

to their environment. Hence, the manual input of device data is necessary in current BIM solutions. As such, future solutions should turn toward BIM enabled with simulation strategies to integrate smart components representation with the building model.

Abstract –

Semantic segmentation of closed-circuit television (CCTV) images can facilitate automatic severity assessment of sewer pipe defects by assigning defect labels to each pixel in the image, from which defect types, locations and geometric information can be obtained. In this study, a deep convolutional neural network (CNN), namely DilaSeg, is developed based on dilated convolution for improving the segmentation of sewer pipe defects including cracks, tree root intrusion and deposit. Sewer pipe CCTV images are extracted from inspection videos and are annotated to be used as the ground truth labels for training the model. DilaSeg is constructed with dilated convolution for producing feature maps with high resolution. Both DilaSeg and the state-of-the-art model, fully convolutional network (FCN), are trained and evaluated on the annotated dataset using the same hyper-parameters. The results of the experiments indicate that the proposed DilaSeg improved the segmentation accuracy significantly compared with FCN, with 18% of increase in mean pixel accuracy (mPA) and 22% of increase in mean intersection over union (IoU) with a fast detection speed.

Keywords –

Dilated convolution; Convolutional neural network (CNN); Semantic segmentation; Sewer pipe defect; Defect segmentation; Visual inspection

1 Introduction

Sewer pipe defects such as cracks, root intrusions through the pipe joints and the deposits inside the pipe are major causes of pipe deterioration, leading to serious consequences e.g. around 23,000 to 75,000 sanitary sewer overflows (SSOs) occurred every year in the United States, causing concerns for the environment and human life [1]. Therefore, discovering and repairing pipe defects at an early stage is significant to prevent sewer system deterioration such that severe consequences can be avoided. Currently, visual inspection techniques such as closed-circuit television (CCTV) are widely utilized for sewer pipe inspection. As the manual assessment is time-consuming, error-prone and subjective, computer vision techniques are studied for defect classification, defect detection and semantic segmentation. Defect detection and classification can inform inspectors of defect type and relative locations in the image. However, automated assessment of defect severity has been rarely studied, although it is important for arranging maintenance activities. Semantic segmentation can facilitate defect severity assessment by providing the defect type, location and geometric information for each pixel.

Semantic segmentation traditionally relies on classifiers such as Support Vector Machines (SVMs) or probabilistic graphical models e.g. Markov Random Fields (MRFs) and Conditional Random Fields (CRFs) for modelling pixel relationships [2], which all require handcrafted feature descriptors. In recent years, deep learning based models such as fully convolutional network (FCN) are developed by learning rich features automatically and have achieved the state-of-the-art performance [3]. However, the consecutive convolution and pooling implementations in previous deep learning models down-sampled the feature maps by a large factor and generate feature maps of low resolution. Such severe spatial information loss results in obscure segmentation for detailed structures or object boundaries after up-sampling. Therefore, the objective of this study is to improve sewer pipe defect segmentation by proposing a deep CNN model, namely DilaSeg, based on normal convolution, dilated convolution and bilinear interpolation. The proposed model is constructed to extract important features by normal convolution, improve the feature map resolution by dilated convolution, refine the segmentation for object with multiple scales by multi-scale dilated convolution and upsample the feature maps using bilinear interpolation. Sewer pipe images with three types of defects are collected and annotated to train both the proposed model and FCN. Model performance is

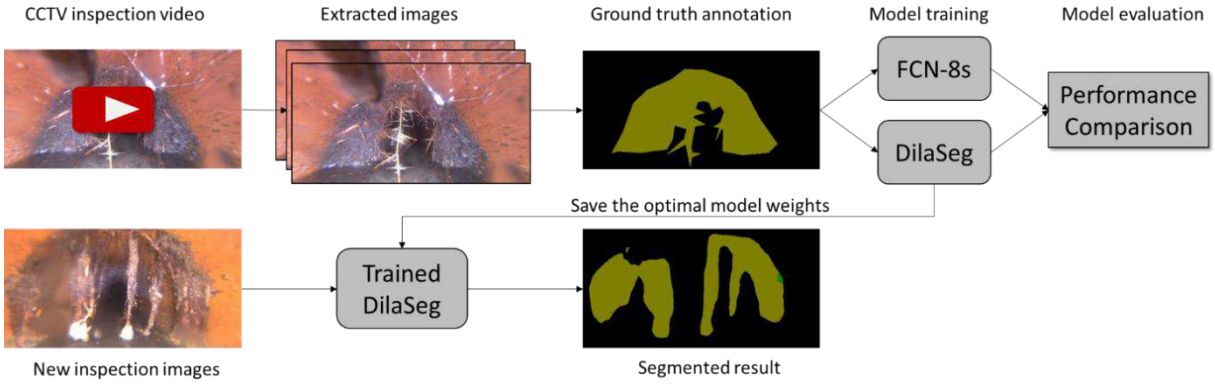

Figure 1. The workflow of sewer pipe defect segmentation using deep learning models

2 Related Work

Computer vision techniques are studied to facilitate the automatic interpretation of visual sewer inspection results. Previous studies have focused on the classification and detection of sewer pipe defects from CCTV images using image processing techniques e.g. morphological operations, histograms of oriented gradients (HOG) and SVMs [4]. More recently, deep learning is applied to address limitations of conventional methods by learning rich features automatically with convolutional neural networks (CNNs). A CNN based model was proposed for classifying multiple sewer pipe defects from CCTV images [5] and a region-based CNN method has been proposed for identifying and locating defects with bounding boxes on sewer pipe images [6]. So far, segmentation of pipe images mainly focuses on pipe components such as joints or segmenting single types of defects using image processing techniques [7]. There are limited studies on the segmentation of multiple pipe defects of sewer pipes, which could provide important references for evaluating the defect severity.

In conventional semantic segmentation, feature extractors such as HOG or scale-invariant feature transform (SIFT) are designed to extract expressive features, based on which small patches of the input image are extracted and classified using local classifiers like random decision forest or SVMs [8]. However, small spatial windows often lead to noisy prediction and require high computational cost. MRFs and CRFs have been widely applied for semantic segmentation [9] by modelling the correlations between variables and incorporating the context knowledge. The main limitation of MRFs and CRFs is that features are obtained from conventional classifiers which are designed for particular cases, during which expertise and efforts are needed. On the contrast, FCN is one breakthrough semantic segmentation deep learning model with higher accuracy than traditional approaches. FCN is developed by transforming the fully connected layers of typical CNNs into convolutional layers and developing a deconvolutional layer for upsampling feature maps [3]. Based on the FCN, many variant networks are proposed, utilizing the architecture of a typical CNN as the "encoder" for generating feature maps and focusing on the development of "decoder" for upsampling images [10]. However, the feature maps generated by FCN and other similar models are of low resolution and predictions are coarse due to the huge spatial information loss during downsampling process.

3 Methodology

3.1 Workflow of Sewer Pipe Defect Segmentation Using Deep Learning Models

As shown in Figure 1, the workflow of implementing deep learning models for segmenting sewer pipe defects mainly includes: (1) extract image from CCTV inspection videos; (2) pre-process and annotate images with different colors for each defect as ground truth labels; (3) build the model architecture and train the model using the annotated images; (4) evaluate and compare the proposed model with the state-of-the-art model; (5) save the best model and apply for new images. Among all the steps in the workflow, the model architecture has great influence on the segmentation performance while the model evaluation provides metrics on the performance. Details of the model and the evaluation are introduced in the following sections.

3.1.1 Architecture of the Proposed DilaSeg

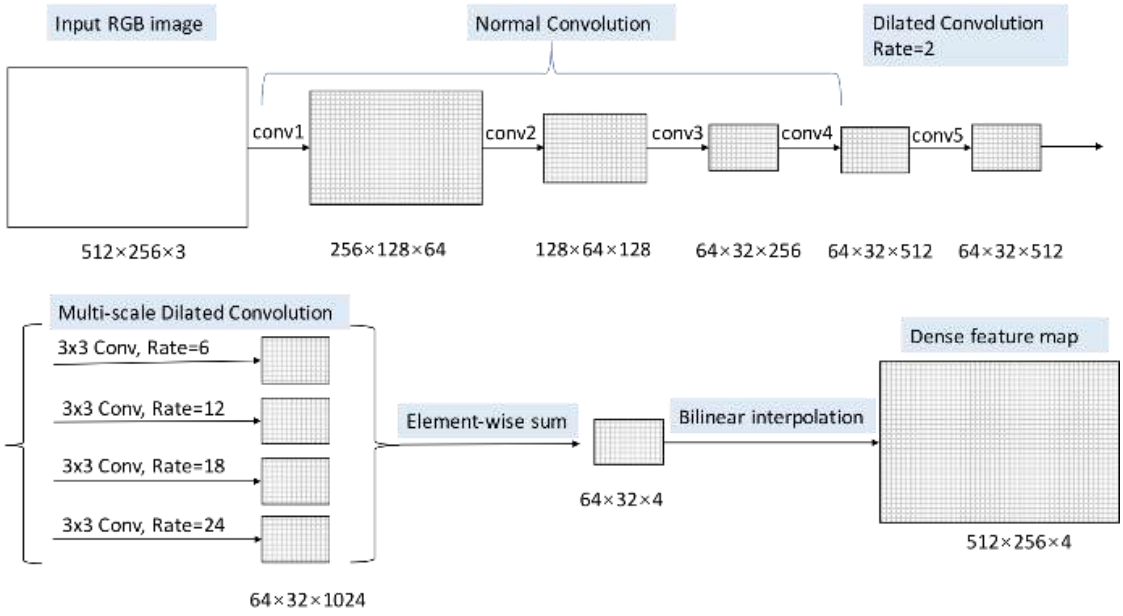

Figure 2. Brief architecture of DilaSeg for generating dense feature maps

To address the problem of large spatial information loss in previous deep learning models, DilaSeg is proposed to improve the feature map resolution and to produce dense feature maps. As shown in Figure 2, the dense feature maps are obtained mainly through (1) normal convolution, (2) dilated convolution, (3) multi-scale dilated convolution and (4) bilinear interpolation. After obtaining the dense feature maps, softmax function is applied for calculating the loss and producing the predicted labels for each pixel.

(1) Normal convolution

During the normal convolution, each image is fed into the network as a three-channel array and a certain number of filters are assigned with random weights at the model initialization stage. In the convolutional layer, the dot product of filters and the convolved image patch is calculated and added with a bias value get the convolution result. In the activation layer, the convolution result is fed into an activation function called Rectified Linear Units (ReLU) so as to add non-linearity to the model. The max-pooling layer is applied after the activation layer, during which only the maximum value in the covered feature map patch is remained to the next layer. The function of the max-pooling is to reduce the spatial dimension of the feature maps such that the computational cost will not exceed the capability. The process of performing a stack of convolution, ReLU and max pooling layers consecutively can be regarded as a down-sampling process, after which the obtained feature maps are of low resolution and may lead to difficulties in the later map upsampling process. Therefore, the resolution of feature maps is controlled through setting different zero padding layers around the feature maps in this study. In the end, the original images are only downsampled by a factor of 8, which is smaller than that by using other networks such as FCN and hence prevents large spatial information loss.

(2) Dilated convolution

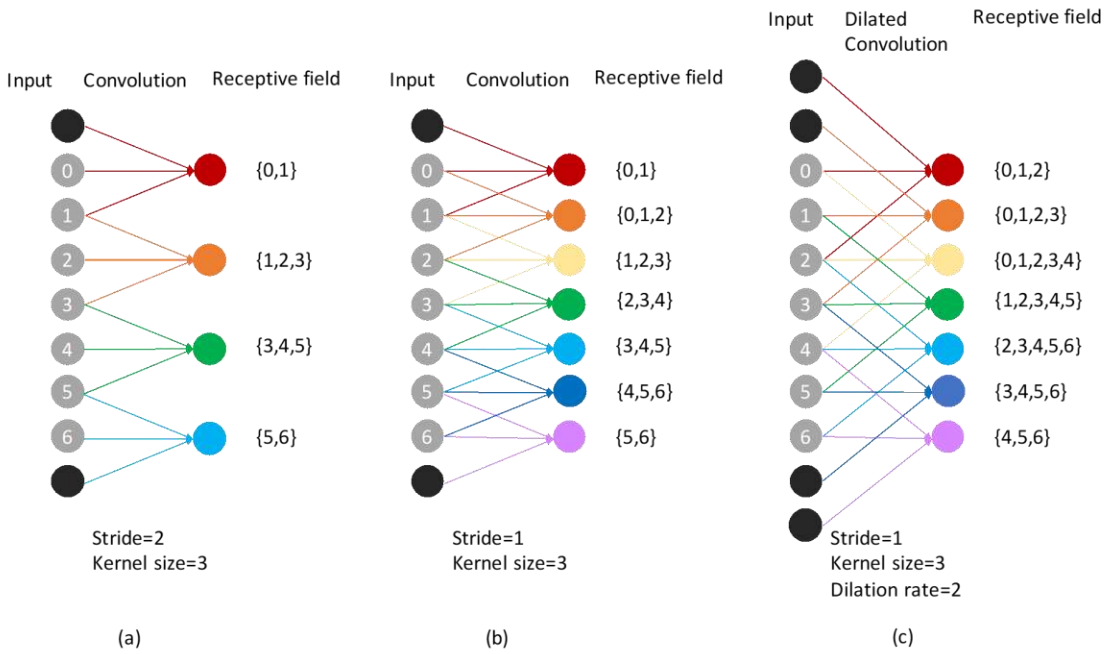

Figure 3. Example of normal convolution and dilated convolution

Another method to prevent too much resolution loss of feature maps is using smaller stride values during the convolution process. For example, the feature map resolution is increased in Figure 3 (b) compared with Figure 3 (a) as the stride value is decreased from 2 to 1. Nevertheless, one limitation of applying small stride values is that the receptive field (i.e. the area convolved by the filters with respect to the original input) is still small, which means there is not much global information incorporated during the learning process. Therefore, dilated convolution [11], is applied in the proposed model such that feature map resolution is improved and the receptive field is enlarged, but the parameter number will not increase. The dilated convolution filters can be treated as normal filters filled with certain number of holes (zeros), which is indicated by the dilation rate. Filters with dilation rate of *k* means that there are *(k-1)* zeros inserted among each consecutive columns or rows of original filters. Specially, filters with dilation rate of 1 are the same with normal filters. Consequently, the scope of the convolved pixels of the original input (i.e. receptive field) is increased while the number of parameters remains the same with that of using normal filters. For example, Figure 3 (c) with the dilation rate of 2 increases the map resolution to the same density as (b) while the receptive field becomes larger, which enables more contextual information involved.

(3) Multi-scale dilated convolution

During segmentation, when aspect ratio of objects is different, convolution using the fix-sized filters only extract features from objects with certain scale while omitting features of different scale objects. Similar case exits for the segmentation of sewer pipe defects, considering different scales of the sewer pipe defects, e.g. scale of cracks is similar to long and thin rectangle while deposits tend to have square scale. Therefore, multi-scale dilated convolution layers are added in the developed model. Specifically, dilated convolution with 4 different dilation rates i.e. {6,12,18,24} is performed in parallel to generate feature maps respectively, the process of which is similar to convolution using filters of different sizes. With the aim not to reduce the feature map resolution, zero padding layers are applied according to the dilation rate of each layer. The feature map values from the four parallel layers are summed pixel-by-pixel and the fused results are used for the final interpolation.

(4) Bilinear interpolation

After the parallel dilated convolution, the generated feature maps are upsampled using bilinear interpolation, which is a common method used for upsampling. As shown in Figure 4, on the feature map to be upsampled, the value of each pixel is known. With the information of both location and values two pixels, the value of pixels in a certain location between them can be calculated through linear interpolation. Similarly, the value of pixels at other positions can also be obtained. For example, based on the known coordinates of all the pixels on the feature map, the value of pixel e can be obtained through the P_a and P_b while P_f can be calculated from P_c and P_d. In the end, P_g is obtained

using P_e and P_f. By repeating this process, the feature map can be upsampled to the original resolution with values for each pixel.

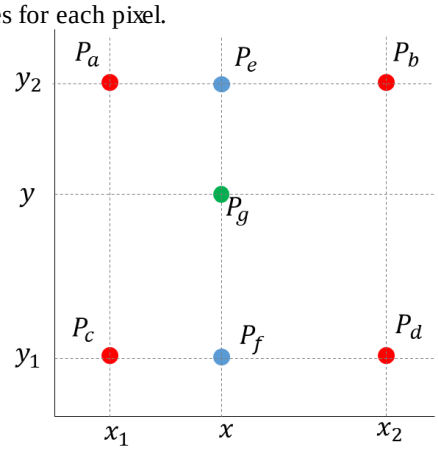

Figure 4. Example of bilinear interpolation

3.2 Model Evaluation

The proposed model is designed for real-time defect segmentation, the model implementation and computational cost should be feasible for on-site inspection while the segmentation accuracy should also be satisfying.

3.2.1 Accuracy

The four indices in [12] are used for measuring segmentation accuracy. As shown in Figure 5, assume the total class number is $k+1$ (including k objects and 1 background class), p_{ij} is the number of pixels of class i but assigned with class j and can be treated as false positives. p_{ji} can be interpreted as false negatives while p_{ii} represents true positives. Circle A represents the total number of pixels of class i, i.e. $t_i = \sum_{j=0}^{k} p_{ij}$. Circle B represents all the pixels predicted to be class i and the intersection C between A and B represents all the true positives.

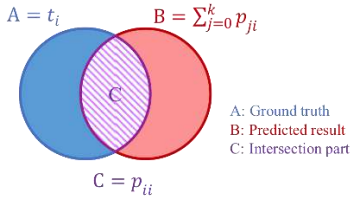

Figure 5. Graphical representation of the predicted results and ground truth

(1) Pixel accuracy (PA)

PA is the simplest evaluation by calculating the ratio of pixels correctly classified over the total number of pixels.

$$PA = \frac{\sum_{i=0}^{k} p_{ii}}{\sum_{i=0}^{k} t_i} \tag{8}$$

(2) Mean pixel accuracy (mPA)

mPA is calculated based on the pixel accuracy for each class, by computing the ratio of correctly predicted pixels over the total pixel amount in each class and taking the average value for all the classes.

$$mPA = \frac{1}{k+1}\sum_{i=0}^{k} \frac{p_{ii}}{t_i} \tag{9}$$

(3) Mean intersection over union (mIoU)

IoU is the dominant metric for evaluating segmentation accuracy and is calculated by taking the ratio of the intersection between predicted results and ground truth labels over the union between these two sets. The intersection is the true positives while the union is the sum of false positives and false negatives and subtracted by true positives. mIoU is obtained by taking average value of the IoUs for all the classes.

$$mIoU = \frac{1}{k+1}\sum_{i=0}^{k} \frac{p_{ii}}{t_i + \sum_{j=0}^{k} p_{ji} - p_{ii}} \tag{10}$$

(4) Frequency weighted intersection over union (fwIoU)

As the percentage of pixels belonging to each class may be different in the training dataset, evaluating the accuracy considering pixel occurrence frequency is also important.

$$fwIoU = \frac{1}{\sum_{i=0}^{k}\sum_{j=0}^{k} p_{ij}}\sum_{i=0}^{k} \frac{p_{ii} t_i}{t_i + \sum_{j=0}^{k} p_{ji} - p_{ii}} \tag{11}$$

3.2.2 Computational Cost

The computational cost is a significant evaluation aspect to ensure a desired segmentation speed for real-time segmentation of sewer pipe defects. The computational cost of the models is evaluated for the inference stage using the segmentation speed as well as the training stage using training duration and model convergence performance. Compared with training stage, evaluation of the inference stage is more important as the inference speed affects the real-time performance of the model.

4 Experiments and Results

To validate the proposed models for sewer defect segmentation, experiments are conducted to evaluate

FCN-8s and the DilaSeg in terms of accuracy and computational cost.

4.1 Experiment Dataset and Implementation Details

Images containing three types of defects i.e. cracks, deposits and tree root intrusions are extracted from CCTV inspection videos of sewer pipe inspection company in the United States. 90% of 1510 annotated images are used for training (1,359 images) and 10% are for testing (151 images). The annotation files are generated through LabelMe [13] by plotting the polygon along the boundary of each defect. All the pixels inside the same polygon are assigned with the same defect class. In the end, each defect is annotated with different colors and the background is set to be black. Caffe [14] is one common library for building deep learning models. As the functions of the dilated convolution are not included in the initial Caffe, source code of Caffe was revised and recompiled for training the proposed model. All the segmentation models are trained on Ubuntu system with Intel® Core™ i7-6700 CPU @ 3.40GHz × 8 and GPU of GeForce GTX 1080. During each training iteration, images are fed into the network with a mini-batch of 16, to reduce GPU memory requirement and improve the training efficiency. The "poly" learning rate is applied with a base learning rate of 0.01, momentum of 0.9 and weight decay of 0.005. Each model is trained using the re-compiled Caffe for 50,000 iterations and saved every 500 iterations to evaluate their accuracy on validation dataset.

4.2 Experiment Results

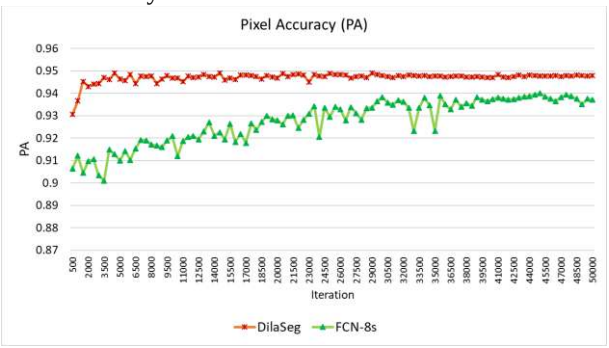
4.2.1 Accuracy

As shown in Figure 6 (a), the pixel accuracies of the two models follow a similar trend, i.e. within a certain number of iterations, PA increases with the increase of training iteration. The increase is obvious during first few thousand iterations and gradually becomes small in the later training period. Finally, the PA reaches a plateau and no longer yields increase. The point where the model reaching the plateau indicates the convergence of the model and is different for each model depending on the convergence speed. The DilaSeg has higher PA values than FCN-8s, indicating the effectiveness of dilated convolution.

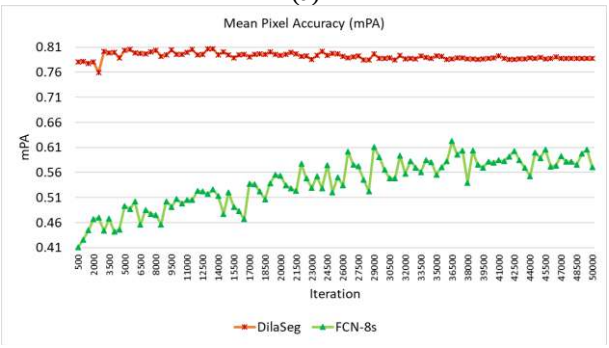
As shown in Figure 6 (b), the mPA values of both models are increasing during the training process. Although FCN-8s has a more obvious increase trend, DilaSeg achieved much higher mPA value than FCN-8s. As shown in Figure 6 (c), in terms of values of mIoU, the overall varying situation is similar to PA and mPA, with an increase at first and reaching a plateau in the end. The mIoU values of FCN-8s also increase with the training iterations, but the overall mIoU values are much lower than the proposed model. The mIoU values of DilaSeg are higher than FCN-8s during the whole training process, which reflecting the stronger capability of the developed model for segmentation. The fwIoU values which considers the pixel occurrence frequency when calculating IoU are shown in Figure 6 (d). Almost during the whole training, the fwIoU values of DilaSeg are higher than FCN-8s.

The best accuracy values of the two models are shown in Table 1. It can be seen that accuracies in terms of the four indices obtained using DilaSeg are higher than FCN-8s. The developed model improved the segmentation accuracy largely, especially with 18% of increase in mPA and 22% of increase in mIoU using DilaSeg.

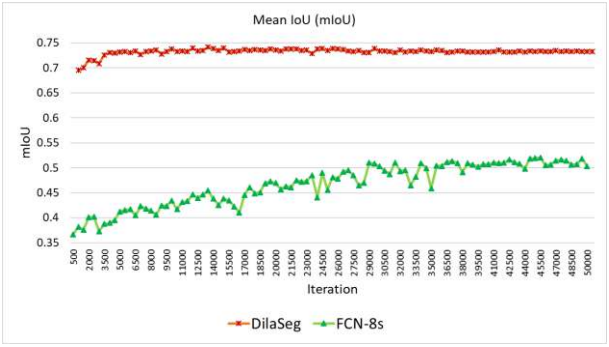
Some of the segmentation results are analysed. As shown in Figure 7 (a) and (b), for crack segmentation, FCN-8s can approximately provide the locations but cannot detect the correct defect type. One reason is that the model cannot recognize the defect type due to the color similarity between the cracks and other defects.



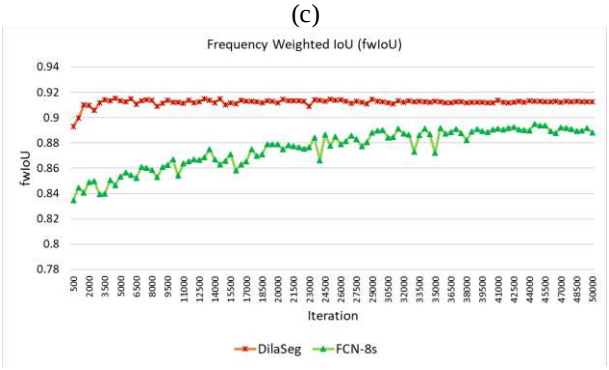
(a)



(b)



(c)



(d)

Figure 6. Accuracy of the two models for segmentation of sewer pipe defects

The DilaSeg performed better than FCN-8s, with segmentation of more parts of cracks, although some cracks are not segmented completely. In terms of deposit and tree root, FCN-8s achieved better results compared with segmenting cracks. However, segmentation of deposit and tree root are mixed with each other as shown in Figure 7 (c) and some defects are not segmented completely as shown in Figure 7 (d). On the contrary, DilaSeg is capable of segmenting both deposit and tree root much better with fewer mixed segmentation cases. In addition, more areas of the defects can be segmented by DilaSeg and more complete segmentation results can be provided as shwon in Figure 7 (e).

Table 1. Accuracy of the two models

	FCN-8s	DilaSeg
PA	0.939	0.949
mPA	0.623	0.807
mIoU	0.521	0.742
fwIoU	0.895	0.915

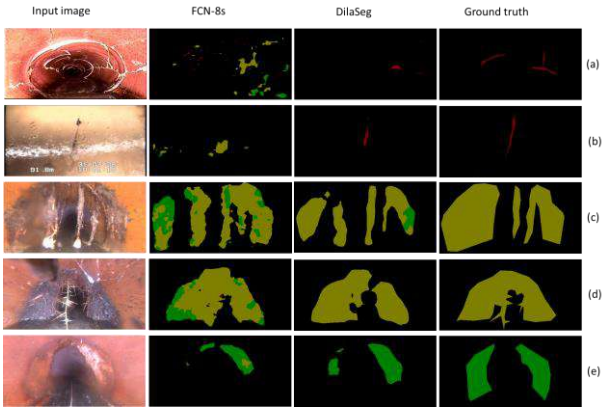


Figure 7. Examples of segmentation results (red color represents cracks, lime color represents roots and green color represents deposit)

4.2.2 Computational Cost

The computational cost of the two methods is evaluated using the detection speed (i.e. the time taken for detecting each image), training duration (in hours) and converge iteration (i.e. the number of iterations taken for the model to obtain convergence). The training duration and converge iteration indicate the difficulty for training the model to achieve desired performance while the detection speed reflects the possibility of real-time segmentation. As shown in Table 2, although the training process of DilaSeg is longer than FCN-8s, the detection speed of DilaSeg is relatively faster during model inference. In addition, the training loss of DilaSeg is dropping quickly within the first few thousand iterations and achieved a plateau at around 15,000 iterations, as shown in Figure 8 (a). However, the loss of FCN-8s was much higher and was dropping at a quite slow rate during the whole process, achieving a converging point after 45,000 iterations. The training loss trend reflects the proposed model can learn image features and optimize weights more efficiently.

Table 2. Computational cost of the two models

	FCN-8s	DilaSeg
Detection speed (s/image)	0.352	0.265
Training duration (h)	3.417	17.405
Converge iterations	45000	15000

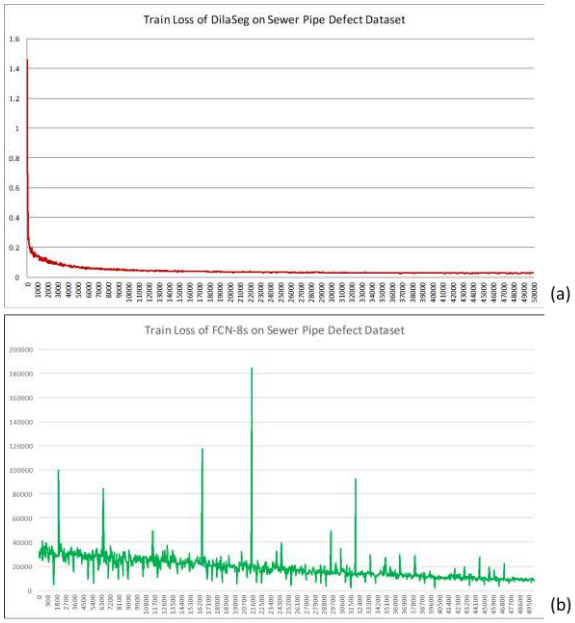

Figure 8. Training loss of DilaSeg and FCN-8s

5 Conclusion and Future Work

Computer vision techniques are attracting attention for automatic interpretation of sewer inspection results. Previous studies mainly focus on classifying and locating defects in images, which cannot provide information about the severity level of different defects. In addition, the requirement of the practical implementation of models on CCTV robots, e.g. the computational cost is rarely considered. This study aims to obtain the segmentation of three different types of sewer pipe defects i.e. crack, deposit and tree root, from CCTV inspection images to facilitate real-time severity assessment in the future.

To address the problem of large information loss during the down-sampling process of most previous deep learning models such as FCN, a new model called DilaSeg is developed in this study for semantic segmentation based on dilated convolution to increase feature map resolution. The proposed model is featured for performing several modules to obtain dense segmentation results, including normal convolution, dilated convolution, multi-scale dilated convolution as well as bilinear interpolation. Important features are extracted using the normal convolution and the feature maps are down-sampled due to consecutive convolution and max-pooling. Dilated convolution is implemented to prevent too much spatial information loss, which is also applied for objects with different scales through multi-scale dilated convolution. In the end, the feature maps are upsampled to original scale using bilinear interpolation. Experiments demonstrate that compared with FCN-8s, DilaSeg improved segmentation accuracy significantly in terms of all the evaluation indices. Especially, there is 18% of increase in mean PA and 22% of increase in mean IoU. Furthermore, the inference of the DilaSeg is faster than FCN-8s, which indicates the advantage of the proposed model for real-time application. Regardless of the improved accuracy, there are still some negative segmentations, possible reasons and potential solutions need to be validated in the future.

Abstract –

In this study, we propose information exchange process for the effective integration of building information modeling (BIM) into an augmented reality (AR)-based smart facilities maintenance (SFM) system. The proposed SFM system refers to a system that combines technologies such as AR and IoT sensors in the field maintenance work. This requires the acquisition of data from various sources followed by transformation of these data into an appropriate format. Construction operation building information exchange (COBie) is widely used as a means to effectively integrate and utilize information for maintenance. Therefore, SFM system has a requirement attribute information system with reference to COBie. But this information should be linked to the maintenance work procedures in the actual use case scenario and it is necessary to define the information exchange process. To solve this problem, we uses the following methods to enable SFM system development with applications for BIM and AR technologies in the FM of the building sector of public facilities. First, it analyzes the previous studies on BIM-based maintenance works and AR technology. Second, it divides the SFM work process utilizing the BIM-based COBie system, and it defines the COBie data required for each work phase. Third, it develops a scenario-based business process modeling notation (BPMN) for the SFM system prototype. Finally, it proposes an implementation method of SFM system architecture.

Building information model; Facility maintenance; Augmented reality; Business process modeling notation

1 Introduction

1.1 Background and Objectives of the Research

One of main purposes of facility management (FM) is to realize the expected asset value by maintaining or complementing qualities of facilities planned in the design phase and secured in the construction phase. FM phase accounts for the longest proportion in the building life cycle, and the cost consumed in this phase occupies 85% of the life cycle cost (LCC) [1]. Facility information generated in the design and construction phases is utilized as basic implementation data of the facility management system (FMS) for effective and systematic operation and maintenance, but it takes a considerable amount of time and money to implement basic data in the FMS through defining and verifying the required information in the operation and maintenance phases. To resolve difficulties in current FMS implementation process, building information modeling (BIM) technology has been introduced, which can act as an alternative system to systematically and efficiently operate and maintain the facilities. BIM is structured with objects, attributes, and relationships. Since all attributes and relationships are defined based on objects, BIM can manage the required information for operation and maintenance by function, space, and use purpose.

Building owners and facility maintenance mangers have an opportunity to reduce a large amount of cost during a much longer maintenance period than that of design or construction phase by utilizing BIM-based information. However, although utilization of BIM information in the facility maintenance phase has many advantages, BIM information has not yet been utilized in on-site maintenance work. This is because a variety of information required for facility maintenance has not been defined, and, in many cases, this information is not included in BIM-based design.

To solve this problem, a large number of studies have been conducted to develop a system to transfer BIM information generated over the design and construction phases into the facility maintenance phase. As a result, data exchange format called construction operation building information exchange (COBie) was developed by public institutions, which took project ordering tasks of major facilities in the USA.

Meanwhile, AR technology has been utilized in various areas, such as product review and production system design. More recently, with the advancement of smart devices, users can now employ AR more easily than ever before. The construction industry is also actively introducing on-site facility data visualization and real-time collaboration features by utilizing AR technology. However, few studies have been conducted on the utilization of AR technology in the maintenance phase as compared to the design and construction phases, even though economic benefits would be the largest in terms of LCC.

Thus, as one of the few studies on SFM for automation management and efficient execution of facility maintenance, this study aims to discuss the current trend of BIM and AR technology; it measures of how to link information and proposes an AR-based SFM system. In addition, this study sets the COBie system as a benchmarking target—which has been developed as a system prototype in the USA and is now widely recognized in the world—to define the required information exchange process for implementation.

1.2 Study Method and Procedure

This study uses the following methods to enable SFM system development with applications for BIM and AR technologies in the FM of the building sector of public facilities. First, it analyzes previous studies on BIM-based maintenance works and AR technology. Second, it divides maintenance work process utilizing a BIM-based COBie system, and it defines COBie data required for each work phase. Third, it develops a scenario-based business process modeling notation (BPMN) for the SFM system prototype. Finally, it proposes an implementation method of SFM system architecture.

2 Analysis of Previous Studies

2.1 Building Maintenance Using BIM

When BIM is applied in the maintenance phase, it can be utilized in analysis data for the purchase procurement of machine equipment, control systems, and other products; it can also check whether all systems are correctly operating after buildings are complete, which is the advantage of BIM to the maintenance phase. It can also act as an interface for sensors; it can remotely operate the management of facilities and provide real-time monitoring of control systems through providing accurate information about space and systems [2]. BIM for FM provides a manual for building users, which can help to locate models visually, such as facilities, attachments, and furniture. BIM also supports contingency plans, security management, and scenario planning [3]. As described above, several studies have been conducted actively to show the advantages of a BIM application to FM.

A study by Yu developed a data model, Facility Management Classes (FMC), which can extract required information from Industry Foundation Classes (IFC) for information compatibility of BIM data into FM [4]. A study by Mendez R. proposed functions that can be utilized by BIM in the maintenance phase; the study developed a web-based prototype to improve the utilization of BIM information [5]. East and Brodt developed a data exchange format called COBie based on a spreadsheet to solve inefficiencies due to unnecessary information in maintenance among information sets created during the design and construction phases [6]. A study by Burcin defined a level of BIM recognition in the maintenance phase through expert interviews, applicable areas, required data, and processes to implement BIM successfully [7]. Lee et al. attempted to improve a facility maintenance system through benchmarking the COBie system, and Choi et al. conducted a study to implement a FM system for sewage treatment based on the COBie [8][9].

One study proposed software architecture to integrate BIM with geographic information system (GIS)-based FMS effectively [10]. Another study proposed integrating BIM-based Mechanical, Electrical, and Plumbing (MEP) information in the operation and maintenance phases [11].

Most of the previous studies on FM utilizing BIM focus on the interoperability with FM system and a measure to link data produced during design and construction phases as well as a direction to application of BIM to FM systems and commercialization has been chosen.

2.2 Utilization of AR Technologies in Building Industry

The trend of utilizing AR technology in building industry has showed that earlier studies focused on the analysis of applicability of virtualization technology Hammad presented the applicability of AR technology to field works of infrastructure, and Koo considered the development of a wireless technology-based, AR-applied system in terms of display, tracking, and servers. Afterward, a study on the presentation of an AR system

prototype for the inspection of steel column construction was conducted [12] [13].

For studies on AR authoring tools, AR modeling through capturing and rendering of exterior structures in real time and 3D modeling can be found. A tool called "Tinmith" was manufactured to interact between users and AR directly [14]. Moon et al. implemented an AR prototype that can select the position of a tower crane appropriately in a high-rise building construction site and conducted a verification procedure through actual building drawings [15].

More recently, studies on the application of AR to building maintenance have been conducted in various ways. A study by Bae et al. proposed a novel method that supported on-site construction and facility management works by documenting on-site problems and progress visually by on-site staff and by making recent project information accessible as a form of AR overlay [16]. Another study proposed a natural marker-based AR framework that can support facility managers digitally when they search FM items or perform maintenance and repair works [17]. Kwon et al. proposed a SFM system that improved existing maintenance work; thy studied a novel maintenance work process and an implementation method to apply AR technology [18].

The analysis results of previous studies have showed that the utilization of AR technology in the building industry has enabled efficient construction management by recognizing design drawings intuitively by users. Four-dimensional (4D) BIM based on existing virtual environments has lacked reflection about the actual construction site conditions. Thus, if AR technology that reduces a cognitive resistance is applied to maintenance sites, its value and utility would be significant in terms of productivity improvements.

3 SFM and COBie System

3.1 Overview of SFM

A SFM system proposed in this study aims to support tasks of workers and managers by introducing Internet of things (IoT)/VR/AR technologies to existing on-site maintenance works. The base data to combine the new technologies are BIM data. To do this, a study on improved process of sequential and repetitive task elements was conducted by applying AR/VR technologies to existing maintenance tasks [18].

Data such as drawings, historical information, and related documents stored in a distributed manner in the facility maintenance tasks are linked and integrated with BIM data to overcome the limitations of simple repetitive tasks and inefficient data utilization.

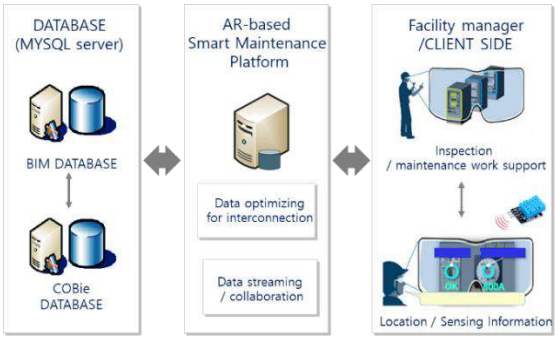

Figure 1. Configuration of proposed system

As shown in Figure 1, variably distributed data can be gathered, and each request can be processed as a hub through the AR-based smart maintenance platform, which manages the facility management database in the center. This study's scope is limited to building interior constructions (floor, wall, ceiling, window, door etc.) among the maintenance target facilities.

3.2 SFM Work Process

A BIM attribute information and the historical management information required by task units in the maintenance work may be different from each other. To define the information clearly and store them in a database for the utilization of AR visualization, task units were classified based on maintenance work scenarios.

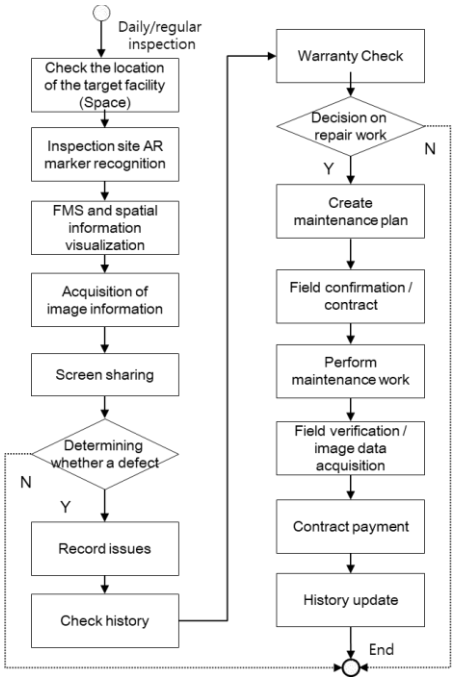

Figure 2. Scenario-based workflow

As shown in Figure 2, an on-site inspector checks the inspection-required facility location and recognizes the AR marker attached to the inspection target space in the daily inspection task scenario. Inspection-required members and checklists in the corresponding space are visualized through the markers by which the inspector can perform visual inspection and photo shooting. In this process, video information through the inspector's camera is shared in real time so that various decision-making participants can judge together whether there are defects or not. If decision making determines that there is a defect through the inspection, historical information, such as installation, warranty, and management companies, is visualized, and the status information can be sent to the corresponding companies directly from the site. After this, a maintenance manager decides whether repair work is needed. If repair work is done, task-related guidance and progress are monitored in the construction process, and stored in the FMS.

The core technologies of AR visualization in this process are the following: 1) AR-based surveillance task support technology, 2) 3D information plus AR overlaying technology, and 3) 3D data conversion technology for AR/VR.

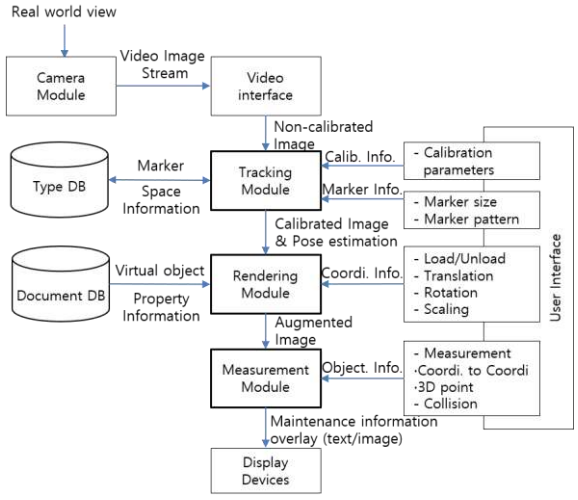

Figure 3. AR visualization process in inspection work

3.3 Definition of the COBie System

To implement the AR-based smart maintenance process proposed in this study, COBie is benchmarked and utilized. COBie is an information exchange data format based on a spread sheet jointly developed by public institutions that take project orders of major facilities in the USA led by the US army corps of engineers. It was developed as a means to replace a large amount of documents related to facility management at the time of completing the construction of a project. COBie includes definitions and formats of information required during the maintenance phase among a BIM information created in a series of phases during construction projects: planning, design, construction, operation, and maintenance.

Table 1. COBie data sheets and contents by phase

Phase	Sheet	Contents
All	Contact	People and Companies
	Document	All applicable document references
	Attribute	Properties of referenced item
	Coordinate	Spatial locations in box, line, or point format
	Issue	Other issues remaining at handover.
Early Design	Facility	Information on Facilities and Standards
	Floor	Vertical levels and exterior areas
	Space	Spaces
	Zone	Sets of spaces sharing a specific attribute
	Type	Types of equipment, products, and materials
Detailed Design	Component	Individually named or schedule items
	System	Sets of components providing a service
	Assembly	Constituents for Types, Components and others
	Connection	Logical connections between components
	Impact	Economic, Environmental and Social Impacts at various stages in the life cycle
O&M	Spare	Onsite and replacement parts
	Resource	Required materials, tools, and training
	Job	PM, Safety, and other job plans

As presented in Table 1, COBie consists of 18 data sheets, and the related detailed contents can be expanded through expandable templates. In the data sheets that can be utilized in the whole phases of construction projects, contract-related items of construction participants, drawings, coordination systems, and building completion-related issues are included. In the initial design phase, facility information

and floors, spaces, and material types are included, and in the detailed design phase, the connection of all members and assembly, system configurations, processes, and costs are added. In operation and maintenance (O&M) phase, replacement and repair items and required resources and tasks are included. In addition, COBie is configured to expand the required attribute information constantly.

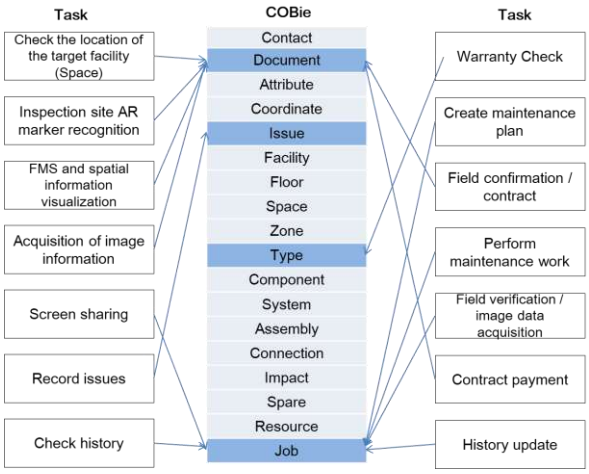

Figure 4. Smart maintenance tasks and COBie data mapping

All of these data sheets are not needed in the COBie system definition, which were required for the previously proposed maintenance work by the scenarios, but it is important to utilize only minimum information considering the link between attribute information and data lightweight, which are essential for AR visualization. Thus, the information required for the previously proposed maintenance work by the scenarios and COBie data sheets was mapped. This process was conducted through prior literature reviews and through interviews and surveys with on-site maintenance workers, as shown in Figure 4.

Through this process, document, issue, type, and job data sheets were found to include attribute information required for the on-site maintenance work. However, excessive attribute information was required in the document and job sheet among these four data sheets, and unnecessary information was also included depending on maintenance work participants. Thus, warranty and plan data sheets were additionally created and used for optimization of AR-based visualization information.

Table 2. COBie data sheet for field maintenance

Sheet	Contents
Document	Submittals and approvals, DWG.
Issue	Other issues remaining at maintenance
Type	Types of equipment, products, materials, model, Warranty data
Job	PM, Safety, and other job plans

Contents included in the newly added warranty data were the product names of the interior finish materials, repair (warranty) responsible companies, contact details, and warranty-related document information. Through this information, which companies are responsible can be identified when defects occur, and requests for repair can be achieved rapidly. A plan data contains information that is utilized when maintenance construction occurs, which includes construction progress status, follow-up tasks, and next maintenance inspection date.

4 Information Exchange Process to Implement the Prototype

4.1 Smart Maintenance BPMN

To implement a prototype of an AR-based, on-site support module for the SFM on the basis of maintenance scenarios proposed in this study, a BPMN, including the current status of data input and output, is required. BPMN is a visualized notation method to represent business processes. It is developed to notate a message flow between activities over a time flow in the process. BPMN that defines and represents the data inputs and outputs required in the maintenance work process, based on daily inspection scenarios, is shown in Figure 5.

Most of the 3D models and attribute information of the inspection-required objects are extracted from a BIM information and stored in a database as COBie Excel sheets. Here, the additionally required attribute information is AR market information, inspection date, and warranty period, which requires a manual input process by the maintenance manager or supplier.

The most important thing in the utilization of BIM in maintenance work is to clarify the definitions of requirements and use cases. Thus, the proposed BPMN facilitates detailed implementation of smart maintenance use case.

between users and managers who use the AR system.

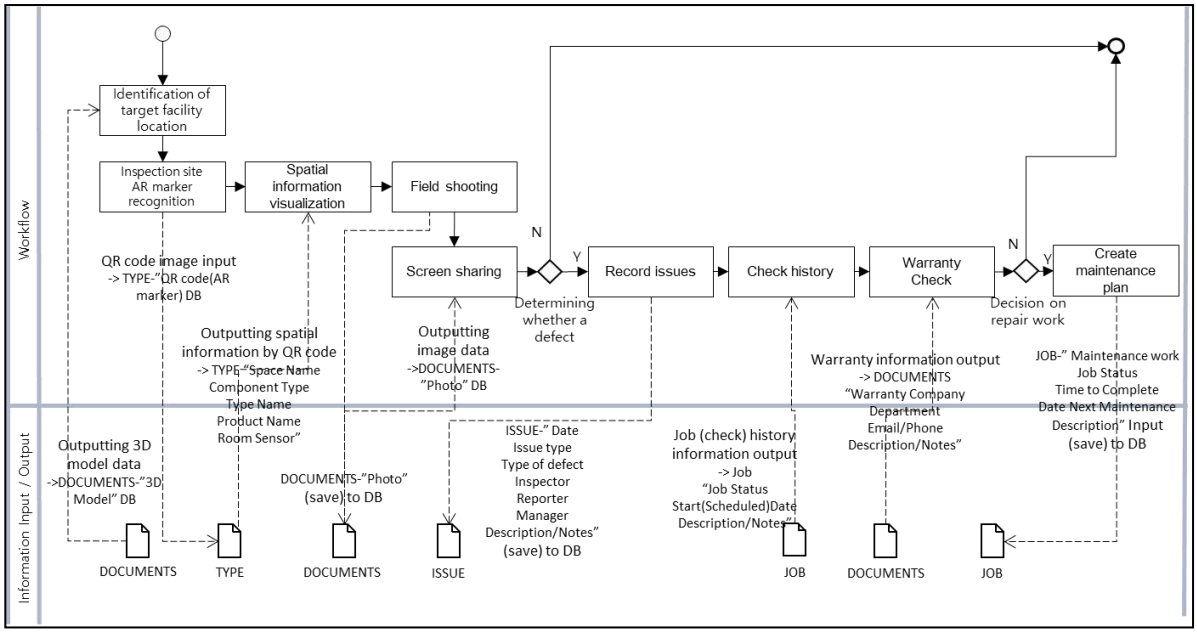

Figure 5. Daily / regular maintenance scenario based BPMN

4.2 Functional Screen Configuration and UI

Basically, an AR system consists of a camera, an image converter, tracking, and a video background render. A camera component helps efficient delivery to the camera frame. A camera frame is provided automatically according to the device, depending on image format and size. Once markers are recognized through the HMD camera, users define the targets that will be observed through the AR via the pixel format conversion. Targets defined in the database configured with COBie system monitors objects through the tracking module. After detected object's status is identified, the 3D virtual objects are modeled, and information is provided on the display. Auxiliary information about augmented 3D virtual object in display is managed by the web-based FMS and augmented through XML. In web service application, auxiliary information about augmented objects was composed of a management system and two-way communication systems. The auxiliary information management system was configured to provide various pieces of information rapidly to users and overcome the existing problem, which only showed 3D object augmentation. Two-way communication system was configured to provide information in real time—which was not provided by the auxiliary information management system—through two-way communication

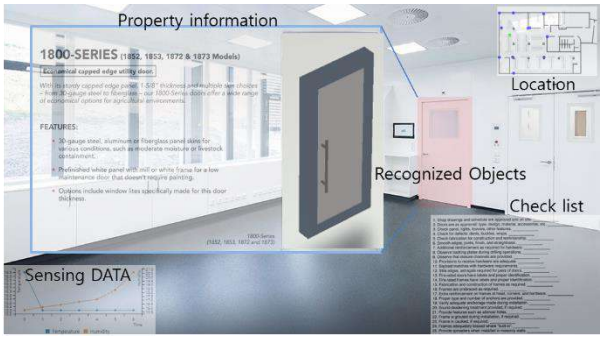

Figure 6. Example of AR-based SFM system UI

UI in the AR application, which emphasizes interaction functions through real world, requires different designs from those of existing mobile applications. Most mobile devices utilized in site are smart phones and tablets, which support a touch-based interface. However, since on-site maintenance support application proposed in this study targeted HMD devices, existing touch-based operations cannot be used. Thus, controls through gesture or voice recognition are needed, which require more user-friendly and intuitive UI. Consequently, menu button items were removed, and required attribute information was laid out on the lower side of the screen. Since augmented reality interacts with the real world, visualized information supports a transparency control function to project the real world.

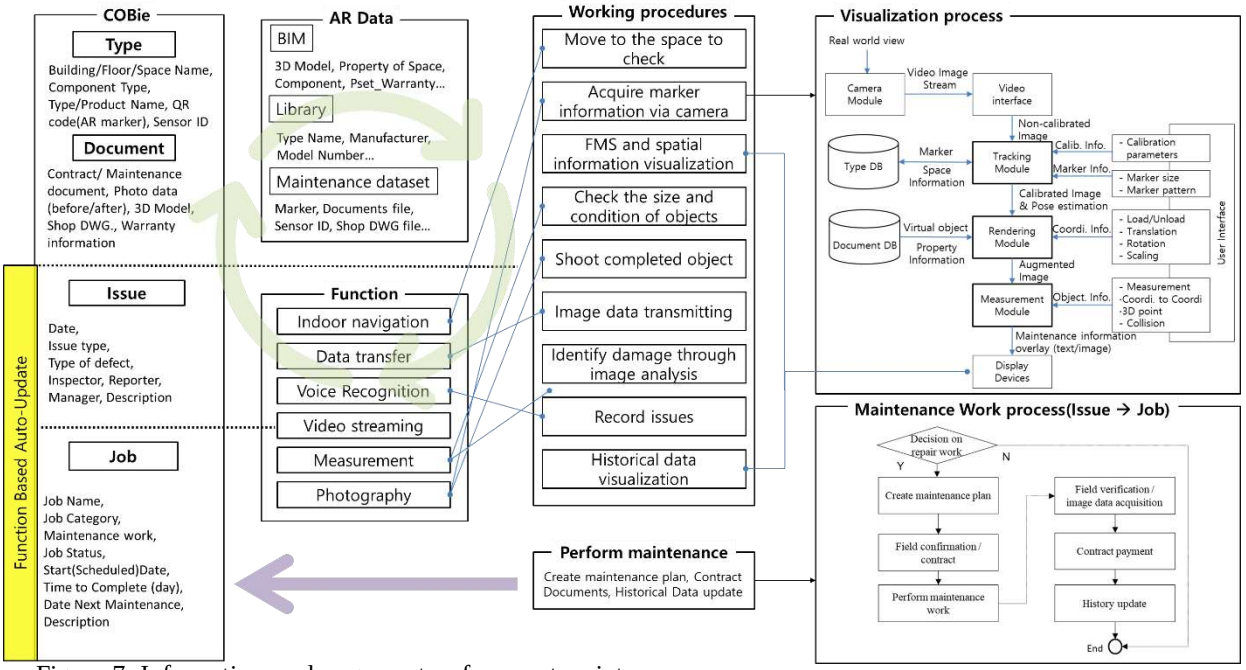

Figure 7. Information exchange system for smart maintenance

This feature excludes obstacles in the view when workers move or perform works, and it helps to verify the worker's location by positioning a navigation map inside the building on the right upper side of the screen. Figure 6 shows the example of the screen configuration of the prototype implementation, in which site inspector visualizes specification information about door. Information about supplier expert who supplied door, information about temperature and humidity of room, and information about interior finish inspection can be found in the lower side of the screen. An inspector observes target facility, such as door, window, wall, and column, and can record inspection results about inspection items through checklist.

4.3 Definition of SFM System Information Exchange System

Entire information exchange process of the SFM System described above is shown in Figure 7. Preliminary data use BIM data at handover. BIM information at this stage includes more detailed information of the space and the interior finishing material, and the space information and the property information of the space are used in conjunction with COBie. Among the information required for AR visualization, 3D model shape information does not work directly from BIM, so it is processed through information processing and optimization, and additional information necessary for maintenance is also included at this time. Basic information required before performing all these operations is stored in the Type and Document sheets of the COBie data.

After that, procedure of performing the work by the site inspector is moved to the site, the marker recognition, the space and absence information are visually confirmed, and the result of inspection is automatically transmitted. In order to recognize the AR marker information and visualize necessary information, modules needed are tracking / rendering / measurement module and implemented through separate API. In addition to the AR visualization function, there is an additional need for indoor navigation, data transmission, voice recognition, video streaming, automatic measurement and photo shooting functions, which are linked to each stage of operation.

When inspection is completed, the result information is stored in COBie's issue sheet, and it is used when maintenance work is in progress. As the maintenance work progresses, newly generated contract information is automatically saved in the Job Datasheet again, and COBie repeats this process and updates it.

5 Conclusions

This study proposed that data exchange procces through data item configuration and functional definition to apply AR technology to on-site maintenance works in a BIM-based SFM system.

As a result, this study determined that when maintenance and management information are configured based on the COBie system, interoperability in various software environment can be ensured. In addition, if AR visualization technology of maintenance information through overlay with real site circumstances

is utilized, it can enable rapid information sharing about on-site working conditions and decision making. Furthermore, the utilization of BIM datasets generated in design and construction phases is meaningful in terms of utilization BIM data throughout the whole life cycle.

However, since the study scope was limited to filed inspection works, the study results cannot be applied to all maintenance works in general. This study also needs some feedback through user satisfaction surveys regarding the proposed system development and UI configuration. For a future study, a technology that can visualize the information of complex facilities which cannot be identified visually should be developed through AR technology by expanding the maintenance target to mechanical, electrical, and plumbing in addition to the interior finish.

Abstract –

On a construction site, progress deviations can cause fatal damages to the project and stakeholders. Therefore, accurately monitoring and managing the construction environment is essential. Efficiently detecting and recognizing the changes will be the key factor for monitor and management goals. In this research, we present a framework for detecting and recognizing changes in repeatedly collected, massive 3D point cloud data from a mobile laser scanning system. The framework mainly consists of three parts; 1) mapping system; 2) analysis system; 3) Hadoop platform. Collecting point clouds is repeatedly executed to detect the changes over different time epochs. For collecting point cloud data, a mobile laser scanning system was developed based on Robot Operating System (ROS). Detecting changes between repeatedly collected point clouds have been processed based on Hadoop platform. Finally, detected changes are then implemented to a semantic mapping process which is based on deep learning. Developed framework have potential for wide application in massive point cloud data processing, construction site monitoring, street level change detection, and facility management.

Mobile laser scanning (MLS); ROS; Deep learning; Change detection; Hadoop

1 Introduction

Due to the remarkable developments of sensor technologies and processing algorithms for point cloud data acquisition and registration, mapping over large spaces became more accessible than ever before. Over the last few decades, research groups focused on formulating a metric map, within which the mapping system explores the area without any information and gets self-localized using, Simultaneous Localization and Mapping (SLAM) techniques. The next step in mapping technology is the ability to produce maps directly understandable by humans, semantic mapping, which consequently integrates the robots into human environments [1].

From civil engineering perspective, metric and semantic maps from various data sources have been applied to environmental monitoring [2], building change detection ([3], [4]), disaster management ([5], [6]) and construction/infrastructure monitoring ([7]–[10]). The above mentioned applications share a primary analysis technique which is 3D change detection. 3D change detections has growing demands and possibilities for applications in environmental and civil engineering fields [11].

Despite the recent developments and possibilities, huge size of 3D point cloud data often leads to system slowdown or failure [12]. To overcome the issues, [13] and [14] introduced a distributed system to process point cloud data in a high memory cloud computing environment. However, it was costly to set the hardware environment. [14], [15] and [16] introduced a general solution for point cloud data processing based on Hadoop. In terms of cost, Hadoop had advantages, however, studies had limitations on analytic operations. Most previous studies mostly handle well-constructed data or operate on incompletely constructed data for distributed computing frameworks. Also, previous studies carry out research on only a small fraction of the whole process from beginning to the end.

In this research, practical framework including point cloud acquisition to point cloud management and analysis was conducted. The contributions of this paper is as follows: (1) ROS based 3D mapping system, which consists of three 2D Laser Range Finders (LFR) was introduced; (2) Hadoop based massive point cloud analysis system, which interacts with users using web interface was developed; (3) Deep learning algorithm was applied for point cloud based semantic segmentation and the feasibility was verified.

2 Integrated Framework Design

Our integrated framework consists of three main parts. Firstly, the mapping system based on ROS, automatically and repeatedly achieves metric maps. Second, analysis

system detect changes from collected metric maps. Additionally, semantics were provided to the detected changes based on deep learning algorithm. Lastly, detecting changes and visualizing point clouds has been operated upon developed Hadoop platform.

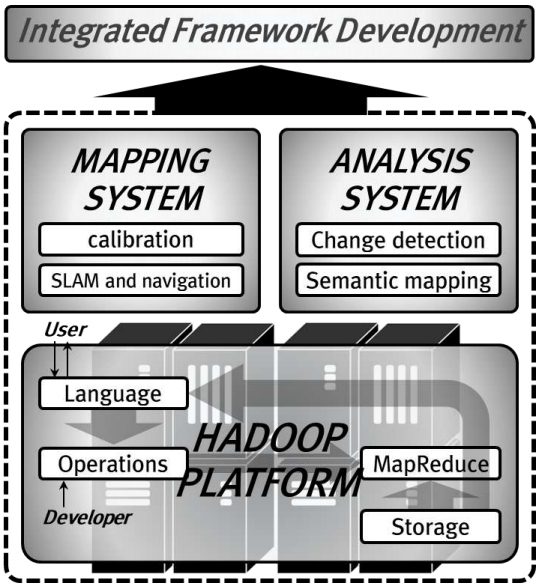

Figure 1. Integrated framework architecture

2.1 Design of Mapping System

The ROS platform is extensively used in this research since it can simply interconnect multiple programming languages and machines in seamless way. Due to this fact, ROS is the most popular robotics platform. It provides a set of tools, libraries and drivers in order to help developing robot applications, also with hardware abstraction [17]. In this research, the mapping system is based on ROS using packages for collecting data from sensors, constructing map from data and navigating through the map.

The mapping system is equipped with three 2D LFRs (UTM-30LX, Hokuyo, Osaka, Japan). It provides a scanning range of 270° with angular resolution of 0.25°. It can measure distances up to 60 meters, but without guaranteed reliability. One full scan cycle lasts for 25 milliseconds, which supplies a 40Hz measurement frequency. Pioneer 3DX mobile robot from ActivMedia Robotics, provides a stable platform for LRF sensors (Figure 2).

Over past decades, the number of SLAM algorithms were developed and the performance of the algorithms were compared . Popular SLAM algorithms such as GMapping [18], Karto SLAM [19], Hector SLAM [20], and Google Cartographer [21] were compared each other with diverse approaches ([22]–[26]). Evaluation results on every paper indicates that Google Cartographer delivers most accurate and precise results compare to others. Therefore, in this research Google Cartographer was used to construct the map, which is a robust solution on most input sequences. Cartographer provides real-time SLAM in 2D and 3D across multiple platforms and sensor configurations. It is a graph-based solution which stores a map of environment as associations for nodes and edges. Nodes represent a submap which has been created using scans, and edges represent transformations between corresponding submaps.

Using previously constructed map and navigation stack from ROS, the mapping platform autonomously navigates the given environment safely based on proper operation. The Adaptive Monte Carlo localization (amcl) [27] package was used to localize the platform itself in the previously constructed map. Additionally, the 'move_base' package [28], which links the global and local planner together, was used to accomplish navigation tasks. Standard A* path planning algorithm was used for global path planning and Dynamic Window Approach (DWA) [29] was used for local path planning. To perform navigation task efficiently, essential goal point needs to be set for our system. To achieve the goal points, morphological skeletonization [30] was applied in the 2D occupancy grid map. Among the exported candidate points from skeletonization, the goal points for the navigation stack was selected manually.

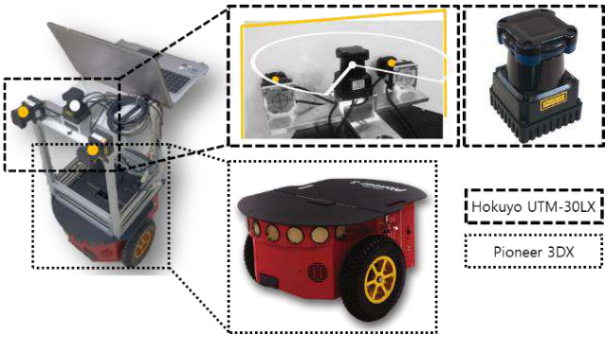

Figure 2. Mapping platform

2.2 Design of Analysis System

Semantic mapping explains the surrounding environment with various components, provides intuitive understanding of the situation to humans and bridges the gap between robots and humans. This could improve efficiency on conventional applications in infrastructure monitoring fields, since it can reduce the human labor on manually giving attributes to geometric information.

Recent developments in autonomous driving and robotics applications accelerate the necessity of point clouds semantic mapping. However, the development stage for point cloud is far behind image segmentation using Convolutional Neural Networks (CNNs). There

have been only a few studies related to semantic mapping with 3D point datasets.. PointNet [31] and PointNet++ [32] are the pioneers in this area which introduces efficient and flexible ways to deal with point cloud data.

In this study, PointNet++ was implemented to analyze the geometric point cloud data. PointNet++ processes a set of points sampled in a metric space in a hierarchical manner. It first partitions the set of points into overlapping local regions by the distance metric of the underlying space. As well as extracts local features capturing fine geometric structures from small neighborhoods; such local features are further grouped into larger units and processed to produce higher level features. This process is repeated until algorithm obtains the features of whole point cloud data. PointNet++ presents more robust result regardless of the density [32].

2.3 Design of Hadoop Platform

The overall architecture of our Hadoop platform with the three main layers is depicted in figure 3. The framework consists of 3 layers: (1) Storage layer; (2) Operation layer; (3) Interactive layer. The storage layer is optimized by indexing techniques to accelerate the Hadoop Map-Reduce applications. The operation layer is equipped with two powerful modules including "Change Detection" and "3D Geometric Model" for efficient monitoring. In this study, only change detection module was used. More details for 3D geometric model will be introduced in our future paper. Lastly, The Interactive layer enables users to approach a distributed computing model on Hadoop without requiring deeper related knowledge.

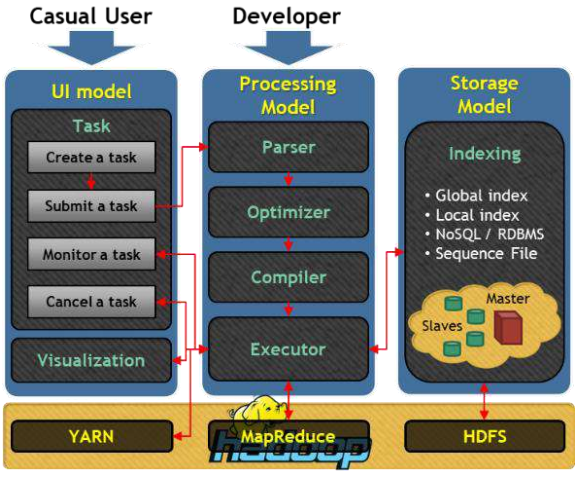

Figure 3. Hadoop platform architecture

3 Implementation and Experiment

The overview of this research is as follows.

- Using the mapping platform 3D point cloud map was constructed.
- Based on the pre-constructed map, mapping system navigates the manually defined goal points automatically and constructs another map.
- Change detection was processed based on Hadoop platform between 2 maps.
- Semantic segmentation was implemented to detected changes.

3.1 Mapping System Experiment

3.1.1 Calibration

Calibration is the process of estimating the parameters that need to be applied to correct actual measurements to their true values. According to the parameter types, calibration also can be divided into intrinsic and extrinsic forms. This research assumes that the intrinsic sensor calibration is completed and focuses on the extrinsic calibration of multiple LRF sensors to identify the rigid transformation from each sensor frame to the platform body frame.

Figure 4(b) shows three 2D LRFs in the mapping system and the configurations of the three coordinate systems. The middle LRF is mounted horizontally, other two LRFs are mounted vertically to scan the profiles of the surrounding environments. For carrying out the calibration, the double-deck 3D calibration facility was developed as shown in figure 4(c). The alignment errors usually are computed by least squares using a set of target points captured from the scanners. Since this research is not focused on calibration, further information about the least squares system equation and experimental results can be referred from [33].

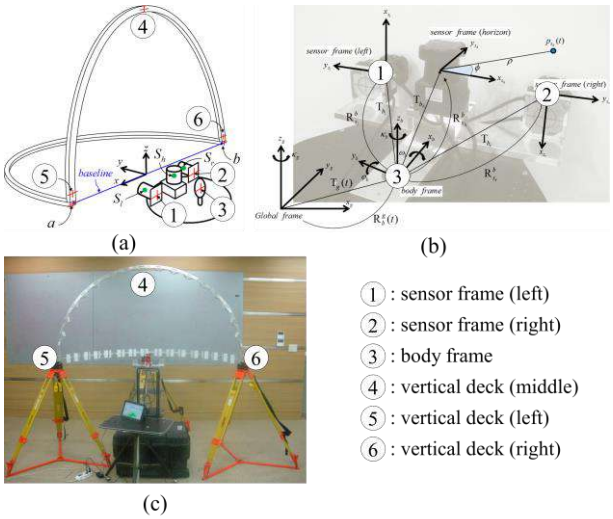

Figure 4. Double-deck calibration facility

3.1.2 SLAM and Navigation

The implementation of Google cartographer SLAM was conducted in seminar rooms and corridors in the Engineering building at Yonsei University. Map was built twice in the same location with intentionally caused changes. Figure 5 shows two types of intentionally caused changes, which is newly added space and added furniture in existing space. Figure 5(a) is an added seminar room which can be seen in the left part of the figure 6(b). Additionally, chairs were added in figure 5(b) which were located in middle of the corridor as shown in figure 6(b). Figure 6 shows the map where high intensity values are represented bright.

To build the second map, consecutive goal points were manually selected among the junctions from the skeletonization result of pre-constructed map. Figure 7(a) shows the skeletonized result, and red dots in figure 7(b) shows the path consists of manually selected goals.

3.2 Analysis System Experiment

3.2.1 Change Detection

Change detection between two maps were processed based on the Hadoop operation layer. The Hadoop cluster was configured with 8 nodes of the same capacity, i.e. Intel Core i5-2300 2.80GHz*4, 16GB memory.

Figure 8 shows the two maps and change detection result, using the web User Interface (UI) based on Hadoop platform. Detail explanation for the WebUI will be in our future paper. The red and green part represents the first and second map respectively. Blue dots are the parts which have been detected as a change. Developed platform can simply upload and overlay different point clouds and visualize them. The detailed description for the change detection algorithm is introduced in section 3.3.

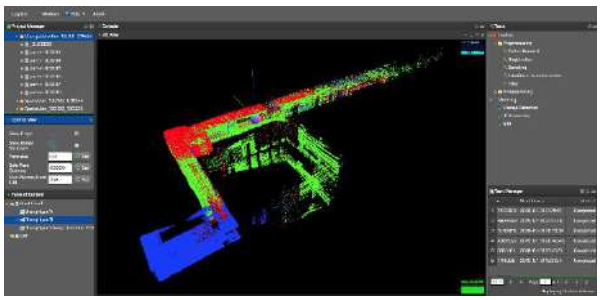

Figure 8. Change detection result in webUI

3.2.2 Semantic Mapping

For training the model for point cloud segmentation for semantic scene labeling, the Stanford Large-Scale 3D Indoor Spaces Dataset (S3DIS) [34] was used. The dataset was acquired using Matterport scanners in 6 areas for 271 rooms. 13 classes were annotated to each point. The model was trained using S3DIS from area 1-5 and tested using area 6. The overall per-point accuracy of the trained segmentation model was 83.4%. Per-point accuracy compares the predicted label and real label for each point.

Trained model was implemented to the map which was detected as a change between the first and second map from mapping system. To evaluate the accuracy of the semantic segmentation result, annotations were manually assigned to each point in the map. Figure 9 shows the semantic segmentation result for seminar room.

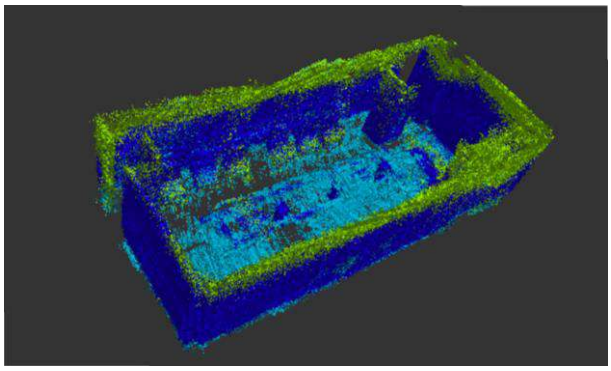

Figure 9. Semantic mapping result (point cloud)

Table 1. Semantic mapping accuracy

Overall accuracy	72.76%
classes	IoU
Ceiling	0.502
Wall	0.721
Floor	0.527
Door	0.050
Chair	0.000
Table	0.000

Overall per-point accuracy for experimental data was 72.76%. IoU in Table 1 stands for Intersection over Union, which is calculated by equation (1).

$$IoU_i = \frac{TP_i}{FP_i + FN_i + TP_i} \quad (1)$$

Where TP is the true positives FP is the false positives FN is the false negatives and i stands for each class such as ceilings, wall etc.

In figure 9, ceiling points were colored in deep green, wall points in blue, floor points in sky blue and doors in pink but not visible in the figure. As listed in table 1, table and chairs were not detected. Firstly, the top surface of the table was not collected enough in our data, since the height of the table top and the sensor was similar. Secondly, there were too many sensor noise for chair data. Compared to the S3DIS training dataset, the data acquired from our mapping system contains more noise since it was acquired while moving through the environment and no additional process were conducted after acquiring. To segment the movable objects, such as table, chair, sofa, bookcase and boards, further improvements are necessary for the mapping system.

3.3 Hadoop Platform

To optimize the storage layer in the Hadoop platform, Sort-Tile-Recursive (STR) algorithm [35] was applied to construct a global index. STR groups nearby points in each minimum bounding rectangle (MBR) which does not exceed 128MB. After constructing a global index, an Octree local index is also implemented on each block.

Based on the storage layer, change detection was tested for the operation. Change detection is based on a soft-join algorithm which is an application of point-to-point change detection in a distributed system (Figure 10).

The interactive layer was developed based on web UI. Interface provides simple access to users and visualizes massive point cloud data directly from Hadoop, which is useful for analytical processes.

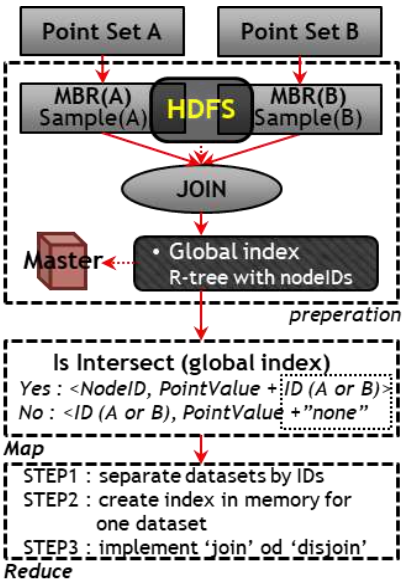

Figure 10. Change detection on Hadoop platform

4 Conclusion

An integrated framework for processing massive point cloud data was introduced in this research. It is

consisting of three main parts: mapping system; analysis system; and Hadoop platform, for the integrated framework developed as a prototype. However, this comprehensive system is a pioneer work related to massive point cloud data producing and processing. Future works for this prototype version will be focused on each system. For mapping system, additional sensors which can provide more information, should be implemented. Also, navigation algorithms will be improved for fully automated system. For analysis system, change detection process need to be focus on algorithm perspective, since it is now focused managing massive point cloud data. Applied semantic mapping process will also be included in the process more practically.

Abstract –

Large plant construction has numerous works, and the proportion of hoisting operations in the total construction work is high. In the hoisting operations, many things should be considered to keep the operations safe, and the work steps of the hoisting operations are planned by considering them. However, it is difficult for novice construction workers to understand the work steps with conventional two-dimensional drawings. Thus, to have those workers understand it well, we developed the hoisting-operation simulator considering the physical behavior of a load in conjunction with 3D viewer and physics engine. The simulator can visualize the work steps as three-dimensional animation. Moreover, by associating the simulator with mixed reality technology, we developed the system superimposing the 3D animation on reality space via head mount display. Experiments verify that the 3D animation of a load moves with the vibration due to the inertial force and that the 3D animation generated by the simulator is superimposed in the work site.

Simulator; Mixed reality; three-dimensional measurement

1 Introduction

Large plant construction has numerous works, and in particular, the proportion of hoisting operations in the total construction work is high. In the hoisting operations, many things should be considered to keep the operations safe. When a load is hoisted in a narrow work site, the clearance between the load and the surrounding equipment should be considered. In addition, considering the forces of each lifting point (i.e., the placement of lifting tools) is also important. According to those information, the work steps of the hoisting operations are planned. In conventional planning, work steps were determined with two-dimensional drawings. However, novice construction workers take time to understand the details in the 2D drawings. In fact, the proportion of the novice construction workers in the total workers increases due to the decrease of skilled construction workers. For the reason, it is imperative to develop the system that make the novice construction workers understand the work steps of hoisting operations.

In recent years, some examples of using three-dimensional design software and 3D viewer have been reported to make construction workers understand their works. In particular, Building Information Modeling (BIM) associating information of design, construction and maintenance with the 3D model of buildings is used to various construction works [1]. As examples of recent BIM, Zhang et al. developed safety checking platform that detects the opening in a 3D model and automatically places guardrails for preventing fall-related accidents [2]. Sugimoto et al. developed a simulation system for quantitatively evaluating the validity of crane-deployment plans by integrating 3D models and a time dimension [3].

Moreover, Augmented Reality (AR) and Mixed Reality (MR) (i.e., a technology superimposing computer-generated objects on a reality space) has been promoted to use in construction works. Singh et al. indicated that AR has the important role in automating the site layout planning on construction projects [4]. Yeh et al. proposed a wearable device that can project the construction drawings and related information to on-site space [5]. Riera et al. reported the implementation and evaluation of an AR application to the education of building engineering [6]. On the other hand, as examples of recent MR, Ammari and Hammad developed a BIM-based system to facilitate on-site data collection and to support inspectors in evaluating building elements via MR [7]. Chalhoub and Ayer reported that using MR reduced the time required to understand the design of electrical conduit and led to fewer errors during the assembly process as compared to using traditional 2D drawings [8].

As above, many BIM and AR/MR technologies have been developed in order to make construction workers

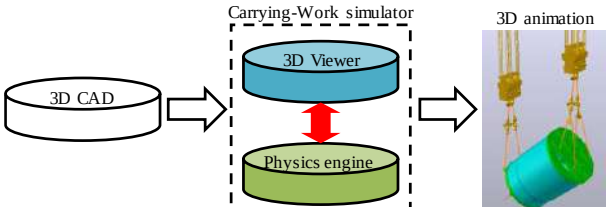

Figure 1. System flowchart of the animation application

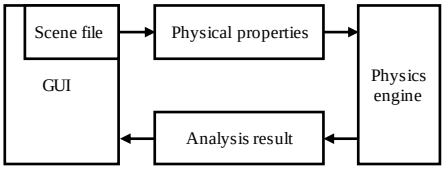

Figure 2. System diagram of the 3D viewer and the physics engine

understand their works. However, Most of them are not specialized in hoisting operations. Specifically, the physical behavior such as the vibration of a lifted load are not considered in the conventional BIM and a computer-generated lifted load including the physical behavior are not superimposed in conventional AR/MR. Hence, we have developed applications focusing on hoisting operations.. The features of the applications are as follows.

1) It creates 3D animations considering the physical behavior of a lifted load in conjunction with 3D viewers and physics engines.

2) It calculates forces applied to lifting points to define the position of lifting points and lifting tools.

Furthermore, we devised a system associating the above applications with MR technology. The features of this system are as follows.

3) It superimposes the 3D animation created by 1) to the reality space.

This paper is structured as follows. Chapter 2 gives the overview and method diagram of 1) and 2). Chapter 3 explains the overview and method diagram of 3). Chapter 4 presents the results of experiments to verify some proposed applications and systems. Finally, Chapter 5 concludes the paper.

2 Applications for Hoisting Operations

2.1 Animation Application Considering the Physical Behavior of a Lifted Load

In order to plan the hoisting operations for a lifted load considering physical behavior, we have developed the application that cooperates physics engines with by using the Application Programming Interface (API) of 3D viewers. Figure 1 shows the system flowchart of the application. Herein, this application is Hoisting

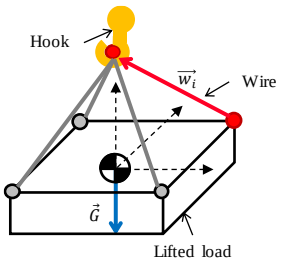

Figure 3. Configuration diagram of multi-point

Operation simulator (HO simulator).

First, the 3D model of a lifted load is made by 3D CAD. In order to perform the physical calculation on the 3D viewers, the center of gravity (the pink cube in Fig. 1) and the lifting points (the orange cube in Fig. 1) are incorporated in the 3D model.

Next, the 3D hoisting-operation animation is generated by using physics engines. Figure 2 shows the system diagram of the 3D viewer and the physics engine. The scene file is loaded into the 3D viewer's graphical user interface (GUI). Then, physical properties (e.g., the mass of each element in the model, friction coefficient and restitution coefficient) and the constraint condition are defined in the scene file. The defined file is handed over to the physics engine, and the analysis result is feedback to the GUI. These systems make it possible to generate the 3D animation considering the physical behavior and the planning of hoisting operation is performed more efficiently.

2.2 Force-Calculation Algorithm of Each Lifting Point

In the hoisting operation of large equipment into a work site, "multi-point lifting" is often used. The multi-point lifting is the method that carries a lifted load with many lifting tools. By using the multi-point lifting, the forces of lifting tools decrease and the attitude of the lifted load is more stable than single-point lifting. When using this method, the calculation of accurate forces of each lifting point and the selection of proper lifting tools are important.

Figure 3 shows the configuration diagram of multi-point lifting. Herein, F_i is the force of the lifting point, $\overrightarrow{w_i}$ is the three-dimensional vector from the lifting point to the hook, m is the mass of the lifted load, and g is the gravitational acceleration. The number i is numbered from No. 1 to No. n counterclockwise. The equation of motion of Fig. 3 is given as

$$[\overrightarrow{w_1} \quad \cdots \quad \overrightarrow{w_n}] \cdot [F_1 \quad \cdots \quad F_n]^T = [0 \quad 0 \quad mg]^T \tag{1}$$

$$\Rightarrow \vec{W} \cdot \vec{F} = \vec{G},$$

where the size of $\vec{W}$ is 3 × n, the size of $\vec{G}$ is 3 × 1, and

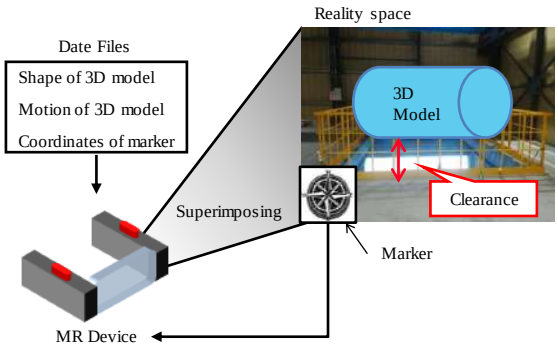

Figure 4. System diagram to superimpose 3D animations

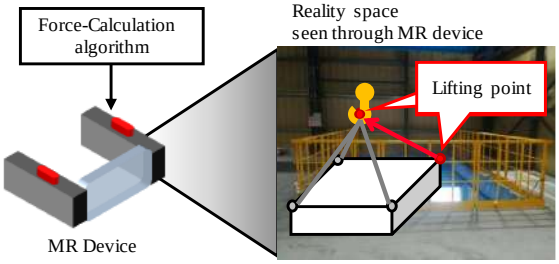

Figure 5. System diagram to calculate the forces of each lifting point

the size of $\vec{F}$ is 1 × n. Thus, when n is larger than 3, Eq. (1) is defined as an overdetermined equation system and general physics engines cannot calculate solutions accurately.

Therefore, we developed an algorithm that can calculate the forces of each lifting point even equations are overdetermined. Herein, this application is the Force-Calculation algorithm (FC algorithm). In the algorithm, a redundant equation is solved by regarding when the sum of root square of $\vec{F}$ is the minimum as the solution of Eq. (1). The solution of Eq. (1) is derived as

$$\vec{F} = \vec{W}^T \cdot \left(\vec{W} \cdot \vec{W}^T\right)^{-1} \cdot \vec{G} \quad (2)$$

By Eq. (2), the forces of each lifting point in the multi-point lifting are calculated.

3 System Combining the Applications with MR Technology

As noted in Chapter 2, the HO simulator can generate 3D hoisting operations animations. However, it is desirable to explain how the hoisting operations is performed at a work site to managers and workers in order for them to appreciate the hoisting operation. In addition, the 3D animations are likely to interfere with the equipment in the plant because the work site does not always correspond with a map of that. Taking these matters into consideration, the application that can display the 3D animations in realty space is indispensable. Thus, the system that superimposes 3D animation on reality space by utilizing Mixed Reality (MR) technology is developed. Figure 4 shows the diagram of the proposed system.

First, the shape date of the 3D model, the motion date of the 3D animation generated by the HO simulator, and the coordinate date of a two-dimension marker model on the 3D viewer are stored in a HMD.

Next, a marker is set at the coordinate position defined in the 3D viewer. The marker is photographed by the RGB camera mounted on the HMD, and is recognized in the device. The initial position and direction to superimpose the 3D animation is defined. After recognizing the marker, the position of HMD itself in the reality space is defined by using the image data acquired by the monocular camera, and the animation is accurately superimposed according to the relative position between the marker and the device itself. At the same time, the surrounding environment seen through the HMD is meshed. Therefore, the 3D animation can be superimposed at an initial position in the reality space even a HMD wearer moves in the reality space. Moreover, in order to review the same scene as necessary, the system supports rewind, temporary stop, and frame-by-frame playback (rewind). Furthermore, the system supports measuring the distance between the 3D animation and the surrounding object (e.g., floor surface and wall) in the real space since the three-dimensional reality space where the HMD exists is meshed.

In addition, by combining the FC algorithm in Section 2.2 with the MR technology, the system that grasp the forces of each lifting point in a work site can be realized as shown in figure 5. Since the distance from a lifting point to a hook can be measured, the vector $\overrightarrow{w_i}$ is determined. Therefore, the forces are calculated by the equations (1) and (2).

4 Verification Testing

4.1 Verification of Animation Application and Superimposition System

Experiments were performed to verify the HO simulator and the superimposition system. Figure 6 shows a 3D work site model of the experiments. The beam (length: 8.0 m, weight: 1.8 t) was lifted by an overhead crane and carried from the first floor to the second floor through the aperture (dimension: 6.0 m×4.0 m). The beam and the overhead crane were connected by chain blocks and the attitude of the beam can be arbitrarily changed by hoisting the chain blocks. In the carrying experiments, the following things should be considered.

1) The attitude and the carrying path of the beam for

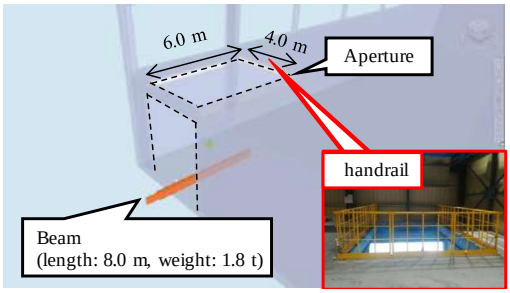

Figure 6. 3D work site model of the experiments

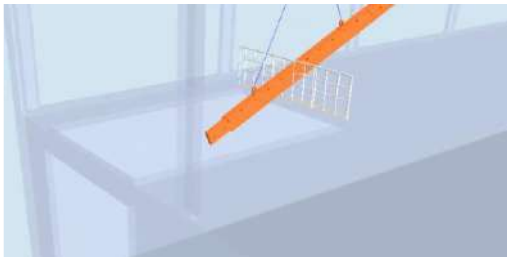

Figure 7. One scene cut out from the 3D animation

Fig. 8 3D animation superimposed on the work site

it to pass through the narrow aperture.

2) The clearance between the handrail (dimension: 4.0 m×1.3 m) around the aperture and the beam.

3) The collision between the second floor and the beam due to the vibration of the beam while carrying.

In order to examine these matters, the hoisting operations was planned with the HO simulator by using a beam model and the work site model. In addition, the 3D animation of the work was superimposed on the work site. Herein, in order to check the superimposed animation either on the 1st floor or the 2nd floor, markers were set at the positions indicated by the red letters in Fig. 6.

Figure 7 shows one scene cut out from the 3D animation. The 3D animation shows that the beam moves with the vibration due to the inertial force. Moreover, the 3D animation also shows that the magnitude of the vibration is changed by the influence of the length of the chain block. By realizing this vibration, checking the collision between the beam and the second floor is performed more realistically.

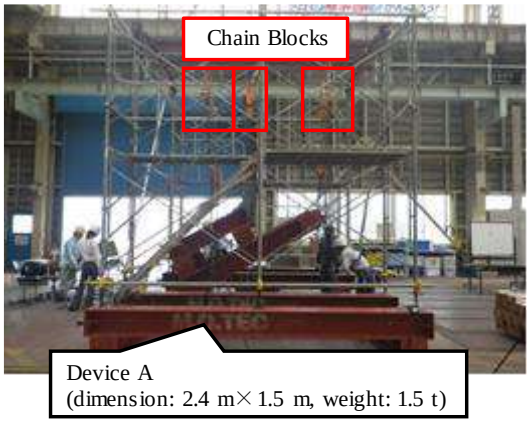

Figure 9. Equipment for the verification experiment of the Force-Calculation

The result of superimposing the 3D animation on the work site is shown in Figure 8. The RGB camera of the HMD successfully authenticated the marker and the 3D model of the beam is superimposed on the 1st floor. Then, it was confirmed that the 3D animation was superimposed at the initial position even when the HMD wearer moved due to the self-localization function of the HMD. Also, the same motion as the motion created on the HO simulator was superimposed in the work site.

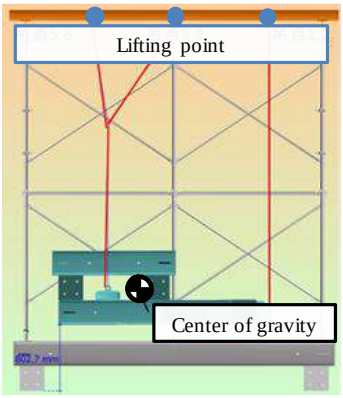
4.2 Verification of Force-Calculation Algorithm

An equipment for a verification experiment is shown in Figure 9. The attitude of a device A (dimension: 2.4 m ×1.5 m, weight: 1.5 t) was changed by operating the length of six chain blocks. The angle between the bottom surface of the device A and the ground surface was changed from 0 degree to 60 degree. Forces of each lifting point were measured with load cells (i.e. total number of load cells is 6) and the angle was measured with a digital angle sensor attached on the bottom surface of the device A. The measured results were compared with analyzed results from the algorithm in Section 2.2. The analysis was conducted under same conditions as the ones in the experiment.

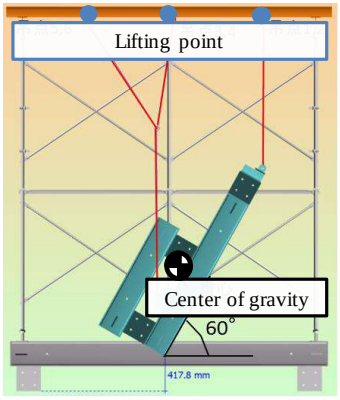
Figure 10 is a side view of the device A at 0 degree and 60 degree, and Table 1 and 2 show measured results and analyzed results under each degree. Table 1 and 2 also include relative errors based on the analysis values. The difference between the measured results and the analyzed results is ± 10% or less at each hanging point. Therefore, the effectiveness of the algorithm is verified.

5 Conclusion

In order to improve secure the safety of hoisting



1) 0 degree.



2) 60 degree.

Figure 10. Attitude of a device A at each degree

operations, the paper proposed an application for planning a hoisting operations. Furthermore, in order to have construction workers understand the plan of hoisting operations, the paper proposed a system associating the applications with MR technology. From the results of verification testing, we got the following conclusion.

1) The application that creates 3D animations considering the physical behavior of a lifted load was developed. The application was realized by cooperating physics engines with Application Programming Interface (API) of 3D viewers. The application make it easy to check the clearance between a lifted load and the equipment in a plant and to plan an appropriate hoisting operation procedure.

2) The system that superimposes 3D animations to reality space was developed. The system was realized by using MR HMD that includes many sensors. The system make it possible to predict the dangerousness of a hoisting operations at a work site.

3) The application that calculates forces applied to each lifting point was developed. The application can calculate the forces of each lifting point even a simultaneous equation is redundant. The application make it easy to define the position of each lifting point and lifting tools.

Table 1. Comparison of measured forces and calculated forces at 0 degree

Number of Lifting point	Measured Force [N]	Calculated Force [N]	Error [%]
1	1200	1300	8
2	1200	1300	8
3	205	220	7
4	205	220	7
5	5200	5030	3
6	5200	5030	3

Table 2. Comparison of measured forces and calculated forces at 60 degree

Number of Lifting point	Measured Force [N]	Calculated Force [N]	Error [%]
1	1175	1297	10
2	1175	1297	10
3	1550	1430	8
4	1550	1430	8
5	4000	3866	3
6	4000	3866	3

E-mail: rl508@cam.ac.uk, ib340@cam.ac.uk

Abstract –

The automation of digital twinning for existing bridges from point clouds has yet been solved. Whilst current methods can automatically detect bridge objects in points clouds in the form of labelled point clusters, the fitting of accurate 3D shapes to detected point clusters remains human dependent to a great extent. 95% of the total manual modelling time is spent on customizing shapes and fitting them to right locations. The challenges exhibited in the fitting step are due to the irregular geometries of existing bridges. Existing methods can fit geometric primitives such as cuboids and cylinders to point clusters, assuming bridges are made up of generic shapes. However, the produced geometric digital twins are too ideal to depict the real geometry of bridges. In addition, none of existing methods have evaluated the resulting models in terms of spatial accuracy with quantitative measurements. We tackle these challenges by delivering a slicing-based object fitting method that can generate the geometric digital twin of an existing reinforced concrete bridge from labelled point clusters. The accuracy of the generated models is gauged using distance-based metrics. Experiments on ten bridge point clouds indicate that the method achieves an average modelling distance smaller than that of the manual one (7.05 cm vs. 7.69 cm) (value included all challenging cases), and an average twinning time of 37.8 seconds. Compared to the laborious manual practice, this is much faster to twin bridge concrete elements.

1 Introduction

The United States (US) and United Kingdom (UK) spend a lot of money every year ($12.8 billion and £4 billion, respectively) to address deteriorating bridges and maintain their road networks. The reasons behind these massive costs are in part because bridge owners face a major challenge with structuring and managing the data needed for rapid maintenance and retrofit of their assets. The data available in Bridge Management Systems (BMS) does not meet the standard of information needed for sound decision-making. There is a need for at least 315,000 bridge inspections per annum across the US and the UK, given the typical two-year inspection cycle [1] [2]. Visual inspection is still the most common form of condition monitoring. The resulting condition information from visual assessment is then entered into a BMS, such as the AASHTOWare (US) or the NATS (UK). However, these BMSs are geared primarily to make system-wide prioritization decisions based on high-level comparisons of condition data. They do not assess the actual condition of a particular bridge component and of a particular location of the component. Having a Geometric Digital Twin (gDT) would be quite useful for this purpose as texture and damage information can then be properly integrated with the geometry at the component-level of the virtual 3D representation of a bridge. However, bridge owners today do not create such gDTs for existing bridges in the maintenance stage [3]. The following text reviews the current practice of digital twinning using point clouds, i.e. the process to acquire a gDT for an existing asset. This explains why the gDT implementation is so limited.

Major vendors such as Autodesk, Bentley, Trimble and ClearEdge3D, etc. provide the most advanced digital twinning software solutions. For example, ClearEdge3D can automatically extract pipes in a plant point cloud as well as specific standard shapes like valves and flanges from industry catalogues followed by fitting built-in models to them through a few clicks and manual adjustments. This means ClearEdge3D can realize a certain degree of automation. However, ClearEdge3D can only recognize and fit point cloud subparts with standardised shapes such as rectangular walls, pipes, valves, flanges, and steel beams, based on an industry specification table. Other commercial applications do not automate object detection nor arbitrary shape fitting. Fitting accurate 3D shapes to individual point clusters is challenging because the set

of allowable primitives is limited in most software applications. Reinforced concrete (RC) bridge components usually have complicated shapes, containing skews and imperfections, and cannot be simply fitted using idealized generic shapes. Modellers must manually create an accurate solid form to fit each point cluster as none of the existing software packages can do this automatically. Although modelling software such as Revit provides fine flexibilities that allow users to design a shape in a freeform manner (via Revit's

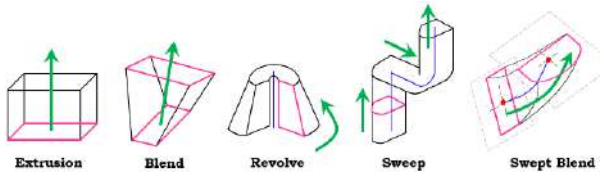

Figure 1. Forms available in Revit family

Family editor) (Figure 1), 95% of the total modelling time is spent on customizing shapes and fitting them to point clusters [4].

2 Research Background

Unlike building geometries which are defined in a grid system, real-world bridge geometries are more complex, which are defined with curved alignments, vertical elevations, and varying cross-sections. Extensive manual effort is required for practitioners to manually customize 3D accurate models to fit the underlying bridge components in arbitrary shapes in point clouds. We define "fitting" in this context as leveraging computer graphic techniques to form the 3D shape of a point cluster, a subpart of a point cloud. The 3D shape is approximate in the sense that it describes the geometry or the shape of a point cluster to produce its digital 3D representation to an acceptable quality based on the specific required level of detail.

2.1 Fitting Techniques

There is no universal solution to describe an object. How to choose a representation mainly depends on (1) the nature of the object being modelled, (2) the particular modelling technique that we choose to use, and (3) the application scenario where we bring the object to life. Existing shape representation methods can be categorized into four groups: Implicit Representation, Boundary Representation, Constructive Solid Geometry, and Swept Solid Representation. We review each of these in the following texts.

2.1.1 Implicit Representation

One solid modelling approach is based on the representation of 3D shapes using mathematical formulations, i.e. implicit functions. Common implicit surface definitions include, but are not limited to:

Table 1. Common implicit surfaces

Shape	Equation
Plane	$ax + by + cz = d$
Sphere	$x^2 + y^2 + z^2 = r^2$
Ellipsoid	$(\frac{x}{r_x})^2 + (\frac{y}{r_y})^2 + (\frac{z}{r_z})^2 = 1$

Given that only a very limited number of primitives can be represented exactly by algebraic formulations, implicit functions are of limited usefulness when modelling bridge objects. There is a trade-off between the accuracy of the representation and the bulk of information used for shapes that cannot be represented by mathematical formulations. We present three other basic modelling types: Boundary Representation (B-Rep), Constructive Solid Geometry (CSG), and Swept Solid Representation (SSR), in the following texts.

2.1.2 Boundary Representation (B-Rep)

Boundary Representation (B-Rep) is a method to describe shapes using their limits. The model represented using B-Rep is an explicit representation, as the object is represented by a complicated data structure giving information about each of the vertices, edges, and loops and how they are joined together to form the object. The geometry of a vertex is given by its (x, y, z) coordinates. Valero et al. [5] developed a method to yield B-Rep models for indoor planar objects (walls, ceilings and floors). Valero et al. [6] then upgraded their method to detect more objects in an indoor environment. Both Tessellated Surface Representation (TSR) and Polygon/Mesh Representation (PR/MR) can be considered as B-Rep types. A final model of TSR or PR/MR, is represented as a collection of connected surface elements. Oesau et al. [7] leveraged a graph-cut formulation to reconstruct a synthetic building point cloud into a mesh-based model. Representing an object using polygonal facets or mesh is the most popular representation in computer graphics. However, there are some problems with polygon mesh models: 1) Level of detail. High resolution could be unduly complex. An option is to reduce the polygon resolution without degrading the rendered presentation. But by how much? 2) Missing data, i.e. occlusions. Large occluded regions are hardly smoothed. Thus, PR/MP does not guarantee that a group of polygons facets can form a closed mesh model. 3) No sense of volume. It is difficult to extract geometric properties such as the radius of a cylindrical column on a mesh representation.

2.1.3 Constructive Solid Geometry (CSG)

Constructive Solid Geometry (CSG) is a high-level volumetric representation that works both as a shape representation and a record of how an object was built

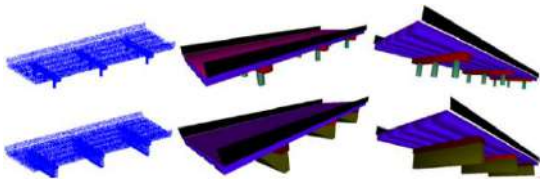

Figure 2. Fitted IFC entities in synthetic bridge point clouds (Zhang et al., 2014)

up [8]. The final shape can be represented as the combination of a set of elementary solid primitives, which follow a certain "logic". The primitives can be cuboids, cylinders, spheres, cones, and so on. When building a model, these primitives are created and positioned, then combined using Boolean set operators such as union, subtract, intersect and so on. Xiao and Furukawa [9] introduced an algorithm called "inverse CSG" to reconstruct large-scale indoor environments with a CSG representation consisting of volumetric primitives. However, this method uses only cuboids as volumetric primitives, assuming that they are the most common shapes found in indoor walls. Zhang et al. [10] (Figure 2) designed a classifier from surface primitive features to classify both infrastructure components (pier, beam, deck etc.) and 3D shape entities labels (cuboid, cylinder, sheet etc.) However, this method is tailored for idealized or simplified topology designs that do not consider the real geometries of bridge components. For example, a real sloped slab with varying vertical elevation cannot be simply modelled by a single sheet.

2.1.4 Swept Solid Representation (SSR)

Swept Solid Representation (SSR) or Extrusion is a representation of model which creates a 3D solid shape by sweeping a 2D profile that is completely enclosed by a contour line along a specific path. The sweeping line could be a straight line perpendicular to the contour surface, or it could be a curve in 3D space. Ochmann et al. [11] presented a method to reconstruct parametric 3D building models from indoor point clouds. Laefer & Truong-Hong [12] introduced a kernel-density-estimated-based method to identify the cross-sections of steel beams in point clouds. A cross-section is matched to one real steel type from a steel standard library and is extruded along the alignment.

2.2 Industry Foundation Classes (IFC)

2.2.1 IFC and MVD

IFC provides a set of definitions for all object element types encountered in the construction sector and a text-based structure for storing those definitions in a data file, based on an open data exchange standard, i.e. the IFC schema. It defines three basic components for modelling constructions: objects, relationships, and properties. An object is an abstract super-type entity, *IfcObject*, structured in an order hierarchy. An instance of the entity is used to represent a real-world object. The concept of relationships is the objectified relationship, *IfcRelationship*, relating different objects to each other, and the property definition, *IfcPropertyDefinition*, is the generalization of all characteristics and context information that can be added to an object. Ji et al. [13] introduced an extension to the IFC-Bridge format, providing a means of interchanging parametric bridge models. They describe in detail the necessary entities introduced to define parameters and capture dimensional and geometric constraints. Likewise, Amann et al. [14] suggested a generalized alignment model that can be extended with cross sections to describe a road body. This model can be further used for other product data models of linear infrastructure contractions, such as tunnels, roads, and bridges.

IFC is huge and defines a detailed schema of roughly 800 data types for representing building objects, their relationships, and associated lifecycle information. Specific uses of IFC have been narrowed to smaller subsets using a fraction of the data definitions, called Model View Definitions (MVD). The SeeBridge research team compiled an Information Delivery Manual (IDM) [16] to ensure that the final bridge DT would be sufficiently semantically meaningful to provide most of the information needed for subsequent bridge repair, retrofit and rebuild work.

2.2.2 IFC Geometric Representation

The section represents the most important IFC geometry representations. According to Borrmann et al. [15], all geometry representations in IFC data model can be grouped into four classes: Bounding Boxes, Curves, Surface models, and Solid models.

Specifically, bounding Boxes can be represented using *IfcBoundingBox*. Bounding Boxes are highly simplified geometric representation for 3D objects that are usually used as placeholders. *IfcBoundingBox* is defined by a placement corner point and dimensions of the three sides as a cuboid. *IfcCurve* and its subclasses *IfcBoundedCurve*, *IfcLine*, and *IfcConic* can be used to model line objects. Freeform curved edges (i.e. splines) and curved surfaces are required to model complex geometries. Surface models are used to represent composite surfaces comprised of sub-surfaces. They can be curved surfaces, such as NURBS surfaces or flat surfaces, such as mesh. *IfcTriangulatedFaceSet* can be used to represent the tessellated surfaces, i.e. polygons with an arbitrary number of edges, or triangular mesh. TSR cannot represent curved surfaces ideally but approximate them into triangular facets. In this case, the curved surface can be described using a finer mesh size, if accuracy is a concern. Specifically, *IfcBSplineSurface* can be used for representing curved surfaces. One

classic way to generate 3D objects as solid models is through CSG. *IfcCsgPrimitive3D* and its subclasses such as *IfcBlock*, *IfcRightCircularCylinder*, *IfcSphere*, and so on can be used. However, the use of CSG is very limited due to the fact that the use of primitives is very restrictive. By contrast, SSR is widely used for creating 3D objects in IFC. Possible representations include but not limited to the classes summarized in the following. In general, IfcSweptAreaSolid and its subclasses *IfcExtrudedAreaSolid*, *IfcRevolvedAreaSolid*, *IfcFixedReferenceSweptAreaSolid*, and IfcSurfaceCurveSwptAreaSolid can be used to present extruded solids. A closed profile *IfcArbitraryClosedProfileDef* is necessary for this representation. When using *IfcExtrudedAreaSolid*, the ExtrudedDirection is defined so that *IfcArbitraryClosedProfileDef* can be extruded along the direction. When using *IfcRevolvedAreaSolid*, both ExtrudedDirection and axis are defined so that *IfcArbitraryClosedProfileDef* can rotate around the axis up to a given angle. Then, *IfcFixedReferenceSweptAreaSolid* allows the extrusion to be done along any curve in space through the attribute Directrix. That is to say, the profile is extruded along a specific axis defined by the attribute FixedReference. By contrast, *IfcSectionedSpine* and *IfcSweptDiskSolid* are two representations working in a different but similar way. Detailed descriptions can be found in [15].

Among existing 3D object fitting work, almost all methods are used for generating building or industrial elements, such as walls, ceilings, floors, and standardized industrial elements. These objects are simply represented as extruded planes elements, cuboids, cylinders, and extruded steel beams. The gDT generation for existing RC bridges is almost missing in the literature. The problem of fitting 3D solid models in IFC format to real bridge point clusters has yet to be addressed. No effective method can reconstruct bridge point clusters into 3D IFC objects. In addition, no standardized metric is available for the quantitative evaluation of a gDT.

3 Proposed Method

3.1 Scope

Our method focuses on four types of bridge components: slab, pier, pier cap, and girder, in typical RC slab and beam-slab bridges. These two types of RC bridges represent 73% existing and 86% planned future bridges in the UK. These four types of components represent the most important and the most detectable structural components in the two types of bridges.

3.2 Overview

A definition of the level of detail (LOD) for gDT generation of existing infrastructure is missing in the literature. We use the LOD specification suggested by BIMForum as guidance. Table 2 illustrates an example of the interpretation of the LOD for a highway bridge component: a concrete precast girder.

The inputs of the proposed method are the four types of labelled point cluster. The outputs are two IFC files, containing various *IfcObjects* making up a bridge gDT and corresponding to two different LOD: LOD 200 and LOD 250—300. We define the LOD 250 as a LOD that is higher than LOD 200 but may not necessarily totally reach LOD 300. Figure 3 illustrates the workflow of the proposed method, which consists of two major steps: Step 1, geometric feature extraction of point clusters; Step 2, *IfcObjects* fitting to the extracted features. We use the MVD proposed by Sacks et al. [16], which proposes a binding to the IFC4 Add2 standard for exchanging bridge DTs.

3.3 LOD 200 gDT generation

We use TSR to create the Oriented Bounding Box (OBB) for each point cluster. The reason to choose TSR is because the OBB of a point set is a parallelepiped of 12 edges, 8 vertices and 6 faces. TSR is an explicit way to present an OBB. The parallelepiped geometry can be represented using the tessellated geometry model through *IfcShapeRepresentation*, expressing it as a triangulated tessellation. The coordinates of each vertex are provided by an index into an ordered list of Cartesian points *IfcCartesianPointList3D*. We introduce the property set *Pset_BoundingBoxProperties*, in which the method adds the attributes such as the length, width, and height of each OBB and composes them into an *IfcPropertyset*.

Table 2. LOD specification for highway bridge precast structural girder

LOD	Interpretation	Schema
200	Elements are generic placeholders. Any information derived from LOD 200 elements must be considered approximate.	
300	The quantity, size, shape, location, and orientation of the element as designed can be measured directly from the model.	

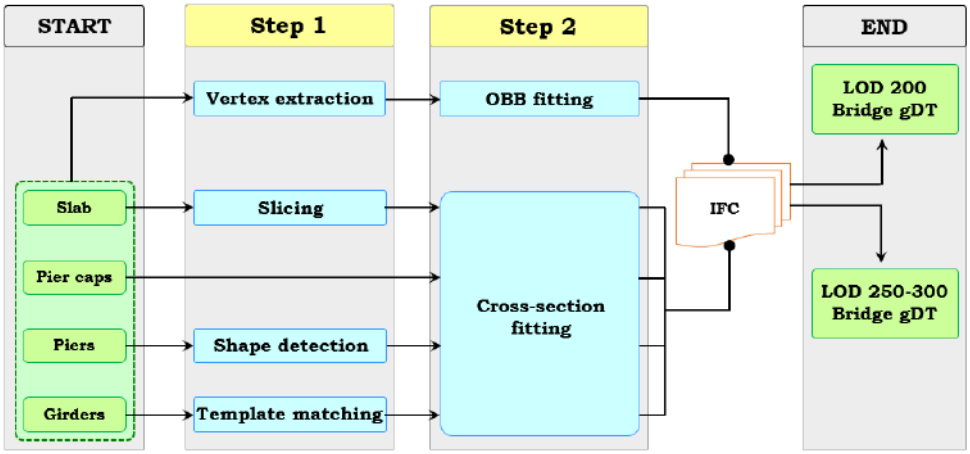

Figure 3. Workflow of the proposed IFC object fitting method

3.4 LOD 250 – 300 gDT Generation

Solid extrusions are preferred wherever possible if the cross-section in each slice model is deemed to be constant.

3.4.1 Slab – *IfcSlab*

Real-world bridges are neither straight nor flat. To circumvent or be compatible with the existing constraints of road geometry, many highway bridges carrying roads are on a curved alignment and the supporting structure follows that curved alignment. We use a similar but not identical slicing method to that proposed in [17] to slice the deck slab into J slices. The slicing does not take a parallel pattern but is rather oriented along the normal direction of the slab curved alignment. According to Kobryń [18], a circular curve is assumed to be the horizontal alignment of bridges investigated in this research. We then project the deck slab point cluster onto the XY-plane followed by fitting it with a unique second-degree polynomial to derive the parabola of the deck slab alignment. Next, we compute the tangent, slope, and normal at each interpolant of the parabola. The deck slab is then segmented along the direction of the normal of each interpolated position into J slices (Figure 4).

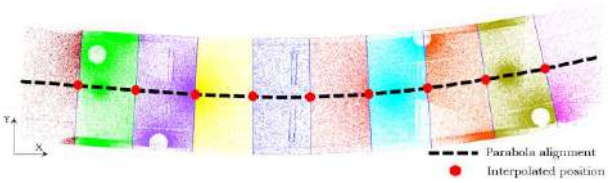

Figure 4. Deck slab slicing

Then, the problem of modelling the whole deck slab is transformed into modelling each straight slab slice assuming each slice is straight along the tangent direction and the cross-section of each slice is constant. For each slice, we rotate the slice around the Z-axis:

$$\begin{bmatrix} x' \\ y' \\ z' \\ 1 \end{bmatrix} = \begin{bmatrix} \cos(-\varphi_j) & \sin(-\varphi_j) & 0 & 0 \\ -\sin(-\varphi_j) & \cos(-\varphi_j) & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \cdot \begin{bmatrix} x \\ y \\ z \\ 1 \end{bmatrix} \quad (1)$$

where the rotated angle φ_j is the angle between the normal direction of the alignment of the slice j and the global Y-axis. The updated points (x', y', z') are used to define the cross-section of each slice and descripted using a 2D α-shape. Each hull of the α-shape is represented as a 2D Cartesian point *IfcCartesianPoint*. A profile *IfcArbitraryClosedProfileDef* is used and the slab slice geometry is then represented using an extruded geometry model through *IfcExtrudedAreaSolid* and *IfcShapeRepresentation*, expressing it as a Swept Solid. The ExtrudedDirection is defined using the tangent direction of the mid-point of each slice. We introduce the property set *Pset_SlabSliceProperties*, in which the method can add the attributes of each slab slice.

3.4.2 Pier Cap – *IfcBeam*

Similar to how the slab slice is extruded, when modelling a pier cap point cluster, we project its points onto the XY-plane. We then use 2D α-shape to describe the projected contour such that each hull is stored in a 2D Cartesian point *IfcCartesianPoint* followed by mapping the contour with a list of *IfcPolyLine* objects. Like the slab slice, a pier cap is also represented as a Swept Solid through *IfcArbitraryClosedProfileDef* and *IfcExtrudedAreaSolid*.

3.4.3 Pier – *IfcColumn*

Piers can take many configurations. The shape of a pier is defined by the shape of its cross-section. To

simplify the problem, we group pier shapes into 3 classes: Shape 1 – Circular, Shape 2 – Quadrilateral, and Shape 3 – Others. Unlike simplified scenarios and synthetic data, real objects embedded in point clouds are similar to hand-drawn geometric shapes that usually contain imperfections or distortions. To tackle this challenge and identify the cross-section shape of a pier, we use a fuzzy-logic-based shape descriptor. We project a pier point cluster points onto the global XY-plane followed by calculating the perimeter of the projected points (denoted P_{ch}) and the bounded area (denoted A_{ch}). We then compute the area of the enclosing rectangle, i.e., the 2D oriented-bounding-box (denoted A_{er}) and the area of their largest-quadrilateral (denoted A_{lq}). if ${P_{ch}}^2/A_{ch} \cong 4\pi$, then the cross-section is a circle; else if $A_{ch}/A_{er} \cong A_{lq}/A_{er} \cong 1$, then the cross-section is a rectangle; Otherwise, the cross-section takes another shape. Similarly, cylindrical pier is represented using *IfcExtrudedAreaSolid* and *IfcShapeRepresentation*, expressing it as a Swept Solid. Attributes such as Position, Direction, Diameter, and Length. Then, stacked representation is used to approximate the overall pier shape through multiple slice models for quadrilateral and other piers (Figure 5).

Figure 5. An RC bridge point cloud (L) and the stacked representation (R)

3.4.4 Girder – *IfcBeam*

The girders studied in this research are assumed precast as the majority of existing and planned future RC slab and beam-slab bridges in the UK select precast elements. We suggest a template matching method to find the best-match girder type in existing precast bridge beam catalogues. We use three criteria to specify the girder type in each span: 1) Span length *sl*; 2) Girder bottom flange b_f; and 3) Web depth *d*.

We use the span length *sl* to narrow down a possible range of girder types. Then, the averaged girder flange b_f and the web depth *d*, computed using [17] can select a specific girder from the range of girders. Next, we store each of the cross-section feature point of the identified girder in *IfcCartesianPoint*. A 2D profile *IfcArbitraryClosedProfileDef* is used to describe the profile. Similarly, the girder is represented as a Swept Solid.

4 Experiments

4.1 Ground Truth Data and Results

We used the 10 bridge point clouds collected in [17] to conduct our experiments. The raw data is available at: http://doi.org/10.5281/zenodo.1233844. We also manually generated two sets of models *GT A* and *GT B* (Table 3), which serve as ground truth data:

GT A: The four types of bridge components in this set of models were represented using their tightest cuboids (average modelling time: 0.92 hours). They are used to compare against the automated generated LOD 200 gDTs.

GT B: The four types of bridge components in this set of models were represented within their precise dimensions (average modelling time: 27.6 hours). They are used to compare against the automated generated LOD 250-300 gDTs.

We implemented the proposed method on Gygax (https://github.com/ph463/Gygax/) as two different classes according to the suggested two different model resolution on a desktop computer (CPU: Intel Core i7-4790K 4.00GHz, Memory: 32GB, SSD: 500GB).

Table 4 demonstrates the results of the automated gDTs: LOD200 gDTs and LOD250-300 gDTs. Compared to manual modelling times, the average modelling time 10.2 seconds for LOD200 and 37.8 seconds for LOD 250-300, are trivial. We only demonstrate 4 bridge results due to limited space.

4.2 Evaluation

4.2.1 Evaluation of LOD 200 gDTs

We computed the volume and the centroid of each GT cuboids (gtBBox) Vol_{gt} and C_{gtBBox} and the automated ones Vol_{auto} and C_{autoBBox}. Denote E_{dc} and FVR are the Euclidean distance and false volume ratio between each C_{gtBBox} and the corresponding C_{autoBBox}.

$$\text{FVR} = \frac{|Vol_{auto} - Vol_{gt}|}{Vol_{gt}} \quad (2)$$

We also computed the point-to-point (P2P) distance, which is Euclidean distance between each vertex of the automated gDT and that of the GT one of each component of each bridge. The averaged $\overline{\text{P2P}}$ of all the 10 bridges was 23 cm (Table 5).

Table 5. Comparison of LOD 200 gDTs and *GT A*

	E_{dc} (m)	FVR (%)	P2P (m)
Bridge 1	0.06	17.6	0.23
Bridge 4	0.17	10.8	0.19
Bridge 7	0.23	24.1	0.35
Bridge 9	0.18	16.1	0.30

Table 3. Manual modelling *GT A* and *GT B*

	Bridge 1	***Bridge 4***	***Bridge 7***	***Bridge 9***
GT A				Time (h)	1.1	1.5	1.75	0.5
GT B				Time (h)	50.2	25.9	26.6	20.1

Table 4. LOD 200 gDTs & LOD 250 – 300 gDTs

	Bridge 1	***Bridge 4***	***Bridge 7***	***Bridge 9***
LOD200 gDT				Time (s)	10.1	9.5	8.2	10.0
LOD250 -300 gDT				Time (s)	25.5	58.1	31.1	37.3

4.2.2 Evaluation of LOD 250 – 300 gDTs

We used a cloud-to-cloud (C2C) distance evaluation to detect changes between *GT B* and the automated ones. To do so, we first converted the *GT B* and the automated gDTs into .obj files followed by random sampling dense points from the generated polygons. Then, both sampled bridge point clouds (denoted GT and Auto) were compared against the reference point cloud, which is each bridge's original point cloud (denoted Real). We followed a local distance strategy to compute a local model Q. A quadratic model is used to fit neighbouring points in the reference point cloud to a surface (radius=0.3m) so that the average local distance from a compared point cloud α to a reference point cloud β is:

$$\overline{\mathrm{dist}} = \frac{1}{n}\sum_{i=1}^{n} \min\{d(q_i, Q)\}, \quad (3)$$

where q_i is a point of the compared point cloud α that is not on the model Q. Then, the estimated C2C distance between the two clouds is the bigger one of the mutual $\overline{\mathrm{dist}}$:

$$\mathrm{C2C} = \max(\overline{\mathrm{dist}}_{\alpha/\beta}, \overline{\mathrm{dist}}_{\beta/\alpha}). \quad (4)$$

An automated gDT is deemed better modelled if its C2C (denoted $\mathrm{C2C_{Auto}}$) is smaller compared with that of the manual model (denoted $\mathrm{C2C_{GT}}$) and vice versa (Table 6).

5 Conclusions

This paper presents an object fitting method able to generate gDTs of existing RC bridges in IFC format, using the four types of point clusters making up the bridge. Compared to the manual modelling process, the proposed method was more consistent, less liable to human errors. The gDTs were evaluated using distance-based quantitative metrics. Most of the automatically generated gDTs were better than the manually generated ones in terms of spatial accuracy. The overall $\overline{\mathrm{C2C}}_{\mathrm{Auto}}$ of 10 bridges gDTs was 7.05 cm while the $\overline{\mathrm{C2C}}_{\mathrm{GT}}$ was 7.69 cm. This value was down to 5.6 cm for $\overline{\mathrm{C2C}}_{\mathrm{Auto}}$ while 7.0 cm for $\overline{\mathrm{C2C}}_{\mathrm{GT}}$, if we didn't take two large distances (*Bridge 7* & *9*) into account. Last, the modelling time was also drastically reduced.

Table 6. Comparison of C2C between *GT E* PCD and Auto PCD against Real PCD

Bridge 1		***Bridge 4***	
$C2C_{GT/Real}$	$C2C_{Auto/Real}$	$C2C_{GT/Real}$	$C2C_{Auto/Real}$
4.0 cm	4.3 cm	7.3 cm	9.4 cm
			Bridge 7		***Bridge 9***	
$C2C_{GT/Real}$	$C2C_{Auto/Real}$	$C2C_{Real/GT}$	$C2C_{Auto/Real}$
15.7 cm	12.5 cm	9.8 cm	5.6 cm

Abstract –

Indoor localization and navigation of unmanned aerial vehicles (UAVs) is a critical function for autonomous flight and automated visual inspection of construction elements in continuously changing construction environments. The key challenge for indoor localization and navigation is that the global positioning system (GPS) signal is not sufficiently reliable for state estimation. Having used the AprilTag markers for indoor localization, we showed a proof-of-concept that a camera-equipped UAV can be localized in a GPS-denied environment; however, the accuracy of the localization was inadequate in some situations. This study presents the implementation and performance assessment of an Extended Kalman Filter (EKF) for improving the estimation process of a previously developed indoor localization framework using AprilTag markers. An experimental set up is used to assess the performance of the updated estimation process in comparison to the previous state estimation method and the ground truth data. Results show that the state estimation and indoor localization are improved substantially using the EKF. To have a more robust estimation, we extract and fuse data from multiple tags. The framework can now be tested in real-world environments given that our continuous localization is sufficiently robust and reliable.

1 Introduction

Due to their capabilities, unmanned aerial vehicles (UAVs) are increasingly being employed for various purposes and in many industries, such as the construction industry. UAVs are able to function in unsafe and inaccessible locales that may be hazardous for humans. In addition, they provide maneuverability and perspective advantages over ground robotic platforms, which is an asset, particularly in multi-story buildings. A UAV can be equipped with various sensors to further enhance the data and insight acquisition. Thus, these features can enhance the collection of informative data in congested and dynamically changing construction environments. For instance, the inspection and monitoring of under-construction buildings [1], progress tracking and assessment [2] [3], site surveying [4], quality control [5], civil infrastructure condition assessment [6][7], and safety inspections [8] are among the broad applications of UAVs in the construction industry.

UAVs can be programmed such that they perform their tasks autonomously. To accomplish autonomous missions, the UAV must be able to navigate a collision-free path and be aware of its pose in the operating environment at any point in time. Autonomous robots in outdoor environments may take advantage of robust external sources of localization such as the Global Positioning System (GPS). However, GPS connectivity in highly congested urban areas with a dense distribution of high-rises (i.e., urban canyons) may be challenging even outdoors. Similarly, localization remains a real challenge in indoor environments.

1.1 Indoor Localization

A robust indoor localization system aims to continuously estimate the pose of one or more mobile agents in an indoor environment in real-time, given that the environment's map is available. Such a system has to not only be accurate, but also be financially, energy, space, and time efficient. It also needs to suitably cover the area. Several methods have been investigated to address this problem in the past decade. These state-of-the-art studies have mostly relied on localization systems based on radio-frequency identification (RFID) [9], ultra-wideband (UWB) [10][11], wireless local area networks (WLAN) [12], inertial measurement units (IMU) [13],

and machine vision [14]. In the construction sector particularly, RFID [15][16][17], UWB [18], IMU [19][20], and machine vision [21][22] are among the most commonly employed types of indoor localization systems.

However, not all the aforementioned systems may be suitable in the case of autonomous indoor flight during construction. For instance, due to the limited UWB signal communication range, dense network infrastructure may be needed. Metallic materials, such as piping and wall framing, may interfere with the radio frequency based systems including UWB [23] and RFID [24]. Non-line-of-sight (NLOS) propagation conditions may induce error in UWB [10], while IMU-based estimates may drift [19]. The most important concern in this regard, however, is insufficient localization accuracy of these systems [20] for autonomous UAV navigation. Although machine-vision-based localization methods such as motion tracking systems (e.g., Vicon systems) provide accurate estimates, they are an impractical solution for this application because they impose extra costs, logistics, complexity, and distraction to the construction site.

1.2 Visual Fiducial Markers

Visual fiducial markers, such as ARTag [25], AprilTag [26][27], and CalTag [28], are artificial landmarks consisting of patterns. They are designed to be easily recognized and robustly distinguished from one another and among other features in a natural scene when they are placed in an environment. Fiducial markers have been frequently used in augmented reality applications for camera pose estimation (e.g., ARTag [25]). AprilTag markers are passive square-shaped payload tags with an external black border and a binary internal code. Unlike QR (quick response) codes, AprilTag markers contain a small information payload. Therefore, they can be quickly detected and localized even when they are rotated or located in different lighting conditions. Indeed, AprilTag markers are two-dimensional barcodes that provide 6-DOF camera position estimation, and are cost-effective in that they can be printed on a standard printer [26]. AprilTag markers have also been found to be robust for indoor localization and object tracking in various mobile robotics applications [27]. AprilTag has different marker family types. The difference between the types are twofold: (1) the number of bits and (2) the minimum Hamming distance. The Hamming distance between two tags is defined as the number of positions at which the corresponding bits are different. For instance, an AprilTag of "Tagn^2hm" refers to an $n \times n$ array (n^2-bit) marker with a minimum Hamming distance of m between any two markers.

1.3 Extended Kalman Filter (EKF)

Since the position estimates and measurements are imperfect and prone to error, prediction and noise reduction algorithms are critical to enhancing these estimates. By minimizing the mean of the squared error, the Kalman filter [29] estimates the past, present, and even future state of a process using an efficient recursive approach [30]. However, since the Kalman filter (KF) is limited to linear systems, it is not able to solve non-linear localization problems. The EKF linearizes non-linear systems so that it can address non-linear localization problems [30][31].

1.4 Summary

In short, this paper presents the implementation of an EKF for improving the estimation module of the previously developed GPS-denied indoor localization framework using AprilTag markers [22]. In this study, it is shown that a probabilistic approach to the data fusion of multiple markers and the IMU using an EKF can substantially improve the estimation accuracy. Given that the 3D coordinates of the fiducial markers are also identified in the building information model (BIM), a camera-equipped UAV can recognize its pose relative to these artificial fiducial markers and then calculate its global location.

2 Overview of Prior Work

To develop a system for indoor localization of UAVs equipped with an onboard camera, the authors previously proposed a framework [22] using AprilTag markers. As illustrated in Figure 1, the calibration of the on-board camera is first undertaken to ensure that the measurements are accurate. The Robotics Operating System (ROS) package for camera calibration is used to estimate the camera parameters. Next, based on the mission plans and the critical locations that are supposed to be monitored by the UAV, the number and the corresponding location of tags are identified using the BIM model. Tags are then generated and the corresponding coordinates are assigned to them.

With the tags placed in the indoor construction environment, the UAV can be localized relative to the tags. Given that the global locations of the tags are available based on the BIM, the UAV's local coordinates can be translated to global coordinates. The authors reported the results of an experimental study designed to verify and validate the performance of the proposed framework. In this regard, the study investigated the impact of four critical parameters, namely, tag size, tag placement orientation, UAV distance from a single tag, and angle of view.

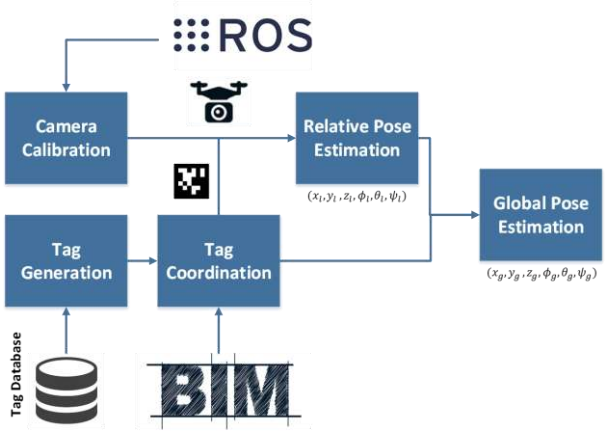

Figure 1. Indoor localization framework overview

That research also identified a number of factors that require further investigation to achieve a more robust indoor localization system. As all sensor measurements contain systematic and random errors, reducing or eliminating these errors is required to improve UAV pose estimation and reduce instability. It is intuitive that data from more sources of information can improve our measurements. Thus, to enhance the estimation process of the previously developed indoor localization framework [22], a standard extension of the KF [29] is used in this study.

In the previously developed method, the UAV used a single-tag detection algorithm. This algorithm only took measurements from a single designated tag at any given time. If this tag was not visible, the algorithm would estimate the UAV's location based solely on the less-reliable IMU measurements. In other words, the previously developed single-tag UAV localization method (hereafter the ST method) produced estimates based on only a single tag or the on-board IMU.

In the EKF method proposed in this work, however, the estimation process accounts for all available measurement data. It can be divided into two steps. The first step is the *prediction step*, which produces a predicted location based on the previous location and IMU data. The prediction is then updated in the *correction step*, where tag data is fused in to produce an overall estimate. This estimate is then used as the previous location during prediction in the next time step, and so on. By so doing, instead of switching back and forth between the IMU and the tag-based localization in different situations, we will combine the information from the IMU and all the visible tags. This multi-tag UAV localization method using EKF is hereafter called the MT method. This process will be investigated further in the next section.

3 The Extended Kalman Filter

Extensions of the KF are able to overcome the linearity limitation of the algorithm and enable the state estimation of nonlinear systems. Generally, the KF algorithm contains two steps: the prediction step and the correction step. In the prediction step, the current state ($\boldsymbol{x_k}$) is estimated based on the previous estimated state ($\boldsymbol{x_{k-1}}$) and the system inputs ($\boldsymbol{u_{k-1}}$) considering a random Gaussian noise ($\boldsymbol{w_{k-1}}$) when using a prediction model ($\boldsymbol{f}(.)$) (See Eq. 1). The estimates are then updated using the measurement model ($\boldsymbol{g}(.)$), which also has random Gaussian noise ($\boldsymbol{v}$). (See Eq. 2)

$$x_k = f(x_{k-1}, u_{k-1}, w_{k-1}) \quad (1)$$

$$y_k = g(x_k, v_k) \quad (2)$$

A simplified dynamic model is used in which the UAV is modeled as a rigid body double integrator system with discretization time step ΔT. An EKF is then employed to first fuse the captured data from the IMU and AprilTag markers and then estimate the UAV's desired state in terms of position, velocity, and orientation. Thus, the state vector that we intend to estimate is defined as $\boldsymbol{x} := [\boldsymbol{p}^T \quad \boldsymbol{v}^T \quad \boldsymbol{q}^T]^T$, where 3D vectors $\boldsymbol{p}, \boldsymbol{v}$ and quaternion $\boldsymbol{q}$ are representative of the UAV's position, velocity and orientation, respectively.

IMU measurements are treated as the input data for the prediction model, which is responsible for propagating the state from one time step $(k-1)$ to the next (k). The process noise of this step is modelled by independent zero-mean Gaussian distributions. The prediction step ends up with a *prior* estimate of $\boldsymbol{x}$, $\check{\boldsymbol{x}}_k$.

In the measurement model, because the position and orientation of all the tags are available, the relative position and orientation of the UAV with respect to all visible tags is measured at each time step *k*. The measurement noise is modeled as an independent zero-mean Gaussian distribution. Based on this model, the *prior* estimation $\check{\boldsymbol{x}}_k$ is updated. The final result of these two steps will be the *posterior* estimate of the state $\hat{\boldsymbol{x}}_k$. This algorithm is implemented based on the EKF ROS node, *ekf_localization_node*.

By so doing, we are able to continuously fuse data from multiple sources, namely, the on-board IMU and visible tags, providing a more robust system than the previous work.

4 Experimental Design and Setup

To study the MT method proposed in this study, an experimental setup is designed. AprilTag markers of type *36h11* are placed at six locations, which are also identified in the BIM (see Figure 2). Corresponding

coordinates are then easily extracted from the BIM. A Vicon motion capture system is employed as the ground truth to verify and validate the algorithm. By so doing, we are able to compare the results under varying experimental conditions using two methods (i.e., ST and MT). The UAV used in this study is a Parrot Bebop 2 in its default configuration and equipped with a camera and an onboard IMU. The overhead Vicon system is also used for control.

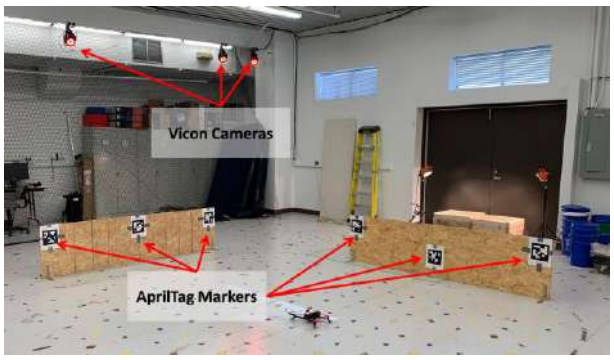

Figure 2. Experimental setup; six AprilTag markers with known coordinates, Parrot Bebop 2 UAV, and overhead Vicon camera system which tracks the motion of the UAV in the laboratory. The Vicon system is considered as the ground truth baseline in this study.

In these experiments, four trajectory scenarios are planned to investigate the dynamic performance of the proposed MT method.

1. *Straight line trajectory*. In the first scenario, a straight line trajectory is designed to investigate the impact of the distance from tags on the pose estimation accuracy. Although the MT method is able to fuse data from multiple sources, previous research [22] showed that the robustness of the tag detection process significantly drops when the distance increases. Thus, the whole pose estimation process potentially becomes more prone to noise and error. As a result, it is important to investigate the performance of the EKF in this situation. To do so, we run the planned scenario and assess the performance of these two methods relative to the ground truth Vicon measurement.

   As illustrated in Figure 3, the UAV starts its motion at a point 4.5m from panel B, which contains three tags. It moves 3m toward the panel at a rate of 0.86 m/s and finishes at a point 1.5m from the panel. In this scenario, all three tags on the panel B are used for the measurement process in the MT method. However, the middle tag is the only tag used in the ST method.

2. *Vertical line trajectory*. To investigate the impact of the angle of view on the MT method, a similar experimental setup is used, as shown in Figure 3. In this case, the UAV takes off from *O(0.0, 0.0, 0.0)* facing panel B, rises to the starting position of *Start(0.0, 0.5, 0.5)* and goes upward to *Finish(0.0, 0.5, 2.0).*

3. *Horizontal line trajectory*. To study the impact of the angle of view, the UAV takes off from *O(0.0, 0.0, 0.0)* facing panel B, and moves to its starting position of *Start(-1.5, 1.0 ,0.5).* It then goes sideward to *Finish(1.5, 1.0 ,0.5).* In this scenario, the ST method uses the nearest tag, and the MT method fuses pose data from of all the visible tags.

4. *A mixed trajectory*. Finally, a combination of the aforementioned trajectories is planned to provide insight into the overall performance of each method in more realistic circumstances. In this scenario, the UAV takes off from *O(0.0, 0.0, 0.0)* facing panel A (see Figure 3). The planned trajectory contains all of the other scenarios and a rotational motion.

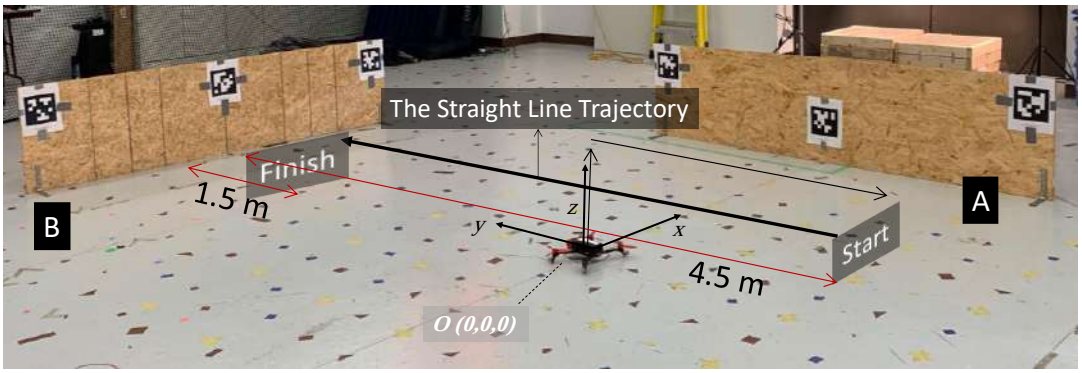

Figure 3. The experimental setup for scenario one; the performance of the methods are investigated at varying distances in the shown straight path. The UAV takes off from the *O(0.0, 0.0, 0.0)* while facing panel B. It flies its path from *Start(0.0, -1.5, 0.0) to Finish(0.0, 1.5, 0.0).*

5 Results and Discussion

The experimental scenarios are designed to evaluate the performance of the MT method in indoor localization of UAVs using AprilTag markers. The aim is to show that this approach makes the prior framework more reliable in real world ever-changing construction environments. To do so, the localization results of the MT and ST methods are compared to the ground truth system. To assess the pose estimation results, the root-mean-square error (RMSE) is used as a quantitative indicator of error reduction. Figures are provided to offer a visual insight of the estimation reliability and show the fluctuations and errors.

First, the impact of distance from tags is investigated while the UAV automatically flies based on the programmed scenario. Figure 4 illustrates in 2D the performance of the UAV in the first scenario. In this scenario, the UAV flies from *Start(0,-1.5,0.5)* to *Finish(0,1.5,0.5)*. The top and bottom graphs in Figure 4 show the performance of estimation using the MT and ST methods, respectively. The Vicon system, as a ground truth system, depicts the actual path taken by the UAV.

In both cases, localization accuracy increases as the UAV gets closer to the tags. However, the estimation error and fluctuation is significantly improved using the EKF in the MT method. In the ST method, where the EKF is not used, localization varies approximately -1m to +0.6m from ground truth whereas the EKF was able to reduce this variation to a range of -0.2m to +0.6m. Thus, it is clear that the MT estimation is smoother and converges toward the ground truth measurements more quickly and at a distance further from the tags. Therefore, it performs more reliably compared to the other method used in the previous study.

To better understand the multidimensional components of the errors, the Euclidean distance between the 3D positions estimated by two methods and the ground truth system also calculated. The results are shown in Figure 5. Here, the MT method performs not only considerably better than the ST method, but also robustly in distances less than 3 meters. Numerically, the RMSE values for the global position estimates using the ST and the MT methods are 0.35 m and 0.20 m respectively. This further supports the finding that MT significantly enhanced our estimations.

Although the proposed framework is not significantly sensitive to the changes in yaw angle and view angle [22], the second and third scenarios are tested to compare the methods' performances. Figure 6 (A) and (B) respectively compare the ground truth measurement of X value in the third scenario with ST and MT estimates. Figure 6 (A) and (B) show that the MT estimates are smoother and more reliable in comparison with the ST estimates.

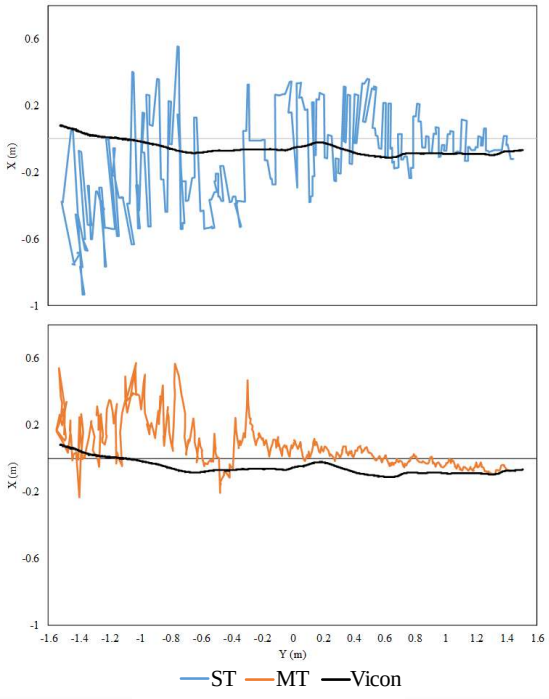

Figure 4. The plan view of the UAV's performance in Scenario 1 and the corresponding estimates: One-dimensional error in the pose estimation of the UAV while it decreases its distance from the tags.

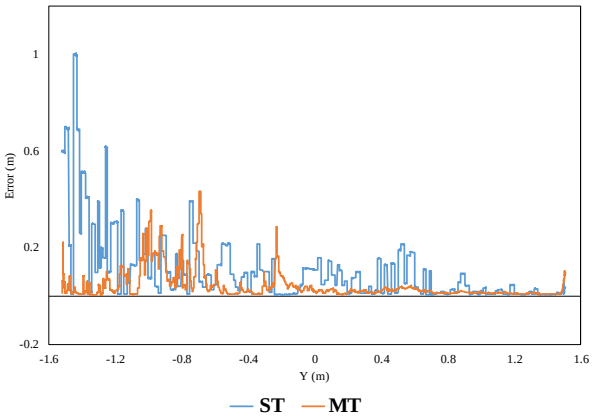

Figure 5. Position estimated error for the ST and the MT methods in Scenario 1

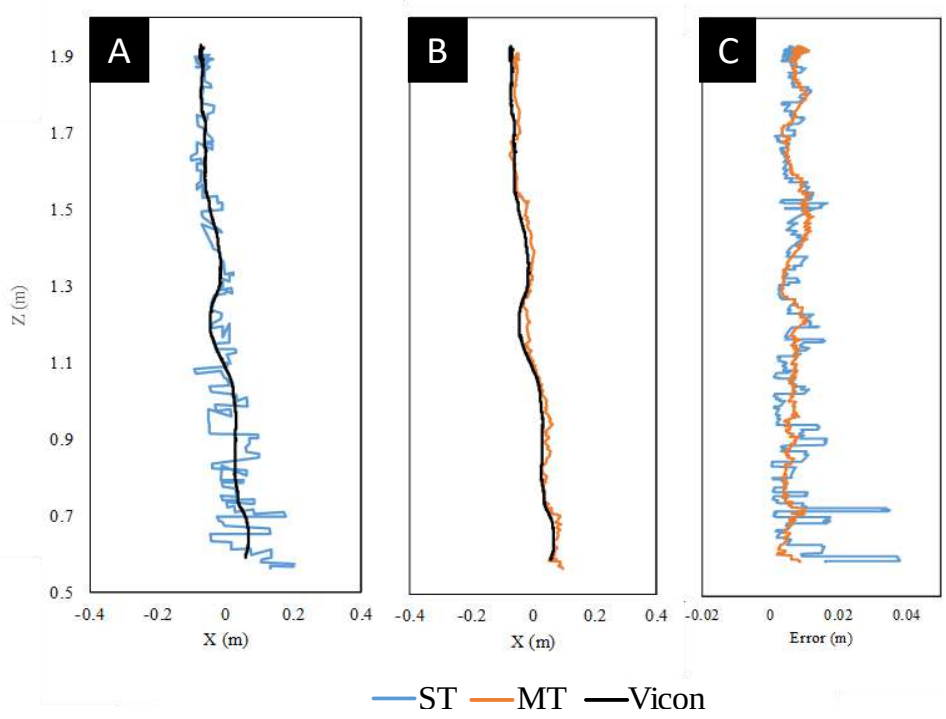

Figure 6. The second scenario: (A) estimated X value using the ST method; (B) estimated X value using the MT method; (C) error for two methods.

The error in Figure 6 (C) is defined as the Euclidian distance between the 3D positions estimated by two methods and the ground truth system. Even though the magnitude of the error is not large, Figure 6 (C) also confirms that the MT method not only performs noticeably more smoothly than the ST method, it also more reliably estimates the UAV's position.

Finally, to evaluate the performance of the proposed improvement in a real indoor construction environment, a full trajectory is tested in the fourth scenario. The estimated and ground truth positions of the UAV within the planned trajectory are plotted in Figure 7. The MT method is able to mitigate localization instability of the UAV by dramatically reducing the estimation error relative to the ST method. This is especially evident when compared in the same graph as shown in Figure 7. In this challenge, the UAV rotates from an orientation facing panel A to one facing panel B (Figure 3). There are some time steps in which the UAV is not able to see any tags, and therefore, the estimate is extremely noisy and unreliable, as evidenced by the ST method estimation performance in area A of the figure. Importantly, the MT method remains smoother and closer to the ground truth in this area.

In short, the overall performance of the MT method is significantly better than the ST method, because it estimates the ground truth position with fewer fluctuations and errors. To measure how these measurement errors are distributed, the RMSE is calculated. The RMSE can provide an overall insight about the performance of these two methods in the global pose estimation of the UAV. The RMSE for the ST method is 0.18m and for the MT method is 0.07m. Thus, it confirms that the MT method successfully improves our pose estimation in all the investigated scenarios.

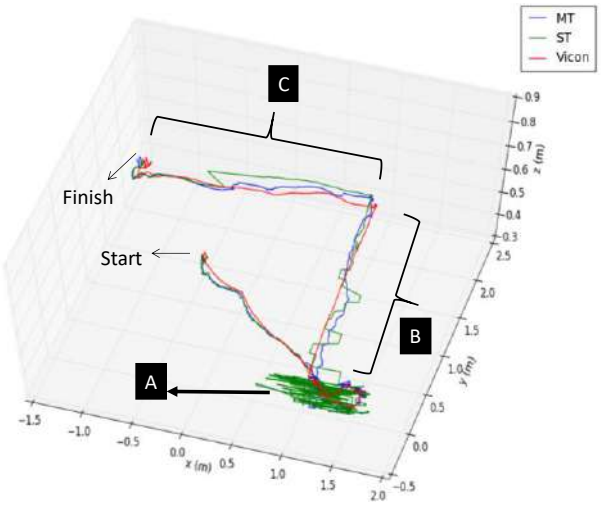

Figure 7. The performance of the methods in the fourth scenario; a planned mixed trajectory

6 Summary and Conclusion

To improve the state estimation process of the previously developed indoor localization framework of UAVs using AprilTag markers (i.e., ST), this study presented the implementation of an EKF (i.e., MT). By using an EKF, not only are we able to improve the estimation process by accounting for uncertainty, but we are also able to fuse data from two sources, namely, multiple tags and the onboard IMU. To evaluate the performance of the MT method within our framework, an experimental study was designed. Four scenarios were implemented, and pose estimation was done using both the ST and MT methods. The experimental results confirmed that the MT method successfully improves our pose estimation in all investigated scenarios. In other words, the estimated path using the MT method is smoother with less errors relative to the ground truth Vicon system. Thus, this approach improves upon our prior framework by making it more reliable for use in real-world and in ever-changing construction environments.

Future work includes using this method to provide state estimates for the control system. To this end, we need to conduct additional analyses and tests and further improve the performance of the state estimation module. For instance, in the proposed MT method, the EKF treats all the visible tags equally. However, localization data extracted from different tags may have different uncertainties (e.g., data associated with closer tags are generally more reliable than farther tags). These improvements should be implemented before any real-world tests are conducted.

Abstract –

Recently, the integration of Building Information Modeling (BIM) technology and Virtual and Augmented Reality (VR/AR) technologies during the operation and maintenance phase has been increasingly adopted. There has also been a surge of interest in the exploitation of Internet of Things (IoT) for constructed facilities, in the form of wireless networks connecting physical objects (e.g., sensing devices, facility assets, equipment, etc.). Recent IoT systems offer data management and visualization solutions. However, to improve issues such as safety and indoor comfort conditions for facilities, most of the existing IoT deployment do not benefit from the enriched digital representations of BIM and its graphical visualization capabilities. Although the integration of sensor data with BIM models has been investigated in academia, storing such real-time data in a standard and structured manner remains to be further investigated. This research aims to visualize live environmental data collected by IoT agents in the AR environment built upon existing BIM models. In our case study, the environmental data, such as indoor air temperature, light intensity, and humidity are captured by sensors connected to Arduino microcontrollers. Sensor reading are then stored in the BIM model and visualized in both the BIM platform and the AR application in a real-time manner.

Keywords –

BIM; sensors; thermal comfort; Augmented Reality; Arduino; Internet of Things (IoT); Visualization

1 Introduction

Since the emergence of Internet of Things (IoT) paradigm, numerous IoT architectures have been deployed to support indoor environmental monitoring and management. Many of those architectures are deployed and used for maintaining optimal comfort conditions with the aid of live streams of sensor data. IoT sensors can provide real-time feedback to building occupants about their surrounding physical environments. This information will be of great value since indoor conditions have a huge influence on the quality of their well-being.

Choosing an appropriate method for sensor data visualization is important as it may help users to intuitively understand and work with the data faster and easier [1]. Conventionally, static visualization techniques are used to interpret the meaning of captured data by turning data into various graphical forms (e.g., line graphs, charts, bar graphs, scatter plots, and maps). However, such static visualization techniques have certain constraints. For example, they can only allow certain data types to be presented and they are unable to present the real-time sensor data, such as indoor/outdoor air temperature, relative humidity, and air-flow rate. Provision of such information will be of essential importance for making prompt decisions for tackling building problems more proactively. As the complexity of relationships between various sources of data increases and the size of datasets continues to grow, 2D static visualization methods become less helpful and such methods need to be improved [2, 3]. In addition, static visualizations significantly suffer from the lack of the capability for representing live data interactively, thereby prohibiting interactive tasks [2].

A number of previous studies have proposed the development of various visualization methods, which allow for faster and more interactive data representation. Kim et al. (2017) [2], developed VisAR system which offers interactivity with static data visualization using Augmented Reality (AR). Sicat et al. (2018) [4] developed data visualization applications for extended reality (DXR), a toolkit for immersive visualization of building data based on Unity development platform. An immersive data visualization embedded in DXR system was developed to present data with interactive 2D or 3D visualizations. Hosokawa et al. (2016) [5] developed a

virtual reality (VR) system to visualize the air flow rate and temperature for an HVAC system by integrating BIM, Computational Fluid Dynamics (CFD) software (i.e., OpenFOAM) data, and VR.

In addition, other methods have been proposed to improve data visualization and facilitate decision-making throughout building lifecycle. For example, Motamedi et al. (2014) [6] investigated a knowledge-assisted BIM-based visual analytics approach for failure root-cause detection. In the mentioned study, BIM is integrated with other sources of FM knowledge (such as fault-tress) and inspection data to provide customized visualizations. Such visualizations assist technicians to utilize their cognitive and perceptual reasoning for problem-solving purposes. In an another study, Natephra et al. (2017) [7] proposed a method to integrate BIM and thermographic images together with environment sensing data in order to visualize spatio-temporal thermal data of building surfaces to support the assessment of indoor thermal comfort. Based on the previous studies, preprocessing of data is a crucial step before proceeding to incorporate digital models into virtual environments. To the best of our knowledge, effective methods for generating visualizations of live data streams for immersive environments are currently missing within the existing body of knowledge.

On the other hand, IoT and real-time sensing technologies are being increasingly used and applied in various platforms to enhance quality of life [8]. Vaccari (2015) [9] stated that IoT enables data streaming from network-connected devices to be delivered and transformed into other types of information to be included in virtual simulations.

Research efforts to integrate IoT and BIM for creating platforms to facilitate various processes in the architecture, engineering, construction and facilities management (AEC/FM) industry have already started. Dave et al. (2018) [10] developed Otaniemi3D platform, which integrates the BIM model of a campus and its corresponding environment data with IoT sensors. The system was used to monitor energy usage, occupancy and user comfort. Pasini et al. (2016) [11] presented a framework for connecting BIM with IoT for operating cognitive buildings. IoT sensors and BIM virtual models were integrated to track the behavior of occupants and provided an opportunity to predict building performance. Previous studies on the integration of BIM and IoT are mainly focused on automating the transfer of sensor information to BIM models [8]. However, when integrating BIM and IoT, in addition to data transfer, special attention must be also paid to the visualization of sensor data. Generating appropriate and targeted visualizations helps stakeholders better comprehend sensor outputs and eventually make better decisions.

In a board sense, BIM refers to a digital transformation of information throughout the building lifecycle [12]. The integration of IoT systems with BIM models remains a great challenge, though, it offers potential benefits for operation and facility management [13]. Integrating BIM and sensor data facilitates measuring environment parameters, such as comfort conditions. Although such integration has been investigated in recent research projects, storing real-time sensor readings and visualizing calculated comfort-related parameters have not been explored sufficiently. To respond to the aforementioned research gaps, this research presents a novel method for live sensor data visualization. In particular, an AR-based visualization technology has been used for indoor comfort condition monitoring. This paper presents a framework for integrating BIM information and IoT sensor data to support visualization of live data streams.

A number of Arduino-based sensing devices have been used to capture real-time values of comfort parameters including, air temperature, humidity, and light intensity. The sensor data are then transferred from Arduino units to BIM and then stored in the BIM file using visual programming. The developed virtual charts are provided with a real-time display of sensor readings in a dedicated AR application. Autodesk Revit, Unreal Engine, and a number of plugins for scripting in those environments were used in our developed prototype system.

2 Proposed Methodology

The proposed architecture for AR live sensor data visualization is an integrated framework for storing IoT sensor data in BIM models, as well as visualizing sensor information in an AR environment for monitoring indoor conditions and assessing indoor thermal comfort. The proposed system provides a real-time measurement and representation of physical environmental variables influencing the experience of indoor environment. Moreover, it provides occupants and facility technicians an ability for identifying problematic issues with indoor conditions in a real-time manner while moving within the facility. The proposed system utilizes a marker-based localization scheme for AR registration. The AR system can visualize the measured values of environmental conditions by augmenting corresponding virtual charts each of which assigned to a predefined maker. The detection of markers triggers the display of the charts on a real-world scene. The system works on the basis of a seamless connectivity between various sources of real-time sensing data, an existing BIM model, and an immersive AR environment. The realization of the proposed framework consists of five steps (as shown in Figure 1). The first step is to install IoT sensors to collect real-time data about environmental variables (e.g., indoor

air temperature, humidity, and light intensity). Localization markers are also installed at this step. The second step is to create a BIM model of the facility and to identify the locations of the markers in the BIM model. The locations of the markers and sensors in the model correspond to their real-world placements. In this step, the BIM model together with the location information of markers and sensors are transferred to a game environment. In the third step, sensor readings are transferred by an IoT controller (Arduino in our prototype system) to the BIM server and are stored in the BIM database. In the fourth step, an effective connection is established for allowing a seamless flow of sensor data to the game engine environment. For this purpose, this study takes advantages of visual scripting features of selected game engine. For our experiment, four types of virtual charts have been created for displaying comfort-related parameters in the game environment. These charts are assigned to represent data about indoor air-temperature, humidity, light intensity, and thermal comfort chart which shows acceptable range of air temperature and humidity values according to the Predicted Mean Vote (PMV) method [14]. The virtual charts are registered with respect to the markers' locations. The predefined markers allow accurate registration of the virtual charts for the AR experience. In the last step, the live sensor data and the result of the indoor thermal comfort assessment are visualized in an AR application in a handheld device.

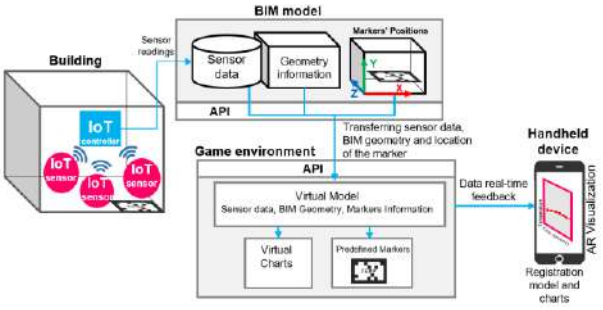

Figure 1. Overview of the proposed framework

3 Prototype system

Figure 2 shows the steps of using the developed prototype system. It follows the steps presented in the previous section. First, a BIM model is created using a BIM authoring application, and sensors devices are installed to collect environment data. Autodesk Revit (Version 2017) is used to create the BIM model of an existing building in our experiment. As mentioned previously, our prototype system uses a marker-based AR localization method. Hence, coordinates of the markers are defined in the BIM model. Environmental data (i.e., indoor air temperature, relative humidity, and light intensity level) is captured using sensors compatible with Arduino microcontrollers. The physical markers are then placed in the facility according to their assigned positions (Figure 2a). The sensor readings are then automatically stored in the BIM model. In order to store sensor readings in the model, a software application is developed using Dynamo, which is a visual programming environment for Revit (Figure 2b). The locations of markers are transferred to the game engine from the BIM model. The third step is to connect sensor readings to the game environment. Unreal Engine is used as the game authoring environment in our prototype system (Figure 2c). In this step, sensor readings are linked to the game environment using visual scripting feature of Unreal Engine. The live stream of sensors in the game engine is maintained using the developed tool. In the fourth step, virtual charts are created in Unreal Engine to represent the measured parameters of the physical environment (Figure 2d). In the fifth step, the sensor readings are visualized in the AR environment. The virtual charts are developed to display real-time data plot of sensor data in AR visualization agents (e.g., smartphone). To display virtual charts, the markers in each room need to become readily visible to the camera. The system then detects the location and the orientation of the smartphone relative to the marker and visualizes the appropriate virtual chart (Figure 2e). Users can quantitatively analyze the environmental condition and assess the indoor thermal comfort based on the PMV method by checking the charts in the AR environment (Figure 2f).

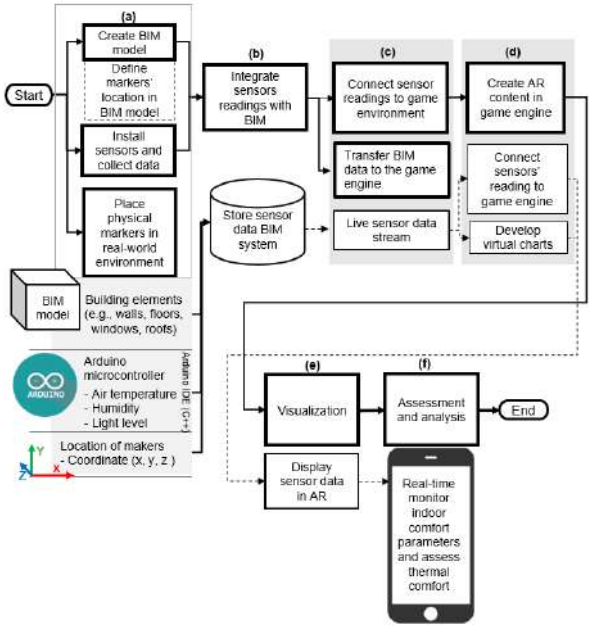

Figure 2. Process flow for integrating IoT sensors and BIM with AR

Figure 3 shows the user interface of our developed prototype system. The initial interface includes a scanning tool (Figure 3a). A marker is used to represent different environmental sensor outputs at once (Figure 3b). Once the smartphone camera recognizes the coordinates of the detected markers, the virtual charts augment the scene (Figure 3c).

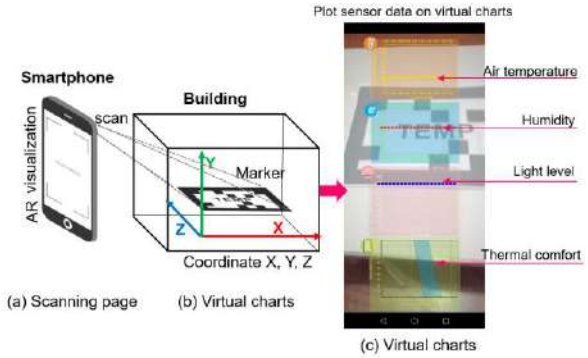

Figure 3. Screenshot of the prototype system

4 Case study

A case study for monitoring indoor comfort-related parameters was implemented using our developed application. To evaluate the capabilities of our prototype system, an apartment on the 7th floor of an existing residential building at Mahasarakham University was selected as an experimentation area. The apartment has two bedrooms with a living and kitchen areas, as shown in Figure 4. The environmental data was captured in the winter (December) from 9 a.m. to 6 p.m.

4.1 BIM modeling and installation of environmental sensors

Autodesk Revit version 2017 was used to create the BIM model of the case study. The markers were placed in the center of each room at a height of 1m from the floor (Figures 4a). For each room, specific visual charts to present related environmental parameters were associated to the corresponding marker. Three measurement points for capturing indoor air temperature, relative humidity, and light intensity were chosen at the level of 1m above from the floor (Figure 4b). Arduino Uno with its compatible sensor, (i.e., DHT11) were used to measure indoor air temperature and the percentage of relative humidity. Temperature range of the chosen sensor is from 0 to 50 °C, with ±2°C accuracy. Humidity range of the sensor is 20- 90% RH, with ±5% RH accuracy. Light intensity of the case study was measured by Photoresistor sensors. The sensors were set to collect data with time intervals of 1 second.

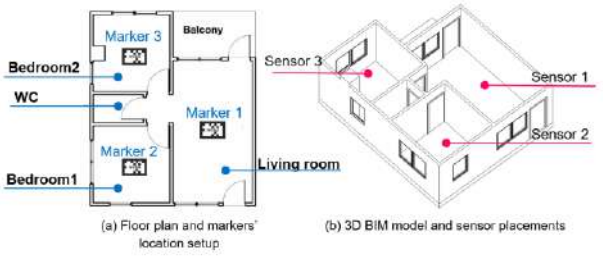

Figure 4. Experimentation room, makers' and sensors placements

DHT11 environmental sensor modules were connected to Arduino Uno microcontroller (Figure 5a). DHT 11 provides digital signal outputs of relative humidity and temperature. Arduino Integrated Development Environment (IDE) was used to build the code uploaded to the physical board. DHTLib library was installed to Arduino IDE to collect humidity and temperature readings. In this experiment, pin signal of the sensor was connected to a digital port of the Arduino board to read data output from the sensor. To measure the light intensity, photoresistor sensor modules are installed on Arduino boards. Analog pin A0 was used to read value of lighting level. Once the procedure to upload the developed code to Arduino boards is done, sensors start to capture readings. The code used to setup and run sensors for measuring the specified comfort parameters is shown in Figure 5b. Three variables are measured and displayed in the serial monitor (Figure 5c). The outputs of temperature, humidity, and light intensity level readings were represented in Celsius (C), percentage (%) and Lux (lx), respectively.

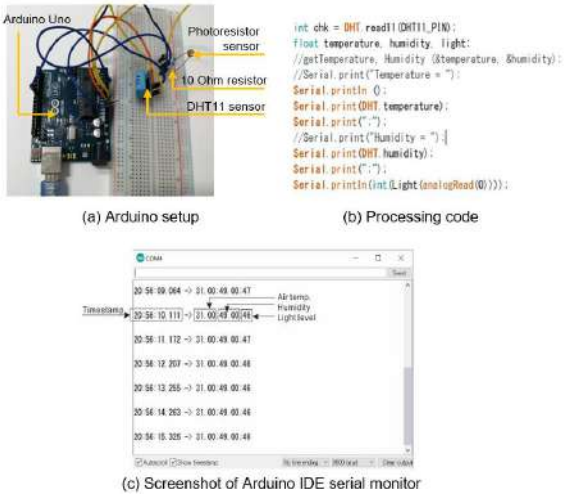

Figure 5. Circuit board setup, processing codeand sensor reading outputs

4.2 Sensor reading, BIM, and game engine integration

The procedure of connecting sensor readings with BIM is shown in Figure 6. First, DHT11 and photoresistor sensors were interfaced with Arduino board (Figure 6a). After uploading the developed code to the board, environmental parameters (i.e., air temperature, humidity, and light intensity level) were captured and the outputs of sensor data were displayed on the serial monitor console (Figure 6b). In order to transmit sensor readings from Arduino Uno to BIM, Firefly plugin provided in Dynamo (a BIM visual programming tool) was used (Figures 6c and 6d). To link Arduino sensor outputs with Unreal Engine, UE4Duino2 was used (Figure 6e). This plugin makes it possible for the Unreal Engine to retrieve data from Arduino in real-time. The user interface for representing sensor data in AR is created using Unreal Engine (version 4.20) (Figure 6f). Google ARCore, a plugin for Unreal Engine and an Android smartphone was utilized to build the AR application (Figure 6g).. Consequently, the AR live data visualization in smartphone can be performed. Consequently, the AR live data visualization in smartphone can be performed.

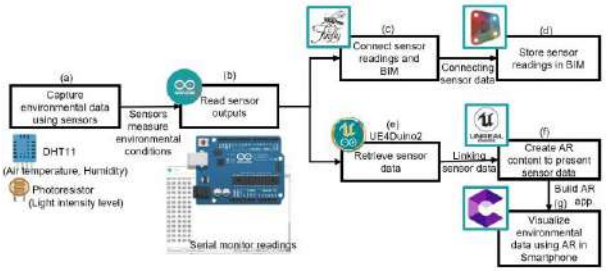

Figure 6. Sensor readings transfer to BIM and game engine

4.3 Connecting IoT sensor outputs with virtual chart in game engine

In order to visualize the measured values from IoT sensor readings, virtual chart widgets were created in Unreal Engine using Kantan Charts, a simple Unreal Motion Graphics (UMG) chart plugin. To monitor environment variables in real-time, Time Series Plot charts were used to represent the sensor outputs containing environmental information over the specified time intervals (Y-axis presents value of the measured values of environment parameters, X-axis presents time, in seconds). Cartesian Plot chart was used for real-time representation of indoor thermal comfort (Y-axis presents value of the measured relative humidity values, X-axis presents dry bulb temperature value).

4.4 Creating AR application using Unreal Engine

Our prototype application was run on an Android smartphone. In this experiment, the handheld device to support ARCore was a Huawei Y9 2019 (Android 8.1). To setup target markers in the AR application, the locations of the marker were obtained from the BIM model. The target images were imported to the Unreal Engine and added as a data asset using *GoogleARCoreAugmentedImageDatabase* and *GoogleARCoreSessionConfig*. To allow the AR content to be built and target image to be tracked by a smartphone, *Start ARCore Session* node was used. The created data asset was added in the configuration input.

4.5 Storing data in BIM and data visualization in AR

To store sensor data in BIM, readings were retrieved using Firefly visual programming plugin. Figure 7 shows sensor readings in Dynamo. Sensor readings along with their timestamp were saved as text file (Figure 8a), which can be used for tracking operation history for further indoor condition analytics. Figure 8b shows an example of the environmental data output visualization using the developed system.

5 Conclusions and future work

This paper presented a method for developing a live sensor data visualization of indoor comfort variables using AR technology. According to the real-world experiments reported in this study, integration of BIM, IoT-driven environmental sensing, and AR based visualization provides the opportunity for real-time monitoring of comfort-related parameters and indoor comfort condition tracking. The system also provides the possibility for the assessment of those indoor environmental variables that have significant effect on indoor comfort. The proposed system can assist users in the identification of problems in a real-time manner. The information collected about indoor environmental conditions can be stored within the BIM database to be further analyzed for knowledge discovery from historical data about the facility indoor conditions.

For the delivery of AR experiences, an AR application was designed and developed with the aid of marker-based localization method. The results demonstrated that the sensor data retrieved from Arduino Uno can be successfully transferred to the BIM model, and sensor outputs were also successfully integrated with the game environment. To build the AR application, Google ARCore plugin for Unreal Engine and ARCore for smartphone were used. In our prototype system, the developed AR application was able to successfully deliver the augmentation of the real-time sensor data in the form of virtual charts on a smartphone.

Some challenges need to be addressed in our future works, such as improving the system to assess thermal and visual comforts by integrating other sensors including, air-flow rate, infrared radiations, noise, and air quality. Additionally, calculating other variables necessary for comfort assessments (e.g. MRT) will be added. Regarding the visualization method, in order to provide a greater level of immersion for users, integrating the prototype system with other Mixed Reality (MR) solutions should be developed. The interaction between users and the virtual environment can also be improved by adding an ability to move the AR objects in the AR application. Further, investigating methods to use the developed system for other use cases in facility management, training, and design processes should be investigated. Further research should also focus on improving the system to automatically track the current environment conditions and push alerts to occupants' personal digital devices and warn them about the prospective causes of the detected undesirable comfort conditions. Finally, a method to use BIM as a central storage of sensor data which is connected to the AR system will be developed.

Abstract –

Images acquired by UAV can be analyzed for resource management on construction sites. However, analyzing the construction site images acquired by UAV is difficult due to the characteristics of UAV images and construction site images. This paper proposes an image augmentation method to improve the performance of an object detection model for construction site images acquired by UAV. The method consists of three techniques: intensity variation, image smoothing, and scale transformation. Experimental results show that the method can improve the performance of the detection model (Faster R-CNN) by achieving a recall and a precision of 53.08% and 66.76%, respectively. With future studies, the method is expected to contribute to UAV-based resource management on construction sites.

Keywords –

Image augmentation method; Faster R-CNN; UAV; Resource management

1 Introduction

Previous studies have been conducted to analyze the images acquired by Unmanned Aerial Vehicle (UAV) for on-site construction management [1,2]. UAV is advantageous in acquiring images on a wide area in a short time, unlike closed-circuit television (CCTV). The use of UAV is more effective in large-scale construction sites where daily monitoring is difficult to perform. For generating managerial information on construction sites, it is necessary to recognize construction resources such as workers, construction equipment, and materials. The information on construction resources can be used for safety assessment, productivity analysis, and material tracking.

The object detection methods using image processing and machine learning algorithms have been proposed for construction resources [3-5]. Although previous studies have shown excellent performance in resource detection on construction sites, it is difficult to directly apply them to analyzing construction site images acquired by UAV, as shown in Figure 1. First, the quality of the images varies due to the diverse conditions such as the flight situation of UAV, external illuminations, and weather conditions. Second, vibration in UAVs makes the acquisition of blurred images frequent. Third, the same object is recognized as a different size based on the UAV position.

Image detection models should be trained from datasets with a large number of labeled data for improving their generalization capability. In general, a dataset composed of construction site images acquired by UAV is extremely inconsistent because it has both characteristics of construction site images and UAV images. Therefore, the dataset requires a large number of labeled data reflecting various situations. However, the publicly available image data in the construction industry are scarce, unlike datasets consisting of millions of images with labels, i.e., ImageNet Large Scale Visual Detection Challenge (ILSVRC) dataset [6], COCO dataset [7], and Open Images dataset [8]. Kim et al. [3] released the dataset of 2,920 construction equipment images including dump truck, excavator, loader, mixer truck, and roller; however, its size is not big enough compared to the datasets in computer vision domain. Furthermore, it is difficult to find publically available datasets of construction site images acquired by UAV.

We propose an image augmentation method that increases the number of training images while preserving the labels of construction site images acquired by UAV. For solving the aforementioned challenges regarding the UAV images, three image augmentation techniques (intensity variation, image smoothing, and scale transformation) are applied to each

Figure 1. Examples of construction site images acquired by UAV

training image. Our datasets consist of 10 classes: workers, four types of materials (tarpaulin, rebar, H-beam, concrete pipe), and five types of equipment (drilling equipment, crane truck, excavator, concrete truck, and dump truck). The faster region-based convolutional neural network (Faster R-CNN) proposed by Ren et al. [9] is used for construction resource detection. To validate the effectiveness of the proposed method, we compare the detection performances between the Faster R-CNN trained with the 593 images and the network trained with the augmented 11,800 images. The experimental results show that the proposed method is effective in augmenting the training dataset for significantly improved detection results in the UAV images.

2 Related Works

Many researchers have proposed vision-based object detection methods for construction resources such as workers, materials, equipment, and buildings at construction sites. Golparvar-Fard et al. [10] presented a computer vision-based method for equipment action detection. A Support Vector Machine (SVM) classifier used in the method recognized and localized equipment actions using the features of Histogram of Oriented Gradients (HOG). Park and Brilakis [11] proposed a detection method for construction workers in video frames. They used background subtraction to detect moving objects and used HOG features and an SVM classifier to extract objects like human-shape and used a hue, saturation, and value (HSV) color histogram and k-Nearest Neighbors (k-NN) to detect workers. Kim and Chi [4] presented a method for tracking construction equipment using functional integration of a detector and a tracker. They focused on solving the problem that the target equipment could be occluded due to its dynamic movements and site conditions. Hamledari et al. [12] suggested a computer vision-based algorithm for detecting the components of an interior partition. The partition including studs, electrical outlets, insulation, and three states for drywall sheets (installed, plastered, and painted) was detected by using image processing and machine-learning algorithms such as Otsu algorithm, k-mean clustering, and SVM. Kim et al. [13] proposed a data-driven scene parsing method to recognize the whole area of construction site images. The methods classified not only the construction resources such as workers, equipment, material, and structures, but also the background such as ground, sky, and tree.

The object detection methods using a convolutional neural network (CNN) have shown promising performances in computer vision tasks. These methods use the feature-maps extracted from the convolutional layer for finding candidate regions in which objects may exist. Girshick et al. [14] proposed the regions with convolutional neural network (R-CNN), which was known for the first attempt at implementing a CNN for object detection. In this network, the candidate regions extracted by using a selective search method [15] was input into the pre-trained AlexNet [16]. Girshick [17]

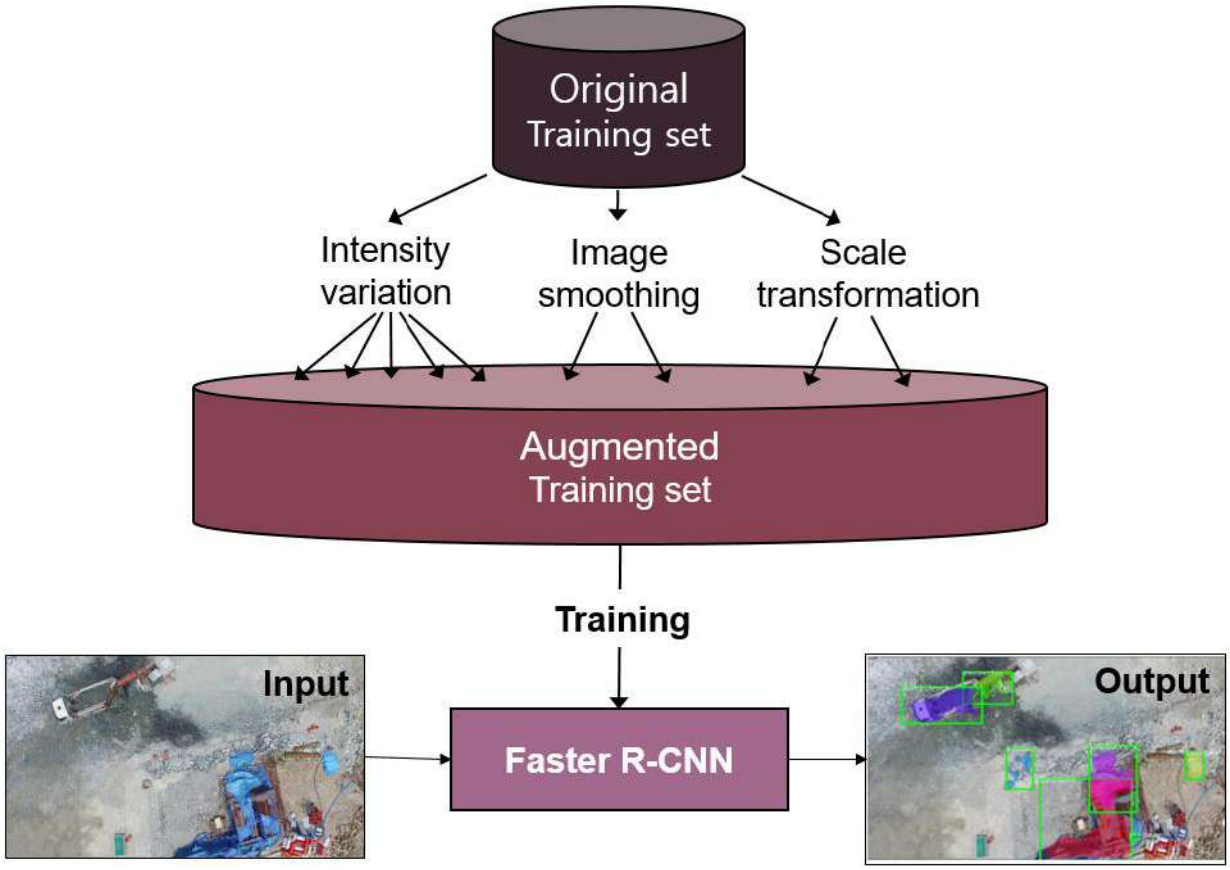

Figure 2. Overview of the image augmentation method

proposed Fast R-CNN to directly input the target image into the pre-trained AlexNet, unlike R-CNN. However, two networks (R-CNN, Fast R-CNN) took tens of seconds for processing an image because these networks used the selective search method to exhaustively generate bounding boxes regardless of aspect ratio and scale. To solve this problem, Ren et al. [9] proposed Faster R-CNN to perform the region proposal by adding a region proposal network (RPN) instead of using selective search methods. The RPN moved nine different size sliding windows on the feature-map obtained from the CNN and generated several bounding boxes with the expectation values indicating the probability that an object exists. This attempt has led Faster R-CNN to achieve promising performance in object detection.

CNN has been recently used successfully in construction resource detection. Kim et al. [3] proposed a method to detect construction site equipment using a region-based fully convolutional network (R-FCN). The R-FCN showed outstanding performance, achieving 96.33% mean average precision in identifying construction equipment. Kim et al. [18] proposed an integrated method of simulation and CNN-based monitoring for an earthmoving process in a tunnel. The CNN was successfully used for detection of excavator and dump truck with a 99.09% average precision.

3 Image Augmentation Method with Faster R-CNN

An UAV-based resource management strategy on construction sites can be developed using a CNN, which has shown outstanding performances in object detection. Although UAV can efficiently acquire a large amount of data, the quality of construction site images acquired by UAV varies greatly depending on UAV flight situations and outdoor environments. Furthermore, it is difficult to obtain a sufficient number of labeled images due to the lack of publically available dataset in the construction industry. In this context, image augmentation techniques are required to generate training images with preserving label information.

In this paper, we address three variables of construction site images acquired by UAV. The first variable is illumination changes due to ambient light exposure. The time of day, weather condition, and light exposure can affect the intensity of images. The second

variable is image quality change due to the vibration of UAV. Unlike other image collection devices such as CCTV, hand-held camera, and smartphone camera, UAV is likely to generate blurred images due to its continuous moving. The third variable is scale change in images due to the difference in flight height of UAV. The same visual data can be recorded as different sizes in different images depending on the distance between the construction site and the UAV.

Considering the three variables, we apply three image augmentation techniques: intensity variation, image smoothing, and scale transformation. Intensity variation is a technique to add or subtract the same value to all pixel in original images. Image smoothing is a technique to generate blurred images by applying a Gaussian filter to original images. In the case of the two techniques, we use the same label information as that of original images because the position of objects in augmented images does not change. Scale transformation is a technique to generate images using 2D scale transformation while preserving the aspect ratio of original images. In the case of third technique, the label information indicating the bounding box coordinates of objects are adjusted in accordance with the scale change of images. The following image augmentation techniques allow generating a sufficient number of training images in reflecting the characteristics of the construction site image acquired by the UAV. Figure 2 shows the framework of the proposed method.

4 Experimental Study

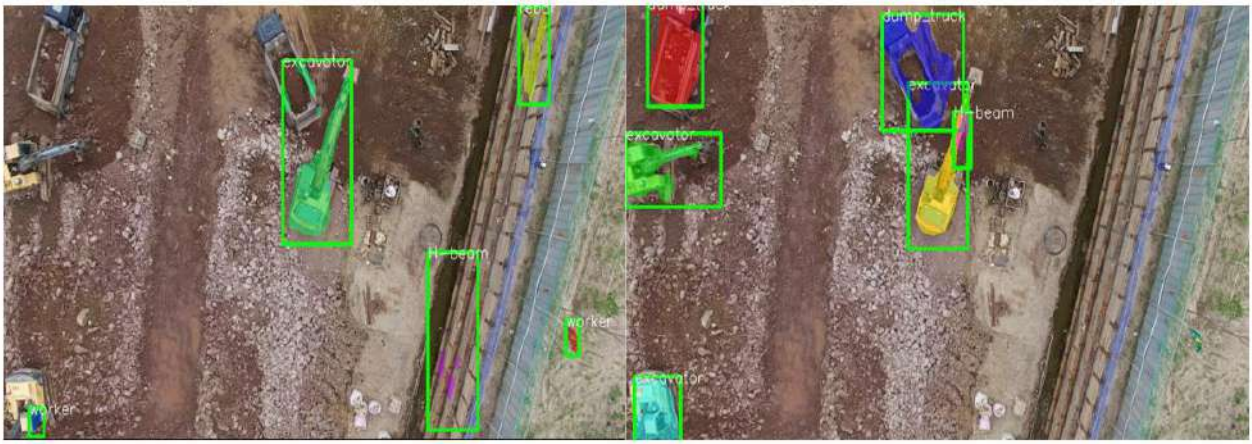
The effectiveness of the proposed methodology was validated through experiments. All experiments were conducted on the Ubuntu 16.04 operating system with GTX 1080 Ti GPU and an Intel Core i7-7700 processor, using the Python programming language and Tensorflow. The experimental dataset consists of 703 images collected at five construction sites. Among them, 593 were used as training images, and the remaining 110 were used as test images. We defined the construction resources as the 10 classes. The proposed method was used to generate 11,860 additional training images based on the 593 original images. Table 1 shows the parameters of three techniques. Figure 3 shows examples of the prediction results, and Table 2 summarizes a comparison of the performances. Because both methods learned the same network (Faster R-CNN), the computational speed at which the network processes images and detects construction resources is the same. The experimental results show that the image augmentation method improve the detection accuracy of the Faster R-CNN on construction site resources.

Table 1. The parameters of three techniques

Technique	Parameters
Intensity variation	(adding value) -60, -30, 0, 30, 60
Image smoothing	(σ value of Gaussian filter) 0, 1
Scale transformation	(scale factor) 0.8, 1.0

Table 2. Result evaluation on the dataset and computational speed

Method	Precision	Recall
Faster R-CNN trained with 593 images	39.10%	68.65%
Faster R-CNN trained with 11,860 augmented images	53.08%	66.76%



(a) (b)

Figure 3. Comparison of construction resource detection results using Faster R-CNN: (a) a detection result without our method; (b) a detection result with our method

5 Conclusion

This paper proposes an image augmentation method for UAV-based resource management on construction sites. The proposed method consists of three image augmentation techniques: intensity variation, image smoothing, and scale transformation. Faster R-CNN, one of the CNNs achieving promising results in object detection, was used for validating the method. Of the 703 construction site images acquired by UAV, 593 were used to train Faster R-CNN, and the remaining 110 were used to test the network. The Faster R-CNN trained with 11,860 training images augmented by the method showed a recall of 53.08% and a precision of 66.76%, which is superior to the performances of the trained network without this method. However, this study has the following limitations. First, it is difficult to improve the ability to detect new objects in terms of shape or color, which do not exist in the training dataset. Second, since contextual information between objects and backgrounds are not generated, it is difficult to successfully detect objects in the images having a different context from training dataset. Future researches are needed to improve the detection performance for practical implications in construction sites.

Abstract –

The modular construction technique is the one key technology that can substantially advance the competitiveness of the construction industry. However, the industry is having difficulty creating an optimum environment for broader and more effective use of modularization due to one key barrier: implementing a modular construction technique, that is, shipping modules from the fabrication shop to the build site. Multiple issues are potentially challenging to overcome, such as module size and center of gravity, rigging, tie-down, site access, site congestion, and transportation regulations, as well as the availability of local heavy lift equipment. The researchers propose to implement drones as a way to address module transportation challenges and innovative logistics of modules. The primary research objectives are to innovate logistics with a new drone-based module lifting/transporting method, consisting of a drone lifting/transporting a module from below, similar to a pallet. In this paper, the researchers present key challenges and potential advantages, which have been identified from a manual test flight of the new method, with a drone lifting/transporting an acrylic cube box from below. The key challenges identified from the manual test flight are 1) limited payload, 2) limited power supply, 3) dynamic properties of a module; 4) agility/instability of unmanned aerial systems (UAS), and 5) regulations. Through the use of the drone-based module method, the researchers expect that lifting/transporting times and costs can be significantly reduced, eventually diminishing total installation costs, and expediting the overall construction process. This study will lead to the development of a drone-based module transportation framework for practitioners in the construction industry.

Modular construction; Modularization; UAS; Drone; Logistics; Module transportation; Lifting

1 Introduction

Modular construction is a manufacturing and installation technique that specializes in exporting site-based development to an offsite location. The modular construction technique has been utilized for centuries. Yet, in the past, modular construction was limited to lower levels of modularization. Moreover, many modular projects failed to achieve expected levels of performance or full benefits due to poor planning, poor management, late scope commitment, design changes, union jurisdictional problems, and/or module shipping failure. However, thanks to the advancement of robotics, information technology (IT), and Building Information Modeling (BIM) technologies, as well as an increased awareness of green construction and lean principles, the modular construction technique has rapidly evolved. This has enabled practitioners to plan and manage a modular project better, fabricate modules more precisely, and apply the modular technique to bigger and more complicated projects. It is now evident that practitioners and researchers in the construction industry recognize the value of modular construction. The potential of the modular construction technique will continue to grow [1] as the productivity growth of fabrication shops increase [2].

An inevitable disadvantage of the modular construction technique, compared to the conventional stick-build method, and one key barrier to implementing this technique is shipping modules to the build site and lifting/placing modules at final installation locations [3–6]. Multiple issues, such as module size and center of gravity, rigging, tie-down, site access, site congestion, onsite storage areas, transportation rules, regulations, delivery time restrictions, traffic, and local heavy lift equipment availability can potentially add costs for module transport and lift [3,6]. If the construction industry can innovate module logistics and shipping processes, the industry may accomplish broader and more effective use of modularization.

For the first time, the researchers propose to implement drones as a way to address module transportation challenges and innovative logistics (lifting/transporting) of modules. The primary research objectives are to innovate logistics with a new drone-based module lifting/transporting method, consisting of a drone lifting/transporting a module from below, similar to a pallet. In this paper, the researchers present key challenges and potential advantages identified from the literature review, as well as a manual test flight of a new drone-based module lifting/transporting method, with a drone lifting/transporting an acrylic cube box (a module) from below.

2 Methods

This research process for this paper is as follows: 1) problem identification with the process of module logistics; 2) extensive literature review on modular construction and drone applications; 3) development of a new method of a drone lifting/transporting a module from below; 4) fabrication of a prototype unmanned aerial vehicle (UAV); and 5) manual test flight of the new UAV-based module lifting/transporting method. Detailed research steps are described below.

First, the researchers identified the need for innovation of module logistics in modular construction in order to accomplish more effective uses of modularization. One of the researchers' past findings showed that one key barrier to implementing the modular construction technique is shipping modules to sites and lifting/placing modules at final installation locations [3,4]. Additionally, executing a preliminary transportation evaluation based on a full understanding of module limitations is the most critical success factor (CSF) for modularization [1].

Second, to define the research problem clearly and to find gaps in the existing knowledge, the researchers conducted a review of the literature on modular construction methods as well as drones. In this paper, the researchers summarized the current applications of drone in the construction industry and the challenges of module transportation.

Third, the researchers proposed and developed a method of implementing drones as a way to address module transportation challenges and innovative logistics (lifting/transporting) of modules. To better understand the new method's potential and challenges, the researchers developed/fabricated a small-scale prototype and tested it. The details of the proposed method, the development process of the prototype, and the specifications of the prototype can be found in the Results and Discussion section.

Finally, the researchers conducted a manual test flight of the new UAV-based module lifting/transporting method, with a drone lifting/transporting an acrylic cube box (a module) from below. A discussion of the identified potential and challenges are summarized below.

3 Results and Discussion

An unmanned aerial vehicle (UAV) is defined as:

> "an aircraft which is designed or modified, not to carry a human pilot and is operated through electronic input initiated by the flight controller or by an onboard autonomous flight management control system that does not require flight controller intervention." [6, p.7]

While flying robots/aircraft are commonly referred to as UAVs, a term, unmanned aerial systems (UAS) (typically referred to as *drones*), is used to indicate the entire infrastructure, systems, and human-machine interfaces required for autonomous operation [8]. UAS are classified as fixed-wing UAS (FW-UAS) and rotary-wing UAS (RW-UAS). FW-UAS tend to use the most power efficient flying principles, while RW-UAS are tailored to increased maneuverability and stationary vertical flight [8]. This research implements an RW-UAS, as it has higher maneuverability and stationary vertical flight ability.

3.1 Current Applications of Drone in the Construction Industry

Currently, drones have been deployed in [8]:

1. remote sensing – pipeline spotting, power line monitoring, volcanic sampling, mapping, meteorology, geology, agriculture, unexploded mine detection, pipeline risk assessment and repair, power line maintenance, real-time mapping, crop care and mine defusing;
2. disaster response – chemical sensing, flood monitoring, wildfire management, infrastructure repair, flood mitigation, and wildfire fighting;
3. surveillance – law enforcement, traffic monitoring, coastal and maritime patrol, border patrols, crowd control, traffic redirection, and inspection of maritime and trucking containers;
4. search and rescue – assessing the care and delivering first-aid support;
5. image acquisition – inspecting industrial and civil structures, and conducting maintenance work tasks;
6. communications;
7. transportation – small- and large-cargo transport and passenger transport; and
8. payload delivery – firefighting or crop dusting.

Numerous researchers have demonstrated drone applications in the construction industry as well, such as

drones to assemble structures (proof-of-concept) [9,10], with manipulators [11–15], and to probe and repair civil infrastructure [16,17]. Lindsey et al. [9] and Willman et al. [10] demonstrated proof-of-concept of workpiece pickup and drop-off (with self-connect, using magnets or pre-machined joints) to defined locations. Some researchers are equipping RW-UAS with manipulators to illustrate more dexterous tasks like inserting, screwing, and removing workpieces [11–15]. Darivianakis et al. [16] and Marconi et al. [17] have presented drones that can physically probe bridges, pipelines, and power lines to repair and replace parts. These efforts led to the inspection of a real power plant boiler using a multirotor vehicle and tightly integrated visual-inertial algorithms [18]. Many practitioners have also shown interest and participated in large consortia to implement drones in the construction industry (e.g., Petrobot Project [19], Aerial Robotics Cooperative Assembly System [20], European Robotics Challenges [21], ARGOS Challenge [22]).

3.2 The Current State-of-the-art of Heavy Aerial Lifting by Drone

Scientists in the UAS domain have demonstrated a system like a flying taxi, which will be commercially available shortly. EHANG 184 has test-flown successfully in Dubai in 2017; it is designed to carry a 100 kg payload for 25 minutes [23]. The Boeing company just conducted first test flight with their Air-Taxi prototype design in January 2019. The specifications are not open to the public yet, but they are planning to launch air-taxis operating in Los Angeles, and Dallas Texas by 2023 [24]. Lastly, Bell Helicopter unveiled a full-scale air taxi concept in 2019 at Las Vegas. The concept is designed to carry one pilot and four passengers [25]. The current state-of-the-art of heavy aerial lifting is described in table 1.

Table 1. The Current State-of-the-art of Heavy Aerial Lifting by Drone

Name	**EHANG 184**[23]	**Boeing Air Taxi**[24]	**Bell NEXUS**[25]
Test Flown	2017	2019	N/A
Weight	260 Kg	N/A	2720 kg
Capacity	100 Kg Payload 1 passenger No pilot	2~4 passengers No pilot	272 kg Payload 1 pilot, 4 passengers
Flight Range & Speed	Time: 25 minutes Speed: 100 km/h	Range: 80 km	Range: 240 km Speed: 240 km/h

Considering the speed of recent technological advancements of UAS, as scientists have demonstrated, a system like a flying taxi will be commercially available shortly, a drone will be available for heavy aerial lifting in the near future.

3.3 Problem Identification with the Process of Module Transportation

Compared to the conventional stick-build method, the process of module transportation, including rigging, lifting, and installation is unique to the modular construction method. According to two recent surveys [4,26], this process was selected as one key barrier to implementing the modular construction technique. There are many issues related to modules that need to be considered, such as design/fabricate/install strategies, module type, number of modules (one box or multiple assemblies), contract, supply chain, transportation restrictions (length, height, width, and weight), and critical constraints (water access, road access, and overhead obstructions) [1]. Additional issues, such as module size and center of gravity, rigging, tie-down, site access, site congestion, onsite storage area [27], can be potentially additive and more difficult to overcome for transporting and lifting modules. Proper engineering, planning, and project support are required for a successful module transport effort. However, planning module transportation is a very complex task [28]. Because many municipalities, counties, and townships have their own restrictions, without an experienced shipping and traffic coordinator, transport is not easy to manage [29]. In particular, transportation restrictions determine maximum module sizes [30,31] and that fact can impede the implementation of modularization.

3.4 A New UAV-based Module Lifting/ Transporting Method

The researchers propose a new method (hereafter known as *the new UAV-based module lifting/ transporting method*) of *a drone lifting/transporting a module from below* like a pallet, as illustrated in **Error! Reference source not found.**, to replace the traditional modular transportation process.

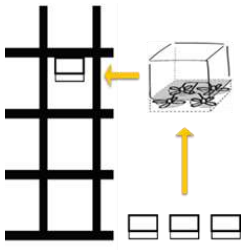

Figure 1. The new UAV-based module lifting/

transporting method

As Figure 1 illustrates, in this study, the researchers focus on transporting and lifting a cube shape, light building/facility module (i.e., HVAC and utility skids) with one UAS.

3.5 Development of a Prototype UAV

To test-and-evaluate the UAV-module, the off-the-shelf component Q450 V4 glass fiber frame is selected. The UAV-module consists of a Pixhawk autopilot controller and four 920kv (RPM/V) brushless motors fitted with 9.5-inch propellers. The selected battery (3-cell, 2.2 A, 11.1 V lithium poly) yields a UAV that can carry up to a 4.5 kg payload. The size of the UAV-module is 0.45m by 0.45m. A cubic-foot sized acrylic box was chosen for transportation. Lastly, a 3D printer is used to customize a suitable holder for the battery and acrylic cube box (Fig. 2). The UAV-module is manually deployed by FrSky Taranis X9D plus a transmitter (Fig. 3).

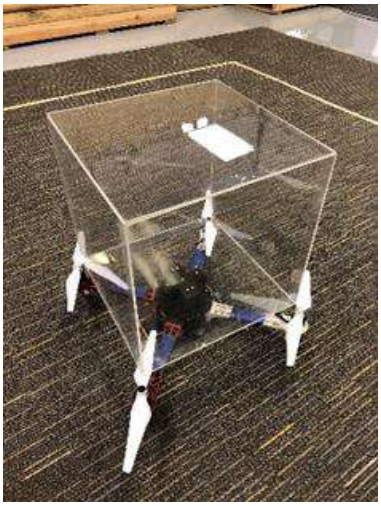

Figure 2. Prototype UAV with an acrylic cube box (a module)

Figure 3. Prototype in-flight testing

3.6 Manual Test Flight

The researchers conducted a manual test flight of the new UAV-based module lifting/transporting method, with a drone lifting/transporting an acrylic cube box (a module) from below (see Figure 3). The key challenges that have been identified from the manual test flight are 1) limited payload, 2) limited power supply, 3) dynamic properties of a module, 4) agility/instability of UAS, and 6) regulations.

First, there is a significant gap between a current drone's payload capability and a typical module's weight. Scientists in the UAS domain have demonstrated a system like a flying taxi [23–25,32], which will be commercially available shortly. However, a module's weight can be heavier than a drone's current maximum payload capacity. The second key issue is the power supply of a drone. Currently, with an 11 Volt, 2.2 Ampere Lithium-Polymer (Li-Po) Battery, a typical hobby quadcopter Q450 can only fly about 15 mins and lift 4.8kg, including the parts. As the flight duration is negatively correlated with the weight of the drone and module, the new UAV-based module lifting/transporting method may able to fly for only a few minutes without an improvement of the battery. Due to these weight and size restrictions, the choice of sensors, processors, and algorithms also impose technical and scientific challenges [8,33].

Third, the dynamic properties of the module, such as length, height, width, weight, and center of gravity, introduce additional technical and scientific challenges for implementation of the new UAV-based module lifting/transporting method. The manual test flight revealed that with the current flight control system, it is very difficult to manually adjust and control the UAV when the center of gravity of the module is not in the center. This issue leads to the problem of enhanced instability of the UAS. A UAS itself is very agile, which means that it is continuously moving and cannot be stopped to acquire sensor readings. For the new method, as the center of gravity of a module is not always in the center, additional technical and scientific challenges are imposed. To solve the instability issues, new algorithms and autonomous navigation systems are needed.

Finally, regulations related to drone application are key barriers to the new method. Regulations are needed for multiple reasons, such as safety, security, and privacy. Currently, the Federal Aviation Administration (FAA) requires the registration of all different UAV types for all purposes. Additionally, some purposes require certifications, training, and permits. For successful implementation of the new method, several requirements must be met: 1) overcome all of the issues and challenges addressed above; 2) demonstrate its application in terms of capability and reliability; 3) obtain advanced permits.

The high maneuverability and stationary vertical

flight ability of RW-UAS give engineers the potential to innovate the module logistics. The test flight demonstrates that the module transportation process can be significantly reduced through the implementation of the new UAV-based module lifting/transporting method. With the new method, once HVAC modules arrive on a jobsite, the modules can be transported directly to the installation location, without a need for the workers to set up or hook the modules into a module lift frame or spreader bars. Moreover, there is no need for scissor/boom lifts, tower cranes, forklifts, or transporters. Due to these reasons, the UAV-based module method can reduce transportation, lifting times, and costs significantly, eventually diminishing total installation costs and expediting the overall construction process.

4 Conclusion

The process of module transportation, rigging, lifting, and installation is unique to the modular construction method, one of the critical barriers to implementing the modular construction technique and executed inefficiently by practitioners. If the process is innovated, the construction industry will achieve broader and more effective use of modularization. Recently, drones have drawn increasing attention from researchers and others in the construction industry due to rapid advancements in related technologies and applications.

The key challenges that have been identified from the manual test flight are:

1. limited payload;
2. limited power supply;
3. dynamic properties of a module;
4. agility/instability of UAS; and
5. regulations.

However, if these challenges can be overcome through the use of the UAV-based module method, transportation times, lifting times, and costs can be significantly reduced, eventually diminishing total installation costs, and expediting the overall construction process. This innovative method will help the industry to overcome key barriers of modular construction: site access problems, site congestion issues, and the limited availability of local heavy lift equipment.

To make this new method application viable to the industry, the development of new batteries, motors, and propellers may require the next level of advancement (increasing size and capacity of motors and propellers, and changing power sources) in order to lift heavy modules. The researchers believe substantial efforts are necessary in the future to solve these issues. However, as scientists in the UAS domain have demonstrated, a system like a flying taxi, which will be commercially available shortly, can be solved within five years, considering the speed of recent technological advancements.

This study will lead to the development of a drone-based module transportation framework for practitioners in the construction industry, including but not limited to, general contractors, module fabricators, and module transporters.

5 Acknowledgments

Abstract –

Automated, real-time, and reliable equipment activity identification on construction sites can help to minimize idle times, improve operational efficiencies, and reduce emissions. Many previous efforts in activity identification have explored different machine learning algorithms that use time-series sensor data collected from inertial measurement units mounted on the equipment. However, machine learning algorithms requires large volume of training data collection from the field, as inadequate and smaller amounts of data results in model overfitting. This study proposes an automatic and real-time activity recognition framework by using data from multiple IMUs attached to equipment's moving and articulated parts. In doing so, first a time-series data augmentation technique called *window-warping* (WW) is introduced to generate synthetic training data from a smaller volume of field-collected data. Two supervised machine learning algorithms, artificial neural network (ANN), and K-nearest neighbour (KNN) were trained and evaluated using the augmented training data to identify equipment activity. The developed data augmentation methodology is validated using a case study of an earthmoving excavator. The results show the potential for using time-series data augmentation in training machine learning algorithms for construction equipment activity recognition using minimal data collected from the field.

Data augmentation; Activity recognition; Time series; Construction equipment; Machine learning; IMU

1 Introduction

Automated, and real-time activity recognition of construction equipment plays an important role in construction operation analysis by enabling productivity monitoring [1-2], preparation of input for near real-time simulation [3–5], and automated cycle-time analysis [2-6]. It is also a key necessity for real-time safety applications on the construction site [7–9] and for automating environmental assessments [11-12]. Equipment activity identification can also enabled several applications in AR/VR visualization [12–15]. Despite being a necessary component for all the aforementioned applications, activity identification in construction site has historically been a manual effort. The manual approach of observing, recording, and analysing an equipment's action is prone to human error and requires excessive time, effort, and cost. In order to overcome these shortcomings, past efforts have investigated vision-based, as well as inertial measurement unit (IMU)-based activity recognition frameworks to automatically identify the activities that are performed by construction equipment in real-time or near real-time. Previous efforts in IMU-based frameworks have mostly used a single IMU attached to the equipment's cabin in order to capture the vibration of the equipment [9–11]. The vibration data were then used to train different machine learning algorithms that then classified an equipment actions. However, training machine learning algorithms requires a large volume of initial training data, which can be challenging to acquire from an active construction site due to the cost and effort inherent in such an endeavour that requires equipment and their operators to perform tasks that are extraneous to the work involved with their operation. Collecting data from an equipment during the course of its regular operations results in data that needs to be manually labelled and data that is non-uniformly distributed over the various activities that the equipment could be performing. These factors result in low-quality training data that result in poor performance of the training algorithm. Moreover, a small volume of training dataset poses a challenge in identifying a higher number of activities performed by the equipment as it creates an imbalance in the dataset. This paper describes a means for increasing the amount of training data for machine

learning algorithms for equipment activity identification by using the technique of data augmentation.

In the machine learning domain, specifically in object recognition, handwriting recognition, and speech recognition, data augmentation is a popular technique to generate synthetic training data when only small training sets are available [17]. By augmenting training data, errors of the classifiers due to variance can be reduced. The issue of model overfitting due to a dearth of learning examples can be overcome by introducing synthetic data generated by data augmentation. Even though literature is rife with examples that have applied data augmentation techniques for images, handwriting, and speech, data augmentation of time series data for classification purposes has not be fully explored yet.

This paper thus presents a real-time and automatic activity recognition framework for construction equipment using augmented data from multiple IMUs that mounted to articulated parts of the equipment. A time series data augmentation technique called *window-warping* (WW) is introduced to generate synthetic training data, thereby eliminating the need for obtaining large volume of field data. The developed framework is validated by carrying out a case study using an excavator from an actual earthmoving site.

This paper is organized as follows. First, a review of the state-of-the-art in IMU-based construction equipment activity recognition and data augmentation is provided to set the context for this research and highlight research gaps. Then, the methodology section discusses the main components of the proposed framework. Next, the results of the case study are presented. Finally, the results and main contribution of this work is summarized along with the limitations and future directions of this research.

2 Related Work

The framework presented in this paper consists of an activity recognition platform for construction equipment using multiple IMUs and a time-series data augmentation technique. This section provides a comprehensive literature review in IMU-based equipment activity recognition and data augmentation techniques in classification.

2.1 IMU-based Equipment Activity Recognition

IMU-based approaches for equipment activity recognition leverage the location and/or the vibration of the equipment in order to identify its activity at a specific time. El-Omari and Moselhi (2011) [18], and Ergen et al. (2007) [19] proposed a framework combining radio frequency identification (RFID) and global positioning system (GPS) technology for automated localization and tracking of construction equipment. Vahdatikhaki and Hammad (2014) [5] enhanced the performance of equipment state-identification approach by adopting a multi-step data processing framework combining location and motion data. Song and Eldin (2012) [20] developed an adaptive real-time tracking of equipment operation based on their location to improve the accuracy of project look-ahead scheduling. Although location-based operation tracking can identify the state and operation of construction equipment at a coarse level (e.g., *idle* and *busy* states), it is incapable of classifying the activities performed by equipment when it is stationary. Such limitations of location-based operation tracking have inspired researchers to explore the feasibility of both independent [10] and smartphone embedded [9 - 10] inertial measurement units (IMUs) for automated equipment activity recognition. Ahn et al. (2015) [10] used a low-cost accelerometer mounted inside the cabin of an excavator to collect operational data from an earthmoving worksite. Several classifiers were tested to classify three different states (i.e., engine-off, idle, and busy) of an excavator. Mathur et al. (2015) [6] utilized smartphone-embedded accelerometer by mounting it inside an excavator cabin to measure various activity modes (e.g., wheel base motion, cabin rotation, and arm movement) as well as duty cycles. Akhavian and Behzadan (2015) [16] adopted a similar approach by attaching a smartphone to the cabin of a front-end loader to collect accelerometer and gyroscope data during an earthmoving operation, upon which several classification algorithms (i.e., ANN, DT, KNN, LR, SVM) were tested. Their study also investigated the impact of different technical parameters such as level of details, segmentation window size, and selection of features on the performance of different classification algorithms. The same approach and technical parameters were further extended for construction workers [21].

2.2 Data Augmentation for Classification

Numerous data augmentation techniques have been tried and tested in computer vision [24–28] and speech recognition domain [29–31]. Charalambous and Bharath (2016) [24] introduced a simulation-based methodology which can be used for generating synthetic video data and sequence for machine/deep learning gait recognition algorithms. D'Innocente et al. (2017) [22] proposed an image data augmentation technique which zooms on the object of interest in an image and simulates the object detection outcome of a robot vision system. The goal of this paper was to bridge the gap between computer and robot vision, utilizing data augmentation. Most of the advanced object recognition algorithms utilizes various image augmentation techniques on images, such as flipping, rotating, scaling, cropping, translating, adding Gaussian noise etc. in order to generate synthetic data for

training and testing machine/deep learning algorithms [25,26,30]. Moreover, in the speech recognition domain, studies have applied techniques such as vocal tract length normalization [27-28], speech rate, and frequency-axis random distortion [27], label-preserving audio transformation [29] to improve the performance of learning algorithms.

Despite the frequent implementation of data augmentation techniques in the computer vision and speech recognition domains, data augmentation in time series classification have not been deeply investigated yet [31]. Guennec et al. (2016) [32] proposed two time series data augmentation techniques; window slicing, and window-warping to train a convolutional neural network (CNN). In order to reduce the variance of a classifier, Forestier et al. (2017) [17] introduced dynamic time warping (DTW) for time series classification. Um et al. (2017) [31] proposed the most comprehensive set of time series data augmentation techniques in order to monitor Parkinson's disease patients using wearable sensors.

2.3 Research Gaps and Point of Departure

Several machine learning approaches in IMU-based activity recognition for construction equipment have been explored in the recent past. Machine learning models usually benefit from larger training dataset because small and inadequate training data leads to model overfitting [33]. Moreover, small training dataset prevents a classification algorithm from learning parameters for identifying a higher number of classes due to an imbalance in data [16]. Furthermore from a practical standpoint, collecting large volume of IMU data from equipment operating in active construction sites poses challenges related to cost, time, and effort. In order to overcome these challenges, this paper aims to develop an equipment activity recognition framework which uses augmented training data, decreasing the effort of collecting large volume of field data. In doing so, a time-series data augmentation technique named *window-warping* (WW) is developed.

3 Methodology

The general architecture of the designed framework for data augmentation and classification is presented in Figure 1. In this methodology, accelerometer and gyroscope data are collected from multiple IMUs attached to different articulated elements of the equipment. The raw data is first divided into training and test data. The raw training data are used for data augmentation. The raw and augmented training data are combined together to train the machine learning algorithms. The trained models are then evaluated using the test data, separated at the beginning of the data processing.

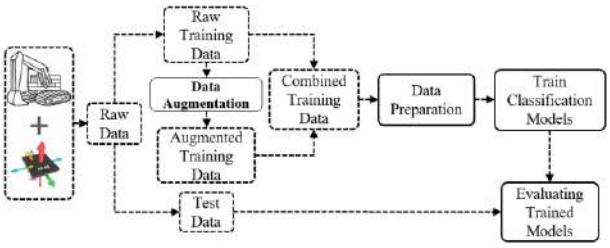

Figure 1. Developed framework for data augmentation and classification model

The following sections discusses the methodological details of data augmentation and model training.

3.1 Data Augmentation Using Window-Warping (WW)

Data augmentation can be regarded as an insertion of prior knowledge about the invariant properties of the data against certain transformations. The resulting augmented data can cover an unknown input space, prevent model overfitting, and increase the generalization capability of the classification model [31]. It is well known in the computer vision arena that minor changes (or augmentations) of the image in terms of jittering, scaling, warping, and rotating do not change the data labels as they can happen in real world observations. But not all data augmentation techniques implemented in computer vision domain are applicable to time-series data augmentation. This study utilizes a time-series specific data augmentation technique named *window-warping* (WW). Figure 2 provides a visualization of the WW augmentation technique proposed in this research. This data augmentation technique is implemented by warping the time-series data of each activity by speeding it up or down. This technique is logical in context of this research as the construction equipment can perform any specific

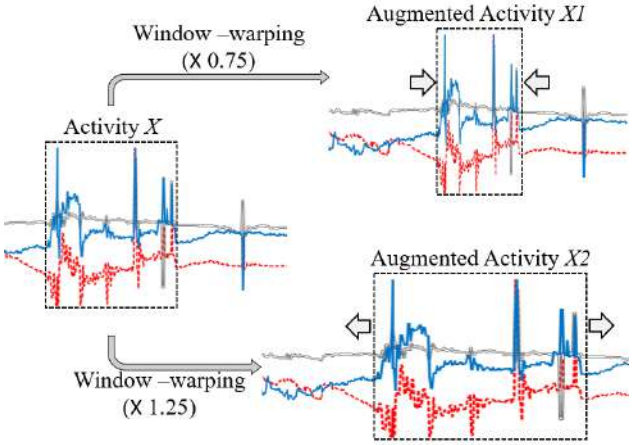

Figure 2. Window-warping (WW) data augmentation

activity at slightly different speeds. Thus, synthetic data

can be generated, which generalizes IMU data for different operational speeds of the equipment. In this paper, warping ratios of $1/2$, $3/4$, 1.25 and 1.5 were considered. In other words, the raw training data are speeded up to 1.25, and 1.5 times and slowed down up to $1/2$, and $3/4$ times. Figure 2 illustrates the WW technique with warping ratio $3/4$ (top), and 1.25 (bottom) for a specific activity *X*, which generates two augmented activities; *X1*, and *X2*. Applying four different warping ratio, training data are increased 5-fold, considering raw training data as 1-fold. This method generates training data of different lengths, which cause difficulties in training the machine learning algorithm. This issue is dealt with segmenting all training data (i.e., raw training data and augmented training data) with sliding window technique of fixed length and 50% overlap. More specifics about the data preparation and classification model training are discussed in following section.

3.2 Data Preparation

The data preparation step of the methodology includes data segmentation and feature extraction from the field-collected data. A single data point of the IMU sensor does not provide useful information about the activity of the equipment, since it just represents a momentary position of the equipment, similar to a snapshot image. In contrast, the activities of equipment consists of sequential motions distributed over a period of time, similar to a sequence of images or a video. Thus, data streams containing individual data points are segmented into data windows (i.e., consecutive time-series data points). In this paper, data windows of 1 second fixed length is considered with a 50% overlap between adjacent windows. After segmenting the time-series data into windows, a set of time-domain statistical features are extracted from each window. These features represent the pattern of the signal in the corresponding window and are eventually used as inputs in the classification algorithms. In this paper, 12 statistical features are extracted from each window, and they *are mean, maximum, minimum, standard deviation, mean absolute deviation, interquartile range, skewness, kurtosis* and, *4th order autoregressive coefficients*. Using these features as inputs, classification models are trained as discussed in the next section.

3.3 Training and Evaluation of Classification Model

Activity recognition frameworks are developed using both supervised and unsupervised classification models. However, since supervised learning algorithms provide better performance for equipment activity recognition [34], a network-based learning algorithm, *Artificial Neural Network* (ANN), and a distance based classification algorithm, *K-Nearest Neighbour* (KNN), are considered for training. Both ANN and KNN models are trained using the combined (raw and augmented) training data. After each model is trained, they are evaluated with the test data, which were separated from the raw data before the data augmentation phase. The performance of the model is evaluated using *accuracy*, *precision*, *recall*, and *F-1 score*. Confusion matrices are also generated in order to analyse inter-activity confusion of the trained model. The following section discusses the results of the case study carried out in this research, using motion data captured from an excavator.

4 Case Study and Results

In the case study, three IMUs were attached to the bucket, stick, and boom of an excavator. The excavator was operating on an earthmoving site, loading trucks with soils and levelling the ground. In addition to IMU data, video data were also collected for 2 hours for labelling purpose. The entire operation of the excavator was divided into 9 different classes: *Engine Off, Idle, Scooping, Dumping, Swing Loaded, Swing Empty, Moving Forward, Moving Backward*, and *Ground Levelling*. Raw data from the IMUs were labelled using the video, with numeric numbers (1 to 9) being assigned for each activity. Next, the raw data was separated into training and testing data with 50-50 ratio. Raw training data were used for the *window-warping* (WW) data augmentation, generating 4-fold augmented training data (with warping ratio of $1/2$, $3/4$, 1.25, and 1.5), thus increasing the volume of the training data 5- fold (4-fold augmented data plus raw training data). Table 1 summarizes the number of instances of each of the activity in raw and augmented dataset in the case study.

Table 1. No. of instances of raw and augmented data

		No of Instances				
Label	Act. Name	Raw data	Raw testing data	Raw training data	Augmented training data (4-fold)	Combined training data (5-fold)
1	Eng. off	166	83	83	332	415
2	Idle	34	17	17	68	85
3	Scooping	78	39	39	156	195
4	Dumping	81	40	41	162	203
5	Swi. Loaded	80	40	40	160	200
6	Swi. Empty	87	43	44	174	218
7	Mov. For.	5	2	3	10	13
8	Mov. Bac.	7	3	4	14	18
9	Grnd. Level.	17	8	9	34	43

For example, *Scooping* activity happened total 78 times during data collection, 39 of them were separated for testing, and 39 for training. 39 training instances were used for 4-fold WW augmentation, generating total 195 training instances for *Scooping*. Next, two supervised classifiers (i.e., ANN, and KNN) were trained for 9 classes of activities using combined 5-fold training data. Finally, the models were tested using the 50% raw test

data.

Figure 3 and Figure 4 illustrates the effect of WW data augmentation by comparing the use of 1-fold raw training data vs. 5-fold combined training data. From both the figures, we see that training the models with 5-fold augmented data improves their performance substantially from just training with raw training data. For example, the accuracy, precision, recall, and F-1 score of KNN improves from 51.7% to 97.9%, 49.5% to 96.4%, 44.2% to 96.8%, and 45.6% to 96.6% respectively by training the model with augmented data. It can also be observed that, improvement in the performance indices (i.e., accuracy, precision, etc.) is higher for KNN than ANN.

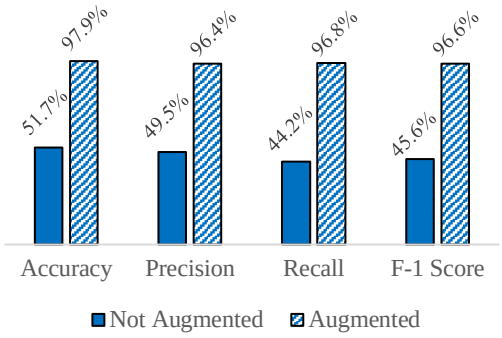

Figure 3. Performance measures of KNN

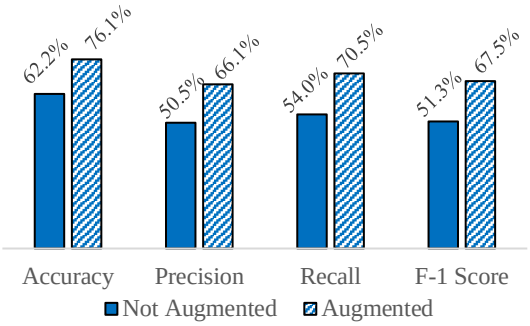

Figure 4. Performance measures of ANN

Next, a sensitivity analysis was conducted using different volume of training dataset (e.g., 1-fold, 2-fold, etc.) for the model training. KNN was trained with raw training data (i.e., 1-fold), 2-fold, 3-fold, 4-fold, and 5-fold augmented training data. Figure 5 illustrates that F-1 score of KNN increases with the volume of augmented training data. We see that KNN performs best for 5-fold training data, and worst for 1-fold training data.

Figure 6, and Figure 7 are confusion charts of KNN with 1-fold, and 5-fold training data, respectively. The confusion charts are generated to explore the improvement of inter-class confusion of the trained

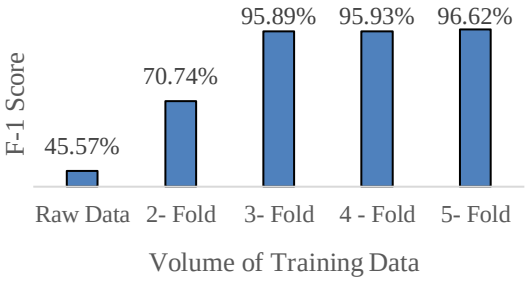

Figure 5. Performance of KNN for different volume of training data

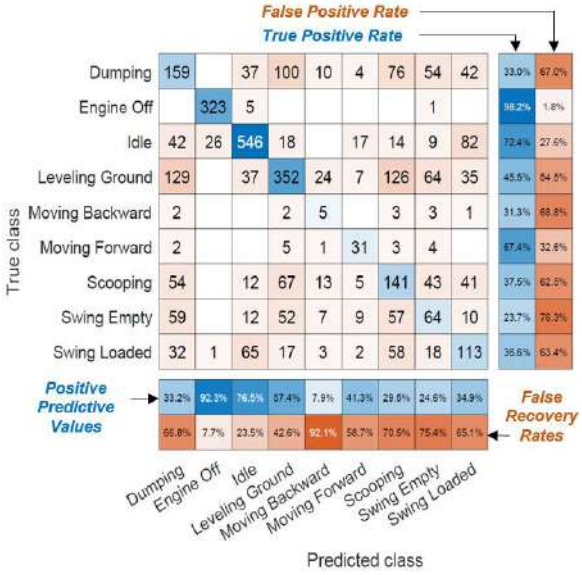

Figure 6. Confusion chart of KNN with 1-fold training data

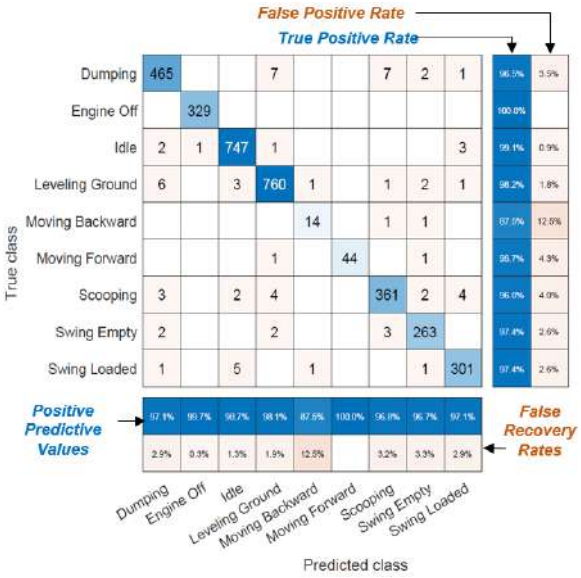

Figure 7. Confusion chart of KNN with 5-fold training data

model before and after data augmentation is implemented. Training the model without any augmented data (Figure 6) results in significantly higher percentages of error. Moreover, the KNN confuses in predicting activities with similar type of signal patterns such as, *Moving Forward* and *Moving Backward*, *Swing Empty* and *Swing Full*, *Scooping* and *Ground Levelling*, *Dumping* and *Ground Levelling* etc. On the other hand, error of the model decreases significantly while augmented data is used for the training (Figure 7). Also, the KNN can successfully identify similar kind of activities.

5 Conclusions and Future Work

Automated and accurate recognition of construction equipment's activity can help to improve productivity, safety, fuel use, and overall management and monitoring of the construction operations. To this end, this study presents an activity recognition framework for construction equipment using multiple IMUs. Moreover, as machine learning algorithms performs better for large volume of training data, a time series data augmentation technique, *window-warping* (WW) is proposed to generate synthetic training data. The methodology was validated using a comprehensive dataset collected from an excavator from a real construction site. The result of this study shows significant improvement in classifier's performance while using augmented training data. Specifically, data augmentation results in 51% and 16.2% increase in F-1 score for KNN, and ANN respectively. This indicates the potential of adopting data augmentation methods in equipment activity recognition which eliminates the necessity of collecting large volume of data from the field.

Future works of this study include testing the methodology for multiple types of equipment, such as loader, hauler, dump truck etc. Moreover, other types of time series data augmentation techniques will be explored to see their effect on the classification algorithms. Deep learning methods such as, convolutional neural network (CNN), recurrent neural network (RNN) will also be explored to analyse time series sequences for higher accuracy.

Abstract –

In the Japanese construction industry, it is predicted that during the next ten years, more than a million veteran technicians will retire, and a sudden shortage of experienced technicians will be inevitable. One way of countering this problem now being considered is the use of robotics technology to support inexperienced operators. To develop such systems, it is important to first quantitively compare differences of the working efficiency, working quality, operating methods etc. between experienced operator and inexperienced operator.

Hence, experiments were performed to compare how experienced operators and inexperienced operators execute base course material grading work using a motor grader. During the experiments, the time required to complete the work, and the finished height at a pitch of 1 m were measured in order to quantitatively identify working efficiency and working quality. To clarify operating methods, the line of sight of the operators during work was measured. Moreover, similar comparative experiments were performed with the introduction of MC to verify its impact on experienced and inexperienced operators.

Construction machine; Experienced operator; Inexperienced operator; Machine control

1 Introduction

In recent years, the number of young people entering the Japanese construction industry has been decreasing, and the veteran workforce is aging [1] (Figure 1). It is predicted that during the next ten years, more than a million veteran technicians will retire, and a sudden shortage of experienced technicians will be inevitable. The same patterns have appeared among construction machine operators, and a sudden shortage of experienced operators is predicted. One way of countering this problem now being considered is the use of robotics technology to support inexperienced operators. This means using robotics technology to perform some aspect of construction machine operation to assist inexperienced operators so that they can execute work at the same performance level as experienced operators. As a robotics technology that automates some of the operational work, machine control (MC) has already been introduced in motor graders and bulldozers [2][3]. MC refers to a system

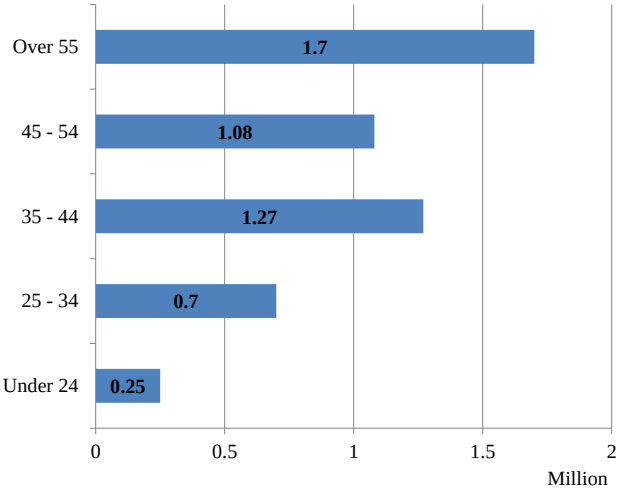

Figure 1. Labour force population by age group in construction industry (2015)

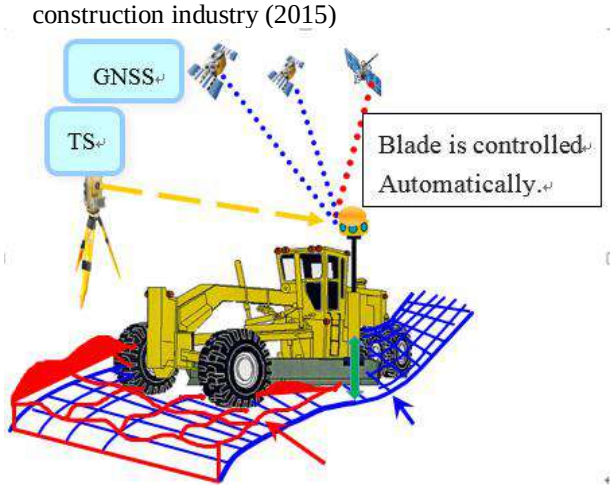

Figure 2. Machine control (MC)

that uses Total Station (TS), Global Navigation Satellite System (GNSS), etc. to identify the position of a construction machine, and calculates the discrepancy between the design value and the actual position of the working device (blade, etc.) so that the working device is automatically controlled in real time to remain in a position that conforms to the design value (Figure 2 [2]). It is presumed that expanding this kind of robotics technology to other types of machines and other types of work would be an effective measure of countering the future shortage of experienced operators. To develop such systems, it is important to first quantitively compare differences of the working efficiency, working quality, operating methods etc. between experienced operator and inexperienced operator. However, while differences between these two classes of operators have been partially verified, for excavation by hydraulic excavators for example [4][5], these differences have not yet been quantitatively confirmed. In order to evaluate the present state of MC and develop it further, it is important to also clarify the effects of MC on working efficiency, working quality, and on the operators. No studies that quantitatively clarify such effects of MC have been conducted.

Hence, experiments were performed to compare how experienced operators and inexperienced operators execute base course material grading work using a motor grader. During the experiments, the time required to complete the work, and the finished height at a pitch of 1 m were measured in order to quantitatively identify working efficiency and working quality. To clarify operating methods, the line of sight of the operators during work was measured with reference to the line of sight measurements used in the field of automated driving [6][7]. Moreover, similar comparative experiments were performed with the introduction of MC to verify its impact on experienced and inexperienced operators.

2 Outline of the Experiments

2.1 Outline of the Experiments

A subgrade with a width of 6 m and total length of 65 m (straight: 45 m, curved: 20 m) was prepared, and a motor grader was used to experimentally grade the base course material (M40) so as to generate a 30 cm thick layer on the subgrade. Each operator used the same motor grader (KOMATSU DG655) to perform the work, once without MC ("normal operation"), and once with MC ("MC operation"). The view of the experiment is shown in Figure 3.

2.2 Operators

The ten operators shown in Table 1 performed the experiment. Operators A, B, C, and D were experienced operators with at least 15 years of experience, and operators E, F, G, H, I, and J were inexperienced operators with less than 10 years of experience.

2.3 Measurement of the Data

The following data were collected:

(1) Working time: time from the start of each work

Figure 3. The view of the experiment

Table 1. Operator

	age	Year of experience	
A	57	35	Experienced Operator
B	52	33	
C	37	17	
D	36	16	
E	31	9	Inexperienced Operator
F	30	8	
G	24	6	
H	24	2	
I	23	5	
J	22	1	

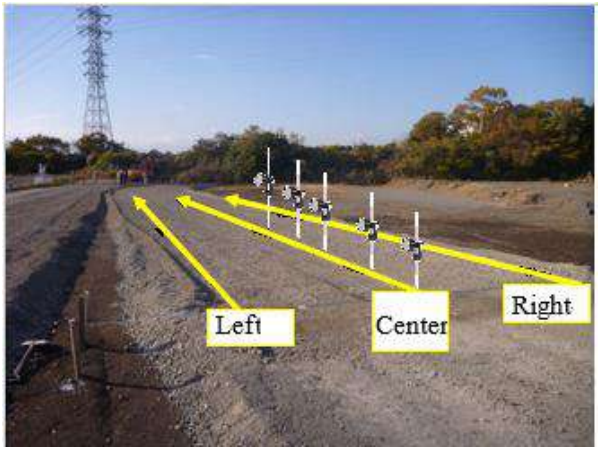

Figure 4. Finished height measuring points

until the height at the measurement points (every 10 m) was within 1 cm of the designed height (Japanese standard).

(2) Finished height: height at a pitch of 1 m along three measurement lines—center, right, and left—after completion of the work, measured by TS (Figure 4).

(3) Operator's line of sight: operator's line of sight during the work. This measurement was taken with an eye tracking system (NAC, EMR-9, Figure 5), and only during the operation of operators A, C, E, G, and H.

(4) Operator's heart rate: the heart rate of each operator during work was measured by a heart rate monitor (EPSON, SF-850, Figure 6) , and only during the operation of operators A, C, E, G, and H.

3 Results of the Experiments

3.1 Working Time

Figure 7 shows the average actual working times of experienced operators and inexperienced operators for normal and MC operation. The actual working times include only the time spent grading, and do not include time spent backing up, or measurement time.

According to Figure 7, in the case of normal operation, the working time of inexperienced operators is approximately 1.8 times that of experienced operators, which shows that the working efficiency of inexperienced operators is much lower than that of experienced operators. For this reason, it can be surmised that the future shortage of experienced operators will have a serious impact on the construction industry, and that it is necessary to implement countermeasures such as the introduction of robotics technology.

In the MC operation, working time of inexperienced operators was approximately 40% shorter than it was when they performed normal operation, while the working time of experienced operators was almost the same for normal operation and MC operation. For this reason, it can be inferred that MC had a considerable effect on inexperienced workers, and that introducing MC could enable inexperienced operators to work at a working efficiency equal to that of experienced operators. Meanwhile, there was almost no difference between the normal operation working time and MC operation working time of experienced operators, revealing that MC had little impact on the experienced operators.

3.2 Finished Height

As an example of the results, Figures 8 and 9 show the measurements of finished heights for operator D (an experienced operator) and operator J (an inexperienced operator). The horizontal axis of the figure represents the working length (total length: 65 m) and the vertical axis represents the difference between the measurement data and designed (target) height.

Figures 8 and 9 show that it is possible to estimate working quality based on the discrepancy between

Figure 5. Eye tracking system

Figure 6. Heart rate monitor

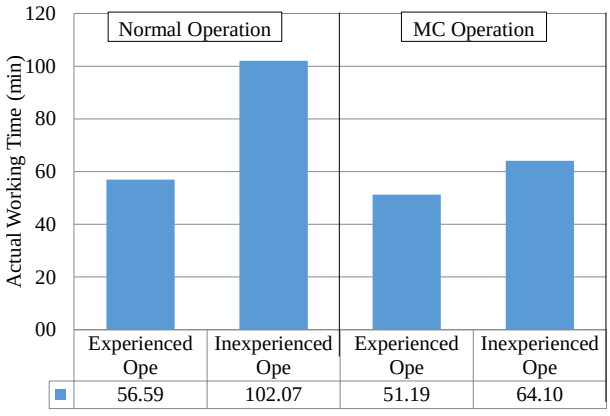

Figure 7. Actual working times

actual height and target height. It can be presumed that the working quality of the normal operation by operator D is better than that by operator J, and that the working quality for the MC operation by operator D and that by operator J are not very different.

To quantitatively represent working quality, all the finished height measurement data obtained for experienced operators and for inexperienced operators are represented by frequency polygon (frequency line graphs) in Figures 10 and 11. The figures also indicate the standard deviations.

According to Figures 10 and 11, in the case of

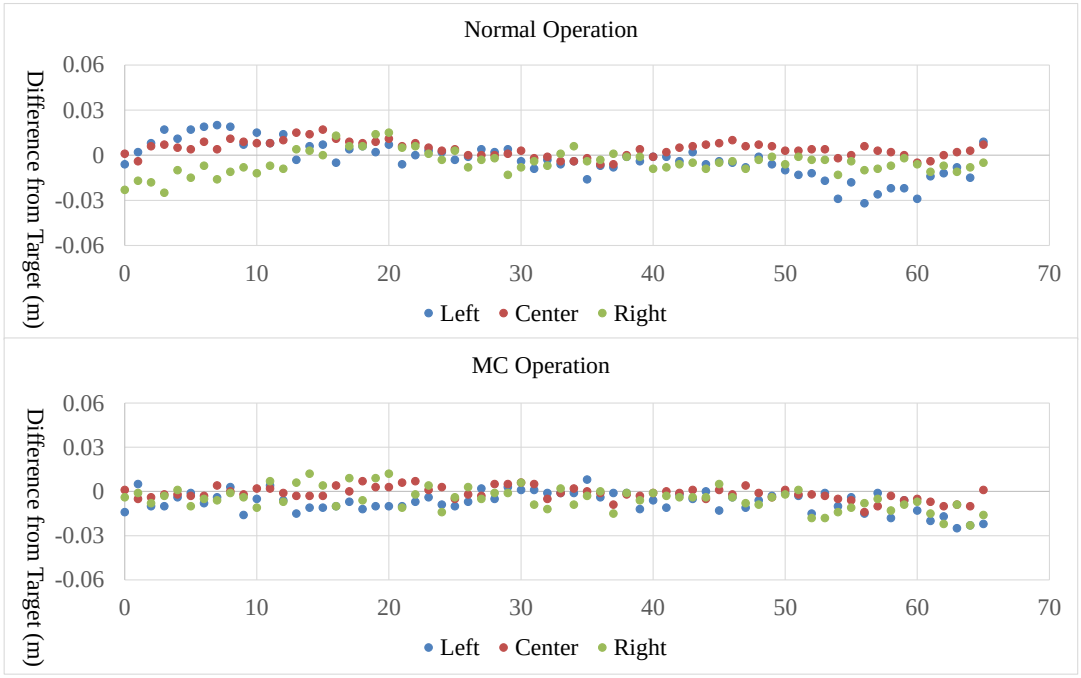

Figure 8. Finished height of operator D (experienced operator)

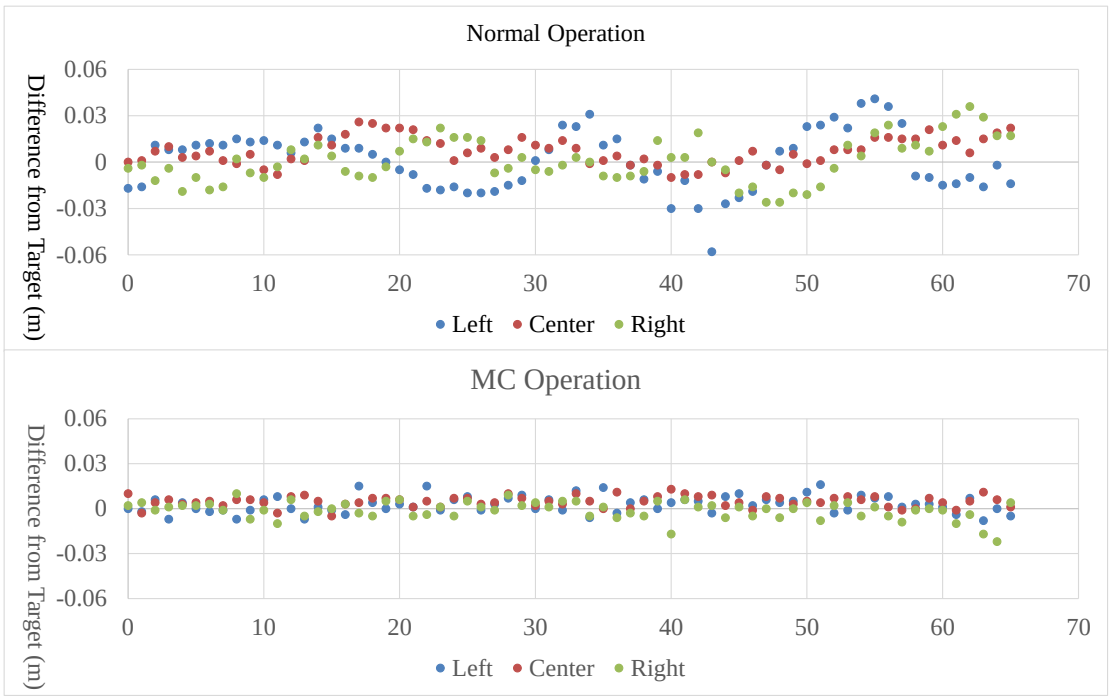

Figure 9. Finished height of operator J (inexperienced operator)

normal operation, the standard deviation of inexperienced operators is approximately double that of experienced operators, indicating that the working quality of inexperienced operators is much lower than that of experienced operators. For this reason, it can be stated that, as shown by the working time results in the previous section, the future shortage of experienced operators will seriously impact the construction industry, requiring countermeasures in the future, such as those based on robotics technology.

The standard deviation of inexperienced operators in MC operation was approximately 50% lower than it in normal operation, while the standard deviations of experienced operators in normal operation and MC operation were almost equal. Similar to the working time results shown in the previous section, this reveals that MC has a considerable effect on inexperienced operators, and that introducing MC could enable inexperienced operators to work with an working quality equal to that of experienced operators. While the effects of MC on experienced operators would be minimal.

3.3 Line of Sight of Operators

In order to organize the line-of-sight analysis data, the view of the operator is divided into three as shown in Figure 12, "near (the blade)", "forward," and "other" (outside the range of Figure 12, at monitors, etc.). And the time ratio of looking at each is shown in the Figure 13. Unfortunately, line-of-sight data during MC operation for operators C and G could not be obtained.

According to Figure 13, in the case of normal operation, the percentage of time that operators A and C (experienced operators) were watching "near (the blade)" were about 70%. On the other hand, that of operators E, G, and H (inexperienced operators) were 80% and 90%. From this, it is presumed that the inexperienced operators concentrated primarily on the area "near (the blade)" that was grading the base course material, and could not identify the state of the surroundings, but that the experienced operators paid attention to the area ahead, permitting them to predict the course the machine would travel smoothly and work high-quality.

In the MC operation case, the percentage of time that operators E and H (inexperienced operators) paid attention to the area "near (the blade)" fell substantially. This presumably occurred because, thanks to MC, they did not have to pay much attention to the blade operation, giving them opportunity to observe the

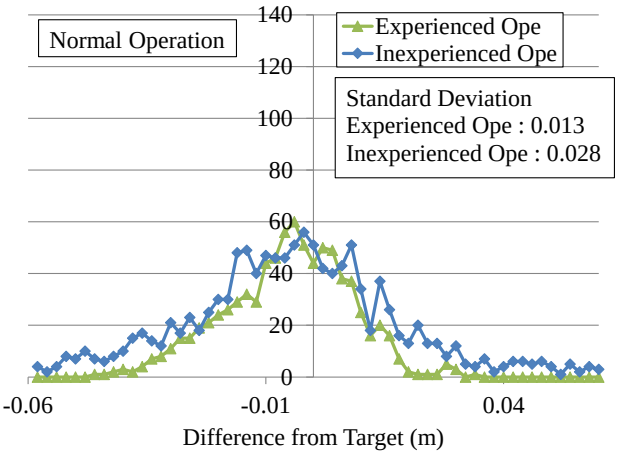

Figure 10. Frequency polygon of finished height data in normal operation

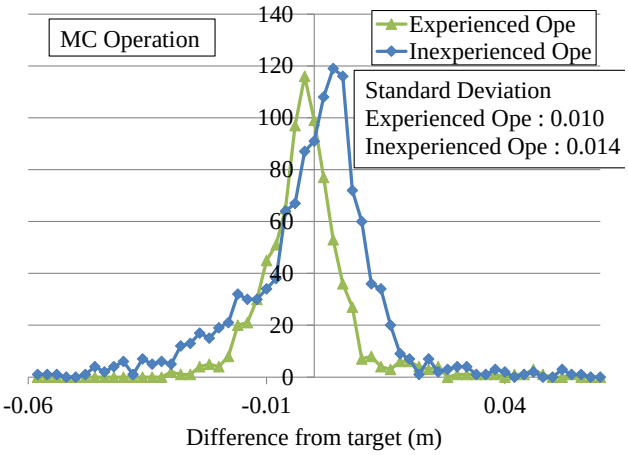

Figure 11. Frequency polygon of finished height data in MC operation

Figure 12. Operator's view

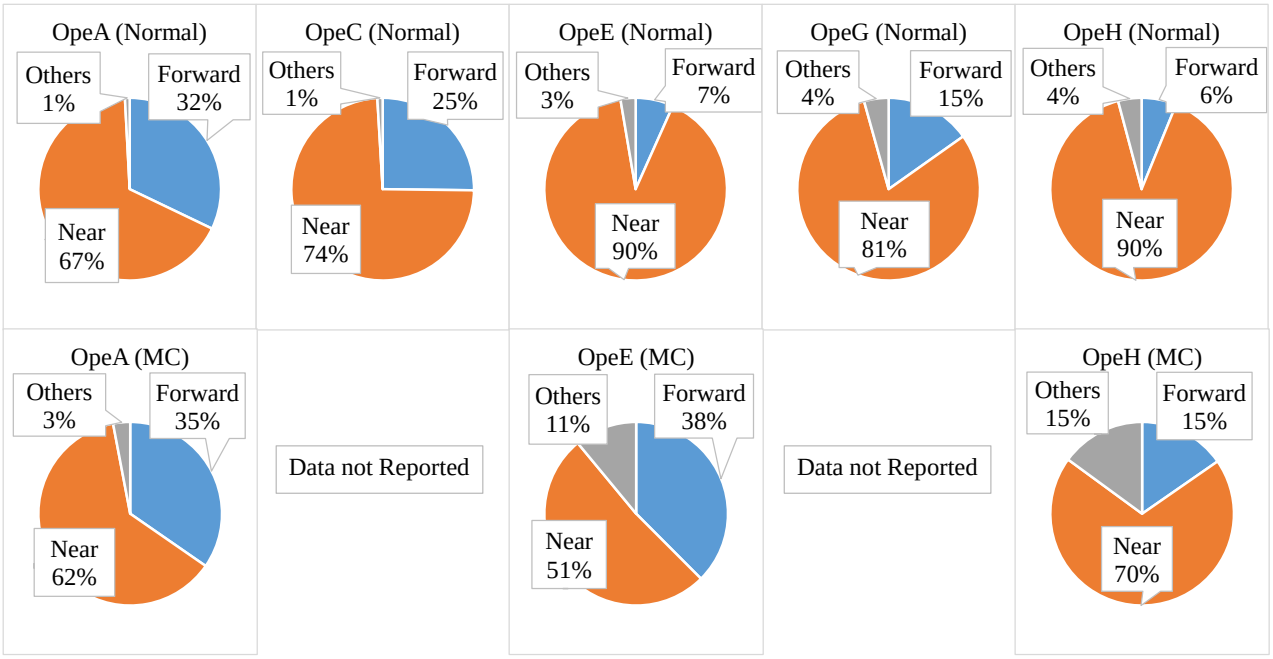

Figure 13. Time rate of looking

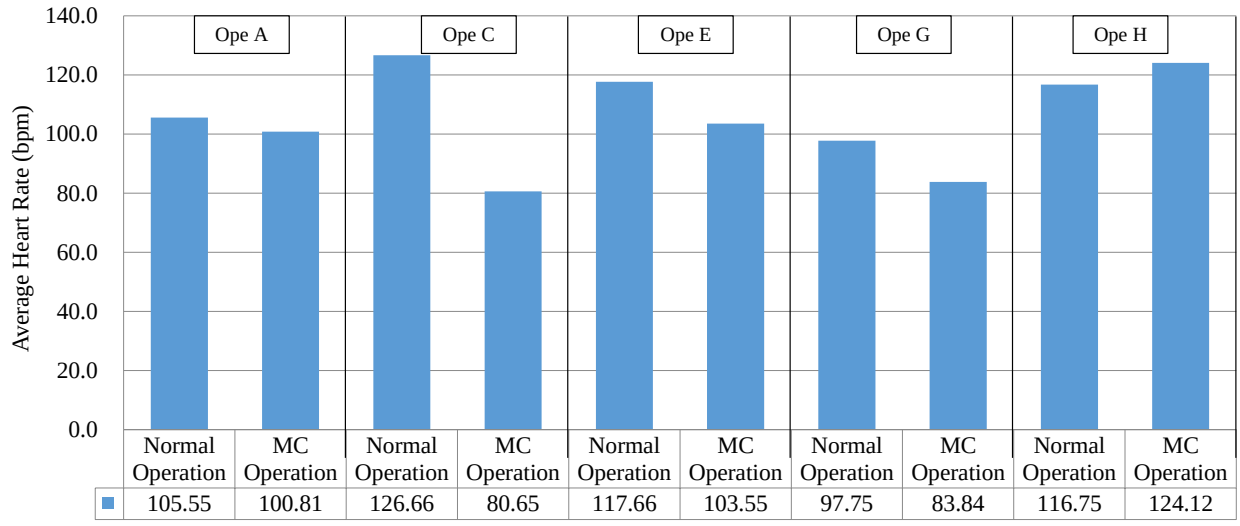

Figure 14. Average heart rate during operation

surroundings. For this reason, it can be stated that the introduction of MC would not only permit inexperienced operators to smoothly perform high-quality work, but it would also permit safer operation as they pay more attention to the surrounding conditions.

Meanwhile, it also shows that like working time and finished height, the line of sight of experienced operators would not be greatly affected by MC.

3.4 Heart Rate During Operation

To verify the effects of MC on operator mental burden, operator's heart rate during operation was measured. The average heart rate during operation are shown in Figure 14.

According to Figure 14, during MC operation, the average heart rate of all operators except operator H were lower than they were during normal operation. It is difficult to draw a conclusion based solely on heart rate, but results suggest that the introduction of MC could lower the mental burden of both experienced and inexperienced operators.

4 Summary

This study compared the working result of experienced operator and inexperienced operator when grading base course material using a motor grader. And also this verified the impacts that MC would have on both operators too. The results illustrated the following points:

(1) In the case of normal operation, the working time and finished height standard deviations of inexperienced operators are approximately double those of experienced operators, revealing that the working efficiency and working quality of inexperienced operators are much lower than those of experienced operators. This shows that the future shortage of experienced operators will have a serious impact on the construction industry, and that it is necessary to implement countermeasures such as the introduction of robotics technology.

(2) According to the line-of-sight analysis results, inexperienced operators concentrated only on the area "near (the blade)" that was grading the base course material, and thus they could not observe the surrounding conditions, experienced operators paid attention to the area ahead of the machine and predicted its travel path to smoothly perform high-quality work.

(3) MC had a considerable impact on the working time, finished height standard deviations, and line of sight of inexperienced operators, and the introduction of MC could permit inexperienced operators to achieve working efficiency, working quality, and safety equal to that of experienced operators.

(4) In the case of experienced operators, on the other hand, MC had only minimal effect on working time, finished height standard deviation, and operator line of sight.

(5) Introducing MC could lower the mental burden on both experienced and inexperienced operators.

The aging of experienced technical workers, and the oncoming shortage of these workers in Japan's construction industry poses serious challenges. This study has clearly shown that if the situation remains unchanged, it is highly likely that the construction industry will be seriously impacted. It has been confirmed that the use of MC or other robotics technology would be an effective way to counter these problems. In the future, we wish to continue conducting research intended to introduce robotics technology in machines other than motor graders. And also we wish to research to fully automate these machines instead of automating only some machine operations.

Abstract –

The application of robotics in the construction industry has been growing recently. However, it suffers from the lack of construction dedicated systems. The industry is characterised largely by designers and researchers scrambling to adapt systems from other industries and trying to apply them to the construction industry. In the application of Curtain Wall Module (CWM) installations, "HEPHAESTUS" is a European founded project that is engaged in designing a Cable Driven Parallel Robot (CDPR) automatic system capable of 1 mm positioning accuracy. It can perform other tasks such as drilling on the building by using a dedicated Modular End Effector (MEE). Conventional CWM installation from the outside of the building can be done in the case of 15 m/s wind but, to be competitive, the automatic cable robot system should be able to perform the task in similar outdoor situations. However, the cable robot – like other mechanical systems – has a specific stiffness which means that it could move slightly in the event of an external load such as wind, depending on the exerted load and stiffness. This movement should not be transferred to the final tool (e.g. the driller) while it's performing tasks on the building. To prevent or minimise the effect of the external load on the final tool in the chain of the mechanically connected system, a damping system should therefore exist. This paper introduces the novel hexapod-shaped passive damper. The damping system will be mathematically modelled and simulated using the Matlab Simscape software. The simulation results give logical consequences on the design. The designed damper and model can be used in other applications or dimensions with some simple modifications.

1 Introduction

The construction industry plays a crucial role all over the world. In many countries, it supports the economy, the development of other industries and helps maintain high employment rates [1], [2]. However, some tasks at construction sites involve dangers and risks and, in addition to this, need performance improvements. As a consequence of these challenges, the study of automatic construction robotics has recently been growing [3], [4] and [5].

The installation of a Curtain Wall Module (CWM) is one of such instances where high labour effort is required. This task involves several hazards for manual workers because it is performed on the outer edges and top floors of incomplete buildings. In addition, this operation is time consuming as it requires a lot of attention for completion. Therefore, automatic installation of curtain walls is required on grounds of safety and productivity [6].

This study is part of the HEPHAESTUS project [7], which was founded by the European Union. The focus of the project is on the installation of a Curtain Wall Module (CWM) as it is considered to be a high risk, yet critical, construction task [8]. The Cable Driven Parallel Robot (CDPR) moves on the face of a building and carries the CWM, while the Modular End Effector (MEE) works on the CDPR platform to set the brackets which are needed in advance for the installation of the CWM [9].

Excessive vibration from the CDPR caused by live loads like wind load could prevent the MEE from functioning properly while performing tasks such as drilling. Therefore, a damping system is necessary. A damping system is crucial because, when the frequency of vibrations from external forces is the same as the natural frequency of the structure, the structure may collapse like the Tacoma Narrows Bridge in 1940. Globally, there are many different kinds of damping systems. For example, a Tuned Mass Damper (TMD)

consists of a mass, a spring and a viscous damper, and is used to reduce the amplitude of vibration of a structure caused by environmental forces or other factors. The largest and heaviest TMD is situated in the Taipei 101 skyscraper in Taiwan [10], [11]. There are other ways to classify damping systems: passive, semi-active and active [12]. The passive damper does not need an energy input, i.e. electricity. On the other hand, the active damper has actuators that require a high quantity of energy to function. The semi-active damper has variable dampers that require less energy than the active damper. The passive damper is less efficient than the active damper; however, it is cheaper and less complex. An example of an active damper that is in use is an active stabiliser for the CDPR which was developed by (Lesellier et al, 2018)e [13].

A hexapod-shaped spring-damper was applied in this paper as a passive damping system, which is represented by the Stewart Platform [14]. A hexapod is a 6-DOF robotic parallel manipulator. Although it is light and compact, it has a large payload. A hexapod is used in many other fields of study [15] such as milling machines, flight simulators or in medical science.

In this paper, first the design of a hexapod-shaped spring-damper between a cable robot and an MEE is proposed and modelled. Next, the analysis of the kinematics and dynamics of that model and simulation in Matlab® is presented. Finally, a conclusion is derived from the results that were obtained.

2 Passive Damper Design

In the application of the HEPHAESTUS project, a fully constrained cable-driven parallel robot (CDPR) [8] exists on one end and on the other end there is a Modular End Effector (MEE) [9] which is gripped to the side of the building when in operation. Between these two mechanical components, there is a passive damper that was designed as shown in Figure 1.

For the tasks of the MEE to be performed with precision on the building, it is required that its base remains stable throughout the duration of the task.

Figure 2 shows the connection in a simplified manner, for example, the CDPR connection to the building and the ground are shown with just one connection and spring whereas, in reality, it consists of 6-9 cables providing the stiffness and damping in six dimensions including three translational and three rotational. As demonstrated in [16] and [17], studies have been carried out in this area. On the design of the CDPR, the stiffness could be one of the design parameters. Put simply, the higher stiffness means stronger cables, motor and gearboxes, which is one of the design constraints.

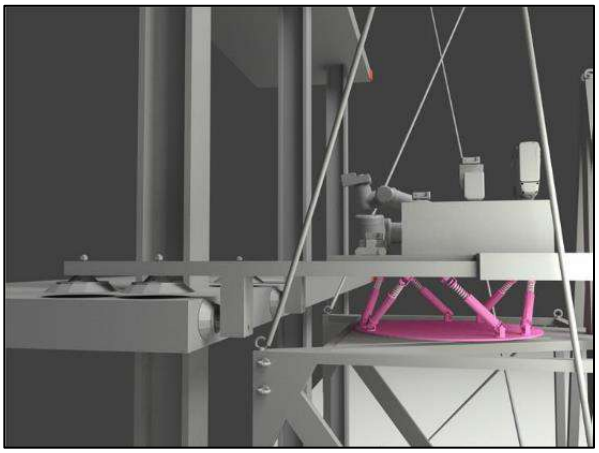

Figure 1. Hexapod-shaped damping system between the MEE and CDPR

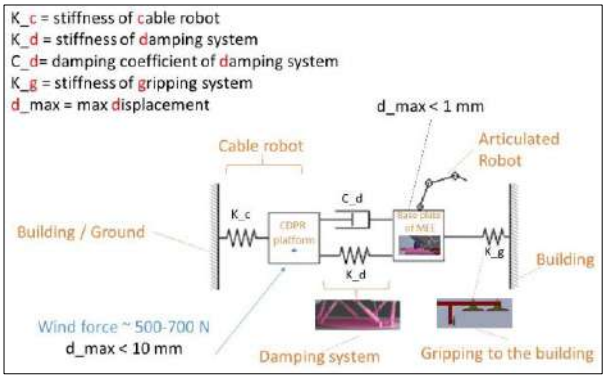

Figure 2. The chain of systems mechanically coupled

For the application of the HEPHAESTUS project, it is considered that the maximum displacement of the CDPR platform is less than 10 mm in the case of a wind force of 700 N which is caused by a 15 m/s wind speed on the CWM with a size of 150×350 cm. The relationship between these parameters can be seen using the following equation from [18]:

$$\boldsymbol{F}_W = \boldsymbol{p}_d A = \frac{1}{2}\rho v^2 A \quad (1)$$

where $\boldsymbol{F}_W$ = wind force (N), A = surface area (m^2), $\boldsymbol{p}_d$ = dynamic pressure (Pa), ρ = density of air (kg/m^3), and v = wind speed (m/s). ρ is equal to 1.2 kg/m^3at 20° C. $\boldsymbol{F}_W$ is an estimation of the force, caused by the pressure acting on a surface. The surface slows the air and the dynamic energy in the wind is transformed into pressure. Here, the drag force is not considered.

This research focuses solely on the damping system of the chain shown in Figure 2. The final goal of the design is to keep the maximum displacement of the MEE base to less than 1 mm, while keeping the displacement of the "connection point of MEE and

CDPR" other end to a maximum of 10mm. To do so, a model of the damper is required, which is the main subject of this paper. The model is generic, which means that the dimensions (size of the linear cylinder as well as the diameter of the upper and lower plate of the damper) and physical characteristics (mechanical properties e.g. damping and spring coefficient of each linear axis) could be adjusted based on the output requirements which is the maximum displacement.

In the following sections, the mathematical model of the design, together with the dynamic model and simulation in the Matlab® Simscape™ program, are explained.

2.1 Mathematical Modelling

Mathematical modelling of hexapods has been performed in previous researches. Forward kinematics and inverse kinematics have also been studied, as can be seen in [19] and [20]. Although there are researches about the dynamics of the active hexapod e.g. [21] and [22], few studies exist that focus primarily on the dynamics of the passive hexapod. In the passive hexapod model, the following equation can be established:

$$\boldsymbol{f} = -\boldsymbol{K}(\boldsymbol{l} - \boldsymbol{l}_r) - \boldsymbol{C}\dot{\boldsymbol{l}} \qquad (2)$$

where, $\boldsymbol{f}$ is the 6×1 vector of forces exerted at the bottom of the strut from each strut; $\boldsymbol{K}$ and $\boldsymbol{C}$ are the 6×6 matrices containing the stiffness and damping of each strut respectively; $\boldsymbol{l}$ is the 6×1 vector of the strut lengths; $\boldsymbol{l}_r$ is the constant 6×1 vector of the relaxed strut lengths.

Then, the force P and the moment M about the tool point position are given by:

$$\begin{bmatrix} P_x \\ P_y \\ P_z \\ M_x \\ M_y \\ M_z \end{bmatrix} = -\begin{bmatrix} u_{1x} & u_{2x} & u_{3x} & u_{4x} & u_{5x} & u_{6x} \\ u_{1y} & u_{2y} & u_{3y} & u_{4y} & u_{5y} & u_{6y} \\ u_{1z} & u_{2z} & u_{3z} & u_{4z} & u_{5z} & u_{6z} \\ J_{1x} & J_{2x} & J_{3x} & J_{4x} & J_{5x} & J_{6x} \\ J_{1y} & J_{2y} & J_{3y} & J_{4y} & J_{5y} & J_{6y} \\ J_{1z} & J_{2z} & J_{3z} & J_{4z} & J_{5z} & J_{6z} \end{bmatrix} \boldsymbol{f} \qquad (3)$$

where, $\boldsymbol{u}_i = [u_{ix} \quad u_{iy} \quad u_{iz}]$ is the unit vector of the ith strut; $\boldsymbol{J}_i = \boldsymbol{u}_i \times \boldsymbol{b}_i$; $\boldsymbol{b}_i$ is the vector from the centre of the base body to the attachment point of the ith strut. Figure 3 shows a schematic of a mathematical model of the hexapod described above.

This Mathematical model relates the forces $\boldsymbol{f}$ at the bottom of each strut to the forces P and the moments M at the centre of the top plate (tool point position). The mathematical model is introduced here to give the reader an understanding of how the dynamic system works within the theoretical framework of the paper.

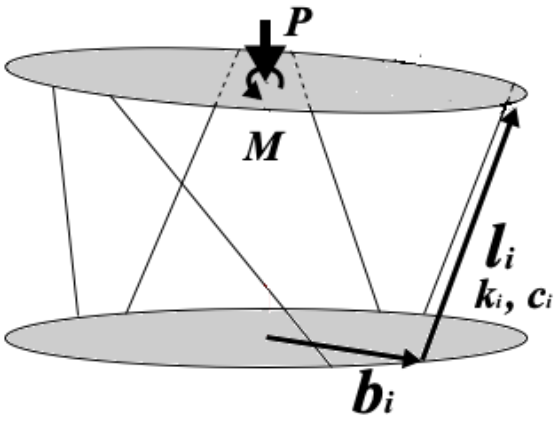

Figure 3. The mathematical model of the hexapod

2.2 Simscape™ Model in Matlab®

For simulation by the Simscape™ environment of Matlab® software, the CAD model in AUDODESK® INVENOR® software is first created and then imported to Simscape Multibody™. The relation and assembly constraints were carefully selected to automatically drive to a Simscape™ proper joint. The material and weight of the physical part were selected so as to resemble stainless steel, the material that the component will most probably be made out of. Once they are all imported, the Simscape™ model was edited to most closely resemble what the system is like in reality. Figure 4 shows the first level of the multibody diagram.

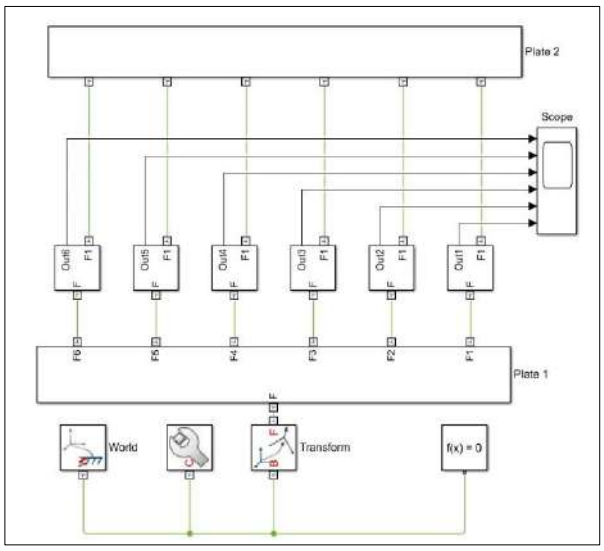

Figure 4. The first level of the multibody diagram

As shown in Figure 4, there are two plates which have between them six spring-damper cylinders. A scope module is also inserted to show the result of the

simulation which is, in this paper, the position of each cylinder. Although several results could be extracted from this model, e.g. the force on each cylinder and the speed of each of them, their positions in this model are shown as an illustration. It would be possible for one to extract more results from this model.

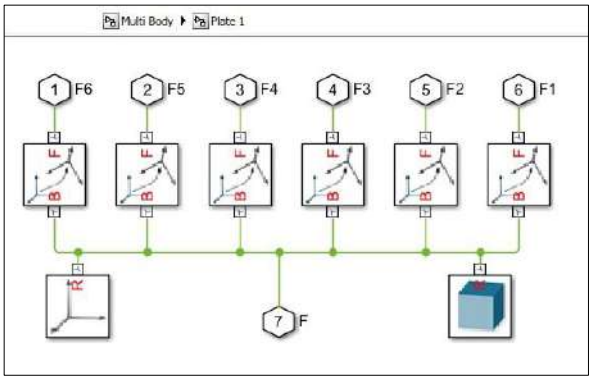

Figure 5. The lower plate of the multibody diagram

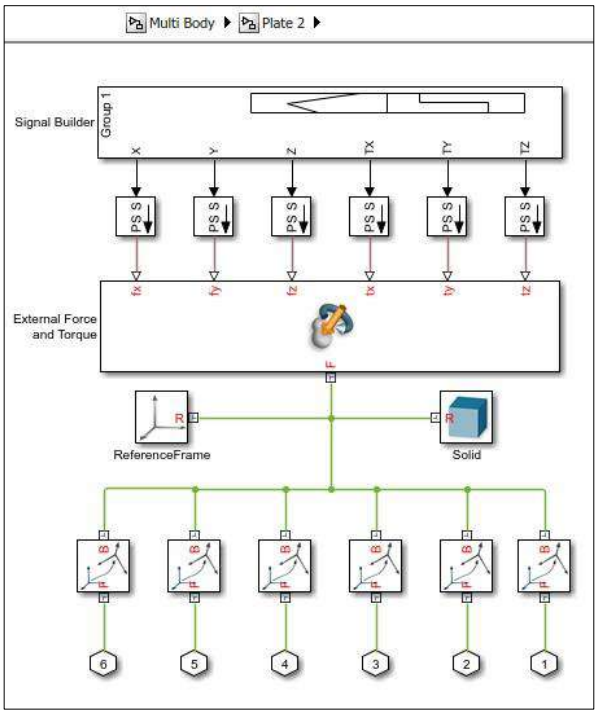

Figure 6. The upper plate of the multibody diagram

In this model, it is considered that the lower body is fixed, as shown in Figure 5, and that the upper body is free to move. Sample forces and torques are applied on the upper body in all directions. The diagram of the upper plate is shown in Figure 6. The purpose of this model is to provide a demonstration on how the model works in general.

Each of the spring-damper cylinders is modelled in Simscape™ with a set of revolute joints and one cylindrical joint as shown in Figure 7. In the properties of the cylindrical joint, the spring and damping coefficient, together with the equilibrium point of the cylinder, could be identified. In this example, the spring factor or stiffness of the damping system is considered to be 31,200 N/m and the damping coefficient of each cylinder is considered to be 2,250 N.s/m which is in the same range of suspension systems as automobiles, which are also considered in [23]. Automobiles are chosen since they are widely used and show that the model works with any conventional spring-damper system. The value is also not unlike off-road motorbike damping systems, which is another example of equipment that is widely used [24].

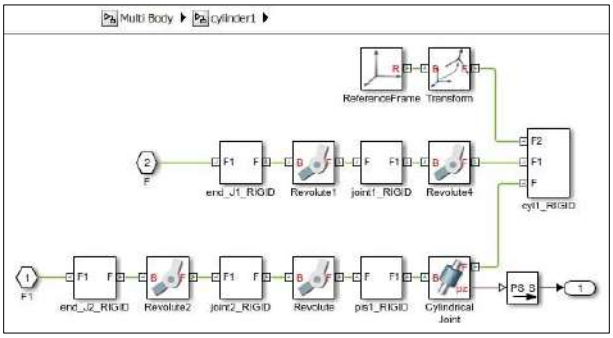

Figure 7. The cylinder level of multibody diagram

The characteristics of the sample damper are shown in Table 1 and the details of the simulation parameters are explained in the simulation results section. As previously explained, the dimensions and mechanical properties could easily be changed in the model, and the dynamic behaviour of the new model could then be established. For future development in the HEPHAESTUS project, the CDPR should be added to one plate on one end and, on the other end, the system that grips to the building.

Table 1. Damper characteristics

Property of item	Nomenclature	Value
Upper bound of cylinder movement	l_0	0.04 m
Lower bound of cylinder movement	l_m	-0.04 m
Spring factor of each cylinder	31,200	N/m
Damping coefficient of each cylinder	2,250	N.s/m

2.3 Simulation Results

For the simulation, one set of sample forces and torques is applied on the upper plate (representing, for example, the wind load applied to the CDPR and the effect it has on the damping system) since the lower plate is considered fixed to the ground (which represents the MEE gripped to the building). These loads are chosen for illustration purposes only; one can edit the input in the model and analyse the simulation results for specific loads. The applied forces are shown in Figure 8.

For the Y axis, a load of 700 N calculated using equation 1 is considered, even though in reality, by using the CDPR, not all of this wind load will be transferred to the MEE.

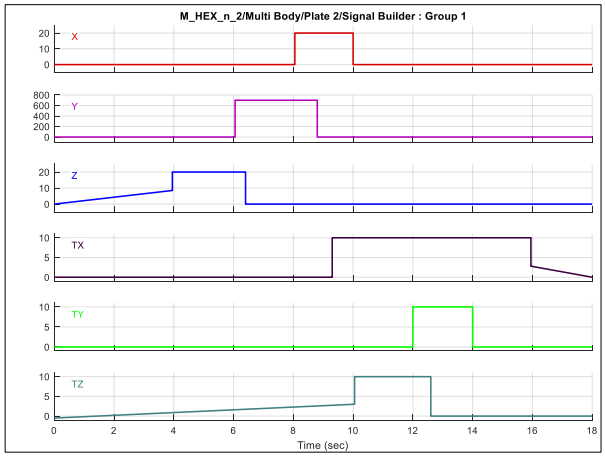

Figure 8. Input forces [N] and torques [N.m] signals

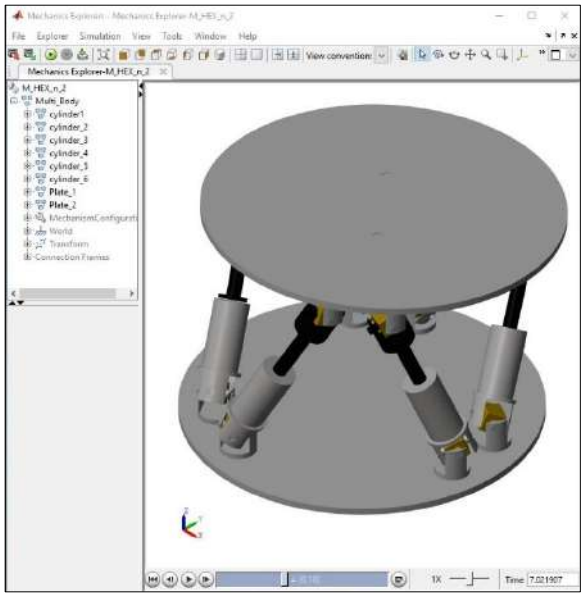

Figure 9. Mechanics explorer windows showing the simulation at the moment: time = 7.02 s

In the Matlab® Simscape™ model, under mechanism configuration, the linearisation delta is set to 0.001. "The linearisation delta specifies the perturbation value that is used to compute numerical partial derivatives for linearisation" [25]. The other solver configuration, the ODE solver, is set to "auto" mode in Matlab®, as this leads to the best matching results. g, the acceleration due to gravity, is considered as 9.80665 m/s^2 in the model configuration. In the solver configuration, filtering time is considered to be 0.001 s and consistency tolerance is considered equal to 1e-09.

As a visual result, in the *Mechanics explorer* window of Simscape™, the movement of the whole damper is also simulated. Figure 9 shows a screenshot of the *Mechanics explorer* windows at the moment: time = 7.02 s.

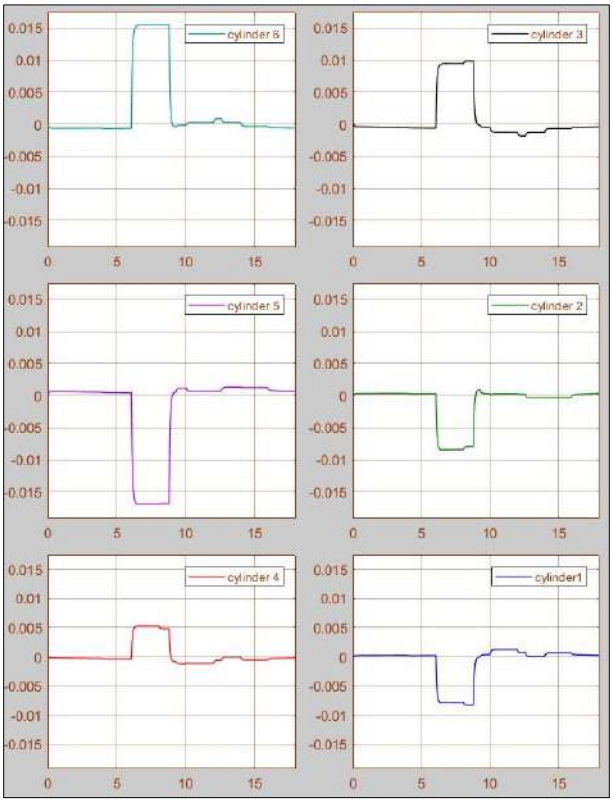

Figure 10. Output of cylinder position in Y axis [m] regarding the time in X axis [s]

As a result, the dynamic characteristics and movements of each cylinder could be drawn in a SCOOP module. It is possible to extract the forces and speeds on each joint. In this paper, only the position of each cylinder (spring-damper) is shown in Figure 10.

3 Conclusion

In this paper, a novel damper for passive damping of

a Modular End Effector mounted on a CDPR has been introduced. If a MEE and CDPR are directly coupled, excessive vibrations from the CDPR (caused by e.g. wind) may render the MEE unable to effectively fulfil some of its tasks (e.g. drilling). This problem calls for the installation of a novel damping system to reduce these effects. The system consists of a hexapod-shaped spring-damper placed between a MEE and CDPR. A mathematical model and Matlab® Simscape™ model are introduced and a simulation has been performed. The displacement of each cylinder is shown; however, other output data such as the forces and speeds on each joint could be extracted from the model for analytical purposes, which are not shown in this paper.

Although the initial design was for the CWM installation application, the model is generic and the characteristics of the mechanical system can be chosen freely. This entails the system can be used in other applications as well.

For future development of the CWM installation with CDPR and MEE, one can add the CDPR stiffness model on top of this model. This approach will be explored together with some other partners of the HEPHAESTUS project. In addition, to make the dynamic model presented in this paper for the damper more precise, one could perform some laboratory tests to optimise the Simscape model; this will be carried in the next steps of the project.

Abstract –

Throughout the life cycle of civil assets, construction, operation and maintenance phases require monitoring to assure reasonable decision makings. Current methods always involve specially-assigned personnel conducting on-site inspections, which are work-intensive, time-consuming and error-prone. Computer vision, as a powerful alternative to manual inspection, has been extensively studied during the past decades. On the basis of existing summary papers, this paper reviews a wide range of literatures, including journal articles, conference proceedings and other resources. Current applications of computer vision during construction, operation and maintenance stages of civil structures are concluded, with a special focus on operation and maintenance phase. This review aims to provide a comprehensive insight about the utilization of computer vision in civil engineering and an inspiring guidance for future research.

1 Introduction

In construction, operation and maintenance phases of civil assets' life cycle, monitoring is required for reasonable resource allocation and decision making. To be specific, monitoring of construction sites paves way for progress tracking, quality control, safety assurance and productivity analysis. When it comes to in-service structures, understanding of their current situations can help engineers to determine repair, retrofit and replace plans. Traditional methods always involve specially-assigned personnel conducting on-site inspections, during which physical measurements can impose extensive workload and potential danger to inspectors [1]. Such manual inspection processes are also time-consuming and prone to the biased judgement of inspectors. Alternatively, the development of reality capture technology and image processing techniques facilitate the utilization of computer vision in Architecture, Engineering & Construction and Facility Management (AEC & FM) industry. As an interdisciplinary field, computer vision aims to generate human-like understanding from digital images or videos, and thus attracts focused attention from researchers worldwide. Numerous studies have been done and impressive progress has been achieved. This paper goes through computer vision's applications in construction, operation and maintenance stages of built assets in a large scale, with a focus on recent researches that are published after existing review papers [2, 3].

The structure of this paper is as follows. Section 2 illustrates research methods. Section 3 presents analysis results and in-depth discussions about current researches. Section 4 provides envisions for future work.

2 Research Methods

2.1 Data Collection

Aiming to obtain a comprehensive insight about vision-based practices in civil engineering, the research started with initial searching and scanning in both web search engine, google scholar, and academic databases such as ScienceDirect and IEEE Xplore. Direct search method based on title, abstract and keywords was employed to collect a wide range of literatures, so as to form a fundamental concept about how computer vision is combined with civil engineering. "Computer vision", "civil engineering" and other related terms such as "machine vision" were search keywords. Different types of literature including journal articles, conference proceedings, even book sections were collected and reviewed. Apart from the relevance, publishing date was regarded as another sift criteria. The emergence of this topic was largely facilitated by the development of computer science and image processing techniques, thus the time limit was set to year 2000 to exclude unrelated studies. After the initial stage of review, top journals embodying high-quality articles in this field were

identified, some (but not all) of which are: Computer-Aided Civil and Infrastructure Engineering, Automation in Construction, Advanced Engineering Informatics, Journal of Computing in Civil Engineering and IEEE. Key authors who made advanced contributions to this field were also recognized. Existing review papers were referred to and set as a time mark for further selection of data. Focused search was then conducted centring on the above-mentioned journals and authors. In total, 71 papers were collected and analysed (Figure 1), including 54 journal articles, 16 conference proceedings and 1 book section. EndNote X7 was used for data storage, management and citations.

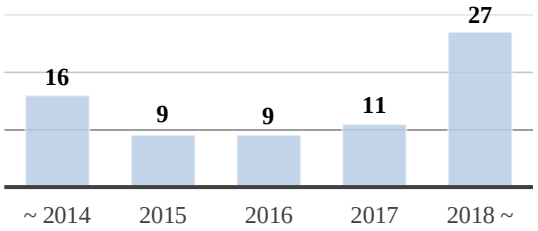

Figure 1. Chronological distribution of articles

2.2 Data Analysis

Preliminary data analysis was completed during data collection by scanning titles and abstracts, followed by context analysis, a typical method for qualitative data analysis. Regarding the application scenarios of computer vision, the literature was divided into two blocks: one that focused on construction phase and the other on operation and maintenance phase. Papers in two parts were then analysed separately. Excel tables were created for note takings while reviewing, with critical information and peculiar contributions of each article highlighted. Notable information included the main purpose of application, area of use, equipment demand, methodology, outcome quality, and future agenda. A comparison was made based on the systematic review.

3 Results and Discussions

Current applications of computer vision in civil engineering are categorized into two groups: (1) construction phase and (2) operation and maintenance phase in structure's life cycle.

3.1 Computer Vision in Construction Phase

Due to an early start of computer vision on construction sites, a thorough research in this area has been developed in the last decade. Summaries and overviews are available in existing literatures [2].

The utilization of computer vision technology in construction jobsites can be categorized into four classes regarding the main purpose of application, namely progress monitoring, quality control, operational productivity analysis [4-7] (which is to what extent onsite resources are being utilized) and safety assurance [8-12]. Combination of multiple purposes was achieved in some researches [13, 14]. Apart from fatality prevention, there is another safety concern named occupational health assessment, referring to [15]. Seo, J., et al. integrated vision-based human kinematics data to biomechanical analysis, so as to evaluate the risk of musculoskeletal disorders faced by workers when conducting lifting tasks.

One important constitution in a vision-based monitoring system is object detection. Typical methods follow two sequent steps, feature extraction and object classification. The most frequently employed image descriptors include, but are not limited to, shape-based features like edges [16] and texture-based ones like Histogram of Oriented Gradients (HOG), which is a local spatio-temporal feature particularly suitable for action recognition. Extracted features are then fed into classifiers for object recognition. In addition to traditional classification algorithms like support vector machine (SVM), deep learning techniques, e.g. faster region-based convolutional neural network (faster R-CNN) in [11], are rising up in recent studies. Its core part is an artificial neural network (ANN) as an analysis kernel during object recognition, categorization and other information extraction [17]. Luo, H., et al. [6] presented a three-stream CNN dealing with RGB images, optical flow images and grayscale images, separately, then fused the results together to identify workers' states in reinforcement installing activities.

Another core task in job sites involves the tracking of detected construction entities (i.e. workforce and equipment). Xiao, B. and Z. Zhu [18] summarized and compared 15 2D tracking methods in past studies regarding the outcome quality (i.e. overlap score and centre location error), highlighting the superiority of methods using sparse representations and generative classification algorithms. The 2D tracking results are then transformed into 3D space through triangulation to gain trajectories of the target, for example, crane jib [19] and excavators [16].

Subsequently, activity recognition of either workers [6, 9] or equipment (especially excavator and dump trunk in earthmoving operations [4], and cranes [19]) constitutes the next level of image processing, allowing the detection of un-safe behaviour and understanding of onsite situations. Moving personnel and equipment were monitored in [20] and by fuzzy inference, potential dangers like struck-by accidents were evaluated in a numerical way for an efficient safety management. Luo, X., et al. [21] managed to identify 20 activity patterns in sites assisted by prior knowledge (i.e. whether two

certain objects cooperate in an activity and their proximity). Similar relevance information was adopted in [5] for interactive analysis of individualized action recognition. Both one-to-one- and group-level analysis led to a precision of 91.27% in situation understanding.

Combination of computer vision and other state-of-the-art technology is also emerging. For example, Jeelani, I., et al. [10] utilized eye-tracking techniques to obtain workers' viewing patterns, which was then integrated into a computer-vision-based localization system to indicate workers' ability to recognize onsite hazards.

3.2 Computer Vision During Operation and Maintenance Phase

The utilization of computer vision in structural health monitoring (SHM) and performance evaluation has been increasingly studied in recent years. Such a scheme can positively contribute to a reasonable management of construction resources, leading to a sustainable built environment. Koch, C., et al. [3] concluded the achievements and challenges faced in this field and since then, notable improvements have been accomplished.

3.2.1 Reality Capture Technology

For data acquisition, two main reality capture techniques include laser scanning and photogrammetry, where point clouds and images/ videos are input and analysed, respectively. Aiming to lower inspection cost, digital imaging was favoured in the literature. 49 out of 51 studies extracted information from photos or video frames, most of which relied on consumer-grade devices like digital single-lens reflex (DSLR) camera [22-25], action camera [26], video camcorder [27], existing closed-circuit television (CCTV) [28], or even smart phone cameras [29-32]. Un-manned Aerial Vehicle (UAV) [33] or flying robot [34] can be utilized to mount cameras to free workers from hand-held cameras and on-site tour for inspection. To note, Dorafshan, S. et al. [35] studied the robustness of crack detection in steel bridges against various camera specifications. Three types of cameras, i.e. Nikon COOLPIX L830, DJI Mavic and GoPro Hero 4, were tested, indicating different crack-to-camera distance requirement for a desirable result.

3.2.2 Image Processing Algorithms

A typical computer vision-based defect detection method involves four levels of image processing, namely image pre-processing, segmentation, feature extraction and pattern recognition. Satisfactory segmentation results can lead to a high accuracy of detection, which, in most cases, was ensured by the use of thresholding-based segmentation algorithms. Defect detection leverages similar features as job-site monitoring, covering edges, diverse interest points, region proposals (especially in R-CNN algorithms), HOG, gradient magnitude and orientation, entropy, and even colour-based ones. Edge detection dominates in previous studies, and Qizhen, H. et al. [36] concluded two classes of edge detection algorithms: ones dependent on first-order derivative, i.e. image gradient, and ones based on second-order derivatives.

In higher-level image processing, deep learning algorithms have gained popularity as mentioned. The form of the core network, ANN, evolves from CNN [37, 38], fully convolutional neural network (FCN) [39], fast R-CNN [29], to faster R-CNN [24, 28]. Along with the superiority to eliminate multi-step image processing, such algorithms are further supported by acceptable performances and adaptability to diversified structures and defect types.

3.2.3 Area of Use

In real life, defect inspection and condition assessment procedures are carried out both regularly (routine inspection) and after disasters.

- Post-disaster inspection

Past work for post-disaster inspection focuses on damaged reinforced concrete (RC) columns due to their critical role to resist lateral seismic loads. Lattanzi, D., et al. [40] established relationship between visual defects (e.g. cracks and spalls) and the maximum experienced displacement of concrete bridge columns for post-earthquake condition assessment. The peak drift estimated through machine learning regression models can facilitate triage evaluation. Similarly, German, S., et al. [41] first adopted computer vision algorithms (e.g. edge detection, region-growing detection, thresholding, etc.) to identify and measure cracks and spalling on RC columns, based on which, a framework for vision-based structural analysis is completed.

- Routine inspection

The allocation of past researches in different areas of use is shown as Figure 2.

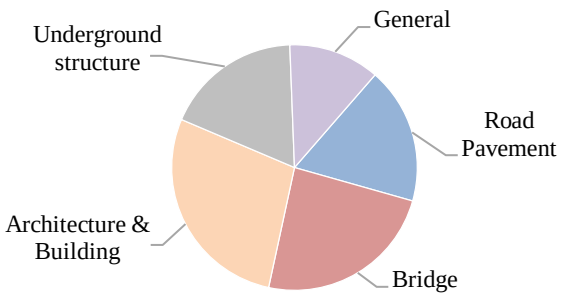

Figure 2. Literature distribution (area of use)

Comparatively, a wider range of civil structures are studied in routine inspection, and an almost even distribution is shown. The aging problem of architectures and buildings attracts the most attention (making up 28% of the literature). 12 out of 51 studies focus on the health of bridges. Roadways (asphalt pavements in particular) and Underground structures (including sewer pipes [28, 42], tunnels [38, 43, 44] and subway system [17]) are also frequently studied fields, accounting for 9 out of 51 papers equally. Different from the majority of studies, Kamal, K., et al. [45] classified various knot defects in wood structures.

There are about 12% researchers developing their proposals in a general scale, testing on laboratory specimen [46] and existing point cloud datasets [47], and aiming to tackle prevailing or critical challenges encountered during applications.

3.2.4 Defect Types

Figure 3 illustrates the allocation of past work in various defect detection.

Cracks appeal the most intensive studies by far, accounting for more than 35% of the literature. Among them, 17 articles study on concrete structures, 3 researches target fatigue cracks on steel structures and 5 papers recognize cracks on road pavement. Around a quarter of past work focus on displacement, based on which structural vibration properties (e.g. natural frequency and mode shapes [48]) are further retrieved. Pothole, as a distress peculiar to roadways, are recognized in 3 out of 51 papers. Other defects include cavities [29, 49], spalling [50], rebar exposure [29, 50], moisture marks on subway structures [17], loosened bolts [44], etc.

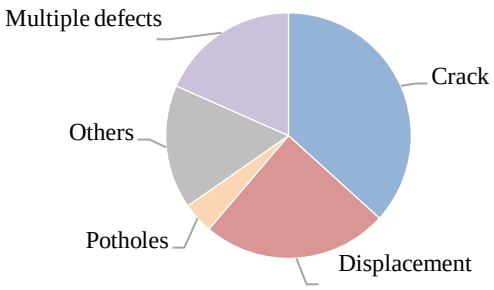

Figure 3. Literature distribution (defect types)

In addition, a few of studies (nearly 20%) recognize multiple defects [51] and cover more damage patterns, such as deposits, tree root intrusions and water infiltrations on pipes [28], steel corrosion, bolt corrosion and steel delamination on general structures [24].

Particularly, artificial markers or specific objects (e.g. lane marker, manhole and patches on roadways) on the asset were utilized to clarify novel methods in [52].

3.2.5 Level of Detection Details

To what extent computer vision can benefit maintenance decision making is fully dependent on the level of detail of the inspection results. The outcome of a computer-vision-based inspection system develops from the mere detection of defects' presence, classification of multiple damages, defect localization, to numerical measurement of critical properties. The progress so far is shown in Table 1. And detailed achievements in each category are illustrated below.

Table 1. Current research progress

Level of detail / Defect type	Defect detection		Defect property retrieval
	presence	localization	
Crack	[23-25, 30, 33, 34, 37, 53-55]	[28]	[22, 39, 56-59]
Pothole		[60, 61]	
Spalling			[50]
Cavity		[49]	
Moisture marks			[17]
Displacement		-	[26, 27, 46, 48, 62-65]
Dynamic responses		-	[66]

Note: The grey area means that this level of defect details has been successfully retrieved using computer vision techniques in the literature (with relevant references listed), while blank area means that few researches included the extraction of such information so far.

- Classification. Identification across defect types were realized in [31] to classify pothole, longitudinal-transversal cracks, and fatigue cracks on pavement. Other researches define category based on damage severity (major/ minor cracks in [42]), defect features (crack orientation in [56]), or different maintenance demand (sealed or ordinary cracks in [67]).
- Localization. Several researches locate the defect-included bounding box in the identified image [28, 60, 61], requiring further processing to gain their positions in global coordination. Additional devices

are deployed as supplementary, such as GPS [31], infrared camera and laser range finder for cavity localization on roadways [49].

- Property quantification. For crack measurement, its length, orientation, max width and mean width are extracted either through skeletonizing operations in static images [39, 68] or by tracking surface discontinuities in video streams [22]. Properties of spalling area, i.e. its length and depth, are obtained by analyzing the region with exposed longitudinal reinforcement [50]. The severity of wet marks on subway structures is quantified in terms of the area's percentage [17]. Displacements are retrieved in almost all relevant researches. One notable improvement is that early studies rely on manually-created markers [64] or speckle created by a laser pointer [66], while recent work achieve target-free inspection using "key points" [63, 69] on structures. Another progress is multi-point displacement measurement using multiple synchronized low-cost cameras [26] or a multithread active camera with Galvano-mirror [48]. Displacements can be further converted to natural frequencies through the Fast Fourier Transform (FFT) [63].
- Structural analysis. Limited research manages to complete this step with vision-based defect information. Post-earthquake fragility curves of RC columns were generated in [41], indicating structural damage states and estimated retrofit cost. Davoudi, R. et al. [32] estimated structural load levels of RC beams and slabs based on crack patterns. Combination with other technology like robotics [58] further facilitates this process.

4 Conclusions and Future work

This paper presents an overview about the applications of computer vision in civil engineering. Researches in construction sites start early and form a relatively mature system, and there are considerable advances in defect property retrieval for existing civil assets. However, challenges remain in this field and promising future work on the basis of current achievements is demonstrated as below.

Currently, vision-based defect information is underutilized due to the lack of relationship between visual data and structural responses. Thus, the integration and utilization of defect information in structural analysis so as to facilitate maintenance decision makings is in the future agenda.

Another task is to establish an enlarged dataset for computer vision. For construction phase, images with a wider range of personal protective equipment (PPE) [8], construction entities, and their activity patterns [11] should be collected. As for operation and maintenance stage, images containing more defect patterns under various environmental conditions can largely contribute to this field. Such enlarged datasets can be used to train classifiers for higher detection accuracy and achieve comprehensive monitoring of both construction sites and aging structures.

Robustness of analysis results against adverse factors encountered during data acquisition should be tested and improved. In jobsites, though effects of various illumination, varying object-to-camera distances, and different levels of occlusion on the accuracy of object tracking have been studied [7], further evaluation concerning other uncertainties, like shadows, should be included in future work. Similar envision applies to in-service assets, even if the impacts of surrounding lighting conditions on crack detection have been assessed [35].

For practical considerations, real-time analysis is desired. In routine inspections, real-time defect recognition and feedback to inspectors are enabled by the simplification of image capturing devices [31]. The leverage of Graphics Processing Unit (GPU) can further shorten computation time. However, when faced with cluttered construction sites and existence of various deterioration patterns, further improvements are in need.

In the future, combination with other advanced technology is encouraged. The utilization of deep learning methods has been proved efficient. Data-driven algorithms also facilitate the vison-based condition assessment [32] , calling for more multidisciplinary applications. Moreover, devices like GPS providing additional information for vision-based system also deserve consideration.

Abstract –

Crane operators fatigue is one of the significant constraints should be monitored. Otherwise, it may lead to inefficient crane operations and safety issues. Recently, many deep neural networks have been developed for fatigue monitoring of vehicle drivers by processing the image or video data. However, the challenge is to distinguish the slight variations of facial features among still and motion frames (e.g., nodding and head tilt, yawning and talking). It can be exacerbated in the scenarios for crane operators due to their constant head moving to track the loads' position and recurrent communication (talking) with crane banksman. In contrast to previous approaches, which models spatial information and traditional temporal information for sequential processing, this study proposes a hybrid model can not only extract the spatial features by customized convolutional neural networks (CNN) but also enrich the modeling dynamic motions in the temporal dimension through the deep bidirectional long short-term memory (DB-LSTM). This hybrid model is trained and evaluated on the very popular dataset NTHU-DDD, and the results show that the proposed architecture achieves 93.6% overall accuracy and outperform the previous models in the literature.

Keywords –

Fatigue monitoring and alerting; Deep learning; Crane operator; Prefabricated construction

1 Introduction

In prefabricated construction, the prefabricated products become more and more complicated for assembly, with the evolution from components (light-weight, e.g., facade) and modules (large and heavy, e.g., volumetric precast bathroom) to pre-acceptance integrated units (larger and heavier, e.g., completed with finishes, fixtures, and fittings) [1]. Given this course of prefabricated products evolution, cranes, with their excellent transportation capacity, perform a decisive role in the assembly of prefabricated products by lifting them vertically and horizontally [2]. To achieve smooth crane operations, the crane operators should not only have enough physical strength but also be agile in the hearing, eyesight, and reflexes. As such, the operations and judgment of the crane operator will be a crucial factor for safety and productivity particular in the construction site of Hong Kong due to the high level of congestion and dynamics. However, the fatigue or drowsiness has been identified as the critical constraint in disturbing the operator's operations and judgment, which leads to the decreased attentiveness and vigilance, as well as casualties by collisions or falling loads [3,4]. In addition, Tam and Fung [3] revealed that around 60.5% of the crane operators would continue to work even feeling fatigue due to the long working hours (tight construction schedule) and about 52.6% of the crane operators are lack of breaks due to the inconvenient and narrow workspace (inconvenience of frequent in and out). Thus, automatically monitoring and warning the fatigue can provide timely support for crane operators, site superintendents and safety directors to make the scientific shifts and breaks.

Although there are seldom studies on developing fatigue monitoring and warning systems for the crane operator, numerous objective approaches have been proposed for detecting the fatigue or drowsiness of vehicle drivers from vehicle trajectory [5], physiological signal [6], and facial expression [7]. The first two approaches in crane operation can measure the fatigue by several parameters such as trolley movement speed, loads path deviation, jib rotation speed, heart rate, electroencephalogram (EEG), electrooculogram (EOG), electromyogram(EMG), and electrocardiogram (ECG). These two methods have shown a good accuracy when monitoring physical fatigue of vehicle drivers. However, crane operation trajectory may be affected by other factors (e.g., operation errors due to inexperience, inefficient communication with site signaller) and the physiological signal should be collected by an annoying

and invasive way to crane operators. Thus, monitoring the fatigue reflected by facial expressions (e.g., eye state, yawning, nodding) can be a more convenient, fast-speed and cost-effective approach. This kind of approach can analyze the facial features extracted from the videos/images of crane operators, and it performs a high accuracy after the boosting of various deep neural networks as it facilitates the computer to learn by itself for capturing the key features. For example, Zhang et al. [8] adopted the convolutional neural network (CNN) to detect the yawning by using the features in nose region instead of mouth area due to the head turnings of vehicle drivers. However, it is still difficult to distinguish easy-to-confuse fatigue states, such as blinking and closing eyes. Huynh et al. [9] provided a more practical solution with the 3D-CNN by considering the broader features on the face and temporal information (sequence of video frames). However, it is still a challenge to distinguish the fatigue states with long-term dependencies, such as yawning and talking. Guo and Markoni [10], and Lyu et al. [11] improved the learning model on the temporal information by integrating CNN with Long Short-Term Memory (LSTM) network, which is a type of recurrent neural network (RNN) that can distinguish the states with long-term dynamical features over sequential frames. However, the potential of CNN-LSTM is far from being fully exploited in the domain of driver/operator fatigue monitoring. The primary limitation in previous studies on CNN-LSTM in fatigue monitoring is that the long-term dependencies of periodic fatigue behavior (e.g., distinguish nodding and head tilt along with loads movements, yawning and talking) are learned from positive-sequence video frames considering only forward dependencies, while backward dependencies learned from reverse-order frames has never been explored that means some useful information may be missed.

To address this issue for improving the accuracy in monitoring and alerting of crane operator fatigue, this study develops a hybrid deep neural network by integrating CNN with deep bidirectional LSTM (DBLSTM) network. The specific objectives of this study are: (1) to accurately detect and align the facial regions with critical fatigue features; (2) to extract the effective facial fatigue features on single-frame images; (3) to distinguish the fatigue state by mining bidirectional temporal clues of sequential features.

2 Literature Review

Crane operator executes the repetitive lift tasks under the fatigue state in a complex construction environment may lead to catastrophic casualties as same as the vehicle drivers. There are apparent signs that suggest an operator/driver is fatigue, such as repeatedly yawning, inability to keep eyes open, swaying the head forward, face complexion changes due to blood flow [12]. As the facial features of operator/driver in a fatigued state are significantly different from that of the conscious state, the real-time monitoring the operator/driver's face by the camera can be an efficient, non-invasive and practical approach to alert the drowsiness and avoid the accidents [13]. PERCLOS (percentage of eyelid closure over the pupil over time) is a reliable measure to monitor the fatigue [14]. In addition, numerous machine learning-based approaches have also been applied to fatigue monitoring. For example, Mbouna et al. [15] developed an approach to extract the visual features from the eyes and head pose of the drivers, and then support vector machines (SVMs) was used to classify the fatigue levels. Choi et al. [16] trained the hidden Markov models (HMMs) to model the temporal behaviors of head pose and eye-blinking for identifying whether the driver is drowsy or not. However, these approaches relied on hand-crafted features which have shown limited efficacy in real-time monitoring and can be inaccurate when driver/operator wear the sunglasses or under considerable variation of illumination conditions [17]. Concurrently, features learned from unlabelled data based on the deep neural networks such as the convolutional neural network (CNN) have been proved to have a significant advantage over hand-crafted features in real-time monitoring of fatigue [14].

CNN is the class of deep and feed-forward neural networks that involves three main elements including local receptive fields, shared weights, and spatial or temporal pooling [18]. The process of fatigue monitoring and alerting by CNN is the same as other machine learning-based methods that can be shown in Figure1. The previous studies regarding fatigue monitoring and alerting by using CNN related models have also been summarized in Table 1. CNN was first applied to fatigue monitoring as the features extractor of static facial fatigue images by Dwivedi et al. [19]. Then, Zhang et al. [8] used the CNNs as both face and nose detectors to show their performances that are quite better than the conventional face detectors such as AdaBoost and WaldBoost with Haar-like features. To achieve real-time fatigue monitoring, Reddy et al.[20] utilized multi-task cascaded CNN with the compression technique to achieve a faster fatigue recognition than existing models of VGG-16 and AlexNet at a reasonable accuracy rate. As the fatigue states are dynamic (e.g., yawning, nodding) and it is difficult to distinguish whether the driver/operator is yawning or talking when only capturing their open mouths, a 3D CNN was proposed to capture the motion information of numerous adjoining frames from videos, and 3D filters

(kernel) were adopted to extract spatiotemporal features [9]. Furthermore, Part et al. [17] integrated three existing CNN-based models including AlexNet, VGG-FaceNet, and FlowImageNet in terms of their efficiency in the extraction of image features, facial features, and temporal features. However, these methods can only extract features with fixed temporal length, and the 3D convolution processes may spend numerous resources and time to impede the real-time monitoring.

Long Short-Term Memory networks (LSTMs) has been proved to be effective in learning long-term temporal dependencies by solving the exploding and vanishing gradient problems that is a Gordian knot for the traditional recurrent neural network (RNN) [21]. And an LSTM comprises typically a cell and three gates (input,output, and forget). The cell can remember values over arbitrary time intervals, and the gates control the information flow out and into the cell. Thus, the integration of CNN and LSTM can be an alternative in fatigue monitoring and alerting. Several studies have adopted CNN to extract frame-level features and then feed them into LSTM to extract the temporal features for determining whether fatigue or not. And several refinement techniques help them achieve the high accuracy such as reducing the hidden layer of LSTM [10], noisy smoothing in post-processing [22], and alignment technology to learn the most critical fatigue information [11]. However, to improve the accuracy, all information included in time series data should be entirely employed. The frames of video are sequentially fed into an LSTM that lead to an information flow with positive direction from time step t-1 to t along the chain-like structure. Therefore, the LSTM can only utilize the forward dependencies, and it is very likely that valuable information is filtered out or not efficiently passed through the chain-like gated structure [23]. Thus, it may enrich the temporal features by considering the backward dependencies. Moreover, the facial expressions of fatigue can be periodical and regular, and even short-term periodicity such as nodding can be detected. Learning the periodicity of time series data, particularly for recurring fatigue patterns, from both forward and backward temporal information can improve the performance of fatigue monitoring and alerting. However, to the authors' knowledge, few studies on crane operator fatigue monitoring considered the backward dependencies. To fill this gap, a deep bidirectional LSTM (DB-LSTM) is integrated into the CNN to form the architecture of fatigue monitoring and alerting system.

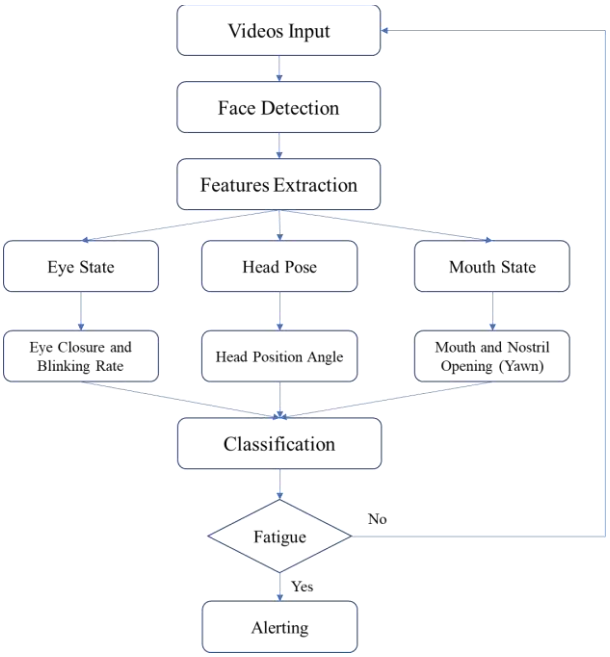

Figure 1. The machine learning-based process of facial fatigue monitoring and alerting

Table 1. The summary of studies by using deep neural networks for fatigue monitoring

Research	Techniques	Database	Accuracy
Dwivedi et al.2014	CNN, Viola and Jones algorithm	Customized	78%
Zhang et al. 2015	CNN, Kalman filter with track-learning-detection (TLD)	YawDD	92%
Huynh et al. 2016	3D CNN, Gradient Boosting	NTHU	87.46%
Park et al. 2016	AlexNet, VGG-FaceNet, FlowImageNet	NTHU	73.06%
Shih and Hsu, 2016	VGG-16, LSTM	NTHU	85.52%
Reddy et al. 2017	Multi-Task Cascaded CNN,	Customized	89.50%
Guo&Markoni, 2018	MTCNN,VGG-11,LSTM	NTHU	84.85%
Lyu et al. 2018	Multi-granularity CNN, LSTM	NTHU	90.05%

3 Proposed Solution

Figure 2 shows the architecture of the proposed hybrid deep neural networks, which comprises three steps and each step maps to a specific model. Firstly, the multi-task cascaded convolutional networks (MTCNN) are adopted as the face detector to locate and align the facial area in each frame of the video. Secondly, the customized CNN model is designed to extract facial

fatigue features from individual-frame images. Finally, a sequence of features within a specific time interval is fed into DB-LSTM to model the temporal variation of fatigue. And the Gaussian smoothing is adopted to reduce the noise and improve the fatigue monitoring performance. Each step of the proposed method is detailed in the following sections.

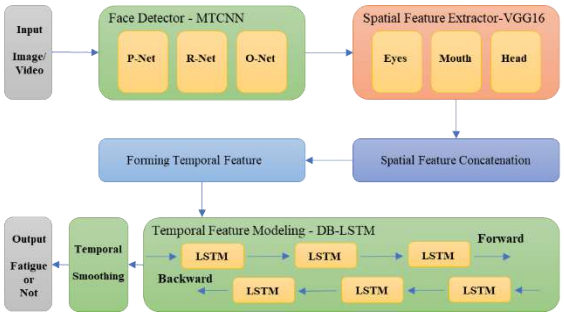

Figure 2. The architecture of the hybrid deep neural networks for fatigue monitoring and alerting

3.1 Face Detection

Precisely detecting and aligning the facial area of crane operator from an image is very critical to achieve efficient extraction of facial fatigue features and fatigue recognition. One of the famous face detectors proposed by Viola and Jones, [24] uses Haar-Like features and AdaBoost to train cascading classifiers, which achieves high detection rate in a real-time manner. However, previous studies have proved and indicated that the accuracy and efficiency of this face detector might reduce with large variations of facial regions [9,16]. These challenges could be exacerbated for face detection and alignment during crane operations in the real-world situations, such as the large pose variations of the operator who should change pose along with the moving loads, extreme lightings or darkness in operation cabin, and occlusions in front of the face. To fill this gap, the multi-task cascaded convolutional networks (MTCNN) proposed by Zhang et al., [25] shows the significant performance improvement in both accuracy and efficiency compared with other face detectors. This study adopts MTCNN to conduct the face detection and face alignment tasks with several stages. Firstly, the input images with various scales should be resized to build an image pyramid. Secondly, a shallow CNN (P-Net) with the input size of 12×12 to fast generate the candidate facial windows that are calibrated based on the bounding box regression vectors, and the highly overlapped candidates are fused by using non-maximum suppression (NMS). Thirdly, a complex CNN (R-Net) with the input size of 24×24 is adopted to reject the non-facial candidates with the same process of calibration and fusion. Finally, a more powerful CNN (O-Net) with the input size of 48×48 is applied to refine the results and produce five landmark points including positions of left-eye, right-eye, nose, left-lid-end, and right-lip-end.

3.2 Spatial Features Extraction

The objective of the features extraction is to learn a CNN-based spatial-domain feature extraction model E for capturing fatigue features F from the individual facial images I. As the feature extraction model E would go through each individual image in I, the extracted F should be general and robust to different input noises. Thus, this study chooses VGG-16 as our basic model which has achieved good performance in various datasets of image recognition [26]. On the basis of original VGG-16, several improvements are conducted to balance the efficiency and accuracy for extracting fatigue feature in a real-time condition. Figure 3 demonstrates the improved VGG-16 architecture V. The original VGG-16 which includes 13 convolutional layers (grouped into Conv 1-5), 5 max-pooling layers (pool 1-5), and 3 fully connected feedforward network layers. However, the input of this study has a smaller size image (64×64 RGB images) than the original VGG-16 (224×224 RGB images), which means the number of parameters can be reduced by using smaller fully connected (Fc) network layers (Fc-6, Fc-7, binary classifier) to avoid over-fitting in the improved VGG-16. Given the input to the improved VGG-16 is a fixed-size 64×64×3 face image, the features both in max pooling 5 and max-pooling 3-4 can be used to obtain the discriminative representation. This considers the fact that forward layers of CNN include more detailed information, while the backward layers summarize the global information. This improvement can be beneficial for improving the accuracy of extracting the small region features that are easily ignored by max-pooling, such as the eyes. To this end, a 1×1 convolutional layer is applied into each of pool 3-5 to approximate the Fc 6 by generating three vectors with the same depth (e.g., 256 in this study). This approximation strategy can not only reduce the number of parameters of Fc layers but also facilitate the Fc layers to extract fatigue-related features by pooling operation automatically. The pooled vectors are concatenated to feed into Fc 7 with fewer parameters to extract the more critical features, which forms the F.

To enable the faster and stable training process in generating the feature extraction model E with good generalization, another improvement for VGG-16 is to use Batch Normalization (BN) [27]. BN is a kind of feature scaling technique that can normalize the sample mean and variance of hidden units before or after the process of activation functions over mini-batch data.

This normalization process helps lessen the internal covariate shift for allowing using the larger learning rates. Meanwhile, the mini-batch including various samples may lead to randomness, which can reduce the risk of over-fitting. In this study, there are 5 BN layers placed before max-pooling layer and Fc layer. Lastly, a binary classifier is placed after Fc7 to predict the fatigue score Y. Given both Y and ground truth label L ϵ {0,1}, the cross-entropy loss function with the Adam optimizer is adopted to minimize the loss. If the Y is larger than 0 and is close to 1, the fatigue degree of the input is higher, and vice versa.

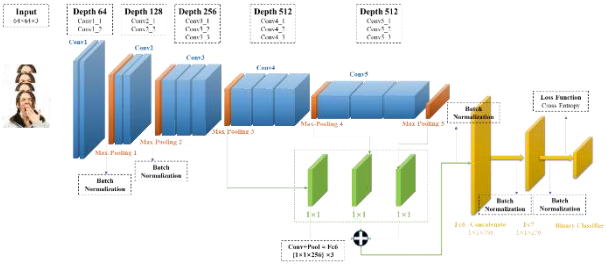

Figure 3. The architecture of CNN-based spatial-domain feature extraction model

3.3 Temporal Features Extraction

Although the feature extractor E has already enabled to predict the fatigue score of each frame based on the spatial features, sometimes it is still hard to discriminate the slight dynamic variations that have strong temporal dependencies such as yawning and talking. Therefore, it can be meaningful to consider both backward and forward information in the sequential frames. To this end, the deep bidirectional long short-term memory (DB-LSTM) is applied to model the temporal features F. DB-LSTM can process the sequential data from two directions by two separate hidden layers and then feed them into the same output layer. The outputs of forward and backward layers (as shown in Figure 4(b)) are both computed by using the basic structure of standard LSTM, See Figure 4.

DB-LSTM has a memory cell to save the state vector which is the sequence of the past or future input data. The current state can be updated on the basis of the current input, output, and the previous state saved in that "cell." DB-LSTM has a gated structure which allows the network to forget the previous state saved in cells or to update the latest state based on the new input data. At time t, the input gate vector, forget gate vector, output gate vector and the state of the memory cell can be denoted as it, ft, ot, and ct respectively. then ct can be updated by the equation (1)-(6).

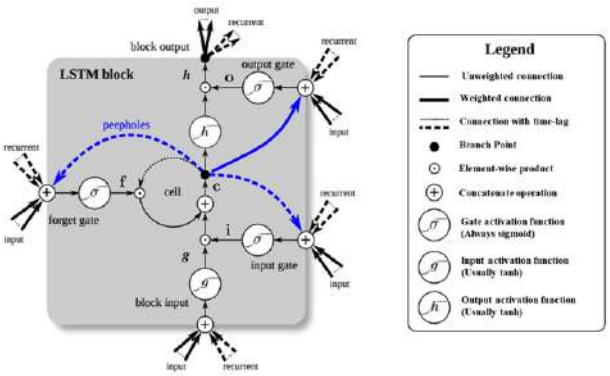

Figure 4 (a). The structure of the standard LSTM [28]

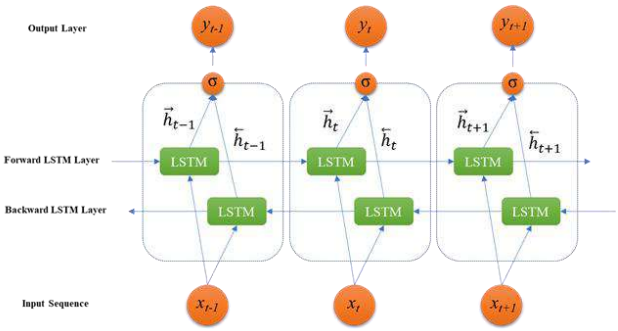

Figure 4 (b). The architecture of the DB-LSTM

$$i_t = \sigma_i(W_{xi}x_t + W_{hi}h_{t-1} + b_i) \quad (1)$$

$$f_t = \sigma_f(W_{xf}x_t + W_{hf}h_{t-1} + b_f) \quad (2)$$

$$o_t = \sigma_o(W_{xo}x_t + W_{ho}h_{t-1} + b_o) \quad (3)$$

$$g_t = tanh(W_{xc}x_t + W_{hc}h_{t-1} + b_c) \quad (4)$$

$$c_t = f_t \odot c_{t-1} + i_t \odot g_t \quad (5)$$

$$h_t = o_t \odot tanh(c_t) \quad (6)$$

Where x_t is the input and σ is the gate activation function, which usually is the sigmoid function. g_t is the state update vector that has activation function ''tanh'' (hyperbolic tangent function) and is computed from the input of the current state and previous state. Forget gate f_t allows the LSTM to forget its previous memory cell c_{t-1} or further memory cell c_{t+1}, and the output gate o_t adopts a transformation to the current memory cell to produce the hidden state h_t. For three gates, the gate can accept the input vector only if the gate value is 1 and reject the input vector when the gate value is 0. Weight matrices $\boldsymbol{W}$ and biases $\boldsymbol{b}$ are the trained parameters. $\odot$ indicates the element-wise product with the gate value. Then, the vector $\boldsymbol{Y_t}$ in feature sequence $\boldsymbol{F}$ is the

concatenated vector by combining the outputs of forward and backward processes as follows:

$$Y_t = \vec{h}_t \oplus \overleftarrow{h}_t \qquad (7)$$

Where $\oplus$ represents the concatenate operation.

In this study, each video can be randomly sampled as the training data by dividing it into numerous video clips with fixed length 50. The DB-LSTM temporal network includes 64 hidden units to predict the refined fatigue score $\boldsymbol{Y_t}$ of each frame (t=1,…,50). The cross-entropy loss function with the Adam optimizer is still applied to minimize the loss.

In the previous stages, both spatial network (CNN) and temporal network (DB-LSTM) are applied to predict the fatigue score of each frame. However, there are still certain noises during the testing on the validation set. In order to achieve a better performance of accuracy, the post-processing techniques including Gaussian smoothing, moving mean/median filtering can be adopted to "smoothing" the predicted fatigue scores.

4 Results and Conclusions

Figure 5 demonstrates the average loss among 20 videos of the training set (orange line), and the evaluation set blue line). The spatial features extraction model E already achieves 85.82% accuracy of fatigue even though its prediction is merely based on a single frame. Figure 6 represents the comparison of DB-LSTM and LSTM on accuracies and convergent performance in the evaluation set. The temporal network LSTM models the temporal variation of the fatigue status, and thus improves the accuracy of fatigue to 92.20%. It is worth noting that a longer clip length T during testing achieves higher accuracies. Finally, after adopting DB-LSTM, it achieves 93.60 % accuracy.

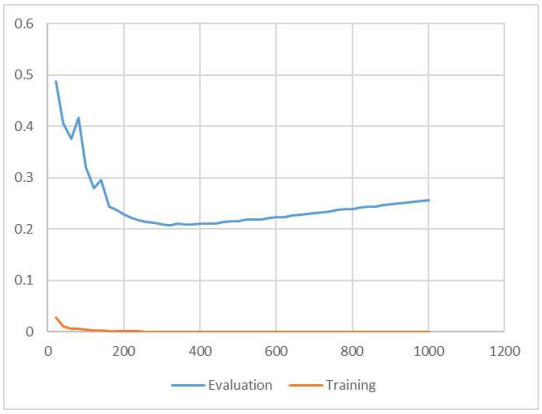

Figure 5. Loss curve of DB-LSTM for both training set and evaluation set

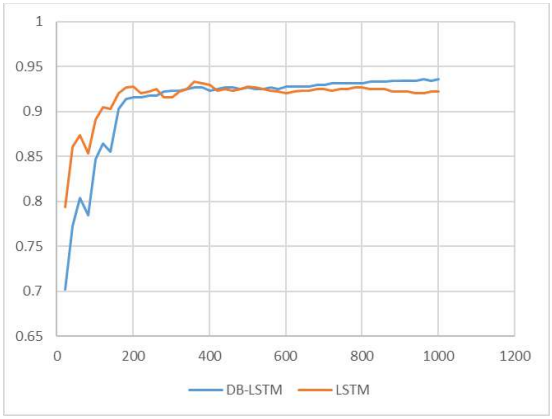

Figure 6. The comparison of DB-LSTM and LSTM on accuracies and convergent performance in the evaluation set

Table 3 represents the average F1 scores and accuracies on the evaluation set. In term of accuracy, the proposed hybrid neural network works pretty well under the sunglasses scenario (98.82%) and Non-Glasses scenario (95.41%). In terms of F1 score, the balanced F1 score among all scenarios shows that the proposed method does not make a biased prediction.

Table 3. Average F1 scores and accuracies for different scenarios

	F1-Score	Accuracy	Number of clips
Night_nonglasses	0.8080	0.8800	125
Night_glasses	0.6061	0.8839	112
Glasses	0.9617	0.9440	125
Non_glasses	0.9655	0.9541	109
Sunglasses	0.9870	0.9882	170
All	0.9286	0.9360	641

This study proposes a hybrid neural network to monitor and alert the fatigue status of the crane operator on the videos. The improvements and contributions in this study are threefold: (1) expand the vehicle driver drowsiness detection to the crane operator fatigue monitoring and alerting; (2) to detect and align the face, and extract the spatial features, the customized CNN is developed based on the baseline models which have excellent performance; (3) a deep bidirectional LSTM (DB-LSTM) is developed by considering both forward and backward dependencies to model the temporal pattern, which can learn compositional representations in space and time. The experiment results indicate that the effectiveness of the proposed hybrid neural network in comparison with several state-of-the-art methods. Further improvements and extensions can be made based on this study. Firstly, the dataset for crane operators should be established instead of using datasets

from the vehicle drivers. Additionally, devising more powerful features by combining multiple signals such as ECG, human audio, other physiological signals can be considered to achieve better accuracy and efficiency in fatigue monitoring.

Abstract –

A mobile robot follows a resident and grabs his/her health condition using a Kinect sensor. The 3D environment of the robot's working space has a huge impact on the design and operation of the mobile robot in two aspects: (1) it defines movements of the resident; (2) it affects the view and trajectories of the robot. This paper proposes an efficient and lightweight floorplan generator which automatically samples 2D semantic floorplans. With the height function, generated floorplans can be converted to diverse 3D indoor scenes. Secondly, based on a floorplan, movements of the resident during a period can be generated automatically with his/her activity schedule. Generated 3D scenes with resident movements will be used to evaluate how indoor spaces affect the design and operation policies of the mobile watching robot. The diversity of scenes with movements has two benefits: (1) providing massive data to constitute a training set for machine learning algorithms; (2) various scenes can be classified for finding statistical conclusions.

Keywords –

Floorplan; Automatic simulation; Mobile robot; Elderly people living alone; Design; Operation policy

1 Introduction

The elderly population around the world is steadily increasing. The estimated number of people aged 65 years and older was 524 million in 2010 and is forecasted to increase to 1.5 billion by 2050. [1] Most elderly people preferred to live with family members, but the proportion of them choosing to live alone has shown an increase in recent years. [2] For elderly people, living alone is associated with elevated mortality, a study undertaken it shortened survival by 0.6 years. [3] Although elderly people living alone would benefit from nursed by specialized agents, the shortage of global aged care workforce makes this difficult.

However, recent improvements in robotic, AI and IoT technologies provide some options to address this challenge. For example, monitoring systems were integrated into smart houses. Generally, there are two schemes to grip the health condition of elderly people by using: (1) wearable sensors, such as wearable inertial sensors [4]; (2) stationary sensors, such as cameras [5], passive infrared (PIR) sensors [6, 7], pressure-based item sensors and magnetic door sensors [7]. Secondly, mobile robots were used to support the independent elderly. These robots mainly observed the state of resident, their functions included fall detection [8] and human activity recognition (HAR) [9, 10], and they had additional functions such as interaction, object grasping, entertainment and floor-clean [8].

We focus on using a mobile robot, e-bio (Figure 1a), to monitor the health condition of elderly independent residents with a Kinect V2 sensor. Figure 1b shows the robot tracking people and observing his walking pattern in a studio apartment. Our robot focuses on resident monitoring and omits the functions like interaction and grasping, which reduces its size and degree of freedom. The advantage is that our robot is more economical and affordable for consumers, but the lower and fixed watching view of the Kinect sensor is more vulnerable to indoor obstacles such as furniture when the robot is tracking people and planning its trajectories.

Therefore, some issues regarding our robot need to be addressed, such as:

- Will the robot work well when monitoring an elderly resident?
- How should we adjust the height of the robot and the fixed angle of the Kinect sensor in different indoor scenes to balance its tracking performance and manufacturing cost?
- What operation policies should the robot use for its purpose?

We plan to address these issues by simulation, so

indoor environments and elder people's movements and activities should be simulated as preconditions. Instead of researching few cases, our aim is to obtain statistical results from diverse indoor scenes, the finalized framework of this study is shown in Figure 2.

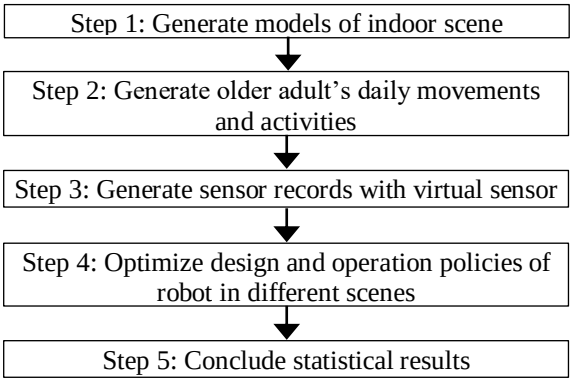

Figure 2. Framework for general study

This paper proposes a generator to automatically produce diverse floorplans for studio apartments, which addresses the primary challenge of Step 1 of the framework. Section 3 describes the basic rules and methodology to generate floorplan; Section 4 details the performance of the generator; Section 5 describes how to convert a floorplan to 3D scene and how to generate resident's paths based on the floorplan.

2 Related Works

2.1 Simulation of Smart House

In recent years, many smart house simulators were proposed because building real smart house test beds was expensive and time consuming. These simulators generated testing data for different purposes such as optimizing the arrangement of house components and sensors [11], human activity recognition [12], ubiquitous application testing [13] and location-based service testing [14].

These simulators enabled smart house designers to verify their ideas and plans. However, they had two shortages: (1) models of house were built manually, (2) virtual residents repeated a predefined schedule or were controlled by users.

To handle the second shortage, Lee et al. [15] proposed a smart house simulator with an automatic virtual resident. This simulator used a motivation-driven behavior planning method to force the resident to interact with the house. During simulation, resident's motivations such as hunger, thirst, and the need to study were generated. However, users still need to build the house model. Furthermore, this simulator did not meet our demands because the virtual resident did not imitate the elderly. The actions and movements of the elderly are slower than the average level and some of them may fall down or suffer from dementia. We should consider these situations in our simulation.

2.2 Floorplan Generation

Floorplan is a 2D semantic map which shows the relationships between physical features of the architecture such as rooms, doors and furniture. Automatic floorplan generation is necessary for our research.

There are two main steps to generate a complete floorplan: (1) deciding the relationships between rooms, (2) placing furniture inside the rooms.

In aspect of the first step, Hahn et al. [16] focused on the interior generation of a large building. They divided the floor into room clusters with parallel hallways. However, the room clusters were regular rectangles and most rooms were the same size. Mirahmadi et al. [17] divided a rectangle house into rooms using Squarified Treemap algorithm. They decided the areas of each room and sorted the areas in descending order, which was the input for the algorithm. This generator is unstable because of the limitation of the algorithm, the areas must be decided carefully. Ma et al [18] generated floorplans based on topological relationship between rooms. They input a topological map and all room blocks, then combined the blocks based on the map. But this generator can not avoid gaps between blocks.

In aspect of the second step, Anderson et al [19] automated desk layouts for diverse offices. Tutenel et al [20] proposed a layout solver which places furniture according to rules defined by users. Users could set rules such as "place X instances of class Y" and "place as many objects of class Z as possible". Henderson et al [21] proposed a data-driven, probabilistic, generative model for room layouts. This model learned statistics from 250, 000 room models designed by human.

For future studies, we hope to develop an efficient and lightweight floorplan generator for residences; the

generators mentioned before do not meet all our demands.

3 Floorplan Generation

Our laboratory's robot has been tested in a studio apartment shown in Figure 3. [22] Different from most dwellings, studio apartments have a large main room where the elderly can sleep, cook and watch TV.

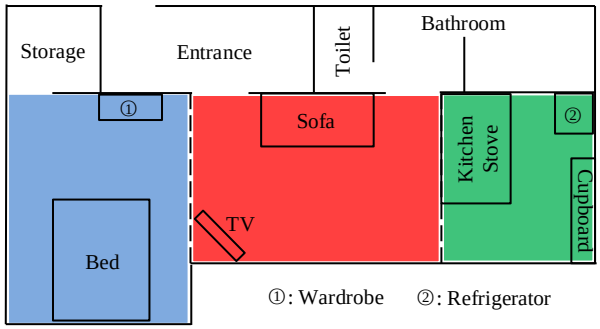

Figure 3. Studio apartment in the test

In Figure 3, the studio apartment includes a main room, entrance, toilet, bathroom and storage. The main room was the working space of our robot, we divide the room into three zones according to the furniture inside them: resting zone (blue area), living zone (red area) and cooking zone (green area). There are no physical boundaries between zones, resident passes through the virtual boundary (black dashed lines) to enter another zone. The walls of the house are represent by black solid lines, and gaps represent doors.

When placing furniture in the main room, normal procedure is: (1) deciding shape and size of the room, (2) dividing room into zones, (3) placing furniture into each zone. But a reverse thinking, deciding size of all zones first and then combining them into the room, has two advantages: (1) The room's shape is usually not a regular rectangle, but the shapes of zones always are; (2) In the future, we will research the dwelling owning separate bedroom, livingroom and kitchen, the reverse method will be more extensive.

3.1 Generation Rules

The desired floorplan describes 2D semantic information of additional rooms, zones, furniture, doors and walls. Additional rooms include a toilet and bathroom, Zones are the working space of virtual robot, which include the resting zone, living zone and cooking zone. There are three classes of furniture:

- Resting furniture includes bed, wardrobe, writing desk-chair set and nightstands.
- Living furniture includes dining table set and sofa-TV set. The dining table pairs one to four chairs.
- Cooking furniture includes kitchen stove, cupboard, refrigerator, wash machine and trash bin.

Each furniture is only inside its corresponding zone. Doors include the entrance, toilet door and bathroom door. The entrance connects zones with external areas (other rooms not in the model or outside of the house). Walls are the boundaries of additional rooms and the union of zones (no walls in the boundaries between zones).

The rules in Section 3.1.1 and 3.1.2 define the size of each element and topological relationship between them.

3.1.1 Rules about Size

In reference to the London Housing Design Guide [23], seven rules are proposed to balance realism and efficiency of our generator.

SR 1. The sizes of the toilet and the bathroom are 0.6 × 1.2m and 1.8 × 1.2m. The 1.2m-long sides are wing sides. The remaining sides are face side and rear side, respectively.

SR 2. The lengths of all sides of all zones are multiplies of 0.2m.

SR 3. The aspect ratios of all zones are less than 2.

SR 4. The area of the resting zone, A_R, is in ($8m^2$, $16m^2$). The area of the living zone is in ($12m^2$, $24m^2$) and ($1.2A_R$, $1.8A_R$). The area of the cooking zone is in ($6m^2$, $12m^2$) and ($0.6A_R$, $0.9A_R$).

SR 5. The furniture size candidates are listed in Table 1.

SR 6. When sampling the size of a furniture item, the area of the zone impacts the generator. Appearance of large furniture in large zones occur with a higher possibility.

SR 7. The lengths of doors are 0.6m.

3.1.2 Rules about Topology

There are seven rules about the topology of generated floorplans:

TR 1. The toilet must connect with the bathroom along one of its wing sides (SR 1). The same with the bathroom.

TR 2. The toilet can connect with the living zone and the cooking zone, the bathroom can connect with the living zone and the resting zone. They connect with zones along their rear sides (SR 1).

TR 3. The toilet and bathroom may be inside or outside of the zones to which they are connected.

TR 4. The generated floorplan must include the resting zone, may include either the living zone or cooking zone or both. The topology candidates of zones are

Table 1. Furniture size candidates

Furniture	Candidate sizes (m)	Furniture	Candidate sizes (m)
Bed	2.1 × 0.9, 2.1 × 1.2, 2.1 ×1.5, 2.1 × 1.8	Writing desk-chair set	1.0 × 1.0, 1.2 × 1.0
Wardrobe	0.6 × 0.6, 0.8 × 0.6, 1.0× 0.6, 1.2× 0.6	Nightstand	0.4 × 0.4
Dining table	0.8 × 0.8, 1.0 × 0.8, 1.2× 0.8, 1.4× 0.8, 1.6 × 0.8	Writing desk	1.0 × 0.5, 1.2 × 0.5
Sofa-TV set	3.0 × 0.9, 3.0 × 1.4, 3.0 × 1.9	Chair	0.4 × 0.4
Kitchen stove	0.6 × 0.6, 1.2 × 0.6, 1.8 × 0.6	Refrigerator	0.6 × 0.6
Cupboard	1.0 × 0.5, 1.2 × 0.5, 1.5 × 0.5	Wash machine	0.6 × 0.6
Sofa	0.9 × 0.8, 1.4 × 0.8, 1.9 × 0.8	Trash bin	0.6 × 0.3
Furniture	Candidate sizes (m)		
TV table with TV	0.6 × 0.4, 0.8 × 0.4, 0.8 × 0.6, 1.0 × 0.4, 1.0 × 0.6, 1.2 × 0.4, 1.2 × 0.6		

Table 2. Topology candidates of zones

Type	1	2	3	4	5
Topology					

listed in Table 2, where ®, © and © represent the resting zone, the living zone and the cooking zone, respectively.

TR.5 There are two relationships between a furniture and walls, against a wall or not. A writing desk-chair set and dining table set are not against a wall, all others are against a wall.

TR 6. A furniture item is at least 0.6m away from any other furniture items and doors.

TR 7. The entrance can appear in any wall except in the toilet's and bathroom's walls. The toilet door and bathroom door appear in the middle of the face wall (SR 1) of the corresponding room.

3.2 Methodology

A sample floorplan is generated in three steps: (1) placing zones and additional rooms, (2) generating walls and doors, (3) placing furniture inside each zone.

3.2.1 Placing Zones and Additional Rooms

As the resting zone must be included (*TR 3*), we first sample its size based on *SR 2* to *4* and set the center of the zone to the origin of the coordinate system. We then sample a topology from Table 2 and combine zones and additional rooms based on sampled topology and *TR 1* and *2*. The toilet's and bathroom's size are defined by *SR 1*. To achieve realism and avoid gaps in the floorplan, we should align connected zones and additional rooms.

Figure 4 shows the principles of the alignment. In Figure 4a, when a zone parallels the resting zone (topology 1-4 in Table 2), it must at least be aligned with a short side of the resting zone, and its connected side must be equal to or 1.2m shorter or longer than the long side of the resting zone (1.2m is the length of toilet and bathroom wing sides). Figure 4b, 4c and 4d show that when the living zone is perpendicular to the resting and cooking zones (topology 5 in Table 2), it must connect with the aligned sides of these two zones along its long side. One of its short sides must be aligned with an edge of the union of the resting and cooking zones or exceed or fall short of the 1.2m edge.

3.2.2 Generating Walls and Doors

After placing the toilet and bathroom, it is easy to generate the toilet and bathroom doors with *TR 7*, and the walls are also easy to define. We then sample a wall to place the entrance. The entrance appearing in a wall shorter than 2.0 m or longer than 4.0 m occurs with a higher possibility due to *TR 6* (most furniture items are against a wall). The entrance should be placed close to one end of the wall rather than in the middle for the same reason.

3.2.3 Placing Furniture Inside Each Zone

After sampling the size of a furniture item, we place it inside its corresponding zone by determining the coordinate of its center as shown in Figure 5. In Figure 5a, *dx* and *dy* are the distances between a furniture item and the boundaries of the zone (black solid lines), the black dashed lines represent possible placements of the furniture item's center, for furniture against a wall (*TR 5*), $dx = dy = 0$m. Besides, we must consider *TR 6*, so the effects of other furniture and rooms are described as obstacle areas shown in Figure 5b, where the yellow rectangle represent a furniture item, room or connected zone (to keep distance from furniture inside the zone), *f* is the minimal distance between the yellow rectangle

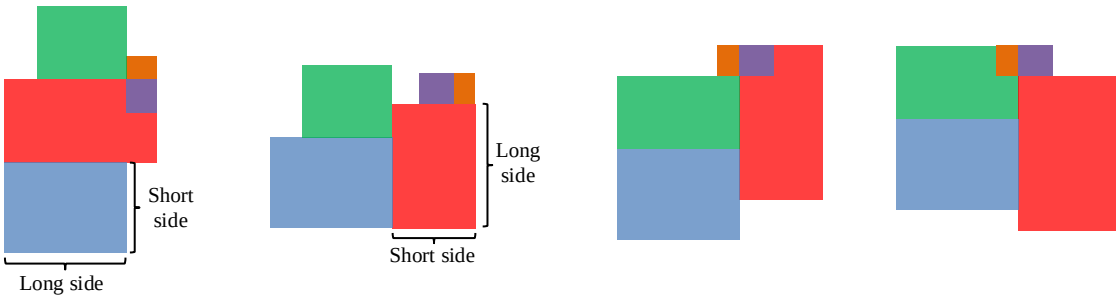

Figure 4. Principles of alignment (resting zone is blue, living zone is red, cooking zone is green, toilet is orange and bathroom is purple): (a) alignment when zones are parallel to resting zone, (b, c and d) alignment when living zone is perpendicular to resting and cooking zones

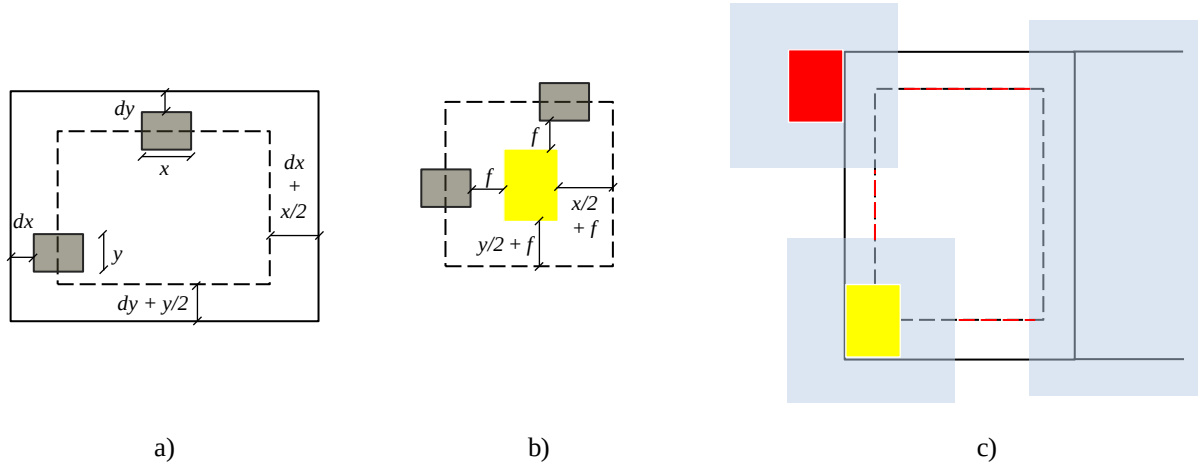

Figure 5. Methodology of placing furniture item inside a zone: (a) possible placements without considering obstacles, (b) obstacle area (b) possible placements considering all obstacles

and the furniture (if the yellow rectangle is a zone, f = 0.3m, otherwise, f = 0.6m). The possible places of the furniture item's center is in the relative complement of black dashed lines in the union of all obstacle areas (Figure 5c).

Therefore, all furniture items are placed by following the procedure below:

1. *List original obstacles including rooms and other zones which are connected with this zone;*
2. *For a furniture item to be placed, sample its size based on SR 5 and 6;*
3. *Considering the furniture can be placed horizontally or vertically, we determine x and y;*
4. *Calculate all obstacle areas;*
5. *If the furniture item is not against a wall, sample dx and dy, otherwise dx = dy =* 0;
6. *Calculate possible placements of the furniture item according to* Figure 5;
7. *Decide the furniture item's placement;*
8. *Add the placed furniture item to the obstacles list and go back to step 2.*

4 Generation Results

The generator is built using Python3. For showing generated floorplans, we sample 1000 times, of which 966 succeeded. The 34 failure cases are caused by the fact that living zones are too small to place the sofa-TV set. All successful samples are shown in this website [24]. We picked two generated floorplans randomly shown in Figure 6. In Section 5, we will describe how to convert a floorplan to 3D indoor scene and how to generate resident's paths with both of them.

We also test the performance of our generator on Intel(R) core(TM) i7-7770 CPU @ 3.60GHz. The generator works 1 million times on average 435.5 seconds with a 96% successful ratio. In the average 959311 successful samples, there are only average 49.2 same floorplans.

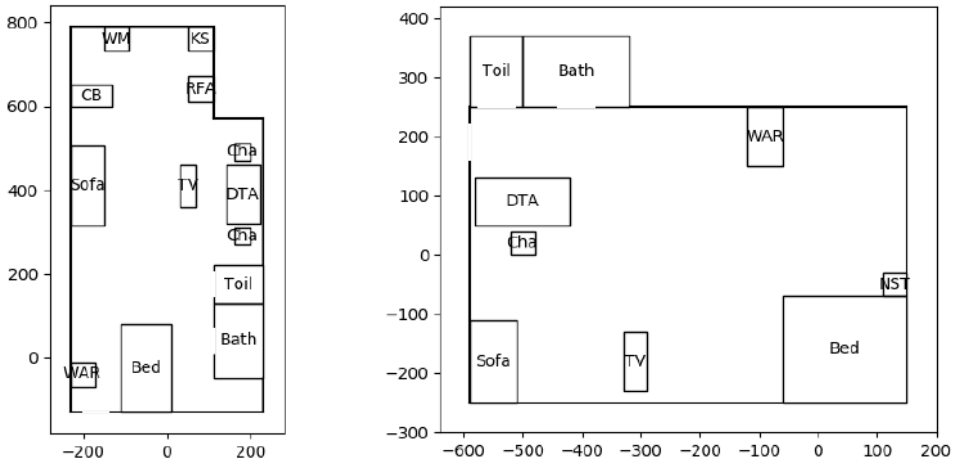

Figure 6. Two generated floorplans (unit: cm, WAR: wardrobe, NST: nightstand, DTA: dining table, CHA: chair, KS: kitchen stove, CB: cupboard, RFA: refrigerator, WM: wash machine, Toil: toilet, Bath: bathroom)

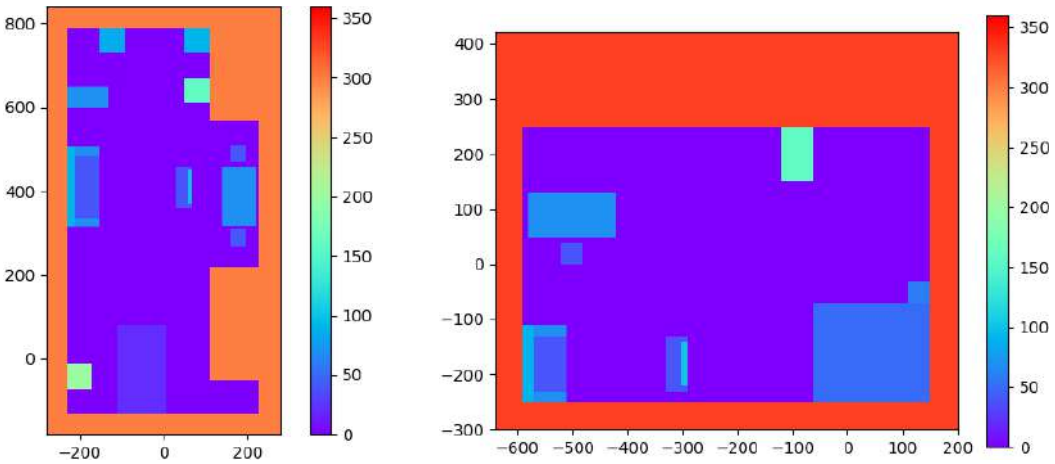

Figure 7. Height functions of two generated houses (unit: cm)

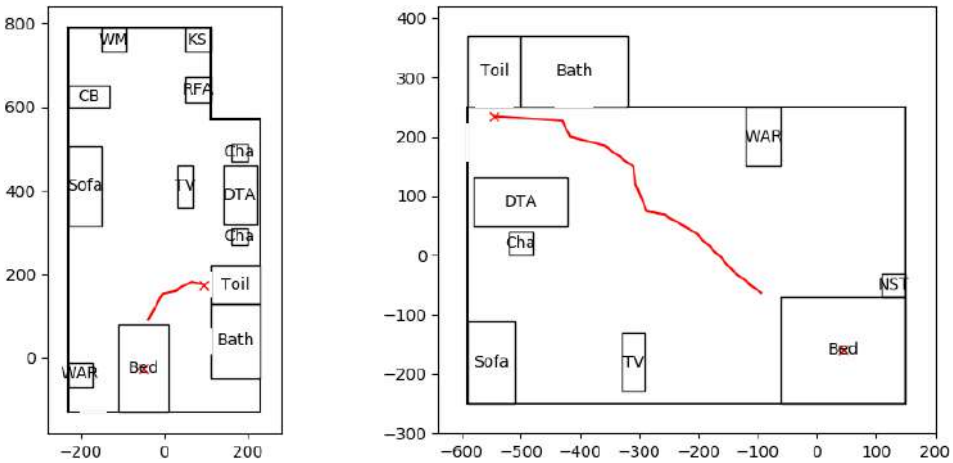

Figure 8. Generated resident's paths from bed to toilet (unit: cm)

5 Utilization of Floorplans

With a floorplan, we can produce a 3D indoor scene with the height function and generate the paths of resident if we know the start and destination points.

5.1 3D Indoor Scene Generation

The 3D scene of a room can be described as a 2D semantic map with the height function if we assume that 3D models of the furniture inside the room are simplified as a combination of cubes. We assume the floor is in the $\boldsymbol{z} = 0$ plane of the 3D coordinate system. For furniture items, their height functions equal the heights of their upper surfaces (we assume all of their lower surfaces are in the $\boldsymbol{z} = 0$ plane). For the floor, its height function is equal to 0. For the toilet, bathroom and external areas, their height functions are equal to the floor height of the house.

After sampling the floor height and heights of all the furniture, the 3D indoor scene is defined. Figure 7 shows the 3D scenes of the two virtual houses with their height functions.

5.2 Resident's Path Generation

Using Rapidly exploring Random Tree Star (RRT*) algorithm, the paths for the resident from the bed to toilet are generated in Figure 8. It reveals that the floorplan has a huge impact on resident's paths, the two paths shown in Figure 8 are quite different despite the fact that they have semantically the same starting point and destination. In the future, we will try different algorithms to generate paths for a more realistic simulation.

6 Summary

A small mobile robot is an amazing option for monitoring the health condition of elderly people living alone. However obstacles inside the house such as walls and furniture may obstruct the robot from tracking resident and disturb its observation. Therefore, it is necessary to optimize the design and operation policies of the robot considering the influence of the indoor space. We hope evaluate the influence and optimization by simulation.

This paper proposes an automatic floorplan generator as a first step in our simulation. This generator is efficient and lightweight, which produces diverse and realistic floorplans. With the generated floorplans, indoor 3D scenes are defined after sampling the floor heights and heights of furniture items. Moreover, the paths of the resident moving from starting points to destinations can be generated.

For the next step, we will generate a resident's daily activities and movements in different indoor 3D scenes. This requires studying daily activities schedules of the elderly and the characteristics of elderly pedestrians. With the schedule, we know when the elderly do some activities, when they move and the starting points and destinations of the movements. With the study of elderly pedestrians, we can grasp the position of body joints during his/her movement, these information will be useful in the simulation.

We will then simulate a virtual robot with a Kinect sensor, and produce virtual sensor records. Finally, we will evaluate the influence of indoor spaces and optimize the robot's design and operation policies based on produced models and sensor records.

In these studies, diverse indoor scenes will help us draw statistical conclusions compared with only researching limited indoor spaces. Massive sensor records are also necessary for machine learning algorithms. These are advantages of our floorplan generator.

Abstract –

As for unmanned dozer operation, this study aims development on infographics to reduce likely mental stress burden to operators in the remote-control room. First of all, this paper introduces problems in unmanned construction and the purpose of this study. Secondly, actor-critic based construction control system is described, which generates infographics. Thirdly, point on construction system is presented, which gathers readings from onboard smartphone for dozer in real-time manner. Fourthly, lesson learned from examples of infographics are reported; Finally, concluding remarks and future works are mentioned.

Keywords –

Unmanned construction; Infographics; Actor-Critic; Loading surface displacement; Underground stress

1 Problems and Purpose

Basically, operators can feel their realistic sensation of their own machine's behaviour based on the seat of the pants under their operations, e.g., distance and clearance perception using front views, possible motion space, and speed, acceleration, jerk, jolting, rattling, rolling, pitching, and yawing of the machine body, and so on. Handling joysticks to operate a machine, either directly or remotely, is an inherently eye-hand coordination task. The eye-hand coordination means to control eye movements with hand movements, and to handle joysticks along with the use of proprioception of the hands, or vice versa, as processing visual representation of the situational views.

Considering unmanned operation, however, the operators handle the joystick controllers to operate construction machines remotely in narrow field of views produced by camera-monitor system at the control room. Here, the operator receives a visual representation of the situational views from the camera monitor, process it, and select an action by handling the joysticks. Although, the operators have to make a decision instantaneously on do's and don'ts in their operations, it is sometimes difficult to ensure line-of-sight for or visuospatial perspective taking to location and movement direction of their machines or positions of their targets. Then they have to mentally translation, rotation and scaling between different frames of references to [1]:

(1) Orient the different sets of information into the same of reference, and

(2) Understand the relationships between the sets of information.

Therefore, the unmanned construction asks the operators to acquire extensive trainings and broad experiences on problem-solving skills. The skilled operators of these kinds are imperative for the unmanned construction. In Japan, however, there are very few skilled operators, and most of them are aged people.

Overcoming these sort of problems, it is significant and requisite to compensate their realistic sensation in order to enhance spatial awareness, in other words, conscious awareness of actions. To do so, we have been and are doing research and development on infographics pertaining to construction state, and trying to build actor-critic based construction control system, which could provide the operators with the infographics in a timely manner. The infographics are a visual representation of construction profile with graphics, numerical tables, quantitative evaluation indexes, and early precautionary messages, which are inferred from outputs of spatiotemporal analysis models built in the critic component as explained later. The construction profile is defined as a set of data to vision characteristics of phenomena being generated along with construction in progress and indexes to show the patterns [2]. The infographic makes it possible for the operators to quickly grasp the essential insights on construction situation at a glance.

As is well known, an unmanned construction process is separated into several operations such as excavation, loading, hauling, unloading, filling, dozing, compacting, slope shaping, etc., which are sometime independently and at other time interactively performed by different operators. Focusing on dozer operation, included in the unmanned construction process, this paper reports research and development on infographics to compensate operator's realistic sensation. Dozer operation presented here is remotely dozing and compacting to build retaining embankment as countermeasures to additional landslide.

First, this paper describes overview of actor-critic based construction control system, which handles readings and derive relevant infographics from a data set of readings. Secondly, lessons learned from examples of infographics are reported. Finally concluding remarks and future works are presented.

2 Overview of Actor-Critic Based Construction Control System

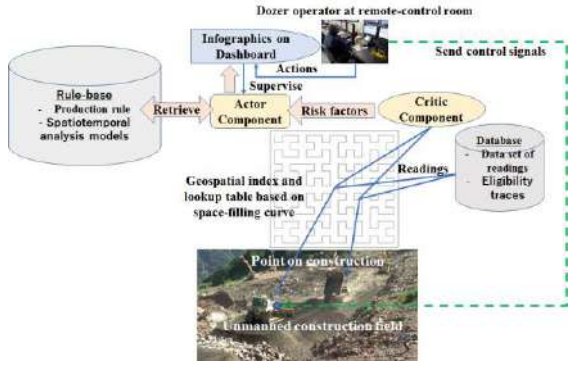

Figure 1. Schematic view of actor-critic based construction control System

The actor-critic based construction control system is largely classified into construction machine, points on construction (hereafter called POC), operator at the remote-control room, rule-base, database, actor-critic architecture, and dashboard as shown in Figure 1.

2.1 Points on Construction (POC)

POC takes sensor-based event detection approach to track construction machines and to automatically and real-timely gather a data set of readings related to events occurred by unmanned construction operations as shown in Figure 2 [3].

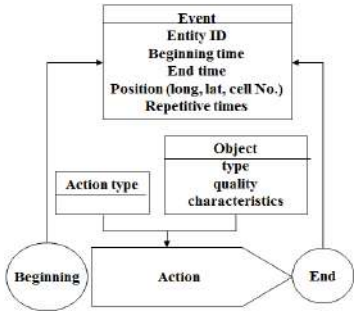

Figure 2. Image of sensor-based event detection approach

In this approach, the beginning and end of action could be automatically detected by sensors built in smart phone (e.g., 3-axial accelerometer, 3-axial angular velocity meter, GPS receiver, and communication module), and otherwise recognized by a button pressed event, that is, pushing predetermined function key on the smart phone by operator. Unmanned construction machine has on-board smart phone whenever it is being operated. And then, the smart phone automatically sends the data set of readings via the Internet to store them into the database. Readings gained from the POC consist of time, longitude, latitude, direction, speed, 3-axis acceleration, 3-axis angular velocity, and son.

2.2 Operator

Operator here includes not only machine operator but also resident engineers and experts in unmanned construction. The operator can supervise the actor by inputting previous setting into the dashboard. The previous setting consists of sampling frequency, various elements of machines, thresholds for discriminations, local coordinates and bounded box of construction area, positions of landmarks (i.e. spots of digging, loading and unloading, waypoints on haulage route), and numerical targets of construction works such as digging, hauling, dozing, the order of priority to select the if-then rule inside the actor, and so on.

Construction site area is expanded by quadrangular work cells with geospatial indexes, which are labelled by the unique number that defines cell's position in order of cell vertices in sequence of space-filling curve, that is, Hilbert curve. This is conversion between positions on the Hilbert curve and local coordinates in geometric range of construction area. The labelled work cells build an index structure that enables us to retrieve information effectively and efficiently.

The operator can choose spots containing the point of interest from the work cells to be controlled, e.g., loading spot, haulage route, dumping spot, embanking spot, compartments of concrete placement, hazards latent in construction area, dangerous phenomena, and so forth.

2.3 Critic Component

The critic fetches the readings sent from on-board sensors built in smart phone, calculates risk factors and propagates them towards the actor. The risk factors consist of:

(1) Descriptive statistics as to running speed, 3-axis acceleration, 3-axis angular velocity;

(2) Composition value of 3-axis acceleration gained by

$$force = \sqrt{ax^2 + ay^2 + az^2} \quad (1)$$

where force: composition value, ax: lateral acceleration, ay: longitudinal acceleration, and az: vertical

acceleration;
(3) Values of jerks: The jerk is the first-order difference of consecutive data elements in time series;
(4) Change-points in mean and variance of the values of jerks;
(5) Run length: The run length in this study is defined as a continuous sequence of repeated upward or downward values in many consecutive data elements;
(6) Distance: distance travelled, distance to other machines and landmarks;
(7) Attitude of machine gained by applying complementary filter to 3-axis acceleration and 3-axis angular velocity;
(8) Dozing area and density; and
(9) Progress rate.

2.4 Actor Component

Largely speaking, actor component includes two mechanisms as follows:
(1) Production rule (If-then rule <state, action, strength>)

This rule associates a condition (if) with an action (then); The rule states what action to perform when a condition is true; The strength indicates firing priority (i.e. rank, utility, severity, probability, cost, etc); The production rule is chosen based on the order of priority predefined by the operator; and
(2) Eligibility trace

Eligibility trace is a temporary record of the occurrence of an event, such as the visiting of a state or the taking of an action, and so on; The eligibility trace marks the memory parameters associated with the event as eligible for undergoing learning changes.

The actor component incorporates spatiotemporal analysis models to analyse the risk factors. These models are applied to:
(1) Visualize travelling trajectory of construction machines, and to show interference among work lines,
(2) Calculate jerks of running speed and to detect occurrence spots of sudden acceleration and rapid deceleration
(3) Calculate composition values of 3-axis acceleration and the jerks, and to calculate frequency of impacts and free-falls and then to show rugged sections or damaged spots on haulage road,
(4) Calculate distances to other machines and any landmark,
(5) Apply complementary filter to 3-axis acceleration and 3-axis angular velocity and then gain attitude of machine, and to show probable turnover and sliding,
(6) Grasp dozing trajectory and to calculate the constructed area, and more to show the progress gauge of the operation,
(7) Grasp compacting trajectory and the compacted density,
(8) Calculate loading surface displacement after dozing and show the time-series changes,
(9) Calculate underground stress below dozing and show the time-series changes, and
(10) As for acceleration and angular velocity in time series, detect change-points in the mean and the variance and to find the trend by counting the run length.

The actor produces list-wise infographics with early precautionary messages, and forwards them to the dashboard. The early precautionary messages inform operator of the phenomena prognosticated from the risk factor. The early precautionary messages are composed of:
(1) Objective: description of the infographic's objective;
(2) Hazard clarified: dangerous behaviour or phenomena identified by the built-in spatiotemporal analysis models, for examples,

1) Dangerous proximity during operating machine when entering into the proximate area of 100 m range from other machine or dangerous spots like those;
2) Dangerous operation:
   a) Sudden acceleration or rapid deceleration, when the jerk value of travelling speed gets larger than the predefined threshold value;
   b) Turnover risk when finding trend for machine body to lean to crosswise or longitudinal direction and value of rolling or pitching more than 15 degrees; and
   c) Defect productivity warning when finding
      - Run length of key performance indicator (hereafter called KPI) changes in time series more than the threshold "7";
      - Any shift in the mean and the variance of KPI; and
      - Actual progress behind the planned baseline.

(3) Early precaution
Referring to ANSI Z535,5 definitions, the levels of precaution are set as follows:

1) Danger: indicate an extreme hazardous situation which, if not avoided, will result in death or serious injury,
2) Warning: indicate a hazardous situation which, if not avoided, is liable to result in death or serious injury, to decrease one's productivity, or to end degradation of construction quality,
3) Caution: indicate a hazardous situation which, if not avoided, is likely to result in minor or moderate injury, to decrease productivity, or to end degradation of construction quality, and
4) Notice: address current practices that are not related to the above hazards.

2.5 Dashboard

A dashboard is a visual display on screen of smart phone, PC or other device that are installed at the

control room or the operators hold. Information displayed on the dashboard is consolidated and arranged on a single screen so that infographics can be monitored at a glance.

2.6 Database and Rule-based Database

Database and rule-based are web-based cloud systems. The database stores a data set of readings. Infographics and early precautionary messages generated by the actor component are displayed the dashboard, and stored in the database. Also, the eligibility trace data is stored in the database. The rule-base stores if-then rule and spatiotemporal analysis models that the actor component uses.

3 Lesson Learned from Examples of Infographics

This chapter reports examples of the infographics that show images of the exploratory spatiotemporal visualizations with wrap-up of lesson learned. The wrap-up of lesson learned is composed of objectives, hazard clarified, dangerous operation identified, early precautionary message, and reflective description on lesson learned.

3.1 Data Set Used to Generate Examples of Infographics

In order to generate examples of infographics, we utilized a data set of readings with respect to remote-controlled dozing and compacting operations applied to build retaining embankments as countermeasures to further large-scale landslide. The data set of readings was obtained from sensors, such as 3-axis accelerometer, 3-axis angular velocity meter, digital compass, GPS receiver, which were built in the on-board smartphone for the dozer. The data set utilized here is structured of meta data and variables as follows:
(1) Machine id
(2) Number of original obs.: 12013
(3) Sampling frequency: 4 HZ
(4) Measurement start time: "2017-03-09 08:24:00 JST"
(5) Measurement end time: "2017-03-09 16:25:00 JST"
(6) Analysis object: 3000 obs. of 11 variables (dd: num Time: POSIXct, long: num, lat: num, speed: num, ax: num, ay: num, az: num, gx: num, gy: num, gz: num)
The observations of analysis object here were chosen from the original observations at random sampling with replacement.

3.2 Travelling Trajectory

Spatiotemporal trajectory of dozing and compacting is shown in Figure 3.

Wrap-up of lesson learned from Figure 5 is listed below.
(1) Objectives: Visualization of travelling, dozing, compacting, and time lapsed
(2) Hazard clarified: None
(3) Dangerous operation identified: None
(4) Early precautionary message: Notice
(5) Reflective description on lesson learned:

By Figure 5, we will be able to explore existential changes in spatial and thematic properties of travelling, dozing, and compacting, and also the time lapsed. This trajectory is plotted along with the vertical time axis and with locations on two-dimensional plane of longitude and latitude coordinates. Stopped and/or idling states of machine are dotted vertically along with the time axis. It can be seen from Figure 5 that the stopped and/or idling time is short during dozing and compacting operations. Total distance travelled here was 6030.622 m.

Furthermore, this infographic can be utilized for a fleet management of several machines, such as backhoes, crawler carriers, dozers, and vibration rollers, and so on. If dotted marks should be plotted at the same time and at the same position, the machine works related to the dotted marks are liable to be interfered with each other. As far as possible, it is desirable for these dotted marks to be plotted at the different start time and then in parallel with each other.

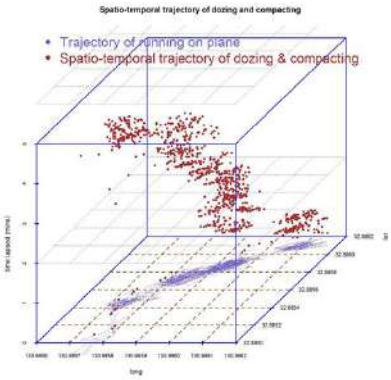

Figure 3. Spatiotemporal trajectory of dozing and compacting (Slate blue dashed line: "running trajectory on plane"; Brown dot "spatiotemporal trajectory of running along with the axis of time")

3.3 Safety Control

It is significant and required to compensate operator's realistic sensation, when remotely operating machine at dangerous spots, for example, at the steep slope, at the ridge of steep cliff, etc. In addition, spatial awareness is very important for operators to infer and understand the present and future surroundings of their own machines and to watch oneself in the work space.

In order to compensate operators' realistic sensation

and evoke their spatial awareness, it would be significant to provide them with physical cues related to appearance and posture of machine body, which would enhance their diagnostic and prognostic capabilities to reflect on their own unsafe behaviour

Examples containing to spatiotemporal visualization of unsafe behaviour and potential hazards are presented below.

3.3.1 Occurrence Spots of Sudden Acceleration and Rapid Deceleration

Upper 95% and lower 5% points in the jerk distribution of running speed are used as the threshold to detect occurrence spot of sudden acceleration and rapid deceleration, and then the if-then rules are shown below:

If (the jerk of speed >= the upper 95%-point value), then it is presumed that sudden acceleration occurred at the longitude and latitude; and
If (the jerk of speed < the lower 5%-point value) then it is presumed that rapid deceleration occurred at the longitude and latitude.

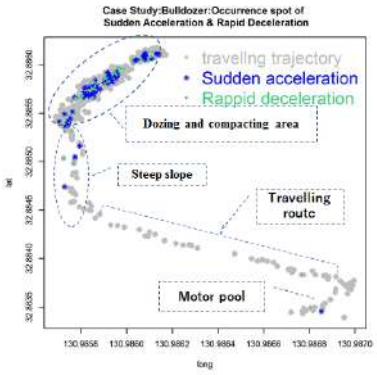

Figure 4. Occurrence spots of sudden acceleration and rapid deceleration while running

Wrap-up of lesson learned from Figure 4 is listed below.
(1) Objectives: Detection of occurrence spots of sudden acceleration and rapid deceleration while running.
(2) Hazard clarified: Many sudden accelerations and rapid decelerations were found.
(3) Dangerous operation identified: It is liable to evoke traffic accident, and degradation of quality as to surface and subsurface soil.
(4) Message: Warning
(5) Reflective description on lesson learned:
Many sudden accelerations and rapid deceleration were found at the dozing and compacting area. It is presumed that the dozing and compacting might be rough or harsh operations, which are liable to trigger disturbing and stirring the ground surface. It might involve risk of quality degradation of the surface and subsurface ground. Many sudden accelerations were found when climbing at steep slope,. Conversely, some rapid decelerations were found when descending.

3.3.2 Detection of Rugged Sections or Damaged Spots on Site

It is more likely to find phenomena of impacts and free-falls at rugged sections or damaged spots. Nevertheless, operators could not easily envisage any hazard latent in a narrow field of view from camera-monitor system at the control room without any background information on unmanned earthwork process.

The if-then rules to identify levels of impact and free-fall are shown as follows:

If (2G<=the 3-axis acceleration composition value) then it is presumed that strong impact occurred at the longitude and the latitude;
If (1.4G =< the 3-axis acceleration composition value & the composition value<2G) then it is presumed that somewhat strong impact occurred at the longitude and the latitude;
If (1.2G=< the 3-axis acceleration composition value & the composition value<1.4G) then it is presumed that impact occurred at the longitude and the latitude; and
If (the 3-axis acceleration composition value<0.7G) then it is presumed that free-fall occurred at the longitude and the latitude.

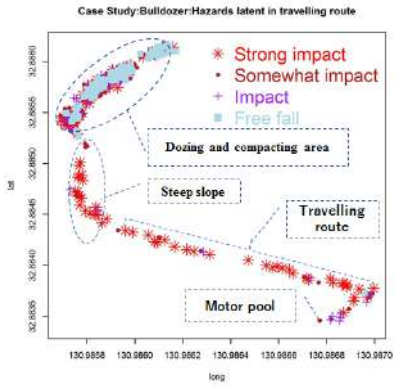

Figure 5. Existing of impacts and free-falls on site

It would be helpful and significant for operators at the control room to see severe dangerous spots with coloured marks, and to watch the early precautionary messages on the screen of their smart phone or PC, when approaching to the severe dangerous spots.

Wrap-up of lesson learned from Figure 5 is listed below.
(1) Objectives: Detection of rugged sections or damaged spots on site.
(2) Hazard clarified: Many strong impacts, and impacts were found everywhere. Furthermore, There were many

occurrences of free-falls in dozing and compacting area.
(3) Dangerous operation identified: Remote operation of dozer might be poorly handled and harsh. There would be otherwise many rugged sections or damaged spots latent in the whole area of the construction.
(4) Message: Alert
(5) Reflective description on lesson learned:
It can be confirmed in Figure 5 that there are many impacts and free-falls within dozing and compact area, and many strong impacts were found everywhere on the travelling route. The former phenomena indicate that dozing and compacting is rough or harsh operations, which are likely to trigger disturbing and stirring the ground surface. It is likely to result in traffic accident, degradation of quality as to surface and subsurface soil. The latter phenomena indicate the travelling route might be severe uneven.

3.3.3 Detection of Probable Turnover and Sliding

It aims to prevent a dozer from accidents of rollover, slide and falling. The method here largely forks the two:
(1) Find signals of turnover, slither, or skid of the machine body, and then issue early precautionary messages, and
(2) Visualize phenomena of rolling, pitching, and vacillation of the machine body in order to prognosticate likely dangerous sections and spots latent in the travelling route to the work zone.

More concretely, both the 3-axis acceleration and 3-axis angular velocities are captured by sensors built in the onboard smart phone, calculated by a complementary filter, and then rolling and pitching of machine body are visualized in time series. Moreover, if and when finding both of run-length more than "7" in the time series of rolling and pitching and the values more than 15 degrees, and then the occurrence places denote dangerous sections and spots latent in the travelling route to the work zone. Figure 6 shows dozer attitude in time series.

Wrap-up of lesson learned from Figure 6 is listed below.
(1) Objectives: Finding dangerous sections and spots latent in the access road to the work zone.
(2) Hazard clarified: None
(3) Dangerous operation identified: None
(4) Early precautionary message: None
(5) Reflective description on lesson learned:
It can be shown from Figure 6 that there are not dangerous sections and spots latent in the access road to the work zone, no matter whether rough or harsh operations

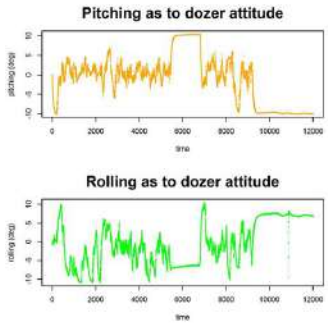

Figure 6. Dozer attitude in time series and the histogram

3.4 Productivity Control

Figure 7 shows dozing trajectory and the area, and the progress gauge of the operation. The progress gauge represents progress rate to the target value.

Kernel density estimation is a nonparametric method for estimation of probability density functions. An axis-aligned bivariate normal kernel is utilized to estimate the dozed area.

Wrap-up of lesson learned from Figure 7 is listed below.
(1) Objectives: Visualization of dozing trajectory and the area, and progress rate of the operation.
(2) Hazard clarified: None
(3) Dangerous operation identified: None
(4) Early precautionary message: None
(5) Reflective description on lesson learned:
Dozing and compacting are being operated as scheduled.

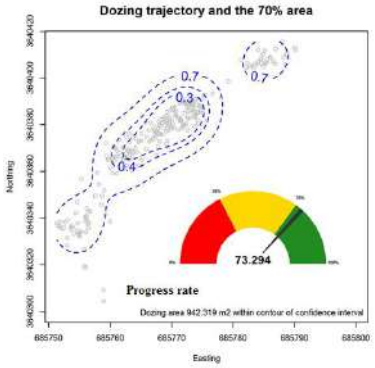

Figure 7. Dozing trajectory and the area, and progress rate of the operation

3.5 Quality Control

3.5.1 Compacting Trajectory and the Compacted Density

Weighted Kernel density Estimate method is utilized to visualize compacting trajectory and the compacted density, where the weight is impulse values. Figure 8 shows compacting trajectory and the compacted density.

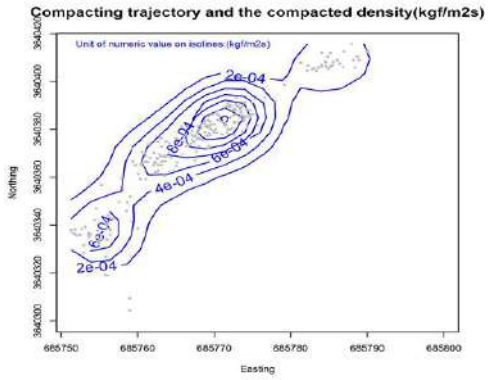

Figure 8. Compacting trajectory and the compacted density

Wrap-up of lesson learned from Figure 8 is listed below.
(1) Objectives: Visualization of compacting trajectory and the compacted density.
(2) Hazard clarified: None
(3) Dangerous operation identified: None
(4) Early precautionary message: None
(5) Reflective description on lesson learned:
Compaction is filled in all the required area.

3.5.2 Grasp of Loading Surface Displacement

Nonlinear dynamical behavior as to loading surface displacement consists of transient term and stationary term.

If the damping ratio ζ<1, the former is given as

$$x(t) = \exp(-\xi\omega_0 t)\frac{v_0}{\omega}\sin\omega t \quad , \qquad (2)$$

where v0 is the running speed. The latter is expressed as

$$x(t) = A\sin(\omega t - \phi), \qquad (3)$$

$$A = \frac{x_{st}}{\sqrt{(1-\lambda^2)^2 + 4\xi^2\lambda^2}}, \qquad (4)$$

$$\tan\phi = \frac{2\xi\lambda}{1-\lambda^2}, \quad \text{and} \qquad (5)$$

$$\lambda = \sqrt{1-\zeta^2} \quad , \qquad (6)$$

where x_{st} is static displacement.

Relationship between the damping ratio ζ and the logarithmic decrement δ is expressed as

$$\delta = \frac{2\pi\xi}{\sqrt{1-\xi^2}} \quad , \qquad (7)$$

If and when the damping ratio ζ <<1,

$$\delta \cong 2\pi\xi \qquad (8)$$

In addition, the relationship between the natural frequency ω_0 and the damped natural frequency ω is presented by the following equation.

$$\omega = \omega_0\sqrt{1-\zeta^2} \quad . \qquad (9)$$

The natural frequency can be obtained from the zero-crossing rate of the 3-axis composition values in time series. And then, the damped natural frequency is calculated.

In this study, the logarithmic decrement δ is obtained from the jerk of the 3-axis composition value. First, Empirical Mode Decomposition (EMD) is applied to the jerk, and then we can obtain the 5-th intrinsic mode function (IMF). This sifting process is shown on the left in Figure 9. We could find carriers with amplitude decay envelope in the close-up of 5-th IMF on the right in Figure 9.

By finding local extrema (e.g., maxima and minima), the logarithmic decrement δ can be obtained and then the damping ratio ζ can be given.

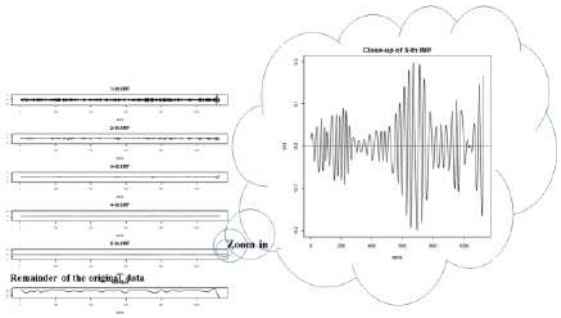

Figure 9. Sifting process of the EMD

Figure 10 shows changes in the loading surface displacement. The solid blue line and the dashed green line are local polynomial regression and the 95% confidence interval, respectively, in the upper illustration of Figure 10. Change points as to the mean and variance of the loading surface displacement in the lower illustration of Figure 10.

Wrap-up of lesson learned from Figure 10 is listed below as follows.
(1) Objectives: Visualization of the loading surface displacement.
(2) Hazard clarified: None
(3) Dangerous operation identified: None
(4) Early precautionary message: None
(5) Reflective description on lesson learned:
Phenomena of spreading fill materials and stepping on them is continuously repeated. The fill material here is lime-stabilized andosol. Unexpected event in this operation is not occurred.

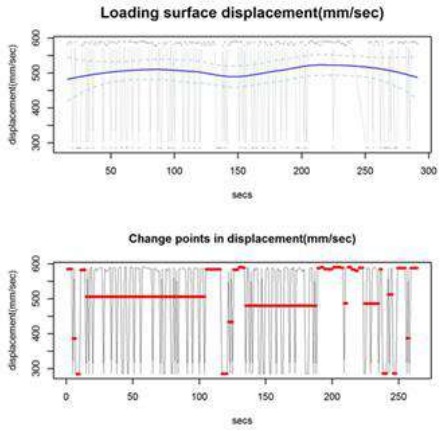

Figure 10. changes in the loading surface displacement

3.5.3 Visualization of Underground Stress

Steinbrenne's stress solution is shown as follows [4]:

$$\sigma_z = \frac{2p}{\pi}\left[\frac{abz}{D}\frac{a^2+b^2+2z^2}{D^2z^2+a^2b^2} + \sin^{-1}\frac{ab}{\sqrt{a^2+z^2}\sqrt{b^2+z^2}}\right] \quad (9)$$ and

$$D^2 = a^2 + b^2 + z^2 \quad , \quad (10)$$

where σ_z is stress at the depth z, the shoe width is 2a, the shoe length 2b, and p is impulse per unit of area.

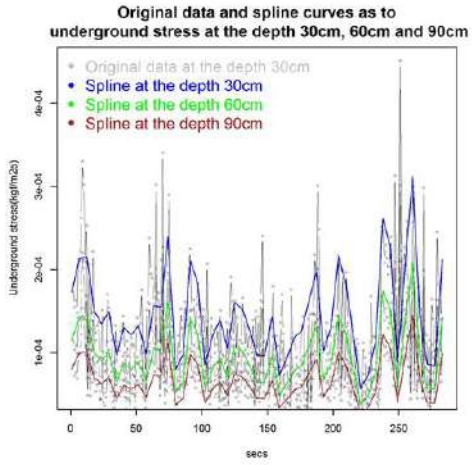

Figure 11. Underground stress in time series

Wrap-up of lesson learned from Figure 11 is listed below.

(1) Objectives: Visualization of the l Underground stress in time series.
(2) Impact clarified: None
(3) Hazard identified: None
(4) Message: None
(5) Reflective description on lesson learned:

Although the waveforms of those underground stresses have almost same shape, the deeper its position is, the smaller the stress value become. Besides the smaller the dispersion gets.

4 Concluding Remarks

The infographics play role in the following matters:
(1) Feedback of physical cues related to machine behaviour,
(2) Spatiotemporal visualization of hazards latent in in-situ earthwork process,
(3) To pick a set of building block of information at the right level of abstraction,
(4) To provide oneself with the opportunities to reflect on their own bearings as facing their own works at hand,
(5) To take timely and quickly correct actions based on detailed visibility of appearances and motions of mobile entities in a whole unmanned construction process, and accordingly, and
(6) To reduce likely mental stress burden to oneself in the remote-control room.

Taken together, these enhancements of conscious awareness of actions would be able to provide operators with the opportunities to reflect on their own bearings as facing their own works at hand.

Abstract –

This article studies the development of a cyber-physical prediction diagnosis system for electric drives of the construction robots. The structure of the five level diagnosis cyber-physical system is described. The optimization problem with the configuration level of the cyber-physical diagnostic system is formulated.The problem of determining the optimal trajectory for a mobile construction robot taking into account the wear of its electric drives is presented. As an example, a construction four wheels mobile robot with a differential drive is considered. The task of the robot is the alignment of the construction site, which involves its sequential bypass. From the standpoint of wheels drives wear, the trajectory is considered optimal if the robot makes approximately equal number of right and left side turns. To design a mathematical model for optimal trajectory determination, graph theory and probabilistic algorithms is proposed. The presented model does not take into account the soil structure and the working space inclination.

Cyber-physical diagnosis system; Building robots; Electric drives; Optimal trajectory; Wear

1 Introduction

Reliable construction work entails the need for continuous monitoring of the technical condition of all its actuators with further optimization of their mode of operation and consequently of the entire technological process as a whole. This can be achieved by using a technical condition monitoring system built into the robot's end-effectors, which continuously measures parameters and analyzing the information obtained and determining the current and future technical condition, and optimizing the parameters of the object's operation mode. Implementation of this approach assumes the integration of computing resources into physical processes, i.e. application of cyber-physical systems [1]. In such systems includes, sensors, mechanical equipment and information systems are connected during all stages of the life cycle and interact with each other using standard Internet protocols. This allows to predict and adapt to changes in operating conditions and technical condition of the equipment. The structural scheme of the cyber-physical predicting diagnosing system of the construction robot is shown in Figure 1.

The cyber-physical predicting diagnosis system has five levels: connecting, conversion, cloud, cognition and configuration [2].

At the “Connection” level, an effective set of diagnostic parameters and the sensors for its measurement are selected. The sensors should be designed for self-connection and self-monitoring of the state of the object.

At the "Conversion" level, the values of diagnostic parameters are measured and their necessary transformations in the case predicting diagnostic methods.

Storage and processing of large amounts of diagnostic information is carried out in cloud servers. This will allow the information flow and communication between the drives of various construction robots. Based on that, the optimization of the technological process starts taking into account the state of a separate actuating element.

At the “Cognition” level, methods of diagnosing and forecasting the technical condition of construction robots drives are chosen [3].

These methods must meet the following requirements:

– the possibility of assessing the technical state in real time; minimum composition of the measured parameters;
– the absence of complex bulky measuring equipment installed on the drive housing, which can affect the operation of process equipment;
– possibility to use on a moving object with high humidity and dustiness; applicable for DC and AC motors;
– the ability to automatically analyze the measured parameters;

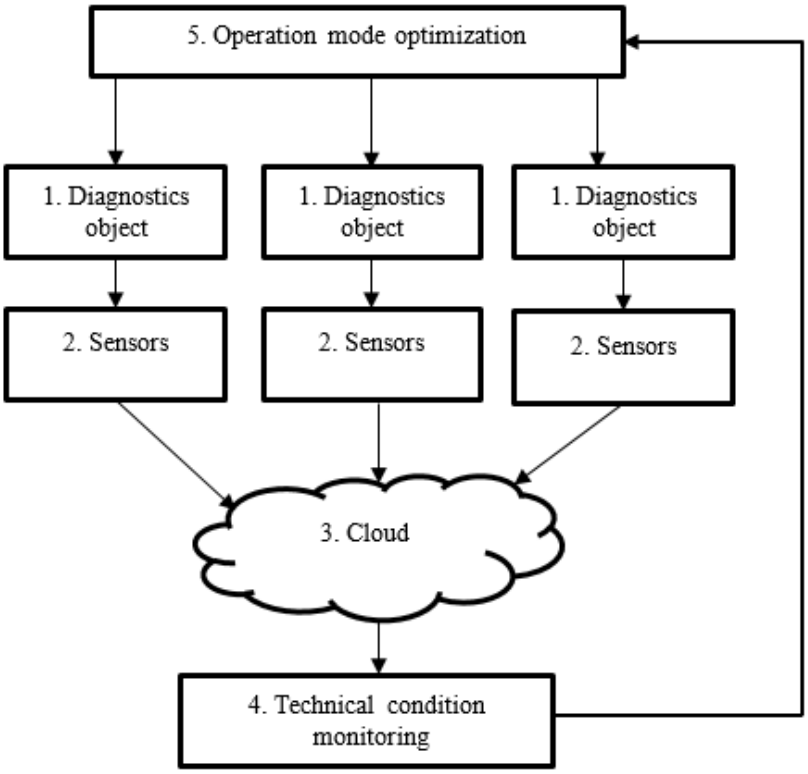

Figure 1. Cyber-physical system of the technical condition prediction diagnosis for electrical drives: 1– Intelligent connection level; 2–Data conversional level; 3–Cloud level; 4–Cognitive level; 5– Configuration level

– the ability to distinguish a malfunction from a change in operating mode; the ability to record and store diagnostic results in a cloud server and to provide the user with an Internet protocol.

The results of diagnostics and forecasting are presented to users and transmitted to the mathematical model of the object for further optimization of the robot operation mode.

At the "Configuration" level, the operation of the diagnostics object is optimized.

Construction robots operate in complex non-deterministic conditions with high alternating loads in conditions of high humidity and dust. Their drives are often installed on a mobile base, which imposes significant requirements for the choice of methods and means of diagnosis such as:

– minimum composition of the measured parameters;
– the absence of complex bulky measuring equipment installed on the drive housing, which can affect the operation of process equipment;
– the automatically analyze the measured parameters.

Analysis of the majority of electrical and mechanical faults of the electrical drive can be detected by monitoring the supply and capacitive current, which can be measured without the use of special sensors.

For the "Cognition" level, a method for diagnosing electric drives of building robots has been obtained [4], which makes it possible, without using expensive measuring instruments, to determine their current state of failure, a malfunction from changing the operating mode. This will increase the efficiency of such robots and the quality of construction operations.

The main part of the cyber-physical system is the "Configuration" level. It implements the task of optimizing the work of construction robots according to the results of diagnosing the technical condition of their electric drives.

After the technical condition of each electric drive of a construction robot is determined, it is necessary to optimize the operating mode of robots in order to increase the equipment life. Significant impact on the electric motor life have loading conditions during operation. The diagnosis will significantly extend the uptime of the electric drive and all equipment as a whole. To solve the increasing the reliability of the electric motor problem separate from the object where it is installed without taking into account the operation of all other mechanisms is impossible. Therefore, this problem should be solved in a group

of drives of an object operating in a certain technological process.

As an example, consider a mobile construction robot used to level the construction site. Tit have four independent electric drives, which are a mechatronic module "motor-wheel" [5]. The task of the robot is to handle rough terrain of a given geometry. In this case, the choice of the trajectory of the robot should be carried out in such a way that the wear of the drives of its wheels was minimal.

2 Robot Wear Model

Consider a model of a four-wheeled mobile robot with a differential drive (Fig. 2). It is assumed that the robot is driven in one of three ways:

1) using the wheels D^1 and D^2 (front wheel drive);
2) using the wheels D^3 and D^4 (tasks drive);
3) using all four wheels simultaneously (all-wheel drive).

The preferred option for controlling, all-wheel robot drives, since the life of the wheel drive is consumed evenly. However, in the event of a failure of one of the engines, the control system can be returned to the front or rear wheel drive.

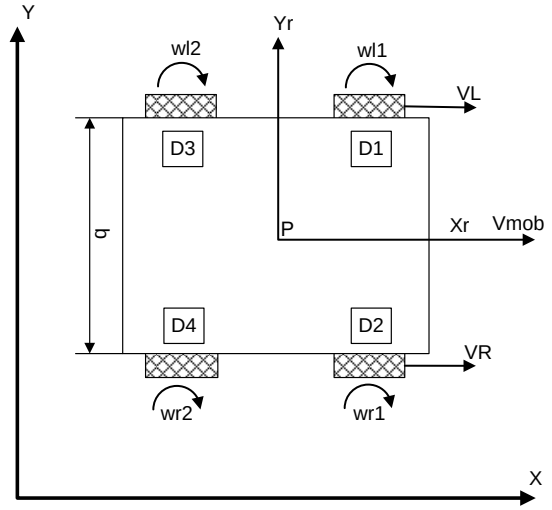

Figure 2. Model of a four-wheeled mobile robot with differential drive

A complete failure of a mobile robot will be considered to be options for working on the right or the left pair of drives (D^1 and D^3 or D^2 and D^4 in Figure 1) or on any one drive, as this leads to a situation of uncontrolled movement of the robot and unreasonable wear of working engines. The degree of wear of the robot is the sum of the degrees of wear of the drives of each wheel when performing a single technological operation t_i (1).

$$P(t_i) = p^1 + p^2 + p^3 + p^4, \qquad (1)$$

where p^1, p^2, p^3, p^4 is the degree of wear when performing a single technological operation of the drives D^1, D^2, D^3 and D^4, respectively.

The wear of the electric drive of each wheel is determined as a function of three arguments (2):

k_{ground} – the soil properties variable (takes on the values: 1 - smooth hard soil, 2 - smooth loose soil, 3 - uneven loose soil);

t_{fun} – the electric drive mode operation variable (0 - passive, 1- "full drive" mode, 2 - active front or rear drive mode);

M_{turn} – the additional motor load variable in a turn (for drives D^1 and D^3 - the right turns, for D^2 and D^4 - the left turns).

$$\begin{cases} p^1 = f(k^1_{ground}, t^1_{fun}, M^1_{turn}), \\ p^2 = f(k^2_{ground}, t^2_{fun}, M^2_{turn}), \\ p^3 = f(k^3_{ground}, t^3_{fun}, M^3_{turn}), \\ p^4 = f(k^4_{ground}, t^4_{fun}, M^4_{turn}). \end{cases} \qquad (2)$$

3 The Optimization Problem Formulation

For experiments in the proposed model of wear, the following restrictions are introduced:

1) the robot moves on a horizontal working space (Z=const);

2) the robot moves at approximately constant speed (V=const).

The trajectory of the robot is selected depending on the configuration of a specific construction site. Examples of their forms are shown in Fig. 2

t_0	t_1	t_2	t_3
t_4	t_5	t_6	t_7
t_8	t_9	t_{10}	t_{11}
t_{12}	t_{13}	t_{14}	t_{15}

a)

t_0	t_1	t_2	
t_3	t_4		
t_5	t_6	t_7	
t_8	t_9	t_{10}	t_{11}
t_{12}		t_{13}	t_{14}

b)

Figure 3. The examples of the construction robot working space

The robot working space being processed is divided into n segments so that each of them uniquely defines the limits of a single technological operation t_i (i = 1..n) .

For processing of construction sites (Fig. 3), it is necessary to set a complex trajectory of movement taking into account the wear of its electric motors.

The task of the robot is to fully implement the technological process (performing all its technological stages) so that the total wear of P_0 electric drives is minimal (3):

$$P_0 = \sum_{i=1}^{n} P(t_i) \to \min . \quad (3)$$

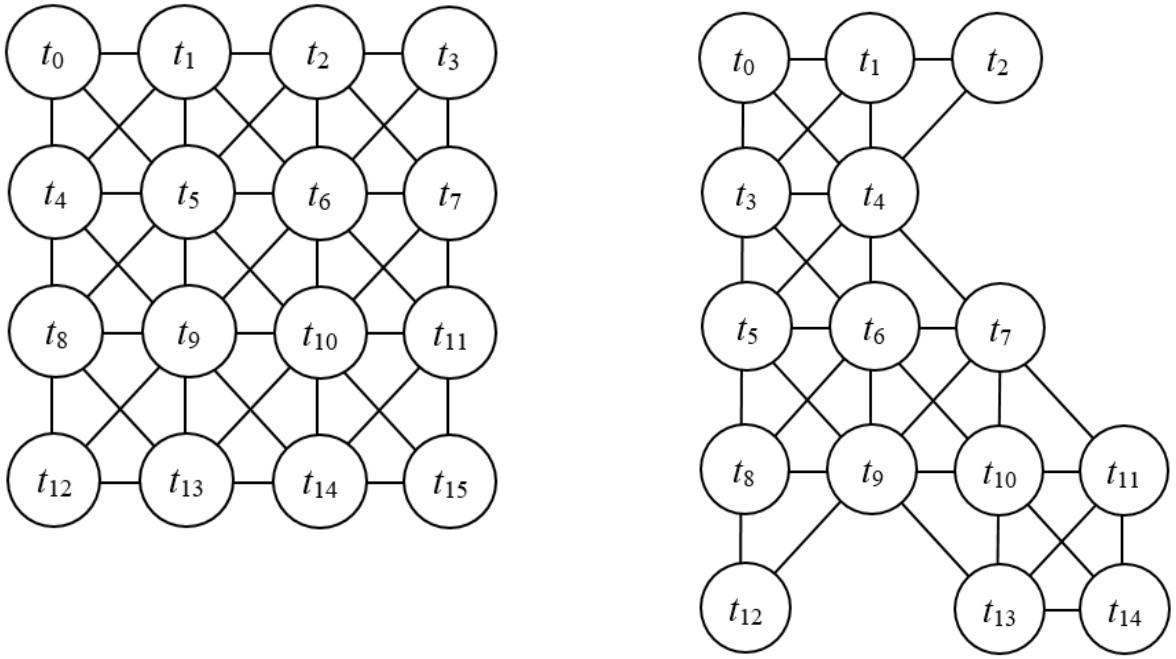
The wear P_0 is assumed to be minimal when it is evenly distributed between the drives D^1, D^2, D^3 and $D^4$is accepted. It is possible to reach with the minimum difference between the right ($M_{turn(R)}$) and left ($M_{turn(L)}$) turns (4):

$$\sum M_{turn(R)} - \sum M_{turn(L)} \to \min . \quad (4)$$

If for a particular construction site all its n segments are represented as the corresponding graph *T (V, E)*, the set of vertices *(V)* uniquely corresponds to the field segments, and the set of edges *(E)* logically defines possible transitions between adjacent segments (technological operations), then the mathematical problem of synthesizing the effective trajectory $G(P_0)$ for processing the construction site can be represented as follows (5) [6,7]:

$$G(P_0) = \left\{ t_i \,\middle|\, f(t) = \sum_{i=1}^{n} P(t_i) \to \min, i = 1...n \right\},$$
$$Z = \text{const}, \quad (5)$$
$$V = \text{const}.$$

The graph representation options for partitioning the working space of the robot (Fig. 3) are shown in Figure 4 accordingly.



a) b)

Figure 4. Variants of the graph representation of the robot workspace

Possible solutions for the cases considered from Fig. 3a and Fig.3,b are followed:

– $G(P_0) = \{t_0, t_1, t_2, t_3, t_4, t_5, t_6, t_7, t_8, t_9, t_{10}, t_{11}, t_{12}\}$

– $G(P_0) = \{t_0, t_1, t_2, t_3, t_4, t_5, t_6, t_7, t_8, t_9, t_{10}, t_{11}, t_{11}\}$

To demonstrate the turns within the selected trajectories the turn matrixes $G(M_{turn})$ is defined,

where 0 - turn within t_i (not performed),

1 - right turn $(M_{turn(R)})$,

2 - left turn $(M_{turn(L)})$.

Then the matrix $G(M_{turn})$ for each of the four previously defined trajectories will take the following form:

1st trajectory:

$G(M_{turn})$ = {0,0,0,1,1,0,0,2,2,0,0,1,1,0,0,0};

2nd trajectory:

$G(M_{turn})$ = {0,0,1,1,2,0,0,2,2,1,1,0,2,2,0}).

The selected trajectory can be considered optimal from the standpoint of minimizing engine wear if the

number of left and right turns for the indicated options of trajectories $G(P_0)$ approximately coincides.

For solving the formulated problem and the need to solve it based on probabilistic algorithms (for example, agent metaheuristics). [8-10]

4 Conclusion

In this paper, the design of a cyber-physical system for diagnosing and predicting the technical condition of electric drives of construction robots is presented. Furthermore, the structure of the cyber-physical system consisting of five levels is defined and the work of each system level is also described. The optimization problem with the configuration level of the cyber-physical diagnostic system is formulated. The problem of determining the optimal trajectory for a mobile construction robot taking into account the wear of its electric drives is presented. From the standpoint of wheels drives wear, the trajectory is considered optimal if the robot makes approximately equal number of right and left side turns. To design a mathematical model for optimal trajectory determination, graph theory and probabilistic algorithms is proposed. The presented model does not take into account the soil structure and the working space inclination.

Abstract –

As modular construction becomes popular, an increasing number of products are prefabricated in an offsite construction environment. While improving the productivity and efficiency of construction-oriented production, it also raises the complexity of process planning. Although the specifications of a product are fully defined by Building Information Models (BIM), no information is provided on how construction products are manufactured and assembled. This paper proposes an ontology-based approach aimed to link construction-oriented product assemblies and manufacturing resources using manufacturing operations. By identifying intersections of connecting members of a product assembly, feasible manufacturing methods and resources are determined based on expert knowledge and machine configurations. The proposed approach is validated using a wood frame assembly.

Keywords –

Building information modeling; Ontology modeling; Offsite construction; Construction automation; Construction manufacturing

1 Introduction

Modular and panelized construction have been promoted and recognized globally as advanced construction techniques for commercial and high-rise residential buildings in the last decade. Thus, an increasing number of buildings are manufactured using off-site construction methods: first, wall panels are prefabricated in an indoor facility; then, shipped on-site for installation. Offsite construction is becoming increasingly popular as it improves productivity of the construction process, reduces material waste, and yields better quality products [1, 2]. With the growing interest in modular construction, industrial automated machines have been developed to satisfy such needs. A prototype was designed at the University of Alberta for automatic light-gauge steel framing [3].

In industry, the current practice of introducing new construction products to an existing or new facility consists of the following procedures: (1) a 3D model of the desired product assembly is generated using the Building Information Model (BIM) specifications; (2) then, it is analyzed by product engineers to determine the manufacturing process (or processes) required and to select the appropriate machines necessary to accomplish such tasks; (3) the machinery is finally analyzed for installation in the indoor facility (i.e., layout design, safety requirements).

The vision of the 4th industrial revolution describes the realization of smart factories, where a higher flexibility and adaptability of production systems is achieved [4]. The challenge arises when deciding if a new assembly can be manufactured in the existing production line or if one or more machines must be commissioned to make a new product assembly. Although BIM models provide information on what the final product assembly would be, it does not offer the benefit of hindsight as to how it is manufactured and assembled. Such challenges are often overcome by engineering experience. As a result, no link between machinery, manufacturing processes and construction product assemblies in the knowledge domain exists. To shorten the decision-making effort in determining machine eligibility, a relationship between product assemblies, manufacturing procedures, and machines needs to be established.

The objective of this study is to create knowledge models that represent components of a manufacturing domain with a special focus on the manufacturing of product assemblies. An ontology-based model is proposed to communicate between three knowledge domains: the 3D BIM model of a desired product assembly, its necessary manufacturing steps, and the key attributes of the machines used for manufacturing. A wood frame assembly is used as a case study.

2 Related Work

Relating product information to the manufacturing domain exists in the machining industry. Computer Aided Process Planning (CAPP) is the use of computer technology to aid in the process planning of a product in manufacturing [5]. CAPP is used to interpret product design data by recognizing features on a part and translating them into manufacturing operation instructions [6]. CAPP has been proven to be successful in providing process planning to manufacture a designed part. The challenges of using CAPP in manufacturing construction-oriented products arise due to the complexity of the products, which usually involves assembling individual parts.

Extracting information from BIM models is the first step involved in fabricating and inspecting the quality of construction-oriented products. Malik et al. successfully extracted product specifications from BIM models and generated safe tool-paths for moving carriages in an automated framing machine [7]. Martinez et al. proposed a vision-based system for pre-inspection of steel frame manufacturing. The proposed approach provides real-time inspection of steel frame assemblies by comparing real frame assembly with manufacturing information from the BIM model [8].

In typical manufacturing processes, knowledge modeling has successfully enabled decision making systems to be defined for such purposes [9]. However, a link between construction-oriented products and construction machinery is yet to be properly defined. Gruber defined ontology as "an explicit and formal specification of a conceptualization" [10]. Ontology is used for various reasons. First, ontologies offer interoperability of information from various knowledge domains; second, ontologies support consistency checking and reasoning; third, concepts used in product and manufacturing domains can be represented by defining classes and properties of the ontology in an intuitive way [11]. A proposal named MASON (MAnufacturing's Semantics ONtology), proposed by Lemaignan et al., created a common semantic net in the manufacturing environment using ontologies for general purposes [12]. This approach successfully related product specifications (entities) and manufacturing related resources using operations. MASON sets the foundation to link construction-oriented products to the manufacturing environment.

Ontologies have been proven useful in extracting information from BIM for practical use. Zhang et al. proposed an ontology-based model to relate on-site construction safety management with job hazards of construction activities. By linking tasks, methods, and the job hazards involved in construction activities, the developed automated system provides a significantly more efficient and formalized job hazard analysis [13]. Liu et al. proposed an ontology-based semantic approach that successfully extracts construction-oriented quantity take-off information. Using this approach, construction practitioners can readily obtain and visualize the relevant information from complex BIM models [11].

3 Methodology

By integrating the work proposed by Lemaignan et al. and Liu et al., this paper proposes an ontology-based semantic approach to relate construction-oriented product assemblies to machineries in a production line that is responsible for manufacturing the products. Extending the methodologies proposed by Liu et al. by using a MASON-based approach to the manufacturing

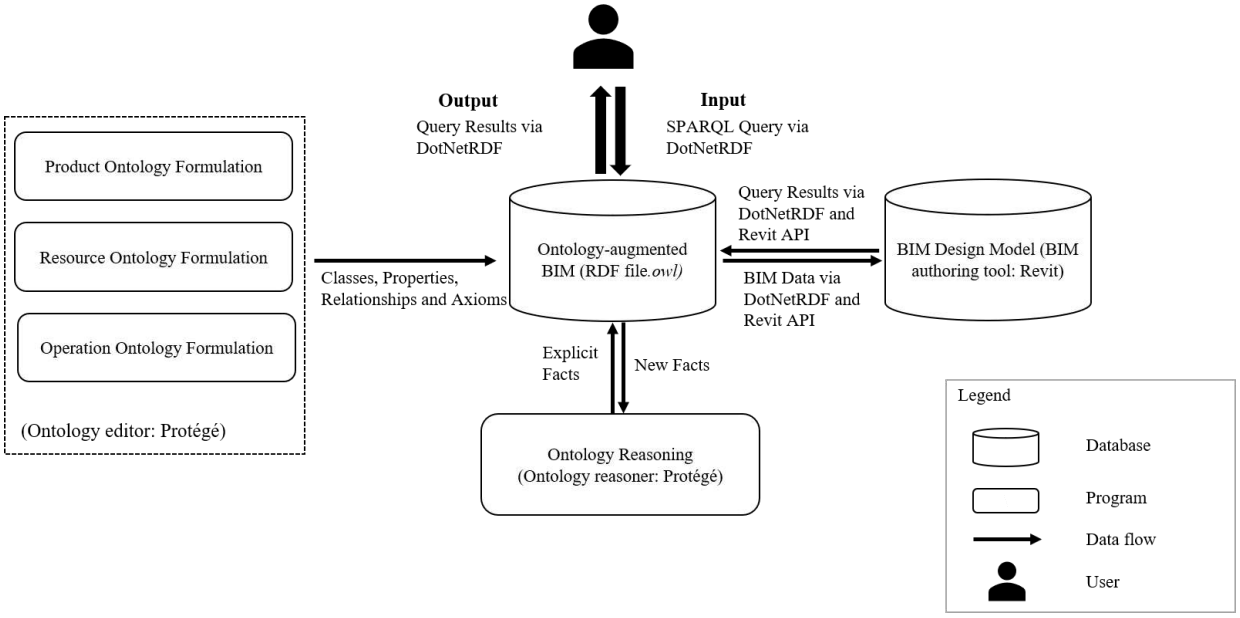

Figure 1. System architecture

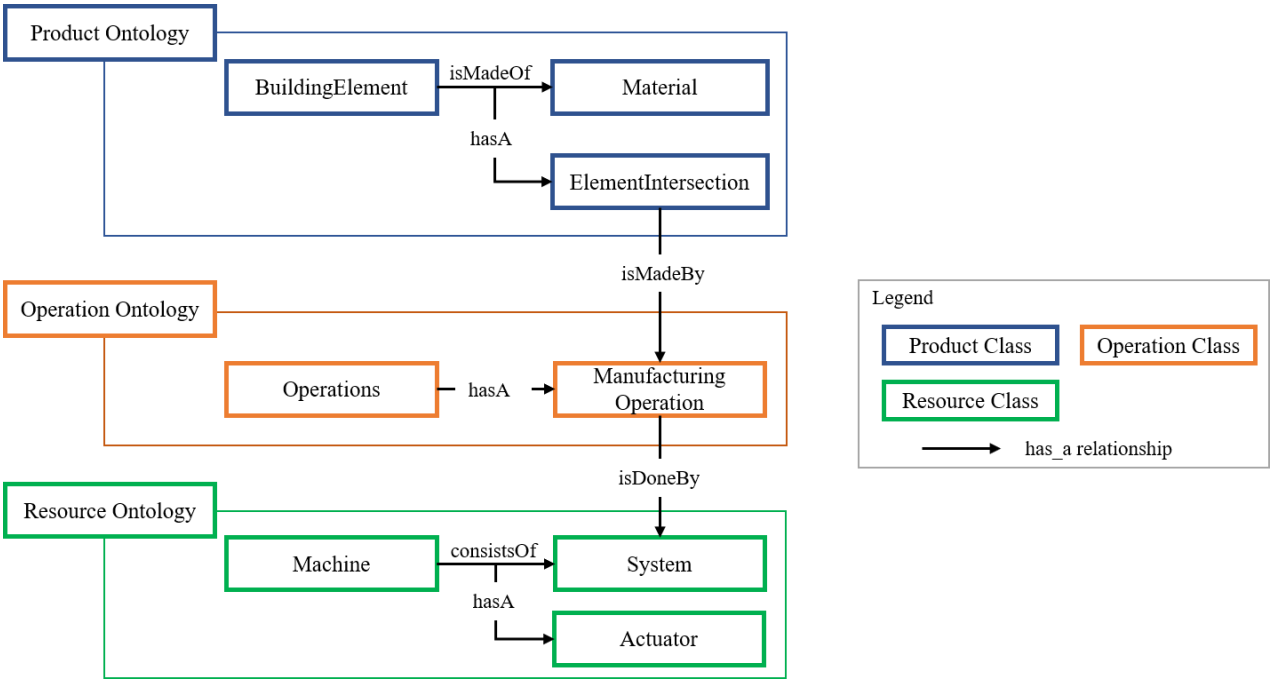

Figure 2. Product, operation and resource ontology models

domain, the proposed system architecture is shown in Figure 1. Three knowledge domains (manufacturing resource, operation, and product) need to be incorporated to build the ontology-augmented BIM model. Each knowledge model is simplified in Figure 2. Protégé, an open source ontology editor and reasoner, was used to build the ontology model using the following steps: (1) Entity class is created to specify construction-oriented products; (2) Resource class is used to describe manufacturing machineries to be used to fabricate and assemble the products; (3) Operation class is then built to relate entities and resources. Once the knowledge domains are constructed, machine eligibilities can be determined.

Using the approach proposed in MASON, classes will be used to define the product, operations and manufacturing domains. Attributes of classes are specified using "Data properties". The relationship between classes are captured using "Object properties". Instances of classes are modeled using "Individuals" [12].

3.1 Product Ontology Formulation

First, the class *Product* containing information from BIM is modeled. BIMs are digital representations of physical and functional characteristics of a facility and contain all the physical information related to a product [14]. In terms of the construction of a building element using machines, the following information will be used to allocate manufacturing resources: material, dimension, and intersection between elements. All machines have limitations as to the material to be processed and the dimension of a product. Since a product assembly is typically made using multiple basic elements, intersections of these elements also place constraints on how the product assembly may be constructed. An intersection is defined as the interface between any two or more members to be connected. Since an intersection is dominantly affected by the product material, each intersection is specific to each type of product. For wood frames, intersections are identified based on 3 criteria: (1) single or double plates/studs; (2) either it is at a corner (LConnection) or inside the frame (TConnection); (3) horizontal or vertical. Six intersections are identified using the above criteria and are denoted by specific notations:

Table 1. Intersections in wood frames

Intersection Type	Notation
Stud_Plate_LConnection	SP_L
Stud_Plate_TConnectionVertical	SP_TV
Stud_Plate_TConnectionHorizontal	SP_TH
Stud_DoublePlate_LConnection	SDP_L
Stud_Stud_Connection	SS
Stud_DoublePlate_TConnectionHorizontal	SDP_TH
Stud_DoublePlate_TConnectionVertical	SDP_TV

Since manufacturing processes depend on the material and the intersections of each product assembly, they must be defined in the ontology model. As an

example, Figure 3 shows the class hierarchy of wood element intersections.

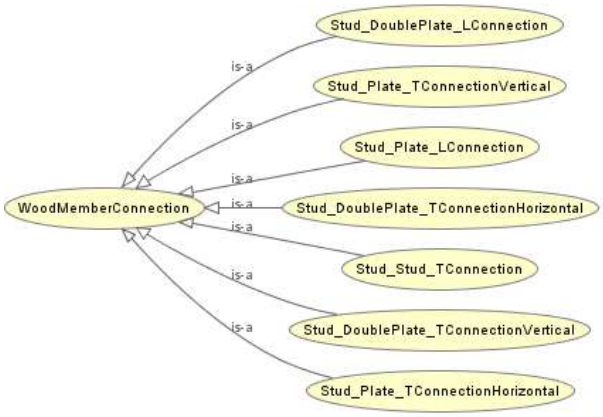

Figure 3. WoodMemberConnection class hierarchy

3.2 Resource Ontology Formulation

Similar to the product model, the resource ontology is also modeled. Although resources consist of multiple categories, only machine resources need to be considered as far as machine eligibility is concerned. A construction manufacturing machine consists of several systems that carry out manufacturing operations. For example, a nailing system in a wood framing machine can shoot nails into the wood frame to create a permanent connection. In this model, the class *Resource* that consists of subclasses *Machine* and *Actuator* are created. Under the class *Machine*, several sub-classes of various machines are created. Systems of certain machines are specified under each *Machine* sub-class. The *Machine* resource ontology model is shown in Figure 4.

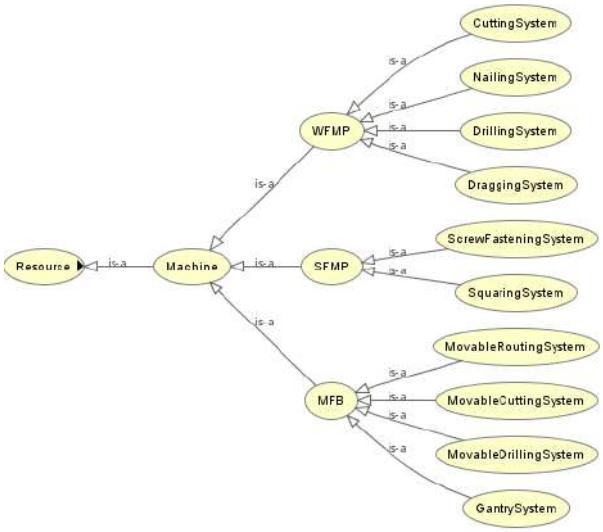

Figure 4. Resource ontology model

3.3 Operation Ontology Formulation

As mentioned before, the BIM model does not include information pertaining to how a product assembly is fabricated. Therefore, manufacturing operations need to be analyzed to form a relationship between product entities and machine resources. Since a product assembly is typically made of several members, intersections of these members require certain manufacturing method(s) to secure these elements. In addition to joining materials, some locations also require the addition and/or removal of materials. These locations, along with intersections, are defined in the BIM model and categorized into classes of connections defined in the *Product* model. Each category of intersection requires specific manufacturing method(s). Therefore, based on the type of connections identified, the manufacturing operation is determined.

In the *Operation* ontology model, the class *ManufacturingOperation* is created to identify feasible product assembly construction methods. By establishing relationship "isMadeBy" between the class *Product* and *ManufacturingOperation*, the system now has clear knowledge about how a product assembly can be constructed. The ontology model of *Operation* is shown in Figure 5.

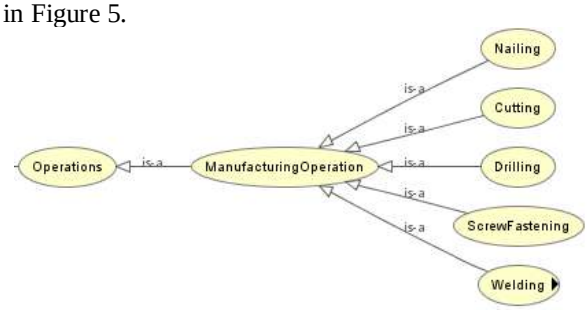

Figure 5. Operation class hierarchy

4 Results and Discussion

In this section, the proposed methodology is validated with a wood framing wall. The advantages and limitations of using ontology models to relate product, manufacturing resources, and operation are also discussed.

4.1 Case Study

A wood frame is to be modelled and studied. The panel is 20 ft (approximately 6 m) long and 10 ft (approximately 3 m) high and is made of 2x6 (38 mm x 150 mm) wood timbers of various length. The frame contains a window and a door component. Note that a single plate is used for the footer and double plates are used for the header. The frame is shown in Figure 6 below.

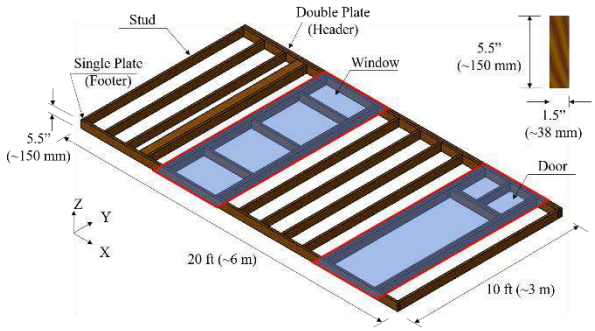

Figure 6. 3D representation of the wood frame case study

First, using the given information, material and dimensions are identified. Next, the possible types of intersections are recognized: stud-to-stud intersections and stud-to-plate intersections. Plates are wood members along the x-axis and studs are the rest of the members. As shown in the product ontology model, all the possible intersections of product assembly of wood framing wall are modeled as sub-properties under the object property "isMadeBy". Since it is a group of properties of the element intersection which requires manufacturing operations, the domain of "isMadeBy" is *ElementIntersection* and the ranges are within *ManufacturingOperations*. This relationship is represented in Figure 7.

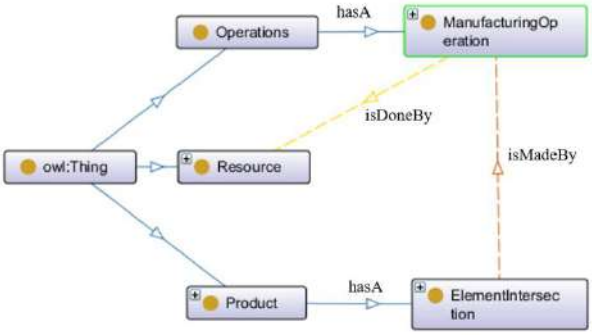

Figure 7. Class wood member intersections

For this wood frame, all types of intersections are identified and matched to the ontology model. These types of intersections are annotated in Figure 8 and are tabulated in Table 2. Note that an integer that follows the letters in the Identifier column represent a specific instance of corresponding wood members.

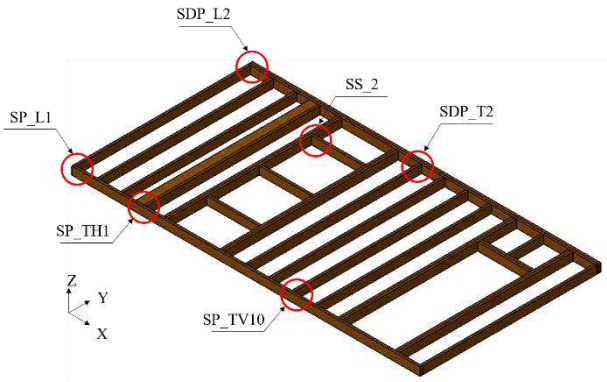

Figure 8. Intersections identified from provided wood frame

Table 2. Connections in wood frame panel

Intersection Type	Identifier
Stud_Plate_LConnection	SP_L1
Stud_Plate_TConnectionVertical	SP_TV10
Stud_Plate_TConnectionHorizontal	SP_TH1
Stud_DoublePlate_LConnection	SDP_L2
Stud_Stud	SS2
Stud_DoublePlate_TConnection	SDP_T2

To represent knowledge of the manufacturing machine domain, resource ontology is modeled for further analysis. As an example, the Wood Framing Machine Prototype (WFMP) built at the University of Alberta is used for this case study. It is a semi-automated framing machine designed to build wood frames. The prototype consists of four independent systems: cutting, dragging, drilling, and nailing. These systems are modeled in Protégé as shown below in Figure 9. Note that WFMP has not equipped with decision-support system to this point. The knowledge of the machine, however, will lead to development of decision-support system in the future.

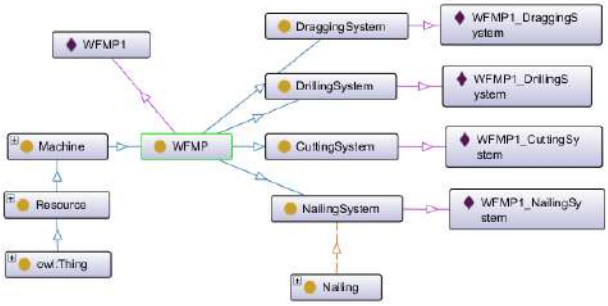

Figure 9. Systems of the WFMP

After knowing element intersections and systems of the machine, the relationship among product assemblies and machine domains can be established by analyzing the manufacturing operations needed to make such product assemblies. Based on expert knowledge, wood

members with intersections presented in Table 2 should be joined using screw fastening or nailing. In the ontology model, this knowledge is embedded in the object property "isMadeBy": the domain consists of element intersections and the ranges contain feasible operations. As an example, a sub-property "SDP_LConnection" of "isMadeBy" is defined in Figure 10.

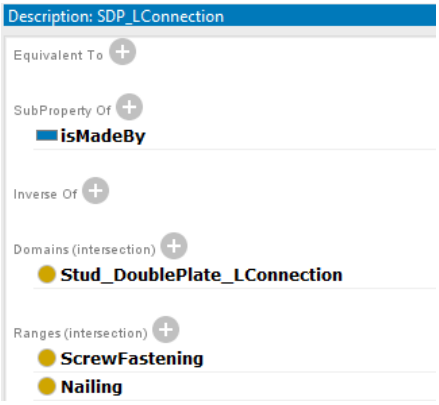

Figure 10. Object properties of SP_LConnection

Analyzing all the intersections in the wood frame, only screw fastening and nailing operations are feasible options for creating permanent connections. Since nailing is more popular for connecting wood timbers in North America, the only manufacturing process required for building this panel is the nailing operation. This result agrees with current industry practice for framing a wood panel.

4.2 Discussion

As shown in the case study, ontology models can not only represent knowledge of construction-oriented product assemblies and machine resources in detail, but also form a relationship between these knowledge domains. Using the product assembly information such as material, dimension, and intersections exported from The BIM model, appropriate manufacturing operations are suggested by the knowledge model. This requires building ontology models for both the product to be built and assembled, and the potential machines to be used to make such product.

A number of advantages are observed after having the knowledge model. First, a machine's capacity fabricate certain construction-oriented products can be determined by analyzing the manufacturing processes required to complete the product assembly. Second, if one machine cannot fulfill the manufacturing requirement, a well-defined model will suggest the appropriate manufacturing activities, such as a combination of machines, to fabricate the product. In addition, the ontology model built in the case study can easily be expanded to a related field. For example, machine logic, actuators, and sensors can be modeled and integrated to the existing model. As a result, a data exchange will be initiated between physical systems such as product assemblies and machines, which will accelerate product fabrication and simplify the modifications to existing production lines if needed.

However, certain limitations are also observed. Building knowledge models is extremely time consuming. A machine cannot decide or suggest manufacturing activities without sufficient knowledge from all relevant knowledge domains. In fact, ontology formulations need to cover all manufacturing resources in a production line. It is common that a product assembly is made by a series of activities and it is not feasible for a single machine to have all the functionalities required. The sequence by which a product assembly is made must be determined in addition to the specific manufacturing operations required. Therefore, future work is needed to address:

1. A more detailed ontology formulation that includes machines of the entire production line and encompasses material cost and manufacturing time estimation;
2. The sequence by which a product must be assembled (process planning of manufacturing processes);
3. The machine-product interaction within a production line has yet been defined.

5 Conclusion

Since the BIM model does not provide information regarding how products are to be fabricated, ontology models are used to bridge the knowledge gap. By building knowledge models for product, operation and machine, the relationship between product and machine is formed. Using expert knowledge, the required manufacturing operations are determined by identifying the intersections in a product assembly.

Once the manufacturing system is equipped with knowledge, it is possible to determine if a machine can manufacture a certain product, even though this is not the main focus of this study. Future more, it can further suggest additional manufacturing activities needed to complete the product in the case where one machine can only fulfill part of the fabrication requirements. In this case, combinations of machines need to be used to make the product. In future work, the proposed approach can be extended to all the machines in a factory to address this issue.

Abstract –

The research of floor-tiling robots aiming to replace the artificial floor tile installation, which is a trend in the development of construction automation. Modular design of the robotic floor-tiling system used embedded PC as the main controller, which has several advantages, such as reliable system performance, convenient modular communication, and simple function improvement. The measuring and positioning system of robotic floor-tiling consists of multiple subsystems. The task calls of each subsystem are allocated in real time through control flow and control algorithms. Feasibility of the measuring and positioning system is proved by test run and the future works are discussed.

Keywords –

Robotic floor-tiling; Control system; Embedded PC; Modular design

1 Introduction

Floor-tiling is a project in the construction industry that is labor intensive, highly repetitive, and testable to the skills and body of workers [1]. There are large quantities of tiles to be consumed and an increasing trend every year all over the world [2]. The environment of floor-tiling process is fully filled with mud, dust, noise, and vibration. Workers will squat or kneel on the floor when installing tiles [3]. If we rely entirely on the workers to set such large quantities of tiles, it will cost a lot of manpower and labor time, also can be physically harmful to workers [4]. Therefore, developing robotic floor-tiling to replace artificial floor tile installation will play a key role in the future of construction industry [5].

To use robotic floor-tiling instead of manual floor-tiling, the robot system must have the advantages in floor-tiling process such as higher efficiency, better quality, lower cost, and so on [6].

In the following of this section, the process of artificial floor-tiling is analyzed first, and then a floor-tiling robot system frame that can fulfill measuring and positioning function is designed.

1.1 Artificial Floor-Tiling Process Analysis

Thinset tiling method is one of the most widely used method in the current floor-tiling. Thinset tiling is also called dryset or drybond tiling [7], it uses a blend of cement, fine sand, and a unique blend of special additives to install tiles on an even substrate surface [8]. Fig.1 shows the thinset tiling process, this method can be described as the following steps [9]:

1. Level substrate by self-leveling epoxy or self-leveling cement.
2. Hold a notched trowel at a slight angle, push down and away to spread the thinset mortar to substrate surface or to tile's back evenly and following the same direction.
3. Set tiles and spacers, plug wedge into spacer to leveling tiles.
4. Repeat thinset spreading, tile setting, spacer setting and tile leveling till all tiles are installed, then grout joints and further clean the room.

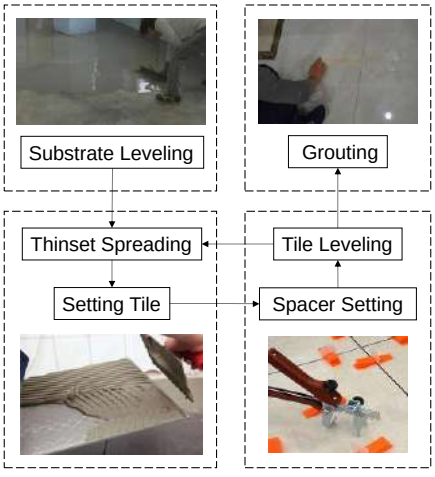

Figure 1. Process chart for thinset tiling

Thinset tiling has the following advantages compared to traditional thick-bed tiling:

- Less steps and easy operation.
- Lower cost and higher efficiency.
- Stronger bonding strength.
- Use less material and save more space.

Therefore, a floor-tiling robotic measuring and positioning system frame is designed based on thinset tiling method.

1.2 Frame Design of Floor-Tiling Robot System

The measuring and positioning system is the most critical component of the floor-tiling robot. By analyzing the artificial floor-tiling process, the measuring and positioning system can be divided into several subsystems to realize the precise placement of tiles [10]. Fig. 2 shows a general floor-tiling robot's measuring and positioning frame diagram, it basically consists of the following subsystems [11]:

- HMI (Human Machine Interface), which is the medium for information interaction between the control system and the operator.
- The main controller, which is responsible for sending control commands to and receiving statuses from the slave controllers of the subsystems.
- The mobile platform system, which is a crucial part of the floor-tiling robot to achieve a wide range of operations.
- The actuator system and robotic arm system, which contribute to the grabbing and placing of tiles.
- The sensor system, which is the key part of the floor-tiling robot, in order to implement measurement and carry out positioning functions when tiling.

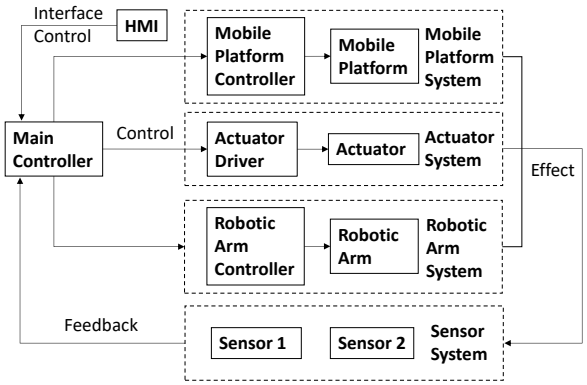

Figure 2. General floor-tiling robot's measuring and positioning system frame diagram

2 Hardware Platform Design

In this section, the hardware part of each subsystem is built according to the previous general floor-tiling robot's measuring and positioning system frame diagram, and the communication of the whole hardware platform is established through various communication modules [12].

2.1 Subsystems

According to the suitable measuring and positioning method used by the floor-tiling robot, the system is divided into the following five subsystems, which are introduced separately.

2.1.1 Point Laser Measurement System

The point laser measurement system contains two sets of measurement modules. Two sensor heads mounted on the end tool can measure one edge of a tile at the same time, and obtain relative position deviation data. Precise positioning function is achieved through position correction algorithm.

As shown in Figure 3, IL-300 is used as sensor head, which has 30 micron repeatability, ±0.25% F.S linear accuracy, 300mm reference measurement distance, and the measuring range is 160 to 450 mm from the laser head. The IL-1000 and IL-1050 are used as amplifiers, and the two amplifiers are plug-in connected to save connection cables and space. The DL-EN1 communication module is used to transmit laser measured data.

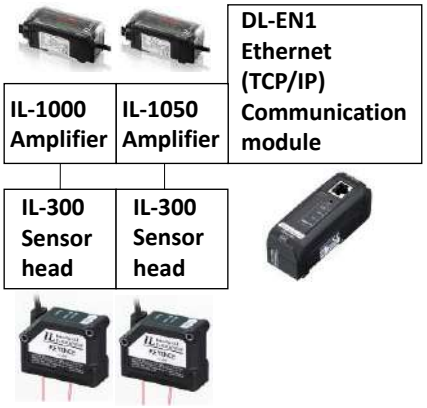

Figure 3. Point laser measurement system frame diagram

2.1.2 Pneumatic System

The using of pneumatic system with the suction cup is the most suitable method for grasping and placing

tiles or other flat objects.

As shown in Figure 4, four suction cups with a diameter of 25mm are used for the pneumatic system to grab and place 300mm×300mm tiles with the weight of about 2 kilograms after calculation and selection. The assembled vacuum generator can monitor the air pressure in real time and control it by switching the supply valve and destruction valve. The air source uses an air compressor and a filter valve is installed at the outlet to clean the air to prevent dust from clogging the vacuum generator.

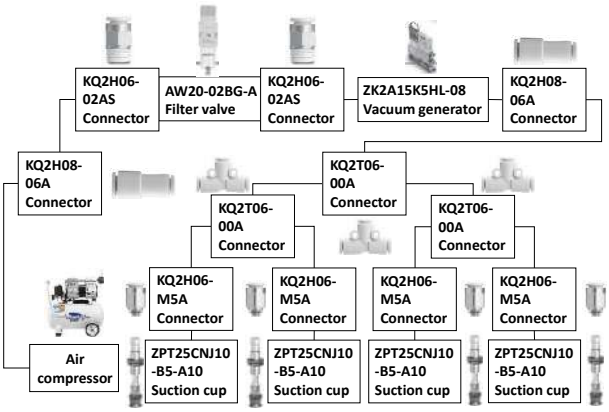

Figure 4. Pneumatic system frame diagram

2.1.3 Main Controller and Terminal System

The German Beckhoff modular products are used for the main controller and terminal system, which have the characteristics of reliable performance, fast transmission rate and convenient installation and disassembly.

As shown in Figure 5, the embedded PC is used as the main controller, which most of the algorithms are compiled and written into. The embedded PC coordinates the work of each subsystem controller. The power system can provide a stable 24V DC power supply, which can not only supply power to the embedded PC, but also support the power requirements of other subsystems. The subsequent terminals are responsible for information interaction with the communication modules of each subsystem, and the multiple subsystems are combined into a complete measuring and positioning system design of robotic floor-tiling.

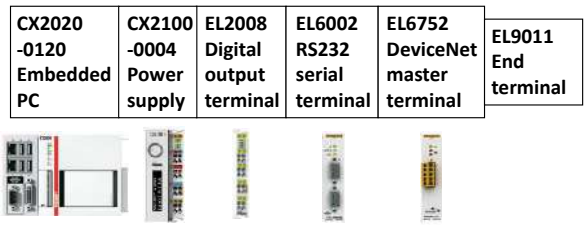

Figure 5. Main controller and terminal system

frame diagram

2.1.4 Robotic Arm System

Figure 6 is the robotic arm system frame diagram. The Yaskawa industrial robot products are used in the robotic arm system. The GP7 industrial robot has six axes of freedom and a load of 7 kilograms, which can meet the requirements of tile measuring and positioning. Each action of the robotic arm is programmed by the teaching programmer and written into the YRC1000micro control cabinet. MOTOPLUS software is used to write the protocol for the data exchange between the control cabinet and the Beckhoff embedded PC, the protocol is programmed on the computer and eventually written into the control cabinet.

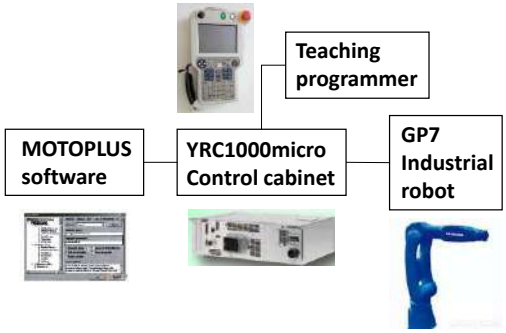

Figure 6. Robotic arm system frame diagram

2.1.5 Mobile Platform System

The mobile platform has a load capacity of 200kg, Figure 7 shows the mobile platform system frame diagram. The mobile platform system uses an STM32-based control board. The movement program in the control board sends drive commands to the four servo drives. Each servo drive drives a servo motor connected to a Mecanum wheel for rotation. The Mecanum wheel is one kind of omnidirectional wheel. The mobile platform based on the Mecanum wheel has a minimum turning radius of 0mm, it is flexible in movement and can move laterally. And the control board is equipped with a wireless module, the mobile platform can be controlled through the remote control.

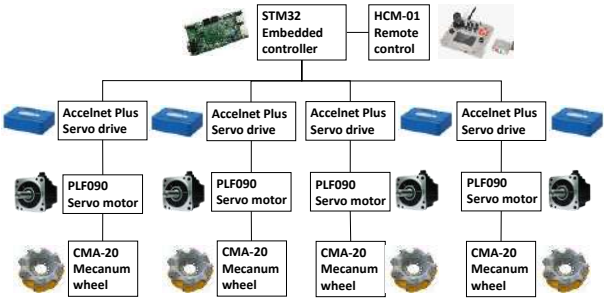

Figure 7. Mobile platform system frame diagram

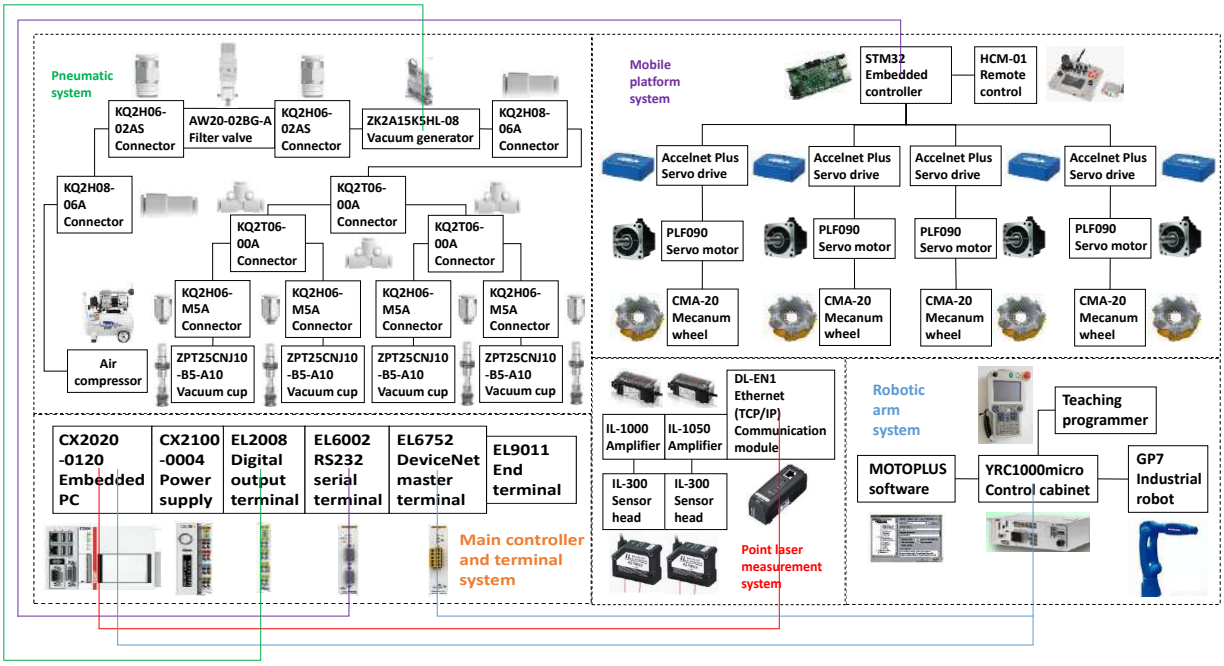

Figure 8. Measuring and positioning system's module communication frame diagram

2.2 Module Communication

As shown in Figure 8, there are several ways to communicate between subsystems.

The main controller controls the vacuum generator in the pneumatic system by EL2008 digital output terminal, and supply valve and destruction valve in the vacuum generator is controlled by the digital output, the communication cable is indicated in green.

Communication between the main controller and the point laser measurement system is realized by Ethernet TCP/IP, and TCP/IP has the advantage of reliable data transmission. The communication cable between the CX2020-0120 embedded PC and the DL-EN1 is indicated in red.

The main controller and terminal system and the mobile platform system is realized by serial port RS232. RS232 is one of the most commonly used serial communication methods, which is suitable for data transmission in non-real-time application conditions. The communication cable between the EL6002 serial terminal and the STM32 embedded controller is indicated in purple.

There are two communication ways between the main controller and terminal system and the robotic arm system. One is the Ethernet TCP/IP, which is used for robotic pose transmission, and the other is the fieldbus DeviceNet. The DeviceNet has the characteristic of high real-time performance, which is used for the transmission of motion commands sent to the robot by the main controller. Both communication cables are indicated in blue.

3 Software Environment Establishment

After the hardware platform of the robotic floor-tiling system is built, the software environment should be established in the system. The software design can be completed in three steps. The principle of tile measuring and positioning is analyzed firstly. Then, the task assignment is performed to figure out which tasks each subsystem needs to complete in a complete measuring and positioning process. Last, the control flow is developed so that each task can proceed in the order.

3.1 Tile Measuring and Positioning Principle

Figure 9 shows the schematic of tile measuring and positioning. Firstly, the end tool picks up the tile 2 and moves along the yellow arrow. When the laser spot of one point laser sensor moves from the ground to the tile 1 and another sensor head's laser spot still shoot on the ground, the end tool will slightly rotate along the orange arrow and continue to move along the yellow arrow until both laser spots shoot on the tile 1's edge. The good parallelism of the gap between two tiles is achieved by this method.

Secondly, the end tool moves back and forth along the green arrow, so that the two laser sensors can measure the range between the two red lines on the tile 1 and determine the placement position of the tile 2. In this way, the good linearity of a row tiles can be achieved.

In the process of measuring and positioning, the good levelness of the end tool is guaranteed by a

gyroscope mounted on the end tool. And the relative position of the tile 2 to the end tool can also be calculated through the two laser sensors data. When laying the second row of tiles, the same method can be used for measuring and positioning by rotating the end tool 90 degrees clockwise.

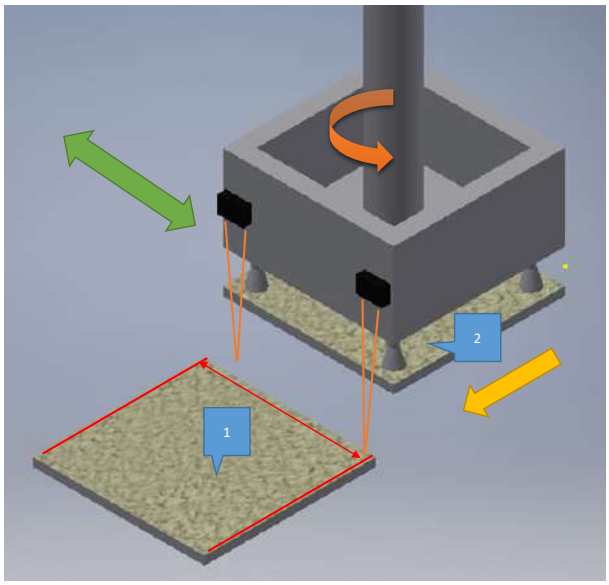

Figure 9. Tile measuring and positioning schematic

3.2 Task Assignment

According to the tile measuring and positioning principle. The process of robotic floor-tiling is divided into the following tasks to complete:

- Reference tile measuring.
- Reference tile calculation.
- Tile picking.
- Tile measuring.
- Tile calculation.
- Target position calculation.
- Tile placing.
- Return to starting point.
- Mobile platform movement.

3.3 Control Flow

The control flow is the actual flow and order of instructions and data between subsystems in the measuring and positioning process for several tasks. Figure 10 is the control flow chart of measuring and positioning process, for example in reference tile measuring task, the main controller sends movement instruction to the robotic arm. By the control flow, system tasks can be executed correctly and orderly.

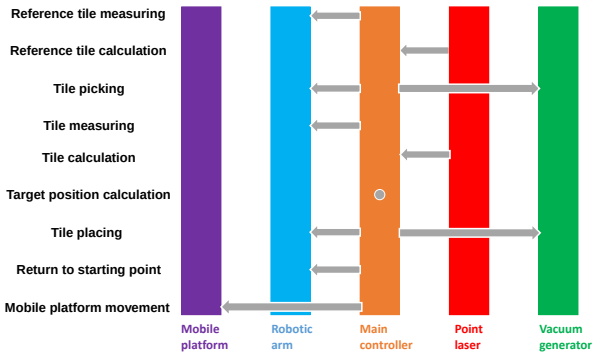

Figure 10. Control flow chart of measuring and positioning process

4 System Test and Results

Before the measuring and positioning test of the robotic floor-tiling, it is necessary to adjust the jump value of the point laser sensors. The jump value of the point laser sensor is the basis for recording the posture of the robotic arm which includes 6 parts: X, Y, Z, Rx, Ry, and Rz in the Cartesian coordinate system. And when the laser spot moves from the upper edge to the lower edge of the tile or reversed, the hopping signal generated by the point laser sensor will cause the robot to automatically record the current posture as a reference value for the test. In this test, the laser sensor has an optimum jump value of 4.2 mm.

Figure 11. Measuring and positioning test of robotic floor-tiling

The measurement and positioning test of the tile is shown in Figure 11. After placing the reference tile, the robotic arm continuously sets 10 tiles according to the position of the reference tile, and the posture of robotic arm will be recorded. Comparing the actual position with the theoretical standard position of the 10 tiles estimated from the reference tile position, the data results can be obtained in Table 1. The linear deviation range is within 0.5mm, and the rotation deviation range is within 0.2°. Results meet test expectations.

Table 1. Tile position deviation in measuring and positioning test

Tile number	X deviation (mm)	Y deviation (mm)	Z deviation (mm)	Rx deviation (°)	Ry deviation (°)	Rz deviation (°)
1	0.420	0.339	0.194	0.125	0.112	0.157
2	0.376	0.491	0.104	0.112	0.194	0.171
3	0.108	0.110	0.178	0.123	0.146	0.120
4	0.466	0.191	0.266	0.123	0.107	0.121
5	0.217	0.151	0.261	0.135	0.195	0.152
6	0.379	0.240	0.339	0.181	0.119	0.140
7	0.175	0.124	0.499	0.165	0.109	0.163
8	0.124	0.173	0.154	0.171	0.140	0.155
9	0.479	0.205	0.483	0.196	0.136	0.191
10	0.258	0.396	0.485	0.199	0.102	0.126

5 Conclusions and Future Works

This paper describes a design of measuring and positioning system for robotic floor-tiling. This system uses embedded PC as the main controller to exchange data with subsystems through various communication terminals. In the system, the main controller communicates with the robot controller via Ethernet TCP/IP and DeviceNet field bus, which can ensure the correctness and real-time of data transmission. And the connection between the main controller and the point laser measurement system is also Ethernet TCP/IP which can ensure the reliable measuring data transmission. RS232 serial port is used to control mobile platform that can save costs and meet non-real-time communication requirements. And digital output is simple and efficient enough to control the opening and closing of the supply valve and the destruction valve in the vacuum generator. The test shows the measuring and positioning system has a high precision. And this system can be seemed as the basis for the subsequent research of the floor-tiling robot.

In future works, the point laser sensors need to be replaced by other sensors, and the measuring and positioning principle also need to be improved cause the low process efficiency. More subsystems need to be added to complement the functionality of the entire robotic floor-tiling system.

Abstract –

In the modular construction industry of Canada, workers experience awkward postures and motions (reaching above shoulder, back bending backward, elbow/wrist flex, etc.) due to improper workstation designs. The awkward postures often lead to worker injuries and accidents, which do not only reduce the productivity but also increases the production cost. Therefore, the ergonomic posture analysis becomes essential to identify, mitigate and prevent the awkward postures of workers when workstation designs are changed. This paper proposes a novel framework to conduct the worker ergonomic posture analysis through the 3D reconstruction of human body from the video sequences captured by a monocular camera. The framework consists of four components: tracking worker of interest; detecting worker joints and body parts; refining 2D worker pose; and generating 3D human body model. The human body model generated from the framework could be used to estimate the joint angles of the workers to identify whether their postures meet the ergonomic requirements. The proposed framework has been tested on real construction videos, and the test results showed its effectiveness.

1 Introduction

The modular construction has gained significant interest in recent years. According to the annual report from the modular building institute, the gross revenue in the modular construction industry in 2016 was roughly $3.3 billion in North America, which was increased by more than 60% from the year of 2015 [1]. Compared with the traditional, onsite construction, the factory-controlled processes in the modular construction provides the benefits of generating less material waste and reducing potential site disturbances [2]. They mitigate the adverse weather impacts on the project and faster the construction schedule [3]. Also, the factory controlled working environments are supposed to be safer for the workers involved.

However, workers' awkward postures are often noticed in several modular construction workshops [4]. These awkward postures might be due to the improper workstation designs in the factory controlled working environments. As shown in Figure 1, the workbenches are not high enough. Then, the workers have to bend their backs forward and strain their necks in order to reach materials and tools. The foot pedals in the machines are set too close. As a result, the workers have to bend their backs backward in order to reach the pedals. Sometimes, the workers are required to lift the materials from one spot to another over their shoulders, twist their wrists and elbows, and kneel or crouch to complete their assigned tasks in the production lines.

Figure 1. Awkward postures of the workers in modular production lines

The awkward postures easily lead to work-related musculoskeletal disorders [5, 6]. For example, the frequent kneeling will cause workers' pain and strain in their low backs and knees, which pose a high risk of developing muscle and joint problems. The musculoskeletal disorders hurt the health of the workers

and result in the absenteeism [6]. Also, they impact the employers simultaneously. Additional time and efforts must be spent on handling the lost-time and disabling injury claims with high compensations; and the workflow in the production lines are delayed [7]. New workers need to be hired to replace the injured ones, which might not always be easy.

In order to reduce the occurrences of the work-related musculoskeletal disorders, the employers in the modular construction workshops are encouraged to conduct the Physical Demand Analysis (PDA) [8]. PDA is a systematic procedure to help the employers quantify and evaluate the physical and environmental demands of a job [9]. One important step in the Physical Demand Analysis is to measure the frequency of the body posture of a worker in a job, such as percentage of the worker's back forward or backward; and then identify any potential ergonomic risk for the worker from the measurements

Traditional measures heavily rely on direct manual observations and self-reporting [10], which are easy to implement with little costs associated in the workshops. However, the manual observations and self-reporting are subjective; and the measurement results are always error-prone [11]. Recently, the idea of attaching physical sensors or tags on the worker's body to record their motions, postures and even muscle activity in the work to indicate whether the muscle is fatigue [12, 13]. The sensors can provide the accurate measurements, but their implementation cost is high. Also, it is not widely acceptable by the workers in practice, who are not willing to wear these sensors and tags during the work [14].

An alternative solution is to use digital video cameras that could be set up in the workshops by the employers. This paper combined different computer vision techniques and proposed a novel framework that relies on the video from one monocular camera to reconstruct the 3D human body of a worker. The framework consists of four main components. First, the worker of interest in the video sequences is identified through the visual tracking. Then, the 2D joints and body parts of the worker are detected. The detected joints and body parts are combined to refine the worker's 2D pose in the video sequences. The 3D human body model is further generated by matching the model with the refined 2D pose in the video sequences. This way, the 3D posture and joint angles of the worker could be estimated for the corresponding ergonomic posture analysis.

The proposed framework has been implemented in Python 2.7 with the support of GPU (Graphic Processing Unit) computing. It was tested with the videos of two real working scenarios. The first video was recorded in the production line of the Fortis LGS Structures Inc., where a worker was cutting and transporting boards. The second one was provided by Alwasel et al. [15], where a worker was laying masonry units. The test results from both scenarios showed that the framework could generate the 3D human bodies of the workers of interest and obtain their joint angles effectively and efficiently. Moreover, the joint angle information could be further input to existing ergonomic posture analysis tools, such as 3D Static Strength Prediction Program (3DSSPP) [16], to identify whether the postures of the workers meet the ergonomic requirements.

2 Related Work

This section first provides a holistic view on the techniques available for ergonomic posture analysis and their limitations. Then, 2D and 3D human pose estimation methods in the field of computer vision are presented. The 2D pose estimation methods are reviewed, since they are the solid foundation to most of existing 3D pose generation methods.

2.1 Ergonomic Posture Analysis

Existing techniques available for ergonomic analysis can be classified into the categories of self-reporting, manual observation, sensor-based direct measurement, and vision-based analysis. Self-reporting is to collect the data from worker diaries, interviews, and web-based questionnaires [10] to conduct the ergonomic analysis. It is straightforward to implement in a wide range of workplaces and appropriate for surveying large numbers of workers at low cost. However, it was found that the self-reporting data were not always precise and/or reliable [11]. Also, the levels of comprehension and question interpretation may increase the difficulty, when adopting the self-reporting in practice [17].

Manual observation mainly relies on experienced experts to record the body postures of the workers in a workplace to conduct the ergonomic analysis. Several tools have been designed and developed to facilitate the observations and evaluation of ergonomic risk factors, such as Ovako Working Posture Analysing System (OWAS) [18]. The observation produces the minimal disturbances to the workers, which makes it applicable in various working environments. On the other hand, the manual observation results are error-prone due to the influence from the subjective judgement of the experts.

Sensor-based direct measurement is to complement or replace the self-reporting or manual observation. A wide range of direct measurement sensors have been developed, and they are directly attached to the workers to improve the measurement accuracy. For example, the Lumbar motion monitor (LMM) [12] was developed to assess the risk of the worker' low back injury. The

electromyography (EMG) [13] was used to study the muscle exertions. Also, the retroreflective markers were attached on the worker bodies. This way, the 3D motion of the joints and body segments of the workers could be tracked with infrared cameras [19]. The measurements with sensors and/or markers are accurate and detailed. However, the workers complain about the physical requirement of attaching sensors and/or markers on the bodies, and not willing to wear them in practice [14].

The vision-based analysis tried to capture the joint motions of the workers and assess their body postures in a marker-less way. For example, Diego-Mas and Alcaide-Marzal [20] computerized the OWAS and processed the RGB-D data from a Microsoft Kinect camera to identify the risk level of each recorded posture. Ray and Teizer categorized the ergonomic or non-ergonomic body postures captured by a Kinect camera with a predefined set of rules [21]. Both methods solely focused on the classification of simple postures, such as lifting and crawling, in the indoor environments.

In addition to the Microsoft Kinect cameras, video cameras are also adopted. For example, in the method of Han and Lee [22], they extracted and matched the visual features of a worker in 2D video frames and then the worker's 3D skeleton can be extracted through the triangulation. This way, the unsafe actions could be detected by comparing the skeleton with pre-trained motion templates and skeleton models.

Compared with sensor-based direct measurement, the vision-based analysis does not have to physically tag workers, which makes it more acceptable in the workplaces. However, the vision-based analysis mainly relies on the data from the range or video cameras to approximate the joint motions of the workers. The accuracy and robustness of such approximation are always affected by environmental factors. Any illumination change, occlusions, and/or far shooting distance might lead to the vision-based analysis inaccurate and non-robust. So far, several methods were proposed to improve the accuracy and robustness of the vision-based ergonomic analysis.

2.2 2D Human Pose Detection

A classical method for 2D pose detection refers to the use of a pictorial structural (PS) model, in which the spatial relationships between various body parts are represented with kinematics priors. One example of the PS models is a tree-like structure, which was adopted by Lan and Huttenlocher [23] in their work of determining the human body pose. Andriluka et al. [24] combined the PS model with a strong human body part detector to make the human pose detection more generic. In addition, the mixture of the deformable parts model (DPM) was also introduced [25]. The introduction of DPM extended the application scope of the PS models, but it requires the substantial computations.

Recently, the 2D human pose detection has been significantly advanced with Deep Learning technologies. For example, DeepPose [26], the first method for human pose estimation with Deep Neural Networks (DNNs), was built on a 7-layered convolutional neural network (CNN). It formulated the pose detection as a joint regression problem and each joint could be directly regressed from a full image [26]. Pfister et al. [27] created the Flow ConvNets to detect 2D human poses, which benefitted from video temporal contexts to improve the pose estimation performance. Also, researchers developed the convolutional pose machines (CPM) [28] and stacked hourglass [29], both of which estimated the human pose without the need of an explicit human body model.

The methods described above have been used only for single-person pose estimation. They typically fail when multiple persons are captured into one image or video frame. This issue was overcome in the method of DeepCut [30], but the computational intensity is high. Its upgraded version, DeeperCut [31], was introduced to adapt to the newly proposed residual network for body part extraction. This way, the computation is reduced significantly and the robustness to the human body pose detection is maintained.

2.3 3D Human Pose Generation

The generation of 3D human pose from 2D images or videos is still one of the promising and popular research directions. Existing methods could be divided into two categories: i.e. multi-view vs. monocular view, depending on the number of video cameras adopted. Multi-view methods were inspired by human vision and infer a 3D human pose from two or more cameras [32]. The main mechanism is to obtain the 2D pose in each camera view first, and then reconstruct the 3D skeletal pose from the 2D poses [33].

Compared with the multi-view methods, it is much challenging to generate the 3D human pose with the monocular view methods. The methods tried to recover the depth information by creating a relationship between the 2D visual features (e.g. silhouette) and 3D skeletal pose [34]. This relationship could even ben learned with deep learning technologies, such as Vnect [35], which regressed 2D and 3D poses jointly through a CNN-based pose prior with Kinematic skeleton fitting. Moreover, Federica et al. [36] described how to automatically generate the 3D pose of a human body as well as its 3D shape from a single unconstrained image.

3 Research Objective

The monocular view methods for 3D human pose

generation are supposed to achieve better performance in terms of the cost-effectiveness and wide-range applicability for ergonomic posture analysis. However, they have not been well studied yet. It is still necessary to improve the 3D pose generation accuracy before the methods could be adopted in practice. One important aspect for improvement is to locate the body joints in the images or videos more precisely, considering that the locations of the body joints are directly related to body angles calculation for the ergonomic analysis.

The main objective of this research is to investigate whether it is possible to improve the 3D pose generation accuracy with the integration of existing computer vision techniques. A novel framework is proposed here for the 3D reconstruction of human poses with one monocular video camera. The overview of the framework is illustrated in Figure 2. Under the framework, the worker of interest is first tracked visually in the video sequences, and represented as a rectangular bounding box. Then, the 2D joints and body parts of the worker are detected. Based on the detection results, the 2D pose of the worker is refined and the 3D human body model is further generated by matching the model with the refined 2D pose in the videos. The joint angles are computed based on the 3D joint coordinates to serve as the input for the ergonomic posture analysis. The proposed framework is expected to function in real modular construction scenarios, which could help to identify the awkward and improper postures of the workers in modular construction workshops.

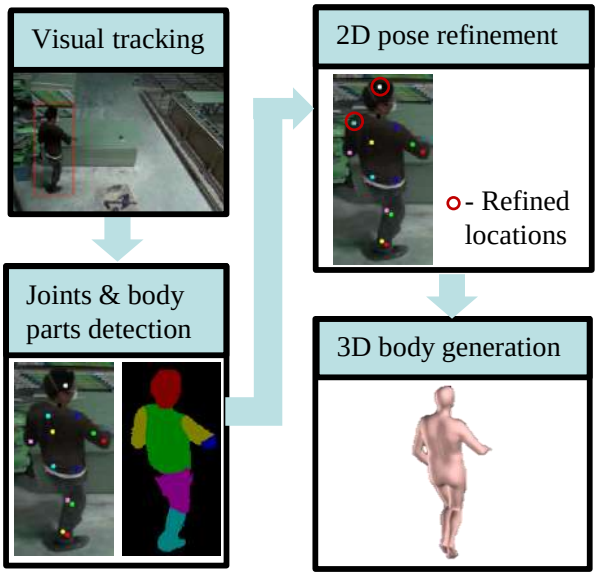

Figure 2. Overview of the proposed framework

4 Research Methodology

4.1 Visual Tracking

Visual tracking here is to locate the worker of interest along the consecutive video sequences. It could narrow down the image region with the less irrelevant background information contained for processing. Here, the CNN-based tracking algorithm *MDNet* [37] was selected due to its significant performance on the human-tracking challenge competition. It is worth noting that the tracking results need to be appropriately resized, since the accuracy of the pose estimation is easily affected by the image size. The size of 150 (width) x 350 (height) pixels was adopted in this study, based on the previous finding that the human pose detection could always perform well, when the standing height of the persons was scaled at around 340 pixels in the images [31].

4.2 Joints and Body Parts Detection

The resized visual tracking results are further processed to detect the worker's joints and body parts. Here, the joint detection is conducted by the DeeperCut algorithm [31]. It could identify a total of 14 joints from their corresponding heat maps, where the probability of each pixel in the image region to be a joint is indicated.

As for the body parts detection, the Deeplab v2 method [38] is modified to have the method only detect 6 body parts, i.e. head, torso, upper /lower arm and upper/lower leg, instead of 24 detailed body parts shown in the Pascal-Person-Part dataset [39]. Moreover, the reliability of the body part detection results is evaluated with the heatmaps produced by the DeeperCut algorithm [31]. A detected body part is considered reliable only when it has a high probability of containing a joint (larger than 0.2 in this research study). For example, the detected head body part is reliable when its probability of containing the head joint is high. The high probability does not mean that it must include the head joint.

4.3 2D Pose Refinement

The joints detected in the previous step compose an initial pose for the 3D reconstruction later. However, this initial pose is not always accurate. This is mainly because each joint is not located perfectly at the joint detection stage. For example, it is highly possible that a left shoulder joint is located on the right shoulder area instead of the left one. Therefore, the initial pose from the joint detection needs to be refined by combining the joint and body part detection results.

The refinement first checks whether the initial joints lie in their corresponding body parts. If not, the joints are relocated in the body parts based on the confidence

values of the body part regions in the heat maps. For example, if the initial head joint does not lie in the head part, then it is relocated in the head part region. The position where the highest confidence value to be the joint point in the head part area is selected. If the initial joints lie in their corresponding body parts, the refinement is then conducted on a case-by-case basis. For example, the head joint will be preferred in the top of the head part area. More details for the adjustment of the joints with the body part detection results could be found in the authors' recent work [40].

4.4 3D Human Body Reconstruction

Based on the refined 2D pose, the 3D human body of the worker of interest is reconstructed. Here, the generative Skinned Multi-Person Linear (SMPL) model [41] is adopted in the reconstruction process. The SMPL model could represent a wide variety of natural 3D human poses with body joints and shapes [41]. Following the workflow of Bogo et al. [36], these 3D poses are projected onto the camera view and compared with the refined 2D pose from the previous step. The one that optimally matches to the refined 2D pose is selected as the final reconstruction result.

The joint angles are further calculated from the reconstructed 3D human body. There are a total 14 joint angles under the consideration: clavicle (left and right), upper arm (left and right), lower arm (left and right), hand (left and right), upper leg (left and right), lower leg (left and right), and foot (left and right). Each joint angle is described both horizontally and vertically. These joint angles could be input into the 3DSSPP program [16] with other work-related information (e.g. external loads, worker's gender, age, height and weight), and assess the risk factors that may produce excessive physical loads on the worker's body.

5 Implementation and Results

5.1 Implementation and Tests

The proposed framework has been implemented in the Python 2.7 environment. It runs under the Ubuntu 16.04 LTS operation system and relies on the support of the GPU computing from an NVIDIA Titan Xp. Two real scenarios were selected to test the framework. In the first scenario, the video was collected from the production line of the Fortis LGS Structures Inc., where the worker was cutting boards in a sheathing table. The second scenario was provided by Alwasel et al. [15]. The worker in the scenario was laying concrete masonry units. He is also equipped with a motion capture suite with the attachment of 17 sensors to record his joint angles during the work.

5.2 Results

Figure 3 showed an example of the results from the first test scenario. Figure 3a illustrated the visual tracking of the worker of interest, where the red bounding box indicated the tracking result. Figure 3b indicated the detection of worker's body parts, which were represented with different colors. Figure 3c showed the refined locations of the 2D joints through the combination of the joints and body parts detection. Figure 3d was the final 3D human body reconstructed from the refined 2D joints.

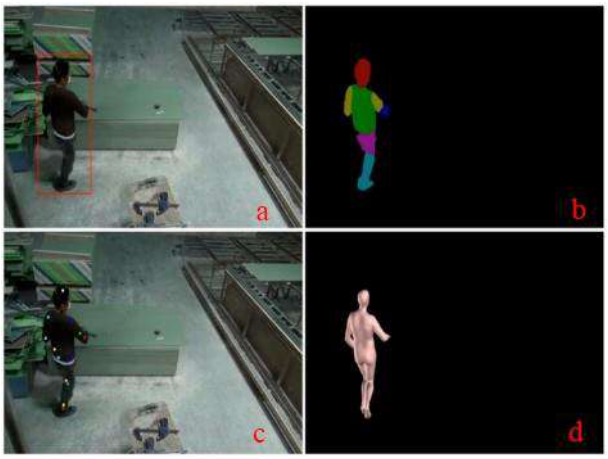

Figure 3. Results from the first test scenario

Figure 4 showed the examples of the results from the second test scenario. In the figure, the reconstructed 3D human body was placed beside the worker in the video sequences, in order to compare their visual similarity. It could be seen that the reconstructed 3D human body generally reflect the worker's posture during the work. Also, the human body could be generated, even when the worker experienced partial occlusions. In Figure 4c, both worker's head and arm were occluded, the human body was still reconstructed through the references from other visible 2D joints.

Moreover, the joint angles estimated from the 3D human body were compared with the sensory data from the motion capture suite in the second test scenario. The suit has the sampling rate of 125 Hz, and the video was captured at 25 frames per second. Therefore, the sensory data from the motion capture suite were down sampled for the frame-by-frame comparison.

Table 1 summarized the estimation error for each joint type. It could be seen that the minimum error (4.5°**)** occurs on measuring the horizontal angle of the lower arm joint. The maximum error (45.2°**)** occurs on measuring the horizontal angle of the upper leg joint. The errors for the remaining horizontal and vertical joint angles range from 10.0° to 28.0°**.** In average, the measurement error is around 17.5°**.**

Figure 4. Results from the second test scenario

Table 1. Estimation error for each joint type

Joint Type	Horizontal Angle	Vertical Angle
Clavicle	11.7°	13.2°
Upper Arm	15.9°	10.0°
Lower Arm	4.5°	10.8°
Hand	14.2°	10.1°
Upper Leg	45.2°	20.2°
Lower Leg	14.2°	20.7°
Foot	19.4°	28.0°

6 Discussion

The errors for measuring the joint angles may come from several aspects. First, the joint definitions in the SMPL model and the measurement from the motion capture suites are not one-on-one matching. The SMPL model has defined 24 joints, while the motion capture suite measured a total of 28 joint data. Therefore, those close to the joint definitions in the SMPL model were selected for the comparison, which may introduce the measurement errors.

Also, the occlusions affect the joints and body parts detection, as well as the quality of the 3D human body generation. Therefore, they may increase the joint angle measurement errors. Figure 5 illustrated the frame-by-frame comparison of the horizontal angle measurements for the lower arm from the 3D human body and motion sensory data in the second test scenario. The worker's head and arm were severely occluded from the 234th to the 388th video frames. As a result, the difference of the joint angle measurement fluctuated significantly during the occlusion period, as shown in Figure 5.

Also, the 2D pose refinement played an important role on the quality of the 3D human body reconstruction. In order to highlight its effectiveness, the pose similarity is calculated and compared for the 3D human bodies generated with and without the refinement step. It was found that the refinement improved the horizontal and vertical measurements of the pose similarity by 7.0% and 2.1%.

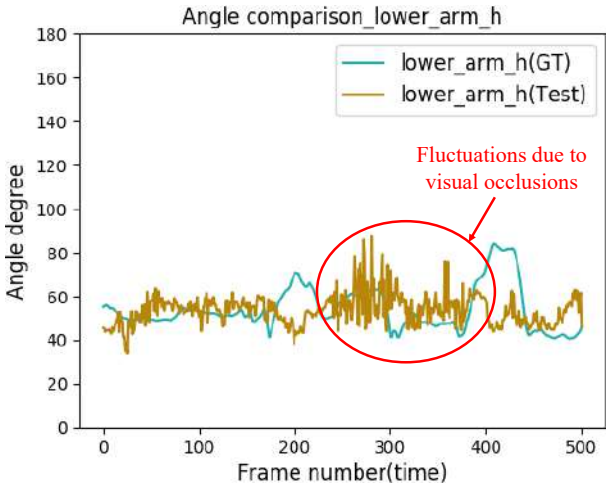

Figure 5. Comparison of the horizontal joint angle measurements for lower arm

7 Conclusions and Future Work

This paper presented an integrated framework for the 3D reconstruction of human body from the videos captured by monocular video cameras. The framework includes four main components: visual tracking, joints and body parts detection, 2D pose refinement, and 3D human body generation. The 3D human body generated from the framework could be used to estimate the body joint angles. This information could be input into the ergonomic posture analysis tool, 3DSSPP, to evaluate the risk factors that the worker may experience in a job.

The proposed framework was tested in two real scenarios. The joint angles of the 3D human body from the framework were also compared with the sensory data directly captured by a motion capture suite. The comparison results indicated that the average error for measuring joint angles was around 17.5°. The error for measuring the horizontal angle of the lower arm was as low as 4.5° and the error for measuring the horizontal angle of the upper leg reached up to 45.2°.

Future work will focus on reducing the errors of joint angle measurements. The temporal continuity in consecutive video frames and the worker's silhouettes in the video frames will be considered. They may improve the accuracy of joints and body parts detection and 3D human body reconstruction in the framework. This way, the joint angle measurement from the 3D

human body could be more accurate.

Abstract –

In recent years, drones have been used exclusively for military missions, but with the advent of new characteristics in UAV technology, more industries are now moving to add this new element to their practices. Engineers and analysts use UAVs to monitor projects, scan the ground, find out its dimensions and reduce the incidence of costly errors. The Drones improved the world over the next years and its use becomes a general trend in all areas, including industrial. Technology can be said to have a way of breaking down barriers and making impossible. The emergence and spread of a technological event is one of the key features that ensure the continuation of technological progress, and also guarantees us the creation of best products that the future holds. In this paper, we analyze a close coordination between dispersed cyber-physical system parts; aiming to mount pre-casted concrete pergola sections on rooftop of a building. The system consist of a manipulating robotized crane, moving the sections of pergola to the top level and positioning them according to a predefined shape. For better positioning of the sections, the trajectory of the manipulating system, in terms of lifting altitude, and two-dimensional positioning, is coordinated using unmanned aerial vehicle.

Cyber-physical system; UAV; Robot path planning

1 Introduction

In the past few years, the importance of unmanned aerial vehicles can be clearly defined in different techno-social fields. The application of autonomous systems is not anymore strictly related to military applications. Nowadays, unmanned platforms are used in medical, construction, rescue and cinematography business. Despite the relative success and the development of market share, the integration of these platforms in our quotidian life cycle is endangered by physical isolation of these solutions from direct contact with end-users, the absence of regulations and laws and relatively late development in human-machine interfaces.

Focusing on the UAV, the challenges are more serious than the ground-based autonomous platforms. The reason might be the importance of skies in military and civil aspects. Hence, the integration of the UAV in day-to day applications is limited due to the aforesaid reasons.

Pertaining to the construction market, the presentation of UAV is limited to photogrammetry and BIM. Researches about these topics are plenty: bridges, light poles, high-rise building and facades inspections are some of them.

In this paper, we would like to take the discussion further more and use the aerial capabilities of the UAV to guide and lead trajectory planning for dispersed cyber-physical system, the goal of which is to install heavy-weight roof mounted pergola.

This research will be composed in three main paragraphs:

- Description of the cyber physical system;
- Odometric approach and calculations of trajectory planning;
- Formation of control tasks and generation of results.

2 Dispersed Cyber-Physical System

By cyber-physical system, we understand the concept of reliable fusion between computational and physical platform embedded within the same body [1], however, enabling better interaction capabilities with the surrounding (world and human operator) though many modalities and processes. In light of that, the terms of interaction, integration and enhancement are

key areas where the research of cyber physical systems is occurring.

Traditionally, the physical system is a consolidated system and not dispersed over selected area. Recently, with the introduction of Internet of things (later IoT), the probability of designing distributed physical systems became achievable, as it overcame the disadvantages of radio systems and the huge cost related to GPS and GLONASS integration in navigation platforms, which made these solution not optimal techno-commercially. In this paper, we introduce the cyber-physical system consisting of the following levels:

- Aerial: a UAV scanning the roof and generating the positioning tasks for the subsequent component of the pergola;
- Cybernetic: analyzing the video-input of the UAV and generating trajectory for the manipulator using visual odometry algorithm;
- Ground: a Mobile robotic crane, receiving the coordinates from the cyber system and performing the laying-out of the pergola blades.

A concept of the solution is illustrated in fig.1 according to which, the UAV will dictated the following parameters as a potential control task to the cybernetic system: the swing angle ϕ, the luff angle θ, the hoist elevation h and the mobility across axis OX and OY, which can be replaced by the angle formed by the hoist and the luff axis [10].

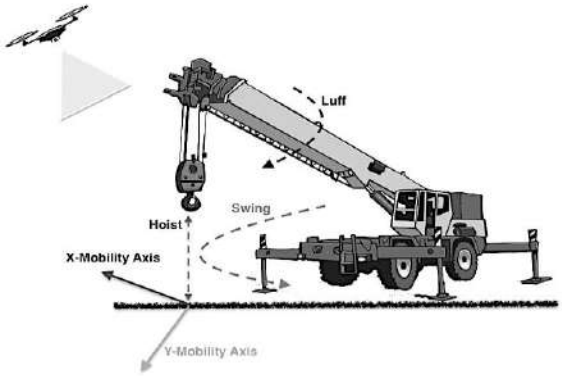

Figure 1. Concept of dispersed cyber-physical system

3 Trajectory Identification

3.1 Optical Odometry

The task of global planning is to fly through checkpoints [2]. This approach has already been applied in determining the position of the UAV and managing altitude using color or shape identification [9]. The difference between the proposed algorithm and the known control methods using machine vision algorithms is that for autonomous localization, the autopilot determines the distance traveled by calculating the rotor speed and rotation axis and establishes the relationship between the pixel system and the associated coordinate reference system (Body-axis). Usually, to determine the location of the UAV, information from the global localization system and the onboard sensors are used. Here, it is proposed to solve the problem using a machine vision and the method of optical odometry, which allows determining the location and orientation of the movement based on the sequence of optical information (images) in each time step. Figure 2 shows the relation between different references systems.

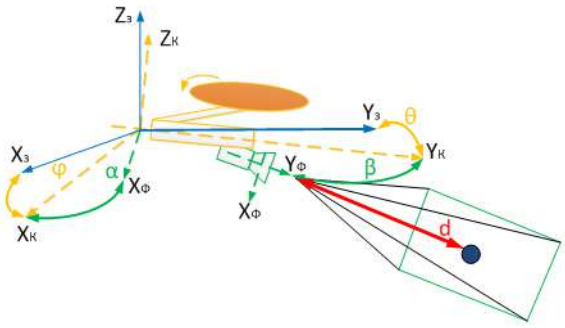

Figure 2. Axis and reference systems

To change the UAV position in relation to the Earth, using camera frames, it is necessary to find geometric relationships between different coordinate reference systems. We consider AR DRONE as UAV, which has a diaphragm deviation diagonally within 64 degrees. Using the laws of trigonometry, we obtain the angles of vertical and horizontal deviations, equal to 43.18 degrees and 51.62 degrees, respectively. The definition of the angles of inclination of the UAV with respect to the fixed axis of coordinates, and the roll, pitch and flight altitude, which are needed to determine the position of the camera in relation to the Earth are as follows: the aperture deviates by 51.62 degrees from the horizontal coordinate system i.e. from the origin of the roll angle (φ), therefore, the deviation of the projection of the image on the horizontal axis of the diaphragm can be computed according to equation (1):

$$\varphi = (51.62 - \alpha), \quad (1)$$

Where $\alpha -$ is the horizontal polar angle in the aperture coordinate system. In the same way we find the vertical projection by the formula:

$$\theta = (43.18 - \beta), \quad (2)$$

Where $\beta -$ vertical polar angle in the aperture coordinate system.

A geometrical representation of the deviation of the diaphragm from a fixed coordinate system is presented in Figure 3.

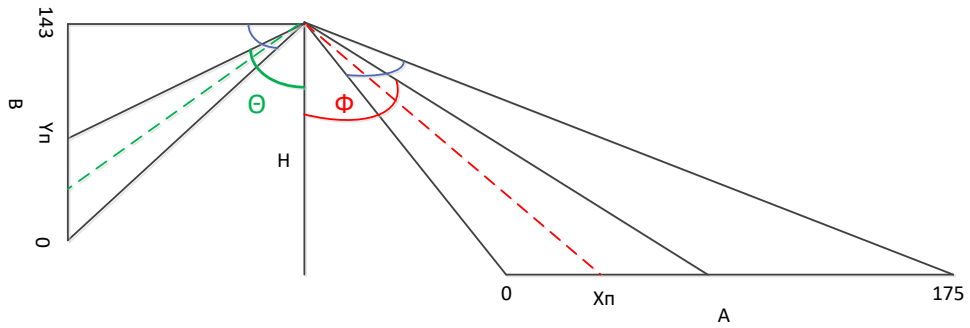

Figure 3. Geometric relationship between the associated coordinate system and the camera reference system

The distance from the camera to a specific coordinate (Earth-axis) is computed using the following equations

$$d(x) = H_{\text{г}} = H * \tan(\varphi + \alpha); \quad (3)$$

$$d(y) = H_{\text{B}} = H * \tan(\theta + \beta), \quad (4)$$

Using equations (3) and (4), we can identify the transformation formulas between different reference systems.

$$\begin{cases} X_{\text{п}} = \frac{x}{\Pi x}.\cos\left(\arctan\left(\frac{H_B}{H_{\text{г}}}\right)\right) \\ Y_{\text{п}} = \frac{y}{\Pi y}\sin\left(\arctan\left(\frac{H_B}{H_{\text{г}}}\right)\right) \\ \rho_x = \sqrt{{X_{\text{п}}}^2 + {Y_{\text{п}}}^2} * \cos\left(\arctan\left(\frac{H_B}{H_{\text{г}}}\right)\right) \\ \rho_y = \sqrt{{X_{\text{п}}}^2 + {Y_{\text{п}}}^2} * sin(\arctan\left(\frac{H_B}{H_{\text{г}}}\right)) \end{cases} \quad (5)$$

Where $X_{\text{п}}$ and $Y_{\text{п}} -$ are the pixel coordinates, x and $y -$ are the body axis coordinate and ρ_x and ρ_y are the angular pixel coordinates.

3.2 Minimum Jerk Trajectory

The pixel coordinates calculated in equation (5) has to be fed to the crane as a desired trajectory for its manipulator. In light of that, the obtained coordinates and rotational angels have to be transformed to metric again in terms of swing and luff angles, elevation and 2D mobility. We will assume that the height of the building is known and the influence of the wind is negligible; hence the elevation parameter will be considered as an input value and the dragging coefficient of the pergola blades will be neglected aerodynamically.

The remaining four parameters can be directly correlated with received by computing equation (5) and interchanging equivalence. The difficulty remains in generating a trajectory that achieve minimum jerk to the manipulator as it might cause risks, false positioning of the moved piece and possible abortive works [5,6]. To achieve an optimal trajectory to the manipulator, the movement will be posed and solved as quadratic programming using multi-segment Chebyshev orthogonal collocation for transcription.

Using the two dimensional Chebyshev-Gauss collocation method to obtain possible numerical solution of differential equation by partially is differentiating it in time and discretizing it using finite difference method [4]. Taking into consideration that the trial or candidate trajectories $f_k(x)$ will be set on homogenous Dirichlet boundary conditions [3], the approximate solution can be presented in the following equation

$$U^N(x,t) = \sum_{k=0}^{N} a_k(t)\, f_k(x) \quad (6)$$

In the collocation approach, the differential equation has to be satisfied by the approximate solution at the collocation points in the assigned domain [8]. The derivative at each node can be found by multiplying the value at any Chebyshev point by a differentiation matrix.

3.3 Results

Implementing the equations in sections (3.1) and (3.2), and running the quadratic programming listing on Matlab, the result of multi-segment trajectory simulation based on the aforementioned modeling constraints is depicted in Figure 4.

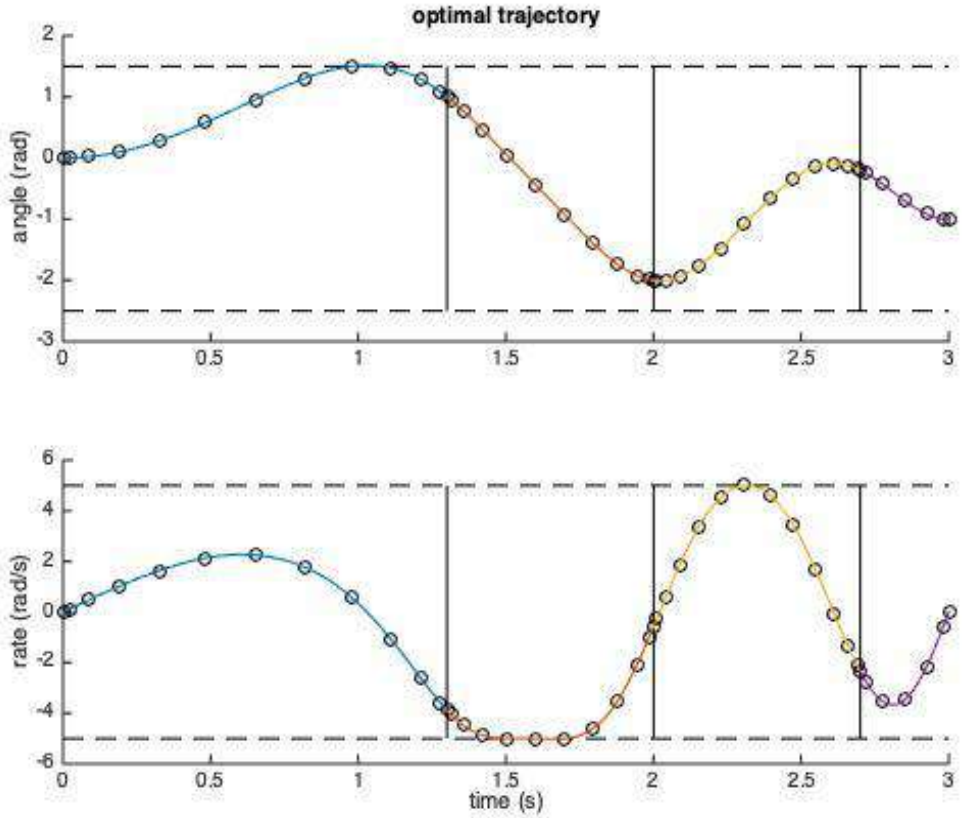

Figure 4. Results of multi-segment trajectory

In figure 4, we can clearly see, that the trajectory is passing by all the Chebyshev node points, where the initial an final velocity rated in rad/s is zero and the angle of the final trajectory is almost negligible.

By applying the same concept to the both sections of the manipulator, with specific boundaries and input trajectory, we can see that the arm end-effector holding the bald is travelling smoothly, on the doted lines, shown in Figure 5, taking into consideration for joint 1 and 2, the initial velocity is zero (starting point of lifting task), and the resultant final velocity of the end-effector is also zero rad/s, which corresponds to discharge of the manipulator after laying task.

4 Conclusion

This paper presented an operational simulation of dispersed cyber-physical system performing a lifting and disposing pergola blades on certain rooftop of a building. The system consisted of UAV, the task of which is to analyze the surrounding and generate an optimal trajectory to a robotic manipulator (crane) considered as a Chebyshev orthogonal collocation points based on optical odometry. The task was formulated as a quadratic programming problem. The obtained results endorsed the theoretical approach and showed that both the joints of the lifting crane have followed the optimal trajectory, passing by all Chebyshev points with minimum jerk considering that the initial velocity of the joints is zero and the final velocity should be obtained zero rad/s with minimum to zero overshooting angles.

Abstract -

Microbial corrosion of concrete is a severe problem that significantly reduces the service life of underground sewers in countries around the globe. Therefore, water utilities are actively looking for in-situ sensors that can quantify the biologically induced concrete corrosion levels, in order to carry out preventive maintenance before any catastrophic failures. As a solution, this paper introduces a drill-resistance based sensor that can accurately measure the depth of the microbiologically corroded concrete layer. A prototype sensor was developed and evaluated in laboratory test conditions. The lab experiments proved that the developed sensor has the ability to measure the depth of the microbiologically corroded concrete with millimeter level of accuracy. Additionally, the sensor can also locate and accurately measure the size of concrete aggregates as well as potential cracks, effectively creating a sub-surface 'scan' of the concrete at the targeted point of interest. Therefore, providing valuable extra information for assessing the condition of the sewer concrete.

1 Introduction

Reinforced concrete sewers undergo significant microbiologically induced corrosion caused by sulphuric acid producing bacteria, particularly in countries with warm climate conditions. This sewer concrete corrosion leads to sewer pipe deterioration and consequential structural failures by incurring losses that are estimated to be in the order of billions of dollars per year worldwide.

Furthermore, microbial corrosion of concrete increases the likelihood of catastrophic structural failures that can cause not only detrimental damage/harm to urban-dense populations but also irreversible damage to the surrounding environment. The annual cost of corrosion for drinking water and sewer systems in the United States alone is about USD36 billion [1] including maintenance, rehabilitation, and replacement. In the United Kingdom, the total replacement cost of sewer mains was estimated to be 104 billion pounds [2] whilst in Germany, the rehabilitation cost for sewer concrete corrosion was estimated to be 100 million Euros [3]. In addition, the rehabilitation of sewer concrete pipes cost AUD40 million annually in Australia [4]. Therefore, sewer corrosion is a significant problem worldwide which needs to be identified promptly, so water utilities can intervene and carryout the the necessary maintenance before any catastrophic failure [5].

A key parameter that water utilities use for decision making in sewer infrastructure maintenance is the estimation of the Remaining Service Life (RSL) of the sewer pipe, which is often estimated by measuring the depth of the remaining intact concrete left to the reinforcement bars. RSL gives an estimation of how many years the sewer can be used without further rehabilitation. In general, sewer wall corrosion rates are very slow (could be less than a millimeter per year) and hence, depth of the microbiologically corroded concrete layer needs to measured precisely to accurately estimate the RSL. However, due to the non-homogeneous nature of concrete combined with the harsh conditions of a sewer pipeline, particularly with extremely high humidity and acidity, conventional sewer monitoring sensors are prone to malfunctions [6, 7], struggle to reliably and accurately measure the depth of the microbiologically corroded concrete in field conditions. The most conventional way for measuring the depth of the corroded concrete is done by taking core samples from the sewer walls, which is a time consuming process and expensive endeavour. Additionally, prolonged exposure to sewer environments poses serious occupational health and safety issues for the workers in the sewers [8]. Hence, wastewater managing utilities are looking for innovative sensing technologies which can assess the level of the microbial induced corrosion of concrete accurately and quickly so the required maintenance can be carried out promptly.

Over the years, there have been remarkable strides in developing drill-technology capable of operating in challenging conditions. Drills are often perceived to be destructive tools, yet we often overlook that there are many precise and delicate micro-invasive applications for drills, such as in brain surgery or orthopaedic repair.

Drill-resistance based measuring methods are a useful sensing option for differentiating non-homogeneities in a given material as the mechanical drilling component guarantees penetration through the material. Unfortunately, due to the misconceived destructive nature associated with drills, this sensing approach has not been so widely adopted in the past. However, the unique ability to accurately characterize many materials at various given depths (i.e. whether the material at a certain unit of depth is hard or soft) below the surface in real-time makes drill-resistance based measuring an excellent candidate for developing a sensor technology that can accurately measure the depths of corrosion in concrete for both human operator and autonomous robotic applications.

Previously, drill-resistance based sensors have been developed for sampling the ring-growth pattern in tree-trunks [9, 10, 11], which was later evolved into using the sensing approach to measure decay in trees - substituting the use of X-ray as result of several advantages such as simplicity, portability, and accessibility in comparison. Later on, drill-resistance based sensing was adapted for assessing the strength of fire-damaged concrete [12, 13] yet it was not until early this decade drill-resistance based sensing was developed for measuring the decay in natural stone and marble as part of conservation projects of irreplaceable cultural heritage monuments and buildings [14]. Whereas this paper will go into the design and development of a prototype, which is the first of its kind to demonstrate accurate depth of the boundary layer between corroded and intact concrete, even with the presence of hard aggregates within the relatively soft corroded layer. The sensor can provide a scan of any corroded concrete target area in real-time without any need for calibration or advanced/heavy post-processing.

2 Background

2.1 Concrete Corrosion

Figure 1 shows the microbiologically induced corrosion process inside sewer system. Sulphate-producing bacteria that reside in sewage produce dissolved H_2S in wastewater under anaerobic conditions. This dissolved H_2S is released as a gas phase due to turbulence in the wastewater as it flows down the pipeline. In general, surface pH of newly installed sewer concrete pipes ranges approximately between 12-13. When the pH value falls to 9, the bacteria begin to colonize on the concrete surface [16]. The chemoautotrophic bacterium that exists on the sewer concrete surface oxidizes the gas phase H_2S into biogenic sulphuric acid H_2SO_4, which reacts with the cementitious material of concrete leading to concrete corrosion [17, 18]. The corrosion process transforms the effected concrete into calcium sulfide, commonly known as gypsum - a soft brittle material whose presence introduces focused areas of strength loss in a structure. In addition, gypsum is moderately water soluble - the combination of a soft brittle gypsum under structural load in a highly humid environment makes the gypsum layer prone to breaking off with the subsequent material loss in the pipeline structure, leading to structural failure if left untreated.

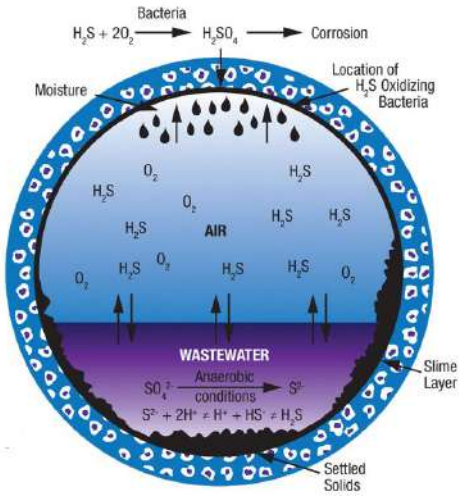

Figure 1. Sewer Corrosion Process [15].

2.2 Conventional NDT Sensing Modalities

Conventional Non-Destructive Testing (NDT) sensing systems like Ground-Penetrating-Radar (GPR) and ultrasound sensors are widely used for detecting concrete defects like delamination in concrete civil infrastructure. Therefore, these sensors have the potential for detecting the depth of the boundary layer between the microbiologically corroded concrete and intact concrete. However, use of these sensors for detecting microbiologically corroded concrete in sewer environment is challenging. The GPR signal measurements can be potentially affected by the moisture conditions of the exposed sewer surface [19], and the ultrasound techniques need sound coupling with the sewer wall [20], making it practically challenging to use on uneven rough surfaces of the sewer pipes. Besides direct measurements, predictive models have been developed for estimating the corrosion throughout the sewer network. Quality of such model prediction rely on the data supplies by the sensors [21, 22, 23, 24].

2.3 Drill-Resistance Sensing

Drill-resistance is an unconventional sensing approach in the sense that it is an integration of multiple sensors functioning in parallel but also that the main principles of drill-resistance based measurements are based on mechan-

ical principles rather than physical phenomena. There is a direct correlation between the reaction force exerted on the drill-bit and drill-bit penetration per drill-bit revolution [25]. Therefore, the penetration rate of the drill (Δd_p) and the drill speed (ω_d) must be kept constant in order for the reaction force per ongoing depth measurement to show an accurate and valid representation of the material being drilled. Assuming those parameters are kept constant, the hard material will exert a higher reaction force on the drill-bit compared to a softer material as more energy is required for penetrating into the harder material per unit distance per drill-bit revolution.

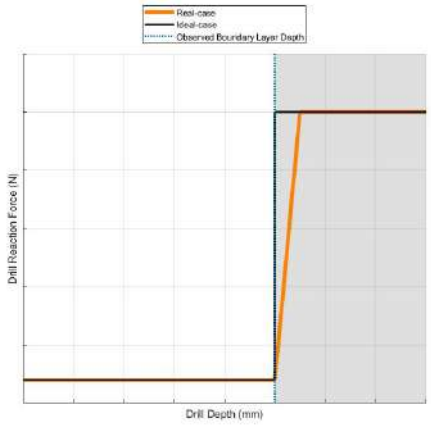

Figure 2. Boundary layer identification between two different materials based on force-depth readings: The point where there is a significant change in force-depth gradient signifies a different material at that corresponding drill-depth.

Figure 2 shows a simplified example of the measured thrust (reaction) force acting through the drill-bit per increment in drill depth whilst drilling through two different material layers. The depth where there is significant change in the force-depth gradient signifies a different material at that depth. Maximising the drill-bit penetration per drill-bit revolution (or $\Delta d_p : \omega_d$ ratio) will cause the force-depth readings to become closer to the ideal case (i.e. creates a sharper force-depth gradient) - making significant points of inflection, and therefore, boundary layers easier to identify. Consequently, doing so can increase wear on the drill-bit and reduce its effectiveness to cut through material [26]. In addition, it can also increase the likelihood of exceeding the load capacity rating of any force-measurement sensors embedded in the drill assembly. Alternatively, reducing the $\Delta d_p : \omega_d$ ratio scales down the reaction forces acting on the drill as the drill-bit is removing material significantly faster than it is penetrating material - consequently reducing the sensitivity to changes in force due to changes in material, leading to losses in accuracy as well as operation time due to the subsequently slower penetration rate.

3 Drill-Resistance Prototype Development

In this design iteration, a stand-alone drill-resistance prototype was developed with a modular design to carry out a vast array of tests with controlled concrete lab samples. This prototype is capable of drilling depths up to 120mm without any need for physical interaction/bracing from a human or robotic operator. This decision was made to ensure result validity and repeatability of measurements under various test cases. Figure 3 shows the overall breakdown of the prototype, which consists of an off-the-shelf cordless drill that was reverse-engineered into a custom 3D-printed housing - allowing the drill to be fitted with a load-cell for thrust force measurements, and an independently driven lead-screw for controlling the penetration rate.

The prototype works by using the lead-screw to push the drive plate at a constant rate which in turn achieves a constant penetration rate for the drill assembly into the concrete. As a result, the reaction force along the drill axis is transfered along the drill assembly, allowing this force to be measured by the load-cell sub-assembly. Simultaneously, the linear position of the drill assembly along the drill axis is measured using a linear potentiometer - thus allowing a measured drill-reaction-force to be linked to its corresponding drill depth at its given instance in time. Therefore, allowing the ongoing force-depth readings to be acquired as the drill penetrates the concrete - showing the changes in material and building a subsurface 'scan' of the targeted corroded concrete area in real-time as demonstrated in Figure 4.

4 Methodology

This paper focuses on tests with controlled concrete lab-samples with gypsum layers with and without aggregates as shown in Figure 5. A fixed high-speed drill setting (1200 rpm) is used to maintain a low penetration rate to drill speed ratio whilst using a 5mm diameter tungsten-carbide masonry drill-bit. In addition, no hammer drilling was used in the reported experiments in order to see if it is possible to acquire accurate results without the risk of propagating micro-stress cracks [27].

The first main experiment uses the concrete lab-sample with a 20 (±1)mm layer of gypsum without any aggregates on top of a 30mm layer of intact concrete. The Drill-Resistance prototype is placed on top of the target sample and the depth where the drill-bit meets the surface of the lab sample is recorded for reference. For example, the drill is measured to have moved 42mm from its starting

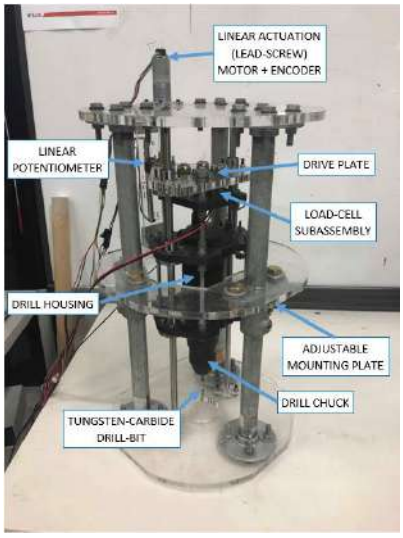

Figure 3. Drill-resistance system prototype design.

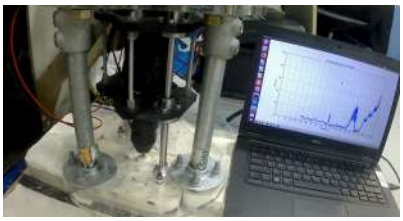

Figure 4. Drill-Resistance real-Time force-depth readings of a concrete lab sample with the presence of aggregates.

Algorithm 1 Boundary Layer Depth algorithm

$i = 2$ ▷ Start index at 2nd data point to ensure a (i-1) and (i+1) data point
$d_m = \infty$ ▷ Set large initial value for measured depth
while $i \leq (n-1)$ **do** ▷ where n is the sample size
  $F\dot{D}(i) = (F(i+1) - F(i-1))/(2\Delta d)$ ▷ calculate gradient
  $F\ddot{D}(i) = (F(i+1) - 2F(i) + F(i-1))/(\Delta d^2)$
  if $F\dot{D}(i) \geq \alpha \wedge F\ddot{D}(i) \geq \beta$ **then** ▷ significant increase check
    if $d(i) < d_m$ **then**
      $d_m = d(i)$ ▷ Records first depth of significant force increase
$D_B = d_m - d_s$ ▷ Boundary layer depth w.r.t surface

position (i.e. drill depth = 0mm) when the drill-bit comes into contact with the surface of the concrete. The drill is then reset back into its starting position before engaging both the drill and linear actuating motors to drill into the concrete sample and observe the force-depth readings in a controlled manner. The drill is retracted once the force-depth real-time plot shows there has been an increase and then plateau, signifying the hard intact concrete layer has been reached and slightly penetrated. This experiment was designed to investigate the Drill-Resistance prototype's ability to accurately distinguish the boundary layer between a homogeneous soft gypsum and hard concrete depth from the surface. In addition, this experiments tests an algorithm that was developed for autonomously measuring the depth of the boundary layer between a homogeneous gypsum layer and intact concrete. The pseudocode for autonomous boundary layer depth measurement of no-aggregate gypsum is given in Algorithm 1.

The second experiment is a repeat of the first experiment except the concrete lab-sample has a 30 (±1)mm gypsum layer with 10mm aggregates present to investigate the Drill-Resistance prototype's ability to accurately distinguish the boundary layer with hard obstructive material present, similar to those in corroded layers of concrete. Finally, the third experiment is a variant of the second by adjusting certain lengths in the prototype (such as the adjustable mounting plate - refer to Figure 3) - causing reference lengths to change, thereby altering the surface relative to the drill depth. For instance, initially the drill came into contact with the surface at 42mm relative to the starting position of the drill - the linear potentiometer mounting position is shifted 10mm along the drill axis and away from the concrete surface - now the surface relative to the drill depth becomes 52mm. This experiment was added to see if the surface could be detected by only allowing the linear actuator motor to run, such that when the static drill-bit meets the surface, a sudden force spike would be registered at the corresponding depth. This information could then be used as a marker for identifying the surface relative to the drill depth within the force-depth readings rather than recording this reference value separately before drilling. If successful, this allows all relevant information to be contained in one data set (i.e. the force-depth readings) for easier interpretation of results. Thus, streamlining the operation for users measuring the depth of the boundary layer relative to the surface of the material being drilled.

5 Experimental Results

5.1 Drilling Without Aggregates

Initial assessment of Drill-Resistance prototype readings through the no aggregate gypsum layer concrete lab sample shows remarkable accuracy in measuring the depth of the boundary layer between the gypsum and concrete layer (see Figure 6). The surface relative to the drill depth was measured at 59mm, therefore with a 20mm gypsum layer, the drill depth of the boundary layer of the lab sample would be expected at 79mm. The point at which the force-depth readings exhibit a significant increase can be observed at a drill depth of 78mm, which would result in a measured boundary layer depth of 19mm from the surface with an error of -1mm.

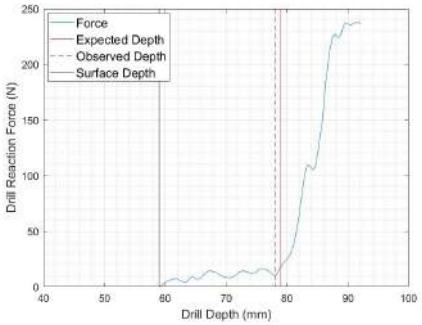

Figure 6. Drill-Resistance prototype force-depth readings of concrete with 20mm gypsum layer with no aggregates present: Increase and plateau in force can be observed to begin at 78mm drill depth, indicating the boundary layer - the surface was recorded at 59mm drill depth resulting in a measured gypsum layer depth of 78 - 59 = 19mm from the surface.

Figure 7 shows the developed Boundary Layer Depth algorithm being applied to the 'No-aggregate gypsum' experimental results from Figure 6. The calculated boundary layer depth of 19.45mm (+0.55mm error from the expected 20mm depth) is more precise than the observed depth of 19mm, thereby demonstrating a proof-of-concept towards autonomously measuring the boundary layer depth correctly and accurately.

5.2 Drilling With Aggregates

Experimental results of the Drill-Resistance prototype through a 30mm gypsum layer with 10mm aggregates consistently reveal the depth of the boundary layer between the gypsum and concrete layer. The surface relative to the drill depth was measured at 58mm, therefore with a 30mm gypsum layer, the drill depth of the boundary layer of the lab sample would be expected at 88mm. The Drill-Resistance prototype force-depth readings shown in Figure 8 detects

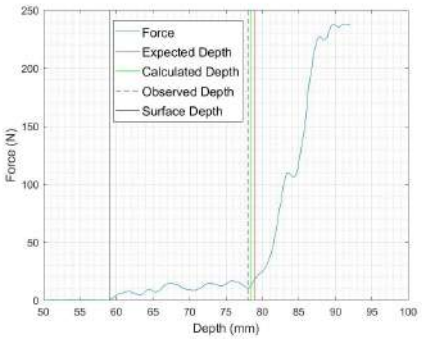

Figure 7. Boundary Layer Depth algorithm applied to the 'No-aggregate gypsum' lab sample data. The resulting calculated boundary layer depth was 19.45mm from the surface compared to an observed depth of 19mm

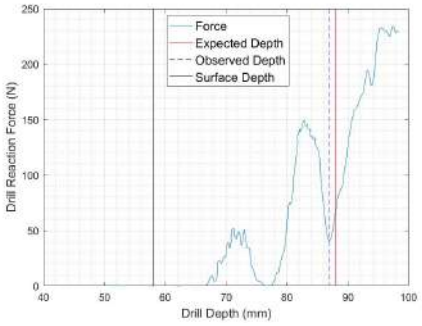

Figure 8. Drill-Resistance prototype force-depth readings of concrete with 30mm gypsum layer with 10mm aggregates present - boundary layer observed at 87mm despite going through two aggregates at 66-76mm and 78-88mm. The surface was recorded at 58mm drill depth, resulting in a measured gypsum layer depth of 87 - 58 = 29mm from the surface.

an aggregate via the force increase at 66mm and 78mm drill depth and respective force decrease at 76mm and 88mm (thus validating 10mm aggregate sizes). A larger force is observed to begin and plateau at 87mm which indicates the concrete layer has been reached, indicating a boundary layer depth of 29mm from the surface resulting in -1mm error.

Another Drill-Resistance prototype measurement was taken from where an aggregate was visible to the surface on the same concrete lab sample, where such a harder material on the surface would reflect most ultrasound or GPR signals before reaching the gypsum itself, let alone the boundary layer. Before this sample was taken, a replacement drill-bit that was 3mm shorter was installed, resulting in a change in the measured surface relative to drill depth to become 55mm. Figure 9 shows reaction

force on the drill rise and fall at 55mm (surface) and 64mm drill depth respectively. The low forces observed between drill depths 64mm and 85mm signifies the soft gypsum material. The sharp force increase observed at 85mm signifies the boundary layer was reached, which matches the expected boundary layer drill depth, measuring a 30mm boundary layer depth from the surface.

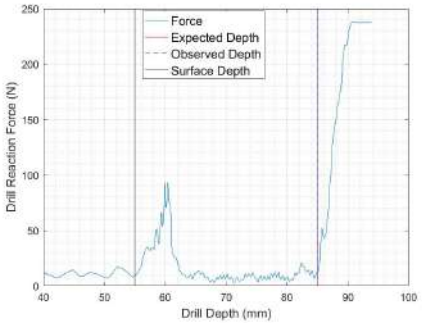

Figure 9. Drill-Resistance prototype force-depth readings of concrete with 30mm gypsum layer with 10mm aggregates present - boundary layer detected at 85mm despite an aggregate (55-64mm) at the surface (55mm) - resulting in a measured gypsum layer depth of 85 - 55 = 30mm from the surface.

5.3 Surface Detection

Figure 10 and Figure 11 demonstrate the Drill-Resistance prototype can also be used to detect the surface relative to the drill depth as in Figure 10, which shows the surface to be detected at drill depth 53mm, resulting in an expected boundary layer drill depth of 83mm. A 10mm aggregate is detected at 71mm drill depth as seen by the increase in drill reaction force which then subsides at 81mm drill depth, followed by a larger increase in force observed starting at 84mm drill depth, resulting in a measured boundary layer depth of 31mm from the surface (+1mm error). Similarly, Figure 11 records a surface detection at 51mm, prompting an expected boundary layer depth of 81mm for the given 30mm gypsum layer. A 10mm aggregate can be observed between 69mm and 79mm drill depth followed by a force increase and plateau at 81.5mm, resulting in a measured boundary layer depth of 30.5mm from the surface (+0.5mm error).

6 Discussion

All the experiments were conducted within the iPipes Lab facility. Gypsum layered samples were fabricated as an alternative to the real corroded layer [28] for the preliminary sensor evaluation. The gypsum layer brittleness is similar to corroded concrete. After assessing

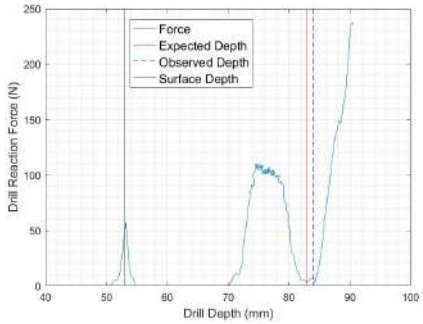

Figure 10. Drill-Resistance prototype force-depth readings of concrete with 30mm gypsum layer with 10mm aggregates present - surface (53mm), aggregate (71-81mm) and boundary layer (84mm) all mapped in this one data set. The measured boundary layer is 84 - 53 = 31mm from the surface.

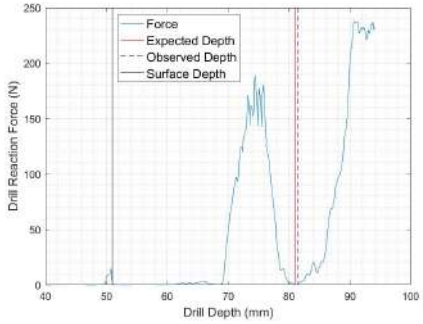

Figure 11. Drill-Resistance prototype force-depth readings of concrete with 30mm gypsum layer with 10mm aggregates present - surface (51mm), aggregate (69-79mm) and boundary layer (81.5mm) all mapped in this one data set. The measured boundary layer is 81.5 - 51 = 30.5mm from the surface.

all experimental results, the maximum deviation in observed/measured boundary layer depth from the expected boundary layer depth was 1mm regardless if aggregates were/were not present in the gypsum layer of the concrete lab sample being analysed. We must disclose that during the final experiment with regards to surface detection, there were observed instances of mechanical compliance along the drill axis (i.e. the drill could slightly move freely along its axis) because of frequent ongoing tests. This behaviour can be observed in the beginning of Figure 10 and Figure 11 where although the drill was in contact with the surface, there was slack in the mechanism that would allow the drive plate (and therefore linear potentiometer) to still move a few more millimeters – resulting in a 'wind up' of force across a small distance. Hence, the true surface relative to drill depth is when the force

asymptotically increases with no increase in drill depth. In addition, allowing the drill mechanism to wind-up the reaction force at the surface removes the mechanical compliance whilst drilling into the concrete, thereby eliminating the error in the force-depth readings as a result of mechanical error. We must also highlight that the concrete lab sample fabrication/curing process has a ±1mm tolerance when pouring/layering the concrete and gypsum into the mould. Hence a 20mm or 30mm gypsum layer could range between 19-21mm and 29-31mm respectively. Therefore, the maximum error in results of 1mm reflects exactly this sizing tolerance of the depth/thickness of the gypsum layer (boundary layer depth), making the force-depth readings an entirely valid pin-point subterranean 'scan' of a gypsum-concrete section – with the potential for sub-millimetre accuracy.

The results from the first experiment, shown in Figure 6 demonstrate the Drill-Resistance prototype can accurately measure the depth of a boundary layer between a soft homogeneous material and hard non-homogeneous material respectively from the surface with millimetre accuracy compared to NDT sensors such as ultrasound or GPR. However, in the case of the second experiment, the presence of large aggregates either obstructs conventional NDT sensors from detecting boundary layers or inhibits their ability to do so accurately and reliably. Whereas the Drill-Resistance prototype can penetrate through these large, hard aggregates – providing force-depth readings like the ones shown in Figure 8 and Figure 9 that provide a complete/detailed 'scan' of the gypsum layer; not only revealing the boundary layer depth between gypsum and concrete within 0-1mm error but also revealing/validating the depth and thickness of the aggregates themselves. Furthermore, not having the drill running before coming into contact with the surface in the final experiment shows the Drill-Resistance prototype can also detect the surface relative to itself – making it an entirely self-sufficient sensor with no need for reference/calibration values such as material density or signal velocity or in this case, surface depth relative to drill depth, to be known prior to using the sensor to find and measure the boundary layer depth. The Drill-Resistance prototype can be placed over any point and drill accordingly to provide an accurate real-time force-depth 'scan' of the subsurface.

7 Conclusion and Future Work

This paper introduced a novel drill-resistance based sensor for detecting the depth of the concrete affected by microbial corrosion. According to our knowledge, this is the first instant that such a sensor was developed and verified. Several lab experiments were carried out to validate the sensor measurements on carefully prepared lab samples. The lab experiments revealed the developed drill-resistance sensor is capable of measuring the corroded concrete depths with mm accuracy. In addition, the sensor has the ability to accurately identify aggregate location which could be useful in evaluating concrete structures.

In the future, the developed prototype can be miniaturized based on the requirements of the sewer operators and lab testing will be done on the corroded samples obtained from the Sydney based sewer.

Abstract –

Construction monitoring plays a vital role in modular construction practice, since faulty installation of individual parts could incur significant delays and extra cost to the project, modular construction eagerly requires a real time progress monitoring. Previous researchers tended to get as-built site data back at first, like making cloud points model or taking photos, and then use it to compare with as-designed BIM model. Such an approach cannot find any potential problem before it happens and will still bring unexpected economic loss and schedule delay. In converse thinking, this paper developed a real time 4D AR system for modular construction progress monitoring, which uses the as-designed AR model to compare with the as-built site, in which a markerless AR registration method is established to link the 4D BIM data with the as-built ones directly. In addition, mock up components are used as a scale model to validate the system. The result indicated that, the system can facilitate users to avoid possible errors by giving helpful assembly sequence monitoring and powerful tool for schedule control.

Construction progress monitoring; Modular construction; 4D BIM; Augmented reality

1 Introduction

Construction progress monitoring has been regarded as a critical successful factor in a construction project. Timely construction progress monitoring brings efficacious manner and helpful decision-making to management team members such as construction manager and on-site supervisors. In a modular construction project, every unit gets its own assembly sequence and position, any wrong assembly would definitely bring project delay and extra cost for rework. Thus, compared with onsite project, real-time construction progress monitoring between as-planned and as-built progress is much more important to modular construction.

1.1 BIM in Construction Progress Monitoring

Building Information Modelling (BIM) can be expected to help the management team in a modular construction project to make decision for assembly sequence simulation and work plan control before constructing. It has been proved that 4D BIM (3 dimensions digital model with timeline) gives effective support for construction scheduling and site monitoring by updating onsite data and comparing with 4D BIM models (Hamledar et al., 2017). Another method via using 4D BIM in concert with 3D data obtained by remote-sensing technology was proposed, in which continuous scanned data are obtained and compared with BIM model, but it assumed that there is no deviation from original construction plan (Kim et al., 2013). Partial point cloud device equipped in construction workers' protection helmets was also used for continuous construction progress monitoring, and the device can get as-built 4D BIM model which can be compared with 4D as-designed BIM model to check current progress status, but it needs workers to go through project site to collect data, and it is possible to miss cloud point data of some corners (Zoran et al., 2018). Also photos taken by UAV can be used to make cloud points model for progress monitoring, comparison between as-built and as-planned is visualized via using a corresponding point cloud and source image with re-projected geometry (Braun et al., 2018).

1.2 AR in Construction Progress Monitoring

On the other hand, Augmented Reality (AR), which adds computer generated objects into real world images, links 4D BIM data with real construction site and bring systemic and comprehensive progress monitoring and control (Lee et al., 2006). 4D progress simulation could

be overlaid on time-lapsed photographs via AR, such augmented photographs with 4D AR (AR contents show future work overlay on 3D objects in real world) simulation could compare discrepancies between the as-planned model and the as-built model in a consistent platform. However, the comparison was static and could not give real-time response. (Golparvar-Fard et al., 2009). In addition, augmented reality combined with 4D BIM could be used for automated operation-level construction progress monitoring, where onsite workers take daily photos and built 4D AR model which can detect materials to infer the actual state of progress. Nevertheless, this method needs taking many photos to build 3D point cloud model (Kevin et al., 2014). Further, a framework for cloud-based augmented reality using real time information for construction progress monitoring was proposed, which creates an automated real-time bidirectional flow between construction site and planning office, but it still need passive data acquisition at the first step (Soman et al., 2017).

1.3 Limitations in Previous Research

Previous researches by using BIM method or AR method do improve construction progress monitoring and schedule control, but they tend to get the as-built data from construction site as first step and then compared with as-designed 4D BIM. Thus, management team members only find discrepancy after it happened. Such lagging method cannot be used for finding potential problems and conducting real time construction site monitoring. In addition, construction workers still have to spend long time on data acquisition like photo taking or spend high cost for laser scanning device. There is a totally different situation for modular construction. Modular construction, in which all units are produced in manufacturing factory then assembled on construction site in a planned sequence, and have shorter schedule than onsite construction in similar volume. Moreover, any wrong assembly will definitely cause schedule delay and extra cost for rework. So real-time progress monitoring system avoiding wrong assembly before error happens is required by modular construction.

In order to improve modular construction progress monitoring and solve problems mentioned above, this study aims to develop a prototype by integrating real time AR and 4D BIM. To achieve our research goal, we focus on three questions: how to link 4D BIM with construction site directly via AR content, how to check modular components assembled in correct position and unit, and how to ensure modular components assembled in right sequence and date. In following text, workflow of this system and AR registration method will be introduced at first. Next we demonstrate what functions this system has and how it works step by step for progress monitoring. Finally we give discussion and conclusion about our system.

2 Method

2.1 Workflow

The as-designed 4D BIM data of modular components contains: 1) 3D information such as shape, size and floor; 2) 4D information like sequence and date. Firstly all the 4D BIM information related to construction progress monitoring is imported into this real-time 4D AR system via screen display, 3D BIM information is transferred into such AR registration part, which refers to the alignment of spatial properties (Schmalstieg et al., 2016). Meanwhile 4D BIM information is be restored into AR database for progress monitoring. Afterwards target position at as-built construction site will be located according to AR registration method, so construction management team is able to use displayed 4D AR content to compare as-built status in real world. The workflow of the 4D AR progress monitoring system for modular construction is shown in Figure 1.

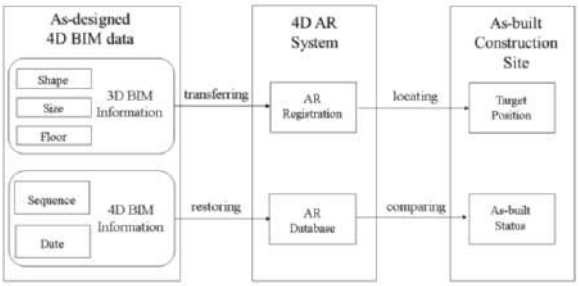

Figure 1. Workflow of 4D AR construction progress monitoring system

2.2 AR Registration Method

Fiducial makers are usually used for AR representation, however there are many limitations of marker-based AR on construction site, e.g. AR representation is easily failed by partial occlusion (João et al., 2018). Compared to marker-based AR, markerless AR method, in which any part of the real environment can be tracked in order to place virtual objects, is suggested for construction engineering (João et al., 2018). Even markerless AR methods can support construction process, currently major types of common markerless AR representation rely on features recognition (Teichrieb et al., 2007). As progress goes on, features for AR registration are always changed because site scenes keep changing, which means common markerless AR methods cannot show AR content

seamlessly and there are still limitations for AR uses on construction sites. In those cases construction progress monitoring is still hysteretic and unexpected loss may still exist.

To give real time monitoring, construction site, 4D BIM and AR content should be linked with each other. In the described concept we use another markerless AR registration method related to relative coordinate system between objects and camera. There are two concepts in BIM model: 1) Project Base Point, which defines the origin (0, 0, 0) of the project coordinate system and becomes reference point for measurements across the site; and 2) Survey Point, which identifies a real-world location near the model and defines the origin of the survey coordinate system to provide a real-world context for the model. We coincide Project Base Point and Survey Point in a same origin and build up the World Coordinate System which is related to real-world objects, then every point of a modular unit gets its own coordinate. If there is a real fixed monocular camera facing to objects in real world, then every point of this camera will also get its own coordinate. Such fixed camera could be put on crane mast, which is helpful to determine its position and simulate in BIM model. We make this real camera into a simplified computation model named Pinhole Camera Model in computer vision area and choose camera's optical center as origin to build a new coordinate system, which is called Camera Space in computer vision area. Because there is no object deformation between the two coordinate systems, we can transfer every unit's coordinate in World Coordinate System to Camera Space by rigid transformation. Through this method, AR content representation is registered by relative coordinate to camera space instead of any marker or feature, so that AR content can be linked with real construction site directly. Even there are people, machines or scaffolding in the camera image, AR content will not be affected. Fig.2 shows relationship between these two coordinate systems, a rotation matrix R and an offset vector $\vec{T}$ makes object transfer coordinate systems, and AR content of objects was shown by Camera Space.

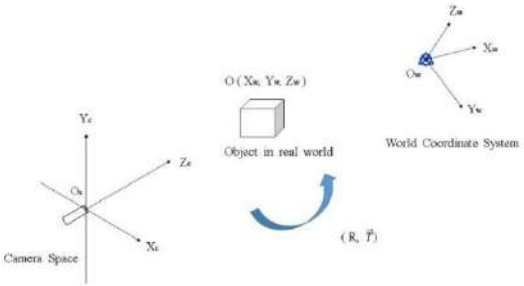

Figure 2. Relationship between world coordinate system to camera space

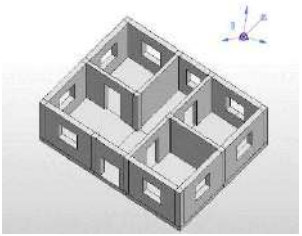
The equation for coordinate system transformation is shown in Eq.1. (X_c, Y_c, Z_c) means object's coordinates in Camera Space, (X_w, Y_w, Z_w) means object's coordinate in World Coordinate System. R means rotation matrix and $\vec{T}$ means offset vector. By using this transformation method, there is no change of objects' shape and size, objects shown in screen will reflect actual views in real world.

$$\begin{bmatrix} X_c \\ Y_c \\ Z_c \\ 1 \end{bmatrix} = \begin{bmatrix} \boldsymbol{R} & \boldsymbol{T} \\ 0^T & 1 \end{bmatrix} \begin{bmatrix} X_w \\ Y_w \\ Z_w \\ 1 \end{bmatrix} \quad (1)$$

3 System Development

To verify the method mentioned above, we developed a prototype system. This progress monitoring system, developed for construction project management team, represents AR content at beginning and use as-designed AR content to compare with as-built site status in real time. The system developed 3 function modules: 1) 4D Date Module, this module restores date information of 4D BIM, users can choose and see finished work and planned work in different dates through AR; 2) 3D BIM Module, in this module 3D BIM information like shape, size, etc. is transferred into AR content, we use 3D AR overlay as target position which is ensured by such AR registration method, then modular units will be moved and matched with AR overlay; and 3) 4D Sequence Module, in this module we release 4D assembly sequence via 4D AR animation, it gives both progress monitoring and navigation to construction area. In next part we will express details about how to use these function modules step by step. BIM software Revit and game engine Unity3D is used for AR prototype system development. A modular BIM model and mock up components are used for demonstration, shown in Figure 3.

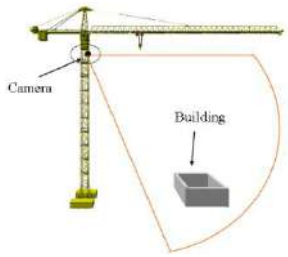


(1) BIM model with World Coordinate System

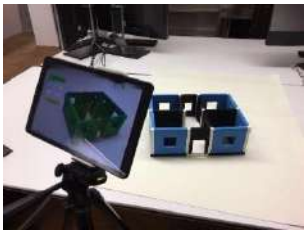
(2) Mock up components

Figure 3. BIM model and mock up model

To simulate real construction situation, we used a tripod as crane mast and an Android pad as fixed camera and monitoring screen. Such prototype is shown in Figure 4.



(1) Fixed camera on crane mast



(2) Simulation by tripod and Android pad

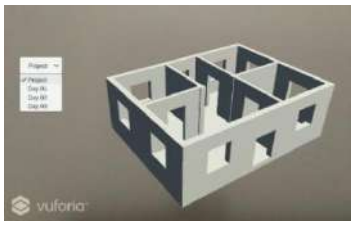
Figure 4. Prototype of this AR system

4 Case Study Based on a Mock Up

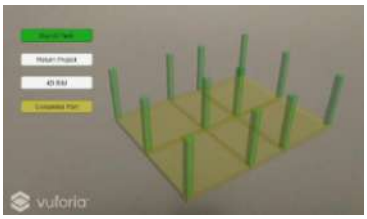
To show how this prototype works, we use a case study based on a mock up here. The mock up, consists of several components like floorslabs, walls and columns in one floor, is used as a modular construction project. Then we use an Android pad fixed on a tripod to simulate camera on crane. This system works on assembly process, users just need fix the camera and click some AR buttons. By using this system, users can check whether every unit is assembled in right position, sequence and date. There are three main steps to use it: (1) Date Selection; (2) Real Objects Match; and (3) 4D AR Animation. In following text we will give details about how to use our system step by step.

4.1 Step 1: Date Selection

The first step is choosing date in 4D Date Module. After starting our system, users can choose date to represent AR content of date information via a dropdown menu. On such AR user interface, *Project Button* in initial scene shows the final construction project status and different construction dates. Day Task scene (*Day 01, Day 02, Day 03 Buttons*) shows finished work in previous days via yellow overlay and intraday work via green overlay. Click *Return Project Button* will leave current date scene and come back to initial project scene, which helps users check AR data between different dates. In the presented case, initial start scene shows the completed status of modular BIM model in white opacity, Day 02 scene includes finished floorslabs in yellow overlay and planned columns in green overlay, shown in Figure 5.



(1) Project button and day task button



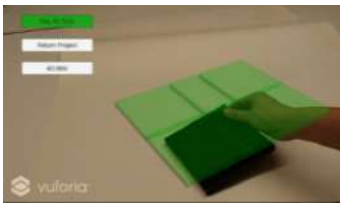
(2) Day 02 task scene

Figure 5. Different buttons and scenes

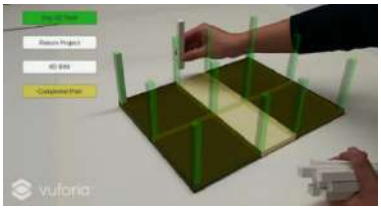
4.2 Step 2: Real Objects Match

Second step is to match real objects with green AR overlay. AR content is represented before components' match. There are 4 match scenarios in our system: 1) Match before construction, this scenario presents works of first day, in which there is only green overlay in this scenario because no component is assembled before construction; 2) Match with finished work and planned work, in this scenario finished work has been matched with yellow overlay, planned work will be matched with green overlay; 3) Match with intraday work, this scenario only shows intraday work via green overlay, which can give intuitive combination between real objects and planned work; 4) Match with completed project, in this scenario all the components have been assembled, green overlay is still existed because last modular component is moved to match with green

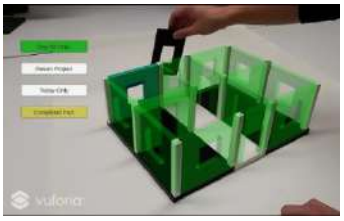
overlay. Every match scenario is related to 3D BIM Module. If a real modular component matches with green overlay perfectly in shape and size, such unit is assembled in right position. By this function, users can check whether a real modular unit is put on right position while it is close to assembly point. Besides if a real unit is deviated or missed from corresponding AR overlay, a construction error happened and users can adjust construction plan immediately. Different match scenarios are displayed in Figure 6.



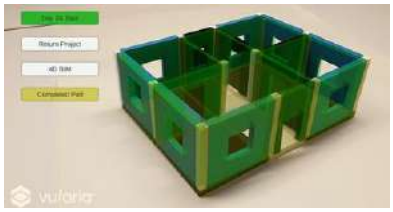
(1) Match before construction



(2) Match with finished work and planned work



(3) Match with intraday work



(4) Match with completed project

Figure 6. As-built objects match with as-designed AR content

4.3 Step 3: 4D AR Animation

In order to give real-time monitoring and navigation of intraday work, the last step to use our AR system is 4D AR animation. Another 4D BIM information, sequence, is also linked with real construction site directly through 4D Sequence Module, shown in Figure 7. *4D BIM Button* shows 4D live animation on its own date scene, in which previous work represented by yellow overlay is also displayed for comparison. Such animation shows assembly sequence extracted from construction schedule plan. By touching *Today Only Button*, AR monitoring system only represent 4D live animation on that date, which match with real world objects precisely and intuitively. Through this progress monitoring function, construction management team can check intraday assembly sequence conveniently. If a modular component follows assembly sequence in 4D AR animation, such unit is assembled in right sequence. By this function, users can check whether a modular unit is assembled in correct sequence while it is close to assembly point.

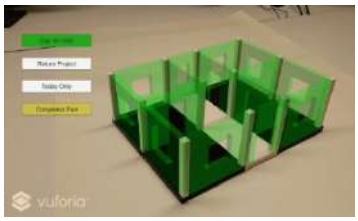
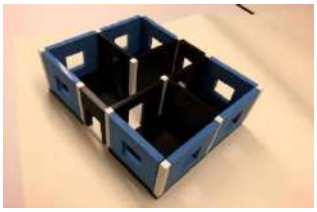
(2) Today Only animation



(3) Final 4D match



(4) Assembled modular components

Figure 7. 4D assembly sequence monitoring

5 Discussion and Conclusion

This paper proposed a real time 4D AR system for modular construction progress monitoring. Also we

introduced workflow of this system, AR registration method this system used, what function modules it has and how this system works step by step. By using a markerless AR registration method represented by relative coordinate and a fixed monocular camera, BIM 3D data like shape, size and floor can be linked with construction site directly. Objects in real world match precisely with AR content. Additionally 4D BIM information such as date and sequence can be restored in AR database and released as live animation, which can give helpful support to progress monitoring and work schedule check. This AR system, targeting at nature of modular construction, can help construction management team avoid potential schedule problems before construction work start. Besides this system make it easier for users to check whether every component is assembled in correct position and sequence. Construction management team will have better construction schedule control and decision making through our AR system, which can both save money and time for a modular construction project. In the future work, we will have a further development of real-time communication function between construction management team and crane operator to avoid wrong assembly of modular components.

Abstract –

This paper details the development of an open-source eye- and gaze-tracking mechanism designed for open, scalable, and decentralized Active and Assisted Living (AAL) ecosystems built on Wireless Sensor and Actuator Networks (WSANs). Said mechanism is deliberately conceived as yet another service-feature in an on-going implementation of an extended intelligent built-environment framework, one motivated and informed by both Information and Communication Technologies (ICTs) as well as by emerging Architecture, Engineering, and Construction (AEC) considerations. It is nevertheless designed as a compatible and subsumable service-feature for existing above-characterized AAL frameworks. The eye- and gaze-tracking mechanism enables the user (1) to engage (i.e., open, shut, slide, turn-on/-off, etc.) with a variety of actuable objects and systems deployed within an intelligent built-environment via sight-enabled identification, selection, and confirmation; and (2) to extract and display personal identity information from recognized familiar faces viewed by the user. The first feature is intended principally (although not exclusively) for users with limited mobility, with the intention to support independence with respect to the control of remotely actuable mechanisms within the built-environment. The second feature is intended to compensate for loss of memory and/or visual acuity associated principally (although not exclusively) with the natural aging process. As with previously developed service-features, the present mechanism intends to increase the quality of life of its user(s) in an affordable, intuitive, and highly intelligent manner.

1 Introduction

The eye- and gaze-tracking mechanism detailed in this paper is situated within the *Active and Assisted Living* / *Ambient Assisted Living* (AAL) discourse [1–4]. Its objective is to enable the user (1) to open, shut, slide actuable windows and doors as well as to turn lights on or off within an intelligent built-environment via sight-enabled identification, selection, and execution; and (2) to extract and display personal identity information from recognized familiar faces viewed by the user. Although this mechanism is designed to be compatible with existing AAL or AAL-pertinent ecosystems and frameworks (e.g., *CASAS* [5], *The Aware Home* [6], *PlaceLab* [7]; and more recently in the last three years: *eServices* [8], *REACH* [9], *WITS* [10], etc.), it is deliberately designed as a service-feature in an ongoing implementation of an intelligent built-environment framework inspired by what Oosterhuis has called a *Society of Home*, where users and their surrounding objects / systems communicate and thereby instantiate a home of *Internet of Things and People*; as well as a *Society of Building Components*, where the intelligent built-environment's objects / systems act, react, and interact computationally as well as physically [11] towards user well-being. In order to realize this *Society of Home*, emerging trends in *Architecture, Engineering, and Construction* (AEC) research laboratories in academia and industry—such us robotic fabrication, computational design and optimization, etc.—are considered in conjunction with *Information and Communication Technologies* (ICTs) as well as allied and resulting technical services that typically dominate the AAL discourse. This dual consideration, while adopted from the early stages of conception and design, ascertains mutual complementarity [12] between ICTs and AEC features where neither requires retrofitting from or to the other. In such an intelligent built-environment, both ICTs and AECs features serve to enhance—in conjunction—the user's quality of life.

The eye- and gaze-tracking mechanism's first objective / feature intends principally (although not exclusively) to assists users with limited mobility to control remotely actuable mechanisms within the built-environment. The second objective / feature intends to compensate for the user's loss of memory and/or visual acuity—with respect to recognition of familiar faces—associated principally (although not exclusively) with the natural aging process. That is to say, these two features serve as extensions of the user's physical and mental capabilities (with respect to the described contexts and scopes) in a way that enables the user to retain a degree of independence otherwise impossible without technical and technological assistance. This is in line with current trends where *Computer Vision* is integrated into assistive services and solutions (see, for example, [13]).

The present mechanism is deployed within an inherited *Wireless Sensor and Actuator Network* (WSAN) [14]. This WSAN's ecosystem is highly heterogenous in architecture, communication protocols, and network topology. Some of its nodes are embedded in the physical environment, while others are embedded in ambulant systems or in wearable devices. Capitalizing on the different levels of integration within the built-environment, all nodes work in conjunction to instantiate and to sustain a variety of intelligent service-features. Some service-features are strictly computational in character, while others involve computation and physical action, reaction, interaction as input or output; some are completely localized (i.e., dependent strictly and solely on the local network) while others are either hybrid (i.e., relying on services present both in the local network as well as in distributed cloud-based services) or based entirely on free cloud-based services via their corresponding *Application Program Interfaces* (APIs). The hardware of the eye- and gaze-tracking mechanism is embedded in a wearable device, which works together with architecture-embedded nodes and systems, as well as with a variety of communication protocols, to instantiate the above-mentioned features. In order to center on the discussed mechanism, the systems and subsystems implemented in the inherited WSAN are presupposed without delving into their description and functionality details.

This paper consists of four main sections. Section 2 details the *Concept and Approach*, where the system is described and the implementation scope is defined. Section 3 explains the *Methodology and Implementation*, where the software and hardware implementations are described and the sequence of operation is detailed. Finally, Section 4 presents the *Results* that validate the present *proof-of-concept* implementation and provides a discussion on limitations, further work, and conclusions.

2 Concept and Approach

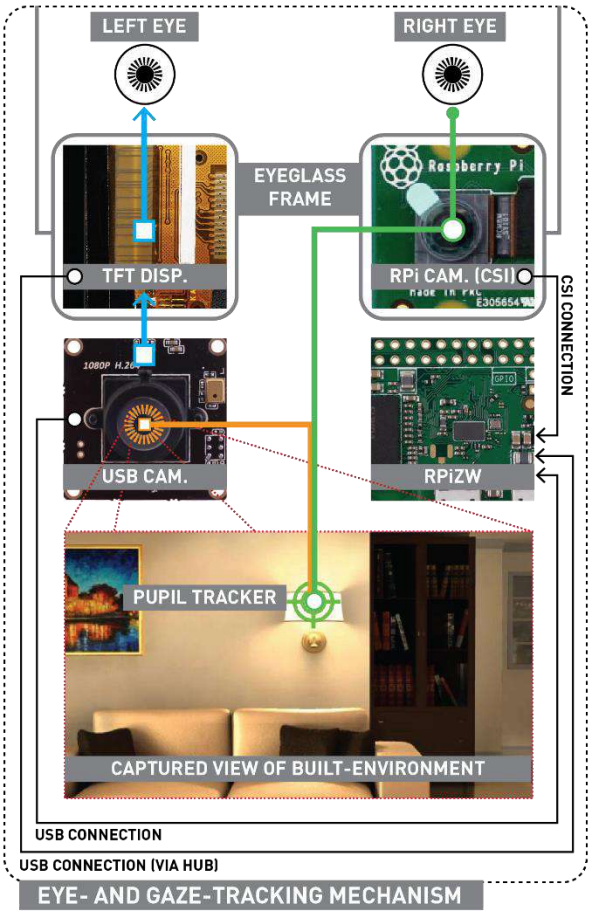

Figure 1. Concept and system architecture of the eye- and gaze-tracking mechanism

The eye- and gaze-tracking mechanism integrates the following hardware components into a generic eyeglass frame: a (i) Raspberry Pi Zero W (RPiZW); (ii) generic USB TFT Display; (iii) generic USB Camera (USBCam); (iv) and a CSI Raspberry Pi Camera v. 2.1. (RPiCam). The RPiCam is used to track the movement of the pupil corresponding to the right eye, while the USBCam captures the environment viewed and projects this scene back to the left eye via the TFT Display with a real-time update frequency. The position of the pupil is mapped on top of the captured scene, and gaze-tracking is enabled by analyzing the position of the pupil—and its movements—in relation with recognizable objects captured in the scene (see Figure 1). The following recognizable objects are presently defined: a (1) sofa, (2) wall-light, (3) window, (4) ceiling-light, (5) bookcase, (6) lamp, (7) wall-art, and (8) a dining table (see Figure 2, *Bottom*). This represents a generic sampling of objects contained in a given built-environment, where some actuate and others do not.

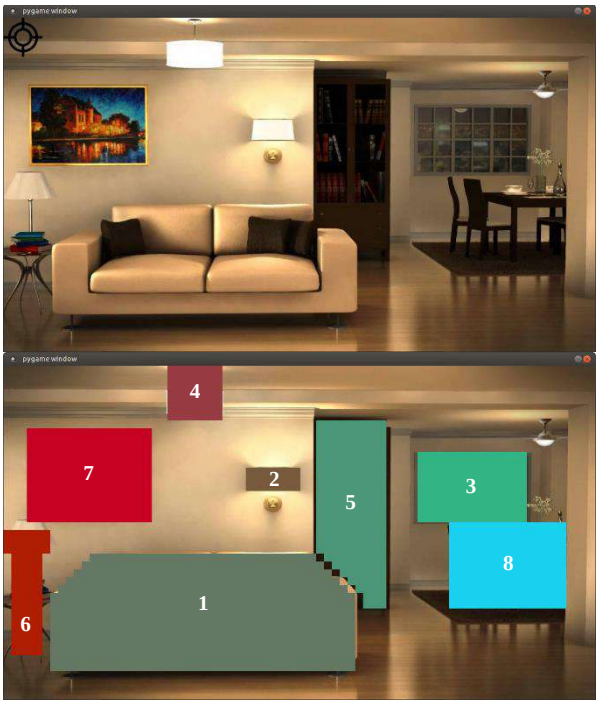

Figure 2. Top: Captured-gaze of generic sample built-environment. Bottom: Object-boundaries overlaid on top of objects represented. Both generated with PyGame.

In this implementation, the engagement with actuable objects and systems (e.g., doors, windows, lights, etc.) is limited to their generic virtual representation (see Figure 2, *Top*). That is, while previous implementations have required the building of physical representations in real-scale, the present development only requires confirmation of engagement at a software level to ascertain its functionality. Accordingly, a black-box approach is adopted with respect to the other subsystems of the inherited WSAN. In this manner, the present mechanism is said to actuate a window, a door; or to turn on/off a light, etc., if the user is detected to be engaging with a given object / system and the eye- and gaze-tracking mechanism does indeed respond by sending a signal to actuate or to turn on/off.

A caveat on the architecture / built-environment used as the captured scenes in this implementation: the type of architecture displayed intends to represent an average contemporary built-environment. As such, it is meant as a neutral representation, and not as an illustration of the type of environments to be generated by considering both ICTs and emerging AEC features. Nevertheless, as simple and reduced as representation as it may be, it does serve to illustrate the functionality of the present mechanism in a variety of existing AAL or AAL-compatible built-environments.

As mentioned at the beginning of this section, the position of the tracked pupil is overlaid with frequently updated captured scenes. When the eye-target symbol representing the location of said pupil lands on a non-defined region, its color remains black and no actuation options appear on the display (see Figure 2, *Top*). The eye-target symbol changes color whenever the system detects that it has entered any of the eight defined regions. N.B.: entering a region occurs when the overlap between the eye-target symbol's area and a given object's defined region is greater than 50% of the symbol's overall area—that is, when the majority of the symbol representing the eye is inside a given object's region.

If the eye-target symbol's color turns red (see Figure 3), the console outputs confirmation of recognition of viewed object while warning that no actuations are associated with said object—as Kolarevic points out, an adaptive environment is more appropriately conceived as one containing both high-tech. and low-tech. objects [15], where the former are actuatable while the latter are fixed. If, however, the eye-target symbol's color turns green (see Figure 4, *Wall* and *Wall-Light*), the console confirms object recognition and provides a list of actuation options associated with said object. The user is able to select any of the available actuation options by looking at it (i.e., by moving the eye-target symbol to sit on top of the preferred option) and then blinking twice to confirm selection and trigger actuation execution (i.e., sending a confirmation signal to the responsible node via which the actuatable object is controlled). Finally, if the eye-target symbol's color turns yellow (see Figure 4, *Wall-Art*) the console confirms object recognition and outputs a series of options pertaining not to physical actuation but to other kinds of engagement, namely information finding about the object, etc.—for example, in Figure 4, *Wall-Art*, which represents the user looking at a generic instance of wall-art, options to find information about said art on the web or to take, store, and share a picture of it are outputted by the console.

This first feature concerns the recognition of actuatable and static objects and systems within the built-environment. In addition to this feature, and as mentioned in the *Introduction*, the mechanisms is equipped with a second feature that concerns the extraction of information corresponding to recognized familiar faces. In this second feature, recognized human faces—that is, faces that have already undergone *Machine Learning* (ML)-based training for identity recognition for a given user—are also a *de facto* defined region. If the eye-target symbol enters this region, the console outputs previously stored information about the recognized person (see Figure 5). Since this region is not of the same class as the previously listed eight regions corresponding to the actuatable / static objects

in the present generic built-environment, the eye-target symbol disappears to give way to a rectangular boundary that contains the recognized face. This change of representation explicitly distinguishes identified and viewed non-human and human objects. As illustrated in Figure 5, the probability of recognition of a face is overlaid on top of the captured scene. Accordingly, in this particular figure, the user is informed that the viewed person is "Alejandra" with a 77.98% probability—for simplicity, any probability higher than 75% is accepted as accurate in this implementation.

The console portion of the figure (Figure 5, *Bottom*) shows multiple console outputs, each of which represents the processing of a new instance of a captured scene. In this particular figure, it may be appreciated how the prediction probability fluctuates depending on lighting conditions, distance, etc. Nevertheless, all shown instances correctly and strongly indicate that the person viewed is "Alejandra". Furthermore, in addition to successful prediction probabilities, the console also outputs other useful and pertinent information in order to compensate for loss of memory and/or visual acuity. For example, in this figure, the mechanism informs the user that this is "Alejandra", and that she is: "24 years old"; an "Architecture student"; the user's "daughter-in-law"; and the wife of "Luis Francisco", who may be presumed to be the user's son. All this information pertaining to this familiar face are previously stored for the user and will naturally differ from user to user. In the present setup, only a small set of data (i.e., Full name, Age, Profession, etc.) is provided to illustrate the mechanism's functionality. However, the amount and type of data may be added or removed depending on the user's preference and/or need. The principal purpose of this second feature is to enable to user to always recognize the people in her/his immediate surroundings.

3 Methodology and Implementation

3.1 Eye- and Gaze-Tracking for Object Actuation

The eye- and gaze-tracking mechanism as a means to engage actuatable objects / systems is implemented via two Python programs: (1) *main_eye_detector.py* and (2) *pygame_window.py*. The first (built with *OpenCV* and *Numpy*) is responsible for identifying and tracking the pupil; while the second (built with *Sys* and *PyGame*) is responsible for generating and/or displaying the representation of a given captured built-environment scene. It is in this latter that the regions corresponding to the eight actuatable / static objects are defined; and where the overlapping between eye-target symbol and the defined objects' boundary is calculated.

3.2 Eye- and Gaze-Tracking for Human Identity Recognition

The component of the eye- and gaze-tracking mechanism responsible for human identity recognition depends on the inherited facial-identity and -expression mechanism previously developed by the authors [16]. In the previous work as with the present, the facial identity recognition component is implemented in the local network via Google Brain®'s *TensorFlow*™ [17]. That is, TensorFlow™ is installed in the RPiZW's *Raspbian* operating system and its cloud-based services are implemented via Python. The implementation of this service has two phases. In the first phase, and during execution of its *Multi-task Cascaded Convolutional Networks* (MTCNN) face detection model, the camera captures a given subject's face from different positions, orientations, and angles. All the people to be added to the eye- and gaze-tracking mechanism's users circle of familiar faces must undergo this phase. The second phase is the actual real-time execution of facial recognition, following the successful acquisition of analysed and stored faces from the first phase.

4 Results and Conclusion

With respect to the object actuation feature (see Section 3.1) of the present mechanism, three volunteers (with varying ages) (see *Acknowledgements*) in addition to the authors tested its functionality and performance via the following five steps:

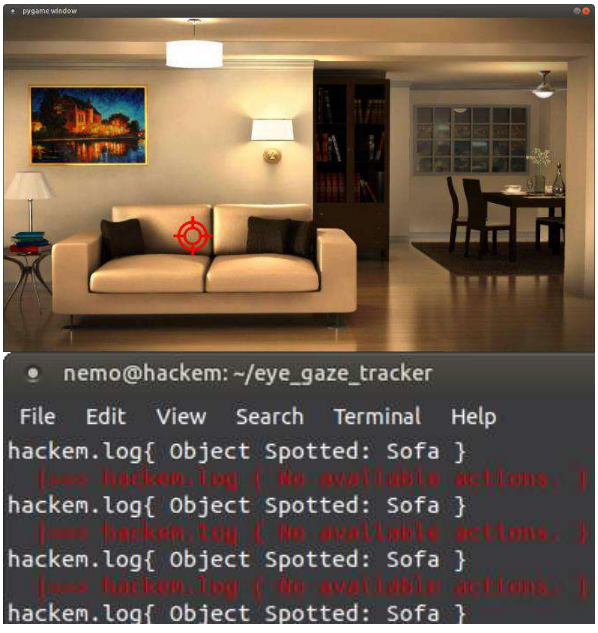

Figure 3. Pupil detected on object *Sofa*, with no available actuations.

1. At initialization of *PyGame*'s represented captured-scene, the eye-target symbol first appears in the upper-left corner. The user then moves her/his pupil in question (i.e., right-eye's pupil) and blinks twice over defined objects in order to first calibrate the eye-tracking component.
2. Once the eye-tracking component is calibrated the user is directed to look at the *window*, at which point the eye-target symbol changes colors to green, and the console first recognizes the actuatable object and the outputs the available actuation options: *open* or *close* (see Figure 4, *Window*). The user selects *open* and a confirmation of a corresponding execution signal sent is ascertained—the same, *mutatis mutandis*, for *close*.
3. The user is then instructed to look at the *sofa*, which is a non-actuating / fixed object that is nevertheless recognized. At this point the eye-target symbol turns red to indicate that no available actuation options exist for this object (see Figure 3).
4. The user's attention is turned to the *wall-art*, which is a non-actuatable object yet is nevertheless an object associated with non-physical actions. That is, after the eye-target symbol turns yellow (to indicate that the object in question is neither actuatable or fixed with no available options), the user is given the choice *to search for more information on the art online* or *to take, store, and share a picture of the art* (see Figure 4, *Wall-Art*). The user is instructed to engage in both, and a corresponding confirmation signal is ascertained.
5. Finally, the user is instructed to look at any of the light fixtures (see Figure 4, *Wall-Light*). Any of these fixtures present the user with two options: *turn on* or *turn off*. The user is instructed to engage in both, sequentially, and corresponding confirmation signals are ascertained.

Again, and as mentioned in Section 2, the present setup has its actuations act on virtual representations of generic objects found in an average built-environment. For the scope of the present implementation, it is only necessary to ascertain that a confirmation signal is sent to a respective enabling-node (enabling of the window, the lights, etc.) in order to demonstrate the successful functionality of the present *proof-of-concept*. In all of the above five steps mentioned, corresponding confirmation signals were indeed ascertained.

In the present setup, only three types of responses / options have been considered: (1) actuatable object (green eye-target); (2) static object (red eye-target); and (3) static object associated with non-physical actions (yellow eye-target). However, other possible responses / options may be envisioned for subsequent iterations of this feature of the mechanism.

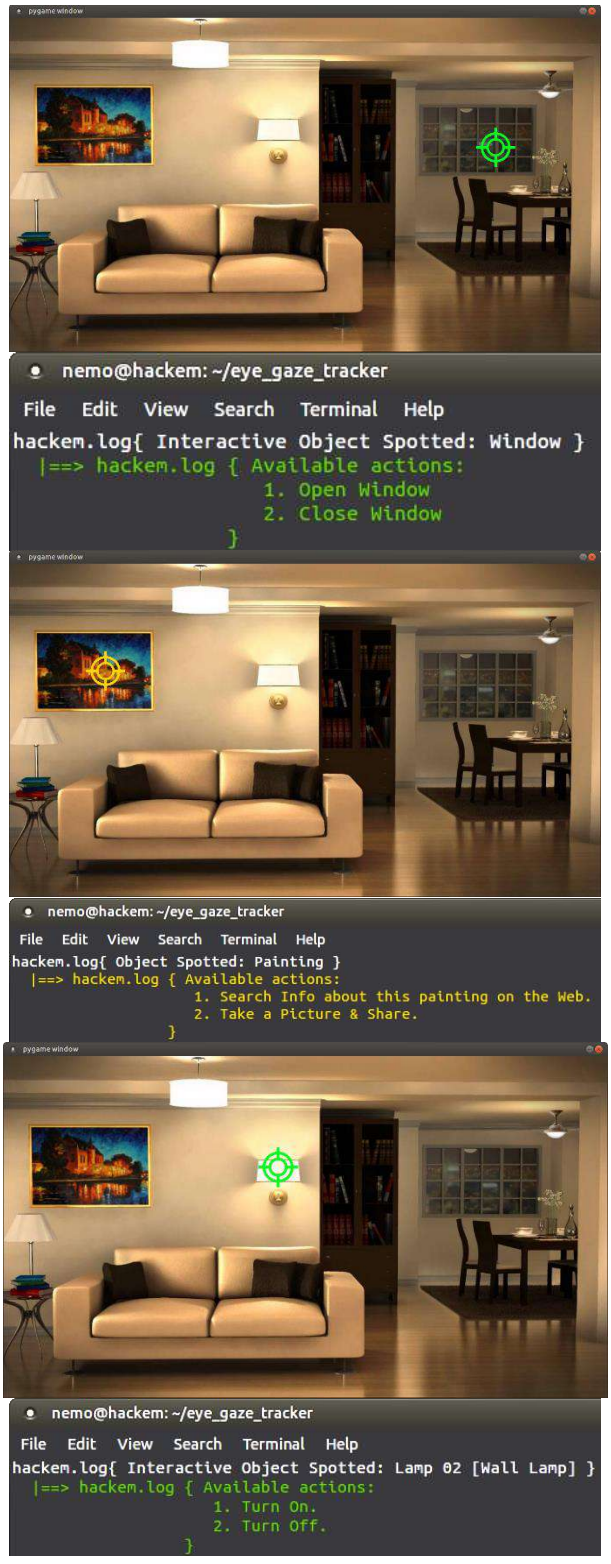

Figure 4. Top-to-Bottom: Pupil on object *Window* (green target/text); *Wall-Art* (yellow target/text); and *Wall-Light* (green target/text).

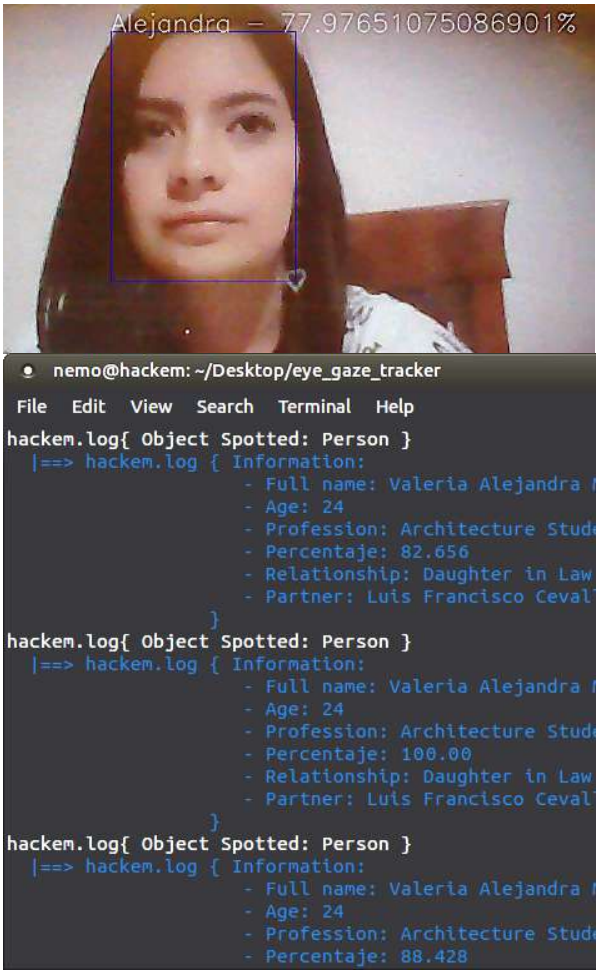

Figure 5. Recognition of a familiar face and corresponding output of associated information pertaining to the identified person.

With respect to the human identity recognition feature (see Section 3.2) of the present mechanism, a database of recognizable faces was first established, followed by a sequence of trials by the same three volunteers and the authors to gauge the feature's human identity recognition capabilities. The feature performed as expected, where the prediction accuracy probabilities were consistently above 70%.

In this paper an eye- and gaze-tracking mechanism has been presented. Said mechanism enables the user (1) to engage (i.e., open, shut, slide, turn-on/-off, etc.) with a variety of actuable objects and systems deployed within an intelligent built-environment via sight-enabled identification, selection, and confirmation; and (2) to extract and display personal identity information from recognized familiar faces viewed by the user. As with previously developed service-features, the present mechanism intends to increase the quality of life of its user(s) in an affordable, intuitive, and highly intelligent manner. Although the present setup is limited and not yet ready for widespread adoption (being in a *Technology Readiness Level* [18] of 5), the detailed *proof-of-concept* implementation's validated functionality and performance indicates further potential for development, which is presently being undertaken. Furthermore, in order to explore facial recognition alternatives in order to enhance the efficiency—with respect to the performance of the local network—of the mechanism, a subsequent version of the eye- and gaze-tracking mechanism is being implemented with *Keras* [19].

Abstract –

In previous study we have already reported fully automated mobile marking robot system in construction site for streamlining marking work that is currently carried out manually. However, marking accuracy and efficiency were not satisfied compared to those of construction worker, further improvement was desired. This paper is the second report of the system. The purpose of this paper is to improve the marking performance of the system. The proposed system consists of a reflectorless three-dimensional measuring instrument and a mobile marking robot. The former accurately directs a measuring laser and measures a distance to the robot. The latter is a mobile robot which has a marking device and a special positioning sensor. It is important to navigate the marking robot to the designated marking position quickly and correctly. Two self-positioning estimation method is combined. The robot position is roughly estimated by the wheel odometry method during movement. On the other hand, it is accurately measured by the combination of a three-dimensional measuring instrument and the special positioning sensor just before drawing a mark on the floor. The marking device draws the mark exactly on the designated position based on the deviation between the designated position and the measured robot position. This paper describes the mechanism of proposed system and some experimental results. It also shows improvement of the marking performance compared to previous prototype.

Marking; Mobile robot; Reflectorless three-dimensional measuring instrument

1 Introduction

In Japan, a shortage of construction workers has become a major social issue. In 2015, the number of construction workers was about 73% of what it had been at its peak in 1997. Therefore, improvement of productivity in construction work is an urgent issue. In the construction process, marking work is indispensable. Before installing building material such as dry walls, free access floors and anchor bolts, construction workers have to draw marks and lines on the floors, walls, ceilings, and so on in construction site. They mean positions for installing building materials. In a big building construction, the number of marks and lines is more than thousands and it is currently carried out manually. Therefore, there is a great need for improving efficiency of the marking work.

The progress of surveying technology in recent years is remarkable. Some measuring instruments such as laser scanner and total station are already being used at construction site. Prior studies on the efficiency improvement for the marking work by using these instruments have already been reported. They are roughly divided into researches on support technology aimed at improving efficiency of marking manually [1-3] and those on automated marking robots [4-6]. If this work is fully automated with marking robots, construction workers will be able to concentrate on installing building materials and productivity will increase.

Several studies on automated mobile marking robot have already been done. Inoue et al. reported a system that combines a marking robot having a cross-mark stamp and a total station [4,5]. It is roughly navigated a designated marking position by using a laser range finder and its position and orientation is measured by the total station. After that, it stamps a cross mark accurately on the designated position. “Laybot” developed by DPR construction [6] can draw lines for installing drywalls on a floor. Its position is also measured by using a total station. Kitahara et al. reported a system that combines a marking robot having a XY plotter and a total station [7]. In the system, an operator of the system moves the marking robot to a marking position with operation of a remote controller. The total station measures its position and orientation and the mobile robot draws arbitrary figure on a floor based on the measured position.

All of them mentioned above need a total station that can collimate and track prism. However, this kind of the total station is generally very expensive. In author's view point the total station occupies most of the system cost. On the other hand, a reflectorless three-dimensional measuring instrument that does not track and collimate prism is less expensive. Cost is a very important factor for wide spread use of the marking robot system. Therefore, we propose a marking robot system with the reflectorless three-dimensional measuring instrument. As a first step, we intended to automate the marking work for installing free access floors. In our previous study, we reported a performance of a prototype system [8] [9]. The marking robot automatically moves to designated positions and draws cross marks in sequence. These marks mean positions where pedestal bases of free access floors are installed. We succeeded in marking 182 positions automatically in a 6m x 6.5m working area in construction site. Average deviation between drawn mark and designated position was 2.3 mm and average time required for marking a single position was 98 second. However, marking accuracy and efficiency were not satisfied compared to those of construction worker. Further improvement is desired in the working area, the time required for marking and the marking accuracy.

In this study, new marking robot system was developed. Two self-positioning estimation method is combined to improve marking performance. The wheel odometry method is used during movement. The combination method of the three-dimensional measuring instrument and the special positioning sensor is used just before drawing a mark on the floor.

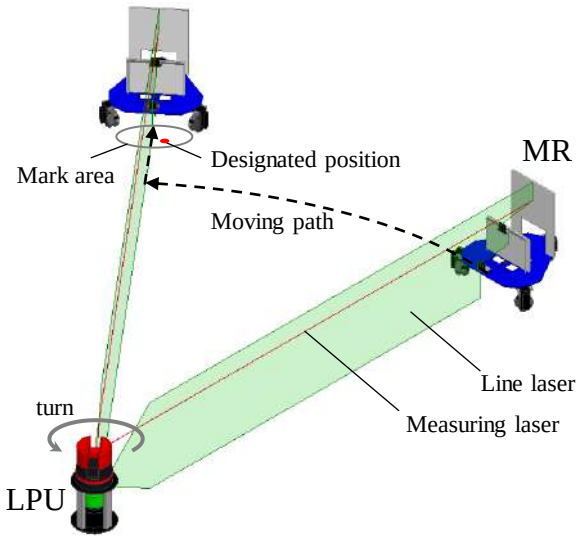

Figure 1. Outline of the marking flow using previous marking robot system

2 Proposed Marking Robot System

2.1 Problems in Previous Prototype

In our previous study, we proposed a line laser tracking navigation method using a laser positioning unit (LPU) and a marking robot (MR). As shown in Figure 1, the MR tracks a rotating line laser generated from the LPU in order to move to a designated position. The MR has two couples of screen and camera to detect the laser line projected on the screen. This method has two problems that deteriorate marking performance. First, when the MR is far from the LPU, the line laser light projected in the screen becomes weak and it is difficult to detect the laser line from a captured image. This is the reason that limits the working area and deteriorates the marking accuracy. Second, tracking path is a combination of the traveling on the circular path and straight path. This means that the MR does not move on the shortest path. Thus long time was required for moving to the designated position. For these reason we concluded that the usage of the line laser deteriorated the marking performance.

2.2 Automated Marking Flow

In order to improve marking performance, we stop using the line laser. The proposed system consists of a marking robot (MR) and a three-dimensional measuring instrument (3D-MI). The MR automatically moves to a marking position and draw marks on the floor. The moving path is a straight line connecting the current position and next designated position. The MR moves to the designated marking position by the combination of a straight traveling and a spin turn as shown in Figure 2. Two self-positioning estimation method is combined. The MR position is roughly estimated by the wheel odometry method during movement. On the other hand, it is accurately measured by the combination method of the 3D-MI and a special positioning sensor attached on the MR just before drawing a mark on the floor.

The 3D-MI is used for measuring the MR position and orientation. Like a motor driven total station, the horizontal and vertical axes of the 3D-MI can be motorized. This can direct a measuring laser parallel to the floor in the direction of the designated marking position and measure the distance to an object on which the laser spot is projected. Although it cannot collimate and track reflector such as prism target, it is less expensive than a motor driven total station used in previous studies already reported [4-7].

The MR is a two wheel differential drive robot with a caster wheel. A marking device is attached to the MR base flame. It is similar with a XY plotter. By controlling the marking device, an arbitrary mark, figure or character can be drawn on the floor. Furthermore, the MR has the

special positioning sensor. It is a key device for measuring MR position and orientation accurately with reflectorless 3D-MI. The detailed measuring mechanism will be described in section 2.3.

In construction site, some benchmarks are already drawn on the floor just before installing building material. The coordinate of the 3D-MI in a construction site coordinate system Σw is calculated by resection. The coordinates of the target marks to be drawn on the floor in the Σw are set based on the floor plan. Automated marking is operated by repeating following steps as shown in Figure 3.

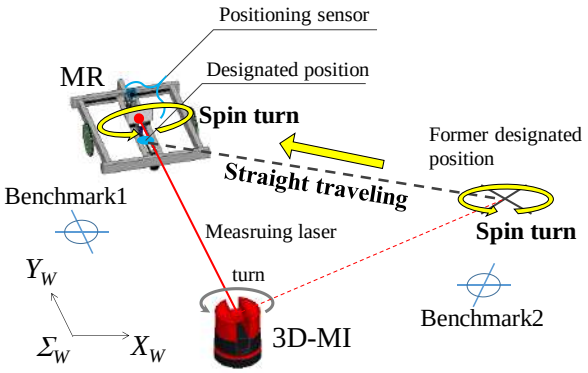

Figure 2. Move to the next designated position

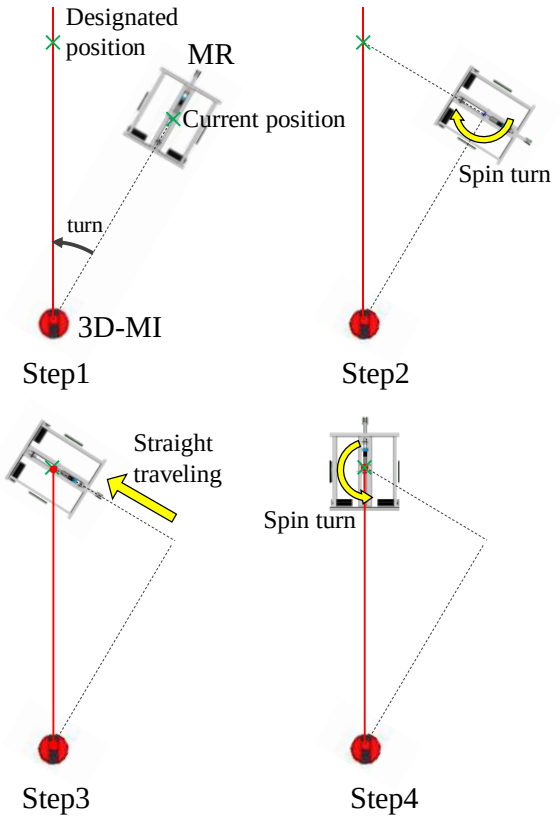

Figure 3. Automated marking flow

Step1: The 3D-MI directs the measuring laser parallel to the floor in the direction of the next designated position.

Step2: The MR makes spin-turn so that the orientation of the MR corresponds to the direction of the next designated position. The turning angle is estimated by the wheel odometry method.

Step3: The MR travels straight so that the MR reaches the next designated position. The traveling distance is also estimated by the wheel odometry method.

Step4: The MR makes spin-turn so that the positioning sensor is perpendicular to the measuring laser. After spin-turn, the MR position is not exactly on the next designated position. The MR position and orientation are accurately measured by the combination of the 3D-MI and the positioning sensor. The marking device is controlled based on the deviation between the measured position and the designated position so that a figure could be drawn exactly on the designated position.

2.3 Mechanism of the Marking with High Precision

The MR position is measured with combination of the 3D-MI and the positioning sensor. The positioning sensor consists of a light diffusion plate and a camera as shown in Figure 4. The measuring laser form the 3D-MI hits on the light diffusion plate. The 3D-MI measures the distance to the light diffusion plate. On the other hand, the camera captures an image of the laser spot projected on the light diffusion plate. The laser spot centroid is measured by an image processing described in section 2.5. After that, the positioning sensor moves y_f in the Y_R axis direction in the robot coordinate system Σ_R as shown in Figure 5. After that, the distance to the light diffusion plate and the laser spot centroid are measured again. By using these measured values before and after moving the positioning sensor, orientation α is calculated as below.

$$\alpha = tan^{-1}\left(\frac{x_{c0} - x_{c1}}{y_f}\right) \quad (1)$$

Here,

Δy: The displacement of the positioning sensor

x_{c0}: The x-coordinate of the laser spot centroid in the Σ_R before moving the positioning sensor

x_{c1}: The x-coordinate of the laser spot centroid in the Σ_R after moving the positioning sensor

From the geometry relation as shown in Figure 6, the MR coordinate in the Σ_w x_{MR} and y_{MR} are calculated following equation.

$$x_{MR} = x_p + r_0 cos\theta_l - x_{c0} cos\phi \quad (2)$$

$$y_{MR} = y_p + r_0 sin\theta_l - x_{c0} sin\phi \quad (3)$$

$$\phi = \theta_l - \frac{\pi}{2} - \alpha \quad (4)$$

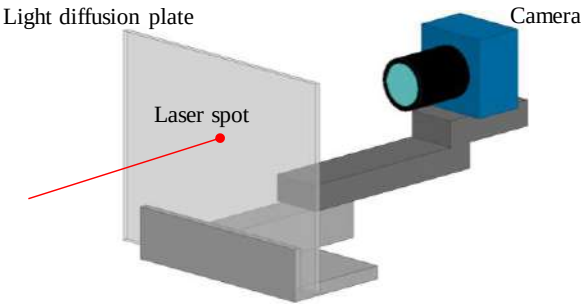

Figure 4. The positioning sensor

(b) After moving the positioning sensor

Figure 5. Before and after moving sensor

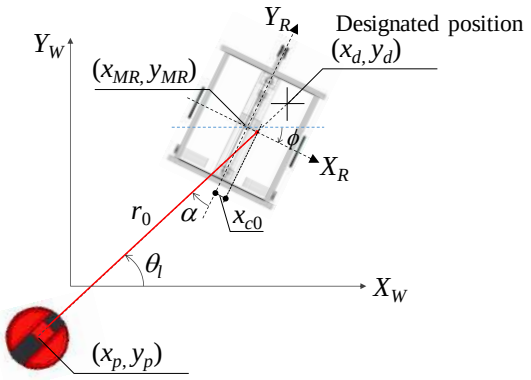

Figure 6. Explanation for calculating the x_{MR} and y_{MR}

Here,

r_0: The distance to the light diffusion plate from the 3D-MI before moving the positioning sensor

(x_p,y_p): The x and y-coordinate of the 3D-MI in the Σ_w

θ_l: An angle of the measuring laser to the X_W axis

ϕ: An angle of the X_R axis to the X_W axis

In proposed system, we prepare the figure to be drawn on the floor as a g-code data. It is commonly used in numerical control manufacturing such as milling and 3D printing. In this code, the start and end point coordinates of a line segment are defined. By controlling the movement of the marking pen based on this code, the figure can be drawn on the floor. In order to draw a designated figure exactly on the designated position with correct orientation, we need to rotate and translate the figure. The transformed coordinate of the point defined in the g-code data is calculated following equation (5). The values used in this equation are already calculated in equation (2)-(4).

$$\begin{pmatrix} p_t \\ q_t \\ 1 \end{pmatrix} = \begin{pmatrix} cos\phi & sin\phi & x_d - x_{MR} \\ -sin\phi & cos\phi & y_d - y_{MR} \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} p \\ q \\ 1 \end{pmatrix} \quad (5)$$

Here,

(p_t,q_t): Transformed coordinate in g-code data

(p,q): Original coordinate defined in g-code date

(x_d,y_d): The x and y-coordinate of the designated position in the Σ_w.

2.4 Component of the Marking Robot System

A photograph of the MR without controller is shown in Figure 7. Representative specifications such as external dimensions are shown in Table 1. As described in section 2.2, the MR is a two wheels differential drive robot with a caster wheel. The marking device is installed at the flame. The marking device consists of the XY movement stage and the pen unit which can move the marking pen in vertical direction by servo motor. By controlling the marking device, arbitrary figure can be drawn on the floor. The positioning sensor consisting of a camera and a light diffusion plate is also attached on the XY movement stage, thus it can move in the X_R and Y_R direction. On the other hand, a photograph of the 3D-MI is shown in Figure 8. Representative specifications such as some accuracies are shown in Table 2. System block diagram for proposed system is shown in Figure 9. Computer installed on the MR controls motor drivers for the vehicle and the XY plotter. Image processing on the captured image is also performed by the computer. 3D Disto is controlled by the computer through Wi-Fi communication.

2.5 Detection Method of the Laser Spot

Since captured image includes the lens distortion and perspective distortion, they are removed by the same method previously reported [8]. Figure 10 shows images before and after removing these distortions. From this

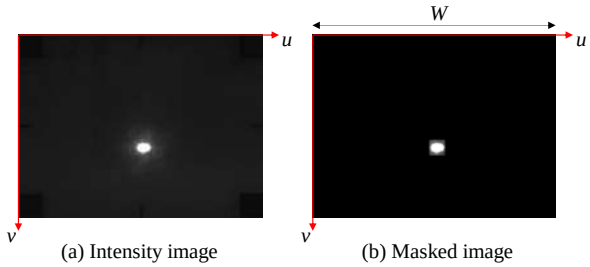
Figure 10. Images before and after distortion removal



(a) Intensity image (b) Masked image

Figure 11. Images for measuring x_c

distortion-removed image, the position of the laser spot is measured. An intensity image as shown in Figure 11 (a) is obtained by averaging pixel intensity of red, green and blue channel image. On the other hand, a binary image is obtained from the intensity image by setting proper threshold level. Temporary laser spot position is obtained as the intensity center of gravity in the binary image. After that, the masked image as shown Figure 11 (b) is obtained by setting the pixel intensity to zero except for the 40 x 40 pixels centered on the temporary laser spot position in the intensity image. The horizontal camera coordinate of the laser spot, u_{max} is calculated as the intensity center of gravity in this masked image. The x_c, which is the x-coordinate of the laser spot centroid in the Σ_R is obtained from Equation (6).

$$x_c = -(\frac{u_{max}}{N_H} - 1/2)W \quad (6)$$

Here,

N_H: Number of the horizontal pixel

W: Width of the image (See figure 10)

This image processing is mainly implemented by OpenCV 3.1 and conducted by the computer.

3 Experiment

3.1 Performance of the Marking Area

In order to evaluate the performance of the marrking area, fundamental experiment was executed. The experimental layout is shown in Figure 12. The MR automatically drew cross mark from Position A to J in order. The distance between two adjacent positions was 2 m. After marking, the coordinates of the every cross

mark center were measured by using a total station. Figure 13 shows Δr_w in each designated position respectively. Here, Δr_w is the deviation between marked position and designated marking position. Position J was 22.47m apart from the 3D-MI. The MR could automatically move to the position 22.47m apart from the 3D-MI and mark with an accuracy of within 1mm or less.

3.2 Performance of the Marking for Free Access Floor

In order to evaluate the marking performance for free access floor, a basic automated marking test was executed. The experimental layout is shown in Figure 14. In the 3m x 3m test area, we set 49 designated marking positions which were grid intersections at intervals of 0.5m. They imitated positions for installing pedestal bases of free access floors. The MR marked from Position A0 to G6 in order. After that, we measured all deviations in the same way described in the previous section.

Figure 15 shows the frequency distributions of Δr_w. Summarized result is shown in Table 3. For the purpose of comparison, the results obtained from previous system [9] are also summarized together. All of the marked positions are within less than 3mm deviation. However this result was obtained in the experiment in the test area which is not the construction site. Further evaluation in construction site is needed. The time required for per position was improved from 98 seconds to 33 seconds. In proposed system, the MR can move on the shortest path from current position to next designated position. As a result, the MR could perform automated marking faster than previous prototype.

Table 3. Summarized result of the marking accuracy

Item	Proposed system			Previous system		
	Δx_w	Δy_w	$\sqrt{\Delta x_w{}^2 + \Delta y_w{}^2}$	Δx_w	Δy_w	$\sqrt{\Delta x_w{}^2 + \Delta y_w{}^2}$
Average deviation(mm)	0.6	0.5	1.0	1.7	0	2.3

Standard deviation (mm)	0.5	0.7	0.5	1.9	1.4	1.6
Maximum deviation (mm)	2.1	1.6	2.1	9.5	4.5	10.2
Percentage where deviation is within 3mm (%)		100			77	

4 Conclusion

In order to improve the efficiency of construction work, we have developed a fully automated mobile marking robot system. In this study, we obtained following conclusion.

- Proposed system is cost effective since it uses a reflectorless three-dimensional measuring instrument which cannot collimate and track prism.
- The MR automatically could move to the position 22.47m apart from the 3D-MI and mark with an accuracy of within 1mm or less. Previous studies did not reported marking area.
- Proposed system improved the marking performance compared to previous system. Average deviation was 1.0 mm. This result was comparable to that reported by Inoue et al. [5], and worse than that reported by Kitahara et al. [7]. Though the number of measured points in their study was 10 or less.
- Average time required for single marking for installing the pedestal bases of free access floors was 33 seconds. It is about 1/3 of that of the previous system. Ohmoto et al reported it took 2 minutes in their study [10]. In the case of 100 square meter marking, proposed system can finish all the marking about 4 hours.

Proposed system currently has some limitations.

- Since the MR cannot detect and avoid obstacles, it is available only in areas without obstacles. We can solve this limitation by using sensor such as laser range finder or bumper sensor.
- Some previous study reported floor inclination affected the marking accuracy [5], [7]. The MR does not measure its own tilt. Thus proposed system is effective in plane area. The inclination angle can be measured by tilt sensor. We can correct the marking position by measured value.

Since we only tested proposed system in a test field, we have to confirm the marking performance in construction site. In this study we reported the result of drawing cross mark for free access floor. If we change the figure to be drawn, the MR can draw arbitrary figure. We are now preparing the automated marking test for dry partition walls in construction site. Marking work for dry partition walls is more complicated than that for free access floors. We consider automated marking for dry partition wall with robot system is more effective for improving productivity.

In proposed system, we have to set the marking positions manually from a floor plan. This work is very laborious. Therefore, we need to develop a tool for making marking position data directly from CAD data.

Abstract –

Various image-based building object recognition approaches have been developed to create as-is Building Information Models (BIMs) of existing buildings. However, existing approaches generally rely on human-designed features to automatically or semi-automatically recognize building objects, which makes them sensitive to input images and difficult to extend to new building objects. Furthermore, when constructing object geometries, most of these approaches are limited to rectangular or pre-defined surface shapes. To address these limitations, this study presents a human-designed features-free, shape constraints-free and fully automatic approach to construct as-is BIM objects from images of a building. This approach adapts Mask R-CNN, a deep convolutional neural network, to automatically recognize and segment building objects with arbitrary shapes (i.e., surface boundary shapes) from images. The segmented objects, characterized by object types and pixel masks, are further geometrically fitted to construct surface geometries. Finally, the constructed building objects are defined in the Industry Foundation Classes (IFC) data format. Three types of building objects (i.e., walls, doors, and lifts) are used in this study. Total 430 images containing these objects collected from the interiors of 4 university buildings are used to train and test the Mask R-CNN model. The test results show that the trained model is accurate and robust to recognize and segment all the three types of building objects. Furthermore, the feasibility of the proposed approach is preliminarily validated by successfully extracting IFC building objects from an image.

As-is BIM object; IFC; Image-based modeling; Deep learning; Mask R-CNN

1 Introduction

As-is building information models (BIMs) are characterized by containing up-to-date building information that can be used to support effective operations and maintenance of existing buildings [1, 2]. In the current practice, creating such a BIM remains a laborious, time-consuming, and costly process [1, 3]. Recent studies have focused on developing automatic approaches to create as-is BIMs. Although considerable progress has been made by exploring approaches that consume 3D point clouds [4], image-based modelling approaches have received increasing attentions. Compared to point clouds-based approaches that usually rely on a laser scanner to collect the data, image-based approaches have significant advantages in the conveniences, efficiency and cost of as-is data collection [1, 5].

Image-based as-is BIM creation generally consists of four steps [1, 6, 7]: (1) data collection, to capture images of a building and/or corresponding "location" data; (2) object recognition and construction, to recognize building objects and extract their geometries from the images; (3) geometry merging, to align constructed building objects in a common coordinate system; and (4) semantic enrichment and as-is BIM generation, to add required semantic information and save the enriched model in a specific data format (e.g., IFC or gbXML). Among these steps, the second step plays a foremost and challenging role. Most of existing approaches in this step rely on carefully hand-crafted features to recognize building objects. The commonly used features include colors [8], textures [8], edges [9], shapes [8, 10, 11], and so on. Unfortunately, these appearance-related features could vary under different environments (e.g., lighting conditions, and camera positions and poses) and/or be affected by uninterested objects (e.g., decorations and small devices that commonly exist in building interiors) in the images. Thus, these approaches are often sensitive to input images and usually require a manual pre-processing to remove noises from the input images or make the features required in downstream detection processes to be more easily extractable. Furthermore, for every new building object, corresponding detection features need to be additionally designed, which largely limits the

scalability of these approaches. In addition, when constructing object geometries, most of these approaches are limited to rectangular and pre-defined (e.g., arch) shapes. As an effort to address the first limitation, Lu et al. [12] developed a neuro-fuzzy based system, which can robustly recognize five types of building objects (i.e., beams, columns, windows, doors, and walls) in complex environments with few appearance features. However, this system is also a hand-crafted features – based approach and does not address the latter two limitations. Moreover, the system is semi-automatic. To recognize objects in an image, considerable manual efforts are required, including drawing the ground line and the ceiling line first and then orderly clicking the corners of the target objects to be recognized.

To address the aforementioned limitations, this study aims to develop a fully automated (i.e., without manual pre-processing of input images and human intervention in the algorithmic process), scalable (i.e., human-designed features-free), and shape constraints-free approach to construct as-is IFC BIM objects from digital images of existing buildings. This approach is based on Mask R-CNN [13], a deep neural network, to recognize and segment building object instances from images. In the remainder of this paper, the principles of Mask R-CNN are introduced first. Then the proposed approach is explained. Next, the implementation of the approach as well as a simple experiment is detailed, followed by the conclusion and discussion of future work.

2 Mask R-CNN for Instance Segmentation

In the computer vision community, instance segmentation refers to detect all interested objects in a given image while also precisely segmenting each instance [13]. It combines two classical computer vision tasks [14]: object detection, which aims to detect interested object instances and return their spatial locations (e.g., via a bounding box) with their category labels; and semantic segmentation, which aims to classify each pixel into a predefined object category list without differentiating object instances.

In the past several years, deep learning techniques have driven significant advances in various computer vision tasks including instance segmentation [14]. Compared to conventional recognition models that consume human-designed features, deep neural networks are powerful as they automatically learn important features from training data themselves [15]. Among various types of deep neural networks, Mask R-CNN surpassed prior state-of-the-art instance segmentation results [13]. It was developed based on another two powerful baseline deep neural frameworks, Faster R-CNN for object detection [16] and Fully Convolutional Network (FCN) for semantic segmentation [17], respectively. Figure 1 shows a high-level Mask R-CNN architecture.

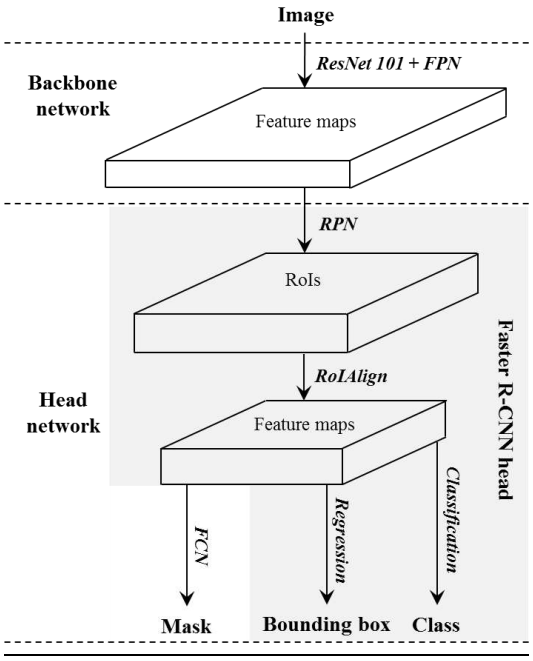

Figure 1. High-level Mask R-CNN architecture based on He et al. [13] and Ren et al. [17].

The Mask R-CNN architecture consists of two connected modules: a backbone network and a head network. The convolutional backbone network is used to extract feature representations from an input image. Then the produced feature maps are fed to the head network for succeeding three parallel tasks, namely object classification, bounding box regression and instance mask prediction. According to He et al. [13], the backbone of Mask R-CNN can achieve excellent gains in both accuracy and speed by combining ResNet [18] and Feature Pyramid Network (FPN) [19]. For the head network, Mask R-CNN was mainly designed by extending the Faster R-CNN head (see the blocks with grey background in Figure 1). The Faster R-CNN head for object detection includes two stages. In the first stage, a Region Proposal Network (RPN) is implemented on top of feature maps produced by the backbone network to propose candidate object bounding boxes (i.e. Region of Interests (RoIs)). In the second stage, high-level features are extracted from each RoI, and then object classification and bounding-box regression are performed. In this stage, Mask R-CNN adds a mask prediction branch, which is a small FCN on top of a feature map, and is parallel with existing classification and bounding box regression branches.

In this study, Mask R-CNN is adapted to achieve a fully automatic building object segmentation from images of buildings. Due to the automatic feature learning ability, Mask R-CNN based building object recognition is expected to be robust to various and complex environmental conditions, and to be scalable to customized building object types. Furthermore, Mask R-CNN allows predicting pixel-accurate masks of objects in images, which provides the potential of constructing building objects with arbitrary-shape surfaces.

3 The Proposed Approach

The proposed approach aims to automatically extract IFC building objects from images of existing buildings to support as-is BIM construction. It consists of three modules (see Figure 2): building objects recognition and segmentation, building object geometry construction, and IFC BIM object generation.

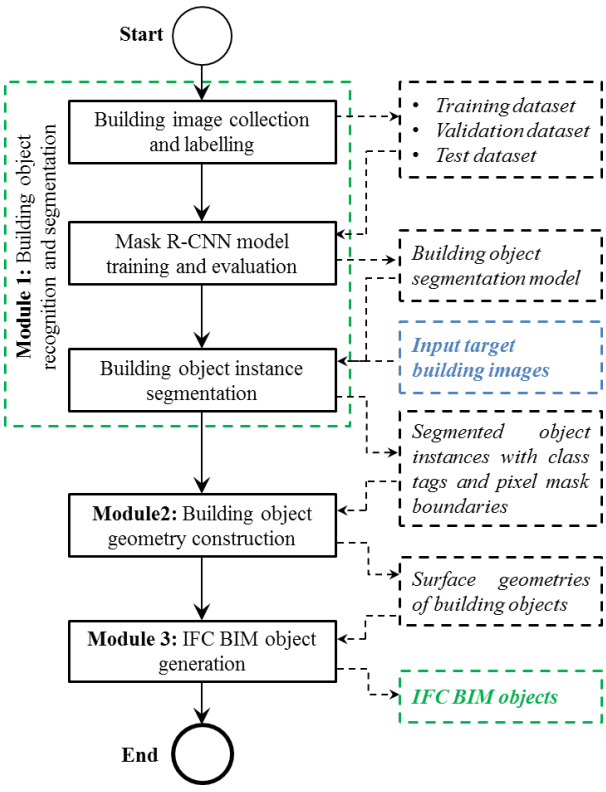

Figure 2. The proposed approach

3.1 Module 1: Building Object Recognition and Segmentation

This module takes building images as an input and produces a list of object instances segmented from each image. Each output instance consists of an object class and a mask boundary of the instance in the image. To link the pixel dimensions with real-world dimensions for object surface construction in the next module, a ruler with a known length (e.g., 1 meter) is used as a reference object in each image. Specifically, this module contains three successive steps: building image collection and labelling (Section 3.1.1), Mask R-CNN model training (Section 3.1.2), and building object instance segmentation (Section 3.1.3).

3.1.1 Building Image Collection and Labelling

Building images (most images, if not all of them, should contain the reference ruler) are collected and labeled to fit the Mask R-CNN model for building object segmentation. To ensure the generalization and the robustness of the model, images of building objects in diverse environmental conditions (e.g., building facades and building interiors, various lighting conditions, and spaces with various usages) need to be considered. Images can be conveniently collected by using handheld digital cameras or smartphones. For each image, all the building objects and the ruler (if present) need to be manually annotated by outlining their masks and adding corresponding class tags. In this study, images are annotated by the "VGG Image Annotator" web tool [20].

3.1.2 Mask R-CNN Model Training and Evaluation

The whole labeled image dataset is randomly split into the following three subsets: a training subset, a validation subset, and a test subset. The Mask R-CNN model is trained based on the image – annotation pairs in the training subset. The goal of the training is to find optimal weight parameters of Mask R-CNN that can map the training images to corresponding annotations with minimal loss. According to He et al. [13], the loss function of Mask R-CNN is defined as a multi-task loss (L) which refers to the sum of the classification loss (L_{cls}), the bounding-box loss (L_{box}), and the mask loss (L_{mask}). Details of L_{cls} and L_{box} can be found in Girshick [21] and details of L_{mask} in He et al. [13]. The validation subset is used to inspect the training process to minimize overfitting. Generally, various training strategies involving the configurations of hyperparameters need to be implemented to obtain an optimal model. For a trained model (i.e., with minimal training loss on the premise of minimal overfitting) obtained under a specific training strategy, it is further evaluated with the test subset. The model that can accurately and robustly segment building objects and the ruler in the test subset is identified and used in the downstream processes.

3.1.3 Building Object Instance Segmentation

Once the Mask R-CNN model is well trained, it can perform the building object segmentation on input

images. Although the model could segment building objects captured in various camera poses, the input images are required to be captured right in front of the target building objects to construct their surface geometries as accurate as possible in Module 2. For the same reason, each input image should contain a well-placed (i.e., vertically or horizontally) ruler (the same ruler used in the training process). By using the scikit-image package (http://scikit-image.org/), the boundary of the predicted mask of each segmented object instance is extracted as a polygon consisting of pixel points in image coordinates.

3.2 Module 2: Building Object Geometry Construction

This module takes the pixel-level mask polygons of objects generated from Module 1 as an input, and produces the surface geometries of objects in two steps: shape extraction (Section 3.2.1) and coordinate transformation (Section 3.2.2).

3.2.1 Shape Extraction

The pixel-level mask polygon of an object is in great detail in terms of shape representation. This step simplifies the shape representation by detecting corner pixels, and then constructing boundary edges (see the example in Figure 3).

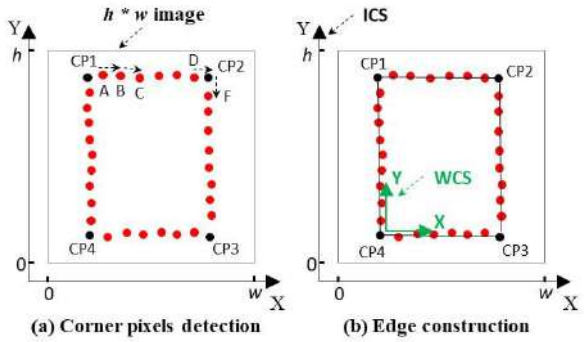

Figure 3. Object shape extraction from a segmented mask

A corner pixel refers to the pixel shared by two adjacent edges to be constructed. Corner pixels are detected by the following procedure. First, for any two adjacent pixels in a mask polygon, the direction vector from one pixel to the other is computed. Second, the angle between two adjacent direction vectors is calculated. Each angle involves a group of three successive pixels. When an angle is larger than a pre-set threshold (e.g., 10 degrees), the corresponding second pixel is recognized as a corner pixel (see CP1, CP2, CP3, and CP4 in Figure 3(a)). Once all the corner pixels are detected, an edge is constructed by fitting two adjacent corner pixels and other pixels between the two corner pixels with a line segment or a circular arc. These two geometric primitives are used in this study is because they are common in representing building object shapes and easy to be processed. As a result, the object shape can be extracted and approximately represented by the constructed edges.

3.2.2 Coordinate Transformation

This step transforms the extracted object shapes represented in an image coordinate system (ICS) into a world coordinate system (WCS), which is used to define the objects' geometries with real dimensions. In each image, objects (e.g., a wall and its hosting openings) on a common plane are assigned with a common WCS. The WCS of an object is set up by taking the lower left point as the origin and keeping x-axis and y-axis of the ICS (see Figure 3 (b)). In this manner, the transformation only involves a translation. To calculate the real dimensions of building objects, the segmented ruler with a known length (i.e., 1m) is used to calculate the pixel dimension by:

$$d_p = \frac{1}{\sqrt[2]{(x_{r_CP1} - x_{r_CP2})^2 + (y_{r_CP1} - y_{r_CP2})^2}} \quad (1)$$

Where (x_{r_CP1}, y_{r_CP1}) and (x_{r_CP2}, y_{r_CP2}) refers to the image coordinates of two endpoint pixels of a long edge of the segmented ruler instance, respectively.

Then for any $\boldsymbol{P}$ (x_{imag}, y_{imag}), its world coordinates (x_{world}, y_{world}) can be computed by

$$\begin{bmatrix} x_{world} \\ y_{world} \end{bmatrix} = d_p \times \begin{bmatrix} x_{image} - x_{o_image} \\ y_{image} - y_{o_image} \end{bmatrix} \quad (2)$$

Where $(x_{o_{imag}}, y_{o_imag})$ refers to the image coordinates of the origin of the world coordinate system.

Since each extracted shape is defined by a combination of line segments and/or circular arcs, the transformation of a shape essentially refers to transform all relevant geometric primitives into the corresponding WCS. For a line segment, its two endpoints are transformed via Equation (2). For a circular arc defined by a center, a radius, two trimming points and an arc direction, the center and the two trimming points need to be transformed via Equation (2).

3.3 Module 3: IFC BIM Object Generation

This module defines the constructed building objects as IFC objects. For each building object, only the visible sections of surfaces (i.e., exposed to a space or the outdoors) are constructed. Thus, the IFC concept of space boundary (SB) (i.e., IfcRelSpaceBoundary) [22], which defines the surface partition of a building object that bounds a space or contacts outdoors, is proper to

store the constructed information. Figure 4 shows the IFC entities and data structure used to define a SB in the IFC4 specification. To be more specific, each building object is defined by an IfcRelSpaceBoundary instance. To store the object type information, this instance references a building element instance that matches the type via the attribute "RelatedBuildingElement". For example, for a wall object, an IfcWallStandardCase instance is created and linked to the IfcRelSpaceBoundary instance via that attribute. The object surface geometry is defined by the IfcRelSpaceBoundary instance via the attribute "ConnectionGeometry" (see Figure 4). It is noteworthy that the created IFC SB instances do not constitute a valid IFC model as other IFC instances (e.g., IfcProject, IfcSite, IfcBuilding and IfcSpace) required by the IFC4 specification are not yet included. All the missing instances can be automatically inferred and added by using the semantic enrichment approach developed by Ying et al. [6].

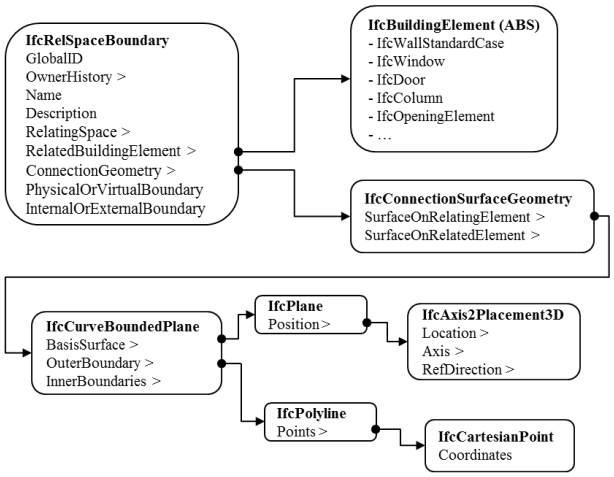

Figure 4. Instantiation diagram to define a space boundary in IFC4 schema

4 Implementation and Experiment

A prototype system implementing the proposed approach was developed in multiple programing languages. Module 1 was implemented in Python. Module 2 and Module 3 were implemented in C#. In the rest parts of this section, the implementation details of Mask R-CNN for building object segmentation are first elaborated and then a preliminary experiment of the entire approach is presented.

4.1 Mask R-CNN Model Implementation

4.1.1 Dataset Preparation

The authors created a 2D image dataset to train a Mask R-CNN model for building object segmentation. The dataset includes 430 images from interiors of 4 multifunctional buildings in the University of Hong Kong with significantly different decoration designs (see some examples in Figure 5). All the images were captured by a smartphone and their sizes are 3024×4032. The dataset also includes the ground truth annotation of each building object contained in each image. The authors randomly split the annotated dataset into three sub datasets: 80% (344 images) for training, 10% (43 images) for validation, and 10% (43 images) for testing. Table 1 shows the number of building object instances in each sub dataset. In this test, only three types of building objects (i.e. walls, doors and lifts) and a reference ruler were considered. Other objects such as columns, beams and windows will be taken into account later.

Figure 5. Varieties of collected building interior images in the dataset

Table 1. The number of building objects in each dataset

Dataset	Wall	Door	Lift	Ruler
Training dataset	599	443	34	99
Validation dataset	68	49	6	11
Test dataset	73	53	2	12

Whole dataset	740	545	42	122

4.1.2 Training

The authors implemented the Mask R-CNN model using an open-source package built on Keras and Tensorflow developed by Matterport [23]. ResNet-101 + FPN are used as the backbone network. Parameters of the sub models of the Mask R-CNN (e.g., ResNet-101, FPN, RPN, FCN etc.) are left in default settings in Matterport's implementation, which basically follows the suggestions in He et al. [13]. It is noteworthy that all the input images (3024×4032) are automatically resized as 1024×1024 for training in the Matterport's implementation. Instead of training the model from scratch, the authors used the weights of a pre-trained Mask R-CNN model on MS COCO (http://cocodataset.org/#home) to initialize the model. In addition, to make the resulting model more robust, a set of image argumentation operations (e.g., horizontal flipping and Gaussian blurring) were randomly used to introduce variety in the training images. The model was trained on a desktop with 61GB RAM and a NVIDIA Tesla K80 GPU with 12 GB memory. The training process consists of two stages. In the first stage, only the head layers that do not use pre-trained weights from MS COCO are trained to adapt the building object segmentation task. In the second stage, all layers are trained to fine-tune the weights to achieve the best performance. The authors set the batch size of 2, the learning momentum of 0.9, and the weight decay of 0.0001 for both training stages, and the learning rate of 0.001 for the first stage and the learning rate of 0.0001 for the second stage. The authors adopted an early stopping strategy to minimize overfitting with the validation dataset. The model was trained with 60 epochs to record the full learning curve. Finally, the model trained at the 50th epoch was selected as the model began to get overfitting after 50 epochs (i.e., the validation loss began to increase).

4.1.3 Assessment

The performance of the trained model was evaluated with the hold-out test dataset from two aspects: (1) the object classification accuracy, which aimed to evaluate the performance of the model in terms of building object and ruler recognition; and (2) the object segmentation accuracy, which aimed to evaluate the performance of the model in terms of the instance mask generation. A positive classification of an instance is acknowledged if the following two criteria are satisfied: (1) the predicted mask of the instance has an overlap with the ground truth; and (2) the predicted class of the instance is correct. Table 2 shows the overall classification accuracy and the object-level classification accuracy with precision and recall. The results show that the trained model can accurately and robustly recognize the building objects and the reference ruler.

Table 2. Classification accuracy of the trained model on the test dataset

		P	N	Precision	Recall
Wall	T	72	0	97.3%	100%
	F	2	0		
Door	T	48	0	100%	90.6%
	F	0	5		
Lift	T	2	0	100%	100%
	F	0	0		
Ruler	T	11	0	100%	91.7%
	F	0	1		
Overall	T	133	0	98.5%	95.7%
	F	2	6		

Note: P – Positive; N – Negative; T – True; F – False; Precision = TP / (TP + FP); Recall = TP / (TP + FN).

For the segmentation accuracy evaluation, the authors use the metric called mAP (the mean of average precision values of all classes), which is commonly used in computer vision community to evaluate the performance of an object detector. Given that the quality of a predicted mask would have a significant effect on corresponding surface construction, the authors set a large threshold value - 0.75 - of IoU (Intersection over Union: the ratio between the intersection and the union of the predicted mask and the ground truth mask of an instance) for the mAP computation. The mAP $^{IoU = 0.75}$ of the trained model on the test dataset reaches 0.912, which indicates that the trained model can generate effective masks.

4.2 Experiment

A new image (i.e., not in the dataset used for the Mask R-CNN model training, validation and testing) taken in an interior space at night, as shown in Figure 6(a), is used to validate the feasibility of the proposed approach. The image mainly contains three building objects, a reference ruler, as well as a noisy object – the emergency exit sign. The three building objects (from left to right in Figure 6 (a)) includes a wall showing a small surface region, a wall showing the entire surface, and a door showing the entire surface. The latter two are the target building objects to be constructed. Figure 6(b) – (f) shows the whole flow of generating interested IFC objects from the image by the proposed approach. In Figure 6 (b), all three building objects and the ruler are correctly segmented by the trained Mask R-CNN model. Then the two target building objects are further distinguished from the segmented wall instance with a partial surface region, and proceed to the downstream

steps with the ruler to construct surface geometries (see Figure 6(c) – (e)). Finally, two corresponding IFC objects are successfully generated (see Figure 6(f)).

Regarding the geometry construction accuracy in the result, the areas of the constructed wall surface and door surface are 8.69 m^2 and 4.78 m^2 respectively. Compared to the real values (measured with a laser range finder), 7.97 m^2 for the wall and 4.184 m^2 for the door, the errors are +9% and +13.97% accordingly. As seen in Figure 6, these errors are mainly caused from the imperfection in the reference ruler placement and its segmentation (Figure 6(b)) as well as the process of determining building object shapes from the extracted mask boundaries (from Figure 6(c) to Figure 6(d)). In future, the Mask R-CNN model needs to be improved to generate more accurate masks for segmented objects.

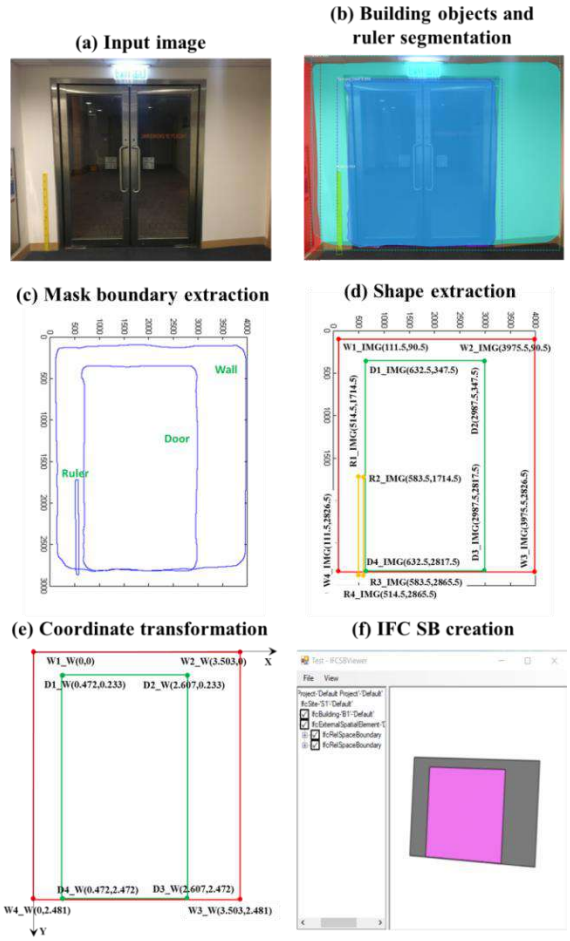

Figure 6. The flow of processing an image by the proposed approach

5 Conclusion and Future Work

In this study, a fully automatic approach is presented to construct IFC building objects from digital images of existing buildings. Unlike previous image-based approaches that rely on human-designed features to recognize building objects, the proposed approach automatically learns important features from training data themselves to segment building object instances. This makes the approach to be robust in various building indoor conditions, and to be efficiently scalable to customized building object types. Furthermore, the approach is able to construct building objects with complex surface shapes. The proposed approach was implemented with three modules: Mask R-CNN based building object recognition and segmentation, building object geometry construction and IFC BIM object generation. 430 images containing three types of building objects (i.e., walls, doors, and lifts) were collected and used to train and test the Mask R-CNN model. The test results show that the trained Mask R-CNN model can accurately and robustly recognize the three types of building objects and the reference ruler (with average precision of 98.5% and average recall of 95.7%), and can generate effective masks for the recognized building object and ruler instances (with mAP $^{IoU = 0.75}$ of 0.912). Based on the trained Mask R-CNN model, the feasibility of the entire approach was examined by successfully extracting IFC BIM objects from an image, while the geometry construction accuracy still has room for further improvement. It is expected that the approach can be useful for researchers and practitioners to develop semantically rich as-is BIMs of existing buildings.

In future, the approach will be further improved in the following aspects. First, the Mask R-CNN model will be improved to generate more accurate masks of segmented objects to support accurate surface geometry construction. Second, the size of the image dataset will be increased with more images from different environments (e.g., building exteriors) and different building types (e.g., residential buildings and commercial buildings) to improve the performance and enhance the generalization of the Mask R-CNN model. Other common building objects such as windows, beams, columns, and curtain walls will be included. Third, more flexible and accurate dimension measurement method (e.g., photogrammetry technique) will be introduced to address the constraint on input image capturing (i.e., taking images right in front of target building objects). Finally, the performance of the proposed approach will be further examined by more case studies.

Abstract –

With increased computing power to render 3D models and affordability of as-built data acquisition technologies, new techniques for enhancing the quality of pre-project planning of adaptive reuse projects can be investigated. The main objective of this research is to present a decision making methodology to select the optimum effort using 3D as-built point clouds to develop a BIM of an existing building. Three value proposition and risk reduction areas are investigated: (1) dimensional, (2) material, and (3) disassembly. To measure the cost and value of developing models with corresponding value propositions, a small case study is conducted. Three different Model Detail Levels (MDL) are defined for adaptive reuse projects, and corresponding models are developed for each of them. The value of each model is considered based on its ability to provide information about dimension, materials, and fixtures within an existing building. The cost of the scan-to-BIM process includes costs of purchasing 3D acquisition device, buying BIM modeling software license, scanning and registration, and developing BIM using scan-to-BIM techniques.

Keywords –

Adaptive reuse; Value of information; Pre-project planning; Scan-to-BIM; Modeling; Existing buildings

1 Introduction

Having a successful project or receiving the best outcome from a project has always been a goal of engineers and project managers. In general, a project is successful when it meets all of its goals and expectations and when all of the stakeholders (e.g. owners, consultants, contractors, suppliers, end-users, community, etc.) achieve their requirements individually and collectively [1]. The Construction Industry Institute (CII) conducted extensive research and concluded that improving the planning process during the early stages of a project lifecycle would be more effective and cheaper in order to improve a project's outcome, as opposed to later stages [2]. Planning during the early stages of a project life cycle is called pre-project planning and is defined as, "the process of sufficient strategic information with which owners can address risk and decide to commit resources to maximize the chance for a successful project" [3]. Pre-project planning would be more effective and ensures higher probability of having successful design, construction, and operation phases, depending on the efforts that have been dedicated to completely define the details of a project's scope [4]. Scope definition is considered as defining the vague and uncertain areas such as area and site investigation, existing brownfields, weather conditions, safety and security regulations that will be used during the detailed design, construction, and operation phases.

Gathering information is the first step of defining details of a project's scope. There are several pre-project planning tools that help a project team (owners, engineers, architects, contractors, investors, and developers) to know which type of information is needed. However, there is not any clear decision making methodology regarding the process and prioritization of information gathering. The methods and technologies to obtain information, the cost and value of each method, the amount of risk reduction, and finally the optimal amount of information are the steps that must be addressed through further research.

The objective of the adaptive reuse approach is revitalizing old and obsolete buildings and returning them to the use cycle. Therefore, as-built condition of an existing building is one of the most important information categories for defining project scope of an adaptive reuse project. However, obtaining useful as-built dimensions of an old existing building can be costly. Typically, either as-built drawings are not available, or they might be inaccurate [5]. Lack of updated as-built drawings brings more uncertainty to the adaptive reuse projects that causes financial loss and time delay during design and construction phases. Thus, it is necessary to provide updated as-built information during pre-project planning and before authorizing a project for the detailed design and construction phase.

Using 2D surveying tools and software is the common way to create as-built drawings of an existing building [6]. However, there are drawbacks associated

with this method of as-built data collection, such as high level of error, long time of surveying, difficulties of obtaining details of building's fixtures and facilities, difficulties of converting the 2D surveying information to the 2D drawings, and complexity of interpreting the 2D drawings. On the other hand, usage of advanced software and technologies that have 3D surveying and drawing capabilities can support the process of developing more exact and less complex as-built drawings. In addition, 3D as-built drawings can provide more information regarding the existing conditions of a building to the project team.

The objective of this paper is to fill the mentioned knowledge gap by presenting a decision making methodology for finding the optimal amount of effort in the data collection and modeling step in adaptive reuse projects. This methodology will be presented by conducting a case study to select the optimum effort required in the 3D data acquisition step (laser scanning and structured lighting has been utilized) and to develop a 3D as-built BIM (Building Information Model – defined and described in more detail in section 2.5 of this paper) of an existing building. The method, which has been used in this case study to obtain as-built information, can be generalized to find the optimal amount of information about other project scope elements.

2 Literature review

2.1 Adaptive Reuse

There are numerous definitions for "adaptive reuse" in the literature. In this research, adaptive reuse is accepted as the process of extending the useful life of a historic, old, obsolete, and derelict building, considering new usage compatible with historic background, new socio-cultural demands, political and environmental regulations of a building's location and applicable building codes, maximizing the reuse and retention of existing structures and fabrics, and improving financial performance and economic viability of buildings [7], [8]. Since adaptive reuse specially deals with old and historic building restoration, UNESCO defines it as a respectful process to the form, character, structure, and historic integrity of buildings, while finding an appropriate use for them [9].

Extending building useful lives, preserving natural resources, reducing waste production, controlling negative impacts of old buildings, satisfying new demands, and preserving cultural, historical and social aspects of a building are among the most important key drivers of the adaptive reuse approach [10]. Hence, adaptive reuse is a novel sustainable approach to fulfill previously mentioned key drivers.

2.2 Uncertainty and Information

In the project management literature, uncertainty is used as a general concept and is defined as the degree of deviation between actual outcomes of an event from its predicted outcomes. In fact, uncertainty is the effect of lack of knowledge and information about an event. There is an inverse relationship between information and uncertainty level [11]. Providing more information increases the knowledge of the project team about the project and consequently enhances the project predictability and decreases its uncertainty. Although providing more information has the mentioned values, it also adds to the cost of the project. Thus, there is a practical limit to the amount of information needed to reach a reasonable level of uncertainty. As long as the marginal expected value of working with more information (lower uncertainty) is positive, and the cumulative expected value of working with more information is higher than the expected value of working without any information (higher uncertainty), it is reasonable to collect information and reduce uncertainty.

In other words, collecting information more than this limit will decrease the net value, because after the limit point, the rate of information gathering cost would be higher than value enhancement. This limit will differ from scope element to scope element and project to project. So, it is up to the project team to come up with the limit of information for each scope element according to the specific project. Or, where information is fuzzy, applying the 80:20 rule works well, and here we identify ways of prioritizing so that rule can be observed.

2.3 LOD and Other Methods

The project design phase involves an iterative process in which the final product is achieved after several changes and improvements. In construction projects, be it a new project or an adaptive reuse project, design progress starts with conceptual drawings, and a fully coordinated construction model is created after many iterations. While design evolves from conceptual drawing to ready for construction model, details of the model elements and model disciplines become more mature and accurate. In this iterative process determining the detail level of the design is a complicated problem. In the literature there are several frameworks proposed to determine the detail levels of the model elements and model disciplines. One of the known frameworks that focuses on design details of the model elements is the Level of Detail (LOD) framework.

The LOD framework is created in 2005 by VICO Software Ltd. to track cost estimates of the projects, and later it was adopted by the American Institute of Architects (AIA). After AIA improved the LOD framework into specific levels, the meaning of the LOD

acronym was changed to "Level of Development", and in 2008 the definition of different LOD levels were released. AIA defined five LOD levels (LOD 100, LOD 200, LOD 300, LOD 400, and LOD 500) for model elements in a Building Information Model. According to the "AIAE202-2008 BIM Protocol Exhibit" contract document, LOD 100 refers to the conceptual drawing of a model element which shows its area, height, volume, and location, while LOD 500 means that the model element has reached its as-built version, and it would include useful information for operations and facility management phases of a project [12]. However, it is important to note that, there is no defined total LOD or LOD of the whole model. LOD definitions are created for single model elements on a design model [13]. Figure 1 represents five different LOD versions of a steel framing column model element according to the BIM Forum's 2018 LOD Specifications [14].

Figure 1. Representation of different LOD Levels of Steel Framing Column (Source: [14])

CII's Model Maturity Index (MMI) definitions are an example of a framework that can be used for determining the design detail level of a design model and design progress by focusing on information added to the related model disciplines [15]. In 2017, CII published a new set of definitions that is called MMI, and a toolkit called Model Maturity Risk Index to measure modelling progress and productivity in building projects. CII provided these definitions and related tool for 12 disciplines including; Piping, Structural, Instrumentation, HVAC, Equipment, Civil, Electrical, Fire Protection, Layout, Foundations, Buildings, and P&IDs in building type of projects. Defined MMI levels follow similar sequence with LOD levels. There are seven different MMI levels for each modeling discipline varying between Generic Model to Facility Management information added as-built model. Similar to LOD, there is no such total MMI of whole model, these definitions are developed for disciplines in the model.

Inspired by the concepts of LOD and MMI, the Model Definition Level (MDL) is defined in this study to emphasize that there are different effort levels regarding the scan-to-BIM process, which may lead to different value levels.

2.4 3D Acquisition

2.4.1 Laser Scanning

Three-dimensional laser scanning named LiDAR (Laser Detection and Ranging) has been introduced and used in industry since the 1970s as an advanced imaging technology. Due to the high cost and low reliability of the early devices, this technology did not spread widely until the 1990s [16]. Several technologies, such as computer, optics, and micro-chip lasers came together to form the laser scanner as a high-tech device. Laser scanners can be used to capture the geometry of a construction site accurately and quickly [17]. The output of a 3D laser scanner is a dense point cloud for which each point has three coordinate indices "X", "Y" and "Z" based on the scanner's coordinate system. In fact, the laser scanner records the 3D geometry of objects by collecting thousands or millions of points located on the objects' surfaces.

To this date, many researchers have worked on using laser scanners for tracking new construction and fabrication processes, and developing as-built models of construction sites [18]. However, there is limited research about exploiting the capabilities of laser scanner to record 3D as-built of existing buildings and collect some mandatory information to feed the design and construction of adaptive reuse projects [19]–[21].

2.4.2 Structured Lighting

A structured-light 3D scanner is a device for measuring the three-dimensional shape of an object using projected light patterns (infrared light in Microsoft Kinect and Structure IO) and a camera system [6]. The projector projects speckle patterns on the objects and the sensor calculates the distance of a point to itself. In order to use triangulation, two separate images must be captured. In terms of accuracy, the support group of Structure IO (one of the commercially available scanners, which uses structured light technology) claims that the device can achieve an accuracy of 1% of distance measured. While the accuracy of structured-lighting scanners is significantly lower than laser scanners, the ease of use and acceptable accuracy for small objects has made them an acceptable option for rudimentary modeling efforts.

2.5 Building Information Modeling (BIM)

According to international standards, Building Information Modeling (BIM) is defined as "shared digital representation of physical and functional characteristics of any built object, which forms a reliable basis for decisions" [22]. Predecessors of BIM were used for product modeling, and had wide application in the petrochemical, automotive, and shipbuilding industries [23]. BIM can be categorized as having a narrow to broad perspective, based on its capability and the amount of information contained. Narrow perspective may include 3D (building model), 4D (3D plus construction schedule), and 5D (4D plus cost calculation) models of a building.

On the other hand, BIM with broad perspective goes further and considers the energy and environmental performance of a building. As a matter of fact, the narrow and broad perspectives refer to technical and functional issues of a building, respectively [19].

Until recent years, the use of BIM had been restricted to new construction and earlier stages of the building's lifecycle [19]. However, as BIM enables project teams to precisely manage the building's information along the whole lifecycle [24], it is able to support later stages of life cycle as well. Therefore, BIM can be used to manage maintenance, renovation, deconstruction, adaptive reuse, and the stage of building end of life [25].

Although using BIM for existing buildings has many benefits, such as providing valuable as-built documentation and planning renovation or retrofit projects, research studies have indicated infrequent implementation of BIM for existing buildings. The need for high modeling efforts in order to convert collected data to a BIM, handling uncertain data and objects, and difficulties in updating the BIM of existing buildings have been the main obstacles of implementing BIM for existing buildings [19]. Thus it is valuable to focus on implementation of BIM for existing buildings and research further into this field.

3 Research Methodology

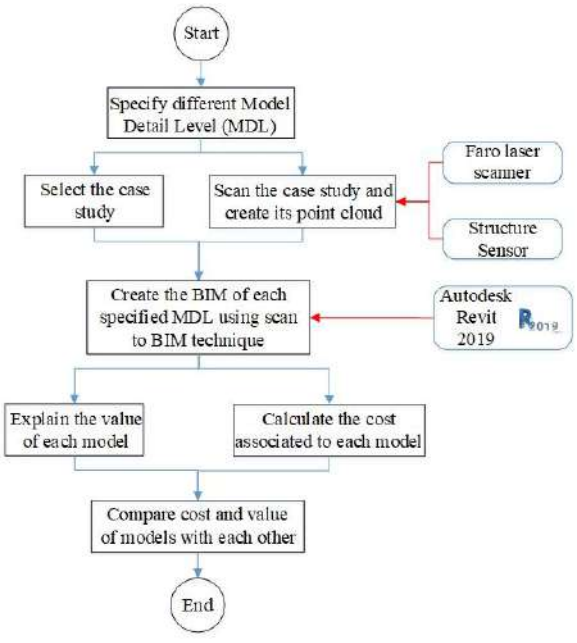

Figure 2. The overview of research methodology

3.1 Model Detail Level (MDL)

3.1.1 Value of Dimensional Information

Collecting dimensions of all physical surrounding is necessary for re-designing a space, whether in renovation or adaptive reuse projects. Furthermore, to optimize the effort required, designers try to minimize the amount of effort required in the disassembly and gutting steps (try to reuse space as much as possible). An important aspect of having a BIM of a project is instantaneous access to all dimensions, such as location of the openings (windows, doors, etc.), location of the elevators and stairs, and the area of spaces in an existing building. On projects where no prior model exists (or they are not accurate) using scan-to-BIM methods can be effective to rebuild an accurate model. As such, having access to the dimensional information resulted from the scan-to-BIM effort is considered as one of the axioms to determine how much effort shall be designated for the process. Access to dimensional information is referred to as "Dimension" and is the only existing value of information provided by MDL 1 models.

3.1.2 Value of Material Information

In addition to the dimensions, it is essential to consider the materials that have been used in an existing building for selecting the most compatible new usage with the prior one. Also, adaptive reuse seeks to fulfil the requirements of environmental sustainability. This goal will be achieved by maximizing the use of existing buildings' materials through recycling, reusing and minimizing the need for new materials. Decreasing the rate of natural resources depletion, greenhouse gas emission, and global warming effects due to lower demand for material production and transportation are benefits of using existing materials. Hence, "Material" of each component is another important type of information that must be considered for designing the adaptive reuse projects.

3.1.3 Value of Disassembly Information

In order to increase the efficiency of recycling and reusing processes, the project team needs to access more detailed information than a building's dimensions and material. Examples of detailed information include the routes of plumbing and wiring networks, location and details of electrical and mechanical facilities, location of sprinklers and smoke detection facilities, type and location of lighting, and location of a building's fixtures and furniture. These kinds of information are called "Disassembly" information, because they will help the project team to efficiently plan for disassembly, recycling and reuse the existing materials.

In this study, the LOD and MMI concepts are utilised, and a new framework that is related to the detail of a

whole design model is defined. This new framework is called Model Definition Level (MDL) and divided to three different levels based on the provided information. A BIM satisfies the requirements of MDL 1 (Dimension information) if contains the dimensional information about an existing building. The BIM will be upgraded from MDL 1 to MDL 2 (Material information) by adding material information of building's components to the model. In addition, adding disassembly information to a BIM that already satisfies the requirements of MDL 2, will upgrade this to MDL 3.

3.2 Case Study

The case study of this conference paper is the Ralph Haas Infrastructure and Sensing Analysis Laboratory, located within Engineering 3 building at the University of Waterloo.

Figure 3. The panorama picture of the case study

The objective is to develop a BIM for each specified MDL by converting the 3D point cloud of the laboratory to the BIM (scan-to-BIM technique). Two different devices including the "Faro Focus M70" laser scanner and the "Structure Sensor" (Structure IO) are used to capture the point cloud. The Faro laser scanner is a professional scanner that can capture up to 488,000 points per second. Its measurement range is between 0.6 and 70 meter, and the ranging error is 3 millimeters. Furthermore, capturing HDR pictures and applying color information to the point cloud is another advantage of laser scanners, which can be useful in the scan-to-BIM process. On the other hand, the Structure Sensor is a structured light scanner which is mounted on Apple iPad. By incorporating an IMU (inertial motion unit) and elements of SLAM (simultaneous localization and modeling), it does real-time registration and does not need manual registration to create the point cloud. Thus, the scanning process is significantly faster when Structure Sensor is used for scanning. Furthermore, the scan registration process using laser scanners requires sophisticated knowledge in post processing software.

Figure 4. Point cloud: Structure IO (left) and Faro (right)

3.3 Developed Models

The captured point clouds are used to develop BIM for each specified MDL. As seen in Figure 4, the captured point cloud using the Structure Sensor does not have enough information (point density, precision and accuracy) to recognize the openings and details of the building fixtures. Therefore, it is only feasible to use it to attain the first MDL (which only contains dimensional values). So, MDL 1 is developed using both point clouds, while MDL 2 and MDL 3 are developed based on the point cloud obtained by the laser scanner.

3.3.1 MDL 1

As explained in section 3.1.1, the first MDL includes only the overall dimensions of the building. The walls, floor, ceiling, windows, and doors are modeled to fulfill the requirements of this MDL. Elements are in the generic state and no material properties are assigned to them. Figure 5 shows the developed BIM model for this MDL using the Structure Sensor and Faro point cloud. Modeling the doors and windows was only feasible based on the Faro's point cloud.

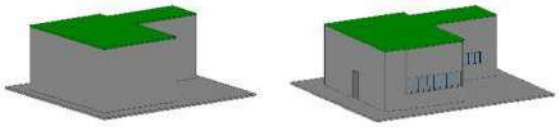

Figure 5. Developed BIM model based on Structure Sensor (left) and Faro (right)

Since a point cloud is a set of discrete points, the placement of a building's elements in the model depends somewhat on the modeller's judgment. Hence, a model's dimensions will be different for the same objects, which are modeled by different modellers. So, to investigate the effect of modellers on the dimensions of BIMs, six different modellers developed the BIMs for the first MDL, using the Structure Sensor and Faro point cloud. The wall height, floor area, and floor perimeter were extracted from each model and the mean value and standard deviation were calculated. According to the Table 1 the coefficient of variation differs from 0.84% to 3.52%, which may seem like a low value, but it is an unacceptable amount of error in absolute dimensions (up to 20 cm) from an engineering design perspective. It may be acceptable from a building operation or maintenance perspective. So, it can be observed, pending more sophisticated experiments and statistical analysis, that inconsistency between different modellers has a more significant effect on error than the type of scanner used in this case.

To compare the accuracy of the Faro laser scanner and the Structure Sensor, the true dimensions of the laboratory are measured by a laser meter. The "wall height", "floor area", and "floor perimeter" are calculated by using the true dimensions, and they are equal to 4.78m, 81.07m^2, and 44.41m, respectively. Also, the error range associated to these parameters are calculated by comparing their true values with the extracted data from the developed models. Figure 6 shows the error percentage range associated to Faro and Structure Sensor. According to this figure, the Structure Sensor dramatically underestimates the dimensions, especially for area and perimeter. On the other hand, the Faro results is closer to the true dimensions, which emphasizes its superior accuracy than Structure Sensor. The error range depends on the modeller's precision during the scan-to-BIM process. The maximum and minimum error range is related to wall height and floor perimeter modeled by Structure Sensor's point cloud, respectively. The error range associated to wall height modeled by the Structure Sensor's point cloud is higher than Faro. While the error range associated to each of the floor perimeter and the floor area is similar for Structure Sensor and Faro.

3.3.2 MDL 2

To develop the second MDL, material information is assigned to elements of the case study. The type of material is retrieved from the Faro point cloud and observations from the project's site. Also, the exact thickness of exterior walls is calculated by comparing the point cloud of the case study from inside and outside view.

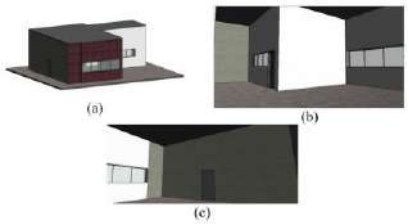

Figure 7. (a) Allocated materials to outside walls (brick cladding, concrete block, dry wall system)- (b) and (c) Allocated materials to inside walls and floor (dry wall system, concrete block, and carpet)

Table 1. The effect of having different modellers on the wall height

	Wall Height (m)		Floor Area (m^2)		Floor Perimeter (m)	
	Structure Sensor (m)	Faro Focus (m)	Structure Sensor (m^2)	Faro Focus (m^2)	Structure Sensor (m)	Faro Focus (m)
Modeller1	4.70	4.83	73.62	78.70	42.6	44
Modeller 2	4.40	4.70	76.21	81.09	42.8	44.40
Modeller 3	4.70	4.80	74.8	80.5	42.5	44.32
Modeller 4	4.90	4.90	74.70	81.5	42.7	44.6
Modeller 5	4.78	4.78	75.30	80.71	42.9	44.4

3.3.3 MDL 3

In this level, detail of plumbing, wiring network, HVAC system, and building fixtures and furniture, including their materials, are added to the BIM.

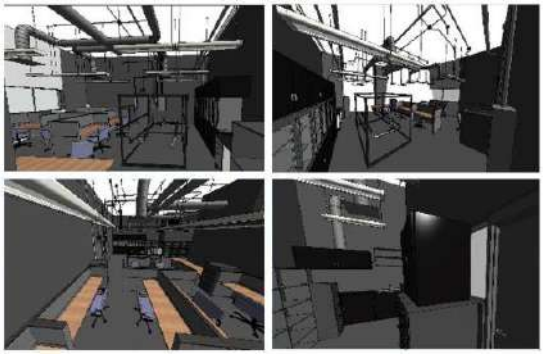

Figure 8. Developed BIM for MDL 3 based on Faro point cloud

3.4 Costs and Benefits

The cost of the scan-to-BIM process includes cost of purchasing a 3D acquisition device, license of BIM software, scanning and registering, and developing the BIM using scan-to-BIM techniques. The average renting cost of Faro M70 is CDN$650 per day. There is no renting option for Structure Sensor and it must be bought at the price of CDN$500. Also, the monthly price of an Autodesk Revit license is CDN$365.

To calculate the cost of scanning and registration, as well as developing the BIM, CDN$100 per hour is considered as the wage of an expert person. The time of completing each activity is multiplied by this wage and the outcome is the cost.

Table 4: The detail of cost calculation

Model Definition Level	MDL1	MDL1	MDL2	MDL3
Type of Scanner	Structure Sensor	Faro	Faro	Faro
3D Acquisition Device	500	650	650	650
BIM Software License	365	365	365	365
Scanning & Registration	17	200	200	200
Scan-to-BIM	33	33	67	2000
Total Cost (CDN$)	915	1248	1282	3215

4 Discussion

The cost of the scan-to-BIM process would increase as the BIM model becomes more detailed. Therefore, it depends on the needs, available budget, and project team's judgment to select which MDL is the most valuable for a project. If the project team is involved in finding a new usage for reviving a building, which is a high level of planning, an approximate estimation of buildings' dimensions might be sufficient for them. In this case, it makes sense to use Structure Sensor and MDL1, which has the lowest cost. At the end, the cost of this alternative would be lower than CDN$915, because of the salvage value of Structure Sensor (it can be sold as a second handed device).

On the other hand, selecting MDL3 will bring more value to an adaptive reuse project if the project involves detailed planning. The cost of this MDL is CDN$3,215. The capability of having exact time and cost estimation, material quantity estimation, disassembly plan, recycle and reuse plan, and design of electrical and mechanical facilities are several values that are provided by MDL3.

When the new usage was selected, and the project team is involved in high level of architectural design (e.g. assigning different spaces to different applications), the planning level is between the two-mentioned boundary level. In this case, MDL1 with Faro, or MDL2 makes more sense and provide both more value and sufficient information to the project.

5 Conclusion and Future Work

Based on the results of this research, the significance of the added value would be different from project to project and it is up to project team to decide which amount of information is optimal.

For the future plan, it is valuable to consider the losses associated to the lack of information in the planning levels and compare this to the cost of developing BIM for each MDL to make a decision in such a way that has the least cost and provides highest value to a project.

Abstract -

To identify and fit geometric primitives (e.g., planes, spheres, cylinders, cones) in a noisy point cloud is a challenging yet beneficial task for fields such as reverse engineering and as-built BIM. As a multi-model multi-instance fitting problem, it has been tackled with different approaches including RANSAC, which however often fit inferior models in practice with noisy inputs of cluttered scenes. Inspired by the corresponding human recognition process, and benefiting from the recent advancements in image semantic segmentation using deep neural networks, we propose BAGSFit as a new framework addressing this problem. Firstly, through a fully convolutional neural network, the input point cloud is point-wisely segmented into multiple classes divided by jointly detected instance boundaries without any geometric fitting. Thus, segments can serve as primitive hypotheses with a probability estimation of associating primitive classes. Finally, all hypotheses are sent through a geometric verification to correct any misclassification by fitting primitives respectively. We performed training using simulated range images and tested it with both simulated and real-world point clouds. Quantitative and qualitative experiments demonstrated the superiority of BAGSFit.

Keywords -

Geometric Segmentation; Primitive Fitting; As-Built BIM

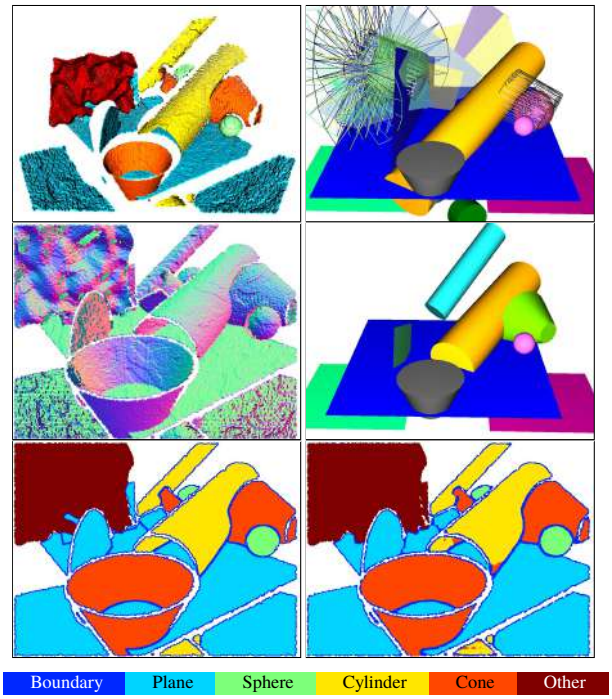

Figure 1: Primitive fitting on a simulated test range image (top left) with BAGSFit (middle right) vs. RANSAC (top right) [4]. Estimated normals (middle left) and ground truth labels (bottom left) are used to train a fully convolutional segmentation network in BAGSFit. During testing, the boundary-aware and thus instance-aware segmentation (bottom right) is predicted, and sent through a geometric verification to fit final primitives (randomly colored). Comparing with BAGSFit, the RANSAC-based method produces more misses and false detections of primitives (shown as transparent or wire-frame), and thus a less appealing visual result.

1 Introduction

The idea of decomposing a scene or a complex object into a set of simple geometric primitives for visual object recognition dates back as early as 1980s when Biederman proposed the object Recognition-By-Components theory [1], in which primitives were termed "geons". Although some real scenes can be more complicated than simple combinations of "geons", there are many useful ones that can be efficiently modeled for the purpose of as-built building information modeling [2, 3], where man-made structures are primarily composed of basic primitives. Also, it is desirable to model individual components in a building separately because they have different functions and were built with different types of material and construction methods. Separated components can then be used in building information modeling systems to carry its relevant semantic information and perform quantitative analysis.

This primitive fitting problem is a classic chicken-and-egg problem: with given primitive parameters, point-to-

*The authors contributed equally. And Chen Feng is the corresponding author.

primitive (P2P) membership can be determined by nearest P2P distance; and vise versa by robust estimation. The challenge comes when multiple factors present together: a noisy point cloud (thus noisy normal estimation), a cluttered scene due to multiple instances of a same or multiple primitive models, and also background points not explained by the primitive library. See Figure 1 for an example. The seminal RANSAC-based method [4] often tends to fit inferior primitives that do not well represent the real scene.

Different from existing work for this multi-model multi-instance fitting problem, we are inspired by human visual perception of 3D primitives. As found by many cognitive science researchers, human "observers' judgments about 3D shape are often systematically distorted" [5]. For example, when looking at a used fitness ball, many people would think of it as a sphere, although it could be largely distorted if carefully measured. This suggests that human brain might not be performing exact geometric fitting during primitive recognition, but rather rely on "qualitative aspects of 3D structure" [5] from visual perception.

Due to recent advancements in image semantic segmentation using convolutional neural networks (CNN) [6,7], it is natural to ask: whether CNN can be applied to this problem with geometric nature and find the P2P membership as segmentation on the range image without geometric fitting at all? Our answer is yes, which leads to the BAGSFit framework that reflects this thought process.

Contributions This paper contains the following key contributions:

- We present a methodology to easily obtain point-wise ground truth labels from simulated dataset for supervised geometric segmentation, demonstrate its ability to generalize to real-world dataset, and released the first simulated dataset [1] for development and benchmarking.
- We present a novel framework for multi-model 3D primitive fitting, which performs both qualitatively and quantitatively superior than RANSAC-based methods on noisy range images of cluttered scenes.
- We introduce this geometric segmentation task for CNN with several design analyses and comparisons.

Related Work Constructive Solid Geometry (CSG) and Boundary Representation (BRep) are the most common 3D representations in building information modeling (BIM) because of their simplicity and flexibility [8]. Both methods model a complex object with a collection of basic primitives. However, creating these models manually can be costly and time-consuming [9], especially for as-built modeling because the dimension of the objects are implicitly constrained by the scanned data. In [8], as-built modeling was separated into several auxiliary tasks, including geometric primitive fitting, point cloud clustering, shape fitting, and point cloud classification. The study of primitive fitting-based as-built modeling in construction mainly focus on the modeling of indoor scene with parametric planar surface [10] or industrial plant with cylinders [9,11]. Such methods lack the capability to deal with complicated buildings with planar walls, cylinder-shaped columns, cone-shaped roofs, and so on. The remaining of this section will investigate existing methods for multi-model primitive fitting.

By assuming the existence of potentially multiple classes of primitives in a scene, it is more realistic than the previous group, and thus more challenging when a cluttered scene is observed with noisy 3D sensors. Previous work with this assumption can be roughly grouped further into the following categories: *Segmentation*: Segmentation methods [12–14] segment a point cloud into individual clusters and performs classification and fitting either during the segmentation or afterwards.

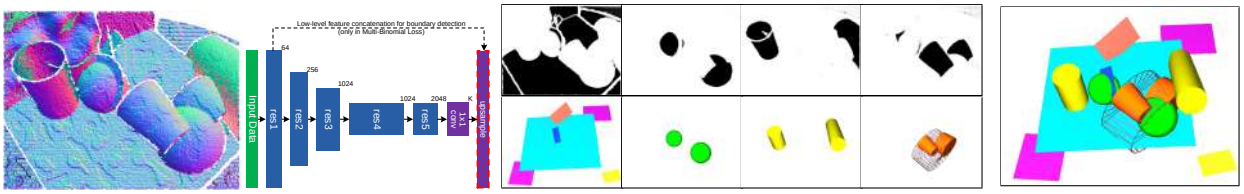
RANSAC: Since the seminal work by Schnabel et al. [4], the idea of selecting sampled primitive hypotheses to maximize some scoring functions becomes a default solution to this problem. In this research, we chose this method as our baseline. In practice, the 3D sensor noise is often more structured (e.g., depth dependent noises for range images) than uniform or Gaussian in 3D as experimented in many of these papers. What really makes the problem difficult is that those noisy points belonging to other partially occluded primitive instances become outliers of the primitive to be fit at hand, causing false detections of "ghost" primitives not existed in the real scene but still with very small fitting errors and large consensus scores, e.g. the ghost cones fitted with cylinder and background points in the top right of Figure 1. More recently, prior probabilities or quality measure of the data [15,16] were used to improve the probability of sampling an all-inlier subset.

Energy Minimization: Unlike the sequential and greedy nature of RANSAC based methods, it is appealing in theory to define a global energy function in terms of P2P membership that once minimized results in desired solution [17–20]. However most of them are only shown on relatively small number of points of simple scenes without much clutters or occlusions, and it is unclear how they will scale to larger datasets due to the intrinsic difficulty and slowness of minimizing the energy function.

2 Framework Overview

Figure 2 gives an overview of the multi-model primitive fitting process by our BAGSFit framework. As introduced

[1] The dataset is available at https://github.com/ai4ce/BAGSFit.



(a) CNN-based Segmentation (b) Geometric Verification (c) Fitted Primitives

Figure 2: BAGSFit overview. In 2a, a proper form of a range image, e.g., its normal map, is input to a fully convolutional neural network for segmentation. We use the same visualization style for the CNN as in [7], where each block means layers sharing a same spatial resolution, decreasing block height means decimating spatial resolution by a half, and red dashed lines means loss computation. The resulting segmentation probability maps $\mathbf{Y}_k$ (top row of 2b, darker for higher probability) for each primitive class k are sent through a geometric verification to correct any misclassification by fitting the corresponding class of primitives (bottom row of 2a). Finally, fitted primitives are shown in 2c. Without loss of generality, this paper only focuses on four common primitives: plane, sphere, cylinder, and cone.

above, the front-end of this framework (Figure 2a) mimics the human visual perception process in that it does not explicitly use any geometric fitting error or loss in the CNN. Instead, it takes advantage of a set of stable features learned by CNN that can robustly discriminate points belonging to different primitive classes. The meaning of a pixel of the output probability map (top row of Figure 2b) can be interpreted as how much that point and its neighborhood look like a specific primitive class, where the neighborhood size is the CNN receptive field size.

Such a segmentation map could already be useful for more complex tasks [21], yet for the sake of a robust primitive fitting pipeline, one cannot fully trust this segmentation map as it inevitably contains misclassification, just like all other image semantic segmentations. Fortunately, by separating pixels belonging to individual primitive classes, our original multi-model problem is converted to an easier multi-instance problem. Following this segmentation, a geometric verification step based on efficient RANSAC [4] incorporates our strong prior knowledge, i.e., the mathematical definitions of those primitive classes, to find the parametric models of the objects for each type of primitives. Note that RANSAC variants using prior inlier probability to improve sampling efficiency are not adopted in this research, because 1) they are orthogonal to the proposed pipeline; and 2) the robustness of primitive fitting is highly dependent on the spatial distribution of samples. Different from spatial consistency based methods [22, 23] mainly dealing with homography detection, in our 3D primitive fitting task, samples with points very close to each other usually lead to bad primitive fitting results [4]. Thus the potential of using the CNN predicted class probabilities to guide the sampling process, while being interesting, will be deferred for future investigations.

The advantage for this geometric segmentation task is that exact spatial constraints can be applied to detect correct primitives even with noisy segmentation results. One could use the inliers after geometric verification to correct the CNN segmentation results, similar to the CRF post-processing step in image semantic segmentation that usually improves segmentation performance.

3 Ground Truth from Simulation

Before going to the details of our segmentation CNN, we need to first address the challenge of preparing training data, because as most state-of-the-art image semantic segmentation methods, our CNN needs supervised training. To our best knowledge, we are the first to introduce such a geometric primitive segmentation task for CNN, and there is no existing publicly available datasets for this task. For image semantic segmentation, there have been many efforts to use simulation for ground truth generation. Yet it is hard to make CNNs trained over simulated data generalize to real world images, due to intrinsic difficulties of tuning a large number of variables affecting the similarities between simulated images and real world ones.

However, since we are only dealing with geometric data, and that 3D observation is less sensitive to environmental variations, plus observation noise models of most 3D sensors are well studied, we hypothesize that simulated 3D scans highly resemble real world ones such that CNNs trained on simulated scans can generalize to real world data. If this is true, for this geometric task, we can get infinite number of point-wise ground truth almost for free.

Although saved from tedious manual labeling, we still need a systematic way of generating both random scene layouts of primitives and scan poses so that simulated scans are meaningful and covers true data variation as much as possible. Due to the popular Kinect-like scanners, which mostly applied in indoor environment, we choose to focus on simulating indoor scenes. And note that this dose not limit our BAGSFit framework to only indoor situations. Given a specific type of scenes and scanners, one

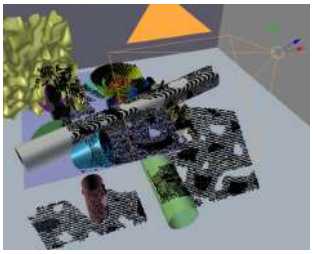


Figure 3: A simulated Kinect scan of a random scene. Black dots represents the scanned points.

should be able to adjust the random scene generation protocols similarly. Moreover, we hypothesize that the CNN is less sensitive to the overall scene layout. What's more important is to show the CNN enough cases of different primitives occluding and intersecting with each other.

Thus, we choose to randomly generate a room-like scene with 10 meters extent at each horizontal direction. An elevated horizontal plane representing a table top is generated at a random position near the center of the room. Other primitives are placed near the table top to increase the complexity. Furthermore, empirically, the orientation of cylinder/cone axis or plane normal is dominated by horizontal or vertical directions in real world. Thus several primitive instances at such orientations are generated deliberately in addition to fully random ones. For planes, two additional disk shaped planes are added to make the dataset more general. To make the training set more realistic, two NURBS surfaces (class name "Other" in Figure 1) are added, representing objects not explained by our primitive library in reality.

An existing scanner simulator, Blensor [24], was used to simulate VGA-sized Kinect-like scans, where class and instance IDs can be easily obtained during the virtual scanning process by ray-tracing. For each scene, we obtain a total number of 192 scans with varying view directions surrounding the scene. Totally 20 scenes were generated following this protocol. 18 scenes, i.e. 3456 scans, were split for training, and the other 2 scenes, i.e. 384 scans, were used for validation. Figure 3 shows the screenshot of such a scan. The test set is generated through a similar protocol, containing 20 scenes (each with 36 scans). Note that invalid points were converted to the zero-depth point avoiding computation issues.

4 Boundary Aware Geometric Segmentation

Our segmentation network (Figure 2a) follows the same basic network as described in [7], which is based on the 101-layer ResNet [25] with minor modifications to improve segmentation performance. While the semantic segmentation CNN architecture is actively being developed, there are several design choices to be considered to achieve the best performance on a given base network for our new task.

Position vs. Normal Input. The first design choice is about the input representation. Since we are dealing with 3D geometric data, what form of input should be supplied to the CNN? A naive choice is to directly use point positions as a 3-channel tensor input. After all, this is the raw data we get in reality, and if the CNN is powerful enough, it should be able to learn everything from this input form. However, it is unclear how or whether necessary to normalized it.

A second choice is to use estimated per-point unit normals as the input. This is also reasonable, because we can almost perceive the correct segmentation by just looking as the normal maps as shown in Figure 2a. Plus it is already normalized, which usually enables better CNN training. However, since normals are estimated from noisy neighboring points, one might have concerns about loss of information compared with the previous choice. And a third choice is to combine the first two, resulting in a 6-channel input, through which one might hope the CNN to benefit from merits of both.

Separate vs. Joint Boundary Detection. When multiple instances of a same primitive class occlude or intersect with each other, even an ideal primitive class segmentation can not divide them into individual segments, leaving a multi-instance fitting problem still undesirable for the geometric verification step to solve, which discounts the original purpose of this geometric segmentation. Moreover, boundaries usually contains higher noises in terms of estimated normals, which could negatively affect primitive fittings that use normals (e.g., 2-point based cylinder fitting). One way to alleviate the issue is to cut such clusters into primitive instances by instance-aware boundaries. To realize this, we also have two choices, 1) training a separate network only for instance boundary detection, or 2) treating boundary as an additional class to be segmented jointly with primitive classes. One can expect the former to have better boundary detection results as the network focuses to learn boundary features only, although as a less elegant solution with more parameters and longer running time. Thus it is reasonable to trade the performance a bit for the latter one. Note that with such a step, we could already move from category- to boundary- and thus instance-aware segmentation by region-grow after removing all instance-aware boundaries.

Handling of Background Class. When generating random scenes, we added NURBS modeling background points not explained by the four primitive classes, for a more realistic and challenging dataset. Thus we need to properly handle them in the CNN. Should we ignore back-

ground class when computing the loss, or add it as an additional class?

For all of the above design questions, we will rely on experiments to empirically select the best performing ones.

5 Geometric Verification and Evaluation

5.1 Verification by Fitting

Given the predicted probability maps $\{\mathbf{Y}_k\}$, we need to generate and verify primitive hypotheses and fit primitive parameters of the correct ones to complete our mission.

One direct way of hypothesis generation is to simply binarize the BAGS output $\{\mathbf{Y}_k\}$ by thresholding to produce a set of connected components, and fit only one k-th class primitive for a component coming from $\mathbf{Y}_k$. However, when the CNN incorrectly classify certain critical regions due to non-optimal thresholds, two instances can be connected, thus leading to suboptimal fittings or miss detection of some instances. Moreover, a perfect BAGS output may bring another issue that an instance gets cut into several smaller pieces due to occlusions (e.g., the top left cylinder in Figure 2a). And fitting in smaller regions of noisy scans usually result in false instance rejection or lower estimation accuracy. since the core contribution of this paper is to propose and study the feasibility of BAGS-Fit as a new strategy towards this problem, we leave it as our future work to develop more systematic ways to better utilize $\{\mathbf{Y}_k\}$ for primitive fitting.

In this work, we simply follow a classic "arg max" prediction on $\{\mathbf{Y}_k\}$ over each point, and get K groups of hypothesis points associated to each of the K primitive classes. Then we solve K times of multi-instance primitive fitting using the RANSAC-based method [4]. Note this does not completely defeat the purpose of BAGS. The original RANSAC-based method feed the whole point cloud into the pipeline and detect primitives sequentially in a greedy manner. Because it tends to detect larger objects first, smaller primitives close to large ones could often be missed, as their member points might be incorrectly counted as inlier of larger objects, especially if the inlier threshold is improperly set. BAGS can alleviate such effects and especially removing boundary points from RANSAC sampling is expected to improve its performance.

5.2 Primitive Fitting Evaluation

It is non-trivial to design a proper set of evaluation criteria for primitive detection and fitting accuracy, and we are not aware of any existing work or dataset that does so. It is difficult to comprehensively evaluate and thus compare different primitive fitting methods partly because 1) as mentioned previously, due to occlusion, a single instance are commonly fitted into multiple primitives, both of which may be close enough to the ground truth instance; and 2) such over detection might also be caused by improper inlier thresholds on a noisy data.

Pixel-wise average precision (AP) and AP of instances matched at various levels (50~90%) of point-wise intersection-over-union (IoU) are used for evaluating image based instance segmentation problems [26]. However, this typical IoU range is inappropriate for our problem. More than 50% IoU means at most one fitted primitive can be matched for each true instance. Since we don't need more than 50% of true points to fit a reasonable primitive representing the true one, this range is over-strict and might falsely reject many good fits: either more than 50% true points are taken by other incorrect fits, or during observation the true instance is occluded and split into pieces each containing less than 50% true points (see Figure 5 for more examples). After all, a large IoU is not necessary for good primitive fitting.

Thus, the IoU is replaced by intersection-over-true (IoT) in this problem. It indicates the number of true inliers of a predicted primitive over the total number of points in the true instance. Thus, a predicted primitive and a true instance is matched iff 1) IoT>30% and 2) the predicted primitive having the same class as the true instance. This indicates that one instance can have at most 3 matched predictions.

Based on the above matching criteria, a matched instance (if exists) can be identified for each predicted primitive. On the contrary, each true instance may have several best matching prediction candidates. To eliminate the ambiguity, the candidate that has the smallest fit error is selected as the best match. To be fair and consistent, fitting error is defined as the mean distance to a primitive by projecting all of the points in the true instance onto the predicted primitive. After the matches are found, *primitive average precision* (PAP) and *primitive average recall* (PAR) are used to quantify the primitive detection quality.

$$PAP = N_{p2t}/N_p, PAR = N_{t2p}/N_t, \quad (1)$$

where N_{p2t} is the number of predictions having a matched true instance, N_p the total number of predicted primitives, N_{t2p} the number of true instance with a best prediction, and N_t the total number of true instances, all counted over the whole test set.

6 Experiments and Discussion

6.1 Geometric Segmentation Experiments

Network Short Names. To explore answers to the questions raised in section 4, we designed several CNNs and their details with short names are listed as follows:

Table 1: Geometric segmentation evaluation. Red highlights the best along a column, and magenta for the top 3 best.

	Precision						Recall						IoU						F1						Accuracy
	BND	PLN	SPH	CYL	CON	AVE	BND	PLN	SPH	CYL	CON	AVE	BND	PLN	SPH	CYL	CON	AVE	BND	PLN	SPH	CYL	CON	AVE

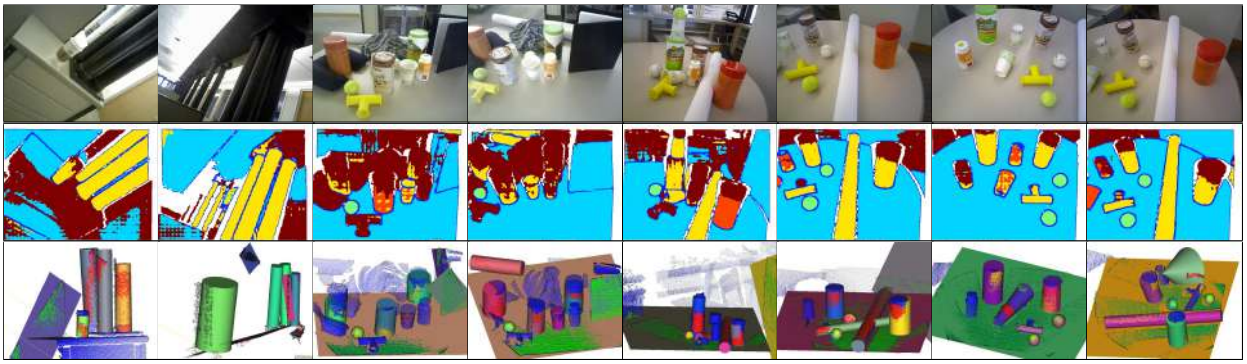

Figure 4: BAGSFit (**N5+BAGS**) on real Kinect scans. Top: RGB image of the scanned scene. Middle: segmentation results. Bottom: fitted primitives (randomly colored) rendered together with real scans.

- **P/N/PN**. Basic networks, using position (**P**), normal (**N**), or both (**PN**) as input, trained with a multinomial loss function, outputting a 4-channel *mutual-exclusive* class probability maps (i.e., each pixel's probabilities sum up to one, $K = 4$). Background class points, the NURBS, are ignored for loss computation.
- **N+BAGS**. Network trained with normal input and BAGS labels (i.e., instance-aware boundary as an additional class jointly trained, $K = 5$).
- **N5**. Same as basic network **N** except treating the background class as an additional class involved in loss computation ($K = 5$).
- **N5+BAGS**. Same as **N+BAGS** except trained using a multi-binomial manner (i.e., boundary and NURBS are two additional classes jointly trained, $K = 6$).
- **N+BO**. Same as **N** except only trained to detect boundary (i.e., a binary classifier, $K = 2$).

Implementation Details. We implemented the geometric segmentation CNNs using *Caffe* [27] and *DeepLabv2* [6]. Normals were estimated by PCA using a 5×5 window. We use meters as the unit for networks requiring position input. Instance-aware boundaries were calculated if not all pixels belong to a same instance (or contain invalid points) in a 5×5 window. Input data size was randomly cropped into 440×440 during training time, while full VGA resolution was used during test time. All of our networks were trained with the following hyper-parameters tuned on the validation set: 50 training epochs (i.e. 17280 iterations), batch size 10, learning rate 0.1 linearly decreasing to zero until the end of training, momentum 0.9, weight decay 5e-4. The networks were trained and evaluated on several NVIDIA TITAN X GPUs each with 12 GB memory, with a 2.5Hz testing frame rate.

Discussions. Evaluation results of all 12 networks on the test set of 720 simulated scans are in table 1.

1. Comparing the **P/N/PN** rows, we found that normal input turned out to be the best, and interestingly outperforming combination of both normal and position. This may be caused by the difficulty in normalizing position data for network input.
2. Comparing the **N** with **N+BAGS**, we found that adding additional boundary detection to the segmentation only have very small negative influences to the segmentation performance. This is appealing since we used a single network to perform both segmentation and boundary detection. Further comparing the **N+BAGS** with **N+BO**, we found that BAGS in fact increases the boundary recall comparing to **N+BO** that only detects boundaries.
3. Comparing the **N5** with **N**, we found that the effect of ignoring background class is inconclusive in terms of significant performance changes, which however suggests the benefit of jointly training the background class, as this enables the following steps to focus only on regions seemingly explainable by the predefined primitive library.

Just for reference, we tried SVM using neighboring 7×7 or 37×37 normals or principal curvatures for this task, and the highest pixel-wise accuracy we obtained after many

Table 2: Primitive fitting evaluation. Red highlights the best along a column, while magenta highlights the top 3 best.

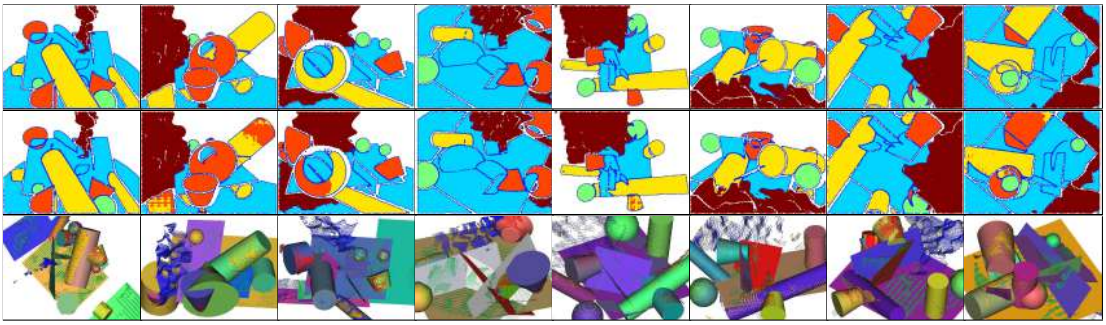

Figure 5: BAGSFit (**N5+BAGS**) on simulated test scans. Top: Ground truth labels. Middle: segmentation results. Bottom: fitted primitives (randomly colored) rendered together with real scans.

parameter tuning is only 66%.

Generalizing to Real Data. Even though we did not tune the simulated scanner's noise model to match our real Kinect scanner, Figure 4 shows that the network trained with simulated scans generalizes well to real world data.

6.2 Primitive Fitting Experiments

For fitting primitives, we used the original efficient RANSAC implementation [4] both as our baseline method (short name **ERANSAC**) and for our geometric verification.

Experiment Details. We used the following parameters required in [4] for all primitive fitting experiments, tuned on the validation set in effort of maximizing **ERANSAC** performance: min number of supporting points per primitive 1000, max inlier distance 0.03m, max inlier angle deviation 30 degrees (for counting consensus scores) and 45 degrees (for final inlier set expansion), overlooking probability 1e-4. The simulated test set contains 4033 planes, 1256 spheres, 2338 cylinders, 1982 cones, and in total 9609 primitive instances.

Discussions. Using respective network's segmentation as input to the geometric verification, the primitive fitting results were evaluated on the simulated test set and summarized in table 2 together with the **ERANSAC** baseline.

1. **ERANSAC** performance is significantly lower than most variants of BAGSFit, in accordance with our qualitative evaluation.
2. **N5** related experiments receives highest PAP scores, which is reasonable due to the recognition and removal of background classes that greatly reduce the complexity of scenes.
3. In terms of average fitting error, **N+BAGS** < **N**, **N5+BAGS** < **N5** which strongly supports the benefit of BAGS as mentioned in section 5.1.
4. **N5+BAGS** gets the lowest fitting error, benefiting from both background and boundary removal.

More results. Figure 5 shows more testing results.

7 Future Work

Our next step is to compare BAGSFit with MaskR-CNN [28], quantitatively evaluate it on real scans, and apply it in as-built BIM generation. We also plan to extend the network so it can directly predict primitive parameters.

Abstract –

Building Information Modeling (BIM) covers the whole lifecycle of a building and facilitates the coordination of activities in the design, construction, and operation stages. However, during the design stages of pre-construction, it is time-consuming for a BIM project team to resolve design clashes as they integrate models finished by individual team members into a composite master model. To effectively overcome the issue, this study proposes a computer programming system. Based on the application programming interface provided by BIM software, a simulated annealing algorithm is employed to determine the layout modifications to minimize the number of design clashes. In this paper, the mechanical, electrical and plumbing (MEP) systems in a clean room on the first floor of an integrated circuit assembly factory are used to validate the effectiveness of the proposed system. The experimental results reveal the feasibility and effectiveness of the proposed system.

Keywords –

Building information modeling; Clash resolution; Simulated annealing algorithms

1 Introduction

As building information modeling (BIM) software matures, BIM is gradually becoming conventional in both design and construction practice worldwide [1]. As first defined in the National BIM Standard–United States®, a BIM model is a digital representation of the physical and functional characteristics of a facility. As such, BIM serves as a shared knowledge resource for information about a facility, forming a reliable basis for decisions during its life cycle from inception onward [2]. In addition to helping in the design stage, BIM provides decision makers with the ability to make informed decisions across the lifecycle, in the construction stage [3], the project closeout stage [4], and the facility management stage [5]. BIM has also become a platform for project management teams to collaborate [6]. Through the digital portal provided by BIM software, team members such as architects, structural engineers, and mechanical, electrical and plumbing (MEP) engineers can collaborate on a design and share their knowledge of a construction development at the design, construction, and post-construction stages [7]. During the design stages of pre-construction, BIM models finished by team members are integrated into a composite master model, which is then tested to detect design clashes [8], The design clashes defined in [6] are 'positioning errors', where building components overlap each other when original individual designer models are merged. During the construction phase, rework caused by design clashes undetected in the pre-construction stage is usually costly. However, resolving these design clashes is a time-consuming task and is imperative to project performance [9]. Obviously, it presents a great challenge for project team members to ensure there are no clashes in a composite master model within a reasonably short time, even with the use of BIM software.

In addition to the modeling functions, BIM software provides an application programming interface (API) for users to effectively achieve multitudinous applications of BIM models. In previous studies, Mangal and Cheng [10] employed a hybrid genetic algorithm (GA) and the API provided by BIM software to develop an automatic system for the optimization of steel reinforcement in RC buildings. Lin and Lin [4] took advantage of API to propose a final as-built BIM model management system

for owners to handle the inspection, modification, and confirmation work beyond project closeout. Based on a repetitive trial-and-error procedure, Xue and Lu [11] presented a novel segmentation-free, derivative-free optimization approach that translates as-built BIMs from two-dimensional images into an optimization problem of fitting BIM components within architectural and topological constraints. Moreover, to evaluate the overall thermal transfer value of the building envelope and the cost of construction, Lim and Majid [12] developed a BIM-GA optimization method by using the functionalities of BIM software, Autodesk Revit, the iterated learning of GA, and the computer programming of PHP. In fact, their method [12] can also be achieved by directly using the API provided by Revit.

To facilitate designer to resolve the clashes, numerous emerging model collaboration systems, such as EXPRESS Data Manager and BIM 360, have been developed to make it possible to have the ability to manage the coordinated workflow required for clash resolution. However, this function still requires human intervention [15].

To automatically resolve the design clashes in a composite master model, this study developed an effectively system by using the API provided by Revit to control building components and adopting a simulated annealing (SA) algorithm [13] to implement iterated learning to simulate coordination cycles. In consideration of the fact that when some clashes are resolved, other clashes may occur, the iterated learning process of the SA algorithm is used. Heuristic optimization methods, such as GA and SA, have been extensively applied to searching the fittest solutions of combinatorial problems. Single thread processing is more efficient for design clashes resolving problem. Therefore this paper adopts SA. The related works such like Hackl, et al. [14] utilized SA to determine the optimal restoration programs for transportation networks. To tackle the search issue in BIM projects. Zeferino, et al. [16] present an efficient simulated annealing (SA) algorithm for solving a regional wastewater system planning model. Focusing on MEP systems, our program detects design clashes with their coordinates and then makes modifications to building components, such as moving or revising them, to gradually minimize the number of design clashes. In the experiment, we tested our system on a real case that occurred during the compilation of a federated BIM model for the MEP systems in the clean room in a factory. The new layout of the MEP systems could be taken as the suggested prototype for the discussion of clash resolution in the design team meeting.

The remainder of this paper is organized as follows: Section 2 introduces the simulated annealing (SA) algorithm. Section 3 explains the proposed system. Section 4 addresses the experimental data and discusses the experimental results. Finally, Section 5 provides the conclusion to this paper.

2 Simulated Annealing Algorithm

The SA algorithm proposed by Kirkpatrick and Gelatt [13] is an extension of the Monte Carlo (MC) method and is widely applied to approximating the global optimum in combinatorial problems. The name SA comes from annealing in metallurgy, wherein the states of molecular structures of a material are changed by heating and cooling. Heating and cooling the material affects both the temperature and the thermodynamic free energy. SA thus employs MC to generate random samples to simulate the states of a thermodynamic system. Unlike MC, which is a completely random method, SA has a mechanism to control the movement of molecules as the temperature decreases to make a converged learning process. The learning process of SA is briefly described in pseudocode in Figure 1.

```
// s0: a given initial state (solution)
// itermax: the maximum iteration number
// T0: a given initial temperature
function SimAnneal(s0, itermax , T0)
    s = s0; // Set current states as s0
    T = T0; // Set current temperature T as T0
    i=1; // Set the iteration number as 1
    while (i ≤ itermax)
        // Create a feasible neighbor state snew
        snew = CreateOneNeighbor(s);
        // The energy function which updates T according to
        iteration times
        T = UpdateTemperature(i, T);
        // Check if accept snew under T
        if Cost(s) ≤ Cost (snew)
            s = snew; i++;
        else
            // Giving an opportunity of accepting a worse snew
            if P(Cost(s), Cost(snew), T) ≥ Random(0, 1)
                s = snew; i++;
            end if
        end if
    end loop
    return s;
end function
```

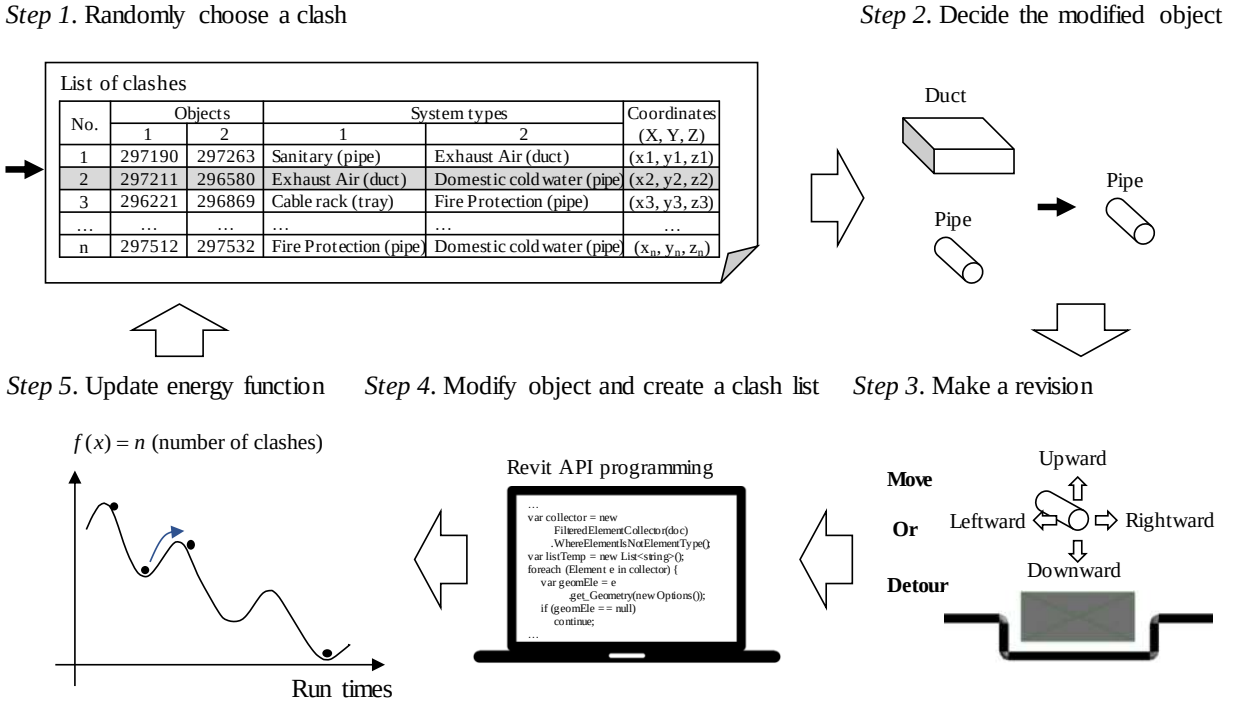
3 The Proposed System Framework

The objective of this study was to develop an effective programming system to automatically resolve the design clashes of MEP systems when BIM models finished by individual team members are integrated into a federated BIM model. The iterated learning process of the proposed system has five steps, as shown in Figure 2. Through the API provided by Revit, attributes of building components such as types, shapes, lengths, widths, and

positions (coordinates) can be controllable and revisable, and even clash coordinates can be detected. More information about the use of the Revit API is available on the official Revit website(http://www.revitapidocs.com/). Below, we will first explain the definition of the clash list used in our system, since the clash list is the core of our system. Then the five steps in Figure 2 will be addressed.



No.	Objects		System types		Coordinates
	1	2	1	2	(X, Y, Z)
1	297190	297263	Sanitary (pipe)	Exhaust Air (duct)	(x1, y1, z1)
2	297211	296580	Exhaust Air (duct)	Domestic cold water (pipe)	(x2, y2, z2)
3	296221	296869	Cable rack (tray)	Fire Protection (pipe)	(x3, y3, z3)
…	…	…	…	…	…
n	297512	297532	Fire Protection (pipe)	Domestic cold water (pipe)	(x_n, y_n, z_n)

Figure 2. The five steps in the iterated learning process of the proposed system

3.1 Definition of Clash List

The core of our system is the clash list, which is created by our programming through the Revit API, and the mission is to minimize the number of detected clashes. An example of a clash list is provided in Table 1, in which there are three main attributes: objects, systems, and three-dimensional coordinates.

Table 1. An example of a clash list used in this study

No.	Objects		System types		Coordinates
	1	2	1	2	(X, Y, Z)
1	297190	297263	Sanitary (pipe)	Exhaust Air (duct)	(x1, y1, z1)
2	297211	296580	Exhaust Air (duct)	Domestic cold water (pipe)	(x2, y2, z2)
3	296221	296869	Cable rack (tray)	Fire Protection (pipe)	(x3, y3, z3)

1. The “objects” attribute shows a pair of building components whose geometric shapes intersect. The values of the objects are the identifiers (id) given by Revit.
2. The “systems” attribute lists the MEP systems to which the two intersected objects belong.
3. The “coordinates” attribute is the three-dimensional position of the clash between object 1 and object 2, plotted in three values of X-axis, Y-axis, and Z-axis. Based on a clash coordinate and the shape profiles of the two objects, our program can revise an object or decide on a moving distance of an object, or the whole system, from the original coordinates to a new position to avoid the clash.

3.2 The Operation Principles

The operation principles are used to determine which of the two objects should be modified and what revision options can be selected in a clash instance. There are two principles, the priority of systems and the available revision options. It is notable that these principles can be experience-based, case-based, or country-based.

According to the case examined in this study, the contents of the two principles are briefly described as follows:

1. Based on [13], the priority order of MEP systems and the reasons are listed in Table 2, in which parts of the system names have been revised to be consistent with the words used in Revit. For example,

if the systems of object 1 and object 2 are "Fire Protection (pipe)" and "Domestic cold water (pipe)", respectively, object 2 should be chosen for revision, rather than object 1.

2. The revision options for MEP objects are defined in Table 3, in which the circles denote the action options available for an object. For instance, "Sanitary pipe" has two possible revision actions, "Moving" and "Sloping", while "Duct" only has the "Moving" action. Note that only the revision action "Moving" is available when our system determines to execute a revision on a whole MEP system to which object 1 or object 2 belongs. Moreover, a brief description of the three revision actions are summarized in Table 4.

Table 2. The priority order for sequential comparison process (source [13] and revised in this paper)

System	Priority/special notes
Exhaust Air (duct)	Usually first due to large size of components
Supply Air (duct)	Follows HVAC Dry due to interdependence of these systems
Sanitary (pipe)	Design criteria for slope essential for system performance
Process piping	Takes the first priority if critical to manufacturing process
Fire Protection (pipe)	Most flexible routing, especially small diameter pipe
Domestic hot/cold water (pipe)	Lower priority because less difficult to re-route
Cable rack (tray)	Flexible routing within safety and architectural requirements
Control systems	Flexible routing but must limit bend radius for pneumatic tubes
Telephone/Data communications	Flexible routing but must limit bend radius for fiber optic cables

Table 3. The revision options for MEP objects

Actions	Sanitary pipe	Duct	Cable rack	Other pipes
Moving	○	○	○	○
Revising			○	○
Sloping	○			

Table 4. The descriptions of revision actions

Actions	Descriptions
Moving	Move an object or a system upward, downward, leftward, or rightward to avoid clashes.
Revising	Make a pipe or a cable rack take a roundabout way to avoid clashes.
Sloping	Adjust the slope of a sanitary pipe to avoid clashes. The minimum acceptable ratios of slopes are defined as 1:100 in USA and 2:100 in Japan. This revision action is only applicable to sanitary pipe.

3.3 The Learning Steps

In this subsection, we present the five steps in Figure 2, which are an iterated learning process in our system. Below, the details of the five steps are explained.

Step 1. Randomly select a clash instance from the clash list as a start of the current iterated learning. Suppose that the No. 2 instance in Figure 2 is chosen.

Step 2. For the selected clash instance, decide which of object 1 and object 2 should be chosen for modification according to the priority order of their systems, as mentioned in section 3.2. For the No. 2 instance, for example, since the systems of object 1 and object 2 are "Exhaust Air (duct)" and "Domestic cold water (pipe)", respectively, object 2 should be chosen for revision.

Step 3. Revise the object or its system as decided in *Step 2* through Revit API. Here, we define a parameter $\theta \in [0, 1]$ as the criterion to determine whether the revision is executed on an object or its whole system. Moreover, we also define a random seed (*rs*) drawn from a uniform distribution [0, 1] as a tester. The revision action that will be taken depends on the following conditions:

1. When $rs \leq \theta$, the modification will be made on the object. According to Table 3 and the object's system, randomly choose an action to make the modification. For example, the candidate actions for object 2 (a pipe) are "Moving" and "Revising".
2. When $rs > \theta$, the modification will be made on the object's system. Our system will then move the whole system.

After deciding to revise an object or its system, the proposed system will compute the spatial information of the object as a reference for the decision on revision actions. The spatial information is the available distance aggregated in the four directions (up, down, left, and right) of the object. First, our system calculates the minimum moving distances based on the geometric parameters of object 1 and object 2, such as the widths, lengths, and heights, and the clash coordinates obtained from the Revit API. In the example shown in Figure 3, it is better to move the pipe upward or downward rather than leftward or rightward. Then our system will compute the distances between an object and the objects of the other systems in its neighborhood and the limit of vertical clearance. In Figure 4 (a), for example, there is a grey pipe under the black pipe. If the black pipe were moved downward to avoid the original clash, a new clash between the two pipes would occur, as shown in Figure 4 (b). Accordingly, the black pipe should move farther to

avoid the new possible clash. The direction having the minimum aggregated distance is adopted for movement, and a construction tolerance (five cm in this study) is added to the aggregated distance to prevent an imprecise construction collision from being caused by insufficient distance. In this study, the action "Revising" is only applicable when the direction is determined to be up or down. Note that once an object is moved, parts of the objects in the same system, such as its branches or the object from which it branches, would need to be accordingly moved and corresponding lengths added or subtracted.

The steps from *Step 1* to *Step 3* are actually the content in the function **CreateOneNeighbor** in SA in Figure 1. The pseudo code of the function **CreateOneNeighbor** is provided in Figure 5.

    α; // the criterion to decide moving or revising
    while
        c = GetOneRandomClashInstance(s);
        o = DetermineRevisingObject(c, θ);
        // in some case, d does not exist because of g
        if IsMinDistanceExist(o, t, g, ref D, ref d);
            if D is up or down and o is object
                if Random(0, 1) ≥ α
                    Move(o, D, d);
                else
                    Revision(o, D, d);
                end if
            else
                Move (o, D, d);
            end if
            return false;
        end if
    end loop
end function
```

Figure 5. The pseudocode of creating a neighbor solution for SA

Step 4. According to the revision action decided in Step 3, a revision is executed on an object or its system and then a new list of clashes is output through our program and Revit API. This step is the function **Cost** in SA in Figure 1.

Step 5. Record the number of clashes and update the energy function to decrease temperature.

According to the operation in SA, when temperature is higher, the algorithm has a higher probability to accept a worse solution to escape from the current local area. Nevertheless, as iteration times increase, it becomes less likely that a worse solution will be accepted.

4 The Experiment

In this section, we will briefly introduce the profile of the proposed case and then discuss the experimental results.

4.1 The Proposed Case

The proposed case is the MEP systems in a clean room on the first floor of an integrated circuit (IC) assembly factory, as shown in Figure 6. The clean room has four MEP systems, as listed in Table 5, and the four MEP systems have a total of 50 Revit elements (excluding fittings). When the first MEP design models finished by team engineers were integrated into a federated BIM model, 20 clashes were detected (red circles in Figure 6).

The 20 clashes and their clash coordinates are listed in Table 6. Below, the two places marked 1 and 2 in Figure 6 are presented as examples in Figures 7 and 8, respectively, to show the clash status.

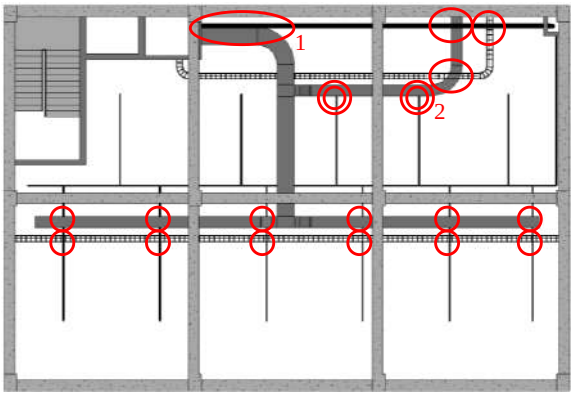

Figure 6. The floor plan of the first floor of the factory

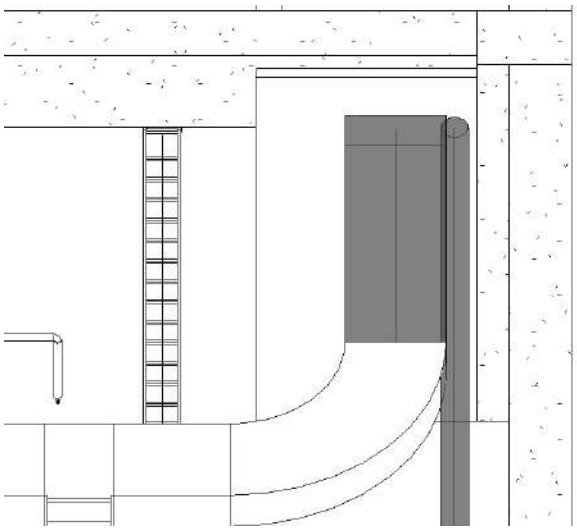

Figure 7. The clash between a duct and a sanitary pipe

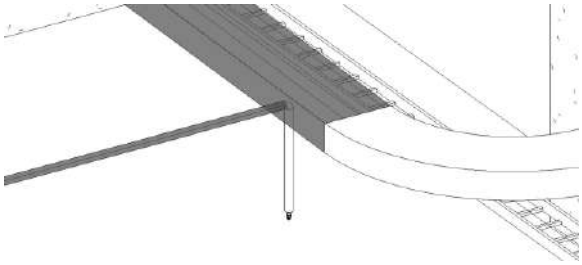

Figure 8. Two clashes between a duct and two pipes

4.2 The Experimental Results

The objective of the proposed system was to resolve the MEP clashes listed in Table 6. The strategy of this study was to set moving as the first priority, i.e., α in Figure 5 is 0.95. The experimental results are summarized in Table 7 and drawn in Figure 7.

Table 7. The details of experimental results

Runs	Clash Numbers	Time (Seconds)
1	14	4.410
2	10	5.822
3	8	5.757
4	2	5.916
5	1	5.788
6	0	5.746
		33.440

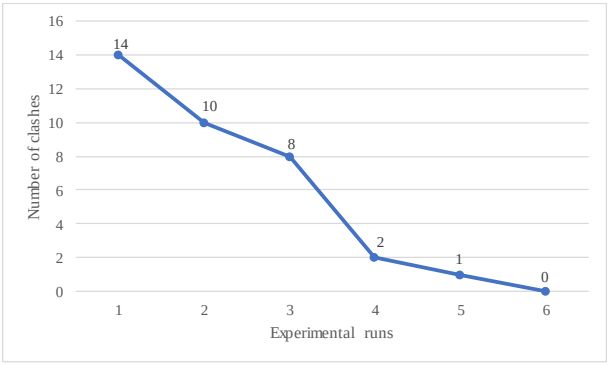

Figure 9. The trend of experimental results

As shown in Figure 9, the clashes were resolved very quickly, in 33.44 seconds. In the first run, six of the twenty clashes were resolved. Although the proposed case is rather simple, it indicates that the proposed system can provide BIM team members an initial reference for further discussions on clash resolution. For comparison with the two examples in Figures 7 and 8, the automatic resolutions are shown in Figures 10 and 11.

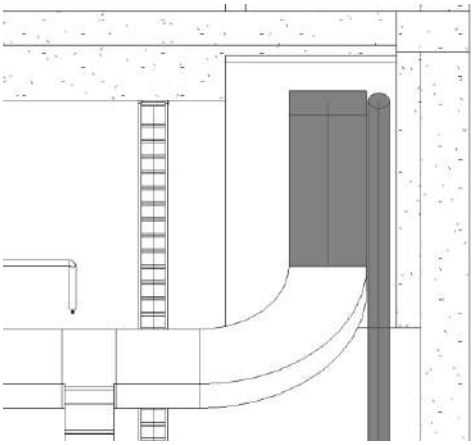

Figure 10. Automatic resolution of a clash between a duct and a sanitary pipe

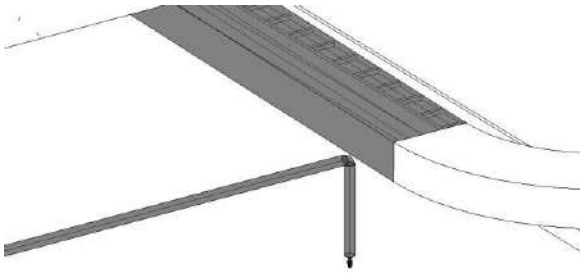

Figure 11. Automatic resolution of two clashes between a duct and two pipes

5 Conclusion

During the design stages of pre-construction, it is time-consuming for a BIM project team to resolve design clashes as they integrate models finished by individual team members into a composite master model. To automatically resolve design clashes, we designed a programming system by employing SA and API provided by Revit. In this paper, a real case of the MEP systems in a clean room in an IC-Assembly factory was employed. In the case, twenty design clashes were detected when the BIM models were merged. The case was used to evaluate the effectiveness and feasibility of the proposed system. The experimental results showed that the twenty design clashes were automatically resolved within a very short time. The revised BIM model can serve as a reference for team members in discussions of how to resolve design clashes. Although the experimental results indicated that design clashes can be automatically resolved in this way, the proposed system still needs more specific guidelines to ensure suitable revisions of building components, rather than random revisions.

Abstract –

Automation in construction manufacturing is becoming increasingly common due to the drive for higher productivity and increased quality. One important consideration in the implementation of automation is the training and maintenance of the equipment. This study proposes an approach to assess the training for assembly/disassembly and maintenance of machines developed for the construction manufacturing industry by using immersive virtual reality (VR). The application of VR allows the collection of data such as the time required to complete the task, the distance travelled, the identification of ergonomic risks (e.g., awkward body posture), and the layout effectiveness, as well as the observation of multiple users performing an identical task under laboratory circumstances. Moreover, VR significantly reduces the costs associated with real mock-ups and the time required for implementation as it allows testing machine designs in a virtual environment that mimics the machine's real operation setting. To demonstrate the proposed approach, a case study (i.e., VR experiment) is conducted. The primary objective of the case study is to use VR to assess the effectiveness of training using the VR environment for maintenance, and the complexity of the task (i.e., the amount of time needed to understand the task). The VR experiment is performed inside an office room dedicated exclusively for that purpose where participants can move freely, and interactions with the virtual environment are possible through the utilization of a headset and wireless controllers. During the experiment, information is collected both by manual observation and automatic extraction of data from the computer. Based on the analyses of the data collected, the average time to complete the task is determined, and potential areas of design improvement are identified.

1 Introduction

The implementation of visualization, communication, and information technologies by the construction industry has been confirmed as a powerful approach to optimize and integrate industrial processes [1]. Virtual Reality (VR), for instance, has proven to be an integrating tool that supports communication between different stakeholders as well as decision-making processes, especially during the design phase [2]. In the past years, several studies were conducted to investigate the application of VR in the construction industry, focusing on a variety of areas such as virtual prototyping [3–5], ergonomic analysis (e.g., detection of unsafe body motions and unsafe worker behaviour) [6–8], safety hazard detection [9–13], construction equipment training [14–19], and educational purposes [2,20,21].

In terms of training, VR offers the possibility of effective training while reducing significantly cost and safety risks related to mock-ups [16,22]. Investments in training strategies are essential to ensure that employees are continuously improving their skills to accurately and safely perform tasks [23]. According to Rezazadeh et al. 2011 [16], VR can assist training since, by utilizing VR, the user has the sensation, to some extent, of performing the activity as he/she would perform it in reality. Besides the mentioned capability, VR also allows users to practice how to perform a task/activity without pressure due to costs, the inability to complete the task, and risk of hazards inherent to real mock-ups [24]. In terms of the impact of the presentation medium used to provide safety training, Leder et al. [25] compare an immersive VR and a Microsoft PowerPoint presentation. Results obtained conclude that the investment on costly equipment for VR safety training is not cost-effective since Microsoft PowerPoint developed with realistic figures and scenes has a similar impact on user risk

perception and learning outcomes [25].

The application of VR technologies to educational purposes is also explored by researchers. Sampaio et al. [2] use 3D modelling techniques and VR to develop models to represent several construction processes. Based on the results obtained, it is determined that introducing 3D models and VR techniques in schools assist students to learn and prepare them to use these technologies in their professional practice. Pan et al. [20] perform a state-of-art research on the concept of VR applied to learning, training, and entertainment, and concludes that the application of VR can enhance, motivate and stimulate learners' understanding of certain events. In addition, it is identified that learners learn faster and are happier using virtual environments than they are when using conventional learning methods [20]. Goulding et al. [21] investigate the utilization of VR to provide a risk-free environment for training construction tasks. The primary goal of Goulding et al. [21] is to stimulate multidisciplinary learning between different construction professionals during the design phase, since faulty work, safety, and health issues are often caused by decisions taken in this stage.

In light of the information provided, it is noted that research has been carried out in the area of VR and the construction manufacturing industry; however, there is still a research gap on VR applications with emphasis on training, especially in terms of machine assembly/disassembly tasks. In this context, the aim of this paper is to design and test a VR experiment to evaluate how two training techniques (i.e., VR experiment and a printed instruction manual) impact the performance of a user conducting a maintenance task.

2 Methodology

This project is the first phase of a larger experiment that will test the effectiveness of VR on training in a construction manufacturing setting. This phase was done to validate the design of the experiment. The overall outline for the project can be seen in Figure 1. This paper will cover the section labelled 'experimental design and testing phase'.

2.1 Experimental Design and Hypothesis

The hypothesis to be tested by this experiment is that users carrying out a maintenance task for the first time in real life will be more successful after completing a training sequence in a virtual reality training environment than users trained by reading an instruction manual. The first run of the experiment was done to analyze the success of the experimental design in testing this hypothesis and to determine whether there were factors that had not been previously considered that should be designed for in the full run of the experiment.

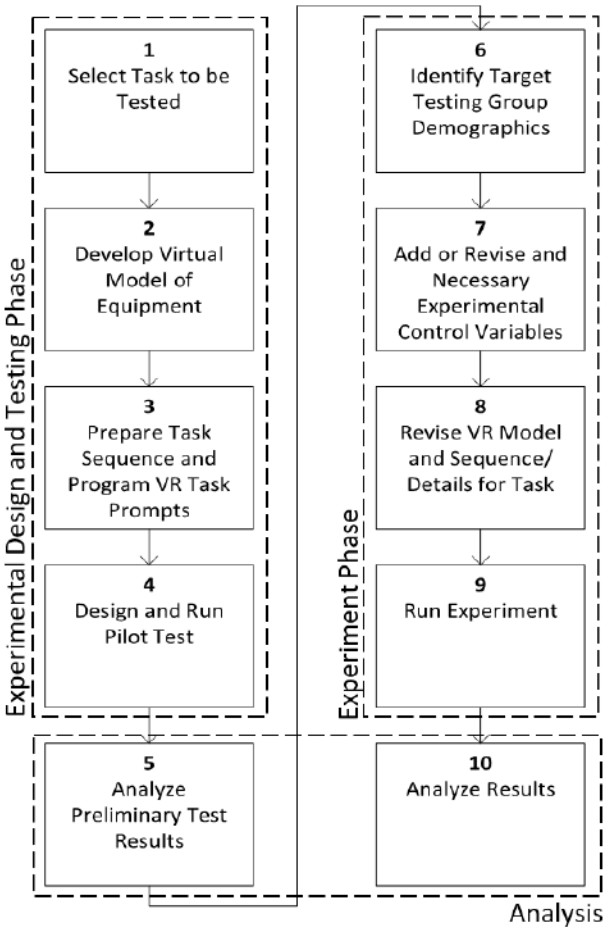

Figure 1. Project outline for testing the effectiveness of virtual reality training for tasks in construction manufacturing and equipment maintenance

2.2 Virtual Environment Design

The VR application used for this experiment was built on the Unity game engine and assets were created using 3DS Max and Photoshop. Standard game engine asset creation workflow was used including using low poly models with baked normal maps and textures to improve performance. Programming was done inside Unity using the C# language. The headset used was an HTC Vive with one hand controller and the application was run on a powerful desktop using a GTX 1080 ti video card. The active physical area of the application was 8' × 8'.

The application itself was developed by a multidisciplinary team including mechanical engineers, construction engineers, a programmer and one digital artist. The 3D model of the machine was based on

SOLIDWORKS files of the real-life machine that was built in our lab. In this way we were able to perfectly match the real life machine that was used for this experiment with the virtual one.

2.2.1 User Experience

An account of the user experience of the VR application is as follows. The user spawns facing the machine fully assembled (since it is to be disassembled first). The controller can have various tools attached to it; however, to begin, it has a placeholder for a hand. To the left of the user is a table with tools that can change the controller placeholder. This is pictured in Figure 2.

Figure 2. Tool selection in VR environment

Behind the user is a table onto which disassembled parts can be arrayed before they are put back together. This table is seen in Figure 3. The task to be performed next is highlighted in yellow, as can be seen in both Figure 3 and Figure 4, for reassembly and disassembly steps, respectively.

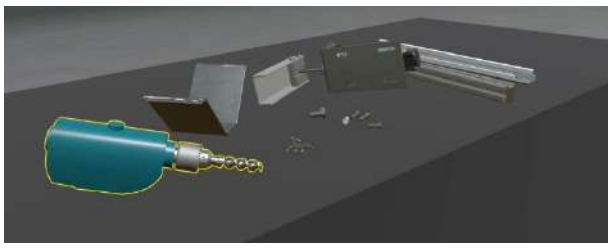

Figure 3. Prompt for the next step of assembly in the VR environment

Figure 4. Disassembly prompt with tool in the VR environment

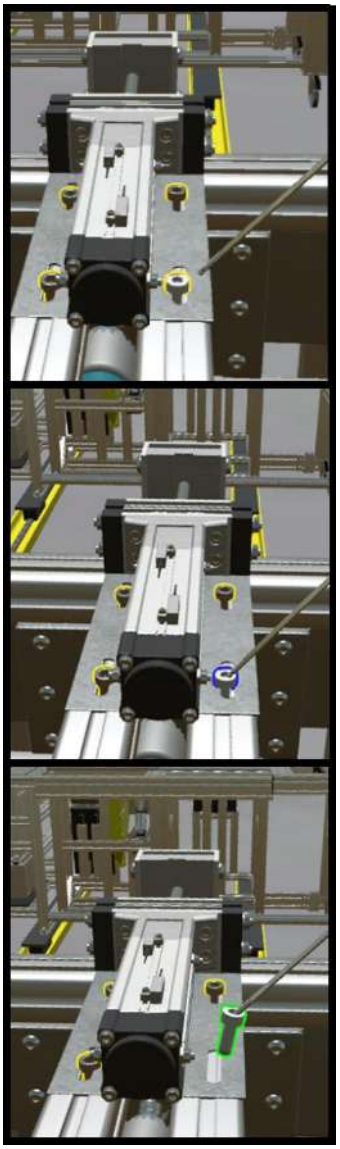

Figure 5. Sequence of colour prompts in the VR training environment

The first step is to take apart screws that connect the top clamp of the machine to the frame. Before detaching the screws, the correct tool must be selected; therefore, as the user first spawns, the tool needed to unfasten these first screws is highlighted in yellow on the table to the left of the user that contains the tools. The user must place the controller (with the hand placeholder) over this tool (that is highlighted in yellow) and activate the controller trigger button. The controller swaps the hand placeholder with the tool and now the screws of the clamp are highlighted in yellow. The user must place the tool in the correct place over one of the screws and activate the controller trigger. Now the screw is attached to the tool and can be moved away from the machine and placed on the table behind the user. When the controller is placed over any yellow part, that yellow part turns blue in order to signify that the controller is touching that part. Parts turn green when the user activates the trigger and the step is completed successfully. This sequence of colour prompts can be seen in Figure 5.

In this manner, by always highlighting the next part in yellow, by giving feedback when the controller is in the right place in blue and highlighting completed steps in green, the user always knows what to do next and whether they are doing things correctly. Over the course of the VR application the user is guided through one full disassembly and one full assembly, and, in theory, he/she would gain a solid understanding of these processes.

2.2.2 Advantages

In theory, the VR training application has the potential to be more engaging from the point of view of the user. VR enables him/her to experience the physicality of the space in relation to the physicality of their own body. In the VR environment the user can freely look to observe the machine and its parts from the same angle and point of view as they would in real life. Moreover, they have ability to reach with their hand into the space and as such they gain an understanding of their own ability to reach into various parts of the machine and to possibly make observations in regard to safety or ease of use that would be impossible to arrive at by looking at a photograph, a technical drawing or written instructions. Moreover, due to the design of the training module, the user is only ever concerned with what to do next and can focus on tasks knowing that the training module will guide them along. The experiential qualities of VR applications are unique and can lead to insights that cannot be arrived at through other means. This allows designers or industrial machinery to test user experience and behaviour in relation to machine operation in ways not previously possible.

2.2.3 Disadvantages

Disadvantages mostly revolve around technical limitations. These include the inability to observe one's body in the space. Currently most VR applications do not allow the user to observe their own hands and body. At best, it is possible to create a 3D model of the user, but even in that case there is a disconnect between one's sense of one's real body and the virtual avatar that acts as a stand-in. Moreover, our application does not account for the user's actual hands. The controller has a placeholder for those instances when the user must use their hands. This is a poor substitute, especially in a training module where using one's hands to put parts together and take them apart is the key component. In order to address this problem, the researchers would have to implement a motion capture system that accounts for hand motion. Hand motion capture is technologically challenging and an area in which advances are being attempted by specialists in that field.

2.3 Experiment Setup

The experiment was carried out in a research facility for three days. Volunteers were randomly assigned to either learn in the VR training environment or by reading an instruction manual. They were then each given six minutes to study the material or use the VR training system. A participant completing the VR training portion can be seen in Figure 6. Next, they were taken to see the physical model for the first time and were tasked with completing the same steps as they were trained. Participants were notified that they would be recorded and scored based on their ability to complete the task, but were not told how aspects of their performance would be weighted when determining their score. Additional instructions on how to perform the task (e.g., bolts do not need to be fully tightened) were given to all participants.

Figure 6. Participant completing the virtual reality training activity before the evaluation activity

2.4 Participants

In total, seventeen people participated in the experiment. Based on how they received instructions to perform the task, they were randomly (as mentioned in the previous subsection) divided into two groups: (1) VR and (2) instruction manual. The VR group had five male and four female participants, while the instruction manual group had five males and three females. All participants were part of the same research group as the authors—the majority of participants, fourteen in total, were graduate students (either master or doctoral students) and three were part of the administrative team. All participants have an engineering background with the exception of two participants, one from each group, and all were under forty years old.

2.5 Data Collection and Analysis

Once the training portion of the experiment was completed, the participants were asked to complete the task on a prototype of the machine. Participants were timed (disassembly time, reassembly time, and total time), as well as marked on the quality of the work completed. This information was used to analyze the differences between the learning methods and performance. A participant completing the last step in the assembly of the prototype machine can be seen in Figure 7.

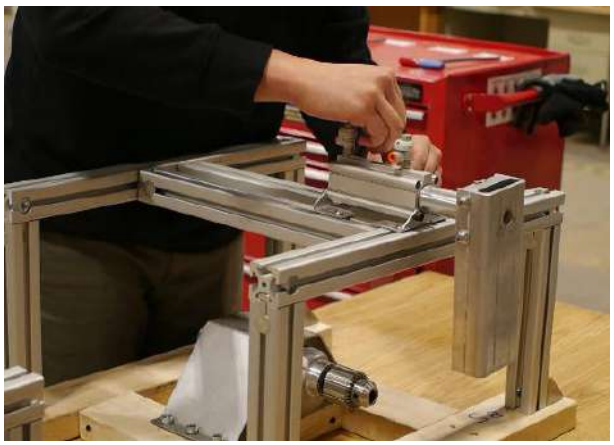

Figure 7. Participant completing the assembly of the prototype

Table 1 shows the number of participants trained in the VR environment or by reading the instruction manual split by gender and by the qualitative aspects of their performance in the experiment, including the final state of the equipment and their organization while completing the task.

Table 1. Count of participants split by training method, gender, and qualitative results

		Count	
		Virtual Reality	**Instruction Manual**
Gender	**Male**	5	5
	Female	4	3
Final State of Equipment	**Operable**	5	7
	Inoperable	4	1
Organization	**Organized**	5	7
	Unorganized	4	1

Table 2 shows the average time taken to complete the task for the participants based on their training type and results. In general, the participants trained using the VR were slower at completing the task. Another interesting observation is that the participants who were able to assemble the prototype so that it was operable again were faster than the ones who left it in an inoperable state.

Table 2. Average time to complete task split by training method, gender, and qualitative results

		Average Time (mm:ss)	
		Virtual Reality	**Instruction Manual**
Gender	**Male**	14:53	11:54
	Female	22:47	16:57
Final State of Equipment	**Operable**	16:31	12:18
	Inoperable	20:45	24:16
Organization	**Organized**	18:40	14:03
	Unorganized	18:03	12:03

3 Results and Discussion

This preliminary run of the experiment allowed for the identification of several parameters that should be identified and possibly controlled for in the next set of experiments. These parameters include the complexity of the project, the deviations from the script in the VR environment that can occur during the test, and the age, experience, and profession of the people completing the experiment.

Figure 8 shows the relationship between the time to assemble/disassemble the equipment in the test. It can

be seen that there is little to no correlation between these times for the population tested in this phase of the experiment. This may be due to the simplicity of the task and we expect to see an increased correlation to these times if the complexity of the task is increased.

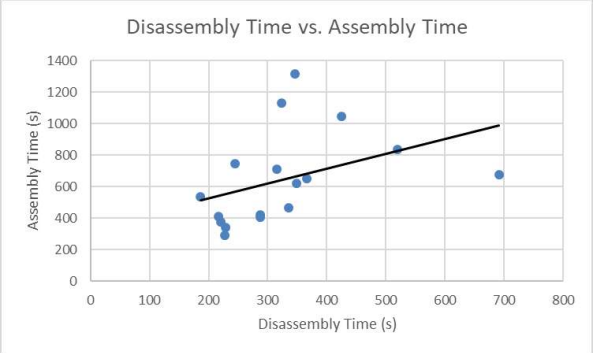

Figure 8. Test results showing the relationship between the time to disassemble and assemble the equipment for each participant

Most of the volunteers were graduate students with undergraduate degrees in engineering. This background would indicate that these volunteers are comfortable with quickly learning through demonstration or reading and analyzing problems.

The complexity of the task is another important factor to consider in the design of the experiment. The task that was used for this demonstration was relatively simple and, given some time, it can be expected that even without the training participants would be able to complete the task. This prompts a separate research question—at what level of complexity does VR training start to outperform text-based training methods, if at all?

Another important observation was the deviations from the VR script. One example of this was how some bars often fell apart when participants loosened them too much, but in the VR training the same bars could simply be slid out of the way. One of these bars can be seen in Figure 9. This prompts an important question regarding the time required to prepare the VR training and what should be included, because as the complexity of the task increases more deviations from the planned path are possible.

4 Limitations and Future Work

This investigation was limited by a relatively small number of tests, as well as by limited diversity in the test group, since all the participants were employed in an office setting and most were graduate engineering students. In the future, the experiment will be expanded to include a demographic that is more aligned with that for whom the VR training technology is to be developed.

Future testing will also be expanded to include more possible deviations from the expected scenario to increase how realistic the VR experience is for the users. Tool orientation, pressure, and level of looseness or tightness that should be accomplished in the disassembly and assembly of the prototype were also issues for the participants. There are several possible solutions to this that could be investigated, including animations of the tools when the right location is selected in the VR environment, or VR options that produce haptic feedback and allow for better tool orientation in the environment.

Figure 9. An example of one deviation from the VR script that occurred in the test

5 Conclusion

As mentioned, this experiment was done to validate the experimental design for a larger evaluation of the effectiveness of VR training on construction manufacturing and maintenance tasks, which will be continued in the future. This test will be repeated with a more applicable and diverse demographic and the task will be modified based on the results of this test. The complexity of the task will be adjusted and the ability for users of the VR to view the proper tool orientation and use will be added.

Since in this test, while the number of participants was limited, the VR users were on average slower and less successful at completing the task, it can be concluded that adding more technology to the training method may not always be necessary; however, more testing needs to be done to determine if, with an increasing task complexity and length, the VR training method may become more effective than traditional training methods.

Acknowledgement

The authors appreciate the technical writing assistance of Jonathan Tomalty and Kristin Berg. In addition, special thanks to Mingjun Zhao, for his

assistance in programming the VR sequence, Hossein Abaeian for insights during the development of 3D models in the VR environment, Anas Itani for assisting with the experiment setup, as well as to all volunteers that participated in the experiment.

Abstract –

Process mining is an emerging tool kit to discover, analyze, and improve workflows. In the construction industry, projects can be large and unique in terms of costs and durations. In such projects, commercial software that support analyses and decision making may be helpful. Process mining software allow construction companies to quickly discover benchmark workflows, conduct conformance checking, and analyze root causes. However, engineers who initially format the event logs, and users who use the event logs for analyses may not share the same knowledge or values. Due to the lack of understanding, knowledge, or experience in these respective domains, companies may not have documented the event logs in the most practical way. With the poorly structured event logs, the software may not be able to provide the most accurate analyses. Therefore, there is a need to pre-process event logs so as to improve their quality. This paper examines a case study on Engineering Change Request (ECR) in the construction industry to explain the importance of pre-processing the event logs before importing them into the commercial process mining software. For large complex projects, the improved quality of event logs will reduce confusion between engineers and analyzers and improve the accuracy of the analysis results produced by the process mining software.

Keywords –

Process mining; Event log; Pre-processing

1 Introduction

Process mining, which is a powerful tool in analyzing workflow and improving its efficiency, has been widely used in the academic fields of many different industries, such as healthcare [1] and banking [2]. Because of their standardized processes and the process mining software's ability to deal with big data, process mining has been successful in these industries. Disco, ProM, and Celonis are some example software that have been used in different research [3]–[5]. In the construction industry, the management of workflow makes the processes easier to monitor and control. Collecting and analyzing event data using data mining techniques allow people to track and validate the processes [6]. Process mining uses event logs to perform analyses on workflows. Event logs record information including Case IDs, Activities, Timestamps, and Attributes (such as people, costs, and locations). As process mining aims at utilizing information in event logs to discover, monitor, and improve processes, the quality of the data imported to the software will greatly affect the clarity and effectiveness of process mining [3].

After uploading the event logs, the commercial software creates a discovered model and conducts conformance checking, bottleneck analysis, and root cause analysis. These analyses provide meaningful insights regarding the efficiency of the existing workflow. However, when importing the event logs into the software, the software may have difficulties in analyzing the event logs, if they are poorly structured. Meanwhile, users may also have trouble in understanding the results. For example, the event logs could have ambiguous naming when multiple activities share the same activity name. Hence, there are needs to pre-process the event logs to minimize the ambiguity and enhance the understanding for the users and analyses from the software. This may include the formatting of the event log names, timestamps, and adding or deleting certain logs.

According to Suriadi et al. [3], a "high-quality" event log is defined as the one with minimal information loss, which is also valid in the context of the domain and for the analysis purpose. Resulting from manually recording the data, poor-quality event logs have missing data, incorrect data, imprecise data and irrelevant data. In this context, to clean up event logs means to address these issues by correcting the errors if possible. However, in this paper, the event logs are assumed to have all the information required, including activity names, timestamps, and attributes. A "high-

quality" event log is thus defined as a structured data that minimizes the confusion and maximizes the ease and clarity for both software and users to analyze and interpret the workflow.

This paper focuses on pre-processing event logs to improve their quality both on their format and content. An event log including 58 cases of Engineering change requests (ECR) of a mega-construction project was used as a case study. The case study elaborated on the importance of the clarity and accuracy of the activity names and timestamps of event logs. Therefore, companies should be aware of pre-processing the event logs before manipulating them if they want to take full advantage of process mining.

2 Literature Review

Construction projects can happen over a long period of time due to large scope. The planning, design, construction, and maintenance stages can take years to happen and complete. In the meantime, construction projects are prone to delays [7]. High uncertainties due to the weather, resources or changes can result in delays. Recent studies have focused on the automation of change management in construction industry to minimize the delays caused by change management [8]. The processes of construction projects have been the area that the researchers and engineers consider as important and try to standardize [9], [10]. When time is the main concern, process mining may provide suggestions by analyzing the patterns from timestamp records. Despite the fact that process mining has been introduced to other industries to minimize the delay and improve the efficiency of the workflow, few companies have adopted process mining in the construction industry. Process mining has shown potential to help in managing construction projects. Due to the long timespan of capital projects, process mining techniques, such as bottleneck analysis and root cause analysis, could be applied to project workflows to find where delays usually occur and what their causes may be. The information could be used to improve the workflow of the latter project stages. The advantage of applying process mining techniques to the same project is that it will produce more accurate results where the time, location, and human factors are most likely to remain the same.

Process mining takes event logs to automatically obtain process models and check conformance. In this case, event logs are considered as construction information whose quality will be important [11]. Moreover, event logs are the main foundation data to identify bottlenecks and deviations, suggest improvements, and predict processing time. For process mining, event logs are the raw data that need to be dealt with to construct models and analysis. The quality of the data, both form and content, is critical in order for the process mining exercise to be successful [12]. Anomalies and impurities lead to higher cost and less benefit for data processing, potentially making it less applicable to the clients [13]. Therefore, pre-processing event logs to improve their quality before conducting a process mining analysis is a necessary task. However, this pre-stage to clean the data for process mining is often overlooked because the task is considered tedious. The proper handling of potential problems and challenges of event logs should be taken care of before moving on to recording logs [14], [15]. In addition, there are also studies to find patterns after event logs are recorded and diagnose the issues afterwards [16], [17]. This paper focuses on ways to pre-process event logs before conducting further analyses, preventing potential confusion and errors. This includes activity definitions and timestamp alignment.

3 Pre-processing Event Log Framework

Although event logs existed before, how to manage and use event logs were not thoroughly investigated. This paper discusses how to improve the quality of event logs to deliver the meanings and intentions better. While there may be many overlaps, there is no consensus on how to define an event log. Therefore, suggested methodology in this paper may not be the unique path to build the data. However, this methodology will be a stepping stone especially for the construction management domain where there are various participants and activities involved throughout a process. In this section, a general framework to obtain a high quality event log is presented. An event log is a combination of "Case ID", "Activity", and "Timestamp" as the main components. Thus, clarifying these three areas of information can be beneficial.

Especially when it comes to activity names, some information can be added or simplified. In order to pursue clarification, the first task is to differentiate two different activities that share one activity name. If this step is skipped, high confusion is expected once the event log is recorded. Usually, activity names include actions. However, in construction management processes, there are many tasks with the same actions but executed by different position performers. In other words, if only actions without performers are included, overlaps may exist which can create confusion. Therefore, in this study, the form of "Action + Performer" is recommended. This way, clarity can be achieved. Note that "performer" and "user" need to be distinguished. "Performer" refers to a participant who is involved in the process, here, the ECR process. "User" on the other hand, refers to the process analyzer.

Additional information can be provided through attributes. However, in this paper, Case ID, Activity, and Timestamp are the main interests. When naming the activities, the authors recommend to use the form of "Verb" + "by/to Noun" for consistency.

The next task would be regarding timestamps. Every case has a different path from start to end. For some cases, errors exist, and completion time information does not exist. For other cases, the case is not formally closed but ends abruptly. Such cases should be treated differently so that the users can extract as much information as possible. Timestamps that receive "NULL" for the completion time by the workflow software have several reasons. First, the activity happened instantly which means the start time and end time are the same. If an activity is informational (notifications) and is automatically generated by the software, this requires no further action from the participants who get it. Second, when certain activities are not completed by the designated performer, the ECR is sent to another performer or again to the original performer automatically. When this happens, the original performer's previous activity receives a "NULL" by most workflow software such as LANA, Celonis, etc. Third, if an activity is not completed by the user before the predefined due date, the activity receives a "NULL" as the timestamp. Fourth, when the action is performed by a group of performers and there exists at least one "NULL" for the completion time, the performer who got "NULL" will receive a timeout warning. However, performers who completed the action in time may also get a timeout warning. For the timeout warning activities, the performers may again receive "NULL". Fifth, there are abort cases which includes "NULL" for the completion time. A summary on the common problems in event logs and their solutions can be seen in Figure 1.

4 Case Study

A case study was conducted to show some ways to pre-process the event logs before uploading them into the process mining software. The data used in the case study was regarding 58 cases of the Engineering Change Request (ECR) in a mega construction project. Figure 2 summarizes the problems of the raw event data that the user attained.

The first problem observed was the duplicated names. As shown in (1) in Figure 2, the activity "Change Request Participants Verification" happened twice. However, the activities were performed by different performers. This can be inferred from the fact that one was followed by "Review (Engineer)" whereas the other one was followed by "Review (Participants)". Considering the fact that "participants" were also ambiguous, the activity "Change Request Participants Verification" should be further analyzed and re-named properly.

The second problem shown in (2) was regarding the "action (performer)" format. Some activities such as "Review (Participants)" and "Approve (Engineer)" included the action performer in the brackets. However, activities such as "Rejected Notification" and "Rejected Close Out" did not include the action performer nor recipient. This is the inconsistent format mentioned in the framework.

The third problem was ambiguous definition. For example, in the raw event log, there existed confusion in "Approve (Engineer)." It turned out that this can mean both approve and reject based on each case.

The fourth problem was missing critical information, such as reasons for warnings. The fifth problem was the timestamp format. Problems shown in (6) and (7) were both regarding the "NULL" completion time. The "NULL" timestamps happened due to a couple of reasons which will be elaborated in section 4.2.

No	Activity		No	Timestamp	
	Problem	Solution		Problem	Solution
1	- Duplicated names	- Rename into different names	5	- Inconsistent format	- Consistent format
2	- Inconsistent format	- Consistent format (Action + Performer)	6	- Missing values due to instant occasion	- Data imputation (e.g. completion time = start time)
3	- Ambiguous definitions	- Remove ambiguity	7	- Missing values due to overtime or group recipients	- Data imputation
4	- Missing information	- Additional information	8	- Missing values in abandoned activities	- Ignore the missing values

Figure 2. Raw event logs and their problems

4.1 Activity Names

Activity names are one of the most crucial components in event logs as they tell users what happened. Therefore, it is important to name the activity names properly and clearly. This section talks about some naming issues encountered during the process mining analysis of the case study and how they were solved. These problems include duplicated names, ambiguous naming and missing information, which had caused confusion.

4.1.1 Duplicated Names

The overview of the raw data can be seen in Figure 2. From the raw data, it can be seen that in Case 216, the activity "Change Request Participants Verification" was followed by two different activities, "Review (Engineer)" and "Review (Participants)". This proves the fact that the "participants" did refer to different groups of performers. When analyzing the processes using software, the activity "Change Request Participants Verification" caused confusion as they were considered as one activity due to the same activity name.

Based on their following activities, "Change Request Participants Verification" was renamed as "Change Request Participants Verification (Engineer)" and "Change Request Participants Verification (Participants)" respectively. "Change Request Participants Verification (Engineer)" was later renamed as "Verify Senior Engineer by Coordinator" whereas "Change Request Participants Verification (Participants)" was later renamed as "Verify Engineer by Senior Engineer."

4.1.2 Activity Name Format

The data set has eighteen different activities in total as shown in Figure 3, referred as original activity names. By observation, there are four problems regarding the naming of the event logs. Firstly, the activity names started with different parts of speech. Majority of the activities started with verbs. However, activities such as "Notification Approved" and "Notification Rejected" started with nouns. After consideration, all the activities were decided to start with verbs for they indicated the actions of each activity clearly.

Secondly, some activity names included the performers / recipients involved, but some did not. For example, the activity "Approve (Engineer)" clearly indicated that the performer who approved the change was the engineer. However, the activity "Verify Detail" did not specify who was the performer that had verified the detail.

Thirdly, some activity names were ambiguous on the individuals who performed or received the action. For example, the terms "Approver" and "Participants" are ambiguous pronouns and not proper nouns that identify real roles or positions in the construction project, which also caused confusion.

Ideally, the activity names should be unique, clear and straightforward. By looking at the activity names, users should be able to know what the action was, who performed the action, and whom the action affected. To make the action clear, the activities have been structured to start with verbs. For example, the name "Notification Approved" means to send out the notification of approval to relevant recipients, although it can be

interpreted as the notification is approved to be sent out. To avoid the confusion, "Notification Approved" has been renamed as "Notify All Relevant Participants of the Approval".

No.	Original Activity Names	New Activity Names
1	Approve (Approver)	Approve/Reject by Assistant Project Manager
2	Approve (Approver) Warning	Timeout Warning to Assistant Project Manager
3	Approve (Engineer)	Approve/Reject by Senior Engineer
4	Approve (Engineer) Warning	Timeout Warning to Senior Engineer
5	Approve (Manager)	Approve/Reject by Project Manager
6	Approved (Close out)	Approved (Close out by Coordinator)
7	Change Request Draft	Initiate Engineering Change Request by Initiator
8	Change Request Participants Verification	Verify Engineer by Senior Engineer
9	Change Request Participants Verification	Verify Senior Engineer by Coordinator
10	Notification Approved	Notify Approval to All Relevant Participants
11	Notification Rejected	Notify Rejection to All Relevant Participants
12	Rejected (Close out)	Rejected (Close out by Coordinator)
13	Review (Engineer)	Review by Senior Engineer
14	Review (Engineer) Warning	Review Timeout Warning to Senior Engineer
15	Review (Participants)	Review by Engineer
16	Review (Participants) Warning	Review Timeout Warning to Engineer
17	Rework	Rework by Initiator
18	Verify Details	Verify Details by Coordinator

Figure 3. Original activity names vs new activity names

To make the action performer and recipient clear, there was an investigation on the hierarchy of the positions and roles involved. Firstly, the "Approver" is not a real position title in the construction company. It is a temporary role, and in this case, it anonymizes the person responsible and results in ambiguous information. As approvers approve and reject the engineering change request, they were identified as the assistant project managers who are at the higher position in the company with the authority to approve or reject the change requests. Note that the names of positions can be flexible, e.g. project director can be added as approver. "Participants" who reviewed the change requests were interpreted as engineers whereas "Engineer" who verified "Participants" were thus inferred as senior engineers. The summary of the original and the new performers'/recipients' names has been shown in the Figure 4.

Moreover, the activity "Approve (Approver)" could mean that Approver approved the change request, or it could also mean that Approver's action or decision was approved. To clearly differentiate the action performer from the action recipient, action performers were added to the activity names as "by someone" whereas action recipients were added to the activity names as "to someone". Realizing that Approver was the one who approved the change request, the activity "Approve (Approver)" was renamed as "Approve by Approver" which was eventually renamed as "Approve/Reject by Assistant Project Manager" as shown in Figure 3.

No.	Original Performers/Recipients Names	New Performers/Recipients Names
1	Approver	Assistant Project Manager
2	Manager	Project Manager
3	Engineer	Senior Engineer
4	Participant	Engineer

Figure 4. Original vs. new performers' / recipients' names

4.1.3 Ambiguous Activity Names

After having carefully investigated the event logs, it could be seen that some activities were not defined properly. For example, by looking at the activity name "Approve (Approver)", users might interpret it as such that the approver has approved the engineering change request. However, in the case shown in the Figure 5, "Approve (Approver)" was followed by "Rejected Notification". Hence, it could be induced that the activity "Approve (Approver)" does not necessarily mean approving. Instead, it refers to the process of making the decision on whether to approve or reject the change request. Therefore, to minimize the confusion, the activity "Approve (Approver)" was renamed as "Approve / Reject by Approver", which was later renamed as "Approve / Reject by Project Manager". Similarly, "Approve (Engineer)" was renamed as "Approve / Reject by Senior Engineer" and "Approve (Manager)" was renamed as "Approve / Reject by Assistant Project Manager." The summary of the original activity names and the new activity names can be seen in the Figure 3.

Case ID	Activity	Start Time	Completion Time	Name	Current Status
15	Change Request Draft	5-10-11 0:43	5-10-11 0:58	Amy	Submit
15	Verify Details	5-10-11 0:59	5-10-11 14:34	Faisal	Send On
15	Change Request Participants Verification	5-10-11 14:34	5-10-11 14:36	Faisal	Send On
15	Review (Engineer)	5-10-11 14:36	5-11-11 19:53	Rudy	Send for Approval
15	Approve (Approver)	5-11-11 19:54	NULL	Andrew	Closed
15	Approve (Approver) Warning	5-15-11 23:00	5-19-11 14:37	Andrew	Reject
15	Rejected Notification	5-19-11 14:38	NULL	Randy	Deleted
15	Rejected Notification	5-19-11 14:38	NULL	Rudy	Deleted
15	Rejected Notification	5-19-11 14:38	NULL	Ken	Deleted

15	Rejected Notification	5-19-11 14:38	NULL	Amy	Deleted
15	Rejected Close Out	5-19-11 14:38	5-19-11 17:18	Faisal	Send On

Figure 5. Event logs regarding "Approve (Approver)"

4.1.4 Missing Information

When investigating the event logs, there was a set of activities named with warnings. The warning events are missing values as the activity names did not indicate

which type of warnings they were. For example, these warnings could mean exceedance of costs, resources or time. The warning activities can be seen in Figure 6. In all the cases, the warning activities were followed by the normal activities without warnings. For example, the activities "Review (Engineer)" were followed by "Review (Engineer) Warning". Keeping such a relationship in mind, it was found that the warning activities happened when the participants failed to respond before the deadline. Therefore, the warnings were identified as the timeout warnings since the performers did not respond in time.

No.	Original Activity Names	New Activity Names
1	Approve (Approver) Warning	Timeout Warning to Project Manager
2	Approve (Engineer) Warning	Timeout Warning to Senior Engineer
3	Review (Engineer) Warning	Review Timeout Warning to Senior Engineer
4	Review (Participants) Warning	Review Timeout Warning to Engineer

Figure 6. Timeout warning activities

4.2 Timestamps

Timestamps are another crucial factor in event logs, which usually indicates the start time and the completion time. In this case study, timestamps included created time, ownership time and completed time as shown in Figure 2. The ownership time refers to the opening time of the tasks by the action performers. However, as there were cases when the performers had already started the work but did not open the task, the ownership time was not the actual start time. The created time was thus used as the start time as that was when the performers are supposed to begin to work on the activities.

There are two main problems for timestamps. One is the inconsistent formatting, and the other one is the "NULL" timestamps. The "NULL" timestamps happened due to three reasons: the activity happened instantly, the activity was aborted, or the performer did not manage to complete the activity before the due time and data. These cases will be further explained in the following sections.

4.2.1 Inconsistent Timestamp Format

After fixing the activity names, the timestamps were also investigated carefully. In Figure 2, it can be seen that the timestamps were documented in different format. The "createddatetime" (start time) in and the "completeddatetime" (completion time) adopted the format of "MM-dd-yy HH:mm". In contrast, the "OwndershipDateTime" (opening time) and the "ResponseBy" (deadline) adopted the format of "yyyy-MM-dd HH:mm". The inconsistency in the format caused confusion for both users and process mining software. For example, if the date is "April 10th, 2011", it will be written as "04-10-11" which could also possibly mean "October 4th, 2011" without a clear definition. To be consistent and avoid the confusion, all the timestamps were reformatted as "dd/MM/yyyy HH:mm:ss."

4.2.2 "NULL" Cases

In the event logs, some activities were triggered and completed instantly. For example, the activity "Notify Approval to All Relevant Participants" referred to the action of sending notification of approval to performers involved. This activity is merely an automated machine-based action that takes place instantly upon the approval or rejection of the ECR by an authorized performer such as Senior Engineer or Assistant Project Manager. With no further action required from the participants, "Notify Approval to All Relevant Participants" had a completion time of "NULL" as shown in Figure 7. The "NULL" timestamps were assigned values using data imputation. The completion time for "Notify Approval to All Relevant Participants" and "Notify Rejection to All Relevant Participants" were therefore changed to the same time as their start time.

Case ID	Activity	Start Time	Completion Time	Name	Current Status
1	Notify Approval to All Relevant Participants	10/03/2011 15:13:14	NULL	Randy	Deleted
2	Notify Rejection to All Relevant Participants	10/03/2011 14:50:12	NULL	Randy	Deleted
3	Verify Details by Coordinator	09/03/2011 18:02:14	NULL	Faisal	Closed
3	Review by Engineer	10/03/2011 14:12:34	NULL	Amy	Closed
3	Review Timeout Warning to Engineer	13/03/2011 23:00:01	NULL	Amy	Abort
20	Review by Senior Engineer	12/04/2011 14:22:26	NULL	Mark	Closed
32	Approve/Reject by Assistant Project Manager	11/05/2011 19:54:17	NULL	Andrew	Closed
54	Approve/Reject by Senior Engineer	02/09/2011 17:52:36	NULL	Mark	Closed

Figure 7. Activities with "NULL" completion time

"NULL" timestamps were also observed for other activities, which have been listed in Figure 7. By looking into the attributes, it was found that these activities all had the current status of either "Closed" or "Abort". The status of "Abort" indicates that the change request was cancelled and no longer proceeded. As a result, the completion time for those "Abort" activities were left blank, for they did not have a completion time.

"Verify Details by Coordinator" was one of the activities with the greatest number of "NULL" timestamps for their completion time. These cases were usually repeated again with a non-NULL completion time. From Figure 8, it was suggested that the "NULL" timestamp happened when the original performer was not able to complete the task in time. As a result, the original performer appears to have a "NULL" completion time, and another performer, authorized as the coordinator, may complete the task. The current status was thus "Closed" instead of "Send on."

Case ID	Activity	Start Time	Completion Time	Name	Current Status
1	Verify Details by Coordinator	09/03/2011 18:31:20	NULL	Faisal	Closed
1	Verify Details by Coordinator	10/03/2011 01:31:21	10/03/2011 14:15:50	Amin	Send On
2	Verify Details by Coordinator	10/03/2011 00:53:26	NULL	Faisal	Closed
2	Verify Details by Coordinator	10/03/2011 00:53:27	10/03/2011 14:14:28	Amin	Send On
3	Verify Details by Coordinator	09/03/2011 18:02:14	NULL	Faisal	Closed
3	Verify Details by Coordinator	10/03/2011 01:02:14	10/03/2011 14:00:46	Amin	Send On
4	Verify Details by Coordinator	09/03/2011 18:14:02	NULL	Amin	Closed
4	Verify Details by Coordinator	10/03/2011 01:14:02	10/03/2011 14:16:41	Faisal	Send On
5	Verify Details by Coordinator	10/03/2011 18:45:15	NULL	Faisal	Closed
5	Verify Details by Coordinator	10/03/2011 18:45:16	10/03/2011 18:59:52	Amin	Send On

Figure 8. Activity "Verify Details by Coordinator"

In the case study, there were also timeout warning activities which have been summarized in Figure 6 in Section 4.1.4. The timeout warning activities happened when the performers did not manage to complete the activities by deadline. In this case, the completion time for the normal activity was recorded as "NULL" and the normal activity was followed by a timeout warning. The solution to the timeout activities was to add up the duration of the normal activity and the timeout activity.

5 Conclusion

Process mining has great potential in the construction industry as it allows people to find out the activities causing delays, thus improving the efficiency. To make sure that process mining provides the best result, it is important to pre-process the event logs. Some of the issues with activity names are duplicated naming, ambiguous naming and missing information. These problems should be identified and fixed before the event logs are used for further analysis. Timestamps are also another critical feature of event logs. Some of the issues with timestamps are confusing format, missing values, i.e. "NULL" cases, and activities that are not completed by the deadline. The discovery of the timeout activities had triggered thoughts on conformance checking. In process mining, conformance checking is conducted between the model discovered using event logs and the target model. The difference between the discovered model and the target model, i.e. missing or inserted activities, can be considered as non-conformance. In the real world, projects usually have a deadline by which they are supposed to be completed. Hence, if the performers are not able to finish their tasks before the predefined deadlines, it should be considered as non-conformance too. This paper mainly focused on the first step of process mining, which is to pre-process the event logs extracted from the construction projects. The next step will be to use the pre-processed event logs to conduct analyses such as conformance checking, bottleneck analysis, and root cause analysis. As every industry has workflows and processes, this paper can be further generalized to all industries, not limited to the construction industry, on how to pre-process and improve the quality of event logs. With event log quality improvement, there will be less confusion for both engineers who created the event logs and users, which results in better accuracy in process mining analyses.

Abstract –

Rebar engineering is a construction method for building structures that is critical to the earthquake resistance of the entire building. The construction process and quality of rebar have always been valued by the construction industry, and it is imperative to improve the quality of reinforcement construction to reduce injuries. In recent years, Building Information Modeling (BIM) technology has been widely applied in the stages of design, operation and maintenance, but less in the construction phase. For rebar works in the construction phase, a BIM model of rebar can facilitate the development of a solution because 3D visualization of the model makes it easier to understand the problem. However, to apply the rebar BIM model to practice, it is necessary to build a model with the rebar takeoff to meet the actual construction status. Thus, how to optimize the takeoff of rebar from the completed 3D model has practical research value. This study takes the on-site construction of rebar as an example. For the main component, a BIM model is built with Tekla software to produce practical rebar takeoff plans with an A-star algorithm based on legal norms and construction feasibility that can reduce the amount of excess rebar material. It also chooses the best rebar takeoff plan to build the rebar BIM model. As a result, the relevant personnel who use the rebar BIM model can correctly solve the actual problems with the BIM model.

Building Information Modeling; Rebar Takeoff; A-Star Search Algorithm; Construction Phase

1 Introduction

Rebar engineering is a construction technology for a building, and it is also a safety factor of the structure. The construction industry has committed to reducing the waste of rebar under safe conditions to decrease the cost of rebar. In traditional rebar engineering, a building is constructed according to a 2D design drawing. But the designed rebar diagram cannot be directly applied at construction sites. It is necessary to perform rebar quantity takeoff to carry out rebar cutting, transportation, construction and other steps to complete the work of rebar engineering. The rebar quantity takeoff work is generally problematic for most untrained construction workers, who have insufficient planning ability and professional knowledge. Problems with incorrect material cutting or improper lashing may result in poor construction quality. Even if the reinforced concrete material is completed, it is difficult to effectively understand whether the takeoff result is the best. In recent years, the introduction of BIM in each stage of the building life cycle has become more diverse through the visualization and parameterization of Building Information Modeling (BIM). For example, a 3D model established by BIM software can quickly show design defects before construction and prevent waste in reconstruction [1]. It can be used to simulate the estimation of cash flow, including equipment, manpower and materials, during construction [2]. It is also possible to conduct conflict analysis for various types of work in advance and as a cross-domain information communication interface [3, 4]. Building Information Modeling has the capability to automate a quantity take-off, which will reduce the time and costs required to estimate a project [5]. The system using Autodesk Revit API automatically generates rebar placement plans for a building structure and labels the placement sequence of each individual bar or set of bars with ascending numbers [6]. At present, most rebar BIM models are established according to the two-dimensional map. The completed BIM model only provides a reference for the relevant personnel to easily understand the conflict positions and quantities of the entire rebar project. Therefore, it is worthwhile to create a practical rebar BIM model and to explore how to continue to use the BIM model to optimize the rebar material quantity to decrease freight, increase the correctness of rebar construction, and mitigate the problems caused by the rebar construction process. Figure 1 shows the research workflow.

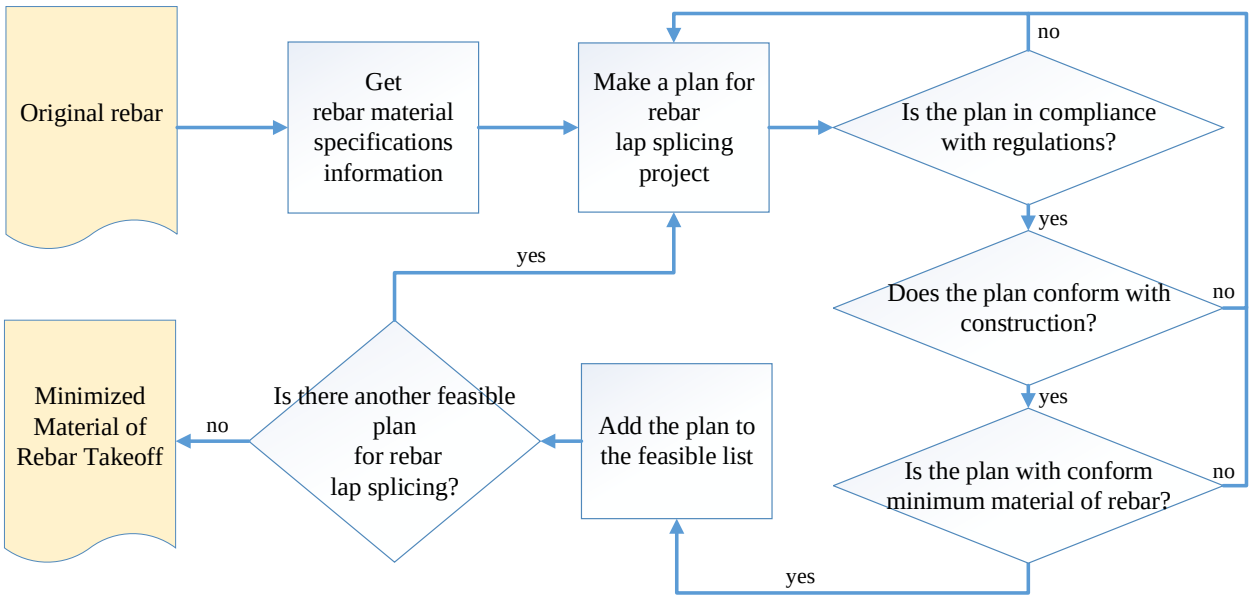

Figure 1. Research workflow

2 Application of Algorithm in Construction Engineering

Appling algorithms to solve problems in construction engineering has been discussed in related studies, which have examined using a genetic algorithm (GA) to optimize the RC beam rebar design to achieve the lowest construction cost [7]. A GA can be used to minimize the cost of RC columns in a reasonable time [8]. Also, a hybrid GA-HJ can be used to automatically generate optimized rebar under the BIM software model architecture. These studies have also solved some practical problems. The rebar cutting problem can use the Maze Problem (MP), for which the Pathfinding Algorithm is used to solve its path or shortest path. This was proposed by the Dutch computer scientist Edsger Wybe Dijkstra in 1956 [9].

Beam and column joint look like the intersection node of maze, we need consider to apply straight rebar or add a hook based on constructivity and cost analysis. According to these characteristics of problem, the A-star search algorithm used in this study is an improved algorithm based on Dijkstra's algorithm [10], which is commonly used in the movement path control of non-player characters in role-playing games. The breakpoint position of the rebar is calculated according to its logic and the construction specifications. The process is summarized as follows: Step 1: Search for the information of rebar in a structural beam and convert it to a quantized node. Step 2: Start from point A and inspect all nodes adjacent to point A. At this time, the program will consider the rebar situation such like straight or hook, only the passable nodes are placed in the open list. Step 3: Set point A as the parent node and move it from the open list to the closed list. Temporarily set each node as the parent node A in the open list and calculate their estimation function,

$$f(A) = g(A) + h(A) \quad (1)$$

where g(A) is the actual distance from the start point to the current node A; h(A) is the estimated distance from the node A to the end point. There are many ways to estimate the distance, depending on the case being explored. Step 4: Select the node with the smallest value as the current node A and move it from the open list to the closed list, while the previous parent node is temporarily called A'. Step 5: Repeat steps 2 and 3, and put the passable node adjacent to point A into the open list. If node B already exists in the list, compare the actual distance of A'→B and the actual distance of A'→A→B. If the former is less than the latter, set the node B to the next point A and repeat this step. If it is more, repeat Steps 2 to 5. Step 6: Repeat steps 2 to 5 until the endpoint is found. Once the endpoint is found, each parent node can reverse its path. When node A' is extended to node A, it determines by node A' and node 2 whether node A is lapped or not. If it is lapped, calculate the lap location and the residual material of node A, i.e., g(A). At the same time, estimate the residual material, i.e., g(A), under the possible lapping conditions with node 3 and node 4. However, if the splicing form of node A is determined, an infeasible situation may occur. For example, node A' and node 2 need to be overlapped, but node A cannot find the offset position of 60 cm so it must be straight through.

The length of node 2 plus the length of node A will be too long and difficult to construct. At this time, it is necessary to re-adjust the splicing form of node A' or 2, and then continue to complete the rebar takeoff operation as shown in Figure. 2.

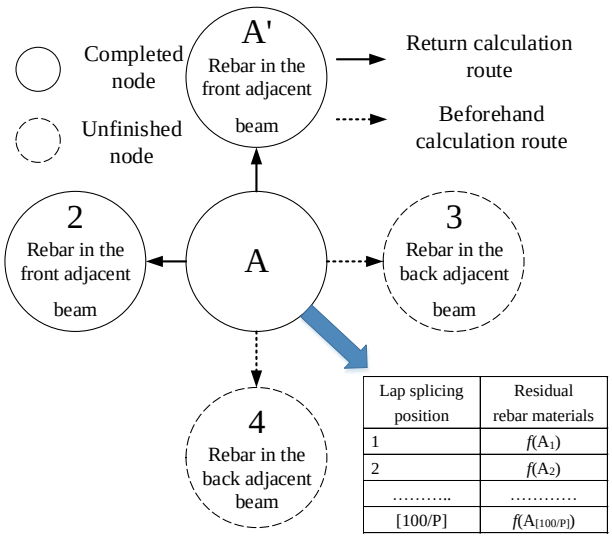

Figure 2. A-star search algorithm for rebar lap splicing scheme

3 BIM Model Combined with Algorithm for rebar takeoff

According to the structural member, the type of rebar lap splicing will be different. In this study, C# was used to program a method to calculate the minimum amount of rebar project and decide the main reinforcement splicing project to create and update the rebar BIM model. When the program needs to decide how to splice the main reinforcement, the length and location of splicing need to follow the law of the concrete construction design specifications. The splicing locations of beam members need to be located on the beam clear span L in the upper pressure zone, the range of L is between 1/4 and 3/4 of the center of the beam member, and the length of this range is 1/2 L. According to the beam clear span, the splicing method can be decided as the double-span for style 1 in Table 1 or the triple-span for style 2 in Table 1. The splicing location of a beam member needs to be located on the range of L from two sides of the beam member to 1/4 of the beam clear span, and the length of this range is 1/4 L. According to the above range, the splicing method can be decided as the cross-column lap for style 3 in Table 1. If the adjacent rebar overlaps, the overlap position can be staggered by 60 cm, as shown in style 4 of Table 1. Because multi-span continuous beam rebar lap splicing is more complicated than the single span beam in practice, the program design regulation needs to consider the following factors of adjacent beams: (A) the size of the section, (B) the quantity of the main reinforcement, (C) the location of the main reinforcement, and (D) the center line. So, in the judgment rule of the program design, the cross-sectional area dimensions (A), the rebar quantity (B), the rebar position (C), and the center line (D) of adjacent beams must be considered. The decided project is lap splicing or non-lap splicing, or anchor in the column member. This research conforms each factor to the decision tree in Figure 3. If the size of the adjacent beam section (A) is the same as the quantity of the main reinforcement, the adjacent main reinforcement can select the project of lap splicing or non-lap splicing.

4 Example analysis

Consider the second floor of a three-story reinforced structure building, which consist of eleven beam members, and the double-span continuous beams are only three of them. This case is easier than most reinforced structure types. Its structural drawing and rebar model created by BIM software are shown in Fig. 4. The reinforcement situation of the multi-span continuous beam can be found by the beam number of the following structure reinforcement drawing, and this drawing can divide the reinforcement of each structure member into items such as the straight main reinforcement, which is in the top and bottom layers, the anchor in the left and right, the non-straight main reinforcement in the top layer, and the non-straight main reinforcement in the center of the bottom layer, and an Excel table can be designed. Finally, that information on reinforcement is inputted into Excel, and following the above, the rebar takeoff and quantity of rebar are calculated. The experimental results of fifty runs are listed in Table 2. Although the first run resulted in the minimum rebar remainders, the total needed rebar length is the maximum in the fifty runs. While the total length of original rebars in the twenty-seventh run is the lowest of the fifty runs, its rebar remainders are not the lowest. Accordingly, this study adopted the twenty-seventh run as the determined scheme due to the minimized material.The detailed cutting results of 3G1 and 3G2 for the twenty-seventh run are summarized in Table 3. Finally, the designer revised the rebar BIM model of structural elements, including columns, beams and walls, according to Table 3, and the results are shown in Fig. 5.

5 Conclusions

Rebar installation causes conflicts and higher costs in the construction stage of a building project's lifecycle. The A-Star search algorithm is applied to obtain the beam element rebar takeoff quantity to match the construction situation and constructability in a BIM model. According to the achievements of this study, the following conclusions can be drawn:

1. Recently, rebar takeoff model is modeled by 2D drawings, the model can not inflect the actual situation on site. Moreover, BIM model without considering rebar splicing and anchor that has the same problems with 2D drawings. Therefore, developing a practical Rebar BIM Model is importent.
2. The A star search algorithm can analyze the rebar splicing and anchor between structural elements and provide various possibilities of rebar takeoff. According to the result, engineers no longer need to operate by personal experience and can obtain the

overall information of rebar takeoff to reduce the rate of material waste and error.

3. At present, this research has only analyzed the situation of a single floor and provided a preliminary result on the rebar takeoff possibility plan. Based on this research, this topic can be extended to related research and BIM technology can be applied more widely.

Abstract –

Currently, numerous approaches to Indoor Positioning Systems (IPSs), such as RSSI (Received Signal Strength Indication), fingerprint, PDR (Pedestrian Dead-Reckoning), and image recognition, have been developed. But each individual positioning method has unique drawbacks. In this study, we provide an IPS with a novel combined positioning method that applies Building Information Modelling (BIM) and Internet of Things (IoT). We employ an Inertial Measurement Unit (IMU) to track people's positions. We then utilize a BIM model that has information (semantic and geometric) and a sensing mat to eliminate IMU drift error in the positioning process. The demonstration field is a research office, and test results show that the BIM based positioning constraint can effectively filter IMU cumulative error along with time; thereby, positioning accuracy can be controlled to a range of 30cm × 30cm. In sum, this paper proposes a new positioning method that compensates for the weakness of the IMU. In the future, this system can be applied to people management, such as telecare for older adults.

1 Introduction

Building Information Modelling (BIM) is widely used in Architecture, Engineering, Construction. BIM not only contains 3d data for visualizations but also provides object geometry and attribute data for the planning, design, building, and operation and maintenance stages of a building's life cycle [1]. Currently, BIM is most often used in the early stages of the project life cycle [2]. Furthermore, person tracking and positioning have potential benefits in later stages of the project life cycle. The IPS (indoor positioning system) has been developed by researchers because the ability to locate and track people could be useful in the Operations & Maintenance (O&M) stage, such as in emergency response [3]. Multiple techniques for acquiring the positions of people have been developed. IPSs are classified into two categories: absolute tracking and relative tracking [4]. Absolute positioning systems can be further classified according to their methods, such as RSSI-based, fingerprinting-based, image-based, and floor-based methods. Both RSSI and fingerprint methods use wireless signals, namely, Wi-Fi, BLE (Bluetooth Low Energy), and magnetic fields, to compute distance, and then they utilize triangulation to acquire an estimated position of a target, or they use a pre-built signal map in an offline phase to compare online signal strength data with map data to estimate position [5]. However, these methods have some drawbacks: (1) Positioning accuracy is affected by variations in signal due to environmental changes, such as people walking or changes in furniture layout, and (2) The offline phase of the fingerprint method is a time-consuming and tedious task. Image-based methods also have some drawbacks: (1) Positioning accuracy is affected by image quality, which varies with environmental factors such as light intensity, and (2) The positioning ability is invalid when targets move out of range and multiple objects need to be tracked in several video fields of view [6]. Lastly, the floor-based method that located object (people or furniture) through measure pressure to detect object position on surface of floor, that through variation of surface pressure in every pixel of floor to know flow of people, but this method has a drawback that cannot aware specific character [7]. The relative positioning method, which uses the Inertial Measurement Unit (IMU), is widely used in personnel tracking, but the IMU has a problem of error accumulation that leads to serious drift error over time [8]. As noted above, each IPS has limitations. The objective of this paper is to propose a method that employs BIM model information and IoT technology to eliminate IMU positioning error and thereby to achieve an IPS with high accuracy and stability.

2 Methodology

To avoid the drawbacks of existing methods, we propose a positioning method that combines IoT and BIM technology to achieve high accuracy, real-time indoor positioning. The system was developed with the Revit API in the Microsoft .NET framework. The flowchart of the indoor positioning processes is shown in Figure 1.

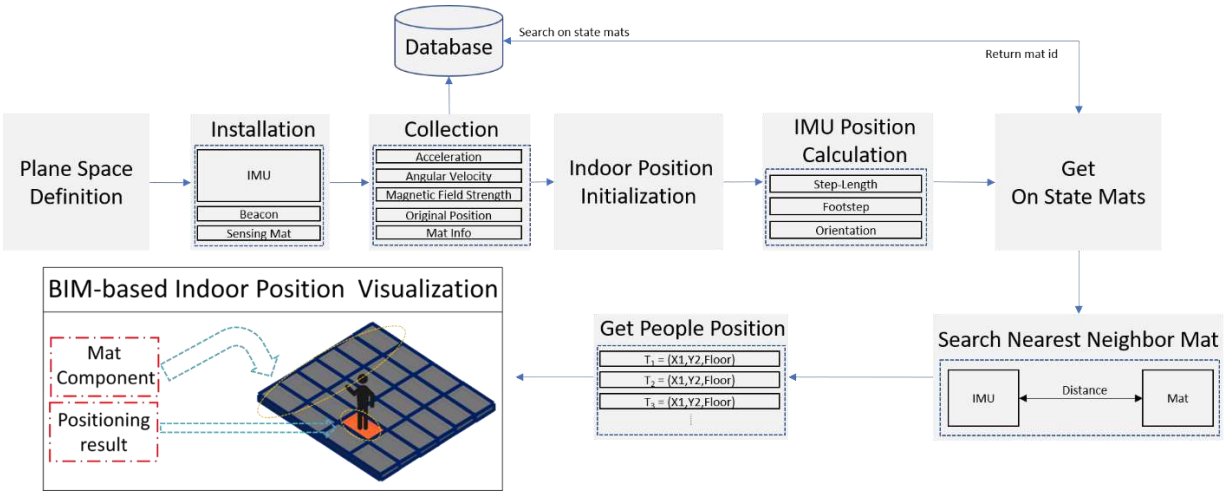

Figure 1. Research workflow of the proposed indoor positioning system.

In this process, we first defined the positioning space for demonstration and constructed a BIM model with Autodesk Revit. The model included a mat model having geometric shapes and specific parameters. Next, we installed sensing mats equal in size to the mat components in the defined space. The Beacon was installed on the door, and IMUs were worn by people. When sensor data were collected, the data of the sensing mats were output to a database. The Beacon's original position and the data on 3-axis acceleration, angular velocity, and magnetic field strength of the IMU were directly output to the positioning server. Upon receiving the original position data, the program initialized the position and utilized IMU data to calculate step-lengths, footsteps, and orientation to obtain the position of the IMU. Once the IMU position was determined, the positioning server searched for all the on-state mats in the database and got each mat id. The program also compared distances between the IMU and each on-state mat. After that, the mat at the shortest distance from the IMU was chosen as a person's position, and this position was used as a new original position for calculating the next position. Finally, the people's position results were displayed with highlights in Revit.

3 Experiment

In this chapter, we describe the entire experiment process, which is divided into four parts that are discussed separately.

3.1 Experimental site

The experimental site was in the research office of the Department of Civil Engineering at National Kaohsiung University of Science and Technology, as illustrated in Figure 2. In this experiment, we mainly focused on whether the reality sensing mat in cooperation with the BIM sensing mat component could effectively constrain IMU-based positioning error. Therefore, since positioning range was not the main topic of this study, we only used 9 block sensing mats in the experimental site.

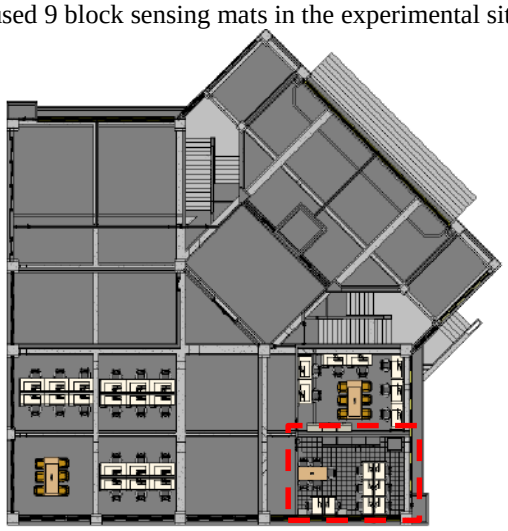

Figure 2. Experimental site

3.2 Sensor installation

The function of each sensor is shown in Figure 3.

The Beacon product model (USBeacon), which served as the original position in this study, was placed on the doorway of the room, as illustrated in Figure 4. The USBeacon is like a broadcast tower that transmits Bluetooth signals ceaselessly to provide UUID = fix, Major = 2, Minor = 2 for an IMU-based positioning system to initialize positions. These parameters stand for building, floor, and room, respectively.

In this study, IMU module is used to overcome the people Identification problem of floor-based method. The IMU product model was MPU-9250. The MPU-9250 can sense 3-axis acceleration, 3-axis angular velocity, and 3-axis magnetic field strength. The IMU device outputs necessary positioning data to the positioning server for a follow-up PDR algorithm to calculate an estimated position. In this study, the IMU was placed on the wearer's foot to easily count footsteps. An MCU (Microcontroller Unit) received raw data from the IMU sensor and the RSSI (received signal strength indicator) from the USBeacon. The MUC product model was ESP-32S. Once the ESP-32S entered the proximity detection range of the USBeacon, which was determined by RSSI value, the ESP-32S sent IMU data packets to the positioning sever via socket interface with UDP (User Datagram Protocol). UPD was used for data transmission because its transmission speed is faster than that of TCP (Transmission Control Protocol).

The sensing mat was the main feature in this study, so the relevant discussion is further divided into 4 points.

1. Composition of Sensing Mat: As shown in Figure 5, the sensing mat had a simple design using cheap materials such as sponge, cardboard, aluminum foil, and a mat. The design was inspired by button devices; the sensing mat is designed as an enormous button. The working principle of the sensing mat is 2 wires placed on the aluminum foil on the back of the mat and aluminum foil on the cardboard, respectively. When people step on the mat, the circuit is completed and the sensing mat will show an "on" state. While the sensing mat is in the "on" state, the Arduino YUN sends data to the positioning server database. To avoid accidental contact and erroneous updates, we used an elastic sponge material to separate the mat from the cardboard.
2. Figure 6 presents the installation positions of the sensing mats. We used 9 block sensing mats to verify the fusion algorithm that we proposed.
3. The sensing mat parameter design is shown in Figure 7. The parameters included UID, Room and Time respectively. "Room" indicated the room number where the sensing mat was located, "UID" was the identification number of each sensing mat, and "Time" was a timestamp for each "on" state. These parameters were used in the follow-up database search.
4. The sensing mat component design in the BIM model is shown in Figure 8. We created the UID parameter as the mapping condition for an actual sensing mat to extract coordinates from the sensing mat by UID parameter.

3.3 Positioning calculation

In this section, we generally introduce the IMU-based PDR algorithm and cooperation of the IMU with the BIM algorithm. Because the PDR was not a main research focus, we used an idealistic method to estimate position. The following sections describe the calculation processes for positioning.

3.3.1 IMU device position calculation

This research employed the Pedestrian Dead-Reckoning (PDR) algorithm. The PDR algorithm requires 3 positioning parameters: step length, orientation, and footsteps. In this study, we fixed step length at 30 cm. We employed Madgwick's method to obtain orientation components including roll, pitch, and yaw [9]. Lastly, we used total acceleration to count footsteps by threshold, and then we could calculate the estimated positions of the people. Figure 9 illustrates the concept of the PDR algorithm. Starting from the target's original position, the target's position at every moment is calculated as equation (1) and (2)

$$X_{k+1} = X_k + S * sin\,\theta_k \quad (1)$$
$$Y_{k+1} = Y_k + S * cos\,\theta_k \quad (2)$$

where (X_k, Y_k) is target's position at k time, S denotes the target's step length, and θ is orientation of the movement, and the θ value is as above-mentioned yaw that is from Madgwick's method, due to the position calculation is not involved three-dimension, therefore we only extract yaw as azimuth to calculate position.

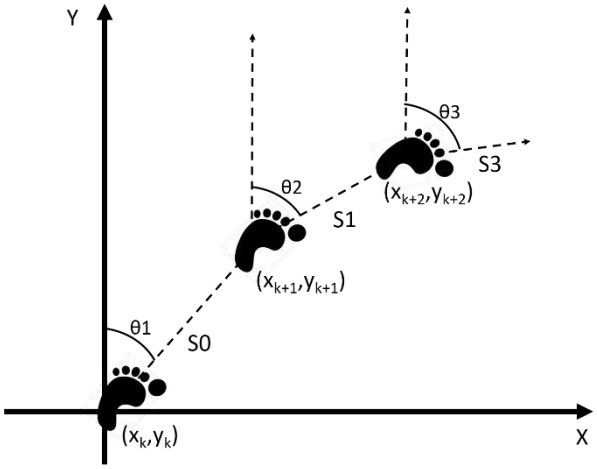

Figure 9. Pedestrian Dead-Reckoning algorithm

3.3.2 Fusion algorithm using Sensing Mat and BIM model

When the IMU device coordinates are calculated completely, we search the database for sensing mats in the "on" state. Next, we compare the sensing mat component from Revit to get a corresponding sensing mat component with the sensing mat UID parameter. Then the distance between the IMU and each sensing mat component coordinate is calculated. The process is illustrated in Figure 10. Afterwards, the sensing mat component with the shortest distance is taken as the final estimated position of the IMU. This final position is used to calculate the next position continually. Whenever the

final position of the IMU device is calculated completely, the sensing mat will be highlighted in orange. If not, the sensing mat with the final position is restored to its normal color.

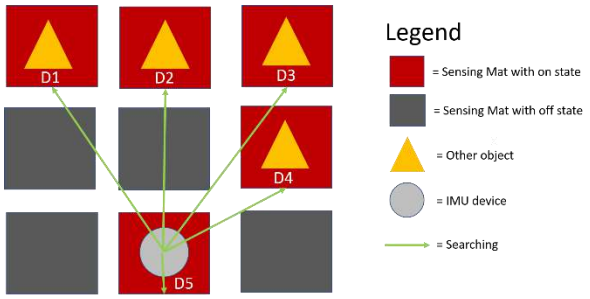

Figure 10. Searching process diagram.

3.4 Demonstration

As shown in Figure 11, we developed the IPS "Start" button in the Revit API and then defined the sensing area. When the user triggers the "Start" button, the program is launched. It starts a new thread in Revit to monitor port 3333. When a target enters the room (Room 202), the ESP-32S obtains original position information for that room, including UUID, Major, and Minor from USBeacon, and then via UDP sends a packet marked “202” to the positioning server. When the positioning server receives the original position of the target in Room 202 and starts receiving IMU sensor data of the target, the IPS will execute the indoor positioning process.

We tested some different states in the system, as shown in Figure 12. Starting in the lower right corner, the test path is shown in Figure 12 (a), (d), and (e). First, we tested the straight path state, then we tested the stretching across one block sensing mat state, and finally, we tested the diagonal path state. The results indicated that the IPS could correctly identify the position of the IMU device in the straight path, stretch across and diagonal path states.

Figure 12. Test case for different walking states in Indoor Positioning System.

4 Conclusions

In this study, we used a simple method to fabricate sensing mats for use as sensors to detect the movements of people and employed a BIM model for integration and visualization to improve IMU-based positioning accuracy. The system presents these following characteristics: (1) simple materials to make sensing mats and easy installation; (2) improved accuracy to 30cm x 30cm zones; (3) a BIM model for visualizing indoor positioning data so that the user can easily know the locations of targets.

In the future, this system can integrate physiological sensors, such as heart rate sensors and blood velocity sensors, to automatically monitor people's conditions. If people have accidents, the system will notify the user or a caregiver. This idea may find application as a nursing home management system for monitoring elderly residents.

Abstract –

This study describes a simple head mounted display(HMD) viewing system for an unmanned construction system(UCS) and an assessment of the work efficiency using the HMD system.

The deployment of a UCS is a significant problem because majority of the construction machines are not compatible with remote operation. In this study, focusing on the deployment problem regarding the viewing system of a UCS, we developed a simple HMD type viewing system. The HMD system provides the visual information so that images are projected on the HMD in the same arrangement as conventional LCD monitor systems.

The HMD system of a hydraulic excavator was tested with respect to work efficiency in comparison with a conventional LCD system using a model task that simulates the excavation and transportation of soil. Experimental results of the model task indicate that the working efficiency of the HMD system was improved compared to the conventional LCD system.

Unmanned Construction Work; Teleoperation; Head Mounted Display;

1 Introduction

In recent years, natural disasters such as a sediment disaster caused by typhoons, heavy rains, earthquakes, and volcanic eruptions are increasing in Japan. Once disasters occur, construction works are conducted for reduction and restoration of the damages. In such cases, an unmanned construction system (UCS) will be used for safe construction to prevent secondary disasters [1]. A UCS is a construction system that uses a teleoperated construction machine, and an operator controls the machine from a safe place, as shown in Figure 1. It was developed to respond to the volcanic disasters occurring owing to pyroclastic and debris flows in the eruption of Mount Unzen-Fugen in 1991[2]. UCSs have been used at over 150 sites, and recently, they were utilized for construction works related to debris demolition in the 2011 East Japan Great Earthquake. the 2016 Kumamoto

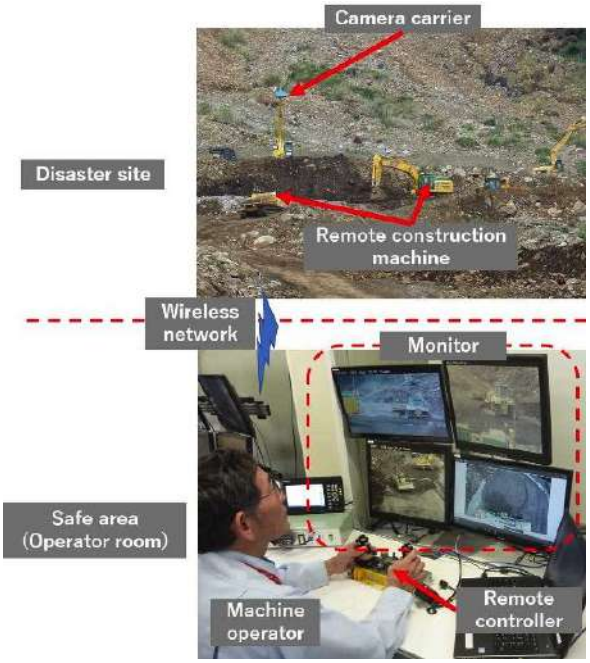

Figure 1. Unmanned construction system using conventional LCD monitors.

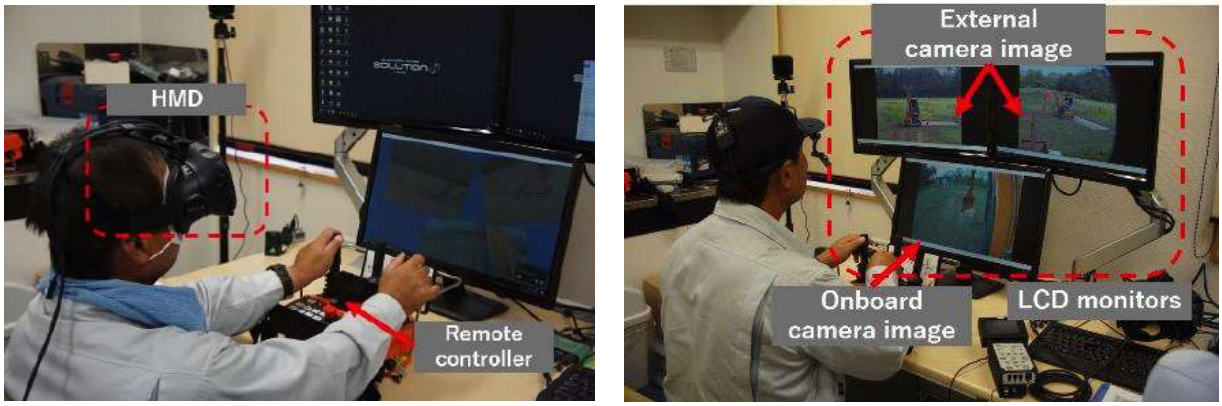
2 VIEWING SYSTEM OF CURRENT UCS AND ITS ISSUES

In a UCS, the operator recognizes the environment surrounding the construction machine via two types of viewing: direct viewing for a near field and non-direct viewing for a distant field. In the direct viewing system, a machine operator controls a construction machine in the near field at several tens of meters using a small and light-weight remote controller. Further, in the non-direct viewing system, a machine operator and camera operator are required to control the machine with



(a) HMD viewing system (b) LCD viewing system

Figure 2. Viewing system

Figure 3. Monitor layouts of HMD viewing system

limited information such as the transmitted image, which is controlled by a camera operator. The camera operator controls camera conditions such as the pan angle, tilt angle, and zoom for the machine operator. In the non-direct viewing system, cameras are usually installed on the construction machine and outside the machine to recognize a construction environment, and wireless communication systems are also installed on the machine. LCD monitors and other equipment are installed in an operator room.

A UCS realizes safe construction work in dangerous areas such as disaster sites. However, a UCS has several disadvantages such as work efficiency reduction and deployment of remote operation systems. Usually, work efficiency owing to UCS usage is approximately 50% compared to a normal manned construction work[5]. The cause of the reduction is considered the lack of information and time delay in data and image transmission. Moreover, the deployment is also a major problem because most of the construction machines are not compatible with remote operation. Furthermore, in a situation where a disaster occurs, the roads may be deteriorated, and it makes it difficult to readily set up the remote operation system.

To overcome such situations, the Japanese government developed a decomposable excavator that can be transported as small parts (3 ton) using a large helicopter. Further, rapid deployment of the remote operation system is still a problem. Several systems were proposed using additional information such as virtual reality and haptic interfaces [6][7]. These intelligent systems improve remote operation, but it is difficult to use them at disaster sites owing to the deployment problem. Teleoperation systems with the objective of rapid deployment were also proposed by [8] and [9]. However, the systems were not verified the work efficiency and effectiveness compared to the current UCS.

In this study, focusing on the deployment problem regarding the viewing system of remote construction machines, we describe a simple head mounted display(HMD) viewing system and an assessment of the work efficiency of the HMD system.

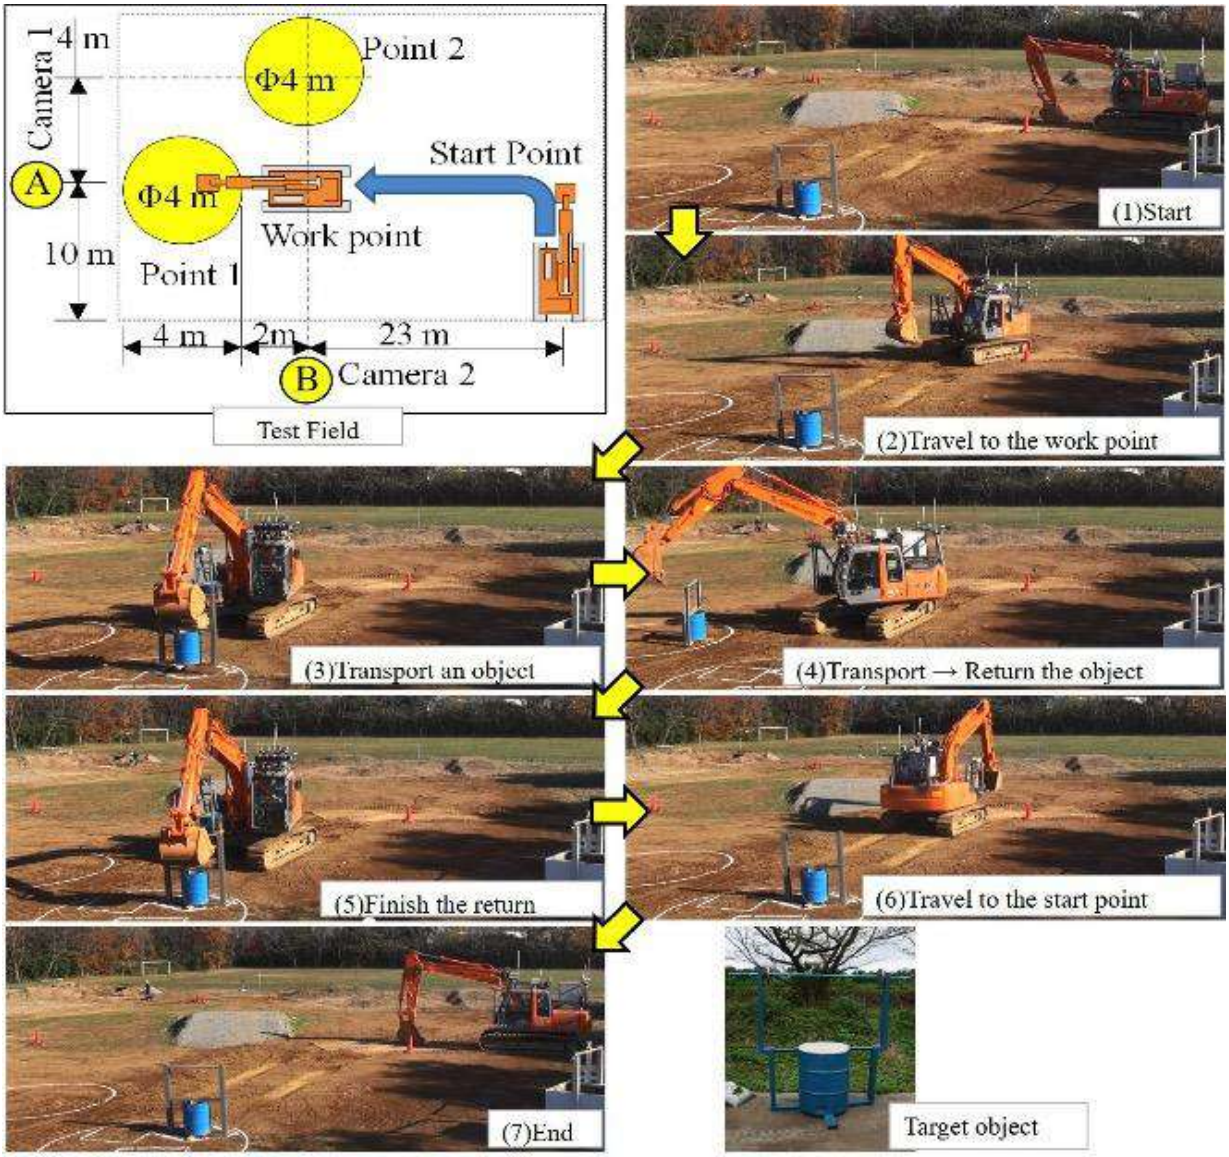


Figure 4. Overview of model task [10]

3 HMD VIEWING SYSTEM

To reduce the setup time for remote operation, we developed a HMD viewing system for the alternation of the current LCD monitor system. Figure 2 shows the HMD and LCD viewing systems, respectively. The HMD viewing system displays a similar monitor layout and similar images as the LCD system on the HMD's monitor as shown in Figure 3. The top two monitors display the image from external cameras, which are installed outside the excavator. In contrast, the bottom monitor displays the image from the onboard camera at the front of the excavator's cabin via a wireless network. The time delay of the transmitted image is approximately within 200 ms in both the HMD and LCD systems.

In addition, the manufacturer's remote controller is used to operate an excavator. The remote controller can teleoperate the excavator several hundred meters away within a delay period of 50–80 ms.

4 EXPERIMENTAL SETUP

4.1 Model task

The work efficiencies of the HMD viewing system and LCD monitor system were evaluated based on a model task. The model task was developed to evaluate

the work efficiency of hydraulic excavators in actual sites, and it simulates the traveling, excavation, and transportation of soil[10]. The model task consists of the movement job and working job. The overview of the model task is shown in Figure **4**. The scheme of the model task is described below:

1) Traveling job: the excavator moves from the starting point to the working job area

2) Working job: the excavator lifts a target object placed in a circle , transports it to another circle, and releases the target object

3) Working job: the excavator lifts the target again and transports it to the initial point

4) Traveling job: the excavator moves to the initial starting point

4.2 Experimental condition

The work efficiency was evaluated in three patterns of conditions as listed in Table 1.

Table 2 lists the specifications of the hydraulic excavator and other equipment used for the experiment. The model task was conducted in ten trials with respect to each pattern; thus, a machine operator conducts the model task using 30 trials in an experiment. The experiment was conducted by ten different machine operators. Table 3 lists the ages of the machine operators and their years of experience in using construction machines.

The camera operations were controlled by the same person. Two external cameras were installed at points A and B in the Figure 4.

H	37	10
I	49	20
J	42	19

5 EXPERIMENTAL RESULTS AND DISCUSSION

The work efficiency is evaluated based on the time taken to complete the model task (i.e., cycle time). In each pattern, the previous three trials are handled as learning trials, and the last seven trials were considered as evaluation data. Figure 5 shows the average cycle time of the forward movement, working, and backward movement with respect to 10 operators. Thus, the onboard operation is executed in 129 s with a standard deviation of 10 s, the remote operation using LCD monitors is completed in 328 s with a standard deviation of 11 s, and the remote operation using the HMD is completed in 292 s with a standard deviation of 10 s. As previously reported in [11], the remote operation depends on the operator ’s skills to understand the environments near the excavator from only the image information. Therefore, the standard deviation of remote operation is larger than the onboard teleoperation, particularly in case of the working job.

The cycle time of remote operation in case of HMD was shorter than that in case of LCD monitor. It is considerable that internal and external factors exist that caused the difference of the cycle time. In this study, we focus on the learning progress and interfaces. The experiment was conducted in the order of onboard operation, remote operation using an LCD monitor, and remote operation using the HMD. Based on the learning effects, the last operation might possess a relatively short cycle time. To confirm the effects, we categorized the learning progress of both remote operations. In terms of the learning progresses in both remote operations, it is considerable that the order of the experiment pattern should affect the results.

The examples of the series of cycle times are shown in Figure 6. In this experiment, the criterion for learning progress was considered as to whether the slope of the regression line is less than -3. Based on this criterion, Table 4 lists the learning progress of each operator. The

learning of two operators (A and G) progressed continuously in both the experiments. Other operators did not seem to be affected by the order of the experiment pattern.

Further, the averages of the cycle time, except for the two operators, are 324 s and 287 s using the LCD monitor and HMD, respectively. Therefore, the influence of the learning effects was small, and it is considered that the difference in the apparatus significantly affects the cycle time.

After the experiment, we interviewed the operators regarding the problems with the HMD. Most of the operators said that it was easy to understand the situation of the excavator, but it was heavy, and it tired them easily.

6 CONCLUSION

This study compares the conventional LCD system with the HMD system regarding the change in the work efficiency owing to the visual interface in the remote control of the hydraulic excavator. The HMD system was constructed so that images are projected on the HMD in a similar arrangement as the conventional one. Experimental results regarding the working efficiency of the hydraulic excavator in model tasks were confirmed, and the efficiency of the HMD system was improved compared with the conventional one.

In terms of the visual device, compared with the conventional system, it is possible to construct a system with only a PC and HMD, and combining with the hydraulic excavator, which can be transported freely, it is possible to respond immediately in the event of a disaster.

The future task is immediate deployment of an external camera. Currently, the external cameras are assembled in the tower or via construction machines with cameras attached to the tip of the bucket called camera carrier, to provide a viewpoint from the outside while working. It is necessary to develop a system that constructs external cameras immediately on site.

Table 4. Learning progress of the model task. O means that the learning progressed (i.e., cycle time became relatively short gradually), and X means that the learning did not progress.

Abstract –

Traffic congestion and roads service level are major issue in many countries. Using technology such as simulation offers effective approach to better understanding the problem, and predict optimal solutions. This paper examines the application of Virtual reality (VR) for evaluating the roads service level of five different scenarios in UAE as new method to evaluate and enhance road service levels, as well as understanding the potential risks and costs for applying those scenarios into reality. The study will test the usefulness of VR simulation to enhance traffic service level, second creation of traffic objects to explore potential usage, third understand the interaction between users and digital objects. All hypothesis have significant impacts toward enhancing service level, and the overall findings are consistent and clear. The level of technological orientation was examined to the overall implementation. The results help understanding key issues and potential service level in development of future VR applications in roads construction.

1 Introduction

Ministry of Infrastructure of Development in United Arab Emirates always strive to utilize the latest technology to enhance its service related to roads and infrastructure. Many scholars reviewed the use of technology to enhance construction modes and experience, construction has seen a significant increase in its productivity since using automation to analyze best practices [1]. The application of virtual reality in construction was described by Sampaio and Matins [2] to provide better understanding of how roads construction are being belt such as bridges with considering related to safety and level of service. Other scholars used virtual reality to study deeper usage of VR in maintaining complexed buildings, Grabowski and Jankowski [3] used this technology to study VR input methods using different HMD hardware setups. Roupé et al. [4] also studied the level of enhancement using VR and body movement, and stated that one of the main implications of VR body tracker is the cost of equipment's and needs a specialized team to be able to utilize this technology, Roupé et al. proved that VR body postures is able to navigate through out city modeling. This paper will study the reflect of changes in optimizing traffic modes toward level of service based on the UAE government needs and reviews. Using Virtual Reality screening methods the system will predict the level of enactments and analyze the results of the interchange with the models update.

2 Literature Review

The Virtual Reality have been used rapidly for many industries recently, and the need of to apply this technology in the construction industry became a need from both government and private sector, and the positive impact of this technology has been demonstrated in many studies [5]. Goedert et al. [6] discussed the impact of VR simulation into construction education and to provide better understanding for different scenarios of building methodologies. The main feature of VR environment is to provide immediate real time results for its applications, especially in interactive activities [7]. VR also proven that it will be great addition for other technologies to enhance understanding and performance of construction sites in addition to analyzing the development of Building Information Modelling (BIM)[8-10]. Following the mixed realities technologies which combines both VR and AR, Russell el al.[11] demonstrated the usage of mixed realities technologies to train and improve understanding of 3D modelling techniques which can

replace the traditional methods using computer – aided design (CAD). Hence, the Mixed realty technology became very acceptable by users and supports interactive visualization [12]. However, the studies related to VR actual application and its application in construction is very limited [13]. And many scholars found immersive technologies using head mounted display (HMD) can be cause errors and unpredictable results for many systematic applications [14]. Yet there are enormous need for studies to prove or to propose a successful usage technologies and to investigate or develop new methods of VR in training and analyzing results [15]. Most of construction drawings use 2D modeling, although using 2D modeling can assist specialists to determine necessary information in construction sites, it cannot interact with real time environment and more important it cannot provide enough information to build the required data. Jang [16] declared that using experimental methods using immersive technologies can enhance practical abilities to better understanding results. Additionally, virtual reality influenced by the way people do their work and provide new opportunities to better understand surrounding environment [17]. Arian and Burkle [18] virtual reality improves the understanding of real time issues in construction sites, and the successful collaboration of virtual reality with real construction sites will improve safety education through experiential learning.

3 Methodology

The analysis methodology that will be followed in evaluating the various roadway elements surveyed; interchanges, junctions, roundabouts and links. The basis of the analysis will be highway Capacity Manual (HCM) using VR scenario modeling. The Highway Capacity Manual (HCM) methodology specifies six levels of service to represent the operational characteristics of a given transportation facility. Roadway Level of service (LOS) describes the operating condition determined from the number of vehicles passing over a given segment of the roadway during a specified period of time. It is a qualitative measure of several factors which include: speed, travel time, traffic interruptions, freedom to maneuver, driver comfort, convenience, safety and vehicle operating costs. The study is based on Al Ittihad road in Sharjah – Sharjah bound.

The six levels of service which have been established as standards by which to gauge roadway performance are designated by the letters A through F and are defined as follows:

- LOS “A” – Free flow, individual users virtually unaffected by the presence of others;
- LOS “B” – Stable flow with a high degree of freedom to select operating conditions;
- LOS “C” – Flow remains stable, but with significant interactions with others;
- LOS “D” – Approaching unstable flow, freedom to maneuver is severely restricted;
- LOS “E” – Unstable flow, with volumes approaching capacity of the roadway; and
- LOS “F” – Forced flow in which the traffic exceeds the amount that can be serviced.

A Passenger Car Equivalent is essentially the impact that a mode of transport has on traffic variables (such as headway, speed, density) compared to a single car. The factors adopted in this analysis are as below:

Table 1. PCE factors

NO	Mode	PCE Factor
1	LGV	1.0
2	HGV	2.5

Signalized intersection LOS describes the operation of the intersection based on average delay per vehicle. To estimate the average vehicle delay for each intersection, average control delay per vehicle is calculated for each lane group and aggregated for each approach and for the intersection as a whole. The six levels of service are designated by the letters A through F. and are defined as follows:

- LOS “A” – Average vehicle delay 10 seconds or less;
- LOS “B” – Average vehicle delay between 11-20 seconds;
- LOS “C” – Average vehicle delay between 21-35 seconds;
- LOS “D” – Average vehicle delay between 36-55 seconds;
- LOS “E” – Average vehicle delay between 56-80 seconds; and
- LOS “F” – Average vehicle delay exceeds 80 seconds.

Unsignalized intersection LOS describes the operation of the individual movement. It is determined by the computed or measured control delay and is defined for each minor movement. LOS is not defined for the intersection as a whole. According to the HCM, six levels of service have been established, designated by the letters A through F. These levels of service levels are defined as follows:

- LOS “A” – Average vehicle delay 10 seconds or less;

- LOS "B" – Average vehicle delay between 11-15 seconds;
- LOS "C" – Average vehicle delay between 16-25 seconds;
- LOS "D" – Average vehicle delay between 26-35 seconds;
- LOS "E" – Average vehicle delay between 36-50 seconds; and
- LOS "F" – Average vehicle delay exceeds 50 seconds

This study proposes a comparison between the application of different models to study the level of enhancements to the same road for each prospective using HCM VR modelling.

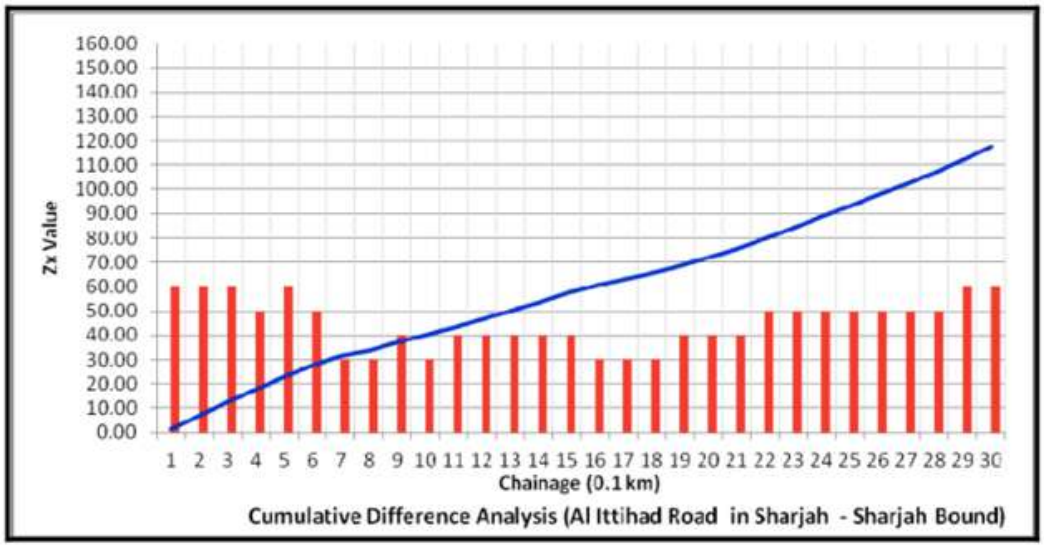

Figure 2. Cumulative difference analysis

The traffic count survey results and the analysis thereof for roadway elements surveyed. The methodology followed in the analysis is also mentioned along with the Level of Service (LOS) criteria.

4 Data analysis and discussion

Traffic count locations were discussed with the Ministry in the project early start as tabulated in the Table 2 - 3 below. The classification followed in the survey was Light Vehicles and Heavy Vehicles. Data were collected in 2018, junctions name were listed as per ministry of infrastructure development classifications.

Table 2. Existing traffic count

Junction No.	Junction type

R/A-3	C	19.6	D	31.2
R/A-4	F*	N/A	F*	N/A
R/A-5	F*	N/A	F*	N/A
R/A-6	F	296.3	F	166.5

Note: (*) Roundabout is failing due to upstream blockage

Data on vehicle classification were collected during the traffic count survey. Vehicles were classified into heavy vehicles and light vehicles. The percentages of LV and HV were calculated for two locations along Al Ittihad Road (Junction 1 and Roundabout 1), during the AM and PM peak periods. An overall summary of this vehicle classification is shown in tables (4) below.

Table 4. LV – HV percentage from traffic survey

Intersection	AM		PM	
	LV	HV	LV	HV
J-1	93.4%	6.6%	95.0%	5.0%
R/A-1	97.6%	2.4%	96.2%	3.8%
R/A-2	97.9%	2.1%	97.5%	2.5%
R/A-3	94.5%	5.5%	97.0%	3.0%
R/A-4	93.0%	7.0%	95.0%	5.0%
R/A-5	95.5%	4.5%	95.5%	4.5%
R/A-6	94.8%	5.2%	97.5%	2.5%
RIRO-1	93.8%	6.20%	95.6%	4.40%
RIRO-2	94.1%	5.90%	97.9%	2.10%
RIRO-3	92.0%	8.0%	97.2%	2.80%
RIRO-4	93.3%	6.70%	96.9%	3.10%
RIRO-5	97.7%	2.30%	95.2%	4.80%
I/C-1	95.60%	4.40%	97.10%	2.90%
I/C-2	92.0%	8.0%	93.0%	7.0%
I/C-3	95.0%	5.0%	94.7%	5.3%
L1	94.6%	5.4	97.4%	2.6%

In the experiments the above data were inserted into the VR prediction software and attributes were specified to study the level of enhancements and the influence of the proposed junctions' layouts in order to obtain future LOS based on average delay values according to the HCM methodology.

The proposed design includes upgrade of number of lanes, upgrade roundabouts to four legged and 3 legged signalized intersections, demolish flyover and replace it with four legged signalized intersection and underground tunnel, upgrade signalized intersections to flyover bridges and underground tunnels, and adding directional ramps to interchanges and eliminating key waving segments. The volumes obtained from the traffic model were used for the analysis. Table 5 tabulates the analysis results based on the recommended option and Figure 1 present the analysis summary. Based on the constructability and phasing of the project improvements two possible scenarios have been considered.

- Ultimate Scenario
- Reduced Configuration

Accordingly, for the reduced configuration scenario all tunnels in Junctions 1, 3 and 5 were removed and the traffic analysis for this option was carried out. Table 5-3 shows the analysis summary results of the reduced configuration scenario.

Table 5. LOS analysis for ultimate design scenarios

Junction #	Type of Junction	AM		PM	
		LOS	Delay	LOS	Delay
Junction 1	Signal + Tunnel	A	10	C	30.9
Junction 2	Signal	A	9.5	C	23.4
Junction 3	Signal + Tunnel	B	17.3	C	20.4
Junction 4	Signal	A	4.4	A	4.3
Junction 5	Signal + Tunnel + Bridge	C	20.9	C	25.7
Junction 6	Single point diamond Interchange	A	9.9	B	16.8
IC-1	Interchange	C	-	C	-
IC-2	Interchange	D	-	D	-
IC-3	Interchange	D	-	D	-

Table 6. LOS analysis for reduced configuration scenarios

Junction #	Type of Junction	AM		PM	
		LOS	Delay	LOS	Delay
Junction 1	Signal + Tunnel	C	23.3	F	87
Junction 2	Signal	B	14	C	30.8
Junction 3	Signal + Tunnel	B	13.4	D	40.6
Junction 4	Signal	B	13.7	A	8.4
Junction 5	Signal + Tunnel + Bridge	C	24.3	E	62.2
Junction 6	Single point diamond Interchange	B	16.4	C	21.9

It can be inferred from Table 6 that Junction 3 operates at an acceptable level of service with the reduced configuration. However, the removal of the tunnels in junctions 1 and 5 depict that the junctions do not operate at an acceptable level of service. Accordingly, the grade separations at junctions 1 and 5 are warranted.

Since Junction 3 was working at an acceptable LOS in previous experiment with the removal of the underground tunnel unlike Junctions 1 and 5, the reduced scenario comprised of the removal of the Junction 3 tunnel. Table 7 tabulates the analysis results based on the ultimate option.

Table 7. LOS analysis for ultimate design scenarios update

Junction #	Type of Junction	AM		PM	
		LOS	Delay	LOS	Delay
Junction 1	Signal + Tunnel	B	10.8	C	33.4
Junction 2	Signal	A	9.9	C	20.4
Junction 3	Signal + Tunnel	B	18.3	C	21.7

Junction 4	Signal	A	9.1	A	5.3
Junction 5	Signal + Tunnel + Bridge	C	26.4	D	37.7
Junction 6	Single point diamond	B	12.7	C	22.5

The analysis summary for the Ultimate Year update was carried out using the volumes obtained from the traffic model based on the proposed design is tabulated as Table 7 and 8

5 Conclusion

Many countries suffer because of traffic congestion problem. To handle it, many strategies have been followed to understand the potential risks and costs of this problem. Therefore, in this project; VR simulation has been used to evaluate the roads level of five different scenarios to obtain insights into alternate roads services to optimize roads service levels. Five different scenarios were proposed. Upgrade of number of lanes, upgrade roundabouts to four legged and 3 legged signalized intersections, demolish flyover and replace it with four legged signalized intersection and underground tunnel, upgrade signalized intersections to flyover bridges and underground tunnels, and adding directional ramps to interchanges and eliminating key waving segments.

As a result of the analysis using VR technology, two possible scenarios have been considered.

- Ultimate Scenario
- Reduced Configuration

The approach adopted in simulation is to understand and analyse service level and plan a better design in the targeted junctions. The resulting outputs can be visualized based on the attributes added into the simulations. The feedback obtained will have significant improve among the accessibility of roads optimizing.

Abstract –

Governments are always looking to monitor safety violations on construction sites. Those violations are not only causing numerous injuries and deaths to workers but also delays and subsequently costs to the project developers. In the hierarchy of control, personal protective equipment (PPE), albeit the least effective, is still one of the most visible and therefore fundamental controls to protect workers from workplace hazards. While PPE should be monitored at all times by the related authorities and project organizations, adequately trained staff and availability to monitor projects often fails short. Therefore, monitoring the right use of PPE electronically has yet to become a recommended practice for safety and health programs. This paper examines the application of legalizing smart hard hat to monitor the use of PPE among construction site workers. Using automated cameras and detection technology the PPE will be detected and analyzed. The proposed approach then automatically identifies violators and safety alerts will be issued correspondingly. The developed technology has been tested on real sites. Results from these tests were used for legalizing this technology for everyday construction application in the UAE.

Keywords –

smart hart hard hat; automation in construction; construction safety; site surveillance technology, legalization, personal protective equipment, worker rights

1 Introduction

Infrastructure development is one of the most important industry to any government and to secure this industry is a major concern for all official department, due to harsh working environment and huge amount of workers, governments are striving to maintain level of safety in any site and enforce the use or personal protective equipment among all labors, however, those personals fail to comply to those rules which lead to catastrophic incidents. According to global statistical data the rate of injuries and death in construction is almost three times higher in construction comparing to other industries [1]. This paper proposes a new method of legalizing smart hat and responds to a frequent question Why government are still using manual inspections to record PPE violations? This question reflects the vision of Ministry of Infrastructure Development in UAE and encourage using innovative technologies to reduce number of injuries and deaths caused by careless site foremen and un educated labors. The proposed technologies can fundamentally redefine government responsibilities with social responsibilities. It will also improve the usage of PPE which has not been really developed since the eighties. The construction industry has reported the highest number of casualties among different industries [2]. Many scholars and governmental reports around the world studied the fatal injuries caused by poor attention to personal safety equipment among workers [3][4]. Therefore to minimize such injuries and causalities in construction sites one of the most important strategic goal of MOID [5]. As a result monitoring workers safety has been a top priority for all governmental sectors in the world and became an important pillar to evaluate the construction sites and companies, nevertheless using technology in this matter has become an urge for its accuracy and fast respond. It is with those information enforcing smart hard hats will lead to monitor safety measures everywhere by creating live on time feed to the concern departments and control workers biometrics and to prevent potential violation. The liberty mutual Safety Index (2018) stated that top 10 causes of injuries in workplaces and those injuries amounted of almost $60 billion dollars [6] (Figure 1)

Figure 1. Top 10 causes and cost of the most disabling US workplace injuries

Workers in major cities and developed countries such as United Arab of Emirates are experiencing very safe environment and less work hazards base on very strict regulations in UAE, while employers are trying to avoid any direct or indirect fines might cause by not setting the right on site regulations and force all workers to follow the government safety regulations. According to research done by Grandview Research the market value of PPE is nearly $34 Billion in 2014 with potential growth of 7.2% [7] (Figure 2).

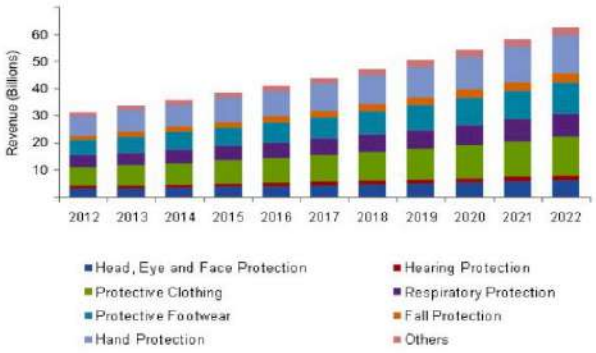

Figure 2. Potential growth of PPE market

Hard hats are designed to protect workers, resist shock, object penetrations, and electrical hazards and this only if workers are using them properly, site marshals with governmental inspectors are expecting the amount of injuries to be reduced since all workers are using the right PPEs [8], however controlling large amount of workers in big constructional sites are almost impossible every time and injuries actually are increasing and study showed that almost 47% of workers injuries are caused by not using the right PPE and no actual monitor took in place to prevent such unfortunate incidents [9]. This paper examines the effects of legalizing smart hard hats to remotely monitor any PPE violations in construction sites and using systematic tools to provide 24/7 surveillance for to detect any workers who are not using their assigned PPE or not using them properly. Studies showed that using smart hard hats for visualizing PPE usage had significant factor for reducing violations and this will lead to reduce number of fatal injuries among site workers [10].

2 Literature review

2.1 Smart Hard Hat

Using smart hard hats will satisfy the needs of safety of clients and will develop a functioning tools to keep the end users safer using the latest technology [11]. Teizer and Reynolds [12] studied the usefulness of smart hard hats to help workers avoid contact with hazard equipment using radio frequency and wireless microprocessors to warn workers once they are close to specified equipment's. Shrestha et al. [13] created a framework to visualize construction safety and detection algorithm. She used CCTV cameras and server side connection to detect workers without their PPEs. Dey S. [14] invented a smart safety gears to calibrate with smart sensors attached to wearable protection equipment, the method is to control the surroundings and measure signal based on the quantity of the element measured. Edirisinghe [15] explained the future context aware using smart sensors technologies in construction sites and real time safety. Gubbi et al. provided evidence that the world is moving to utilize latest technology in enable connectivity of day to day devices and enable IoT for better human enhancements [16] . Par el Al. [17] studied that workers in construction sites need to fulfil 2 main conditions the outline of a person and using PPEs, by using image processing technology to identify whether the person detected is a valid worker or not, In this experiment workers are identified by validating their PPEs from the image processing system can determine whether the person detected is a random person or a worker.

2.2 Image detection

Several research studied image detection for safety measures. [18] used camera features to detect different cues and facial expressions to trigger related warnings for specific incidents. Dai et al [19] developed a software which detect mobile sensors that read personal behaviour and record users action and compare collected data with typical patterns to store any unfamiliar activities. [20] addressed the power of automated visualization using 4D to analyse the relation between Virtual design construction (VDC) with Geographical location (GIS) to detect any faults or

errors among construction sites. Qi et al. proposed a tool for maintaining safety suggestion based on images collected from checking construction sites. [22] studied number of images need to be collected and frequently captured in construction sites to be detected and analysed to produce valid information about how construction sites are performing their daily tasks. Many scholars have developed visual data collection to monitor safety among construction sites using image processing, table (1) list some prior work that used image automation to detect image information.

Table 1. Level automation for image detection [22]

Application	Data Analytics
Damage Assessment	• Image Based 3D reconstruction • Image segmentation & object classification • Machine learning classification
Infrastructure inspection	• Geometric recognition • 3D image processing
Urban Monitoring	• 4D image registration • Orthophoto mapping
Road Assessment	• 3D image based
Geo hazard Investigation	• Orthophoto mapping • Visual interpretation

3 Research Methodology

The paper methodology of PPE monitoring is to collect images data from cameras attached to the smart hard hat including personal traits and PPE availability as well as recording workers face detection and automated object recognition to detect whether is the worker is using the right PPE on the right time at the assigned place as illustrated in figure (3).

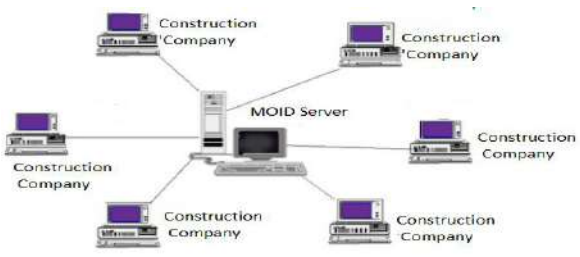

Figure 3. Framework to collect data and send data to MOID server

After the PPE checking by the cameras attached to the smart hard hat, the cameras will identify safety measures system will generate real time report and upload it to the MOID inspection portal and propose the corrective action such as site admin warnings and record fine on the contractor with incident details and visual evidence stored in database.

This paper will study the usage of smart hard hat by analysing three pillars

- Face detection to analyze if the workers already registered in MOID server for the construction site
- PPE object recognition to validate the usage of the correct and valid safety equipment
- Real time report to record all incompliance incidents and record it into MOID database and site manager.

Figure 4. Smart hard hat with detection camera

3.1 Detection device

The detection process of workers and their protective equipment's will rely on face detection and object recognition applications installed into the smart hard hat. The concept is to use the camera attached to the smart hard hat as shown on figure (4) to scan across each worker on site and store several images for each individual to read the data collected independently and analyse it based on the safety standards of MOID. This strategy has two main advantages

- Detecting worker profile: it retrieves the worker data from the database to understand his role and main job functionalities.
- Detecting equipment: over the construction sites many types of equipment should be used as per the safety standards shown on table (5) will be detected and analyzed for its existence

Table 2. List of safety standards

PPE Required	PPE required
Eye gaggles	Grinding, hammering, chopping, abrasive blasting, and punch press operations
Face Cover	Pouring, mixing, painting, cleaning, syphoning, and dip tank operations
Head and Body Cover	Building maintenance; utility work construction; wiring; work on or near communications
Feet	Construction, plumbing, smiting, building maintenance, trenching, utility work, and grass cutting
Hands	Building maintenance; utility work construction; wiring; work on or near communications

3.2 Standards Matching

The system will match serious of standards added by MOID safety department and compare it to a certain measures among construction site. The system will check the similarity and calculate the efficiency of the smart hard hat daily reports. Due to the unified design and shapes of safety equipment, the application will match the images detected on site and match it with template design stored. The template matching algorithms defined as detector (D) and true result (TR) of image detected and template matching (TM) of total image frames per second (n) and (TD) represents safety marshals detection.

$$D = tr\left(\frac{tm}{n}\right)/td\left(\frac{tm}{n}\right)$$

The algorithm will compare the use of smart hard hat detection with traditional way of inspection which use of human inspector or safety marshal to be available on site.

4 System Application

As per one epitome, construction site must be observed during working hours continuously so that workers must be saved from unforeseen situation, casualties and approach of illegal personnel on sites. Staff movement at a building site is followed utilizing electronic hardware incorporated into smart hard hat worn by supervisors at the site.

These smart Hard Hats must be manufactured observing all the requirements e.g., power for long working hours, perfectly working in any activity during construction and environment of construction sites. The smart hard is including an external hard shell joined to the inward shell adjusted to fit supervisor, must not hinder during his routine activities nor too heavy to carry all day long.

The inward shell compromising of most important technical part for smart hard hat having HD camera, environmental interaction sensors (accelerometer, gyroscope), wireless connection (sim card), power source, distress alert, geometric location, pulse measurement. Utilizing Smart Hard Hat technology we can sure to make environment safe and following MOID rules on every construction site.

As prerequisite all construction companies registered with MOID need to record their employees' data on MOID server.

Here we will choose cloud computing for efficient performance as it optimizes the computation partitioning of a data stream application between mobile and cloud to achieve maximum speed/throughput in processing the streaming data. This data storage framework is able to combine and extend multiple databases and Hadoop to store and manage diverse types of data collected from database or either by sensors and RFID readers [23].

On construction sites one or more supervisor wearing smart hard hat will be observing environment while performing his duties. Meanwhile, smart hard hat is in continuous state of detecting and monitoring workers, worn by supervisor situated at the construction site using face detection technology. Meanwhile, a broad range of high-resolution embedded cameras in combination with the development of commercial AI systems allows for a full replacement of traditional security and identification measures with face recognition and provide all above functionality with its additional features. The camera attached to the helmet is able to monitor individual, and looking beyond face recognition, to human analytics. As well as, provides face detection, identification and verification, emotion, age, gender, sentiment, ethnicity and multi-face detection, attention measurements and face grouping in real time.

As soon as human is detected by the hat, it will capture image so that his traits will be examined under the rules of MOID. Smart hard hat being powered by battery and wireless connection will capture working employee and process image on construction sites.

Firstly, the head areas are caught from human pictures. At last, with red, yellow, blue, white and non-helmet image samples, helmet identification based on image processing is used to detect whether workers are wearing helmets or not and to distinguish the shades of helmets if helmets exist. Then, Jackets will be detected due to high reflective clothing workers wear on construction sites. We propose and assess a framework for recognizing people wearing reflective apparel on construction sites by estimating their directions in 3D space under a wide scope of various light settings

during image captured process. If the employee is wearing safety helmet and jacket, it will validate the working employee and if employee is not wearing safety jacket or helmet, smart hard hat will generate alert for MOID server. An alert for MOID server must be latency free, in this regard, we present Mobile Fog, a high level programming model for the future Internet applications that are geospatially distributed, large-scale, and latency-sensitive. Upon validating employee uniform for work, smart hard hat will also recognize employee as register worker or not, again smart cameras will play the role by its powerful system to identify registered employee within fraction of Nano seconds and generate alert for MOID server dependent on the individual data got after recognition process fails.

For instance, the alert may caution MOID and specific work force that they violate rules at the building site or non-registered worker is working on site. Alternatively, workforce action might be intermittently checked and revealed as shown in figure (5).

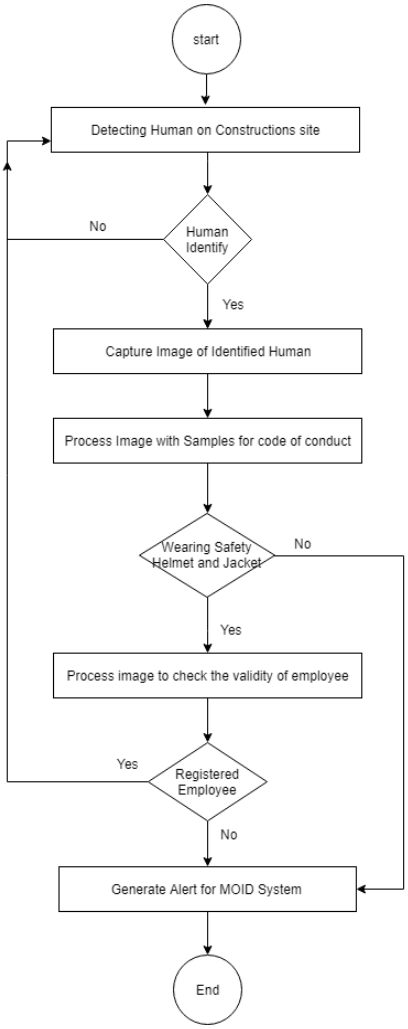

Figure 5. System notification workflow

4.1 System Reporting

The application of smart hard hat is based on wearable device (Safety helmet) which will be used by safety marshals or foreman on each site, and this will allow the user to monitor all site personal without disturbing their daily tasks. The smart helmet will keep recording all objects and human and compare all values with the stored database with the safety module.

4.2 Face detection

The technology will address the face detection using stored meta data, face images, which will be compared with the video captured. In order to communicate with the nature of images collected to a remote node from the camera arrangement. The accuracy of the face detected identify the image frame or field and include the image position. This method will use key frames to recover facial structure, and rely on image similarity which has

been collected and stored in the server. Then the image structure will refine the collected results and add the new data to the targeted database. Based on the results the hat will analyse the face detected along with geolocation of the image taken to evaluate the difference and trigger the notification command.

Figure 6. Face recognition using smart hard hat

4.3 Object Detection

The main goal of smart hard hat detection is to detect objects attached to face of the workers, this goal will check if protective equipment exist at 3 main positions on the worker body

- Focus on the upper area of the worker face
- Focus on the center area of the worker body

The results refer to the degree of the safety equipment with respect to the x-axis, the values between (-1 and 1) indicate if the PPE location is correct relatively to the body and head position. The system will store up to 8 images per second in real time, then the object detection will compare its results with the data collected from the face detection to report whether any safety violations has been registered. In case of no equipment detected a red alert will be raised and report will be generated with incident details and sent to both Ministry Safety Department and site manager.

Figure 6. Face recognition using smart hard hat

4.4 Results & findings

Based on the technology described above, the experiment was divided into two sections: (1) validating construction workers PPE using human inspectors and (2) use smart hard hat to generate safety reports, results are shown on table (3) and (4). The study included 3 sites with over 1500 worker.

Table 3. No. of violations reported per day

Sites	Smart Detection	Site Marshal
Site 1	128	85
Site 2	63	25
Site 3	176	63

As seen on table (3) site marshals are not very accurate on their safety violations reporting as workers are moving around and located in different locations, while using smart camera detection the violations are automatically detected and process time of recording and analysing the image is much faster.

Table 4. Accuracy ratio for different type of detection

Sites	Precision (%)	Speed (s)
Head	95.1	0.201
Body	97.2	0.190
Hand	87.4	0.204
Shoes	56.3	0.204

Table (4) is testing the accuracy of the whole body detection and classify the objects into four categories: head, body, hand, shoes. The result shows that the highest accuracy is the body vest detection for its clear view and because of the reflected stripes it is easy for the camera to detect, however the shoes or feet detection is showing the lowest accuracy as not all images are able to detect the lower body parts of the workers and sometimes the workers shoes are too dirty to be detected.

5 Conclusion

The technology proposed to detect safety violations involves image detection and object recognition. The implementation of the application involves smart hard hat with internet based camera attached to the hat and involves database management for the safety template comparison. The main goal of this research is to legalize the smart hard hat among construction sites by generating real time automated reports and sent to both ministry safety department and site managers, this technology will provide daily reports of safety compliance and will increase the safety awareness among workers.

The system will analyse real-time images for the construction sites and detect workers who are not complying to the safety standards by comparing images taken on sites with standardized templates added by the ministry of infrastructure to reduce number of violations and relatively reduce number of injuries reported.

6 Recommendations

In the future research studying smart hard hat with its application using IoT to generate better understanding of workers daily behaviour in order to reduce number of incompliance, this will produce more accurate data and more automated results for more accurate monitoring for registered construction sites. Additionally further study needed for the effects of data signals transmitted from the hat technology to find better and faster data collection, this study will be able to provide better data analytics should the worker face any drop of negative impact. Furthermore, market analysis to determine the demand for this technology will be also required and would create better applications.

Abstract –

The use of heavy cranes has increased with the impact of modernized modular construction, which in turn has led to heavier modules, with weights often measured in hundreds of tons. As a result, the criticality of such lifts depends primarily upon the ground support health. The traditional approach is to make use of timber/steel mats for ground stability. The use of frozen silt (water and silt frozen mixture) as an alternative to this or to reduce the number of layers of timber mats is a novel technology that is explored in this work. For projects where this technology could be applicable, heavy construction companies will be able to avoid extensive ground preparation and reclamation by adopting this approach. The mechanical properties of frozen silt are comparable to timber mats (Coastal Douglas-fir), but are dependent upon the temperature constraint. This contribution encompasses the use of artificial ground freezing for the preparation of frozen silt matting for ground support. The required mat surface temperature is considered as −10 °C, based on the competitive mechanical properties for its practical use. The freezing process is investigated using Finite Element Analysis (FEA). Simulation is performed to obtain the bottom-up estimate of ground freezing using indirect freezing (brine chillers) and direct freezing (liquid nitrogen) for both the freezing phase and maintenance phase. The simulation is executed under three ambient temperatures (10 °C, 5 °C and 0 °C) in order to make it realistic. The results from these simulations can establish a baseline for cost estimation for the alternative crane matting solution in the form of frozen silt mat.

1 Introduction

Traditionally, the heavy construction industry has relied upon using cranes to build the structures needed in the field since the elements constituting these structures are generally voluminous and heavy. With off-site construction becoming the paradigm of choice for project delivery, complete projects are delivered in the form of modules, which, over the years, have become heavier as an increasing number of components are added to the skeletal modular structure during fabrication. As a result, high-capacity cranes have emerged as the fundamental equipment for the assembly of modularized power plants and refineries. Of course, as the weight of the lifting system (crane + payload) has become heavier, ground-bearing capacity analysis cannot be ignored, since failure of the ground can result in loss of life and property. Today, the traditional approach to improving the capacity of the ground proceeds in two phases: (i) ground preparation, which consists of excavating a given depth of ground that is replaced by a layer (or a mix of layers) of construction aggregates compacted; and/or (ii) addition of one, two or three layers of timber mats. This setup allows the total load of the lifting system to be appropriately distributed. With the adoption of the modular construction paradigm, the demand for crane mats has been augmented. According to market research, in 2014, the total annual mat demand in Canada was in the range of 450,000–750,000, while annual mat production in North America in 2014 was approximately 300,000–600,000, and the number of mats produced in Canada in 2014 was approximately 20,000–25,000. The matting industry increased 200% from 2009 to 2014 [6]. Nevertheless, a study by OSHA reported that, from 2000 to 2009 in the United States, approximately 12% of fatalities on construction sites were associated with crane

work. A total of 587 lives were lost as a result of 571 accidents from crane work during that period, of which 105 were crane operators, 375 were riggers, and eight were signal people. It is estimated that approximately 50 deaths were caused by "Crane Tipped Over", which is directly associated with poor ground support [22]. Interestingly, ground support technology has been largely overlooked by practitioners despite the cost and environmental impact associated with current ground capacity improvement methods. In this respect, with increasing environmental awareness, choosing a technology for a given purpose needs not only to be cost-effective but also to have a low impact on the environment. Using the same characteristics, frozen soil has properties similar to the supporting structural material [1]. Considering the mechanical properties of frozen silt (water and silt frozen mixture), the novelty of using frozen silt for crane matting is a novel idea which transcends traditional constraints and helps to minimize environmental impact. The mechanical properties of frozen silt are comparable to timber matting (Coastal Douglas-fir), but are dependent upon the temperature constraint (i.e., the mechanical properties of frozen silt with the surface temperature below −10°C are comparable to Coastal Douglas-Fir). To achieve this temperature, artificial ground freezing can be used. The earliest documented application of artificial ground freezing was in a mine shaft near Swansea, South Wales, in 1862. Later, this freezing method was patented by F. H. Poetsch, in 1883 with some major improvements [18]. In 1884, excavation of a tunnel in Stockholm was aided with a frozen stabilized arch [2]. In practical usage, there are two types of ground freezing methods: indirect freezing (brine chiller) and direct freezing (liquid nitrogen). In this contribution, the Fluid Flow (Fluent) module of ANSYS (17.1) is used to estimate the usage of indirect and direct freezing for the preparation of frozen silt matting. A model of the proposed frozen mat with freezing pipes is generated and uploaded in ANSYS module. The mat model is placed on the ground to create a real case scenario. We thus create a basis for the practical and onsite application of ground freezing methods for frozen silt mat preparation. Constructed on energy equations and viscosity constraints for heat transfer between mat, ground, and air, ANSYS simulation provides the graphical representation of mat freezing with respect to time lapse. To make it realistic, the simulation is performed under three ambient temperatures (10 °C, 5 °C and 0 °C). The simulation of indirect freezing is performed by taking constant fluid flow of brine, whereas for direct freezing, three different fluid velocities are assigned. The idea is to simulate the weather condition of the north-western part of Canada. The freezing phase and the maintenance phase for the frozen silt mat are analyzed to obtain the cooling requirement in figures (numbers). For indirect freezing, the cooling requirement is in the form of the temperature difference between inlet and outlet of freezing pipes, flow of brine, and, for direct freezing, the amount of liquid nitrogen used for the freezing of the mat. The results indicate how much energy drainage is required to convert silt into frozen silt under the same boundary conditions but at different ambient temperature and different flow velocities of the cooling agent. The results are found to be favourable and comparable to the actual artificial ground freezing. The results from these simulations provide a baseline for the cost estimation for the alternative crane matting solution in the form of capital, operational, and opportunity costs for this novel alternative to the use of timber matting ground support. Based on these results, a value proposition of using frozen silt mat can be generated with better SWOT (Strength, Weakness, Opportunities & Threats) figures.

2 Research Methodology

2.1 Frozen Silt Mat Proposed Design

The first step is to provide a preliminary conceptual design for the frozen silt mat. Based on the data available, a conceptual silt mat design is initiated in this section for ANSYS heat transfer simulation. As per the dimensions of the mat (3.6449 m × 2.4384 m × 0.2032 m), eight frozen silt mats are proposed to be used for a Manitowoc 18000 Crawler Crane (see Figure 1). For analysis purposes, only the crawler crane is selected. The aim of the research presented in this paper, is to perform the simulation for the freezing process of silt mats until the surface temperature reaches or drops below −10°C.

Figure 1 shows the placement of the proposed four frozen silt mats under one track of a crawler crane. For the freezing purpose, conceptually, 10 freezing pipes are used. In the proposed layout, the pipes are placed evenly inside the soil perpendicular to the length of the mat but parallel to the crawler track. It is assumed that each pipe crosses all four mats under one crawler track. The cooling agent enters one end of these pipes and exits from the other end. For insulation purposes, the soil, cost-effective insulation on site, itself can be used as the mat cushion (insulation), where the thickness of the mat is increased to create a mat cushion (insulation) (see Figure 2).

The four silt mats combine to form one long frozen silt mat with mat cushion (insulation). The length of the whole mat (consisting of four frozen silt mats) is considered to be approximately 10.5 m, with a width of 4 m. The proposed height (0.303 m) of the mat exceeds the practical normal mat height (0.203 m). The extra height provides the mat cushion which functions as insulation. If this insulation is not provided, the surface temperature of the mat drops rapidly. A freezing

temperature of −10 °C throughout the mat is required (including the mat surface). 2″ steel pipe schedule 40 is used for the freeze pipes. These steel pipes work as a conducting material to transfer heat from the silt to the cooling agent (either brine or liquid nitrogen).

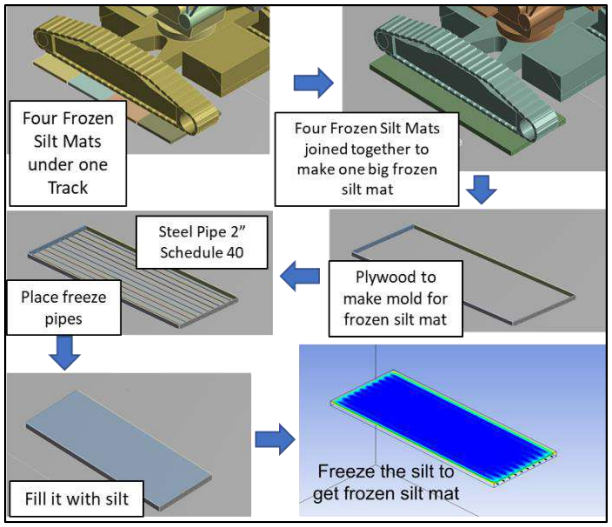

Figure 1: Proposed Frozen Silt Mat configuration

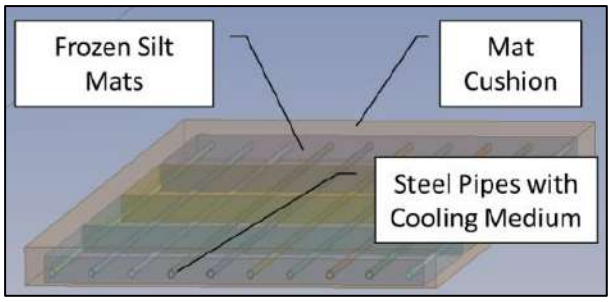

Figure 2. Mat Cushion for insulation

2.2 Mechanical Properties of Frozen Silt Mat

Mats made of frozen silt can sustain the Ground Bearing Pressure (based on the comparable mechanical properties of timber matting) if the mat temperature is below −10 °C. The mechanical properties of the frozen silt mat, it should be noted, are considered from the research done by Yang et al. (2015), and by Wilson (1982) [20][21]. The value of Young's modulus ranges from 0.7 GN/m^2 to 16.5 GN/m^2 with the temperature ranging from 0 °C to −10 °C. The dry density is found to vary from 320 kg/m^3 to 941 kg/m^3, while the water/moisture content varies from 62% to 225% [21]. Based on the above data, the compressive strength of the frozen silt varies from 1.7 MPa to 7.1 MPa [21]. For the purpose of comparison, the surface temperature of frozen silt mat is considered as −10 °C. Table 1 shows the comparison between the mechanical properties of Coastal Douglas-Fir and the proposed frozen silt mat. As can be seen, the properties of the frozen silt are found to be comparable with the timber mat made of Coastal Douglas-Fir.

Table 1. Linear mechanical properties for comparison

		Units	Coastal Douglas-Fir	Frozen Silt
1	Young's Modulus	MPa	13,400[a]	10,000[b, d]
2	Poisson's Ratio		0.449[c]	0.3[e]
3	Tensile Yield Strength	MPa	2.3[a]	5.1[d]
4	Compressive Yield Strength	MPa	5.0[a]	5.0[d]
5	Tensile Ultimate Strength	MPa	5.0[a]	5.1[d]

2.3 ANSYS Methodology

This research on frozen silt mats can be divided into two parts with respect to Finite Element Analysis (FEA):

a. heat transfer to/from proposed frozen silt mat;
b. usage of a cooling agent for the freezing of proposed silt mat for cost comparison.

ANSYS Workbench (version 17.1) is used for this research. For thermal simulation, it should be noted, "Fluid Flow (Fluent)" solver is available in ANSYS to

simulate the computational fluid dynamics (CFD) and thermal variation. The whole process is divided into 5 steps. Step 1 (Geometry Build): In this step, the geometry of the object or structure is drafted or imported from a 3D AutoCAD file. Here the lower the number of geometry parts is, the faster the ANSYS fluid flow solver can analyze and implement the mesh. As the number of parts of a geometry increases, the time required by the ANSYS solution increases exponentially. Step 2 (Generate Mesh): In this step, the model is uploaded to ANSYS Fluid Flow (Fluent) solver "Mesh". This includes meshing of the model to small elements for FEA. The type and conditions of meshing are described later in this section, where, the smaller the meshing element is, the better it is considered to be. However, the accuracy and precision must be monitored to make it workable. It is also preferable to give each surface a separately named selection. (These name selections make step 4 easier.) Step 3 (Apply Boundary Conditions): In this step, the previously determined energy equations are applied to the geometry, and thermal/viscous properties of the fluids are assigned. The interference between different body surfaces is also assigned in this step, as well as cell zone conditions. Finally, the inlet and outlet temperature and fluid velocity are assigned accordingly. Step 4 (Obtain Solution): After obtaining the geometry and assigning the required boundary conditions, the solution to the problem is initiated. The solution depends upon the solution initialization, the number of time steps, the duration of time steps, and the maximum iterations per time step. Step 5 (Display Results): The final step is to obtain the results, where fluid dynamics is the basis of these results. Heat transfer with respect to time is obtained in this step. The results can be shown in the form of graphs, colour variation, or various charts and sheets. The data can be exported to different file formats as necessary for further investigation.

2.4 Thermal Properties

For the thermal analysis, the thermal properties of the material for ANSYS simulation are tabulated in Table 2. The heat transfer occurs in the following manner: (a) heat transfer from the pipes to the cooling agent through conduction and convection, where the thermal properties and the viscosity of the cooling agent cover the estimation for heat rejection from the geometry (frozen silt mat, pipes, air, ground); (b) heat transfer from the mat to the pipes through conduction; (c) heat transfer from ground to the freezing mat, where, during the mat freezing process, the soil under the mat also is frozen with the passage of time and later functions as insulation; and (d) heat transfer from the air to the silt mat in the form of convection (2 W/m^2•K, assumption) and radiation (external emissivity 0.98, assumption) [4][19].

Table 2. Thermal properties of materials involved in frozen silt mat thermal process ANSYS analysis.

Density (kg/m^3)	C_p (j/kg•°C)	Thermal Conductivity (W/m•K)	Viscosity (Poise)
	Steel		
7,500	500	43	0
	Frozen Silt (120%)		
1,100[a]	1,360[a]	1[a]	0
	Ice		
900	2,090	0.08	0
	$CaCl_2$ (30%)		
1,318[b]	2,650[b]	0.5[c]	0.221[c]
	Liquid Nitrogen (−150°C)		
808.5[d]	2,040[e]	0.1396[e]	0.00068[f]

2.5 Freezing Methods

A standard soil freezing installation involves a refrigeration source, a distribution system, and cooling pipes for freezing of the soil (called "freeze pipes") [14]. The distribution system circulates the cooling agent (coolant for the freezing of the soil) from the refrigeration source to the freeze pipes, which extract the heat from the soil. In general, there are two main types of cooling agents: brine solution (indirect freezing) and liquid nitrogen (direct freezing).

In indirect freezing, one- or two-stage refrigeration

plants are the most commonly used refrigeration sources. They are powered by diesel or electric engines. Usually, chilled calcium chloride ($CaCl_2$) is used as a cooling agent to freeze the ground. The cooling agent is pumped through the freeze pipes, and, after withdrawing heat, returns to the unit (see Figure 3). The whole process occurs in three phases. The first phase is known as the **freezing phase**. The temperature of the brine solution increases by approximately 1°C to 2°C during this process. In this phase, the ground is frozen to achieve the required strength. The next step is to maintain the temperature of the frozen soil. This is known as the **maintenance phase**. The energy drainage required to freeze the ground, it should be noted, is greater than the energy drainage required to sustain the frozen ground [12].The final phase, known as the thaw phase, is to terminate the freezing project. In this phase, the ground is left to thaw [9].

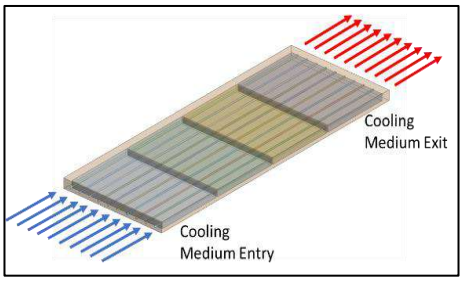

Figure 3. Cooling agent flow through mat

In direct freezing, as indicated by its name, the soil is directly cooled by the freezing agent. Primarily liquid nitrogen is used to freeze the ground in this process. It also involves three phases: the freezing phase, the maintenance phase, and the thaw phase. The coolant is supplied directly from the storage tank, and the soil/silt around each freeze pipe freezes radially. The amount of nitrogen required for the freezing is maintained by means of a temperature-sensing valve. As the valve opens, nitrogen escapes into the atmosphere at a rate that is not dangerous to the environment.

2.6 Heat Transfer Analysis Method

The data from the mat strength analysis provide the basis for the heat transfer analysis. For heat transfer analysis, ANSYS Fluid Flow (Fluent) solver is used to simulate the cooling of frozen silt mat in order to convert silt into frozen silt mat (solid). The process is summarized in the following steps:

Step 1: The mat dimensions obtained from the mat strength analysis are used to propose the design of the frozen silt mat. The freeze pipes are added to the frozen silt mat for the purpose of freezing the soil around the freeze pipes, resulting in a solid frozen silt mat. The proposed design of the mat with the addition of freeze pipes is uploaded in ANSYS Flow (Fluent) Geometry Module, and the proposed mat is placed on the soil model. The parameters of soil and the frozen silt mat are considered equal, with the exception of the differences in the internal temperature of the frozen silt after cooling and the ambient temperature of the loose soil.

Step 2: One end of the pipe is considered an inlet for the cooling agent, while the other end is the outlet for the cooling agent. For indirect freezing, $CaCl_2$ is used as the cooling agent. The velocity and temperature of the cooling agent are adjusted to obtain the heat transfer. For direct freezing, the flow of liquid nitrogen is used to monitor the freezing of the mat. The temperature of the cooling agent is adjusted as per the cooling parameters.

Step 3: The heat transfer rate along the flow of the liquid provides the heat transfer data for estimation purposes, while the cooling administered by the cooling agent is used to determine the freezing refrigeration unit for indirect freezing. For direct freezing, the amount of liquid flow provides the quantity of liquid nitrogen used for the freezing of the mat. The time required for the freezing of the mat surface is also recorded for further analysis.

Step 4: The ambient temperature and the boundary conditions are applied to the model. Prior to this, the geometry is subdivided into smaller elements by applying “meshing”. Meshing is carried out to break the whole model into small finite elements for analysis. The time steps and iterations per step are applied to the solver.

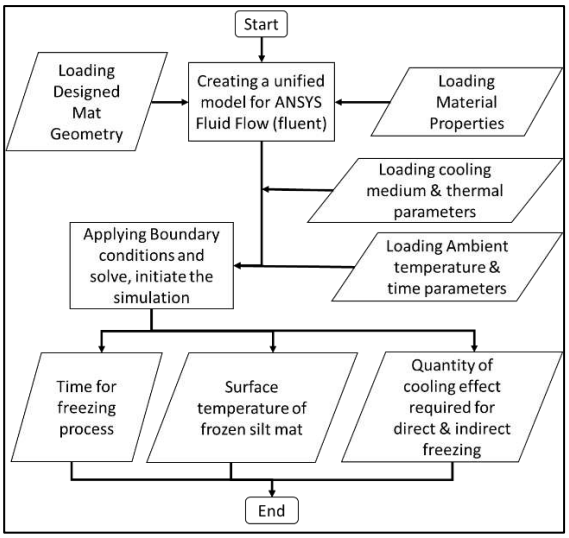

Figure 4. Flowchart for frozen silt mat freezing sequence

Step 5: The solution is uploaded to the results section of the solver, and the heat transfer with respect to time is obtained for the whole system. The surface temperature

of the mat is observed and recorded to check the feasibility of the required frozen silt mat temperature. For indirect freezing, there are three main variables obtained from this exercise: the temperature difference between inlet and outlet temperature of cooling medium; the time required for cooling; and the surface temperature of the frozen silt mat. For direct freezing, there are three main variables: the flow of liquid nitrogen; the time required for cooling; and the surface temperature of the mat.

The above-mentioned methodology is presented in the form of a data flowchart in Figure 4.

3 ANSYS Simulation

3.1 Indirect Freezing ($CaCl_2$)

Calcium chloride ($CaCl_2$) is used as a cooling agent, and its velocity is assumed to be 0.29 ft/s (0.088392 m/s). The inlet temperature of $CaCl_2$ at the start of the analysis is the same as the ambient temperature, but it drops gradually until it reaches −30.15 °C. To avoid complexity, it is assumed that the temperature drop is 5 °C over a 24-hour period (gradual). To simplify the model, the heat generated from the crane engine/crawler track is not considered. For data collection, each step is composed of 3,600 seconds, with 200 iterations, and the number of steps as 720. Hence, the total simulation time is 30 days.

The temperature of the mat surface (under the mat cushion) is recorded and plotted against time (days) in Figure 5. As per the simulation, the surface temperature of the frozen silt mat is close to −10 °C with the ambient temperature of 10 °C, and it takes 8 to 9 days to freeze the silt sufficiently to create a frozen silt mat. In the case of 5 °C ambient temperature, it takes less than 7 days to freeze, and, for 0 °C, it is less than 5 days. The surface temperature of the mat (under mat cushion) ranges between −10 °C and −15 °C for case-2 (5 °C) and it is below −15 °C in case-3 (0 °C).

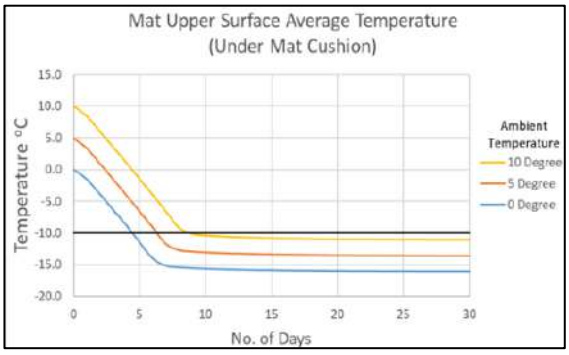

Figure 5. Mat Surface Average Temperature

The heat removal from the proposed frozen silt mat in the simulation is shown in Figure 6. The heat removal value for case-1 (ambient temperature 10 °C) is higher than in the other two case examples. The first part of the graph (the linear part) shows the freezing phase, while the later horizontal line shows the maintenance phase.

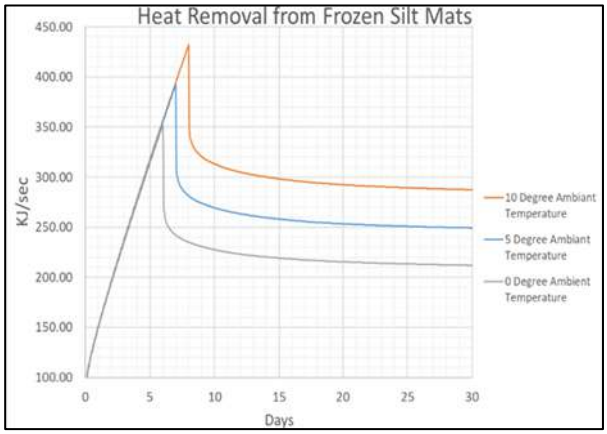

Figure 6. Heat Removal from Frozen Silt Mat

3.2 Direct Freezing (Liquid Nitrogen N_2)

Direct freezing differs from indirect freezing as discussed in section 2.5. The flow of the liquid nitrogen is the main cost driver. For ANSYS simulation purposes, three assumed cases are taken into consideration based on different flow velocities of liquid nitrogen. As per the proposed design of frozen silt mat, there are 10 pipes for each frozen silt mat. The velocity of liquid nitrogen for the outer pipes (pipe 1 and pipe 10) is taken to be constant. The velocity of liquid nitrogen for the inner pipes (pipe 2 to pipe 9) is considered variable with respect to time. Table 3 shows the details of these cases.

Each assumed case is simulated at three different ambient temperatures: 10 °C, 5 °C, and 0 °C. All the remaining parameters are similar to those described in Section 2. The use of liquid nitrogen with respect to the number of days is shown in Figure 7. The flow is found to be maximum for case-1 and minimum for case-3. With every case analyzed under each of the three ambient temperature scenarios, in total nine case examples are simulated for freezing silt mat in ANSYS.

The average surface temperature of the mat decreases rapidly due to the low temperature of liquid nitrogen as compared to brine (the boiling point of nitrogen is −195.8 °C at atmospheric pressure). It is assumed for the ANSYS simulation that the temperature of liquid nitrogen (LN_2) entering the pipe is −150 °C. Due to this low-temperature flow, the temperature of the mat material (silt) decreases rapidly. The graphical representation of the mat surface temperature with respect to time is shown in Figure 8. From this simulation exercise, case-1 is found to perform well at every ambient temperature as compared to case-2 and case-3. The

surface of the frozen silt mat reaches −10 °C faster if the use of liquid nitrogen is increased in the form of higher flow (case-1). The surface temperature for case-1 is found to be lower than that for case-2 and case-3.

Table 3. Liquid nitrogen velocity for three cases.

	Case-1	Case-2	Case-3
Outer Pipes	0.005 m/s (0.016 ft/s)	0.004 m/s (0.013 ft/s)	0.003 m/s (0.0098 ft/s)
Inner Pipes 0 to 24 hr	0.005 m/s (0.016 ft/s)	0.004 m/s (0.013 ft/s)	0.003 m/s (0.0098 ft/s)
Inner Pipes 24 to 720 hr	0.005 m/s (0.016 ft/s) linearly decreasing to 0.002 m/s (0.0056 ft/s)	0.004 m/s (0.013 ft/s) linearly decreasing to 0.0015 m/s (0.0049 ft/s)	0.003 m/s (0.0098 ft/s) linearly decreasing to 0.001 m/s (0.0033 ft/s)

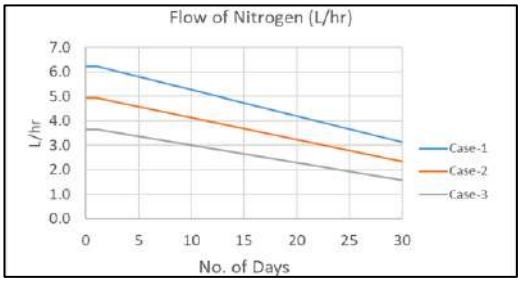

Figure 7: Liquid Nitrogen Total Flow (L/hr)

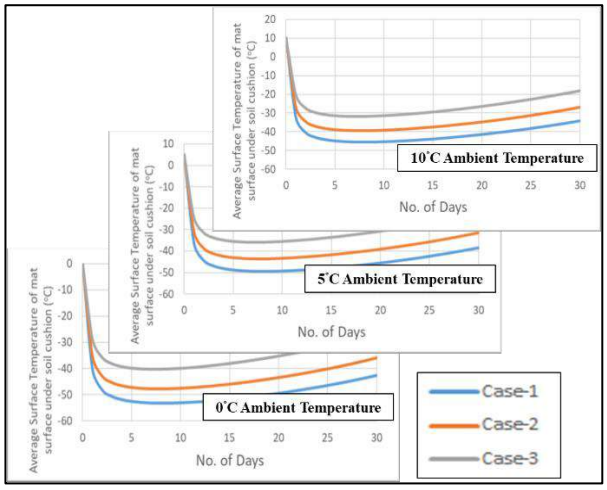

Figure 8: Average Mat Surface Temperature (Direct Freezing - Liquid Nitrogen LN_2)

4 Conclusion

- This research provides a guideline for the freezing process of frozen silt mat. The mechanical properties of frozen silt mat are found to be comparable if the surface temperature is −10 °C or below.
- The results of indirect freezing in the form of the graph representing energy drainage with respect to time are similar to the energy removal graph presented by Newman et al. (2011) [15]. The steep line represents the freezing phase while the horizontal line after the freezing phase represents the maintenance phase to maintain the temperature.
- The results also show that the freezing process in direct freezing is quicker as compared to in indirect freezing. The surface temperature reaches −10 °C in hours in direct freezing, compared to days in indirect freezing.
- This research can be used for estimating the duration of the freezing process for frozen silt mat in cold regions, as less energy drainage will be required. The frozen silt mat can be an environmentally friendly alternative for crane timber mats in some cases, but future study is required in this regard to determine the suitability of this technology.
- ANSYS can be used for the estimation of artificial ground freezing for practical use. The graphical representation of indirect and direct freezing provides a better overview of how moist soil turns into frozen ground as compared to the manual calculations of artificial ground freezing.

5 Recommendation and future aspects of the research

This research indicates that ANSYS can be used to estimate the application of artificial ground freezing methods for the preparation of frozen silt matting. Different fluid flow velocities need to be investigated to obtain a better view and understanding of the mat freezing process. But, before addressing this particular aspect, the stress comparison must be established for the frozen silt mat in accordance with the timber mats (Coastal Douglas-Fir). The physical properties must be verified using ANSYS and later by means of lab/site testing. For frozen silt mats, future research can investigate other soil types (sand, clay, loam, chalky soil, etc.) in order to establish an empirical relationship between mat surface temperature, ambient temperature, soil composition, water content, and different freezing methods. These projected figures further need to be verified by lab/site testing. The variation of Young Modulus with respect to the surface temperature on the

strength of frozen silt mat should also be investigated in detail, as well as the impact of density change on freezing methods. Density anomalies of water/ice/frozen silt with respect to ambient temperature, it should be noted, are not incorporated in this research. These anomalies and their impact on the strength of a frozen silt mat can be considered in future research. The use of mesh/reinforced bars/pulp to increase the stability and strength of frozen silt mat also needs to be studied in detail in order to arrive at a better and more progressive value proposition with respect to timber mats, both technically and financially [17].

Abstract –

Recently, the use of solar panels has increased because of the growing demand for solar energy. To determine appropriate installation sites of photovoltaic (PV) panels, estimating the available solar energy at a certain area is important to predict the amount of power generation and planning PV plant operations. However, traditional data-driven approaches (e.g., machine learning) do not fully reflect the topographical characteristics of surrounding regions in the solar energy estimation, and the impact of data resolution (e.g., map scales) on the prediction accuracy has rarely been investigated. Thus, this paper presents a solar irradiation prediction model using a convolutional neural network (CNN) designed to process digital elevation map (DEM) images. Furthermore, an analysis of the impact of two different resolutions (i.e., 30 m and 60 m resolutions) on the model performance is also presented. A total of 25,000 DEM images are extracted from the national map of South Korea for both resolutions and then used as an input to train the CNN models. The results show that the CNN-based prediction models can be used to estimate the solar irradiation with high accuracy (e.g., mean square errors of 0.0018 and 0.0032 for 30 m and 60 m resolutions). It was also found that data resolution affects the performance of the CNN-based models. With an accurate estimation of the available solar energy at a certain site, the sites generating more power can potentially be evaluated and selected by searching a DEM on a large scale.

1 Introduction

Global carbon dioxide emissions from fossil fuels, which are considered to be the major cause of global warming, have been constantly increasing in the last decade: for example, by an average of 3.1 ± 0.2 GtC yr^{-1} during 2008-2017 [1]. As global warming affects human health and causes the climate change, efforts such as environment regulation, emissions trading, clean energy technology development, and deforestation reduction have been made to control and reduce the pollution. An effective approach is replacing fossil fuel with renewable energy, such as solar energy, wind energy, biofuel energy, and so on. Particularly, the use of photovoltaics (PV) has rapidly grown, nearly quadrupling over the past five years [2]. Unlike other renewable energy sources, solar energy is considered to be economical: solar cells operate for a long period, generally more than 20 years, and require low maintenance expenses [3].

To meet the increasing demand for solar energy, the prediction of solar radiation that estimates the amount of available solar energy at a certain place is a key to planning the power supply [4]. Furthermore, the accurate estimation of available solar energy allows for the optimal selection of PV installation sites, as well as the decision on PV system [5, 6]. Although various approaches to the solar energy estimation (e.g., statistical model, fuzzy logic approaches, machine learning) have been proposed and used in practice, it is still challenging to collect solar radiation data on a large scale and consider the geographical characteristic of adjacent areas in the estimation. For example, solar radiation-related data that is used to estimate available solar energy is often collected from specific observation regions. Although this approach can be suitable for general terrain, it would be hard to assume that simple linear interpolation or any estimating method for topography measurements may work well for other regions far away from the observation stations or complex terrain (e.g., mountains) [7]. Furthermore, in general, statistical methods or conventional machine learning algorithms (e.g., Bayesian networks, support vector machines) do not directly process image or map type-data with the three-

dimensional (3D) shape of an image (i.e., topography) [8]; while recent machine learning algorithms such as convolutional neural networks (CNN) are designed to keep spatial relationships among data points (e.g., pixels) in the modeling process (e.g., optimization of model parameters).

This research thus investigates the use of CNN for modeling and predicting the solar irradiation, taking into account the effect of geospatial features, including elevation, slope, aspect, shadow effect, and so on. Specifically, this paper mainly focuses on the impact of data resolutions on the prediction accuracy in order to understand the effect of map scale and geographical features on solar energy computation. The CNN model is trained with a digital elevation map (DEM) containing such topographical features and solar radiation datasets estimated in pixel levels. With the trained CNN model, performances for DEMs of 30 m and 60m resolutions are compared to evaluate the effect of data resolution.

2 Research Background

This section reviews recent studies that consider topographical features for predicting solar irradiation using machine learning techniques and statistical methods. In addition, the impact of data resolution on forecasting performance of solar irradiation is also reviewed and discussed.

2.1 Challenges in Solar Irradiation Prediction Considering the Topographical Features

Recent studies showed that the topographical features (e.g., altitude, latitude, longitude) considerably influenced the solar radiation prediction performance [7, 9, 10, 11]. For example, [7] estimated daily global solar irradiation by using solar radiation data collected on the complex mountainous terrain; it was found that the most important geographic factor to estimate global solar irradiation on complex mountainous terrain is the altitude. [9] developed the prediction model using solar radiation data observed in different regions in the model training and testing processes, showing that the solar radiation could successfully be estimated for new testing regions not used in the modeling process. Additionally, [10] evaluated geographical factors such as latitude, longitude, altitude in order to find the optimal combination of input parameters and to understand the impact of topographic features.

Overall, these previous studies provide insight into the use of data and the impact of topographical features on predicting solar irradiation by building statistical or machine learning models. Nonetheless, the models and methods proposed in the studies are mostly tested with the data collected at specific observation stations. This issue can become critical when applied to the regions far away from the study areas, where topographical characteristics can significantly be different. In this regard, further studies are still required for in-depth understanding of the topographical features in solar irradiation estimation, when the data-driven approaches are applied to large-scale areas or other areas, as pointed out in [11].

2.2 The Effect of Data Resolution on Solar Irradiation Prediction Model Performance

For machine learning or statistical methods, data resolution is another factor affecting the predicted amount of solar irradiation [12, 13]. The effect of data resolution was thus studied with a focus on the input data such as a DEM used to develop the geometry-based prediction model of solar radiation. In [12], geometry-based methods were developed using solar radiation models such as SRAD, Solei-32, and r.sun, which analyzed the components of solar radiation (e.g., direct, diffuse, and reflected) and geographic elements such as site latitude, topography, shadow cast, and so on. [12] found that the resolution change of a DEM affected the input variables of the prediction model, such as shadow effect, elevation, slope, etc., which resulted in a difference between the predicted solar radiation values and actual values. [13] also showed that a higher DEM resolution improved the performance of solar radiation models. These studies implied that the resolution of a DEM can affect the accuracy of surface angle calculations at the study area, which are the key inputs to theoretical computing of the solar radiation.

Unlike geometry-based methods, the impact of data resolution has rarely been studied for data-driven approaches that attempt to recognize patterns in the relevant data for the solar radiation prediction. It may be because machine learning methods in the previous studies [e.g., 14, 15] generally used solar radiation data (e.g., altitude, latitude, longitude, land surface temperature) produced at observation stations. In this case, the resolution of data may not be of importance for the prediction, as DEM data was not directly used for the modeling process. Consequently, the effect of data resolution still remains unknown when DEM data itself is used as an input for machine learning approaches to solar radiation estimation.

3 Method

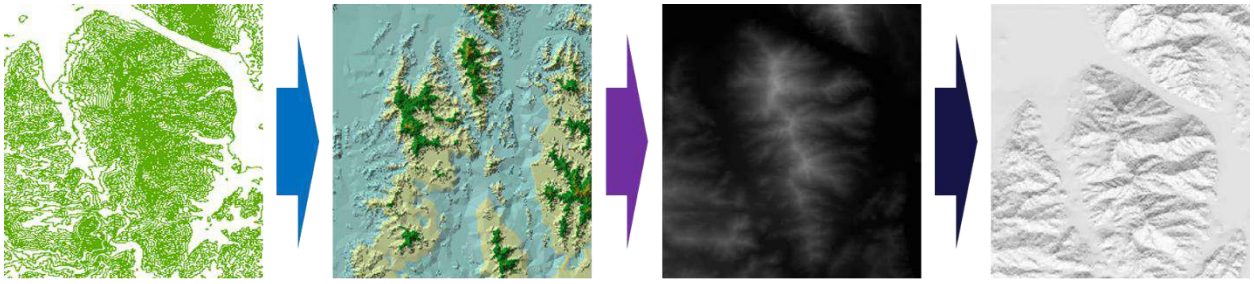
To evaluate the effect of data resolution on machine learning-based solar energy prediction, this study builds and compares two CNN models trained with a DEM with 30m resolution and another DEM with 60 m resolution

along with the average amount of solar radiation for each DEM map of 30 by 30 pixel. Specifically, the DEMs are created with GIS datasets publicly provided by the National Spatial Data Infrastructure (NSDI) in South Korea, and the DEM that covers the entire national territory with the grid cell size of 30 m by 30 m is selected to create the DEM datasets with different resolutions, i.e., the inputs for the CNN models. Meanwhile, the output datasets, which are the estimated solar irradiation in pixel levels (e.g., a raster with 30 m by 30 m), are obtained by applying the computational estimation model presented in the authors' prior work [16]. Then, with the datasets used as an input and an output, CNN models are built and trained through the processes that minimize errors between the actual and predicted outputs. Eventually, the errors between two models with different data resolutions are compared to evaluate the effect of topographical features on the prediction performance.

3.1 Data Collection

For supervised learning, adopted in this paper, input datasets and labeled output datasets are needed to develop the CNN-based prediction model by iteratively learning the model parameters (e.g., weights) from the datasets. In building a solar irradiation prediction model, the CNN architecture consists of an input layer of a DEM image and an output layer of a solar radiation value with hidden layers between the two. The solar radiation amount for the region on each DEM image is extracted from a solar radiation image—produced by [16]—corresponding to the DEM image. In addition, two types of DEM images with 30 m and 60 m resolutions are created to assess the effect of data resolution on solar irradiation prediction. Specifically, for the inputs, DEM images (Figure 1c) are created by converting the contour map (Figure 1a) composed of group of lines joining points of the same elevation, to a triangular irregular network (TIN) (Figure 1b), which are continuous triangular facets with an empty space between contour lines representing the elevation. The generated TIN is then converted to a DEM image in a raster format (Figure 1c), which stores the elevation value at each pixel. This DEM image is eventually used as the input dataset in the CNN model for solar irradiation prediction.

On the other hand, the outputs, solar radiation data is produced by applying the computational method [16] that can estimate solar radiation values at every pixel given a DEN image. In [16], to consider topographical characteristics, a theoretical solar radiation energy model is transformed into a solar radiation model with inclined surface (Equation 1), which consists of reflected radiation (Equation 2), diffuse radiation (Equation 3), and direct radiation (Equation 4). Here, β is the surface tilt angle, ρ is the surface reflectance, and i is the incident angle. $I_{b,N}$, $I_{d,h}$ and I_h derived from [17], which are used to estimate solar radiation for a sunny day, are the radiation per unit area, the scattering radiation in the horizontal plane, and the horizontal solar radiation, respectively. Notably, to calculate the surface tilt angle (β), a tilt angle map is generated from the DEM. Consequently, when the DEM resolution changes, the tilt angle (β), reflected radiation, diffuse radiation, and even solar radiation can also change together. By applying [16], annual solar radiation is obtained as a result, and used as output datasets for the CNN modeling of solar irradiation prediction.



$$I_c = I_{r,c} + I_{d,c} + I_{b,c} \quad (1)$$

$$I_{r,c} = \rho I_h \sin^2(\beta/2) \quad (2)$$

Figure 1. Overview of data collection and processing: (a) contour map, (b) TIN image, (c) DEM image, and (d) solar radiation map.

$$I_{d,c} = I_{d,h} \cos^2(\beta/2) \quad (3)$$

$$I_{b,c} = I_{b,N} \cos i \quad (4)$$

In addition, when generating the two datasets (i.e., for 30 m and 60 m resolutions), the geographic map resolution is determined by the horizontal and vertical length of one pixel (i.e., a raster), which represents the size of the region covered by the information (e.g., an elevation value) in one pixel. For example, the DEM with 30 m resolutions means that one pixel covers 900 m^2 area, and in this study, total 105,000 images are extracted and generated from the national map, while the DEM with 60 m resolution means that one pixel covers 3,600 m^2 area, and total 26,145 images are obtained from the national map. For the experiment comparing two data resolutions, 25,000 images are randomly selected from both datasets for the fairness of model comparison.

3.2 Data Modeling Approach

Deep learning, such as deep neural networks (DNN), is inspired by the human brain, imitating the vast human brain network with interconnected neurons. DNN is composed of an input layer that accepts external stimuli, hidden layers that act as mediators that allow each neuron to receive and to send signals, and an output layer that responds to signals from hidden layers [18]. These processes help to identify patterns and recognize features in an unordered dataset. However, traditional neural networks have a limitation in finding patterns or features in an image because of flattening three-dimensional image data to a single dimension in the learning process [8]. For example, three-dimensional DEM image containing elevation information in each pixel is transformed onto one-dimensional data, for example, a list shape in Figure 2a. In this case, spatial relationships among pixels are ignored in the learning process, and hence topographical patterns in DEM datasets are hardly learned in predicting the solar energy. However, CNN can utilize the DEM image as a three-dimensional input as it is, and the topographical features can still be learned in the modeling process. As DEM images pass through the convolutional layers, filters in the convolutional layers extract the features in DEM images, as shown in Figure 2b. Eventually, the model parameters (i.e., weights) in hidden layers are updated in iterations, in each of which a solar irradiation value is predicted using a regression function and compared to the actual value. Therefore, the CNN-based regression is adopted to solar irradiation given a DEM, taking into account the relationship between the topographical features and solar radiation.

3.3 CNN Architecture for Solar Irradiation Prediction

The architecture of the CNN-based regression is illustrated in Figure 3. The input layer is designed to receive an input image of 30 x 30 pixels, which represents a region of 900 m x 900 m for 30 m resolution data and 1,800 m x 1,800 m for 60 m resolution data. These input images (Figure 4) are extracted from the national map without any overlap, as described in Section 3.1.

The input image representing a DEM when entered to an input layer is then sent to the following convolution layer. The first convolution layer used to extract the feature maps of the DEM image is composed in 30 x 30 x 32 dimensions, which means a DEM window size of 30 x 30 pixels with 32 filters. The size of the filter used in this study is 3 x 3. The first convolution layer is connected to an activation function, a rectified linear unit (ReLU) function that controls and determines the output of the layer, which will be sent to the following layer, as well as to a max-pooling layer that helps reduce computation and overfitting by decreasing the size of input window. For instance, the input image (i.e., 30 x 30 pixels) is reduced to an image of 15 x 15 pixels through the max-pooling layer in the first convolution layer. The second and third layers (Figure 3) have similar structure to the first one, working similarly. The second convolution layer extracts the feature maps from the data of the previous layer by using the same number of filters as the one in the first layer. However, the third convolution layer uses the 64 filters to extract the feature maps, although the second and third convolution layers are also connected to the activation function layer and

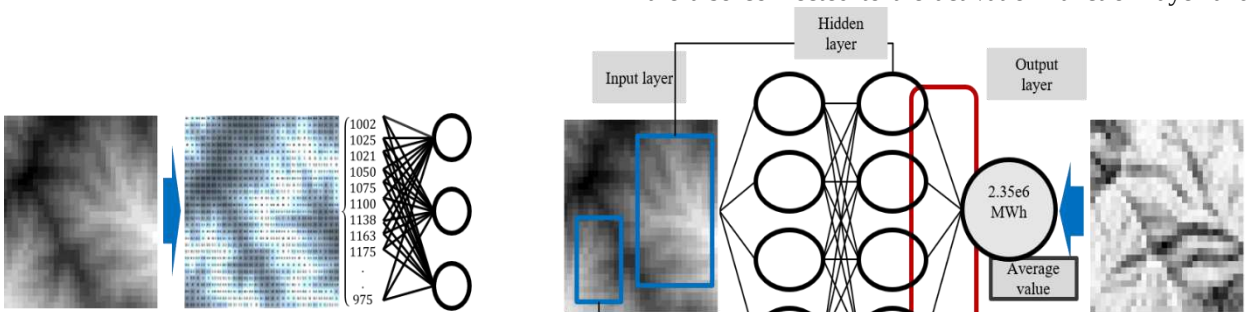


Figure 2. Overview of data modeling: (a) deep learning, and (b) convolutional neural network

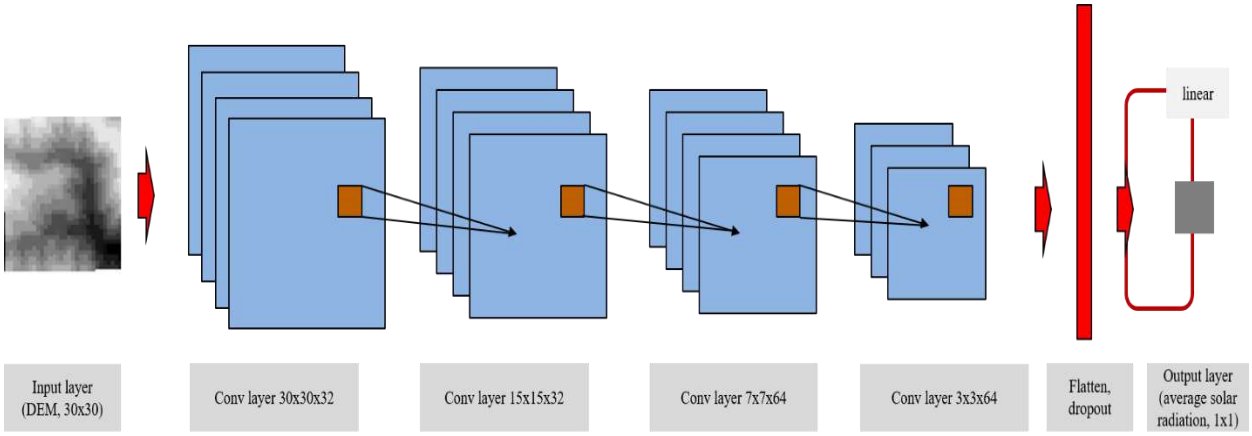

Figure 3. Architecture of convolutional neural network

max-pooling layer. The size of an input window thus decreased from 15 x 15 pixels to 7 x 7 pixels by passing the second max-pooling layer, and the size further decreased from 7 x 7 pixels to 3 x 3 pixels by passing the third max-pooling layer. The fourth layer is also a convolution layer with the same number of filters as the one in the third convolution layer, and the activation function layer; however, no max-pooling layer is included. The input data passed through the fourth layer is then sent to a dropout layer that is used to prevent the overfitting problem, and is in turn sent to a linear function layer for regression analysis (instead of a softmax function generally used for classification).

The CNN model described above is trained by using mean square error (MSE) as the loss function in the process that updates the model parameters (e.g., convolution filters) on the way that minimizes the error difference between the predicted value by the trained network and the actual solar radiation data. The MSE is defined in Equation 5, where i denotes i-th data in the dataset, and n is the number of training or testing samples in the dataset. The learning process of CNN continues in iterations until the minimum MSE, or the number of iterations a user defines, is reached. The resulting predicted value with a minimum error is compared with the actual one, and the coefficient of determination (R^2) is computed to evaluate the model performance. The value of the coefficient of determination is between 0 and 1; and for the higher correlation between the dependent variable and the independent variable, the value of coefficient of determination is closer to 1.

$$MSE = \frac{1}{n}\sum_{i=1}^{n}(actual - predicted)^2 \qquad (5)$$

In this study, the MSEs and coefficient of determination are computed for the two CNN models built for the datasets with different data resolutions, to

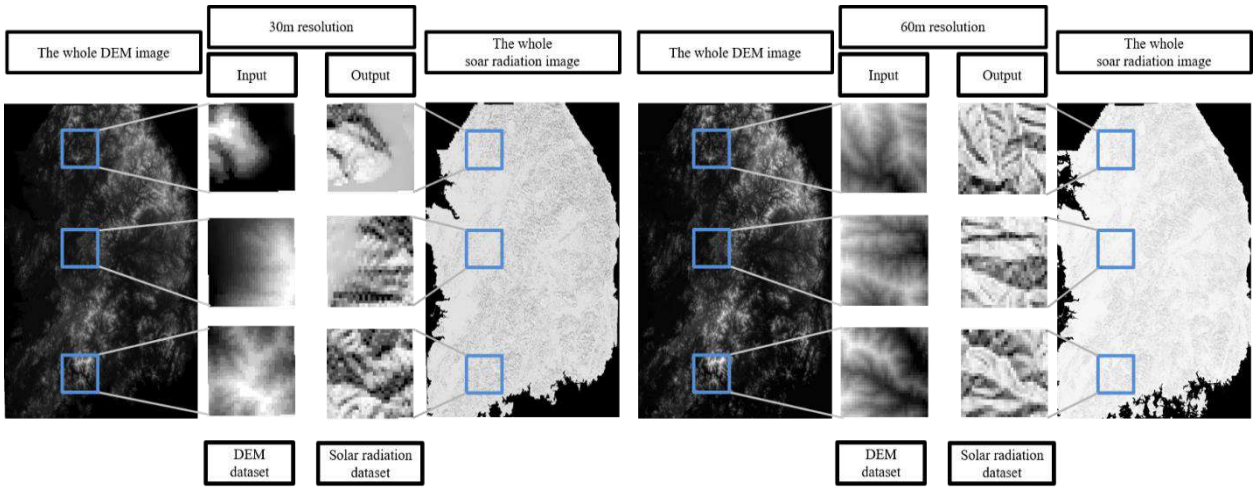

Figure 3. Overview of DEM and solar radiation datasets processing: (a) 30m resolution datasets and (b) 60m resolution datasets

assess the effect of data resolution on the solar irradiation prediction.

4 Experiment Results

Figure 4 illustrates a pair of two datasets: the DEM image and the corresponding solar radiation maps for two data resolutions. From the solar radiation map, annual mean of available solar irradiation is calculated for each map (i.e., 30 x 30 pixels), the mean value is used as an output the model attempts to predict. Particularly, the DEM image and solar radiation value are normalized as a pre-process. This normalization is adopted to prevent the poor learning caused by the wide spread of data values, and the min-max normalization method is applied for scaling the range of raw data to be [0, 1]. As a result, the raw DEM datasets for 30 m and 60 m resolutions (e.g., Figure 4a and 4b), the range of which are initially [0, 1900] and [0, 1550], respectively, are scaled to [0, 1]. The difference in the max values may happen for different DEM resolutions used to estimate the solar radiation. For example, higher-resolution data represents the elevation information more precisely than lower-resolution data [12]. This difference in data resolution affects the solar radiation data, the deviation of which between two resolutions is observed as approximately 11%.

Figures 5 and 6 present the relationship between the predicted and actual results for 30 m and 60 m resolutions, respectively. Overall, both results visually show that the predicted one is strongly correlated to the observed one with R^2 of 0.89 and 0.87.

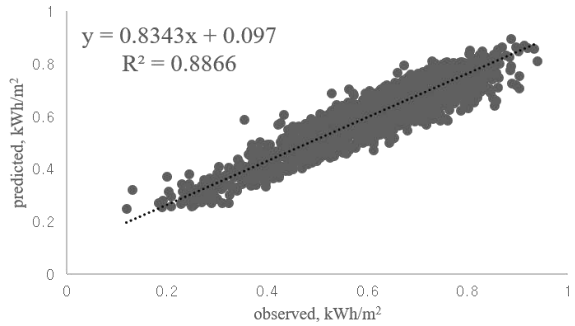

Figure 4. The plot of the relationship between the predicted and actual results for 30 m resolution

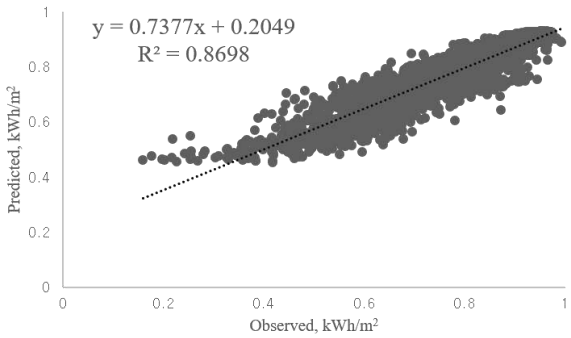

Figure 5. The plot of the relationship between the predicted and actual results for 60 m resolution

Table 1 summarizes the MSE, R^2, and MSE converted in actual units. The R^2 for 30 m resolution dataset is slightly higher than the one for 60 m resolution dataset. It is also observed that the plot of 30 m resolution (Figure 5) is slightly more uniformly distributed than the one of 60 m resolution (Figure 6). Yet, the difference caused by data resolution may not be significant in this experiment. Additionally, it is observed that the MSE value of 30 m resolution is 0.0018, while the MSE value of 60 m resolution is 0.00315. When converted in the actual units, the prediction errors of solar irradiation for 30 m and 60 m resolutions are 3,981 kWh/m^2 and 8,007 kWh/m^2, respectively. In other words, the errors from 30 m resolution data are 1.8 times and 2.0 times lower than the ones from 60 m resolution data in the MSE and MSE in actual unit, respectively. Thus, these results show that in this experiment, the solar irradiation is more accurately predicted when the data with higher resolution is used.

Table 1. Summary of the experiment results

Data resolution	MSE	R^2	MSE-in actual unit
30 m	0.0018	0.89	3,981 kWh/m^2
60 m	0.0032	0.87	8,007 kWh/m^2

5 Discussion

In this paper, CNN-based prediction is adapted to reflect the topographical features in the solar energy estimation. The results indicate that the proposed CNN-based approach produces promising results for the prediction of the solar irradiation on complex terrains or on a large scale. The CNN model learns spatial correlations among individual pixel values stored in each image (e.g., an array) during the training, and thus it can be implied that the solar irradiation is fairly affected by

the topography of a surrounding terrain. For example, the amount of solar irradiation on a surface can be significantly influenced by the shadow created by adjacent hills at high elevation. The proposed approach that can use a DEM image itself as an input thus enables us to utilize a map-type data for machine learning.

The results also reveal that, in this experiment, DEMs with higher resolution outperform ones with lower resolution when a machine learning method is applied. This result is also supported by [13], reporting that a higher DEM resolution produces more accurate results with geometry-based methods instead of machine learning applied in that study. This result may imply that when the topographical features are represented or preserved well in datasets, the solar irradiation can be better estimated, as the neural network is generally affected by the quality of image [19]. Thus, the resolution and quality of DEM inputs should be carefully selected and tested, depending on the level of accuracy required for the solar energy study.

Previous machine learning approaches have mainly focused on evaluating the geographical factors (e.g., altitude, latitude, longitude) as input variables or gathering the data related to solar energy from the meteorological observation sites. However, this study shows through the CNN modeling that geographical features can be reflected in the solar energy estimation model, and the effect of data resolution is also assessed for an CNN application. Nevertheless, there are other factors affecting the CNN performance, which should further be explored. For instance, the size of an image can have an impact on the CNN performance [20]. An input image of 30 x 30 pixel size is used in this study, but other image sizes (e.g., 60 x 60, 90 x 90) need to be studied for an in-depth understanding of the size of an area affecting the amount of solar radiation. On the other hand, the method of calculating the solar radiation used as output data can also affect the predictive performance. In this study, the mean of solar irradiations stored in a pixel level on a DEM image is used as an output the model estimates. As the solar radiation on the surface of the earth depends not only on the surface angle or the shape of the terrain but also on the position of the sun [21], specific regions with higher solar energy may exist. Thus, various regions representing the entire DEM image well (e.g., average, a top region, a middle region, top triangle shape on a DEM) should be tested to understand which part of a DEM can be better estimated with the DEM image.

6 Conclusion

This study investigates the effect of geographical features on a solar irradiation estimation model by using CNN models built based on the datasets with different data resolutions. The CNN uses DEM images in a 3D shape (e.g., an elevation value stored in x-y coordinates) as an input; thus, spatial information is still held and modelled during a learning process. Furthermore, it is found that the use of higher-resolution data can result in more accurate prediction in the experiment. Regardless of the data resolution; however, models for both resolutions produce robust estimation results (e.g., MSEs of 0.0018 and 0.0032). Thus, the CNN approach may allow for the appropriate selection of PV panel installation on a large scale. In our future study, the CNN model will be further developed to estimate the power generated at a PV panel site by investigating the CNN architecture for the use of multilayer inputs, including maps of weather conditions, which are other critical factors affecting the power generation.

Abstract –

Additive Manufacturing (AM), also known as 3D printing, is an emerging technology, not only as a prototyping technology, but also to manufacture complete products. Gravity Separation Spirals (GSS) are used in the mining industry to separate slurry into different density components. Currently, spirals are manufactured using moulded polyurethane on fibreglass substructure, or injection moulding. These methods incur significant tooling cost and lead times making them difficult to customise, and they are labour-intensive and can expose workers to hazardous materials. Thus, a 3D printer is under development that can print spirals directly, enabling mass customisation. Furthermore, sensors can be embedded into spirals to measure the operational conditions for predictive maintenance, and to collect data that can improve future manufacturing processes. The localisation of abrasive wear in the GSS is an essential factor in optimising parameters such as suitable material, print thickness, and infill density and thus extend the lifetime and performance of future manufactured spirals. This paper presents the details of a wear sensor, which can be 3D printed directly into the spiral using conductive material. Experimental results show that the sensor can both measure the amount of wear and identify the location of the wear in both the horizontal and vertical axes. Additionally, it is shown that the accuracy can be adjusted according to the requirements by changing the number and spacing of wear lines.

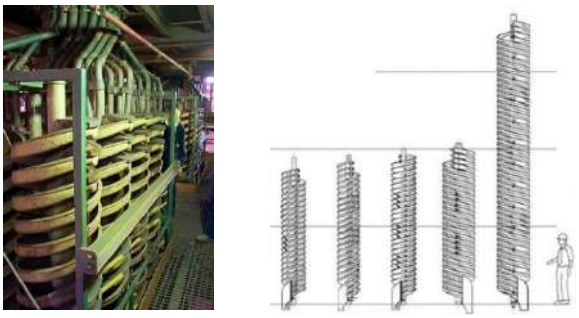
1 Introduction

Additive manufacturing, also widely known as 3D printing [1], is the process of taking information from computer-aided designs (CAD) and transforming it into a printed physical object. Additive manufacturing has passed the rapid prototyping era and is increasingly being used to manufacture finished products.

Combining Cyber-Physical Systems (CPS) and IoT in the industrial domain has led to the fourth industrial revolution (Industry 4.0), and has enabled smart production, smart products and smart services [2]. Using Internet of Things (IoT) for industrial automation is making collaboration between automation and heterogeneous devices and systems more predictable, real-time, fault-tolerant, and closed-loop [3].

Authors of this paper are working on research and development of a 3D printer to print customisable GSS for use in the mineral industry. The focus is to develop a system to print a spiral with embedded sensors, which makes it a smart product that can have its operational conditions remotely monitored. Collected data from these smart spirals can be used to optimise production output, perform condition-based maintenance, maintain worker safety, troubleshoot issues, predict future failures and improve future products.

Measuring wear in industrial components in situ provides many advantages, e.g., the ability to make informed decisions related to: (a) adaptive control of various feeds and speeds to achieve optimum production rate; and (b) planned maintenance and identification of sudden equipment failure [4]. When considering this specific application of printed spirals, it is required that wear be monitored remotely, in situ and in real-time. Such monitoring enables a measure of the amount of wear over time and the location of such wear, and hence opens the possibility of improving future prints by refining the material or printing properties. Sensors should ideally be embedded within spirals, since downtime for inspection generally requires manual intervention and production interference, and ultimately profit loss. Since GSS are used in rural locations all around the world, including Brazil, USA, South Africa, India and Australia, using an IoT solution to gather data from various remote locations is advantageous and possible. Figure 1a shows a bank of these spirals and Figure 1b depicts the relative sizes.



(a) (b)

Figure 1. (a) Spiral banks in the mining site; (b) Selected spiral models and relative sizes. Source: Adapted from [5].

Direct Write (DW) refers to techniques in AM to develop various electronic and functional components using different materials without using masks or subsequent etching [6].

In this paper, a novel sensor is presented, which is developed using DW methods to measure both the amount of wear and the location of wear. The main contribution is the development of a wear sensor, which can be 3D printed directly onto industrial 3D printed components using a conductive filament to monitor the linear dimension and location of wear in situ. The rest of this paper is organised as follows: Section 2 describes related work conducted in this area; Section 3 contains the methodology of development of the sensor; Section 4 presents the results of the experiments conducted, and finally, Section 5 and Section 6 provide the discussion and conclusions respectively.

2 Related Work

Additive manufacturing has evolved beyond a rapid prototyping technology, with many industries adopting AM as their primary manufacturing process [1]. The construction industry is increasingly using AM for topology optimisation, customised parts, in situ repair, and tolerance matching [7]. Additive manufacturing is also used in medical applications such as printing customised airway stents and soft prostheses [8] [9]. Due to the unique capabilities of AM, it is possible to manufacture optimised parts which would traditionally be non-trivial to produce. The benefits of AM have been utilised by the aerospace industry to improve the power to weight ratio of autonomous aerial vehicles through the manufacture of lightweight parts. [10]. Another unique advantage of AM is the ability to combine multiple parts into a single component, reducing assembly complexity. For example, General Electric developed a 3D printed fuel nozzle for their LEAP engine, a part which traditionally was made of 20 individual parts [11].

There are many different methodologies to detect wear in industrial components [4], including, optical scanning, analysing the change in product from equipment, electrical techniques, radioactive techniques, mechanical vibrations/sound analysis, temperature measurement.

Acoustic emission (AE) is the propagation of elastic waves in the range between 0.1 and 1MHz, and these waves are generated by friction [12]. Corrosion or wear will change the AE of a component. The capture and analysis of the AE can be used to identify wear in tools [13]. Douglas et al. [12] developed an AE based wear sensor for piston rings using this method.

Fritsch et al. [14] developed a vibration based wear sensor which detects micro-mechanical resonant vibrations in the low-frequency range. The sensor was developed using a micromachined silicon structure. This sensor is used to characterise vibrations from anti-friction bearings of calendar rolls mainly used in the textile industry.

Researchers have used various electrical based methods to measure wear in industrial components. Bödecker et al. [15] developed a resistance based sensor which can detect wear in the cylinders of diesel engines. Without this kind of in situ sensor, the engine must be decommissioned to inspect the engine for wear, which incurs significant resource costs. This sensor is manufactured with a conductive layer between the two insulating layers, and this conductive layer is constructed in the form of resistive loops. A change of the resistance as these loops are worn away provides a measure of wear. Ruff and Kreider [16] developed a wear sensor using vacuum deposited thin-films. The sensor package consists of two conductive layers that lie on top of the thermocouple layer separated by insulating layers. This sensor can also be used as a temperature sensor. Another thin film-based wear sensor for cutting tools developed by Holger et al. [17] uses a coating technique for the real-time measurement of wear. This sensor is also based on parallel connected electrical resistors. The wear indicator developed by Dyck et al. [18] can be used to measure a wear surface as well as the coefficient of friction for different types of coated geometries. This indicator slides a specimen material through electrical contacts to detect wear.

The proposed method for the wear sensor in this paper includes directly creating conductive traces on the material using a carbon-based composite material. There are many DW methods, with the most common ones being inkjet, aerosol jet, and photolithography methods. Le et al. [19] used inkjet-printed graphene to develop a gas sensor which can detect NH_3 and CO gasses. This sensor is a low-cost, self-powered, battery-less, wireless sensor based on radio-frequency identification (RFID) technology. Micro-scale aerosol-

jet graphene-based additive manufacturing process, which is developed by Jabari et al. [20], uses graphene ink with a particle size below 200nm, to deposit thin graphene layers. Moreover, their results show that this process is capable of printing interconnects with widths in the range of 10-90 μm and with resistivity as low as 0.018 Ω cm. Shen et al. [21] developed a temperature sensor based on extrusion DW techniques, which used a micron-level platinum layer on top of an alumina substrate to print the sensor.

In the area of DW wear sensors, Shen et al. [22] developed a high-resolution wear sensor based on parallel silver interconnects. This process requires heat treatment of the printed part to achieve full performance. In this method parallel conductive lines contain parallel resistors, and when wear occurs, conductive interconnects are progressively removed, and the resistance changes. By measuring the resistance, it is possible to identify the level of wear. Dardona et al. [6] used the same method and tested it with both printed resistors and commercial resistors (Figure 2).

One significant drawback of these methods is an inability to determine the location of wear accurately. Also, they require additional steps and technology to embed traditional resistors and to perform post-treatment of the printed parts. Therefore, the authors propose a new wear sensor design with carbon-based material, which can measure the wear as well as the location of the wear, and does not require the embedment of traditional resistors nor post-treatment.

3 Methodology

The overall project goal is to create a large-scale printer which can 3D print a GSS. Currently, a one-third scale prototype (build volume of 220 x 1200mm) is being tested to verify the printing method. Future stages of the project will focus on constructing the full-scale eleven degrees of freedom multi-material FDM 3D printer (build volume of 700 x 2000mm). This section provides details about the materials and methodology used to develop and embed the wear profiling sensor into the printed GSS.

3.1 Design Principles

3.1.1 Conductive Filament

In order to print the conductive traces, a carbon powder blended with polylactide (PLA) is used. The volume resistivity of the moulded resin without printing is 15 Ω cm. 3D printed parts which are perpendicular to the layers along the X-Y axis have 30 Ω cm resistivity and along with the Z-axis 115 Ω cm. The nozzle temperature of the printer is 195C – 225C and heated bed temperature is in the range of 25C – 60C.

Different allotropes of carbon attracted significant interest in various types of applications in AM. The main reason is it is suitable for low-cost, large-volume applications [23]. For the developed printer project to be successful, it must be possible to produce a GSS in an equal or more economical way than traditional methods, therefore, using silver-based materials in wear sensors like Shen et al. [22] or Dardona et al. [6] is undesirable due to cost considerations. On the other hand, using carbon-based polymer composites has advantages over metal based or metal alloys. Some advantages include the lack of additional processing steps like thermal annealing, ease of printing, readily accessible technology, and longer shelf-life (years) [24].

3.1.2 Design of Printed Traces

The conductive traces shown in Figure 3 are printed using the conductive material mentioned in the previous section. The dimensions of the traces are 20x40x2mm. The number of traces can be determined based on the required wear measurement resolution. Figure 4 shows how multiple conductive layers are printed vertically aligned with each other and the intermediate insulating layers is PLA material. The number of layers can be changed according to the required wear resolution. R_X $(X = 1, \dots, 4)$ represent the resistance of each trace and $R_{LX}(X = 1, \dots, 4)$ represent total individual resistance of each layer. L_X $(X = 1, \dots, 4)$ represents the length of each trace as marked. $W_X(X = 1, \dots, 4)$ represent different locations wear can occur.

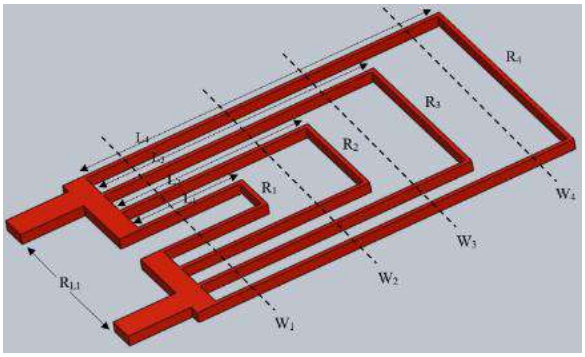

Figure 3. Printed traces in one layer.

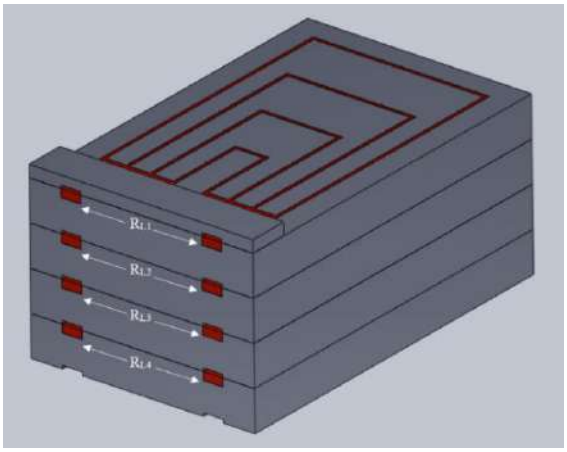

Figure 4. Printed traces in four layers.

3.1.3 Measurement and Localisation of Wear

Since all the traces in one layer are parallel with the terminals, the total resistance of the first layer can be calculated using the Equation (1). Likewise, Equation (1) applies to each trace component in each layer.

$$\frac{1}{R_{L1}} = \frac{1}{\mathrm{R}_1} + \frac{1}{R_2} + \frac{1}{R_3} + \frac{1}{R_4} \quad (1)$$

Without any wear, the resistance of the traces in all four layers will be equal. It is then assumed that wear occurs along W_2 line in layer one and is only just thick enough to cut through the first layer without reaching traces in layer 2. In this case, R_{L1} will be equal to R_1. Since the resistance of each traces are known, it is possible to predict that the wear occurs at a distance at least greater than L_1 but less than L_2. If wear occurs along with W_3line, R_{L1} will be equal to the total parallel resistance of R_1 and R_2. Then by measuring the resistance, it is possible to predict that wear occur at a distance greater than L_2 but less than L_3. Likewise, by measuring the resistance, it is possible to predict the wear location within one layer. Table 1 provides a summary of the detection of the wear locations based upon the resistance in one layer.

Table 1. Wear location and resistance in one layer.

Wear Line (W_X)	Total Resistance (R_{L1})	Wear Location (x)
W_1	∞	$x < L_1$
W_2	R_1	$L_1 < x < L_2$
W_3	$\frac{R_1R_2}{R_1+R_2}$	$L_2 < x < L_3$
W_4	$\frac{R_1R_2R_3}{R_2R_3+R_1R_3+R_1R_2}$	$L_3 < x < L_4$

The depth of the wear can be identified since the trace resistance in each layer is measured independently. Table 1 shows that in each layer, the wear distance can be estimated, which provides details of the wear profile.

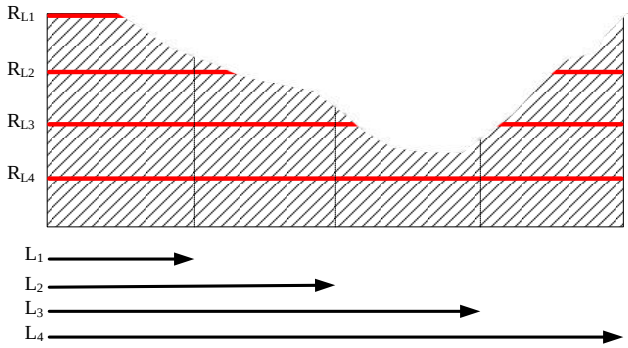

Figure 5. Cross section of the sensor with wear.

Figure 5 shows a vertical cross-section of the sensor with example wear. Table 2 summarises the possible resistance values for this wear profile and the predicted wear location.

Table 2. Wear location according to the measured resistance in each layer.

Resistance (R_{LX})	Wear Location (x)
∞	$x < L_1$
R_1	$L_1 < x < L_2$
$\frac{R_1R_2}{R_1+R_2}$	$L_2 < x < L_3$
$\frac{R_1R_2R_3R_4}{R_2R_3R_4+R_1R_3R_4+R_1R_2R_4}$	No Wear

3.2 Sensor Accuracy

The accuracy of the estimation of the wear location depends on the number of wear lines and the maximum length of the traces in each layer. Equation (2) quantifies this error and n_x is the number of lines and L is the length of the traces.

$$\Delta x = \frac{L}{n_x} \quad (2)$$

The accuracy of the amount of wear depends on the number of wear trace layers printed and the thickness of the material. Actual production sensors will not have traces on the top surface but one below the top. Equation (3) quantifies this error.

$$\Delta y = \frac{H}{n_y + 1} \quad (3)$$

where H is the thickness of the print, and n_y is the number of layers.

4 Experiment Results

4.1 Printing Process

Three printing methods were considered to produce the printed sensor: printing on a multi-material printer; printing components separately and assembling; pausing prints; and embedding printed components into print. To reduce material wastage and print time the sensor was printed separately and assembled, irrespective of the method the functionality of the sensor is the same. The main reason for selecting the assembly method was to prevent the use of a material purge tower and to remove the need to pause the print to embed components. Figure 6 shows the assembled wear sensor.

Each component was printed using the Creality CR-10, with the following print settings, layer thickness 0.1mm, layer width 0.4mm, print speed 60mm/s. The trace components were printed using Protopasta conductive filament, with a print temperature of 220 °C, bed temperature of 60 °C, 100% infill. The insulating layer was printed using PLA filament and a nozzle temperature of 185 °C, bed temperature of 60 °C, 20% infill.

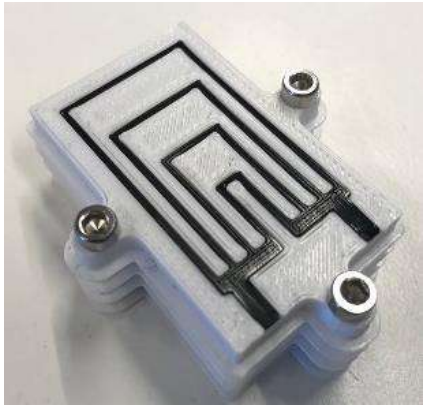

Figure 6. Printed wear sensor.

4.2 Resistance Comparison Between Multiple Prints

To determine the resistance variance across multiple conductive prints, 25 conductive traces printed as in Figure 7 and specific resistance of these traces were measured, and the standard deviation was 0.1005 kΩ. Results are shown in the graph in Figure 8, and according to the results, the resistance between multiple prints are relatively consistent.

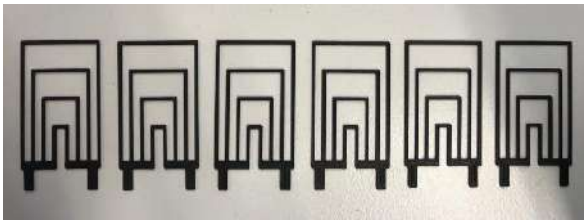

Figure 7. Multiple printed conductive traces.

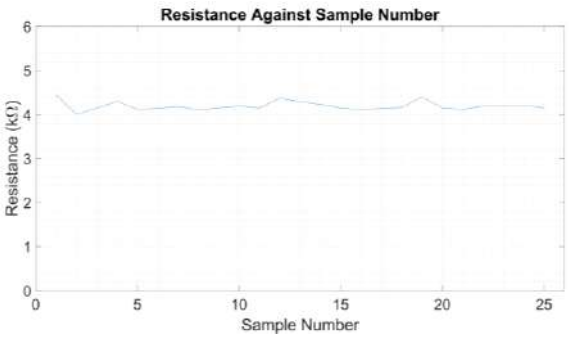

Figure 8. Total resistance against sample number.

4.3 Relationship Between Resistance and Location

The resistance values need to be determined as shown in Table 1 column 2 to identify the wear location. Printed traces were disconnected to simulate wear, as shown in Figure 9, and the resistance was measured. Results are summarised in Table 3 and the trend is shown in Figure 10.

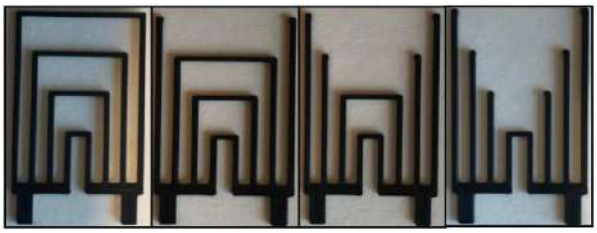

Figure 9. Resistance measurement related to different wear lines.

Table 3. Wear location and resistance in one layer

Wear Line (W_X)	Total Resistance (R_{L1} kΩ)	Wear Location (x mm)
No Wear	4.17	None
W_4	4.83	25< x < 33
W_3	5.41	17< x < 25
W_2	7.23	9< x < 17
W_1	∞	x < 9

Table 4. Predicted and actual wear locations according to the measured resistance in tested wear profiles.

Test	Resistance After Wear ($k\Omega$)				Actual Wear Line			Predicted Wear Line		
No.	R_{L1}	R_{L2}	R_{L3}	R_{L4}	Layer 1	Layer 2	Layer 3	Layer 1	Layer 2	Layer 3
1	5.45	4.82	4.29	4.10	W_3	W_4	–	W_3	W_4	–
2	5.49	5.48	5.43	4.13	W_3	W_3	W_3	W_3	W_3	W_3
3	∞	∞	4.14	4.10	W_1	W_1	–	W_1	W_1	–
4	∞	∞	7.66	4.13	W_1	W_1	W_2	W_1	W_1	W_2
5	7.20	4.18	4.11	4.16	W_2	–	–	W_2	–	–
6	7.28	7.25	4.20	4.14	W_2	W_2	–	W_2	W_2	–

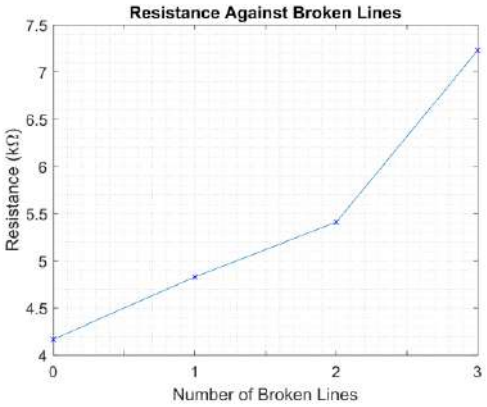

Figure 10. Resistance relative to broken wear lines.

4.4 Results with Different Wear Profiles

Table 4 summarises the test results with different wear profiles and actual and predicted wear locations. Dashes in the table represent "no wear". There was no wear for layer 4 in actual wear and predicted wear and therefore excluded from the table. Figure 11 shows different wear profiles tested. Wear location is predicted by comparing the resistance values of each layer to the values in Table 3 and selecting the closest location. In Figure 11, dash lines show the lengths of each traces (L_X) measured from left to right and W_x represents the wear line locations as in Figure 3.

According to the results above, it is evident that the proposed method provides accurate results for different wear profiles. Resistance values were measured in 25 printed traces to identify the resistance changes between multiple prints and the standard deviation was 0.1005 kΩ. Therefore, using this method as wear detection has good accuracy between multiple sensors as well.

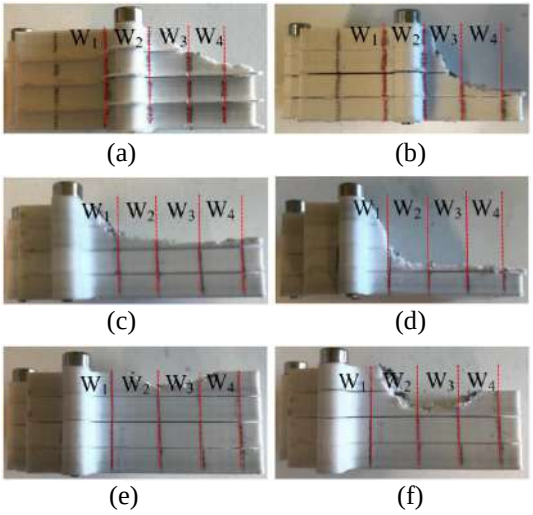

Figure 11. Wear profiles: (a) Test 1; (b) Test 2; (c) Test 3; (d) Test 4; (e) Test 5; (f) Test 6.

5 Discussion

The current design enables the measurement of the linear distance to wear values relative to one axis, parallel to W_1. These measurements can determine the wear profile relative to the datum axis, however, the tested configuration cannot determine wear profiles of the opposing side. It will be interesting to investigate the use of stacked sensors with opposing trace directions as shown in Figure 12. Such a sensor would introduce two datum axes rather than one, enabling the wear profile to be measured from either side. An additional benefit is that this configuration would allow the complete 2D cross-sectional profile of the wear area to be measured. The configuration could be extended by stacking sensors adjacent to each other, enabling a 3D map of the wear profile to be generated.

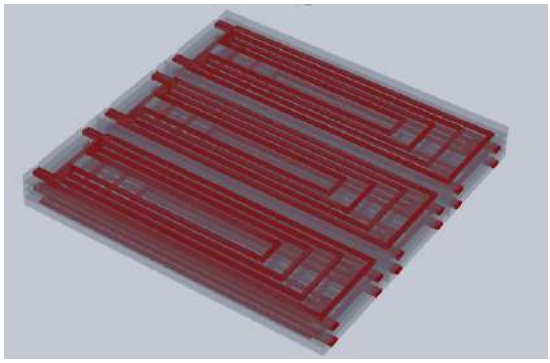

Figure 12. Suggested multi-assembly to get 3-dimensional wear profile.

6 Conclusion

The development of smart spirals, which can self-monitor operational conditions and collect data to improve future manufacturing processes, is underway. A measurement of spiral wear can help to predict its lifetime, and localising the wear provides valuable information about how to improve production. This paper has presented a novel embedded 3D printed wear sensor that can be used to measure both the location and severity of wear. The sensor is composed of printed traces using carbon-based filament, and experimental results have confirmed that real-time resistance measurements in each layer enable the location and severity of the wear to be determined accurately. By designing and printing an enhanced printed pattern it is possible to get a three-dimensional view of the wear. Future work will investigate alternative sensor configurations that will enable the wear profile to be determined in any orientation, and the integration of robustness against various wear conditions.

Abstract –

The development of physical and computational mechanisms aimed at augmenting architectural environments has been one of the foci of research implemented at the Faculty of Architecture and the Built Environment, Delft University of Technology (TUD) for more than a decade. This paper presents the integration of distributed responsive climate control into the built environment based on Design-to-Robotic-Production and -Operation (D2RP&O) principles. These connect computational design with robotic production and operation of buildings. In the presented case study structural elements meet load-bearing as well as functional requirements. Their spatial arrangement creates variable densities for accommodating sensor-actuators that are operating heating and cooling. This mechatronic operation relies on activity recognition for achieving responsive climate control in the built-environment.

Keywords –

Design-to-Robotic-Production and -Operation; Wireless Sensor and Actuator Networks; Responsive Environments

1 Introduction

In the past, spaces were designed to meet human needs by identifying activities for which generic spaces composed of vertical walls and horizontal floors were created. These were adapted to specific needs by furnishing. Today, technological advancements in architectural engineering [1] as well as new scientific insights into health and human comfort [2] provide the basis to design mass-customizable building components and responsive indoor climates by means of Design-to-Robotic-Production and -Operation (D2RP&O).

By connecting robotic production and operation with computational design, D2RP&O contributes to improving both manufacturing processes and performance of buildings. While, D2RO relies on sensor-actuator networks that are establishing cyber-physical mechanisms aimed at introducing responsiveness in the built-environment, D2RP facilitates designing and building such environments. Together D2RP&O establish an unprecedented feedback loop based on human-nonhuman interactions, which have properties that are not reducible to neither human nor nonhuman aspects; instead, they result from the relationships and dependencies they form.

2 D2RP&O

D2RP&O relies on hybrid componentiality. This implies that building components are cyber-physical and that their design is informed by functional, structural, and environmental requirements, while taking into consideration both passive (i.e. structural strength, thermal insulation, etc.) and active (i.e. responsive, etc.) behaviors.

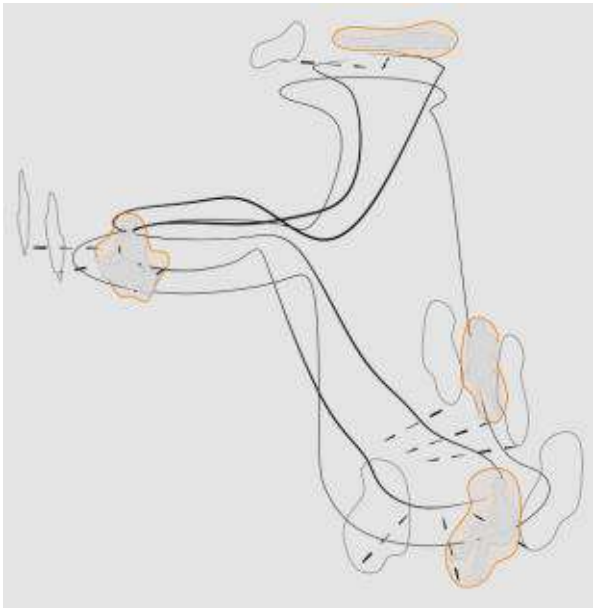

Figure 1-1. Design of the outer skin following body positions and schematic movement of activities

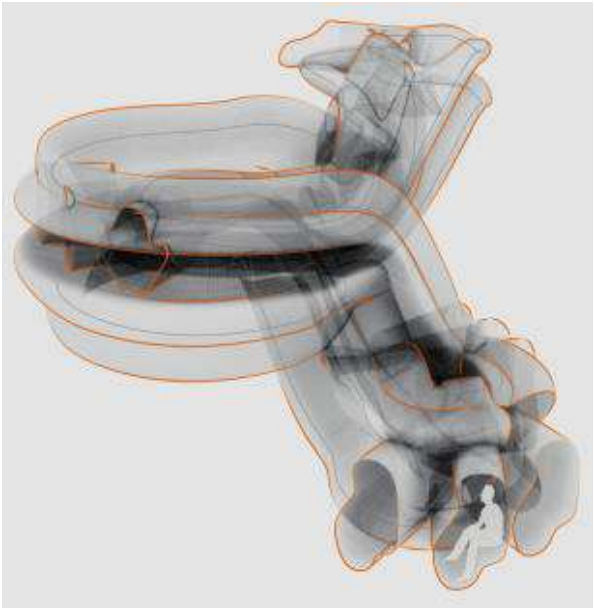

Figure 1-2. Design of spatial envelope based on mapped body positions and schematic movement of activities

In the presented case study, the focus is on the development of student housing units. Spaces are generated by mapping the movement of the human body during daily activities such as exercising, studying/working, relaxing, and sleeping. Each of these activities is described in terms of specific body positions, movement ranges, and their corresponding spatial requirements. These spatial requirements are basis for generating a schematic shape i.e. envelope onto which furnishing and climate control requirements are projected (Figure 1-1 and -2 and Figure 2). While requirements for furnishing focus on accommodating the human body during daily activities (such as seating, lying down, etc.), requirements for climate control provide distributed local comfort. Such an approach takes not only individual comfort in consideration, but also energy-efficiency, in particular when environments are inhabited or used with variable frequency.

2.1 Local Comfort and Distributed Climate Control

The proposed distributed approach to climate control is presently implemented while taking in consideration the uneven distribution and density of heat- and cold-perceiving thermo-receptors [2] in the human body. While the three areas of highest concentration of thermo-receptors are located in the head, the abdomen, and the extremities, their sensibilities vary. For example, cooling is most effective when applied to the head and the extremities [3]. Furthermore, direction of the air flow and variation of physical activity (e.g. sleeping, studying, working out, etc.) need to be considered. Such complex sometime even conflicting requirements require a locally responsive distributed approach.

The presented case study explores requirements for a student housing unit that is accommodating up to three persons at the same time. It answers the question of how the building envelope may be equipped with a set of sensor-actuators that respond to changing physiological requirements. These requirements are first mapped onto the envelope modeled from the simulated movement of the human body in space (Figure 2). Requirements vary in distribution and are effectuated by devices with various sizes. Presently considered heating devices consist of infrared lamps, whose energy is gained from photovoltaic cells integrated in the building envelope, while the cooling system employs vaporized water-streams.

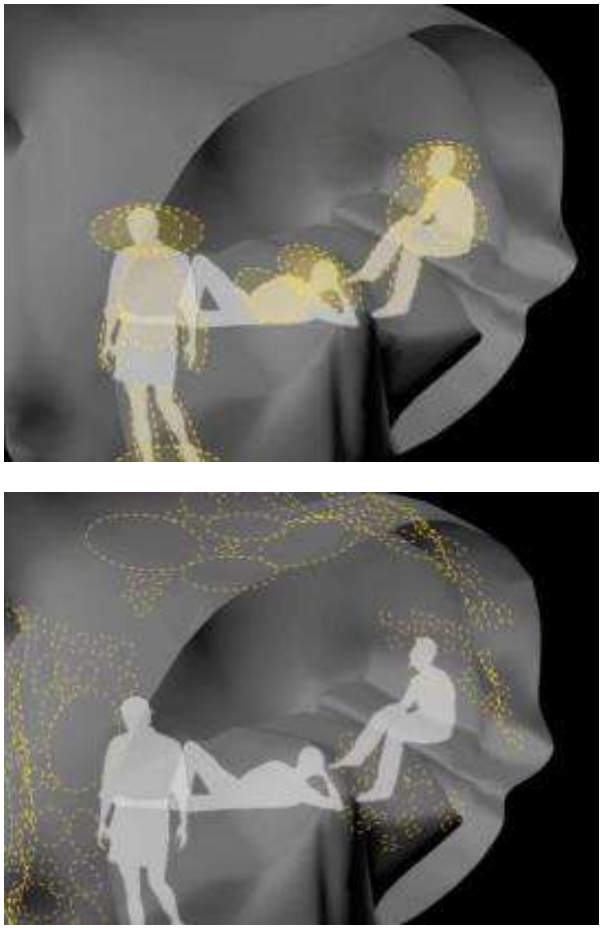

Figure 2. Mapping of physiological requirements on human body (top) and projection of local comfort requirements onto envelope (bottom)

Figure 3. Wooden beams are designed and manufactured to bend around specialized climate control components

Evaporative cooling employs jets of cold air or vapor and takes advantage of the enthalpy of vaporization [5]. The system sprinkles water onto a membrane or pad, through which air is blown. Thus, cooled vapor is created, which can be stored or delivered to the cooling devices (Figure 3). Distributed sensors gather data with respect to occupancy, temperature, humidity, etc. that is feed to the computational nodes, which in turn activate the mechanical system. Both heating and cooling systems turn on and off on demand and while these systems cannot be described as entirely off-the-shelf due to customization requirements, most of their components are already implemented in everyday life scenarios, especially open-air environments needing larger thermal control such as cafes with outdoor seating, etc.

This implementation of D2RP&O builds up on knowledge with respect to user needs [3] and wireless sensor-actuator networks for distributed climate control [4]. Such climate control functions through the use of mechanical devices that are operated by computational nodes establishing together a cyber-physical system. This distributed approach makes indoor environments adaptive and energy-efficient since vast amounts of energy required by traditional centralized climate comfort systems are saved. The novelty of the proposed system lies not in the individual components but in their synergetic operation with users based on computational feedback. This enables an immediate response to changing physiological demands. Devices are distributed and are able to rotate in three directions, in order to follow a moving person. They dynamically respond to the users' movement in space and create personalized climatic areas surrounding them.

2.2 Responsiveness and Interaction

The framework of local climate comfort requires that the building possesses the capacity of *identifying* occupants and environmental conditions in terms of temperature, humidity, etc. This is achieved through the use of architecture-embedded as well as wearable sensors i.e. smart phones.

Sensors collect data from the environment and users, which is then processed in computational nodes that activate or deactivate the distributed devices. They instantiate a responsive behavior that in a next step will be imbued with computational intelligence allowing the system to not only respond but anticipate, learn, and actively propose climatic changes by monitoring physiological and environmental data. In this implementation devices are turned on-off and rotate to track users moving in 3D space (Figure 4). The number of devices that are activated at the same time depends on climatic requirements at that time. While in this case only two kinds of devices were considered for heating and cooling, additional devices for lighting and ventilating that are combining natural and mechanical means would also need in a next step to be considered.

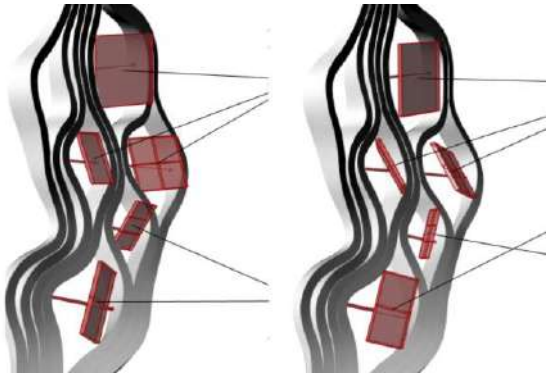

Figure 4. The infrared lamps turn on when people are approaching and rotate to follow their movement in space

2.3 Materialization

In the proposed design, the structural elements create in-between spaces to accommodate mechanical devices of varying sizes and distributions while maintaining structural integrity. Wood has been chosen because of its relative malleability allowing continuous bended beams to accommodate varying porosity requirements. Thus

beams are distributed according to structural forces and porosity requirements (Figure 3). Variation in distribution of beams is accomplished through densification and rarefication, respectively. If densification creates an increasingly compact surface, rarefication introduces porosity that accommodates windows and climate control devices.

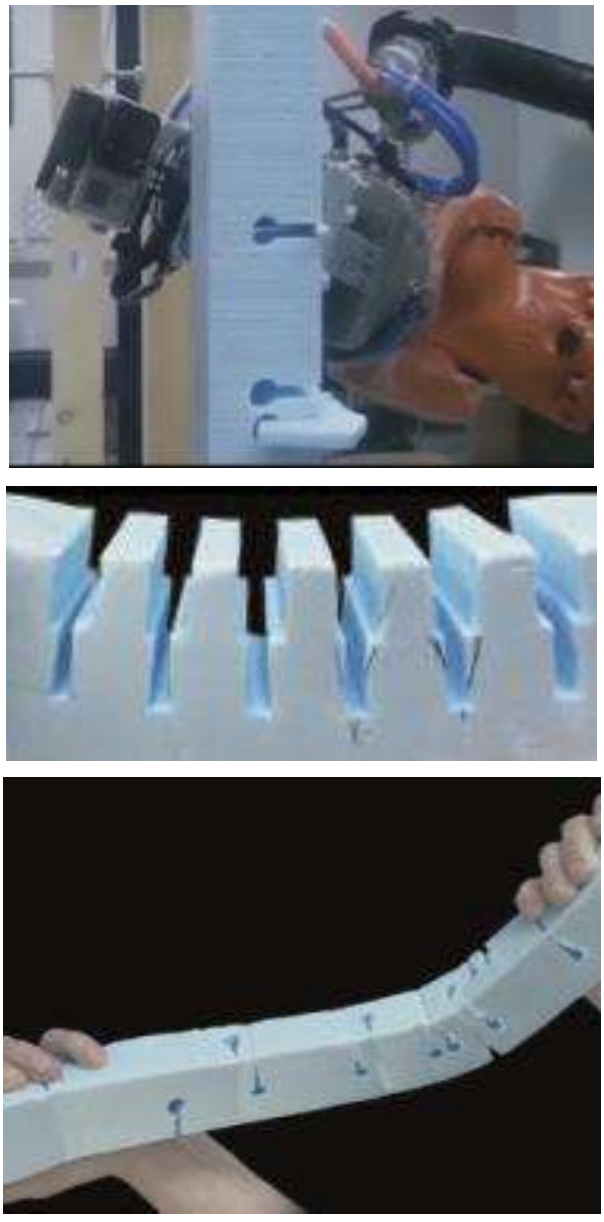

Figure 5. Materialization experiments and robotic production process involve robotic milling (top), preliminary research on the geometry of the milled section (middle) and robotically fabricated component (bottom)

Beams were manufactured using D2RP for kerf bending. This implies material removal for torqueing purposes. By milling a series of parallel cuts into the beam, a bending behavior is generated in the direction opposed to the milling direction. The assumption is that this process is a better alternative to the lengthy and wasteful approaches employing steaming and molding. Given the complexity of the design, this implementation requires extensive preliminary investigations regarding (1) the geometry of the milled sections, which directly affects the torque, (2) the distance between milled sections, which affects the bending angle and (3) the distribution on different sides in order to create torsion.

In a first step, extruded polystyrene (EPS) is introduced as a testing material. While the two materials are very different, EPS is instrumental in understanding the underlying principles and possible limits of the system (Figure 4). D2RP tests yielded relevant results in terms of precision of the computational system and the challenges of the robotic production. For instance, the higher the proximity of the milled sections is, the more the beam would start bending during the production process, resulting in imprecision or even breakage. These criteria are then fed back into the design and computational strategy, thereby establishing a loop of information exchange between the material and computational aspects of the project.

3 Methodology and Implementation

D2RP is integrated with D2RO in order to achieve hybrid architectural components that are able to respond to changing needs by employing motion and proximity recognition.

D2RP involved parametric modeling and structural simulations in Grasshopper and Karamba 3D while environmental simulations will be implemented in a next step. In terms of robotic production, a combined additive-transformative approach was carried out. The additive aspect of this approach refers to the multiple materials and components such as wood beams, mechanical devices, and building envelope that are incorporated into a hybrid whole. The transformative aspect refers to the bending of the wooden beams, which will be implemented in a next step using two robots. The process will start with first inserting a bundle of beams into a feeder. Each beam will be picked up by one of the two robots and will be transferred to a moveable spanning device with an appropriate high retaining system designed for longer beams, which will allow the robots to process the beams. The proposed bending in 3D is of interest because it is accommodating both structural and distributed climate control requirements and is particularly suitable for robotic transformative techniques. This system of bended structural elements works with spatial displacement as well as variation in

depth and width in order to meet structural requirements and accommodate user-defined requirements for illumination, ventilation, heating or cooling (Figure 6). At this stage, the design addresses only heating and cooling requirements, and physical experimentation stays at the level where beams have been only tested in EPS. Furthermore, as proof of concept, D2RO involves the use of distributed proximity and distance ultrasonic sensors, actuators (Servo Motors), and microcontrollers (Arduino Mega). While sensors detect users, the actuators turn on-off and rotate devices according to input from the microcontrollers, which have the programmed behavior to follow the movement of users.

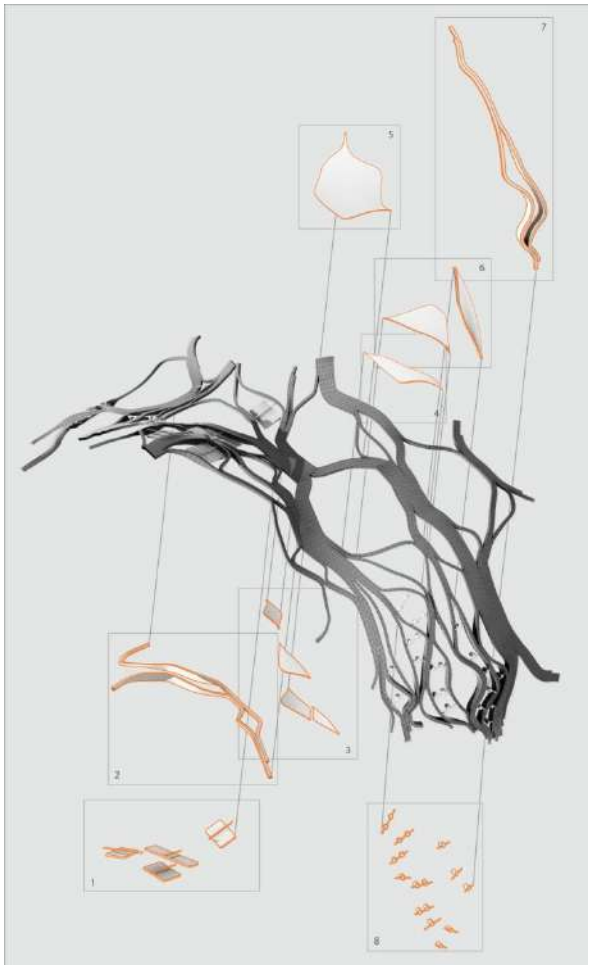

Figure 6. Fragment showing bended beams system accommodating mechatronic devices: (1) heating devices, (2) variable-depth structural elements, (3) small windows for natural illumination, (4) water storage compartment, (5) large window for illumination and views, (6) cooled-air chamber and wetted pads, (7) variable-depth structural elements, and (8) cooling devices.

4 Conclusion

The concept of the presented D2RP&O method relies on linking computational design with robotic production and operation. The implementation by means of D2RP&O of a building envelope that integrates functional, structural, and distributed local climate control requirements demonstrates the potential of this method to develop architectural spaces that accommodate a range of varying user-needs. The integration into the architectural envelope of climate control devices for local comfort using an additive and transformative D2RP approach is of particular interest because of its potential to address customization needs as well as structural- and energy-efficiency requirements. Furthermore, through the development of cyber-physical mechanisms, human capabilities in the physically built environment are extended. Even though in the present development only motion and proximity recognition are deployed, they enable the system to identify users and respond in terms of cooling and heating according to occupancy and use.

D2RP&O proves to be effective in linking computational design with robotic production and operation of buildings. It establishes human-nonhuman interactions in the built-environment, which have properties that are not reducible to those of individual components; instead, they emerge from the relationships they form. Climate control is local and customized to individual needs, where sensor-actuators respond to physiological and environmental variations. While building processes become increasingly automated, buildings evolve towards developing awareness with respect to their occupants as well as their indoor environments by interacting with both via cyber-physical mechanisms.

Acknowledgements

This paper has profited from the contribution of TUD researchers, tutors, and students as well as DIA students. It has taken advantage of two robotic labs at TUD and DIA and the expertise in D2RP&O of TUD researchers Sina Mostafavi and Alex Liu Cheng.

An Approach to Enhance Interoperability of Building Information Modeling (BIM) and Data Exchange in Integrated Building Design and Analysis

T.V. Nguyen [a] and E. K. Amoah [b]

[a b]Mechanical & Civil Engineering Dept., Florida Institute of Technology, Melbourne, FL 32901 USA
E-mail: tnguyen@fit.edu, eamoah2015@my.fit.edu

Abstract –

Achieving high energy-efficient building designs requires conducting energy analyses iteratively starting from the conceptual stage to ensure suitable selection of building components to meet energy performance requirements. In recent years, advanced BIM capabilities have allowed designers to assimilate design and energy modeling processes geared towards improving productivity. However, there are shortcomings in many BIM platforms that circumvent effective data exchange between design/analysis models and essential data/information sources, resulting in reduced efficiency in terms of money, time and effort losses.

This paper proposes an approach to enhance data interoperability to allow seamless integration of design and energy analysis processes. The approach reviews data exchange requirements by key stakeholders in the building lifecycle and analyze how a common platform can address their needs. The paper first surveys existing BIM design and analysis software applications and various data sources to identify individual data interface formats. Autodesk Revit and USDOE EnergyPlus are examples of software tools, and ASHRAE climatic/building data are representative of a typical data source. The paper then develops use cases in which different combination of BIMs and data sources may be selected by the design team. For each use case, data exchange formats are analyzed against BIM data exchange standards to evaluate data interoperability. The objective is to identify suitable combinations of design, modeling, and data interface tools to accommodate the need of integrated design team. Finally, based on the results of the use cases, the paper recommends specific BIM tools that can accommodate the required models and data sources.

Data Exchange; Interoperability; Building Information model; Data Interface; Energy Modeling

1 Introduction

The AEC industry is highly diversified and there are a variety of different information systems being used in each organization. Thus, the transfer of information between different systems is and continues to be an apparent need **[1].**

One key issue in AEC industry today is ineffective information and data exchange. Poor information exchange can lead to three major problems: Costly errors in design/ construction, time wasting in making decisions and shorter life-span of design/construction projects due to poor judgement.

It is no doubt that the industry relies heavily on the use of data/information exchange between different professional disciplines for design, analysis, construction, operations and maintainace activities **[7]**. The construction industry is undergoing fundamental change, not unlike the advent of lean manufacturing in auto-making in the 1980s. A revolutionary tool called Building Information Modelling, or BIM, is the reason. BIM is rapidly transforming complex building processes -speeding project completion, lowering costs and improving overall quality at the same time. The possibilities for leveraging BIM are endless. Building Information Modelling (BIM) is currently attracting significant increased attraction of industry stakeholders with a promise of better collaboration with effective flow of data exchange resulting in higher productivity and better-quality products. The goal of this paper is to focus on identifying a suitable approach to enhance data interoperability to allow for seamless integration of design and analysis activities in building construction projects. This will result in suitable combinations of design, modeling, and data interface tools that accommodate the need of integrated design teams.

Acronyms

AEC: Architectural Engineering & Construction
AIA: American Institute of Architects
ASHRAE:American Society of Heating, Refrigeration, and Air-Conditioning Engineers
BCF: BIM Collaboration Format

COBie: Construction Operations Building Information Exchange
FM: Facilities Management
gbXML: Green Building Extensive Mark-Up Language
HVAC&R: Heating Ventilation Air Conditioning and Refrigeration
IFC: Industry Foundation Classes
IFD: International Framework for Dictionaries
IDM: Information Delivery Manuel
MEP: Mechanical Electrical and Plumbing
NBIMS: National BIM Standard-US
PDT: Product Data Template
XML: Extensive Mark Up Language
EUI: Energy Use Intensity

2 Integrated Information Exchange Process

The initiation of steady, continuous, and unambiguous performance information throughout building lifecycle is seen as a catalyst for building optimization. Stakeholders across architectural, engineering, construction (AEC) and facility management (FM) industry can share and exchange information based on the integrated information structure. For a real open process to occur, three factors need to be in place **[2]**:

a. A common data format for the exchange of information – IFC (Industry Foundation Classes),
b. Rules of which data is to be exchanged and who shall exchange them – IDM (Information Delivery Manual) and,
c. A standardized data model which is properly interpreted on each position of the exchange – IFD (International Framework for Dictionaries).

Figure 1 demonstrates the operation of the integrated information exchange structure. The structure works as a guideline for standardized data exchange. In the structure, IDM provides a universal, repeatable, reusable and verifiable collaborative methodology for initiating information exchange; IFC defines the data format of the information to be exchanged and builds the foundation for data exchange between applications. The structured information exchange framework allows preservation of meaning within different design tools.

A precise data exchange format in the BIM framework will not only lead to enhanced sustainable design and information exchange but will also bring about an increased project life-span, reduced life-cycle cost as well as fast-track design and construction turn-around time. This, when done properly, will create a win-win situation for all project stakeholders.

The subsequent sections will shed more light on how to identify suitable BIM authoring tools and data exchange formats that enable an open process and how they advance interoperability as well as generating reliable data.

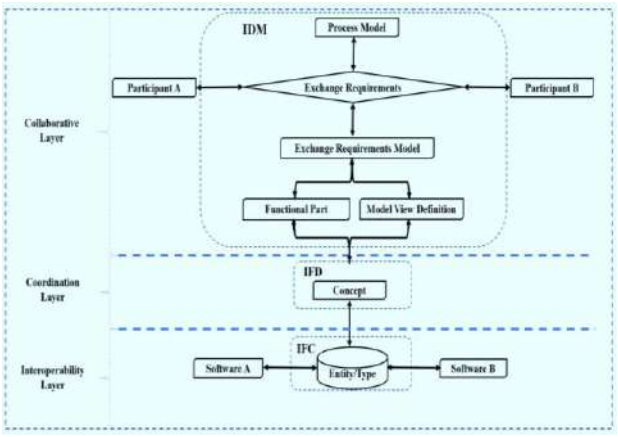

Figure 1. BIM process integrated information exchange structure

Table 1. Existing BIM authoring software application tools

BIM tool	Functionality	Phase(s)
Autodesk Revit	Building energy and carbon analysis & exchange capabilities	Conceptual & detailed design phase
Autodesk FormIt	Building energy analysis	Conceptual & detailed design phase
Revit/Archi CAD	Certification support	Conceptual & detailed design phase
Revit/Vasari	Solar studies	Conceptual &detailed design phase
Vector works	Documentation/collaboration	Conceptual design phase
AECOsim Building Designer	Documentation/collaboration	Conceptual design phase
eTakeoff Bridge	Estimating	Conceptual &detailed design phase
Archibus	Operation/work process	Detailed analysis
Assemble Insight	Support decision making	Web based solution
Tekla BIMsight	Collaboration	Check conflict at design phase
SketchUP	Exchange capabilities	Conceptual phase

3 Survey of BIM Authoring and Analysis Software Tools

There are many BIM design and analysis software application tools available in the market today and each caters to different users.

In many cases, the functionalities of different BIM software over-lapped one another requiring the users to carefully evaluate the software capabilities to ensure that the application will meet their needs. Table 1 constitutes a survey of dominant software applications available for BIM and integrated practice [3]. A brief description of functionalities and the phases of implementation/analysis are provided for information and evaluation purposes. The list is not meant to be exhaustive.

4. Data Format and Exchange Standards

Design and analysis activities in the BIM environment can leverage the wealth of data available electronically from various sources. Today, many manufacturers of building products provide BIM objects that can be imported directly into BIM applications and vice versa. Professional organizations such as ASHRAE (American Society of Refrigeration and Air-Conditioning Engineers) and AIA (American Institute of Architects) develop standards and design guidelines for the AEC industry and those can be used to support the building design and analysis process, although in most cases, much effort is required to integrate them into the BIM environment. Additionally, building codes and research data are available from government agencies such as state building commissions and USDOE (United States Department of Energy) that can be used to enhance the robustness of the design. Table 2, reviews “open standards" and BIM, non-proprietary file format and exchange protocol technologies that have been developed by public, private, and public/private entities [4]. Table 2 also provides a brief summary of different standard data exchange formats and the level of relevancy of each type of format relative to effective data transfer. The level of relevancy indicates the likelihood of the data exchange format would be used by one or more BIM software applications. As an example, BIM authoring software such as Revit and ArchiCAD have functionalities to convert BIM models into COBie, XML schemas, IFC, OmniClass, gbXML etc. There are countless number of supplies of BIM file formats out there [5, 8, 9] few of them are listed in (Table 2) for purposes of this study.

5. Data exchange use case methodology

Use cases are a useful tool in the process of evaluating interoperability of data exchange in the BIM environment. In order to capture the use case, it was necessary to first establish a set of properties by which they can be defined [6]. The data domain categories were also identified which was based on the major information contents of the Data Exchange Use Case. These include:

- The project;
- The site and the building;
- The building stores
- Spaces and their type information (space type, space intended use etc.);
- Building elements and their information (construction type) or building element material information;
- 3D – shape of the building elements (geometry) and;
- Location information of building elements.

The objects (lists) above are applicable according to general product modelling principles, the common information required that all objects should be uniquely identified (through unique ID). The main principle of the information content is that, at least the 3D-geometry data is transferred as a basic input for design analysis.

In the data exchange implementation, the data exchange representation and format for the exchange of the information is content specified. There may be alternative ways of implementing the data exchange for some information content (e.g. the internal format specific software application, default standards, or official standard).

In a specific building projects, the data exchange implementation method must be agreed upon (mostly from the early days of the project) by the stakeholders separately.

Data implementation process using the IFC specification as an example [12, 14] is described here. The description is intended to be used, firstly, by software vendors for their implementation exchange interfaces and, secondly, by the individual stakeholders to select data exchange solutions as their requirements description when the data exchange is to be implemented using IFC.

Data exchange implementation and format description procedure has been briefly explained in the ensuing sections. The use case defines only the representation and format of the implementation i.e. in which form the information should be used during data exchange transaction. The definition by which means the transfer process is done is outside the scope of the use case interpretation.

Table 2. Data format/exchange standards

Standard	Format	Efficiency Level	
		High	Low
IFC	Provides a framework for organizations to produce interoperable software to exchange information on building objects and processes to creates a language that can be shared among the building disciplined	✓	
XML	Set of rules for designing text formats to structure information. XML supports data transaction between different software applications, leading to a better way to communicate information.	✓	
gbXML	gbXML is the most widely supported data format for the exchange of building information between BIM/CAD and energy performance applications.	✓	
CIBSE -Product Data Template (PDTs)	PDTs are the source of consistent data to be used in the management of the constructed asset, allowing facilities managers to find the information they require for operation and maintenance of the facility in a structured and standardized format, improving the efficiency and productivity of the FM process, and supporting automation in the management of asset information.	✓	
COBie	Supports the sharing of data among facility management tools, such as BIM authoring tools, CMMS, and computer-aided facility management (CAFM) software. The standard eliminates the need to re-collect data, and it reduces the number of inconsistencies between similar data sets used for different purposes within a facility management organization	✓	
BIMXML	an XML schema developed to represent a simplified subset of BIM data for web services.	✓	
MVD	Model View Definition, the specification for subsets of all available BIM data to serve a stated purpose or process	✓	
IDM	Information Delivery Manual, the business case specification for exchange BIM data, including end user Exchange Requirements (ERs)	✓	
RVT	This is Autodesk's proprietary format for Revit files. These can vary significantly in size depending on the level of development. They can only be opened in Revit.	✓	
BCF	BIM Collaboration Format, an XML schema that encodes messages to enable workflow communication between different BIM (Building Information Modeling) software tools.	✓	
IFD	Describes what kind of information is exchanged by providing a mechanism that allows the creation of unique IFD IDs, to connect information from existing databases to IFC data models.		✓
PDF	Portable Document Format originally developed by Adobe for the electronic exchange of any printable document.		✓
OGC	Open Geospatial Consortium, international industry consortium for developing standards for geospatial data-enabled technologies.		✓
NWD	This is Autodesk's proprietary format for Navisworks files. NWD files are also read-only, although you may be able to save them under a new name and edit from there if the file was saved with that option enabled. These can only be open in Navisworks Freedom or Navisworks Manage.		✓
DWF/DWF	Design Web Format, originally developed by Autodesk, as a PDF alternative for CAD data/documentation.		✓
OmniClass (UniFormat Std II)	Framework for Classification of Information. A guidance document, and establishes common concepts used in building information exchange	✓	
NIBS-National BIM Guide for Owners	Serves as a shared knowledge resource for information about a facility, forming a reliable basis for decisions making during the life cycle of a facility from inception onward.	✓	

5.1. Data Exchange Implementation using IFC

The data exchange implementation using IFC is based on current release IFC4 addendum 2, publish in July 2016, as a buildingSMART final standard [12]. The Data Exchange Use Case architectural design to HVAC&R (MEP) design is closely related to the predefined IFC coordination view. The main difference is that the construction type is not supported in the coordination view.

5.2. Minimum Content of IFC Product Model

The IFC product model and specification sets some specific minimum requirements for what the information content of file-based product model IFC data exchange should be. Regarding the Use Case, the required minimum IFC product model is specified in Table 3. Separately, for the exchange of the 3D (Revit) model in figure 2 and building product model exchange sub-cases.

Table 3. The minimum IFC product model content in the two sub-case of Use Case

3D Reference model exchange	
Class	Properties
Project	-Identification and owner history -3D coordinate system -Project context and common measurement units
Site, Building & Stores	-Identification and owner's history
Building elements	-Identification and owner history -3D-shape and location
Building product model exchange	
Class	Properties
Project	-Identification and owner history -3D coordinate system -Project context and common measurement units
Site, Building and Stores	-Identification and owner
Space	Space type 3D-shape and location

5.3. IFC Data Exchange Format

IFC data exchange has two alternative formats for the exchange of some information content [14]. These formats are:

- IFC format or IFC part 21 Format, which is based on the ISO 10303 -21 standard,
- The ifcXML format, which is based on an XML Schema definition of the IFC product data model. Currently the specification is based on the IFC4 Addendum 2.

IFC implementations in commercial software application use the IFC part 21 format for IFC-based data exchange.

6. Case Study

Using Autodesk Revit, a BIM-based Architectural model is designed as a test case for this study, see Figure 2. In this example, it is assumed that the owner and architect have decided to use Autodesk Revit for the architectural design. Considering the involvement and the need of various project stakeholders, the objective is to evaluate interoperability of the data exchange in this process. EnergyPlus and Revit energy analyze are considered for energy simulation engine & tool respectively, ARCHICAD is used for structural analysis, and gbXML format was chosen as the data exchange protocol between the architectural model and analysis program.

The owner specified BIM model described below presented an opportunity to identify key interfaces between Autodesk Revit and other BIM authoring software application tools identified in Table 1, for their compatibilities in data exchange protocols.

Three of the BIM authoring tools below were selected in no order of preference for this experiment/demonstration. The authors only had in mind those BIM authoring tools which are not common and not most frequently used.

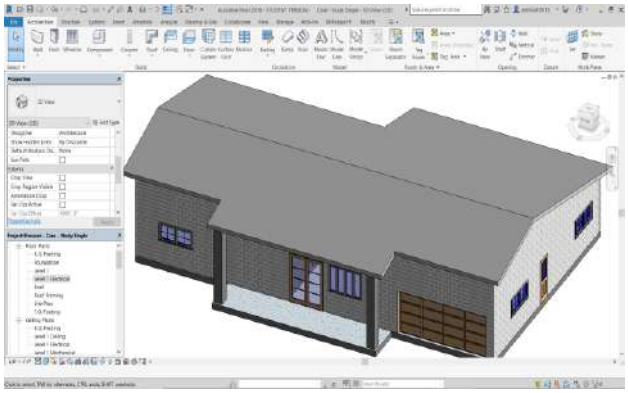

Figure 2. Sample owner specified BIM based 3D architectural model using autodesk revit

6.1. Revit/ArchiCAD Data Exchange Interface

This section discusses the GRAHISOFT ArchiCAD connection for Autodesk Revit. The Add-In improves the IFC based and bi-direction data exchange between GRAHISOFT ArchiCAD and Autodesk Revit [11,15]. The GRAHISOFT ArchiCAD connection Add-In for Auto Revit has three capabilities:

- **Improved IFC Import"** - imports IFC models to Revit using extra features that improve the

interpretation of architectural models;

- **"Link IFC"**- merges IFC models into the current Revit project as a non-editable reference;
- **"Export to ARCHICAD"** - exports Revit model elements in IFC files that are specially enhanced for use in GRAPHISOFT ARCHICAD.

To obtain the best data exchange results, it is important to ensure latest version (18.2.0 or later) of Autodesk's IFC 2018 import-export for Revit is used.

6.2. Revit/Vasari Data Exchange Interface

Project Vasari is a design tool with analysis capabilities available via cloud [13]. The problem is that, Revit/Vasari doesn't know how to pass separate conceptual masses with different building/space types to the analysis engine. There is no provision for separate buildings within the data exchange format from Revit (it is in the gbXML schema). To get around this problem, there are two options that must be considered [10, 11 13,]:

- Model the building as different masses, and run the energy analysis on each space type;
- For the initial analysis, lump the masses together and choose a building type and schedule that is the most appropriate when taken as a whole.

It is possible to make some preliminary conclusions massing and orientation from this rough analysis – and only drill down into analysis of the different space types if the analysis is not justified.

6.3. Revit/Tekla Structures Data Exchange Interface

The general collaboration/exchange with Tekla Structures to Autodesk Revit is best done on a neutral platform built for such purpose [11,16] for example, Autodesk Navisworks or Tekla BIMsight which is dedicated collaboration software with clash-checking and reporting.

Data exchange between Tekla structures and Autodesk Revit can be done using Autodesk approved IFC files through the following process:

- Export from Tekla Structures to Revit using an IFC file (Tekla > Export > IFC) from Tekla Structures,
- Import into Revit. From Revit 2015 version and later, it is possible to Insert > IFC file directly.

Where there are project co-ordinates, use Site Definition in Revit to locate the inserted Tekla Structures model correctly or use a manual model insertion point (Right click IFC model after inserting > reposition to project base point)

BIM can now be employed to co-ordinate the Structural file with the Architectural / MEP project in Revit.

7. Energy Modeling/Simulation

Kamel, E., & Memari, A. M. (2019). "Review of BIM's application in energy simulation: Tools, issues, and solutions", reviewed the challenges, issues, and shortcomings in BIM-to-BEM interoperability process (BBIP) and proposed a detailed classification for these issues and available solutions. This paper also explains how a corrective middleware, which is developed by the authors using Python, can be utilized to modify a gbXML file prior to adoption in energy simulation to resolve the issues related to building envelope in BBIP. The authors initially reviewed different types of BIM schemas such as IFC and gbXML and energy simulation tools capable of reading these files such as Green Building Studio (GBS), DesignBuilder, Integrated Environmental Solutions-Virtual Environment (IES), and OpenStudio [17]. The authors showed that not all the required data for energy simulation such as HVAC system data, schedules, and loads are exported properly to the gbXML file using Revit, and that data need to be added manually.

Autodesk Insight 360 allows architects/ designers to explore the energy impacts of different choices as they design **[11]**. Insight 360 uses EnergyPlus to calculate heating and cooling loads. It provides option of using EnergyPlus to evaluate annual energy impacts **[11]**. Insight 360 offers EnergyPlus simulations to all users through Revit and FormIt.

In figure 3, the authors developed/presented energy optimization and data transfer process framework to allow for seamless integration of design and energy modeling. The study also focused on investigating BIM authoring tools capable of providing a versatile platform for transferring all require data/file with little or no difficulty. During the first stage of the process, material specifications, construction preplanning and key decisions regarding data transfer approaches are considered. Also, the energy modeler/designer and other stakeholders come together to propose assumptions underlying the choice of building envelopes and system types at this stage. The assumptions made are used as a decision process for both design and energy simulation analysis. The authors considered EnergyPlus, gbXML and Insight 360 as the simulation engine and Revit as design tool. EnergyPlus was used to assess the initial heating and cooling loads regarding the impact of the annual energy consumption for envelopes and HVAC systems. These design and energy analysis results are to assist the stakeholders to make an inform decision. gbXML file provided us with a whole building simulation analysis result through Green Building Studio (GBS). Detailed results can be assessed, for example, Annual Energy Consumption in kWh, Energy Use Intensity (EUI) in kBtu/ft²/year, Annual Peak Energy Demand in kW, Annual Lifecycle Energy in kW etc. as indicated in the "Detailed Simulation Analysis portion of

Figure 3. The results are carefully studied, a thoughtful decision is made whether to approve the results or not. If the results are approved, the project moves to construction sage. If rejected, the updates become necessary, new assumptions and materials selection are considered. The framework for Figure 3 allows you to go back to the input stage to kick start your new materials/assumptions.

The main issue and limitation identified in the framework relates to how the key assumptions lies in the hands of the stakeholders, especially the owner who might not have enough technical know-how. If these assumptions are found to be unreasonable at the later of stage the simulation/design process, the entire energy analysis result becomes irrelevant. Fortunately, the process developed by the authors in Figure 3 makes it possible to correct any wrong assumptions made at any stage of the process. In fact, you can always go back to alter the building envelope (walls, windows or roof materials) at any time from the Specs & construction/data transfer decision stage.

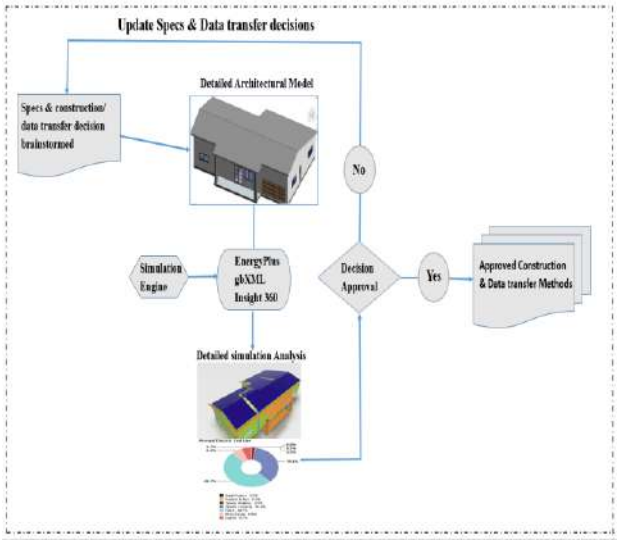

Figure 3. Data transfer decision & energy simulation process

8. Results and Discussion

Data interoperability allowing smooth integration of design and energy analysis has been investigated. The study has identified a suitable process of data exchange requirements to enable stakeholders to address their information exchange needs via a common platform.

The authors developed an integrated information exchange method, in section 2, to identify an unambiguous information sharing process throughout the building lifecycle for the industry stakeholders. The paper defined the data and information flow from IDM (Information Delivery Manual), IFD (International Framework for Dictionaries) and IFC (Industry Foundation Classes). The illustration in Figure 1 summarizes the information exchange process.

In section 3 and 4, the authors investigated several existing BIM authoring software application tools and data exchange formats, respectively. Table 1 lists the state-of the-art existing BIM software tools, their functionalities and performance phases was developed to aid decision making. Table 2 identifies data exchange formats/standards that provide guidelines to leverage data sharing electronically to minimize errors in exchange/communicating information among the team members in an ongoing project. Table 2 also ranks the efficiency level "High or Low" when selecting data exchange file/format. "High" indicates transfer with very minimal or no error while "Low" indicates substantial difficulty regarding data transfer and interpretation. The paper outlined methods for developing Use Cases with an inclusion of data exchange implementation process with IFC (Industry Foundation Classes) as an example. The properties and components that needs to be included in the IFC identified.

Finally, a case study was introduced as an example, demonstrating what constitutes an element of a building model. Autodesk Revit was used to design a BIM-based architectural model. This was used as a test case to demonstrate the data exchange interfaces with other identified BIM authoring software application tools in Table 1 (ArchiCAD, Vasari and Tekla Structures) to assist the stakeholders in making decision in relation to selecting an appropriate design and analysis BIM application tool.

Apart from Building Information Modeling (BIM) currently being adopted by the construction industry to facilitate and promote collaboration between the industry players within projects, there are ongoing deliberations and research on further digitalization and automation of the construction industry. A future research direction is to incorporate an Artificial Intelligence (AI) technology in the BIM process. This area requires more research to bring the power of artificial intelligence to assist the construction industry in tackling some challenges such as reducing design errors, enhancing greater collaboration and better software tools.

9. Recommendations

BIM-based data exchange and analysis processes are constantly evolving with emerging software products and technologies. Based on lessons learned in this study, following recommendations are proposed:

- The industry stakeholders should revolutionize the construction and engineering activities to embrace the artificial intelligence technology solution to

avoid the fast-emerging trend of technological disruption to consume the industry.

- Early collaboration among stakeholders should be made mandatory or guided by strict standards irrespective of the project size to minimize cost and save time.
- Emerging/existing software technologies should be streamlined and be made to follow a cutoff standards and regulation.
- Autodesk Revit was found to be a versatile BIM tool capable of accommodating a wide variety of design and analysis models and data sources.

10. Conclusion

This paper reviewed approaches to enhance collaboration among key stakeholders in building design and construction projects. It analyzed how a common platform could help solve the present needs of data interoperability.

Use cases were found to be a useful tool for evaluating the stakeholders' data exchange requirements, leading to the identification of appropriate software tools and data format for a specific project. Suitable combination of design, modeling, and data interface tools will help improve the project cost and schedule overruns.

The next phase of this research would be centered on using BIM to investigate into generating a comprehensive & interactive database of building data to facilitate smart designs through information to create virtual model from high-powered project data.

Impact of BIM on Electrical Subcontractors

Anoop Sattineni[a] and Bradley Brock[a]

E-mail: anoop@auburn.edu; bjb0010@auburn.edu;

Abstract –

The use of BIM in the electrical subcontractor community has been increasing over the past few years. The practice of using BIM for this sector varies in many ways as compared to the design profession or the use of BIM by general contractors. This study focuses on the current state of BIM implementation among the electrical subcontractors. A literature review of the topic lead to the adoption of a qualitative methodology to study the issue. The results of the qualitative study involved semi-structured interviews with practitioners in the field. The results of the interviews found that the perception among electrical subcontractors regarding the successful use of BIM varies from the general contractor. The study lead to the identification of several key themes that govern the successful use of BIM for electrical construction. The study makes recommendations to electrical subcontractors for the successful use of BIM on projects.

Key Words: BIM; Electrical; Subcontractor; Coordination; Field Installation; Productivity;

1 Introduction

The use of Building Information Modeling (BIM) within the electrical subcontracting community continues to evolve in the United States [1]. There is an ambiguity of existing information regarding BIM usage associated with capital costs and time [1]. Returns on investment (ROI) studies often conclude that BIM is cost effective [2]. However, contrary results do exist, such as the concrete subcontractor recorded by Sawyer [3]. Sawyer [3], found that a subcontractor invested all required time and money in having a working BIM department but did not see any financial benefits. In contrast, other specialty subcontractors are mentioned within the same article and report a positive return on their investment in BIM.

Several things must be considered in the conduct of this research, the main two being time and money. Time must be considered in addition to capital costs involved. Simonian [4], conducted a survey amongst electrical specialty subcontractors. This survey revealed an ambiguity in time savings. For projects requiring BIM, more time is dedicated to creating the model and shop drawings than a two dimensional drawing method without parametric data embedded into it. However, the time put into the model decreased the amount of time required for fabrication and installation because all the details had been considered while modeling.

The time involved in coordination meetings and correcting on-site clashes must also be considered. Korman, et. al [5] outlines the traditional method of a coordination meeting and contrasts it with a coordination meeting utilizing BIM. The findings show that less time is required to resolve more conflicts when utilizing BIM throughout the coordination process. These time-saving factors also transfer into the field because more clashes between mechanical, electrical, and plumbing (MEP) systems are found utilizing BIM and are therefore prevented on the jobsite. Two main factors that are time intensive, but beyond the control of the electrical contractor, are the required level of development (LoD) and the overall area to be modeled [4].

Leite, et al [6] outlines the compounding of time required to increase a model's LoD. When progressing from a lower LoD to the next more detailed level, it may take as little as forty-five additional minutes up to eleven hours. This requirement may be beneficial to the subcontractor, especially mechanical subcontractors, for prefabrication purposes. However, if the subcontractor does not practice prefabrication, the time invested in reaching the required high LoD is virtually wasted. Therefore this factor also relates to financial benefits or detriments of BIM due to the additional modeling time potentially required.

Barlish & Sullivan [7] outline how to measure the benefits of BIM. They noted that BIM is the most helpful in heavy mechanical, electrical, and plumbing (MEP) areas. It is not uncommon for a general contractor to request a typical room to be modeled in addition to the main MEP areas throughout the building. However, general contractors do not all follow the same principles. Therefore modeling unnecessary areas to fulfill contractual requirements may also require unnecessary time.

This research is beneficial because it seeks to

provide in-depth information regarding specialty subcontractor usage of BIM in relation to time and cost. The information gained from the participating subcontractors is vital to uncovering important information in this field. The two main areas in which Simonian received the most ambiguous results directly correlates to either time or financial requirements. Additionally, this study should reveal changes since the Simonian study, conducted several years ago. Since then, BIM has been used in more projects for more applications.

This research uses a qualitative methodology by conducting semi-structured interviews with the practicing subcontractor professionals. It is imperative that those interviewed have hands-on experience with the BIM process pertaining to electrical subcontractors. In order for the results to be effective to the industry, the participants must either be directly involved in the process, or be directly affected by it. By selecting these individuals, this study uncovered detailed nuances of implementation, effectiveness, and weaknesses that individuals outside the process would not be able to provide.

2 Literature Review

Previous research has shown that BIM is used anywhere from 0% to 90% of projects [4]. A survey conducted by Azhar and Cochran [8] found that 32% of reported projects between $10 and $100 million, 55.6% of reported projects between $100 and $250 million, and 50% of reported projects more than $250 million use BIM. BIM can currently be used for visualization, clash detection, prefabrication and on-site installation [9]. An electrical subcontractor's implementation level of BIM depends on its organizational structure [10], percentage of prefabrication [11], regular contractual obligations [7], and project complexity [12].

The trade-off to BIM implementation is modeling time and estimated start-up costs. Time may be saved in the installation phase, but at least a portion of that time is used in the modeling phase. Azhar & Cochran [8] found that 67% of survey respondents reported at least some timesavings. However, they did not report where these time savings came from, or how they were justified. Azhar & Cochran [8] also found that 67% of survey respondents reported at least some cost savings. Once again, the areas in which costs were saved are not provided.

2.1 Productivity

Productivity has historically had many definitions. In order to remain consistent with previous productivity studies, this research will define productivity as: "*labor productivity = output/input = installed quantity/actual work hours*" [13, pg.2]. Park et al [13] developed a productivity comparison system revolving around cost, schedule, changes, and rework. Park et al have also defined five separate subcategories of electrical subcontractor work: electrical equipment and devices, conduit, cable tray, wire and cable, and other electrical metrics. These categories were then broken down into ten different elements: panels and small devices, electrical equipment, exposed or above ground conduit, underground duct bank or embedded conduit, cable tray, power and control cable (600 volts and below), power cable (5 to 15 kilovolts), lighting, grounding, and electrical heat tracing. These are the outputs that are compared with input costs and time to determine an electrical subcontractor's productivity. However, when considering productivity as it relates to BIM for the entire company, the overall amount of work put into a project, not simply installation, must be considered. BIM generally increases site productivity but creates additional expenses during the planning phases of a project [14]. The best two measures of productivity as regards to input are time and money [13]. Time measures the efficiency of using one process over another, and money measures the direct costs associated with using that process.

BIM models are often contractually required from electrical subcontractors for MEP coordination. BIM requirements have noticeable effects to both the time involved in a project and the money required to complete a project. These are the two most ambiguous areas of productivity input to investigate. For example, time is placed into modeling rather than fixing mistakes. Money is used to employ a modeler rather than being applied to RFI work, jobsite clashes, and change orders [4].

2.2 Level of Development

The LoD contractually required is an expensive and time-intensive item which must be investigated. The two main questions that determine the proper level of detail are where to model and what to model. When considering which parts of a project (where) to model for productivity input efficiency purposes, the electrical subcontractor needs to consider the MEP congestion within a given area. For example, certain projects may require large amounts of the electrical systems to be modeled, such as hospitals or data centers, while other buildings may only require MEP intensive rooms and a typical room, such as a dormitory. Leicht [11], conducted a case study in Pennsylvania which laid out four main factors determining required level of development, including, "*interaction with other systems, sequence of installation, prefabrication of components, and layout considerations and density of systems*" (p. 5). Barlish and Sullivan [7], conducted a case study to

determine how to measure the benefits of BIM. Within this case-study, they concluded that BIM is most helpful when utilized in heavy MEP areas such as mechanical rooms and switching rooms.

As the electrical contractor considers what to model, certain processes have an element of diminishing returns. As modeling requirements increase, the improvement to the installation process may not increase at an equal rate [11]. Additionally, Leite et al, [11] conducted a study measuring required level of detail and the returns they provided. Leite et al, found that more detailed models are considerably more helpful in coordination, but do not always increase modeling time exponentially. However, they did conclude that the level of detail should still be determined by the components' purpose and usage. Some components may be very time-consuming to model but also very easy to re-route [14]. These components would not be time or cost effective to model and should only be addressed if used for shop-drawing of pre-fabrication purposes.

Interestingly, as BIM and highly detailed models become prevalent, certain design drawings worsen [15]. In effect, the designers spend less time on the initial documents, knowing the contractors will change the initial drawings to match the installation process. This places an undue burden on the contractors to double-check existing information, fill in missing information, and eventually add all necessary installation details. Therefore the presence of accurate information received plays a heavy role in the required level of modeling detail. Finding, correcting, and replacing either missing or incorrect information is just as time-consuming as detailing existing design drawings.

Sawyer [3] conducted interviews with specialty subcontractors using BIM and discovered that in coordination meetings, what is in the model is not the problem, but what is left out may create a difficult issue to resolve and negate the efforts to conduct BIM clash detection meetings. Electrical contractors have the opportunity to either be highly efficient or sorely ineffective in the area of BIM LoD. Many areas may not require modeling and therefore should be left out for efficiency. However, certain components which are left out of the model may cause much more trouble and time to fix on the job than would have been invested in modeling it initially.

2.3 Clash Detection

BIM usage facilitates coordination through both clash detection methods and scheduling requirements. Savings in both time and money may be realized in this area through greater and more effective communication amongst specialty contractors and the general contractor if BIM is used to a proper level [14]. However it is possible to invest more than required amounts of time and finances towards coordination.

General contractors found a more efficient work process in the area of MEP coordination meetings when utilizing BIM [2]. Akinci and Kiziltas [2], conducted interviews with two different subcontractors over eight different projects and found that the coordination process took less time and was required to meet fewer times when utilizing BIM. Leicht [11], found that clashes discovered in coordination meetings revolve around three issues: the LoD required, a coordination issue, or a design issue. Akinci et al [14] also found that certain items should not be considered in clash detection. For instance, if a piece of 12/2 metal clad (MC) cable is clashing with a mechanical duct, that clash should simply be ignored. It would take much more time to model all of the MC cable in the office than it would to move the same MC cable in the field. Therefore, the ease and flexibility of installation needs to be considered when combing through clashes.

2.4 Site Installation

Site installation within the electrical subcontractor's realm operates in conjunction with the LoD translated to the jobsite. If the electrical contractor increases the model's LoD, then the site superintendents and working foremen will have more information at their disposal to properly install (output) the required components [16]. However, the translation of this information to the jobsite and the benefits thereof will vary from one company to another. It is possible that additional training is required in order to utilize the tools required to effectively translate BIM to the jobsite. Training is an additional cost and must be considered in overall company productivity. On the contrary, BIM may be just as effective for electrical subcontractors in the form of a specialized set of prints which would require no additional training.

When considering outside influences, BIM projects sometimes have a noticeable increase in the amount of information received from the Architects and Engineers [7]. The increased amount of information received helps decrease the amount of Requests for Information (RFI's) and change orders [7]. A reduced number of change orders also constitute a reduced amount of rework; rework is prevented because of fullness and transparency of information received from Architects, Engineers and coordination of subcontractors [11]. If the amount of time and money (input) placed into RFI's, change orders, and rework could be re-routed to jobsite BIM translation and prefabrication, then dollars per unit put in place would decrease due to a fullness of information. Therefore, by the definition used for this study, it will increase electrical subcontractor productivity. One study found that the implementation of BIM resulted in a reduction of time in most of the

construction stages. The largest of these reductions was found within the construction phase [17]. Almost 60% of respondents reported a 12.5% reduction in schedule duration within the construction phase of a project. This reduction is contributed to the pre-solving of installation problems and a better transfer of information from the office to the field. Amongst the pre-solving of installation problems lies the use of prefabrication for site installation.

2.5 Construction Scheduling

Another coordination issue which currently seems to work well is BIM enabled scheduling. BIM enabled schedules help visualize overlapping scheduled activities and aid in equipment coordination [2]. Barlish and Sullivan [7] also define schedule improvements as one of the most quantifiable returns for BIM usage. One way that BIM helps improve a project's schedule is that it allows for earlier coordination meetings and faster resolutions to problem [18]. Therefore, if the coordination meeting process is investigated and a preferred method of conduct is established, then the schedule could also be improved because the amount of time spent resolving MEP coordination meetings could be applied to the overall project schedule.

Additionally BIM may help the schedule by having a 4D model, time being the fourth dimension, for differing areas or pieces of work. When creating a time-loaded model, each component or groups of components have a duration imbedded. Then a schedule can be derived using the imbedded durations for a given area or activity. However, according to the survey conducted by Eadie [19], schedule automation was listed in the last three reasons to implement BIM for any given project. BIM can be used as a visualization tool which informs the general contractor which areas can be completed first so the following sequence of operations will go as smoothly as possible. This is contrasted with attaching a time-based field within each of the BIM model objects or families. As previously mentioned in the site installation section, the majority of participants utilizing BIM found a twelve and a half percent schedule reduction [17]. Therefore, when discussing BIM enabled scheduling, the current use seems to be by the general contractor to inform the proper sequence of operations, not through a time-loaded BIM model.

The results of the literature review show that the impact of BIM within any discipline is a multi-variable, fluid target. The results could change from project to project within the same company. The main areas of investigation are as follows: main factors for BIM use, level of development, clash detection process, site installation, scheduling and modeling impacts. Based on the observations of Miettinen and Paavola [20], as well as Succar [21], the isolation of external variables is virtually impossible. Therefore, a qualitatively nuanced and inductive approach should be used to study the impact of BIM implementation in the electrical subcontracting sector.

3 Methodology

This research implements an interpretive philosophy. The Interpretive philosophy allows for a more situational and flexible approach to data collection. This is necessary because electrical subcontractor productivity is affected by many variables mentioned in the literature review; moreover, those variables are affected by outside influences such as: organizational structure, project general contractor requirements, proficiency in prefabrication, owner expectations, and facility management requirements, all of which are beyond the scope of this research. Due to the outside variables it would be highly unlikely to accurately compare one electrical subcontractor's productivity for a particular project with another electrical subcontractor's productivity on a different project. An inductive approach is deemed appropriate for the purpose of this research. The research strategy implemented semi-structured interviews, as a mixed method choice for a cross-sectional study. The proposed qualitative research method allowed for personal perceptions and situational knowledge to be revealed and explored. Speaking to two current employees working as BIM modelers were used as a pilot test to aid in developing questions. The refined questions were then administered via face-to-face, phone or web meeting interviews. Data saturation for structured interviews usually occurs at twelve interviews [22]. Therefore a total of twelve candidates were interviewed. The observations recorded during the interviews were transcribed and analyzed for correlations and similarities.

The electrical subcontractors considered for interview have been contractually obligated to use BIM on more than three projects. The total number of employees can range from fifty to five hundred. The target personnel interviewed were BIM modelers, BIM coordinators, and project managers who have worked on BIM projects. Guest et al. [23] found that in a sixty participant research study, over ninety percent of all codes, and over ninety-five percent of all important codes occurred within twelve interviews. Therefore, for the purpose of this research, twelve participants were interviewed. The interview results were first transcribed then coded, using open coding techniques. The codes were further consolidated as deemed appropriate. Content analysis techniques were employed in the analysis phase of the study to comprehend the data.

4 Results & Discussion

In performing the qualitative content analysis, six main themes were found. The six themes are: Coordination, Field Issues, Electrical Software, Current Modeling Parameters, Factors for BIM Usage, and Company Factors. Each theme describes an important aspect of the Impact of BIM on Electrical Subcontractor Productivity, and was developed by grouping similar participant responses found in the data. Within each theme are important aspects and subjects which the specific theme covers. Sub-themes helped the researchers to quantify participant responses in a comparable way. The percentages displayed note how many participants mentioned a particular idea, within the same context. Each theme and corresponding sub-themes are discussed in the sections below.

4.1 Coordination

The main theme of coordination covers areas mentioned about the clash detection process and subcontractor collaboration in general. The percentage of participants' responses can be seen in Figure 1. The interviews revealed that most parties involved in the BIM process during the modeling and pre-construction phase seek out and resolve joint problems with pertinent trades. It was also noted that the person running the clash detection process, commonly called the coordination leader, is a very important party with specific responsibilities that impact the entire clash detection process.

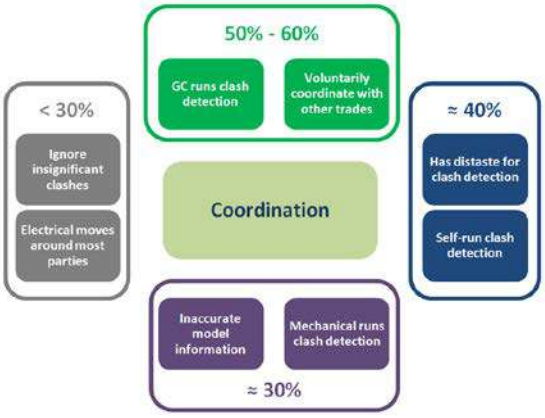

Figure 1. Coordination Qualitative Content Analysis Diagram

4.1.1 Coordination Leader

The data surrounding this topic defines coordination leader as the party responsible for combining coordination models for clash detection, running the clash detection meetings, and determining who moves how far. The majority of respondents mentioned either the GC or the mechanical contractor as being the coordination leader. Only two participants mentioned the possibility of either one taking on this role.

The participants who said the mechanical contractor had to be the coordination leader never mentioned the GC in a coordination role. When both the GC and mechanical contractor were mentioned as potential coordination leaders, the GC was preferred because they have the power to force another party to move. The main power mentioned was withholding payment until requests are met.

Another factor within the coordination role is the mentality of the subcontractors involved. In certain instances, the GC has nothing to do with the clash detection process, and it is orchestrated and run by the subcontractors entirely. Within this instance, if the GC is not viable to be the coordination leader, the mechanical contractor was deemed proprietary, the one with the most to model, the party with the most at risk, and therefore should head up the coordination. The reasoning is, "*we will have to move around them anyways*," so they may as well lead.

Less than thirty percent of participants mentioned that electrical sub-contractors commonly move around other MEP trades. Their reason given is due to code restrictions for mechanical, plumbing and sprinkler locations, versus relatively few codes dictating electrical conduit locations. Therefore, it is reasonable to assume that electrical subs move around other parties on a regular basis. No participant mentioned electrical items being proprietary or having code restrictive locations. This fact makes it even more enticing to coordinate locations with other trades, because it creates less re-work for the electrical modeler in moving obstructive items.

4.1.2 Voluntarily Coordinate with other Trades

The voluntary coordination with other trades takes place regardless of who the coordination leader is. It refers to a willingness to call, email, or otherwise contact another subcontractor you are clashing with outside of a planned coordination meeting. Voluntary coordination is connected to self-run clash detection and distaste for clash detection, as well as moving around most parties, as mentioned earlier.

The participants believe the clash must be cleared up regardless. As one participant put it, "*If we coordinate before the meeting and have a largely clash-free model before the meeting, then the meeting will take less time*" is a main thought. The modelers usually have multiple projects going at once, so the more work they can do in advance the better. Therefore, they will model, call to coordinate large items with other trades, run their own clash detection before upload, and clear up those clashes before uploading the model. This sequence cuts down on the overall coordination meeting time.

A long coordination meeting is one of the main complaints for clash detection. The complaint being that "*you cannot keep the modelers as you go through every little clash,*" coupled with "*sometimes the [coordination leader] is not looking in the proper places for clashes.*" Voluntarily coordinating with other subcontractors helps mitigate the distaste for clash detection, because that subcontractor would usually run his own clash detection, and therefore be required to spend less time in the coordination meeting and have less to fix afterwards.

4.1.3 Inaccurate Model Information

Over thirty percent complained about inaccurate model information. One major shift in modeling expectations sends a chain reaction of field re-work down the chain of subcontractors. The shift can come from modeling omissions, unexpected site conditions, or incorrectly designed components (from any of the designing engineers). This inaccurate information results in one of two things for an electrical subcontractor: either field coordinating previously modeled components (therefore rendering the modeling a waste of time), or waiting until dead last to install whatever was either omitted or incorrect. Installing last absolutely destroys productivity because a straight run turns into a plethora of offsets and ninety's to dodge all the other systems in your way. Not to mention, it needed to be done yesterday because the ceiling crew is following right behind you.

4.1.4 Ignore Insignificant Clashes

Within a clash detection meeting, the parties go through the clashes and designate who moves and how far. This note, if followed, will resolve the clash. However, every clash picked up by the clash detective is not significant. An insignificant clash would be one easily fixed in the field with little to no actual conflict. An insignificant clash would not require field re-work if not resolved. One participant mentioned that "*in a building with one thousand clashes, only about six-hundred will be significant.*" The act of going through and dismissing these clashes, according to the modelers, should be done before conducting the coordination meeting with all the trades together. Going through every clash was noted as a rookie mistake only made by inexperienced coordination leaders.

One company goes as far as saying, prior to upload, they do not even run a true clash detection in Navisworks. Instead they visually inspect what has been modeled, fix visual clashes, and continue. They took this approach because the clash detective picks up so many insignificant clashes. It is more efficient to visually inspect important clashes than wade through all the insignificant clashes.

4.2 Field Issues

BIM must be transferred to the field installation practices, or else, it is largely a wasted opportunity to achieve efficiency. If a model is created, but they coordinate in the field as if there was not a coordinated model in existence, then the modeling time and money was wasted. This theme of field issues encompasses how BIM is transferred to the field, and the effects it therefore has on the field (positive or negative). There were mostly positive reports given regarding BIM's impact on field installation. The respondent percentages and sub themes may be seen in Figure 2 below.

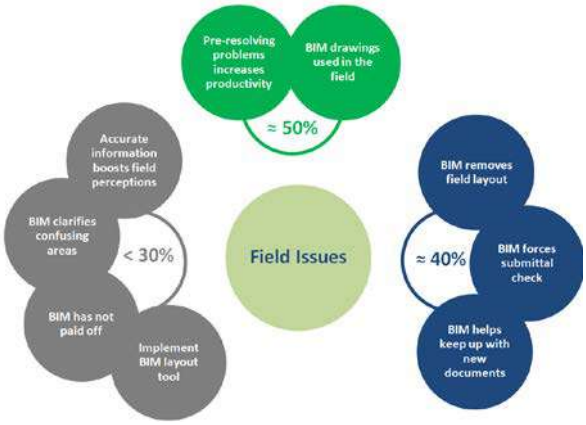

Figure 2. Field Issues Qualitative Content Analysis Diagram

4.2.1 Pre-resolving Problems Increases Productivity

The pre-resolving of problems encompasses other sub-themes mentioned within the realm of field issues. The participants primarily referred to the pre-coordinated location of large conduit runs, or laid out electrical rooms. These items in turn referred to forcing a submittal check and removing field layout. They were placed into three separate categories because they are mentioned in separate locations and help explain one another. Therefore, the following discusses the idea of field layout and submittal checks.

Field layout is the act of the electrical superintendent deciding where to run the main feeders, what can be run underground, how to fit the conduits within the tight electrical room, and discerning where the main areas of confusion will be and who could help clarify these areas. While making these decisions, the field men are staring, waiting for marching orders. This is a typical, non-BIM electrical project. With BIM, the modeler, usually under the direction of the project manager and superintendent, has pre-coordinated many of these decisions. This allows the field men to begin installing conduit according to the coordinated drawings immediately. It also allows the superintendent to focus more heavily on

the areas of contention and confusion. The field will still perform a level of layout, as far as measuring where items will go, however, the bulk of the decisions have already been made.

One of the most important processes of layout is ensuring that the installation components will fit within their designated areas. Usable square footage is precious, therefore non-usable areas, such as electrical rooms, are made as small as possible. If it is discovered in the field that a particular item, a panel, switchboard, light fixture, automatic transfer switch, or transformer, will not fit within its place, then your field men have to waste their time on a mistake that could have been avoided. It would be an easy fix if the project manager or superintendent simply double-checked the submittal sizes. However, as one participant noted, "*getting someone to back check submittal data when they are coordinating the actual installation of items every day is not an easy thing.*" The BIM modeler has an opportunity to ensure these items will fit before they are required to be installed. This is noted by modelers and project managers alike as a very important task. Three inches difference of a light fixture depth in a hospital corridor might as well be a mile.

The pre-resolving of layout and submittal items are the two main "*problems*" that BIM resolves and delivers higher productivity. As previously mentioned, these two items help describe the pre-resolution productivity boost.

4.2.2 BIM Transfer to the Field

The efficiency with which the BIM information is transferred to the field is just as important as the information itself. The respondents described a range of BIM transfer to the field including the following: giving coordinated BIM drawings, providing specialized multi-system drawings, supplying superintendents with tablets loaded with the BIM model, training and providing BIM stations for the entire electrical crew, utilizing a BIM layout tool to establish points. The main thread throughout the entire range of BIM to field transfer is the field's ability to understand and assimilate the transfer method into their workflow. That is the main reason that over fifty percent still use specialized drawings rather than BIM-loaded tablets. The companies are certain their field personnel would not know how to properly use the BIM model. Those not making BIM available to every electrician see more benefit in having the modeler supply pertinent information to the field through paper drawings. Then, if the field has requests for more information, the modeler will provide specialized drawings or model snap-shots.

For those companies that have invested in BIM training for the electricians, the implementation of a BIM layout tool has proved greatly beneficial. One modeler reported that going into the field to lay points creates a synergy between the modeler and field personnel. It brings the modeler into the reality of what is being modeled. Simultaneously, it helps the field understand the benefit of what the modeler is doing. "*BIM total station increases morale between field men and designer because the field men see the benefit of the modeler.*" Additionally, the BIM layout tool decreases the time required for certain tasks. As clearly stated in this quote, "*using the BIM total station, they laid out a floor in one day rather than two weeks.*"

The transfer of BIM information to the field is extremely important. However, that does not automatically mean an electrical contractor should train everyone, buy all new tablets, and create BIM jobsite stations. The most important thing is for the field to use and assimilate the information. Coordinated 2D drawings that are understood would be better than a frustrated crew.

4.2.3 BIM Helps Keep Up with New Documents

Construction projects, often times, release addendums and change orders throughout the duration of the pre-construction and construction phases. Having an additional person dedicated to ensuring the field has the latest and greatest information is invaluable. As noted in the software section under thematic analysis, an electrical subcontractor can be responsible for up to thirty different digital collaboration tools. It is very easy for a change to be missed, and it is crucial for the field to receive every change. Otherwise, mistakes will be corrected at the expense of the contractor. Inaccurate information is still a potential, however, an additional set of investigative eyes helps mitigate the error of outdated information.

4.2.4 BIM has not Paid Off

Two participants specifically mentioned they did not feel BIM has paid off. One performs partial modeling in-house (subbing out larger modeling jobs), and the other subs out all the BIM modeling. One participant clearly stated that "*BIM is a lot of work that just hasn't paid off.*"

The only redeeming factor for one participant is that the clash detection process gets all the trades on the same page. However, he argues it is no different than the process before modeling. Conversely, he mentions a benefit in modeling within congested or complicated areas. Therefore, someone who largely opposes the BIM process still finds benefit in modeling congested areas. However, modeling the entire building is seen as a waste of time, money, and resources, which will not pay off.

Participant ten mainly claim that BIM has not paid off due to a recent project. The project performed the

clash detection process and achieved a clash free model. Upon installation, design changes were made, which threw the "*entire model into chaos.*" Site coordination meetings were foregone by the general contractor in lieu of the coordinated model. This project was "*less coordinated than other projects without BIM.*" Primarily, the only redeeming factor of the BIM process is that it is a source for coordination drawings, which would have to be made regardless. Consistently inaccurate model information has convinced this participant that BIM has not paid off.

Therefore, the two main arguments that BIM has not paid off may be reduced to: we can coordinate most areas much faster in two dimensions, and inaccurate modeling information will ruin a project. Both of which are worthy points for further investigation.

4.3 Electrical Software

The main software dominating the electrical modeling sector are two semi-competing platforms, AutoCAD 3D and Revit. Both are owned by Autodesk, and both create geometry in three dimensions necessary for clash detection. However, only Revit is an actual BIM platform. AutoCAD 3D is a modeling program, but is not capable of having submittal data loaded into it. Figure 3 displays the percentage of participants' software preference and their opinion of electrical software in general.

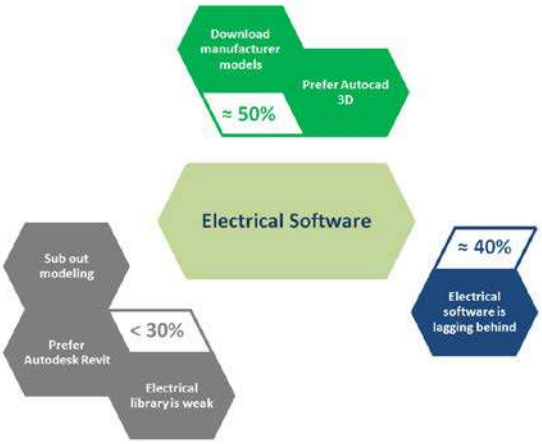

Figure 3: Electrical Software Qualitative Content Analysis Diagram

4.3.1 AutoCAD 3D Vs Revit

As shown above (Figure 3), the majority of participants prefer AutoCAD 3D over Revit. The main reason given is AutoCAD 3D is easier to use and more tailored to the electrical industry than Revit. Those who prefer Revit claim much of the same benefits that AutoCAD 3D users mention with the addition of manufacturer model download capabilities.

According to the proponents of AutoCAD 3D, it is a simpler program, with easier modeling procedures, and can be executed more quickly than Revit. According to one participant "*one of our operators went to school and was trained on Revit, and we trained him on AutoCAD MEP. He said the MEP for what we do is really better, faster, more tailored to what we do.*" AutoCAD is not a smart model and therefore does not require loads, circuits, or any submittal information. At times Revit is called for in the specifications. In these instances, usually the GC will allow the electrical contractor to model in whatever program they are most comfortable with and simply provide a particular export file type.

Of those proponents of Revit, two are modelers and one is a project manager. One modeler jumped straight from AutoCAD 2D into Revit, and has little to no experience with AutoCAD 3D. The other modeler has used both AutoCAD 3D and Revit. His main example of Revit's supremacy derives from being able to download manufacturer models and place them within the model. The project manager prefers Revit because of the ease of information retrieval. Revit can give you the length, size, fill, source, and destination from one click. This greatly helps in information retrieval in the field.

According to all the participants, a data loaded BIM model is a rare request. Therefore, both the AutoCAD 3D and Revit users are primarily modeling for in-house benefit and coordination purposes. That is why the selection of modeling software weighs more heavily to speed and ease of use.

4.3.2 Electrical Software Lagging Behind

Forty percent of participants agree that "*electrical is at the bottom of the [software] food chain.*" This is mostly in comparison to mechanical and structural contractors. The libraries are weaker, component transition is less smooth, and certain items the program may are not even electrically based. Duly noted, "*Here in a couple three years ago, the fittings the software was putting was…like using plumbing fitting or a plumbing configuration to do electrical.*"

A majority of the complaints revolved around lacking a component library. However, this was often offset by commenting on the benefit of retrieving manufacturer created components online. The other complaint was that neither AutoCAD nor Revit are actually tailored to the electrical industry. "*I can make it do what I need it to do, but there's definitely room for improvement on Autodesk's side,*" basically sums up the current standing of electrical modeling software.

One participant expounded on his contact with Autodesk in response to this room for improvement. There are opportunities to provide feedback as well as support communities. Certain support communities, at

least for Revit, are monitored by Autodesk. An Autodesk representative will try to answer operational answers, or at least note a change to be incorporated into later releases.

4.3.3 Sub-out BIM Modeling

Less than thirty percent of research participants subcontract out the BIM portion of the work. The primary reason for subbing out the BIM portion of a job is a lack of resources. Smaller companies do not have the additional resources to dedicate to BIM modeling in-house. In certain instances, there may be an in-house modeling department which will model certain sections of a project, but not the entire building. Although in-house modeling capabilities may be present, "*it is better to not tie up your own resources on very large projects.*"

4.4 Factors for BIM Usage

This main theme covers the main reasons why an electrical contractor will use BIM. The most common reason is, "because the contract requires it." However, this theme also uncovers what will be done when BIM is not required. It also helps delve into the intended primary beneficiaries of the BIM process. If BIM is not required, and certain items are modeled regardless, there is an intended beneficiary and reasoning for executing the additional work.

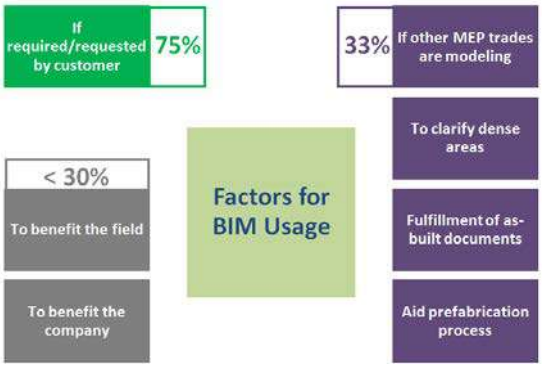

Figure 4: Factors for BIM Usage Qualitative Content Analysis Diagram

4.4.1 If Required or Requested by the Customer

The primary driving force of BIM usage within our range of participants is still the owner and or general contractor. There is over a forty percent gap between those who model when required and those who model for their own benefit. The reluctance for electrical contractors to BIM a job still exists, although most participants would say that BIM has paid off. In other words: BIM has paid off when used in the most desired way. None of the project participants mentioned modeling an entire project solely for company benefit. There are always stipulations, one of the biggest currently being, if it is required?

One of the positions among subcontractors regarding the requirement is, "*this is an additional cost I need to put into my estimate.*" This especially applies to those subbing out the BIM portion of the work. If one includes the additional overhead/subcontractor cost to use BIM on a project, while another does not include that cost the contractor not carrying additional BIM charges will have a financial bidding advantage. Based on the interviews, the BIM model may cost a small percent of the entire project. In a market where a one percent change could be the determining factor between award or dismissal, documentation of a BIM requirement is crucial.

Although the same contractor may realize benefit through the BIM process, either by reduced re-work, shorter installation durations, or more field coordination, this benefit has most likely not been incorporated into the estimating programs. No participant mentioned using the BIM model for an actual bid estimate. Additionally, many modelers mentioned receiving modeling information after the project had been awarded. Hopefully, BIM savings and costs will be integrated into the estimating process, but until then, the documented requirement for BIM will likely remain the primary determining factor for its usage amongst electrical contractors.

4.4.2 If other MEP Trades are Modeling

This reason did not come from those subbing out the BIM scope of work, only from those who primarily model in-house. "*If we are not required to BIM a project, the first thing I will do is call the mechanical sub and see if he is modeling.*" The primary purpose of modeling a project is coordination. There is no reason to model if there is no one to coordinate with. The model will be an added expense with no relevance to installation, and have no potential field benefits.

However, if the other MEP trades intend to model, especially the mechanical contractor, the potential field benefits remain. As mentioned earlier, there are instances where the general contractor does not require or monitor the clash detection process, and the trades do it anyways. In this instance the mechanical contractor will most likely take the coordination leadership role. As noted in the diagram, only one-third of participants are confident enough in their potential savings through the BIM process to proceed under these conditions.

4.4.3 Clarification of Dense Areas and Field / Company Benefit

As mentioned under the company factors theme, at least half of the participants will conduct a post-award meeting. Within this meeting, the project manager,

superintendent, estimator, and modeler will go through the project after its award. This is the meeting in which dense or potentially confusing areas will be identified for modeling. This meeting will also be the prime determinant of what exactly will benefit the field and/or company.

The primary dense area mentioned, which is also noted within the company factors theme, is the electrical room. Fitting all the gear and conduit into this room is described as "*trying to shove ten pounds of [stuff] into a five pound bag.*" Electrical rooms are the primary location where the electrical contractor will have a conflict with himself. Additionally mentioned are hospital head walls and primary corridor intersections, where multiple trades have multiple crucial components.

These are areas where questions will be left unanswered and RFI's unissued until installation. Identifying and detailing these areas before installation benefits the field by reducing re-work and limiting submittal item errors.

4.4.4 Aid the Prefabrication Process

Modeling for pre-fabrication benefit is trumped by the following factors: whether BIM is required in the documents, if other MEP trades are modeling, or if modeling is determined beneficent in the post award meeting. No participant mentioned modeling for the sole benefit of prefabrication. The noted thirty-three percent of participants went into greater modeling detail, within the areas already deemed necessary to model, if it helped the prefabrication process. Therefore, prefabrication may be aided by the modeling process, but does not drive the components modeled. In compliment, the greatest benefits of prefabrication are mentioned to be within complicated, labor intensive areas. To summarize, the areas most likely to be deemed beneficial to model, will also reap the greatest prefabrication benefits. Therefore, prefabrication does not determine components to be modeled. It is an added benefit to modeling certain components in greater detail.

4.5 Current Modeling Parameters

Current modeling parameters would be the external factors of BIM modeling set out in the construction documents. If a project is required to be BIM, there is usually a BIM execution plan within the specifications. This execution plan varies in length, from as little as, "*this is a BIM project*," up to forty pages of details and responsibilities. This plan usually covers what to model, where to upload the model, and sets certain modeling completion benchmarks. It varies depending on owners, designers, and general contractors involved. Figure 5 below displays the commonalities amongst most modeling parameters.

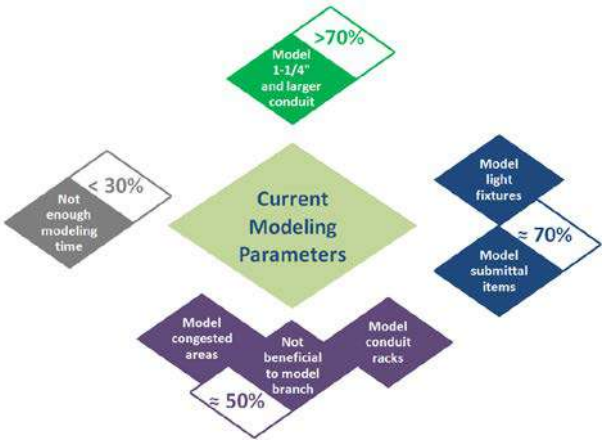

Figure 5: Current Modeling Parameters Qualitative Content Analysis Diagram

4.5.1 Model 1 ¼" Conduit and Larger

The conduit over one inch is usually associated with a project's main electrical feeds located on the single line. The single line is the diagrammatic drawing showing the main power connections between power distribution items, such as: primary power entry from the utility company, primary switchgear, 480 volt panels, transformers, 240 volt panels, uninterrupted power supplies, automatic transfer switches, and certain large pieces of equipment. The feeds are usually home runs and considerably less abundant than branch conduit.

Some participants argue that modeling any feeds smaller than two inches is ridiculous. In this instance they may negotiate modeling requirements with the general requirements. However, as noted above, over seventy percent agree that modeling feeders is a beneficial component to model. One reason is that, conduit over one inch is considerably less flexible than smaller sizes, especially over two inches. Also, the wires inside the larger conduits are usually larger and can be quite expensive per foot, as well as laborious to pull. Additionally more offsets translate into more pull boxes and wire splices which also add material and labor. As one participant said, *"I can assure you, we do not want to run 6 - 4" conduits and have to move them."* Based on other participants, that would include snaking them through other trade's obstructions.

4.5.2 Modeling Light Fixtures and Other Submittal Items

This is another area that is commonly required in the execution plan, and also accepted as beneficial by the electrical contractors. Technically, light fixtures are considered submittal items, but, within the interviews, submittal items refers to special pieces of power distribution equipment, or other bulky, specialized components with longer-than-normal lead times. These

are usually included on the single line.

The high acceptance of modeling light fixtures consists of two main factors: the ease with which light fixtures can be put into the model, and the drastic impact and cost just a few inches of light fixture depth can have on above-ceiling coordination. Concerning the modeling of the light fixtures, over fifty percent will turn to online manufacturer models. From that point, all they have to do is place and position. But once the modeling process has begun, the lighting package has already been scoped out and the electrical contractor has likely issued a letter of purchasing intent to a lighting vendor for their quoted lighting package. If the electrical contractor was in the field and a coordinated component did not fit due to a deeper than anticipated light fixture, the electrical contractor would be responsible for making it work. In other words, changing light fixtures to gain a few inches is an expensive proposition to the electrical contractor. And according to one participant, "*3-inches could make all the difference in a tight space.*"

Submittal items have the same issues as light fixtures, with added lead-time precautions. There are relatively few crucial submittal items in comparison to the entire electrical scope of work. However, unanticipated changes to these precious few items could quickly eat away profits and create labor down time. Akin to modeling light fixtures, modelers may find the manufacturer model for certain pieces of gear online. If not, it does not take much time to create a colored mass of the overall dimensions of the component and place it within the model. For about seventy percent or participants, the duration modeling lights and submittal items is time well spent.

4.5.3 Modeling Branch

The majority of conduit in a project is branch. Branch is the connection from one device to the next in a circuit. The branch wiring is fed by home runs. These are designated as diagrammatic arrows on electrical drawings which go back to one specific panel circuit. Homeruns often run parallel to each other, and, where applicable, run down a main corridor and feed into the appropriate panel.

The modelers are not completely opposed to modeling the home runs. Blocking out this space allows for a much quicker installation within the corridor because fewer offsets and splices would be required. However, the modelers agree that once the home run reaches either the first device or the intended room, the branch modeling should stop. The argument for this is twofold. First, electrical metallic conduit (EMT) and metal clad (MC) cable are very flexible items which can be diverted around most objects. Therefore, if these components are modeled, they will simply cause an irrelevant clash, because the field man can easily divert the conduit. Second, modeling branch is an extremely laborious task with virtually no field benefits. And, if a room is reconfigured, or a wall moved, the entire branch modeling process must be re-done. Simply because fifty percent mentioned that modeling branch was not beneficial does not indicate the other half see the benefit to modeling branch. In fact, only one participant voluntarily models branch for company benefit.

4.6 Company Factors

Each company has its own guidelines and best practices regarding BIM usage. These factors have been compiled into the Company Factors main theme. Figure 6 displays different actions a company may take when faced with differing levels of BIM requirements.

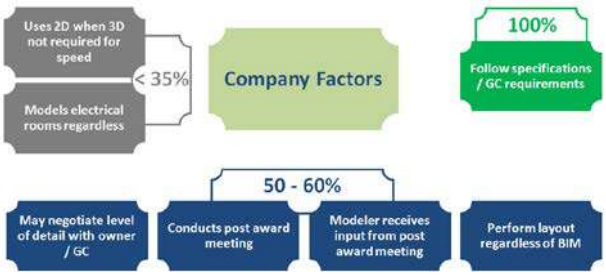

Figure 6: Company Factors Qualitative Content Analysis Diagram

4.6.1 Specifications and Negotiation

Every participant was very clear that the specification documents and GC requirements were to be completely followed. It is the contractual guarantee of the electrical subcontractor to fulfill all requirements listed within the specifications and shown on the drawings. However, there are instances where the electrical subcontractor may negotiate the terms of level of modeling detail requirements.

The possibility of negotiation hinged upon the following three factors: the severity of the initial requirements, the relationship between the electrical subcontractor and the general contractor, and the type of contractual agreement (design-bid-build or design-build). The severity of the initial requirements overrules the following two factors. For instance, if the electrical contractor is initially required to model all items down to the threaded rod, he will "educate" the owner and general contractor on this time-intensive requirement regardless of prior relationship or contractual framework. Likewise, the relationship between electrical and general contractors trumps the contractual framework; positive relationships indicate a level of trust and collaboration necessary for productive

negotiation.

In summary, the electrical subcontractor agrees to follow every item within the drawings and specifications. However, when the possibility to negotiate certain terms of the contract arises, particularly the modeling level of detail, fifty percent of the participants in this research capitalize on that chance.

4.6.2 Post Award Meeting and Modeling

A majority of participants mentioned conducting a post award meeting. This is described as a meeting between the estimator, project manager, superintendent, and BIM modeler for the electrical contractor. After being awarded the project, they will go through the drawings and specifications. The purpose of this meeting is to orient the project manager, superintendent, and BIM modeler to the project. Additionally, this meeting is an opportunity for the project team to point out complicated areas and dictate certain components to be modeled. One participant mentioned they will "*write down what would benefit the project, or what would benefit the company as far as the BIM modeling process*" during the post-award meeting. Another uses, "*forms to determine, what we are going to do on this project, what requires modeling.*" This information is then passed and explained to the BIM modeler so it can be incorporated into the final model.

4.6.3 2D Layout

As shown in figure 6, fifty to sixty percent of participants perform a level of layout regardless of BIM requirements. This layout, at a minimum, consists of drawings red-lined by the superintendent, showing where he intends to run the main components of the project. If BIM is required, the modeler will reflect the markings into the BIM model. If BIM is not required, the markings will be reflected in the 2D coordination study and taken into the field.

4.7 Conclusions

The impact of BIM on electrical subcontractor productivity is too recent to be objectively measured. Participants mention time savings and increases in coordination productivity. However, these measurements have not been completely quantified. Quantification is nearly impossible because of all the variables surrounding any given project, regardless of BIM. Location, electrical project manager, general contractor project manager, owner, electrical superintendent and crew, other subcontractors' managers, relationships with other subcontractors, and project complexity all play a part in electrical subcontractor productivity. However, certain conclusions can be made to the electrical subcontracting community, based on the findings of this research.

- The electrical subcontractor should try to operate under the GC as the coordination leader. If the GC is not willing to be coordination leader, the electrical contractor must should support the mechanical contractor to take up the role.
- Ensure there are no requirements to model items that have no impact on field installation. If required, negotiate with the parties requesting that level of detail.
- Give the field as much information as they can assimilate into their installation. Deliver the information in a format that enhances field personnel productivity.
- The primary areas of benefit with BIM are more thorough submittal checks, coordinated clash detection, and eases in field installation (due to prior coordination and layout). Perform these activities whenever possible and conduct an internal post award meeting.
- Coordinate with the other trades on system layout as much as possible before the BIM modeling process begins. This will reduce the number of clashes and modeling rework.
- When considering who to subcontract the BIM scope of work to, prioritize relationships and timeframes.
- The modeler should only model to an LoD for prefabrication if that area is required or beneficial to be modeled, regardless of prefabrication.
- Consideration to hire personnel who are modeling purposes must be given to those candidates who also possess field experience even if their software usage capability is not the best.

4.8 Future Research

This exploratory research of the impact of BIM on electrical subcontractor productivity opens the door for quantitative research in the future. The main limitation of the findings within this study is applicable due to participant size and location. It would be greatly beneficial to translate many of these findings into a widely distributed quantitative data collection medium, such as a survey.

Also, the topic of modeling timeframes seems to have the least amount of research. However, it has a great impact on coordination accuracy. It is connected with construction start dates, as well as design completion dates. The closer construction commencement edges towards design completion, the less time for underground and first floor coordination. The electrical trade is greatly impacted because the discerning what can be installed underground is largely dependent on the load requirements of the first few floors of the building. The more time between design

completion and construction, the more thorough the underground installation. As underground is one of the least expensive methods of electrical installation, this could potentially lower the overall project cost to the owner. At the very least, it would help maximize electrical subcontractor profits. Although BIM may not have sufficient research to quantify financial impacts, it has the potential to significantly change the construction industry in the future.

Abstract –

In the past ten years, more and more construction companies have adopted and implemented the Building Information Modelling (BIM). Government agencies have addressed the relevant technologies because the application of BIM has brought a lot of benefits to engineering. However, many companies today have neither deployed BIM technology nor confirmed their intention(s) to adopt BIM technology. This is perhaps subject to the limited knowledge about successful BIM deployments. Based on the literature and the experience of an expert, in this study, the influencing factors and a decision hierarchy are identified and developed by using Delphi method. The priority over and the relative importance of these factors and over/of those upper constructs were analysed using the analytic hierarchy process (AHP). These findings are key to enhance the decision-making process of a construction firm which wishes to introduce a BIM system.

Keywords –

Building Information Modelling; Delphi Method; Analytic Hierarchy Process (AHP); System Adoption Factors (SAF)

1 Introduction

Adopting BIM technology in an architecture, engineering, or construction (AEC) project may improve the performance of the project and bring benefit to the project. Establishing an effective BIM evaluation standard can help new users of BIM systems during deployment [1]. However, as the studied case in Taiwan, at this stage, most of the companies that have adopted BIM technology are the construction firms.

This paper studies the influencing factors which may affect a construction firm's decision on the adoption of BIM technologies for deployment and implementation. Except for analysing the priority and the relative importance of these factors, these factors are mounted under four constructs, namely, BIM system integration, BIM use, organisation (organizational factors), and project execution. The relative importance of these constructs, which is also the key knowledge that is to be explored, is also assessed.

This study progresses as follows. First, from a literature study and the expert discussions, the set of initial system adoption factors (SAFs) for BIM were determined. These SAFs are organised as a 'decision hierarchy' [2] [3]. It is a tree which includes a layer of constructs and another layer of factors, while the root of this hierarchical tree is the total decision goal (i.e., the deployment and implementation of a BIM system). Delphi Method, which is also known as the expert survey method, is used confirm the form of the decision hierarchy, with expert discussions polled.

Next, using the analytic hierarchy process (AHP), a questionnaire is designed and the expert opinions are investigated in terms of the pairwise comparison matrices. To facilitate this survey process, Expert-Choice, a computerised tool, is used as an assistant tool to validate the consistency in the data (i.e., polled opinions) and to obtain the weights (relative importance) of the factors/constructs. Finally, these factors are prioritized according to their associated weights. The key factors that influenced BIM system adoption, which is the key knowledge as desired by the decision makers (DMs), are identified. Together with other findings, the set of knowledge can serve as an important guide for any construction firm which is willing to adopt, deploy and implement the relevant technologies of BIM.

2 The Determination of the Influencing Factors Using Delphi Method

Figure 1 shows the way in which this study has applied the Delphi Method.

First, in the literature study phase, the influencing factors of BIM on BIM adoption are identified from the literature, using materials in the research field. The literature and the collected materials are also used as the

important references for subsequent study. A number of influencing factors (i.e., SAFs) are collected in this process. For example, but not limited to, Badrinath summarised a set of 454 initial SAFs [4]. Tsai et al. identified the other set of 123 SAFs, considering the whole life cycle of the building as the research subject [5][6], while in general, the life cycle of a building is mainly divided into four general stages: planning, design, construction, and operation/maintenance.

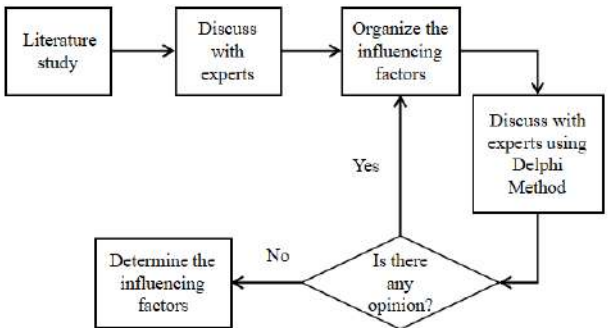

Figure 1. Determining the influencing factors

Second, it is the 'discussion with the expert' phase. The SAFs which are summarized from the literature are given by a BIM researcher in Taiwan. She is in charge of filtering the SAFs and reduce the size of the set of SAFs so that only those factors which are regarded as important for the construction firms in Taiwan are included. So after the discussions, this phase obtains a set of only 25 'initial SAFs'.

Third, the Delphi method (see the right loop in the figure) is used to confirm the obtained set of SAFs, while any addition of a new SAF or removal of an included SAF in the set is possible. The Delphi method, also known as the 'expert survey method', mainly uses communication methods to send questions that are to be discussed to the experts for consultation, to collect the opinions of all the experts, to understand these opinions by discussions and to aggregate the opinions. These aggregated opinions are once again fed back to the experts for further consultation, so their opinions are collected and aggregated more accurately. This approach gradually produces more consistent results for making a precise decision. It uses an anonymous way where the aggregated opinion maintains a general representativeness and is thus a reliable decision-making method.

In this study, through the use of the Delphi method with the experts help, eventually, two new SAFs, i.e., BIM system expansion capability and BIM technology cooperation between the construction firm and downstream subcontractors, are added to the set, but no SAF in the initial set is removed. In the opinion of the expert, the system scalability of BIM technology is very important. In addition, most of the downstream subcontractors of the construction firm will affect the performance of the BIM system owned by the construction firm itself. Therefore, finally, a total number of 27 SAFs are included and studied in this study.

3 AHP Questionnaires and Surveys

In this study, a tree-like hierarchical diagram is established, as to organise the SAFs. This is usually called a 'decision hierarchy'. This decision hierarchy includes not only a bottom layer of the SAFs, but also a middle layer of constructs, where each SAF is mounted under some construct. Thus, a decision construct may have several SAFs mounted. And, all of these constructs are further mounted under the total decision goal, which is BIM adoption.

However, as this decision hierarchy is established by the researchers of this study (see *phase 1* in Figure 2), it requires further confirmation. In this study, this is confirmed by also using the Delphi Method (see *phase 2* in Figure 2). Fortunately, the established decision hierarchy is approved by the expert when it was first established.

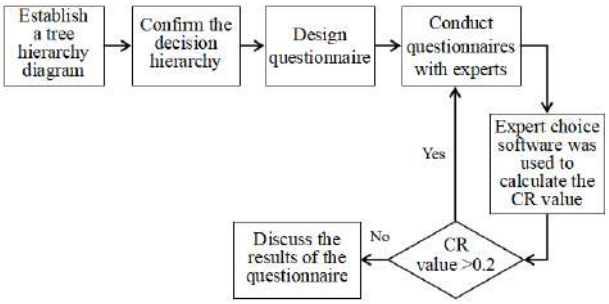

Figure 2. The workflow of AHP processes

Therefore, the confirmed decision hierarchy is used as the basis to design the questionnaires for the pairwise comparisons in the style of AHP. In the confirmed hierarchy, since there are four constructs w.r.t. the goal and there are different numbers of SAFs w.r.t. each construct, there are five questionnaires. This is exactly *phase 3* in Figure 2.

After the questionnaires are designed, they are used for the survey wherein the DM expresses his preferences in terms of pairwise comparisons. The DM is asked for more rounds of interview if the result does not pass the consistency check. This survey process is as shown in the *right part* of Figure 2.

The Analytic Hierarchy Process (AHP) [7] is mainly used for decision problems with multiple evaluation criteria. The purpose is to divide the considerations for a

complex decision problem system into several smaller parts (i.e., the constructs), where each of these smaller parts includes the observable factors (i.e., the SAFs). A decision hierarchy can help a DM to fully understand the influencing factors during decision-making, and the analysis of AHP is a method to assess the (relative) importance of these factors in terms of the results from the pairwise comparisons performed by the DM.

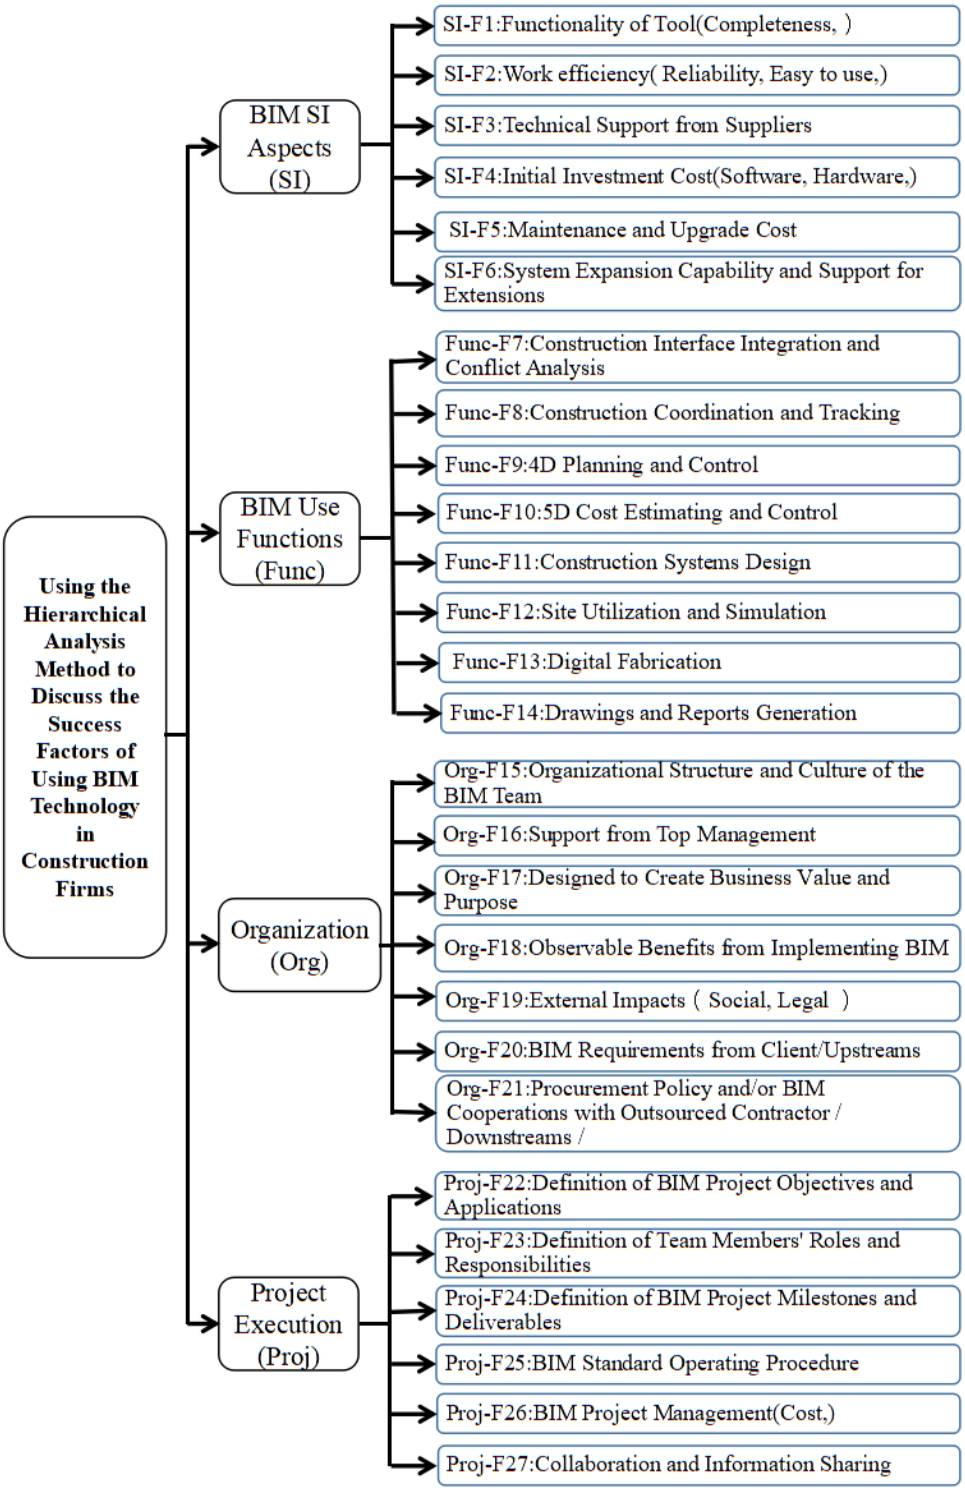

Figure 3. The decision hierarchy diagram

In this study, the decision hierarchy that is confirmed is shown in Figure 3. This hierarchy details what are to be compared pair-wisely.

For the constructs w.r.t. the total BIM adoption decision goal or the SAFs w.r.t. some construct, results from the pairwise comparisons are recorded in a 'pairwise comparison matrix'. Each element in the matrix is recorded as a level revealing the relative importance of a criterion (i.e., a construct or a SAF), C_x, against another criterion, C_y. This is a quantitative measure because the evaluation values in the matrix state the following facts (in the DM's mind): C_x is equal strong (1:1), weakly strong (3:1), strong (5:1), very strong (7:1), and absolutely strong (9:1) than C_y, so the corresponding measured values are 1, 3, 5, 7 and 9, whilst 1, 1/3, 1/5, 1/7 and 1/9 are recorded for the cases vice versa.

The survey work of this study obtain several pairwise comparison matrices in this manner, as the questionnaires that were designed based on the decision hierarchy and were answered the BIM expert had provided data to fill up these matrices. During the survey, the interviewed expert DM specified the relative importance of each pair of two criteria in the questionnaire, and such information became the data source to compose (fill in) each pairwise comparison matrix.

To validate the collected source data, Expert Choice (i.e., a decision analysis software) was used to receive the input, to compose the decision matrix, to validate the answers in terms of consistency ratio (C.R.) and as to calculate the weights of the constructs or the SAFs.

In the consistency analysis, if the C.R. value of the questionnaire was greater than 0.2, the DM was asked to fill the questionnaire once again until the C.R. of the questionnaire yielded a value less than the standard of the inconsistency threshold (C.R. value < 0.2). As in other engineering fields, Zhuang et al. [8], Schmidt et al. [9] and other scholars believe that an AHP questionnaire is acceptable when the C.R. value of a pairwise comparison matrix it infers is less than 0.2.

In this study, actually, the DM was interviewed twice (i.e., the DM was re-interviewed only once as to meet the above data validation requirement). So finally, the relative weight of each construct (w.r.t. the total BIM adoption decision goal) and the relative weight of each SAF (w.r.t. some construct) was obtained and sorted. Based on the information, eventually, the absolute weights of all SAFs were calculated and prioritised. Such knowledge is both critical and significant for a DM to understand the priority over the evaluation criteria of BIM system adoption, as to mitigate the risk of decision-making mistakes.

A mathematical review to AHP (including the data validation process based on C.R. and the determination of the weights) is provided in the subsequent subsection. Readers who are familiar with this method can skip this subsection.

3.1 A Review to AHP's Mathematical Process

In this subsection, the data validation method used based on the pairwise comparison matrix data and the determination of the SAF weights in AHP are introduced. First, the survey process of AHP compared n SAFs pair-wisely. Each of the results is the relative importance between the i-th and j-th SAFs, which can be connoted as: m_{ij}. The matrix $M = \left(m_{ij}\right)$ is the comparison matrix obtained by comparing the n SAFs pair-wisely.

By calculating the eigenvector and finding the maximum eigenvalue $\lambda_{\max}$, they are then used to evaluate whether the respondents' judgments on the pairwise comparison matrix are inconsistent, according to the following equations:

$$v_i = (\sum_{j=1}^{n} w_j m_{ij})/w_i, \text{ for all } i = 1, 2, \ldots, n \quad (1\text{-}1)$$

$$\lambda_{\max} = \frac{\sum_{i=1}^{n} v_i}{n} \quad (1\text{-}2)$$

$$C.I. = \frac{\lambda_{\max} - n}{n} \quad (2)$$

$$C.R. = \frac{C.I.}{\text{R.I.}} \quad (3)$$

where n is the number of criteria for the given decision context; the weight for the i-th criterion, w_i, has been assessed according to a known method (e.g., the following Eqs. (4)-(7)); v_i is the temporary eigenvector element used for calculating the eigenvalue, $\lambda_{\max}$; *C.I.* is the consistency index for M as can be evaluated based on $\lambda_{\max}$ and n; C.R. is the final result which is the consistency ratio that is used to assess the consistency in the pairwise relationships as revealed in M; however, the necessary denominator of Eq. (3), which is the R.I. value, is a value determined (and can be looked up in Table 1) by the dimension of square matrix, which is M; the matrix elements, m_{ij}, are the source data in matrix M, as defined previously.

Table 1. The random index (R.I.)

n	1	2	3	4	5	6	7	8
R.I.	0	0	0.58	0.9	1.12	1.24	1.32	1.41

As can be seen, when the respondent's judgment in the pairwise comparison matrix is not consistent, the values

in *M* will produce a larger value of λ_{max}. Then, the consistency index (C.I.) grows larger. So when C.I. is further divided R.I., which is the Random Index (R.I.) that can be looked up in the Table 1, the C.R. ratio will exceed the threshold that is set in the decision context (e.g., 0.2 in our study). The entire consistency analysis process presented here, which validates the source data for AHP, was proposed and proved by Saaty [7].

Second, the criterion weight vector (CWV) of the factors can be obtained, so it is possible to judge the relative importance of them by prioritizing them [8] [3]. Following from the matrix $M=\left(m_{ij}\right)$, which is the source pairwise comparison matrix that has passed the above consistency check, *M* is expanded as the following:

$$M = \begin{bmatrix} m_{11}=1 & \cdots & m_{1n} \\ \vdots & \ddots & \vdots \\ m_{n1} & \cdots & m_{nn}=1 \end{bmatrix} \quad (4)$$

The column-sums vector, *V*, of the matrix *M* is thus:

$$V = [\sum_{i=1}^{n} m_{i1} \quad \sum_{i=1}^{n} m_{i2} \cdots \sum_{i=1}^{n} m_{in}] \quad (5)$$

Dividing the elements in matrix *M* by the column-sums vector, *V*, another square matrix, *M'*, is obtained, as:

$$M' = \begin{bmatrix} m'_{11}=1/\sum_{i=1}^{n} m_{i1} & \cdots & m'_{1n}=m_{1n}/\sum_{i=1}^{n} m_{in} \\ \vdots & \ddots & \vdots \\ m'_{n1}=m_{n1}/\sum_{i=1}^{n} m_{i1} & \cdots & m'_{nn}=m_{nn}/\sum_{i=1}^{n} m_{in} \end{bmatrix} \quad (6)$$

So the row-sums vector of *M* is exactly the CWV:

$$CWV = \left[\sum_{j=1}^{n} m'_{1j} \quad \sum_{j=2}^{n} m'_{2j} \cdots \sum_{j=n}^{n} m'_{nj}\right]^{T} \quad (7)$$

The main results that are further analysed in the next section are assessed using the abovementioned mathematical process.

4 Results and Discussion

As discussed in Section 3, the questionnaire that was filled out by the DM in the second interview round passed the consistency check (i.e., the CR values of the five pairwise comparison matrices, 0.0975, 0.1805, 0.0884,0.186 and 0.0574, were all less than 0.2). In the first round of interview, because the number of SAFs w.r.t. each construct was close to 7 (i.e., human's psychological limit to make pairwise comparisons over items [10]), the difficulty of filling in the questionnaire increased and led to logical errors by the interviewees.

As shown in the Figure 4, we conclude that the DM believed that a construction firm needs to address the matters about the execution of a BIM project (43.19%) and the organisational factors (38.01%) that may influence the deployment of BIM technologies. The various aspects about the system integration (SI) matters of BIM and the BIM functions that are used can be placed in a secondary position (i.e., 14.68% and 4.13%, respectively).

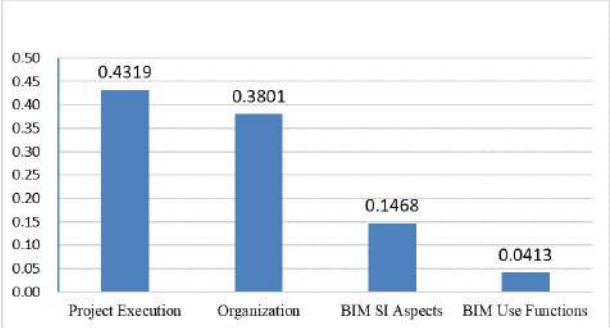

Figure 4. Relative importance of the constructs for BIM system/technologies adoption decision in a construction firm

As shown in Figure 5 to Figure 8, the SAFs for the BIM adoption decision w.r.t. the four constructs are visualised, while their ranks are also sorted according to their relative importance.

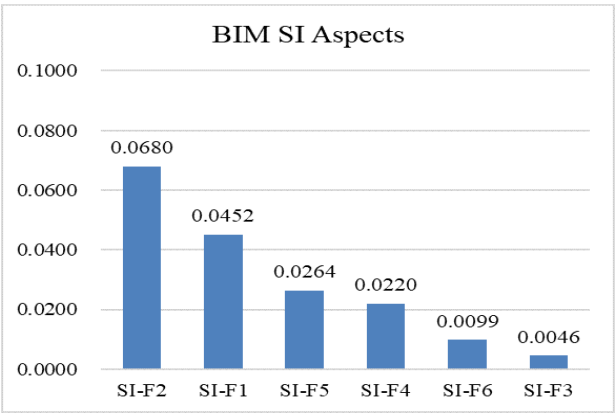

Figure 5. The weights of SAFs w.r.t the 'BIM SI' construct

The top three SAFs w.r.t the constructs are easily observed in these figures. These SAFs are not only the major factors which should be put into consideration when a construct is solely addressed during the introduction of BIM, but also the topics worthy of note in this study.

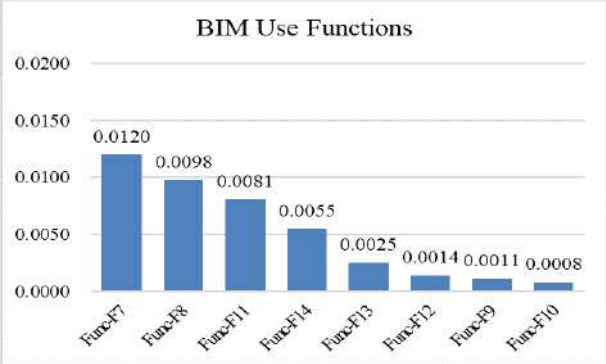

Figure 6. The weights of SAFs w.r.t. the 'BIM use functions' construct

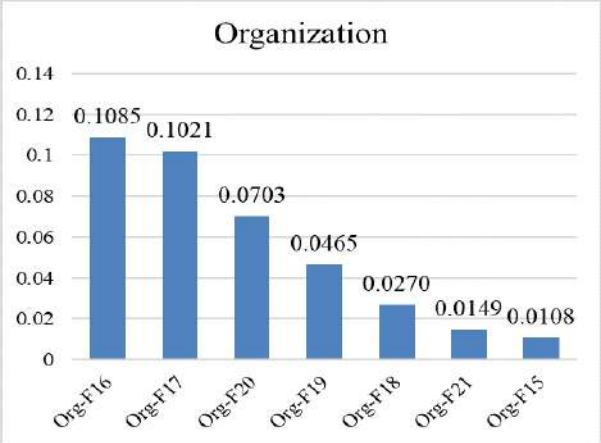

Figure 7. The weights of SAFs w.r.t. the 'organization' construct

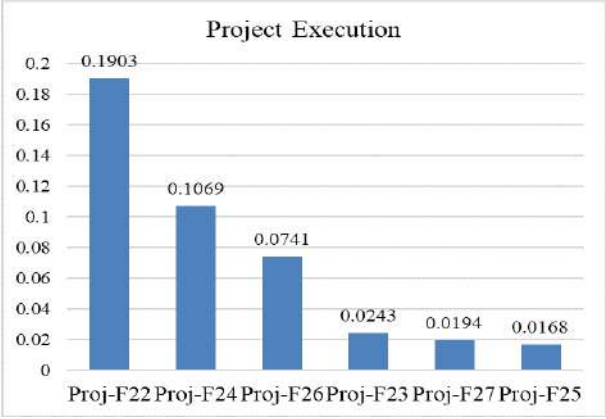

Figure 8. The weights of SAFs w.r.t. the 'project execution' construct

For example, according to the analysis, it is clearly understood that the DM believes that the three most important SAFs w.r.t. the 'BIM SI aspects' construct are the 'efficiency of BIM technology', 'software functions', and 'maintenance and upgrade costs'.

Since there are still other interesting observations which can be made for the 'top three SAFs' w.r.t. other constructs in these figures, relevant discussions are omitted here because of the space reason.

Another significant observation can also be made based on the absolute weights, rather than on the relative weights. For this sake, all of the 27 SAFs that have been confirmed using the Delphi Method are sorted and ranked all together in Table 2. Figure 9 provides a visualisation for Table 2.

It can thus be found that the top five SAFs with the highest absolute weight values are 'Proj-F22', 'Org-F16', 'Proj-F24', 'Org-F17' and 'Proj-F26' (i.e, definition of BIM project objectives and applications, supports from the top management, specification of BIM project milestones and deliverables, whether the design creates and fits business value and purpose, and finally, the BIM project management matters).

Table 2. Weight rankings for all factors

Ranking	SAFs	Weights
1	Proj-F22	0.1903
2	Org-F16	0.1085
3	Proj-F24	0.1069
4	Org-F17	0.1021
5	Proj-F26	0.0741
6	Org-F20	0.0703
7	SI-F4	0.0499
8	SI-F5	0.0465
9	SI-F2	0.0387
10	Org-F18	0.0270
11	Proj-F23	0.0243
12	SI-F1	0.0236
13	Proj-F27	0.0194
14	SI-F3	0.0186
15	Proj-F24	0.0168
16	Org-F21	0.0149
17	Func-F7	0.0120
18	SI-F5	0.0118
19	Org-F15	0.0108
20	Func-F8	0.0098
21	Func-F11	0.0081
22	Func-F14	0.0055
23	SI-F6	0.0041
24	Func-F13	0.0025
25	Func-F12	0.0014
26	Func-F9	0.0011
27	Func-F10	0.0008
Total		1.0000

In other words, the DM believes that these five SAFs play a role of impact when a decision for BIM adoption is made by the construction firms. This is the key knowledge that is discovered by this study: construction

firms should give priority to these five SAFs. When introducing a BIM system or relevant BIM technologies. The results as mentioned above are also verified and confirmed by another expert in the construction industry (than the interviewed DM during AHP investigation or the experts selected for confirming the SAFs set and the decision hierarchy during the use of the Delphi method). In this sense, in this study, works for data validation have been performed not only for the dataset itself (i.e., the C.R.-based consistency analysis), but also for the various empirical aspects from the results.

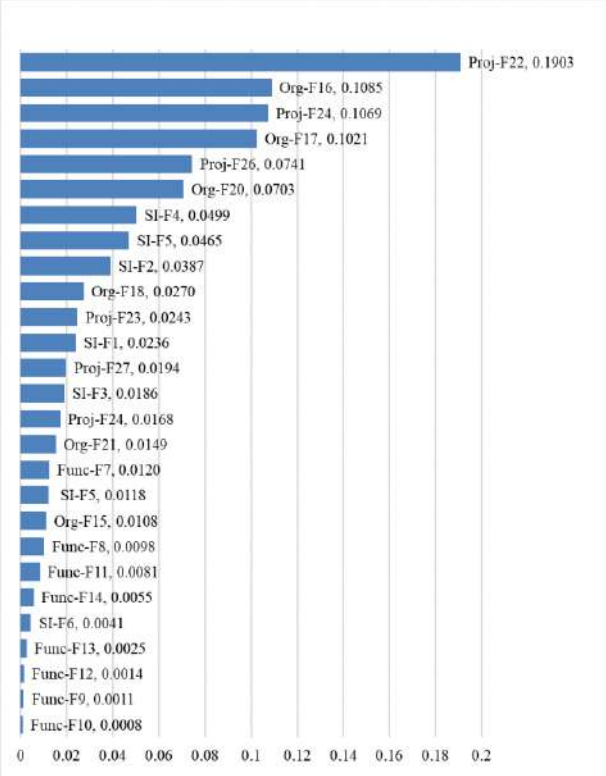

Figure 9. Prioritising the absolute weights of all SAFs

5 Conclusion

This study identified the key SAFs for the adoption of relevant BIM system and technologies and examined the relative importance of them. The initial set of SAFs deemed as important by the authors through literature study is further modified and confirmed by the expert in the construction domain of AEC, using the Delphi Method. In other words, the obtained set of the 27 SAFs consists of the major factors that are to be considered for the adoption of BIM. Given the thoroughness of the original literature review process (see also the reviewed articles [13-25]), this knowledge (i.e., the identified and confirmed set of SAFs) is important for construction firms whenever one such BIM-adoption decision is to be made.

In order to conduct the research for the influence of each SAF on the BIM-adoption decision systematically, a decision hierarchy which introduces an additional layer of constructs and organises the SAFs in a suitable manner is developed and further confirmed by also using the Delphi Method. Such knowledge (i.e., the decision hierarchy) is also a significant sub-product of this study.

The importance of the constructs and the SAFs is then assessed using AHP. The relative importance of each construct w.r.t. the total BIM-adoption decision goal is assessed and ranked. The relative importance of each SAF w.r.t. the construct on which it is mounted is also assessed and ranked. The absolute weight of each SAF is further calculated, and all absolute weights are ranked so that the relation (i.e., the absolute priority) among these SAFs is observed. These have formed another important set of knowledge for BIM-adoption in that the weights are quantitatively assessed. Since preference relations among the SAFs have been easily ordered, some interesting observations are made and the practical implications for the adoption of BIM or the decision to adopt BIM are drawn. For example, from the analysis of this study it is understood that the DM believes the most critical constructs for BIM adoption/introduction include the project execution factors and the organisational factors, which are closely related to the support from the top management. For another example, through the final absolute ranking analysis, it is understood that among the 27 SAFs, the (top five) most influential factors that may affect the expected success of BIM adoption/deployment are the objective of the BIM project, BIM project milestones, BIM project management, and whether BIM can create enterprise value and competitive advantage are important SAFs. These factors form a set of empirical knowledge which can serve as a reference for construction firms in deciding whether to deploy BIM technology or how to implement a BIM project more successfully.

Despite the fact that the results from this study are subject to the interviewee (i.e., a DM of a construction firm in Taiwan) during AHP investigations, the research framework can be generalised to surveys in other AEC domains (e.g., architecture and engineering) and/or in other countries. Not only the survey works themselves but also the possible comparisons that can be made based on the future available data across the nations would draw further more fruitful yet more insightful implications for

the whole civil engineering industry.

Moreover, despite the fact that the study has successfully identified a set of SAFs which a construction firm may think important for the 'successful deployment' of BIM, in the opposite sense, these results can also be used to understand the reasons for why there is 'reluctance' for BIM adoption, which is a fact that is often observed in the industry (to the authors' knowledge). This is also another future knowledge discovery topic worth of exploration.

Finally, given the confident results in this study, more in-depth future researches can also be expected. For example, the number of interviewees may be increased so the knowledge can be explored on a group basis, while the group/subgroup analytical methods can be introduced [2] [3], as the group-based mind-mining process [11] is a focused cognitive topic in the recent development of data-driven decision-making (DDM, or D^3M) [12]. In this sense, this study is a pilot work for subsequent studies which pertain to the decision of BIM system adoption.

Abstract –

LiDAR (Light Detection and Ranging) emerges as a mapping technology that provides fast, accurate, and reliable data with geometric representation of construction facilities. The technology has received high recognition especially since the importance of digital transformation in construction projects has been emphasized. However, the current state of 3D technologies including LiDAR encounters difficulty in recognizing and extracting accurate information on the as-built status of the buildings and construction sites. As a preliminary study for the development of a 3D architectural geometric representation of building and environment, this paper proposes a 3D modeling approach based on point cloud data obtained by LiDAR technology. This paper suggests a novel method for data acquisition on as-built status of construction sites and buildings during construction-operation phases. Furthermore, a field test has been performed for visualizing and modeling of the indoors of a residential house. The results of this paper are expected to inaugurate adaptation of LiDAR technology during the as-built process, and further implementation of digital technology after construction phase in construction projects.

Keywords –

LiDAR; 3D modeling; building construction; digital transformation; point cloud data

1 Introduction

The construction industry is no exception from the changes derived by the fourth industrial revolution [1, 2]. Despite the innate conservative responses of the construction industry to rapid changes, the importance of adopting digital transformation throughout the entire cycle of a construction project has long been emphasized [3]. In particular, the recent trends of applying BIM (Building Information Modeling) and AR/VR (Augmented/ Virtual Reality) technologies have triggered various efforts to revolutionize the productivity and efficiency of construction projects [4].

Meanwhile, several concerns have arose pointing out that the digital technology of the construction industry is mainly applied to the design stage [5, 6]. The main reason is that there exists technical limitations in recognizing multiple objects as separate entities in the interior buildings and external sites during construction and operation phases [7]. Thus, the current state of technologies encounters difficulty in recognizing and extracting accurate information on the as-built status of the facility and sites [8]. As the acquisition of as-built information of buildings is operated manually, digital gaps are occurring during the design phase and construction-operation phase [9]. In order to minimize the processing time of data handling and translation error of as-built data, it is necessary to upgrade the current state of digital technology adopted after the construction phase.

Therefore, as a preliminary study, this paper proposes a conceptual framework for the development of a three-dimensional architectural geometric representation of building construction after the design phase. The final and eventual output of the approach proposed in this study is an integrated platform of buildings and sites, of which the information on the exterior is acquired by using UAV (Unmanned Aerial Vehicle) and the interior by using LiDAR (Light Detection and Ranging). Considering the research process for deriving the final output, this paper focuses on suggesting a novel approach for data acquisition and processing of as-built status of the building using LiDAR technology.

What follows is an extensive literature review on the current state of related technologies, introduction on conceptual framework for 3D modeling based on the point cloud data obtained by LiDAR, applicability of the proposed method, and discussions.

2 Literature Review

There is no denying on the fact that digitalization in the construction industry has erupted a revolution in productivity of construction activities [10]. According to a survey, 93% of the construction industry players have

agreed that digitalization will affect every process [10, 11]. Thus, there is no lack of studies on exploration of digital technologies for application in construction projects.

2.1 LiDAR in construction phase

Regarding the usage of LiDAR as 3D laser scanner that transmits optical laser light in pulses delivers accurate real-time 3D data, most research has primarily focused on acquiring geo-spatial information [12, 13, 14]. High-precision numerical maps of forest areas and steeply sloping roads were created based on the data acquired by LiDAR, and the displacement of the slopes was determined based on numerical maps [14]. A method to automatically extract the 2D outline of a building by merging numerical aerial photographs and LIDAR data has been developed. LiDAR technology is also adopted for semi-automatically construction 2D and 3D indoor GIS maps based on point cloud data [15].

Most, if not all of those studies have focused on extracting the structure boundary of a building or roads while excluding non-structure or any spherical and curves [16, 17]. Even though few studies have attempted to apply LiDAR and point cloud technology in the construction industry, barely any research has suggested an approach for acquiring both indoor and outdoor 3D modeling information of a building. An algorithm for independent recognition and data acquisition of multiple objects with free forms – with lines, spheres, and curves – needs to be developed in order to visualize a full indoor 3D model of a building. Insofar, however, algorithms such as Douglas Peucker have been utilized mostly for extraction of boundary lines [18]. There has been hesitant implementation of digital technologies on building sites or built facilities, especially on the interior of a space with multiple objects to be recognized. This insinuates that the construction industry needs to catch up even on the building interior and sites.

2.2 3D modeling in building construction

The potential of integrating LiDAR with Building Information Modeling (BIM) for 3D modeling has been highlighted in few studies. A framework on the level of details on modeling of a building in BIM regenerated through reverse engineering has been proposed [19]. Furthermore, a semi-automatic three-dimensional modeling has been performed by dividing point cloud data into grids and extracting outlines [20]. Nevertheless, application of BIM is recognized as 'digital planning', insinuating that the technology is first utilized during pre-design and design phases. The data acquired during the two phases does not flow easily to construction and operation phases.

Considering the application of LiDAR and point cloud technology in construction projects, few research has aimed to promote reverse highly effective and efficient reverse engineering in construction industry [21, 22].

Reverse engineering, as the process of recreating the current state of information of a part without detailed information (drawings, bill of materials, required parts specification, engineering data), is mostly applied for detection and comparison between a CAD/BIM model created during pre-construction phase and as-built model created during and after construction phase [23]. Creation of an as-built model follows the process depicted on Figure 1.

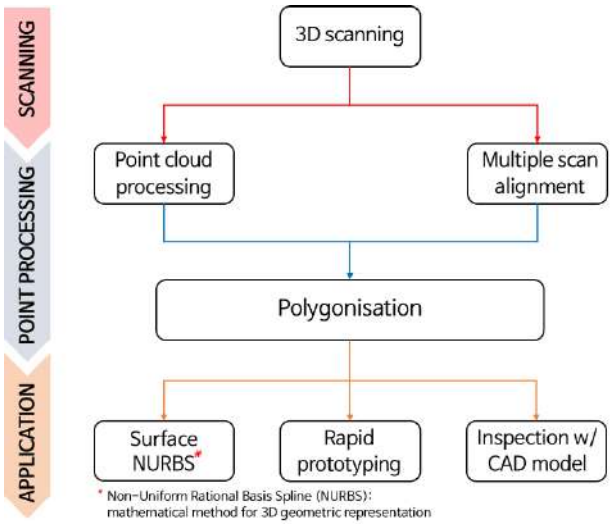

Figure 1. Process of data acquisition by LiDAR & application for reverse engineering

A three-dimensional scanning operation is performed, and then the point cloud data acquired through scanning is processed. In the case of scanning multiple targets, the merging operation of the data proceeds. After the merging work is finished, the polygonised work is applied for surface model creation, inspection with CAD model, and rapid prototyping. Throughout this process, the key element of successfully recognizing each of the multiple objects detected on the scene of scanning is developing a visualization algorithm. However, three-dimensional visualization algorithms related to construction industry are recognized as simple tools for data processing of scanning method, and the scope of application is mostly limited to earthwork construction. Most of the 3D visualization algorithms are optimized for other industries rather than the construction industry. To acquire accurate data and information on multiple objects, including structures and movable attachments, a new processing technique involving algorithms of segmenting and outlining the point cloud data are required.

3 Conceptual framework of 3D modeling approach based on LiDAR technology

As previously stated, an approach that registers, analyzes, and creates 3D models based on point cloud data delivers a reasonable source of digitalized information. To date, few studies have attempted to apply LiDAR and point cloud technology in the construction industry, but barely any research has suggested an exquisite method for acquiring 3D model of building interior with detailed information on the structure and non-structures. The current state of algorithm for visualizing data acquired as point clouds is processed for registration and surface creation. The surfaces and boundaries created by alignment of point clouds are extracted as structures of a building or infrastructure. However, a visualization algorithm that can register multiple objects independently from each other and define both the structures as well as non-structures and movable attachments is crucial for 3D modeling of an interior.

The conceptual framework of a 3D modeling approach created by point cloud data acquired by LiDAR is depicted on Figure 2.

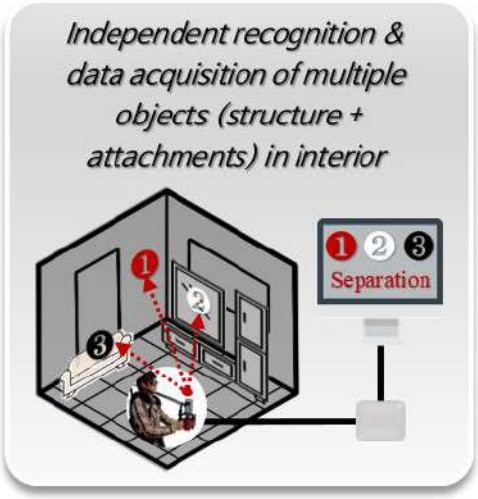

Figure 2. Conceptual approach for data acquisition

The process for ultimate modeling of building interiors based on point cloud data is defined as the following (Figure 3):

1. Data acquisition through LiDAR: 3D scanning of the interior
2. Data processing: Registration of point cloud data & segmentation by RANSAC(Random & Sampling Consensus) method, outline tracing by removing outliers & noise, surface creation based on region growing method, and input of algorithm for detection & separation of movable attachments from structures
3. Data integration & Application: Visualize the results by integrating with image processing technology, and create 3D model

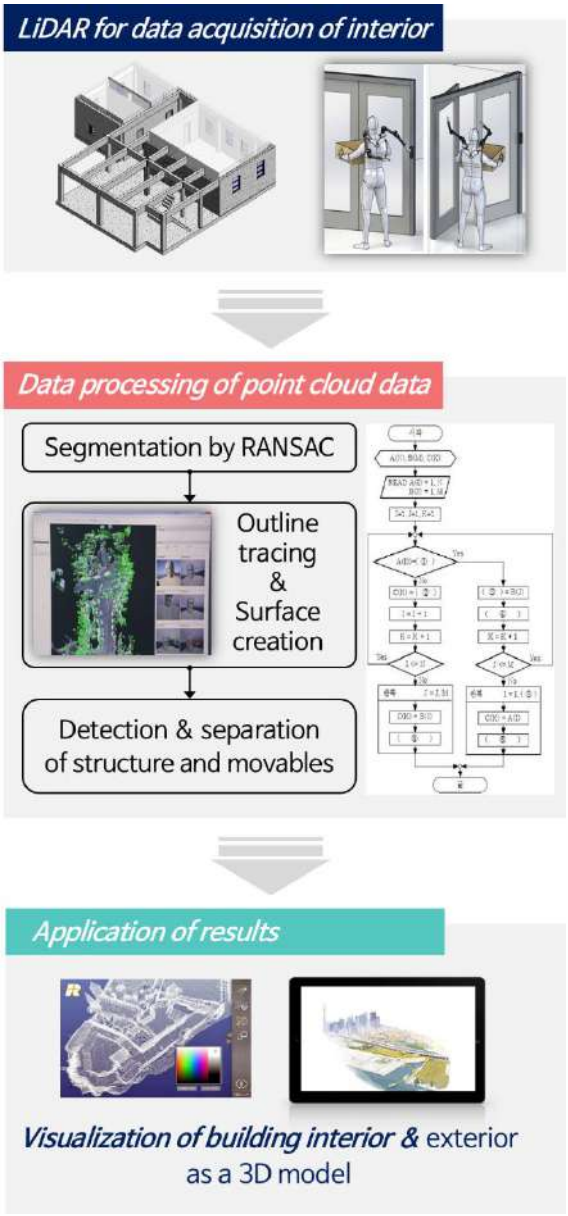

Figure 3. Process for 3D modeling based on point cloud data retrieved by LiDAR

The algorithm for segmenting the point cloud data and visualize them as three-dimensional is primarily based on RANSAC method. RANSAC is an iterative method for estimating parameters of a target model from a set of data. RANSAC is used to identify points that belong to identical planar planes from a cloud of data. Unlike the least square method, which uses all the data to

estimate the parameters of the model, RANSAC includes the process of excluding the outliers based on the hypothesis and test evaluations. The outliers are removed based on SOR (Statistical Outlier Removal) algorithm.

A sample (P) with a predetermined certain range is acquired from the entire point cloud data, and then a minimum number of data (S) is selected for estimating the parameter (θ). The model (M) is determined by the function (f_m) and parameter (θ). Considering the two equations (Eq. 1, 2) for segregating the inliers from a certain threshold (δ), the Consensus Set (CS) with outliers excluded is defined as Eq. 3.

$$P = \{d \in R^2 \mid d_1, \dots, d_n\} \quad (1)$$

$$M = \{s_n \in P \mid f_m(s_n; \theta) = 0\} \quad (2)$$

$$S(\theta) = \{d \in D \mid e(d, M) \leq \delta \quad (3)$$

The process of segmentation for exclusion of outliers from inliers is depicted on Figure 4. Among a total of 50 points (P), three points (S) are randomly selected and aligned on a surface plane. Blue points are segregated as inliers within the threshold, while green points are considered as outliers and thus eliminated.

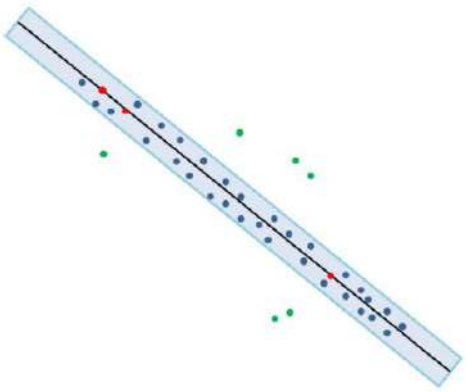

Figure 4. Process of eliminating outliers from RANSAC [20]

Point cloud data is projected under a refinement grid to verify validity for further outline tracing. During the process for outline tracing, the point cloud data is converted into a binary image using a grid as in the refinement process, and the outline is further extracted using the vectorization technique. The size of the refinement grid can be set differently according to the characteristics of the indoor environment. A cluster of planes are constructed, which results in the formulation of boundaries within 2D and 3D drawings.

When the outline extraction process ends, the binary image is inverted to extract the outline of an empty area in a segment area for visualization of the surface. At this time, the outline extraction is performed only for an empty space having an area larger than a predetermined size, and the extracted outlines are recorded in a file in the form of VRML (Virtual Reality Modeling Language). Afterwards, the point cloud data is visualized based on ICP (Iterative Closest Point) algorithm, resulting in the independent recognition of boundary structure and non-structures (movable attachments such as furniture in the interior of a building space). After the data processing phase is completed, a 3D model that provides a comprehensive information on the interior of a building and its exterior.

4 Applicability test: Results & Analysis

A field test is performed to verify the validity of the approach proposed in this study. The test was conducted mainly to secure the reliability of data acquired and processed by LiDAR technology. The interior and exterior space of a deteriorated house with all furniture properly located at its place were scanned to construct an as-built model, of which the accuracy was verified by comparing with previously completed 2D drawings. The overview of the applicability test is depicted on Figure 5.

Location:	Donae-dong, Duckyang-gu, Goyang-si, Gyeonggi-do, Korea
Area of Measurement	Basement B1 (72.48 ㎡) 1st floor (133.68 ㎡) 2nd floor (66.06 ㎡)
Number of times scanned	4 times (2 interior, 1 interior + exterior, 1 exterior)
LiDAR used	Velodyne HDL-32E

Figure 5. Overview of applicability test

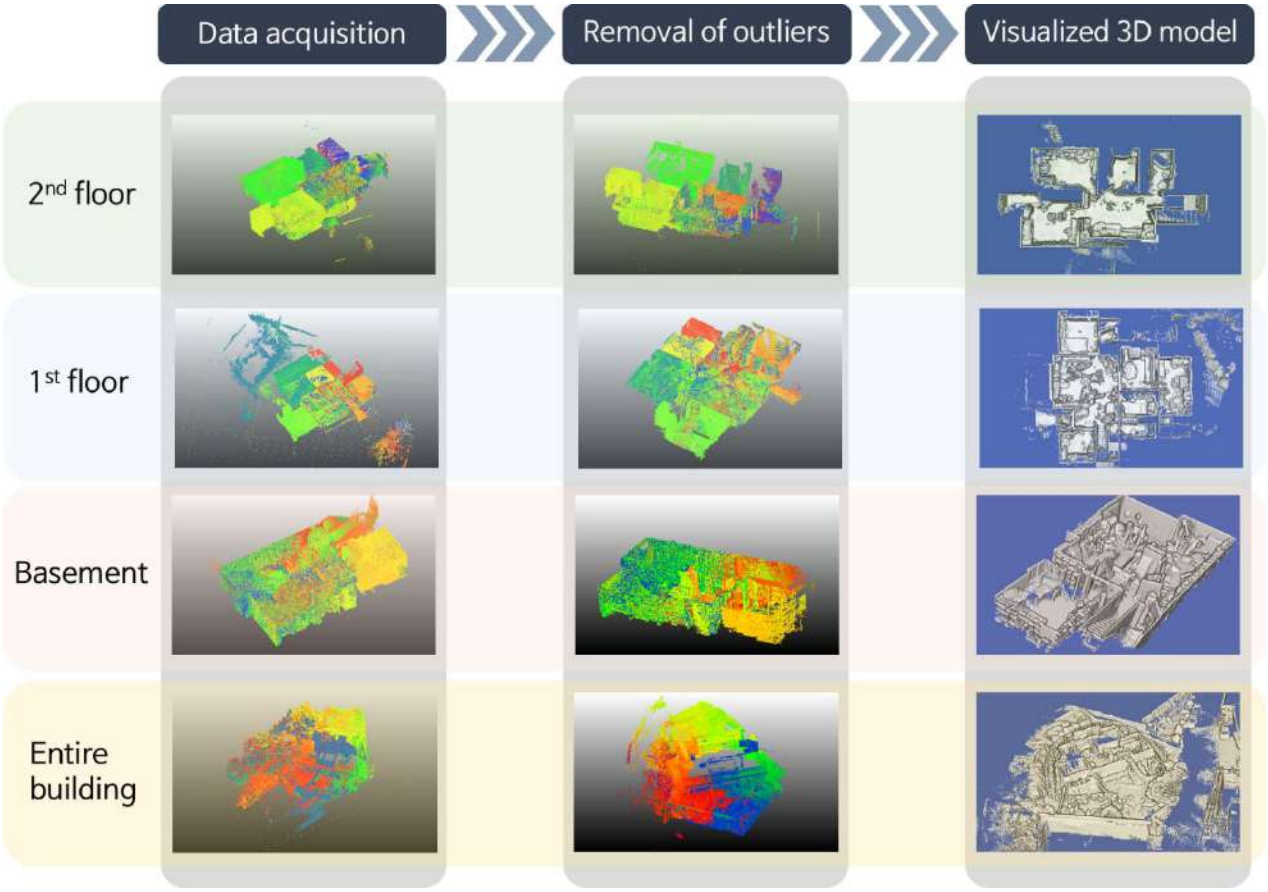

Figure 6. Results of data acquisition & processing, visualization as 3D model

The 3D scanner used for data acquisition is a backpack-type Velodyne HDL, a LiDAR scanner capable of scanning 700,000 points per second with the accuracy of 2 mm @ 200 m. The interior of the house was scanned twice; the interior was first measured from the basement to the second floor continuously at once, and then each floor was scanned separately at the second time. Also, after scanning the living room on ground floor, the scanner was moved continuously to the outside to measure the exterior. Finally, the exterior of the house, including woods, garage, and garden, was scanned. The LiDAR scanner was connected to a laptop, and thus all acquired data was accumulated on the software (Cloud Compare). Cloud Compare was used also as the software for data processing of point cloud data. As previously stated, SOR algorithm was applied within the Cloud Compare software to remove outliers, and then the processed data was visualized using ICP algorithm.

The results of acquired and processed data are depicted on Figures 6. Even though the software and applied algorithms automatically was suitable for processing the point cloud data for 3D model, some parts of the acquired data inevitable had to be modified manually. For instance, there were seven people total who conducted the field test. Five people, apart from the one who scanned the scene with the scanner while moving around and the other who held the laptop connected to the LiDAR, tried to be out of sight on the scene but were caught on some of the point clouds that were obtained after the scan. The inspectors and some of the furniture that was overlapped in some points of the scan had to be removed from the model. Additional measure are expected to be taken in case of 3D scanning.

Meanwhile, the result of data acquired on structure boundaries and non-structures is depicted on Figure 7.

As depicted on Figure 7, structure parts such as staircase, wall, and window opening are visible. All the movable items are visualized as 3D, but not easily recognizable in the current state of technology. In other words, the current 3D model simply visualizes the figures of detected object elements in three dimensions. Further studies are needed to improve precision of data processed for separating movable objects from the wall and floor of the interior. More in-depth studies are also expected to be performed for independent recognition of multiple objects.

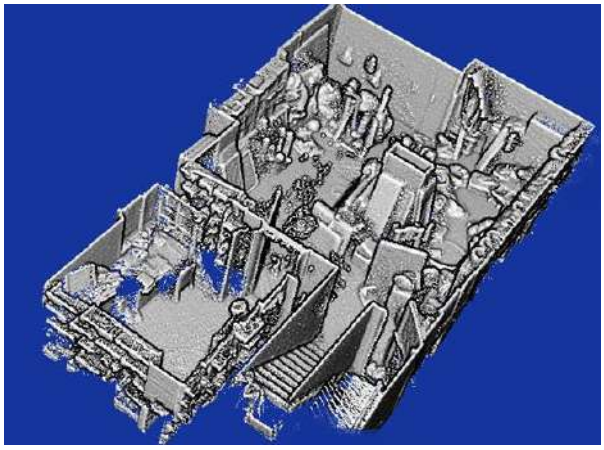

Figure 7. Scanned interior of basement

5 Conclusion

As-built data of buildings, both the exterior and interior, has been acquired manually by experts inspecting by hand using tools. However, the possibility of error arises in cases of field measurement on a manual basis, as well as the probability of safety accident occurrence. As a means to automate the data acquisition of as-built information and enhance productivity of previous work, this study proposed a novel approach for acquiring, translating, and applying as-built data retrieved under safe site conditions. The key issue of visualizing point cloud data collected by LiDAR in this study is related to the post-processing and removal of outliers for further integration with data retrieved by UAV. During this study, the outline of the building is derived through the horizontal layer division of point cloud dada based on the data acquired by LiDAR, all of which results in the creation of 3D drawings and models. In order to fully develop an automatic 3D visualization algorithm, it is necessary to consider the interference caused by the non-structure parts when setting the contour of the building. Nevertheless, the field test conducted in this study proved the possibility of adopting the novel approach in construction and operation phases.

The conceptual approach proposed in this study can provide an immediate 3D architectural geometric information visualization platform. Furthermore, the results of this study is expected to upgrade the current technology level by improving the speed and accuracy of as-built information of construction sites and buildings. Even though this paper does not address the application of UAV for measuring the exterior of buildings and the integration of retrieved data with those achieved from LiDAR, further study is expected to be conducted to visualize the conceptual framework addressed in this study.

Abstract –

Current forms used in the construction site are faced with problems such as casting quality, increased labor costs and longer construction period. To solve these problems, a new system form that reflects the opinions of people who actually use it in the construction site. In this study, a new system form design process using Quality Function Deployment (QFD) and TRIZ method was proposed. It is expected that it will be possible to make an improved system form by providing a solution that combines the needs of form users and the technical elements.

Keywords –

System form; Concrete structure; Quality function deployment (QFD); TRIZ;

1 Introduction

Currently, with the buildings becoming larger and taller, reinforced concrete (RC) structures, which are advantageous in terms of usability and economics, have been increasing. Formwork is one of the most important types of reinforced concrete structure construction, accounting for 30 to 40 percent of structural construction costs and 10 percent of overall construction costs [1].

However, the form commonly used in formwork was developed approximately 40 years ago. As building construction become larger, there have been limitations such as increase of material loss rate, increase of input labor force, increase of labor cost, and defective concrete surface [2]. Therefore, it is necessary to develop a new form to solve the problem of existing forms.

Quality function deployment (QFD) is a systematic design support technique that has been used to improve the construction system [3]. The QFD method has great advantages for users because it not only translates customer requirements into technical characteristics, but also prioritizes characteristics. However, the QFD technique is accompanied by contradictory problems, and systematic analysis is needed to solve them.

A theory of creative problem solving (TRIZ) was developed to propose innovative solutions with numerous tools that enable a targeted and systematic problem-solving method [4]. Mayda and Borklu implemented a method using TRIZ to identify innovative concepts, then using QFD to meet customer's needs [5]. Hajime Yamashina et al. [5] integrated the QFD and TRIZ to analyze the customer needs by calculating the most needed technical factors and the weight of the factors. Lim et al. [3] proposed a system form design process using QFD and TRIZ. However, this was a system form design process that was limited to the table form used in skyscraper.

Therefore, this study proposed a system form design process commonly used in the construction site. The proposed system form design process reflects the needs of the customers who use the form in the field and converts them into technical characteristics. In addition, priorities of technical characteristics were determined and reflected by considering the relationship between technical characteristics.

2 Literature review

2.1 Quality function deployment

QFD is a tool used to improve product quality. It has been used successfully in assisting product developers systematically incorporate customer requirements (CRs) into engineering characteristics (ECs) to plan and manage product and process development [7]. From the interrelationships between CRs and ECs and the correlations between ECs, the main task of product planning using QFD is to determine target values of ECs to achieve higher overall customer satisfaction[8]. The House of Quality (HOQ) supports defining the relationship between CRs and ECs through comparison and analysis of data. Because of these advantages, HOQ is regarded as a QFD core element technology that reflects customer needs [9]. This is shown in Fig 1.

2.2 TRIZ

TRIZ was proposed by the Russian researcher Altshuller (1984), who was using it to solve "creative" problems, which usually have the features of paradoxical and conflicting demands [8]. TRIZ helps find

contradictions and find solutions to overcome those contradictions. In Table 1, TRIZ analyzes and summarizes 39 engineering features through the contradiction matrix, and Table 2 shows 40 innovative principles corresponding to the contradiction matrix [10].

2.3 Integration of QFD and TRIZ

QFD is a good tool to convert CRs into ECs. However, it has its limits. Applying the contradiction matrix through TRIZ to solve these limitations and provide various optimal solutions. In this study, the relationship between the results of technical characteristics and the contradiction matrix of TRIZ was as shown in Fig 2. Among the technical features derived through HOQ, technical features with negative correlation were derived and converted to 39 standard features. Repetition of this mechanism gave a reasonable understanding of the contradiction of technical features and also provided a systematic solution.

2.4 A case study using QFD and TRIZ

Franica et al. applied QFD and TRIZ to 3D PrinterCAD to provide innovative design methods and results in improved manufacturing processes [11].

Donnici et al. completed the QFD analysis of the hover board and suggested the solution principle to realize the hover board as urban transportation through the TRIZ method. This study demonstrated that the integration of QFD and TRIZ provides an innovative solution to the problem that has not been solved [12].

3 Proposal of Improvement System form using QFD and TRIZ

3.1 Conversion of CRs into TCs utilizing QFD

3.1.1 CRs Importance Calculation

Two interviews were conducted to derive the CRs. To collect objective CRs, the interviewees were designated as two high-rise building project directors, four formwork company presidents, and six formwork experts. The final 15 CRS were derived from the two interviews, which were as summarized in Tables 4. In order to calculate CRs significance, The IPA survey was conducted on 15 field managers in five major construction companies in Korea and 28 field workers with more than 10 years' experience. Finally, 35 surveys were completed and returned. The weighted priority of the system form CRs was determined through the IPA survey, and the overall significance related to CRs and design was classified by item. The figures from the IPA survey were translated into 100 points, which made it possible to sequence CRs importance. The three most important sequences were CR1: Easy assembly and disassembly, CR2: Reduced noise during dismantlement or assembly and disassembly, CR13: Compatible with existing formwork units. The remaining importance shown in Table4. 14 TCs was derived from the same experts and correlated them with CRs as seen in Table 3.

Table 3. Relationship between TCs and required quality

No.	Technical characteristic (TC)	Related required quality
TC1	Shape of outer frame	CR1, CR4, CR6, CR13, CR14, CR15
TC2	Weight	CR4, CR6
TC3	Size	CR1, CR4, CR13, CR14, CR15
TC4	Number of repeat uses	CR7, CR8, CR10
TC5	Shape of the inner structure	CR5, CR9, CR10
TC6	Assembly type	CR1, CR9, CR10
TC7	Installation method	CR1, CR2, CR4
TC8	Dismantlement method	CR1, CR2, CR4
TC9	Impact resistance	CR7, CR8, CR9, CR10
TC10	Allowable load	CR5, CR9
TC11	Material of panel	CR2. CR3, CR7, CR8, CR10, CR11
TC12	Material of frame	CR7, CR8, CR9, CR10
TC13	Lifting method	CR4
TC14	Structure of panel frame	CR2, CR10

3.1.2 Correlation Analysis between CRs and TCs

In this section, a correlation analysis was conducted between CRs and TCs previously classified. Correlation analysis was performed with the help of the same form developers. The degree of correlation between CRs and TCs was set to 1-low, 3-normal, 9-high. To give priority to the technical characteristics reflecting
the required quality, the absolute weight was first obtained. Absolute weight is the sum of the multiplying values of the importance index and the correlation coefficient as shown in equation (1). Equation (2) divided the absolute weight for each technical characteristic into the sum of the total absolute weight by obtaining the relative weight. The priority of each technical characteristic was judged through these two equations as shown quantitatively in Table 5.

$$\text{Absolute weight} = \sum \text{Importance Index} \times \text{Correlation coefficient} \quad (1)$$

$$\text{Relative weight} = \frac{\text{Absolute weight of technical charateristic}}{\sum \text{Absolute weights of technical characteristics}} \quad (2)$$

3.2 Required TCs Contradictions

The important required technical characteristics categorized above are contradictory to each other. To solve these contradictions, the technical characteristics that reflect the requirements were summarized as follows:

1. If the external factors (TC1, TC3) are changed to simplify the assembly and disassembly, contradictions arise in compatibility (TC6, TC7) with existing forms.

Table 4. CRs-Importance Index

No.	Category	Customer Requirement	Impor-tance Index	Rank
CR1	Constructability	Easy assembly and disassembly (it fits and fastens together with reasonable ease)	91.3	1
CR2		Reduced noise during dismantlement or assembly and disassembly	87.4	2
CR3		Easy removal from concrete	76.2	8
CR4		Efficient lifting and carrying	79.6	6
CR5	Safety	Not distorted or deflected during concrete placing	56.3	15
CR6		Reduced safety accident (struck by object)	57.7	13
CR7	Durability	High repeat use with constant module size	83.2	4
CR8		Recyclable material usage	61.4	12
CR9		Durable against falling and external impacts	64.2	10
CR10		Easy maintenance and cleaning	69.9	9
CR11	Reliability	Low thermal conductivity (low temperature sensitivity)	59.1	14
CR12		High concrete surface quality	78.8	7
CR13	Conformance	Compatible (size, height, fixing method) with existing formwork units (e.g., Euro form, Aluminum form, Skydeck)	86.7	3
CR14		Hybrid (concurrent usage) usage for vertical (wall and column) and horizontal (slab) forms	63.1	11
CR15		Provide various module sizes to minimize on-site work (filler, conventional formwork)	81.9	5

2. Changes to the base metal of the material to reduce noise (TC11, TC12) contradict the form performance (TC2, TC9, TC10).
3. Reducing the weight (TC2) for efficient operation and movement causes a contradiction in form performance (TC9, TC10).
4. Changing the fastening method to the bolt assembly (TC6) for the maintenance of the form contradict the form performance (TC9, TC10).
5. Changing the material (TC11) of the panel to improve the quality of the concrete casting contradicts the reuse rate (TC4).

3.3 Proposing a new System form using TRIZ

3.3.1 Conversion to TRIZ features

In order to present ideas using TRIZ, it was necessary to relate the technical contradictions derived above to standard features. Therefore, in this section technical contradictions that deteriorated were matched during the improvement process and standard features as shown in Table 6.

3.3.2 Apply contradiction matrix of TRIZ features

Apply contradiction matrix of TRIZ features. First, apply the contradictory standard features to the contradiction matrix and extract the intersecting items in Table 7. Next it was proposed in Table 8 with the general

Table 5. A calculation matrix for absolute & relative weights between TCs and CRs

CRs \ TCs		TC1	TC2	TC3	TC4	TC5	TC6	TC7	TC8	TC9	TC 10	TC 11	TC 12	TC 13	TC 14

5	TC11	27. Reliability	TC4	25. Loss of time

solutions and the improved approach to the contradictory standard feature corresponding to the intersection. Our study improved the general concrete form through the principle of contradiction matrix of TRIZ.

3.3.3 Proposal of improvement form

This study associated contradictions in the technical characteristics with standard features and applied them to the contradiction matrix to provide a systematic and logical solution to form improvement. As a solution, first, the problem of compatibility and size was solved with existing form by changing integrated form into assembly type. Second, the external frame, the inner frame, and the panel were separated to satisfy the requirements of each part, and the weight was reduced, thereby improving the working environment and improving the productivity. Third, with rubber material on the corners, the problem of damage due to impact was solved. Fourth, a very thin film was applied to the panel to facilitate detachment from concrete without using form oil. Finally, forms satisfying segmentation, composite materials, prior compensation, and flexible membranes/thin films were as shown in Table 9.

Table 7. Application of the principle of Invention of TRIZ

	2	13	14	32	25
6	–	–	–	40, 16	–
27	–	–	–	–	10, 30, 4
31	35, 22, 1, 39	–	–	–	–
34	–	2, 35	–	–	–
39	–	–	29, 28, 10, 18	–	–

Table 8. Ideal development based on general solutions of TRIZ

Contradiction	Invention principle	General solutions	Idea development
C1	1. Segmentation	Divide an object into independent parts Make an object sectional, easy to assemble/disassemble Increase the degree of fragmentation of segmentation	The form's frame could be divided into three main parts (inner, outer, and panel) to reduce the weight of forms, avoid usage of form oil, and also for ease of maintenance
C2	40. Composite materials	Change from uniform to composite (multiple) materials	Plastic-based noise-reducing materials(joint apparatus) are used
C3	40. Composite materials	Change from uniform to composite (multiple) materials	Lightweight composite material (aluminum and magnesium composite) frames could be used
C4	11. Prior compensation	Prepare emergency means beforehand to compensate for the relatively low reliability of an object	Rubber-based impact-reducing materials are used
C5	30. Flexible membranes/thin films	Use flexible shells and thin films instead of 3D structures Isolate the object from its external environment using flexible membranes	Very thin films are applied to avoid attachment of concrete

Table 9. Improvement solution according to the ideas

Idea	Improvement solution	
1. Segmentation	1	
40. Composite materials	2	40. Composite materials	3	11. Prior compensation	4	
30. Flexible membranes/thin films	5	
4 Conclusion

This study combined QFD and TRIZ to prioritize the technologies required by construction site system form users and to derive contradictions between their correlation and technical characteristics. It also used TRIZ contradictory metrics to provide solutions to those contradictions. The study proposed a systematic and logical system form design process that reflects the requirements of form users. The study is expected to solve the problem of compatibility with existing form by presenting the assembled form based on this system form design process. In addition, to solve the weight problem of existing form by separating external frame and panel and reducing weight. Furthermore, it will contribute to shortening the construction time, reducing the construction cost, noise and eco-friendly construction.

The systematic design process proposed in this study is expected to be applicable not only to form but also to other construction materials in construction sites. This will contribute to the reduction of the construction costs, shortening the construction time, and establishing a safe working environment.

In the future study, this process will be to make an optimal system form and conduct field test to verify form strength, concrete casting quality, noise reduction and productivity analysis. In addition, a satisfaction survey of the products produced from this study will be conducted to verify the validity of this study and conduct a complementary study of the form design process.

Abstract –

The design of rebar in reinforced concrete (RC) structures is a mandatory stage in building construction projects. Due to the large number and complicated arrangement rules of rebar in each design code, it is impractical, labor-intensive and error-prone for designers to avoid all clashes (i.e., collisions and congestion) manually or partial automation by using computer software. Therefore, the building information modeling (BIM) technology has been employed in the present architecture, engineering, and construction (ACE) industry for clash free rebar design. However, it is worth noting that most of existing BIM based approaches are using optimization algorithms for moving components, which can only be applied for regular shaped RC structures. In particular, shapes of rebar are fixed which means the optimized path of rebar cannot bend to avoid the obstacle in current studies. Furthermore, most of the existing studies cannot meet design constraints after avoiding clash, lack automatic and intelligent identification and resolution of rebar clash for complex RC joints and frame structures.

Therefore, we present a framework towards automatic rebar design in RC frame without clashes via multi-agent reinforcement learning (MARL) system with BIM. In particular, by treating each rebar as an intelligence reinforcement learning (RL) agent, we propose to model the rebar design problem as a path-planning problem of multi-agent system. Next, by employing FALCON (A fusion architecture for learning, cognition, and navigation) with immediate evaluative feedback as the reinforcement learning engine, we design particular form of state, action, and rewards for reinforcement MARL for automatic rebar design. In addition, the design of rewards and some strategies in MARL are presented for build-ability constraints. Comprehensive experiments on one-story RC building frame have been conducted to evaluate the efficacy of the proposed framework. The obtained results confirmed that the proposed framework with MARL is effective and efficient.

Building Information Modeling; Reinforcement Learning; Multi-agent; Rebar Design; Clash Resolution; RC Joints

1 Introduction

Rebar design is a mandatory and important stage in reinforced concrete (RC) structures construction projects. According to Chinese design codes for RC members design (GB50010-2010), the design of rebar has to meet the seismic and the bearing capacity requirements of RC members. Besides, rebar design needs to be constructed easily, safe and cost effective. Since the rebar are densely located and the arrangement rules for rebar are extremely complex as per design codes, it is impractical, labor-intensive and error-prone for the designers to manually avoid all collisions (hard clash) or congestions (soft clash) in the RC structures even using computer software [1]. In addition, current clash detection software like Autodesk Navisworks Manage and Solibri Model Checker, have realized detection and visualization of the clash members [2]. However, the current software mainly focuses on the clash identifications of construction members after the design stage. It cannot automatically avoid the clash of the rebar or offer implementation resolution for solving clashes, which thus are lack of automatic arrangement in rebar design.

Recently, building information modeling (BIM) has been widely in the current Architecture, Engineering and Construction (AEC) industry. BIM technology allows us to represent the detailing of rebar digitally and transfer the detailing information to structural analysis software [5]. However, automated resolution of rebar clashes is lacking in the existing BIM software packages. Therefore, developing a framework for solving the problem of clash detection and resolution for automated design of rebar connects with the exiting BIM technology will be

significant value in the AEC industry.

Various researchers in the past have tried to solve the problem of the clash detection and resolution for automated design of rebar with the aid of BIM technology, in the literature, Park [3] developed a BIM-based simulator to determine the sequence of rebar placement, and the clashes of rebar were identified by a developed application programming interface. Nevertheless, it focused on the simulation of the placement sequence and the spatial clash has to be solved manually. Next, Radke *et al.* [4] proposed an identification and resolution for mechanical, electrical and plumbing (MEP) systems. The offered resolution was moving one of the two clash entities to solve spatial conflicts. In fact, design constraints were not verified after moving one object. Besides, it provided manual resolution for resolving limited types of clashes. Moreover, Wang *et al.* [2] carried out a knowledge representation for spatial conflict coordination of MEP systems. The clash knowledge representation included description, context, evaluation and management details. However, the developed presentation pattern only provided a documentation to store clash information without any clash resolution strategy for identified clashes. Mangal and Cheng [5] proposed a framework based on BIM and genetic algorithm (GA) to realize rebar design and avoid clash at RC beam-column joints. However, the proposed framework only offered clash resolution strategy for moving components by using GA and can only applied for regular shaped RC structures. In particular, the optimized path of rebar cannot bend to avoid the obstacles, which thus limits its practicability in real-world complex RC joints. The main drawbacks of existing approaches can be summarized as follows: (1) Due to the complex design codes of rebar, most of the above studies cannot meet design constraints after avoiding clash by moving one object. (2) Most of the above studies lack automatic and intelligent identification and resolution of rebar clash for real-world complex RC joints and frame structures.

In machine learning, in light of its strength, RL algorithms have achieved many important achievements in the field of complex adaptive systems such as mobile robot path planning. What's more, a MARL system can lead to greater level of adaptivity and effective problem-solving [6]. Furthermore, the clash detection and resolution problem for the rebar design can be treated as a path planning of multi-agents in order to achieve automatic arrangements and bending of rebar to avoid obstacles. The similarity between the path planning of multi-agent and the arrangement of rebar, enlightens our work in this paper. Therefore, we propose a framework via a MARL system with BIM for automatically and intelligently provide clash resolution of rebar design in RC frames. To the best of our knowledge, this is the first modeling clash detection and resolution problem for the rebar design as a path-planning of multi-agent in the literature.

In particular, the three-dimensional coordinate information of the clash free rebar is then obtained by collecting the traces of the agents, considering longitudinal tensile, longitudinal compressive and shear rebar. To evaluate the efficiency and effectiveness of the proposed MARL, comprehensive experiments about one-story RC building frame having RC beams, columns, beam-column joints and beam-beam joints, including 63 RC beams and 23 RC columns with 1120 longitudinal rebars. Lastly, the obtained results including the success rates confirm that the proposed system is effective and efficient.

The contributions of the present study can then be summarized as follows:(1) To the best of our knowledge, this is the first modeling clash detection and resolution problem for rebar design as a path-planning problem of multi-agent in the literature. (2) To achieve automatic rebar design in complex RC joints, by employing FALCON as the reinforcement learning engine, we design the particular form of state, action, and rewards for the reinforcement MARL. (3) Comprehensive experiments on one-story RC building frame are performed to verify the effectiveness of the proposed framework.

2 Preliminary

Section 2.1 introduces the basic module of reinforcement learning. In Section 2.2, we describe the formulation of multi-agent path planning for rebar clash problem at RC beam-column joints. Section 2.3 presents rebar spacing requirements for RC members.

2.1 Introduction to Reinforcement Learning

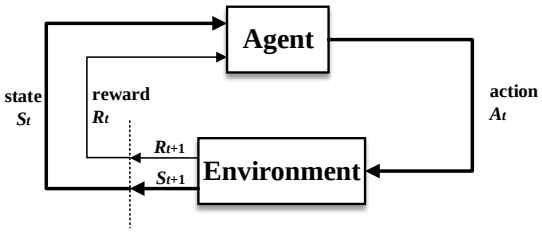

Figure 1. Basic Module of Reinforcement Learning

A multi-agent reinforcement learning (MARL) system [6] can be developed as effective tools for path planning problem-solving. RL is a natural learning paradigm to both single-agent and multiagent-agents. It creates an autonomous agent that learns and then adjusts its behavior through the action feedback (punishment and

reward) from the environment, instead of explicit teaching. Following the framework of a Markov decision process (MDP), a RL agent performs learning through the cycle of sense, action and learning [6]. In each cycle, the agent obtains sensory input from its environment representing the current state (**S**), performs the most appropriate action (**A**) and then receives feedback in terms of rewards (**R**) from the environment. It is important to note that how to turn a real-world environment into digital environment with clear reward signals is a key point to carry out RL.

2.2 Formulating Rebar Design as Path Planning of Multi-agent System

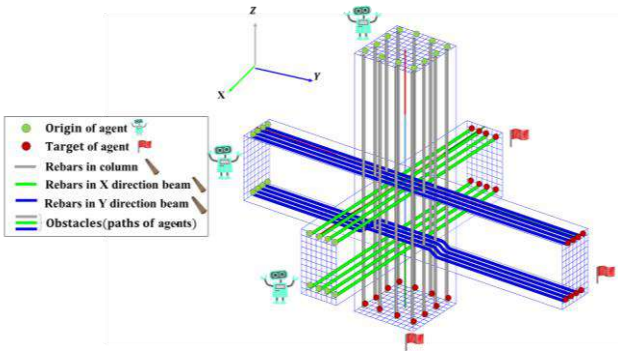

Figure 2. Problem formulation for RC beam-column joint

In particular, by treating each rebar as an intelligence reinforcement learning agent, we propose to model the rebar design problem as a path-planning problem of multi-agent system. It can be further modeled with a team of agents tasked to navigate towards defined targets safely across a RC beam-column joint that is gradually filled with obstacles which are rebars generated in the previous steps. available. In this task, the unmanned vehicle can choose one of the five possible actions, namely, up, down, forward move, left, and right at each discrete time step. The task or objective of the agent is to navigate successful through the joint towards assigned targets within the stipulated time, without hitting any obstacle. With the proposed MARL, the three-dimensional coordinates of the clash free rebar design are then obtained by collecting the traces of the agents.

Specifically, the process of rebar design in the RC beam-column joint is divided into three phases as illustrated in Figure 1: (1) In the first phase, the longitudinal rebars in the column are regarded as a group of agents from the origins navigating to the targets across the column and beam-column joint 3D environment. And there are no other obstacles (rebars) at the joint area in the first phase. (2) In the second phase, x direction beam longitudinal rebars are regarded as a group of agents and column rebars including longitudinal and shear rebars are regarded as obstacles. (3) In the third phase, y direction beam longitudinal rebars are regarded as a group of agents and rebars of column and x direction are regarded as obstacles.

2.3 Formulating Steel Rebar Spacing Requirements for RC Members and Origins and Targets for Agents

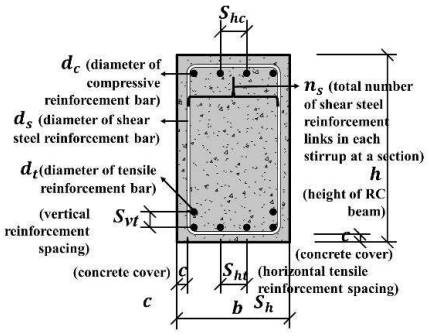

Figure 3. Spacing between rebar in an RC beam

In order to pour concrete easily and ensure the compactness of concrete around rebar, the spacings between longitudinal rebar are determined as per the provisions of GB50010-2010 (Figure 2). $S_{hc}$is horizontal compressive spacing for longitudinal compressive rebar, which is specified as $S_{hc} \geq 30$ and $\geq 1.5d_{c,max}$. In addition, S_{ht} is horizontal tensile spacing for longitudinal tensile rebar, which is specified as $S_{ht} \geq 25$ and $\geq d_{t,max}$.

N_t denotes the total number of tensile rebars, and $n_{t,min} \leq N_t \leq n_{t,max}$.

$$n_{t,min} = (b - 2 \times c)/\, S_{ht,max} \quad (1)$$

$$n_{t,max} = (b - 2 \times c)/\, S_{ht,min} \quad (2)$$

Where b denotes the width of RC beam, and c denotes the concrete cover. $S_{ht,max}$ and $S_{ht,min}$ are the maximum and minimum spacing between tensile rebars, respectively. Further, $S_{ht,max}$ and $S_{ht,min}$ are used in MARL to decide the origins of agents in each mission.

Similar to the longitudinal tensile rebar, spacing demands for compressive rebar are straight forward and require no explanation.

The calculations of spacing demands in RC column design are similar to those in RC beam design and require no explanation. The spacings between longitudinal steel reinforcement bars S_h are decided as per the provisions of GB50010-2010(Figure 3), and 50mm$\leqslant S_h \leqslant$ 300mm. Specifically, when the width of column is more than 400mm, the spacings between longitudinal rebars S_h must to be less than 200mm [1].

The origins of agents in each mission are decided by

the $S_{ht,max}$ and $S_{ht,min}$, meanwhile the targets of agents in each mission are also decided by the $S_{hc,max}$ and $S_{hc,min}$ as per the provisions of GB50010-2010, as illustrated in subsection 2.3.

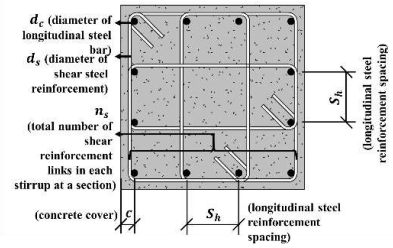

Figure 4.Spacing between rebar in an RC column

3 Proposed MARL system with BIM Solving the Path-Planning Problem for Clash Free Rebar Design

The presented framework for clash free rebar design is based on Mangal and Cheng [5] framework. The framework consists of 4 modules named (a) BIM Model Extraction, (b) Structural Analysis, (c) Structural Type Analysis, (d) Multi-Agent Reinforcement Learning System shown in Figure 5. The first three modules are clearly clarified in Mangal and Cheng [5] framework. The last module is explained in the following subsection.

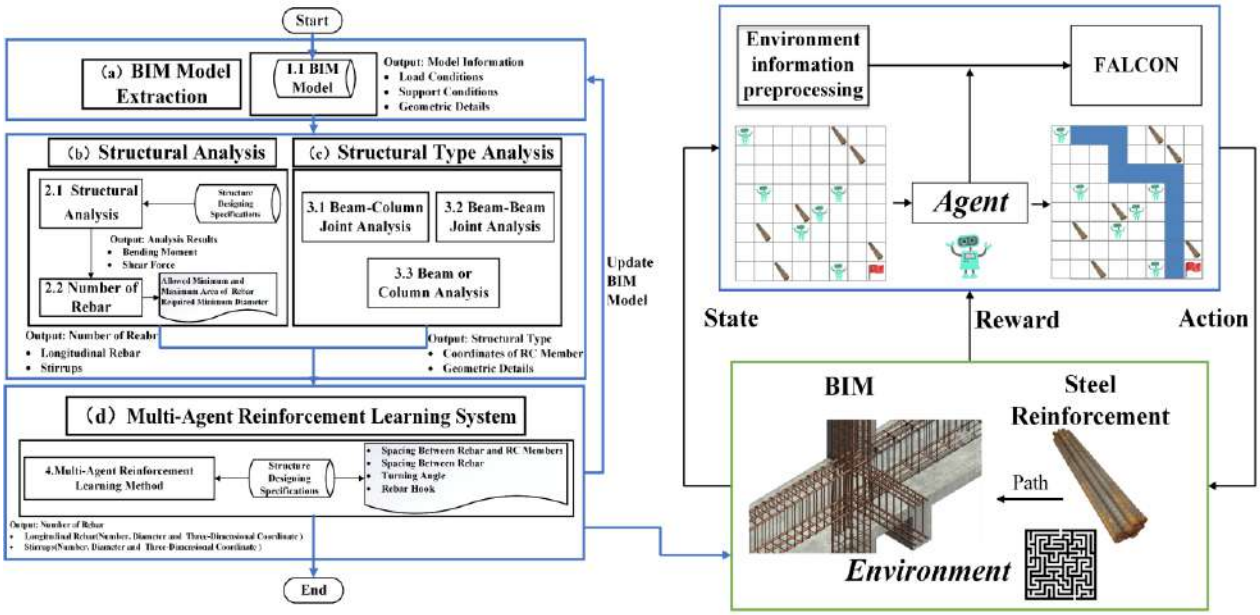

Figure 5. The presented framework for clash free rebar design via MARL with BIM.

3.1 Environment Information Pre-processing of RC Members

In addition, the RC members have to be transformed into a digital environment that is suitable for MARL system. Furthermore, we transform the BIM model of RC member into tessellated mesh environments approximating the geometry of the RC members with known boundary conditions, as illustrated in Figure 6. Then in tessellated mesh environment, a team of agents tasked to navigate towards defined targets safely.

Each tessellated mesh dimension Di of environment is the dimension of a single square mesh, which can be calculated as:

$$Di = \min(d_c \; and \; d_t) \tag{3}$$

Where d_c denotes the diameter of longitudinal compressive rebar, and d_t denote the diameter of longitudinal tensile rebar.

Therefore, the size of tessellated mesh environment Sz depends on Di and the dimension of RC members,

$$Sz = floor(D/Di) \tag{4}$$

Where D denotes the dimension of RC members, which can be length, width and height of RC members, and $floor()$ denotes the integer rounding down function in order to limit the range of Sz.

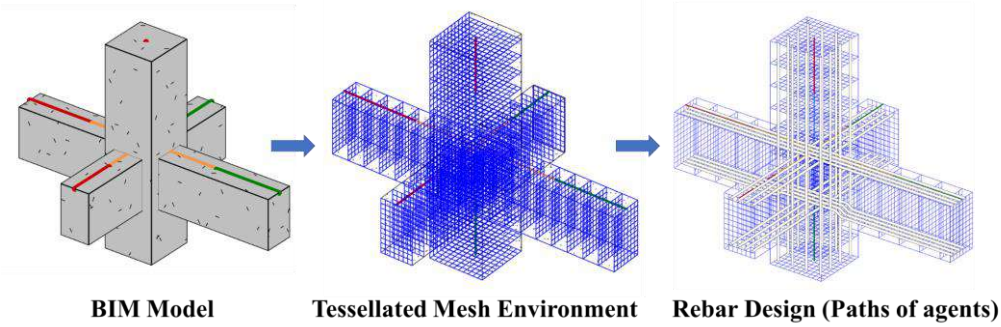

Figure 6. Environment information pre-processing of RC members

3.2 Neural Network Architecture of Each Agent

The architecture of each agent takes the form of FALCON [6], which has a three-channel neural network architecture (Figure 7), consisting of three modules: (1) State: a sensory field F_1^{c1} for saving and representing current agent states, (2) Action: a motor field F_1^{c2} for representing available actions, and (3) Reward: a feedback (reward) field F_1^{c3} for representing the internal states of an agent, as well as external feedbacks from the environment. It has a cognitive field F_2 where agents calculate the maximum expected future rewards for action at each state, which encodes a relation among the patterns in the three input channels.

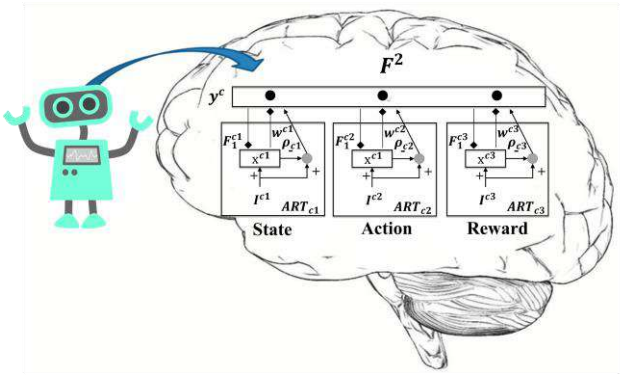

Figure 7. Neural network architecture of each agent

3.2.1 State Module

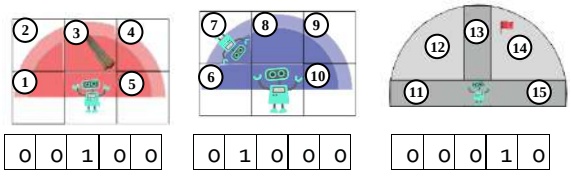

Figure 8. Illustration of states in 2D

MARL system involves numbers of agent equipped with a set of sonar sensors that has a 180° forward view. Meanwhile, input attributes of sensory (state) vector consist of obstacle (path of other agent) detection, other agent position detection and the bearing of the target from the current position. Therefore, without a priori knowledge of the three-dimensional coordinate information of the obstacle and targets, each agent is equipped with a localized view of its environment.

3.2.2 Action Module

In MARL system, the agent can choose one of the five possible actions (left, forward move, right, up and down at each discrete time step).

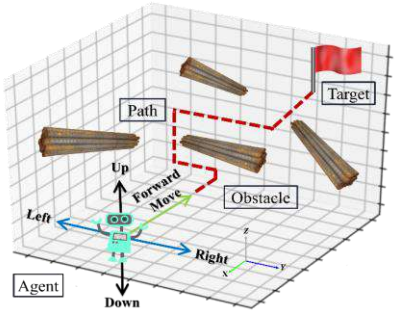

Figure 9. Illustration of five possible actions

3.2.3 Reward Module

In MARL, the design of reward, punishment and some specific strategies are presented for build-ability constraints. In particular, the reward and punishment strategies are described in Table.1:

Table 1. Reward and punishment strategies for agents.

Reward and Punishment Strategies	
Reach targets without hitting obstacles	+1.0
The distance between agents and targets decreases	+0.4
Hit obstacles (paths of other agents)	-1.0
Hit other agents	-1.0

Within the range of other agents' paths	-1.0
Run out of time	-1.0
Take actions (left, right, up and down)	-0.5
Take action (forward move)	0

A reward of +1 is given when the agent reaches the target without hitting obstacles and running out of time. A reward of +0.4 is given when the agent takes action that can get close to the target to encourage agents search for defined targets. A punishment of -1 is given when the agent hits an obstacle (paths of other agents), collides with another agent or runs out of maximum time in order to avoid clash of rebar. A punishment of -1 is given when the agent moves into the specified range (1.5 × diameter of rebar) of paths or positions of other agents, therefore the spacing demand of rebar is satisfied. A punishment of -0.5 is given when the agent takes actions including left, right, up and down in order to make sure agent to move as straight as possible, therefore the layout of rebar is most likely to be a straight line unless obstacles are encountered. A reward of 0 is also assigned when the agent moves forward and does not find the target in the maximum allowable time.

Figure 10. Illustration of multi-agent path planning including reward, punishment and mission endings in 2D

3.3 FALCON in MARL

The architecture of FALCON based on 3-channel Adaptive Resonance Associative Map (multichannel ARAM) [6], an extension of predictive Adaptive Resonance Theory (ART) networks (Figure 7).

Input vectors: Let {**S**,**A**,**R**} denote the input vector, where **S** = $(s_1, s_2, \ldots, s_n)$ denotes the state input, and s_i indicates the value of sensory input i ; **A** = $(a_1, a_2, \ldots, a_n)$ denotes the action vector, and a_i indicates a possible action i; **R** = (r) denotes the reward vector, and $r \in [-1,1]$is the reward signal value.

Activity vectors: Let x^{ck} denote the F_1^{ck}activity vector. Let y^c denote the F_2^c activity vector.

Weight vectors: Let w_j^{ck} denote the weight vector associated with the jth node in $F_2^c$for learning the input representation in F_1^{ck} . Initially, all F_2^c nodes are uncommitted, and the weight vectors contain all 1's.

Parameters: The FALCON's dynamics is determined by choice parameters $\alpha^{ck} > 0$ for $k = 1, \ldots, K$; learning rate parameters $\beta^{ck} \in [0;\ 1]$ for $= 1, \ldots, K$; contribution parameters $\gamma^{ck} \in [0;\ 1]$ for $= 1, \ldots, K$; and vigilance parameters $\rho^{ck} \in [0;\ 1]$ for $= 1, \ldots, K$.

3.3.1 From Sensory to Action

Given the state vector **S**, the system performs code competition and selects an action based on the output activities of action vector **A**. The detailed algorithm is presented below.

Code activation: Given activity vectors $x^{c1}, x^{c2}, \ldots, x^{cK}$ for each F_2^c node j, the choice function T_j^c is computed as follows:

$$T_j^c = \sum_{k=1}^{K} \gamma^{ck} \frac{|x^{ck} \wedge w_j^{ck}|}{\alpha^{ck} + |w_j^{ck}|} \quad (5)$$

Code competition: All F_2^c nodes undergo a code competition process. The winner is indexed at $J$where

$$T_J^c = \max\{T_j^c : \text{for all } F_2^c \text{ node } j\} \quad (6)$$

Action selection: The chosen F_2^c node J performs a readout of its weight vector to the action field F_1^{c2}such as

$$x^{c2} = w_J^{c2} \quad (7)$$

The chosen action a_I is then determined by

$$x_I^{c2} = \max\{x_i^{c2} : \text{for all } F_1^{c2} \text{ node } i\} \quad (8)$$

3.3.2 From Feedback to Learning

Upon receiving a feedback from its environment after performing the action a_I, the system adjusts its internal representation based on the following principles. Given a reward (positive feedback), the agent learns that an action executed in a state will result in a favorable outcome. Therefore, the system learns to associate the state vector **S**, the action vector **A**, and the reward vector **R**.

Template matching: Before code J can be used for learning, a template matching process checks that the weight templates of code J are sufficiently close to their respective input patterns. Specifically, resonance occurs if for each channel k, the *match function* m_j^{ck} of the chosen code J meets its vigilance criterion:

$$m_j^{ck} = |x^{ck} \wedge w_J^{ck}| \,/ |x^{ck}| \geq \rho^{ck} \quad (9)$$

Learning then ensues, as defined below. If any of the vigilance constraints is violated, mismatch reset occurs in which the value of the choice function T_J^c is set to 0 for the duration of the input presentation. The search process repeats to select another F_2^c node J until resonance is achieved.

Template learning: Once a node J is selected for firing, for each channel k, the weight vector $w_J^{ck}$is modified by the following learning rule:

$$w_J^{ck(new)} = (1-\beta^{ck})w_J^{ck(old)} + \beta^{ck}|x^{ck} \wedge w_J^{ck(new)}| \quad (10)$$

3.4 Proposed MARL System

Algorithm 2 Pseudo Code of MARL System

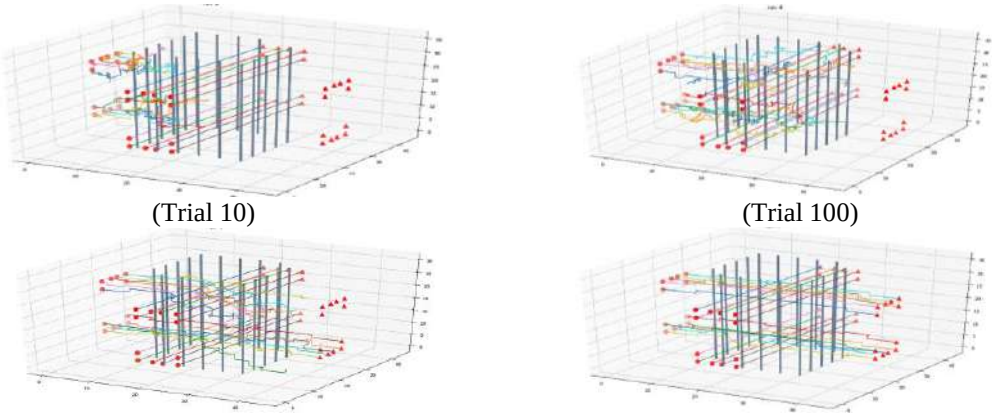
Initialization: Generate the initial *m* agents
While (a mission ending conditions are not satisfied)
For each agent
  If (agent dose not fail or not arrive the target)
    Perform FALCON algorithm
  Else
    Stop training
  End If
End For
End While

The basic steps of the proposed MARL system are outlined in Algorithm 2. In the first step, a population of *m* agents is initialized. An agent fails when hitting obstacles, exceeding 30 sense-act-learn cycles (running out of time). A mission ends when all agents fail or arrives at the target successfully. A mission will also be deemed to have failed if an agent collides with another, as depicted in Figure 10.

4 Empirical Study

4.1 The Example of Training Process in RC Beam-Column Joint by MARL

In the initial stage of mission as shown in Figure 11, agents are encouraged to explore new possibilities and try to reach defined targets without hitting obstacles or running out of time, therefore the paths of the agents looks messy, cluttered or indirect in trial 10 and 100. In the late stage of mission such as trial 500 and 1000, agents converge gradually to the global optimum and find the optimum paths for the clash free rebar design. Furthermore, along with the experimental training, the paths of agents have also gone from chaos to the gradual and orderly process of development. Finally, the global optimum of the agents' path will be selected to generate the clash free rebar design.



(Trial 10) (Trial 100)

(Trial 500) (Trial 1000)

Figure 11. The training process in beam-column joint by MARL

4.2 The Example of RC Frame

Figure 12. one-story frame

In this section, the empirical study is established to study the effectiveness of the proposed model. One illustrative example about one-story frame as shown in Figure 12 will be used to test the proposed model. In this tested frame, there are 63 RC beams and 23 RC columns with 1120 longitudinal rebars.

An agent having reached the target without hitting obstacles or running out of time is defined as a success. The success rate S_r can be calculated by Eq. 1:

$$S_r == \frac{1}{Nm} \times \sum_{i=1}^{N_m} \frac{N_t^i}{N_t} \times 100\% \quad (7)$$

where N_m denotes the number of total missions, N_t denotes the total number of participating agents and N_t^i stands for the number of agents that reach the targets successfully in mission i without hitting obstacles.

We analyzed the averaged success rate S_r on 40

simulations on the proposed MARL. The averaged success rates S_r presented in Figure 13 indicate that the proposed MARL successfully solving the path planning problem of rebar design after training. The design of reward, punishment and some specific strategies can satisfy build-ability constants.

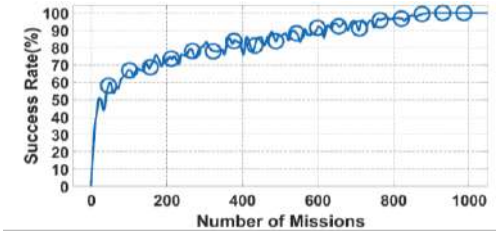


Figure 13. The success rates of MARL system

The automated 3D BIM outputs of the rebar in RC frame are given in Figure 14 and 15. Design of rebars of the RC frame are based on the result of the proposed system. It can be observed that there is no rebar clash in RC beam-column joints and frame by clash detection of the 3D BIM output.

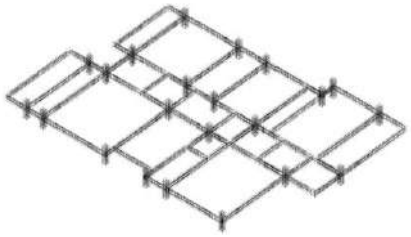

Figure 14. The simulation result of considered one-story RC frame

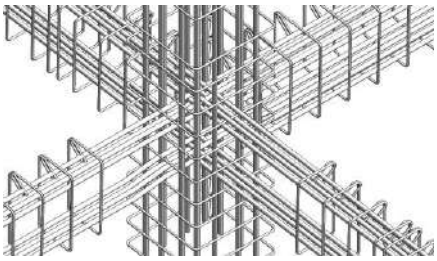

Figure 15. The simulation result of considered one-story RC frame

5 Conclusions and Future Research

In this paper, we model the clash detection and resolution problem for clash free rebar design as a path planning problem of multi-agents in order to achieve automatic arrangements and bending of rebar to avoid obstacles. Therefore, a framework via MARL system with BIM has been proposed to identify and avoid rebar spatial clash in complex RC frames. The three-dimensional coordinate information of the clash free rebar including bending of rebar is then obtained by collecting the traces of the agents. The design of reward, punishment and some specific strategies for build-ability constants are also put forward in MARL. Next, according to FALCON, the agent selects the suitable action and reaches the defined targets without hitting obstacles or running out of time. Subsequently, agents converge gradually to the global optimum along with the experimental training. Finally, the paths of agents are extracted to BIM model generating the rebar design. The simulation study in terms of the success rate have shown the effectivity and efficiency of the proposed system on the design of rebar in one-story RC frame.

However, the proposed framework via MARL system with BIM still has a few limitations. (1) It only applied for regular RC beams, columns, beam-column joints and beam-beam joints. (2) Furthermore, the system only considered the design codes GB50010-2010. Therefore, extending the system for more complex RC members or fabricated RC members and other design codes will be considered in the future work.

Abstract –

The localization of a robot is a crucial part of any task that involves the mobile manipulation of objects. The precise repositioning of a mobile robot within the workspace is particularly important for on-site construction in situations where the operating area is much larger than the reach of the robot arm. This research presents a localization method utilizing a generic surveying and measurement device – a robotic total station.[1] The localization of the mobile robot in reference to the total station is investigated through the positioning of a reflector prism, mounted on the robot's end-effector, at different known locations in robot's coordinate frame. Through this localization method, the opportunity to remove the reliance on fixed reference points is tested in a large-scale outdoor experiment, which would alleviate the need for a full enclosure around the mobile robot to help constrain its pose.

On-site construction; Localization; External measurement systems

1 Introduction

Robotic fabrication has traditionally been associated with high-tech industrial environments, where fixed positioning and constant conditions determine the role of the robot in the fabrication process. Unlike in facilities employing stationary robots, construction sites are spatially complex and unstructured, and mobile robots operating in such environments may be exposed to gradual change and unpredictable events [1]. One of the greatest challenges to the employment of robotic systems in such situations is maintaining their globally consistent localization (across a large building space), and assuring their perception of the immediate surroundings. In other words, a construction robot must "know" its own position if it is to localize itself and to manipulate its surroundings. In addition, every operation on a building site is unique in terms of the dimensions of the materials used and their range of tolerances. The methods adopted to facilitate the mobility of a construction robot on site should be sufficiently flexible to satisfy the various requirements of the building techniques and materials used. Accordingly, the two main problems can be identified as: (1) task-independent flexible global localization and positioning accuracy; and (2) task-specific local perception of the context.

This research addresses the first problem through a set of real-scale experiments in which the full potential of robot localization and positioning across a large building space is investigated using a generic surveying and measurement device of the type commonly used on construction sites. Rather than developing a task specific sensing device or technique, the goal is to explore viable methods of on-site robotic construction that do not require a full enclosure around the mobile fabrication unit. Such an In-Situ Fabricator (IF) would allow for flexibility in the production of building components larger than a workspace constrained by fixed references.

2 Background and Motivation

The mobile robot, the In-Situ Fabricator (IF), was developed within the scope of an interdisciplinary research project by Gramazio Kohler Research (GKR) and Agile & Dexterous Robotics Lab (ADRL) at ETH Zurich, in pursuit of the goal of bringing robots to the construction site. Over the last few years, IF has been successfully deployed in different projects [2], [3], exploring multiple strategies for localization. Prior to these projects, an earlier version of IF, the Echord dimRob [1], was utilized to explore localization with on-board sensors relative to its environment. The research

[1] A robotic total station allows for the remote measurement of vertical and horizontal angles and the slope distance from the instrument to a particular point.

[2], [3] focused mainly on on-board sensing and SLAM for the pose estimation of the robot end-effector to ensure minimal dependency on external sensing systems. Even though these methods proved to be successful, they came with certain limitations, such as in the achievable accuracy of the manipulator and the reliance on a full or partial enclosure around the robot to ensure reliable pose estimations.

This project explores a method in which an external tripod-based measuring system (an off-the-shelf robotic total station found commonly on construction sites, Figure 1) is employed to investigate the potential of localizing a mobile fabrication unit like IF with an external tracking strategy, without fixed reference points around the robot to help constrain the pose, thus eliminating the need for a full enclosure.

Figure 1. Setup exploring the use of an external measuring system in the form of a robotic total station for localization.

3 State of the Art

There are many methods that can be employed today for the localization of objects within a large space. The global positioning system (GPS) is used for localization on the Earth's surface, in which a network of satellites orbiting the Earth broadcast precise timing information, from which those receiving the information can calculate their position based on the timestamps of these messages. The US Department of Defence, as the developer of the system, states in [4] that the accuracy of GPS on an open field is 7.8m in the 95th percentile. A construction site, however, rarely exhibits the conditions of an open field, being mostly indoor environments, and methods that rely on GPS measurements to attain the required precision for a construction application would be more suitable for outdoor environments, such as the way the construction robotics start-up Built Robotics [5] use GPS measurements augmented with on-site base stations, fused with on-board Lidars (laser based measurements).

Recently, light detection and ranging (Lidar) devices have attracted considerable attention in the field of on-site construction involving the employment of mobile robots. Such devices measure all points in the visible environment as a point-cloud to aid localization through the use of Lidar point-cloud data, and a map of the visible environment is also needed that can either be given a priori or built simultaneously (SLAM). To exemplify, in a Mobile Robotic Brickwork project [2], an on-board laser range finder is used to scan the environment and the built structure so as to align the point-cloud data with the CAD model of the structure, and to manage the localization of IF through the creation of an enclosure around the robot to help constrain the pose.

Instead of measuring all points in the visible environment, an external measurement system, such as a robotic total station, can be used to measure the distance to a reference point – in this case, a reflector prism – in an exploration of methods to overcome limitations in positioning accuracy. A number of different approaches have been suggested involving the use of a total station for the localization of mobile robots in construction. One such approach involves placing the measurement device on the mobile hardware, which in the case of [6] was s a trolley pulled behind an asphalt paver carrying an automatic theodolite. The setup is augmented with robotic beacons placed in known locations within the surrounding environment and the theodolite rotates around its vertical axis to provide a continuous measurement of the distance to these beacons. These measurements, together with the readings from an encoder wheel on the trolley, are fused with an extended Kalman filter to obtain a position and an orientation estimate. Through the experiments conducted to date, it has been shown that an accuracy of $\pm 3cm$ in the x and y axis, $\pm 1cm$ in z and $\pm 0.1^{\circ}$ in pitch and roll were achieved in 95% of the measurements. Another approach is to mount the reflector prism on the mobile hardware, as exemplified in [7], and as adopted by construction robotics start-up N-Link with the mobile drilling robot. In such systems, two prisms are mounted on the mobile base of the drilling robot and the total station carries out sequential measurements within an environment constrained by a fixed reference point. The mobile drilling robot is then localized based on the relative distances between the prisms.

In the present project, the opportunity to remove the dependency on fixed reference points within the environment is explored. For this purpose, a reflector prism was mounted on the robot end-effector (Figure 3) to allow the measurement of the point at the location of the prism from different trajectory points (instead of the

robot base or at fixed locations within the workspace). The goal was to use these flexible points as reference points for the external measurement device (robotic total station), as a substitute for fixed reference points within the environment (Figure 2), hence allowing for building within an unconstrained space.

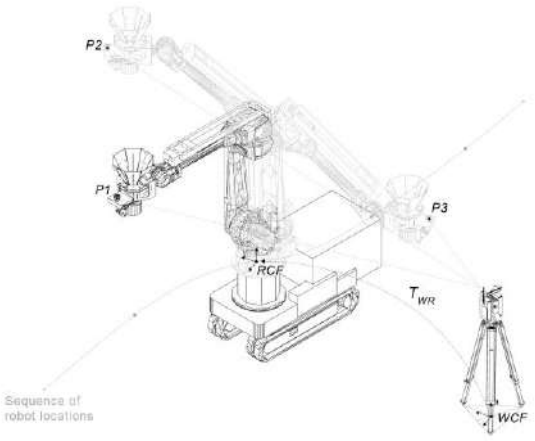

Figure 2. The substitution of "fixed reference points" with three end-effector trajectory points obtained from the mobile fabrication unit (IF).

4 Method

4.1 The setup

To localize IF using a robotic total station, a 360° reflector prism was mounted on its end effector (Figure 3), providing it with flexibility in the setting of arbitrary trajectories within the robot workspace as reference points, and ensuring a clear line of sight.

Figure 3. Reflector prism mounted on the end-effector of IF.

4.1.1 Hardware setup

A total station measures spherical coordinates (ϕ, θ, d) in an environment that is bounded by reference points, giving the precise interpolating range. The total station used in the present project was a Hilti POS 150, together with its tablet computer POC 200 and a set of $360°$ reflector prisms. The POS 150 offers distance precision of $2mm \pm 2ppm$, an angle precision of $5''(\approx 0.00139°)$ and a measurement range of $\approx 1000m$.

4.1.2 Software setup

Communication with the IF controller in the experimentation process was based on specific libraries developed previously at ETH Zurich. All developments for localization were implemented in Python, and could be easily integrated into the overall fabrication workflow (in Rhino Grasshopper), with the most basic approach to controlling the end effector being chosen (sending poses together with speed information to the robot controller). This permitted the robot end-effector, mounted with the reflector prism, to be moved sequentially to various points in the robot workspace.

4.2 Three-point Localization

In this first method, the first point is chosen by the operator of the system; the second point is then located along the robot's X-Axis at distance d; and the third point is located along the robot's Y-Axis, again at distance d. The coordinates of these points P_1, P_2, P_3, in the robot coordinate frame, are obtained directly from the robot (Figure 2). As each of these points is also measured by the total station, the coordinates, M_1, M_2, M_3, are also known within the global frame. Based on the special configuration of the points, the axes of the robot coordinate frame can be inferred directly as:

$$\begin{aligned} X &= M_1 - M_2 \\ Y &= M_3 - M_2 \\ Z &= \vec{X} \times \vec{Y} \end{aligned} \tag{1}$$

While $X, Y, Z \in \mathbb{R}^3$, to simplify the next set of computations, these vectors can be normalized as:

$$\bar{X} = \frac{X}{\|X\|}, \qquad \bar{Y} = \frac{Y}{\|Y\|}, \qquad \bar{Z} = \frac{Z}{\|Z\|} \tag{2}$$

In the next step, the origin of the robot coordinate frame is calculated. As the direction of the axis of the robot coordinate frame in the world coordinate frame is known, the origin can be extrapolated from the measurements:

$$O_w = M_2 - P_2^X * \bar{X} - P_2^Y * \bar{Y} - P_2^Z * \bar{Z} \quad (3)$$

where O_w is the origin of the robot coordinate frame in the world coordinate frame, and P_2^X, P_2^Y, P_2^Z are the x, y and z components of localization point P_2.

The transformation from the world coordinate frame into the robot coordinate frame is expressed in a homogenous transformation matrix. The $\bar{X}$, $\bar{Y}$ and $\bar{Z}$ vectors, as well as the origin O_w of the robot coordinate frame are expressed in the world coordinate frame. Deriving the homogeneous transformation matrix from the robot coordinate frame to the global coordinate frame is equivalent to calculating the change of the basis matrix:

$$T_R^W = \begin{bmatrix} \bar{X} & \bar{Y} & \bar{Z} & O_w \\ 0 & 0 & 0 & 1 \end{bmatrix} \quad (4)$$

As the transformation from the global coordinate frame to the robot coordinate frame is missing, the inverse transformation is computed by:

$$T_W^R = T_R^{W\,-1} \quad (5)$$

Therefore, for any given point Q_W the coordinates can be calculated within the robot coordinate frame by:

$$Q_R = T_W^R Q_W \quad (6)$$

4.3 Arbitrary Point Localization

When using arbitrary points for localization, there is no inherent information about the orientation of the robot coordinate frame. However, similar to the point set registration problem, the two significant sets of measurements are known to differ only in rotation and translation. For the point set registration problem a multitude of algorithms exists in [10]. As previous, the coordinates of n points P_i in the robot coordinate frame and the n measurements M_i in the global coordinate frame are derived. The sum of the deviation between localization point P_i and measurement M_i of the same point is calculated as:

$$f(O,X,Y) = \sum_{i=1}^{n} \left\| O + \underbrace{P_i^x * X + P_i^y * Y + P_i^z * (X \times Y)}_{Localization\ Point} - M_i \right\|_2 \quad (7)$$

With the addition of the constraints, the problem is defined as follows:

$$\begin{aligned} &\min_{O,X,Y} f(O,X,Y) \\ &X * Y = 0 \\ &|X| = 1 \\ &|Y| = 1 \end{aligned} \quad (8)$$

The first constraint ensures that the X-axis and Y-axis of the robot coordinate system are perpendicular; while the second and third constraints fix the length of the X-axis and the Y-axis at 1, thus simplifying the formulation of the objective function. The objective function, as well as the constraints, are both non-linear, meaning that the optimization problem falls within the realm of non-linear optimization problems. Resolving the problem using such a solver as the SciPy optimization package returns a local optimum. Although brute force methods for the global optimization of non-linear functions exist, such as basin-hopping [11], by choosing the initial guess of the robot coordinate frame close to the origin, in all of the experiments, the solver converged with the global optimum. Accordingly, the result of the optimization is the robot coordinate frame being expressed within the global coordinate frame. Similarly, the calculations explained previously in the three-point method can also be applied here to obtain the transformation matrix from the coordinate frame.

4.3.1 Point Selection

While setting up the total station, the fixed reference points are expected to bind the area in which the measurements are to be conducted (for the accurate interpolation of the targets to be measured). When using the robot as the reference point for the setup of the total station, this aspect is violated, as only points within the robot's workspace can be given as references, and after moving the robot, all points outside this workspace are measured (resulting in an extrapolation). To minimize the error introduced during the total station setup, the optimal points within the robot's workspace are to be selected, and this can be formulated as an optimization problem, as follows:

$$X = [P_1, P_2, \ldots, P_n], \qquad P_i \in \mathbb{R}^3 \quad (9)$$

$$\max_X \sum_{i=1}^{n} \|P_i\|_2^2 + \sum_{i=1}^{n} \sum_{j=i+1}^{n} \|P_i - P_j\|_2^2 \quad (10)$$

where the first part of the sum is the distance from the origin, and the second part is the distance between points. To ensure all of the points are within the robot's workspace, the following constraints are added:

$$\begin{aligned} \|P_i - (0,0,h)\|_2 &\le r, \qquad 1 \le i \le n \\ P_i^X &> 0 \\ P_i^Z &> 0 \end{aligned} \quad (11)$$

where h is the height of the arm above the ground ($h = 1m$ for IF) and r is the reach of the robot arm ($r = 2.55m$ for IF). Furthermore, the X and Z coordinates of the points are restricted to be positive – i.e. they need to be in front of IF and above the ground. The optimization problem was implemented in Python and resolved with [12].

4.3.2 Obstacle avoidance

One important aspect in the use of arbitrary points for localization is to prevent the collision of the robot arm with the structure being built. Accordingly, the heuristic algorithm used to select a point close to the desired localization point ensures that the end effector does not collide with the structure. The algorithm works as follows:

1. Set r = 10 cm
2. For each point P that does not fulfil the criteria:
    a. Set r = r + 10 cm
    b. Generate points
    c. Check criteria
    d. If all criteria are fulfilled, return point, otherwise go to step a.

Following the steps above, the points are generated as an equally spaced grid on a sphere at radius r from the original point.
In step 2c, the following criteria are checked for each point:

- $Z > 0$: Point should be above ground
- $X > 0$: Point should be in front of robot
- No collision: If the end effector is placed at the candidate point, it should not collide with the structure. A bounding box approximation of the end effector is used to provide some safety margins.
- Inside the robot's workspace: The point must be within the robot's reach.
- No obstacle between the point and robot: An obstacle between the robot base and the localization point may result in a collision with the arm.

For each iteration, the first point that fulfils all the criteria is returned.

5 Experiments

5.1 Procedure

The large-scale outdoor experiment was carried out at the Hönggerberg Campus of ETH Zurich, where the target points were evenly distributed on-site between the fixed reference points (Figure 6). The fixed reference points were used to provide a ground truth to validate the precision of the approach using the flexible references obtained from the mobile fabrication unit at arbitrary locations, and by evaluating the proposed method against the existing methods that rely on the existence of fixed references for localization.

The main goal in the experiment was to see how the errors propagated over time within the proposed flexible localization method, using different end-effector trajectory points as a reference to establish the total station (global) coordinate frame (Procedure A). To demonstrate the concept, a large-scale outdoor experiment was conducted using the "arbitrary points" method, in which two different procedures were followed (Figure 4):

- Procedure A: Setting up the total station using IF (different end-effector trajectory points) as reference (Figure 4, steps 1-4)
- Procedure B: Setting up the total station with fixed reference points on site (Figure 4, steps 1-6)

As mentioned above, Procedure B was introduced to establish a global reference frame using the fixed reference points on-site to validate the precision of Procedure A (proposed flexible localization method using different end-effector trajectory points as reference).

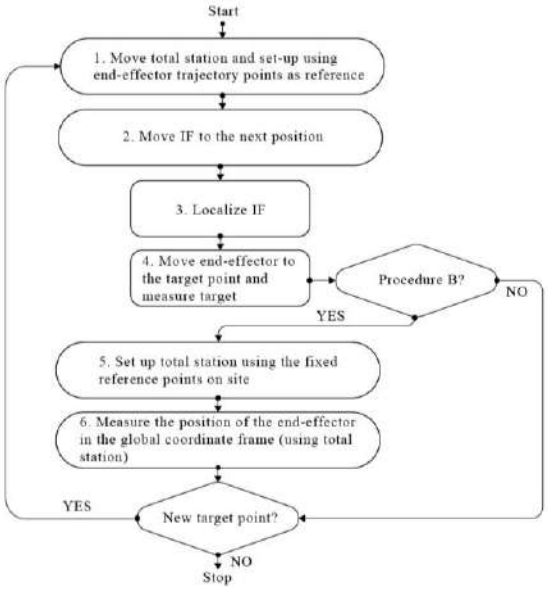

Figure 4. The full experiment flow for the acquisition of one data point.

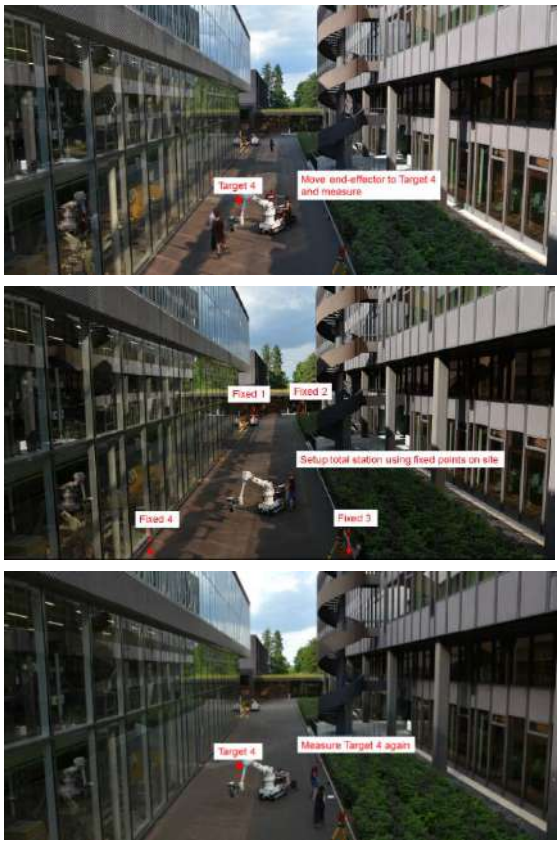

Figure 5. Steps 4, 5 and 6 of the large-scale experiment, executed for Target 4.

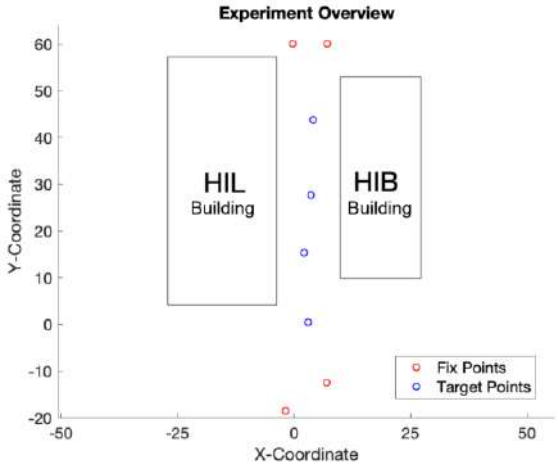

Figure 6. Large-scale outdoor experiment performed with target points distributed on site.

5.2 Results

The procedure was repeated five times for the acquisition of five data points.[2] Each cycle resulted in one measurement of the estimated target point, with the deviation from the planned target point calculated as:

$$D_i = P_i - M_i \tag{12}$$

where P_i represents the coordinates of the planned target points and M_i represents the coordinates of the estimated target points (calculated from the measurement of the end effector pose at that target point). As can be seen in Figure 7, the longer the experiment runs, the greater the deviation in the XY–plane gets, (with Procedure A, setting up the total station using IF as the reference), with an average of +-3cm and peaking at about +-7 cm at the end (Figure 7) relative to the measurements taken with Procedure B during which the ground truth is determined (for the evaluation of the proposed approach).

[2] Only four target points are marked in Figure 6. For the fifth data point, the fourth point was used a second time.

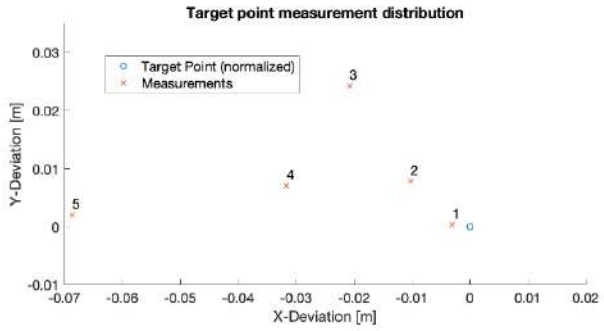

Figure 7. Deviation of the estimated points from the actual target positions in the XY-plane, at each iteration of the experiment.

6 Discussion and Future Outlook

The approach proposed in this paper aims to remove the need for fixed reference points for the localization of a mobile fabrication unit, with the intention being to address the problem of restricted workspaces in a defined enclosed area, and the possibility of building within an unconstrained space, as for on-site construction, the operating area is much larger than the reach of the robot arm. The approach makes use of an external measurement system for the evaluation of two methods: a three-point localization and an arbitrary point localization. Although the three-point localization approach lacks the required flexibility for a dynamic fabrication process, it carries a low computational cost and is easy to implement. In the arbitrary points method, the errors are minimized through the use of an optimization algorithm based on the sum of the squared distances between measurements. Furthermore, the points in this approach can be selected flexibly meaning that the robot can be prevented from colliding with the structure being fabricated. However, this method carries a high computational cost (as a non-linear optimization problem needs to be solved for each localization procedure) and is more difficult to implement. Both methods come with minor limitations, in that they require a clear line of sight from the reflector prism on the end-effector to the measurement device – in this case, the robotic total station.

All in all, the findings of the present study do not identify a single method that can be implemented for localization with external measurement systems. Such systems described in this research lack the perception component, which is needed for robotic fabrication in the context of construction sites, but target a precise pose estimation from point-to-point measurements (e.g. from the total station to the reflector prism on the end-effector). A future study could explore the possibility of merging this method with an on board-sensing system to increase the accuracy of global positioning.

Even though the method developed in this project was used in the context of a digital fabrication project, Jammed Architectural Structures [13] (Figure 8), the method is to be further investigated with a sensitivity analysis based on the precision of multiple devices. The goal is to introduce secondary devices, such as an iGPS system [14], to obtain ground truth for the validation of both the proposed localization method and the total station accuracy. The results of these experiments will be integrated into the present research.

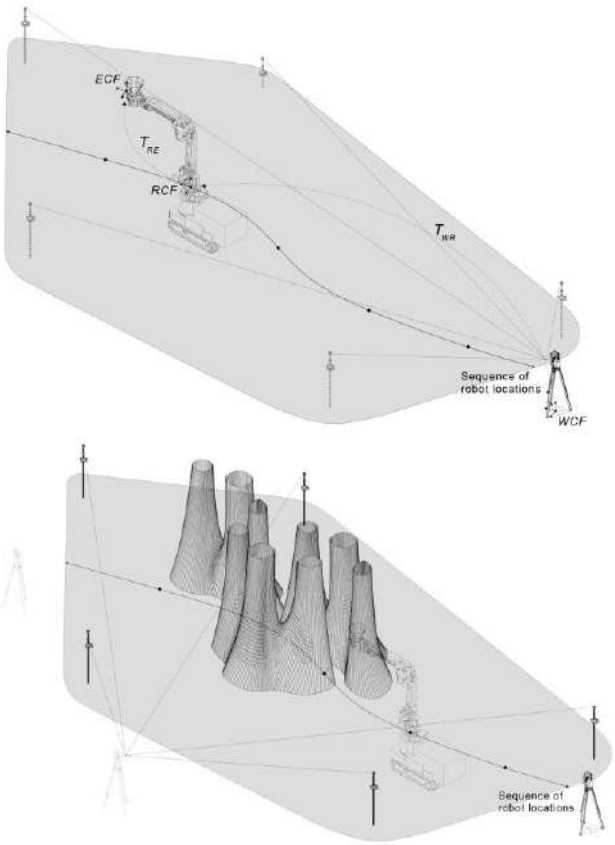

Figure 8. The method developed in this project was used in a digital fabrication project (Jammed Architectural Structures) deploying IF.

Abstract –

Selection of appropriate project delivery system is key for project success. It also gains much importance in a fast developing economy like India where there is a greater emphasis on development of housing and infrastructure involving huge investments. The present practices of project delivery led to inefficiency and distrust among the employer, consultant, contractor, and suppliers. Integrated Project Delivery (IPD) is a project delivery approach that integrates people, systems, business structures and practices into a process that collaboratively contributes to optimise the project results. However, the adoption of IPD in Indian construction is in its formative stage due to the challenges that are faced by various stakeholders. The objective of this study is to analyse the perceptions of the beneficiaries and intermediaries in the construction sector, on these challenges. An exploratory study has been conducted among various beneficiaries and intermediaries of construction sector in India using a questionnaire survey to gain insight into the perceived challenges. It has been observed that the intermediaries and beneficiaries differ in their perceived challenges, which is also found to be significant in legal issues. An in-depth analysis also revealed that the stakeholders perceived the following challenges significantly different: *Employer's unwillingness to share consultant in the profits of the project (Finance), Resistant to change (Culture), Disengagement agreement of the parties to implement the project on time (Legal),* and *Unfamiliarity with BIM (Technical).*

Keywords –

Indian construction; Integrated Project Delivery; intermediaries

1 Introduction

India is one of the fastest growing economies in the world and construction is the second largest contributor to Indian economy. There is a consistent drive to develop housing and infrastructure in India that involves huge investments in built environment projects. However, there are inefficiencies in traditional project delivery methods used in India that hampers the progress. This also has led to distrust among the various stakeholders in the construction sector such as client, consultant, contractor, and suppliers. Integrated Project Delivery (IPD) is an alternate project delivery system that promises to overcome some of the challenges faced in traditional systems [1].

IPD is a project delivery approach that integrates people, systems, business structures and practices into a process that collaboratively contributes to optimise the project results [2][3][4]. However, the adoption of IPD in Indian construction is in its formative stage due to the challenges that are faced by various stakeholders [5]. The objective of this study is to analyse the perceptions of the beneficiaries and intermediaries in the construction sector, on these challenges. An exploratory study has been attempted among the key stakeholders to assess the critical challenges along the financial, cultural, legal and technical dimensions. Salient findings are reported in this article. It has been observed that there is a significant difference between the perceptions of the beneficiaries and intermediaries in general and the same is predominant in legal aspects of implementing IPD.

2 Literature Review

Choice of project delivery system is key in the success of a construction project. Several project delivery systems being practiced in the field of construction such as Design-Bid-Build (DBB), Design-Build (DB), Construction Manager at Risk (CM@Risk), Engineering Procurement Construction (EPC), Job Order Contracting (JOC), and Partnering & Alliancing [6]–[8]. There are challenges reported in successful implementation of these systems (lack of stakeholders' involvement in the early stages, unbalanced risk & reward sharing, lack of trust & respect, standalone decision-making, unclear project goals, ineffective communication, incompatible technology, improper organisation & leadership as found in Figure 1) [9][10][11].

IPD includes presence of all key factors of the project from outset in an integrated manner, and using their experiences and constructive cooperation in a multilateral contract to have a more successful project and participation in risk and reward for all stakeholders in project life cycle [4][12]. This technology-driven delivery method has been implemented in a number of projects at various parts of the world [1][9]. It has been reported that there are certain challenges in adoption and successful implementation of IPD[13]–[22]. The implementation of IPD in Indian construction is in its formative stage[5], [21]. All such reported challenges/barriers can be classified into four major categories: financial, legal, technical and cultural aspects [5]. 34 such factors that influence the adoption/implementation of IPD were identified from the existing literature and presented in Figure 2 [5][9][17][18], [19].

Stakeholder engagement and satisfaction is also one of the critical success factors for project delivery. It is implied that there is varied level of acceptance for IPD from difference project stakeholders [5], [23] but there is limited literature on the perspectives of the beneficiaries and intermediaries involved in the construction projects at a macro level.

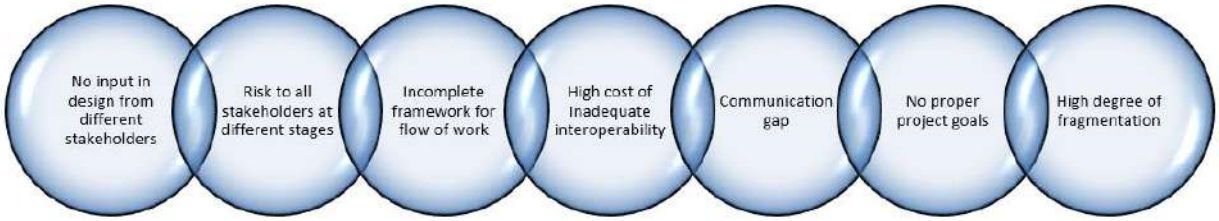

Figure 1. Challenges in Traditional Project Delivery Systems

Factors influencing the IPD adoption

Finance

F1	Compensation structure
F2	Employer's unwillingness to share consultant in the profits of the project
F3	Lack of transparency in spending done by the contractor
F4	High bids due to inexperience
F5	Confusion & Misunderstandings regarding accounting of contingency
F6	Lenders may demand 'hard pricing' for implementing IPD
F7	No specific plans for encouraging and rewarding

Legal

L1	New framework for legal practice is needed
L2	IPD contract types are not tested or understood
L3	Multiparty agreement for entire project lifecycle
L4	No insurance coverage for IPD
L5	No Dispute resolution clause
L6	Contractor's unwillingness to participate in the design phase
L7	Disengagement agreement of the parties to implement the project on time

Technical

T1	Unfamiliarity with BIM
T2	Interoperability issues
T3	Changes in the original design during construction phase
T4	Loss of focus on the aesthetic components of design due to earlier participation of other stakeholders
T5	Integration of information and knowledge management systems
T6	Early involvement of key participant
T7	Early definition of target goals without fully developed design

Cultural

C1	Lack of IPD awareness among stakeholders
C2	Training & Skill enhancement
C3	Absence or lack of respect and trust of the project parties to each other
C4	Organisation culture
C5	Resistant to change
C6	Inexperience with each other & IPD
C7	New approach take time
C8	Difficult to measure its benefits
C9	Unwillingness of employers, consultants and contractors to carry out the project in a team with common interests

Others

O1	Joint ownership of documents
O2	Who owns BIM? Who will pay for it?
O3	Shorter projects cannot spend time on organizational efforts for IPD
O4	Formation of Entity for "Real" IPD

Figure 2. Factors influencing IPD adoption

Beneficiaries are the stakeholders who are getting benefitted directly by the facilities developed; they are owners/clients, customers, developers and facility managers. The intermediaries shall include the design consultants (including architect, structural engineers, MEP engineers), project/construction managers, contractors, suppliers, etc. who are contributing to the development of the facilities (Please refer to Figure 3).

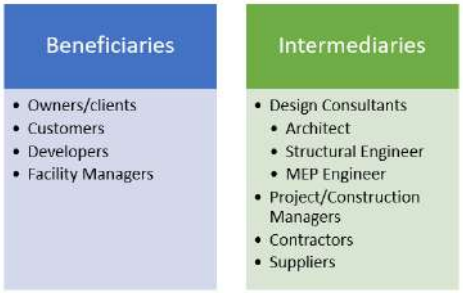

Figure 3. Beneficiaries and intermediaries in construction projects

Both beneficiaries and intermediaries would reap certain common and specific benefits when IPD is implemented. At the same time, the challenges that they face while implementing IPD also would vary due to various reasons ranging from cultural, legal, financial and technical context of the organisation. There is a need to study this characteristic of contrasting business interests of intermediaries and beneficiaries and its impact on the adoption of IPD. This would enable formulating strategies for improved adoption of IPD in construction projects.

3 Research Methodology

It has been attempted to use a questionnaire survey-based exploratory study to analyse the perceptions of beneficiaries and intermediaries on the factors influencing the implementation of IPD in Indian construction. The research methodology used is presented in Figure 4. An instrument has been designed to collect the data from the respondents (on a 5-point two-sided Likert scale; 5-Strongly Agree & 1-Strongly Disagree) on the agreement of the respondent with respect to the perceived challenges as shown in Figure 2. The respondents have been chosen using independent random sampling technique and drawn from the population of various beneficiaries and intermediaries. There were about 200 such prospective respondents invited to participate in the study and 90 responses were received (corresponding to 45% response rate). After careful scrutiny only 60 (out of 90) valid responses were used for analysis.

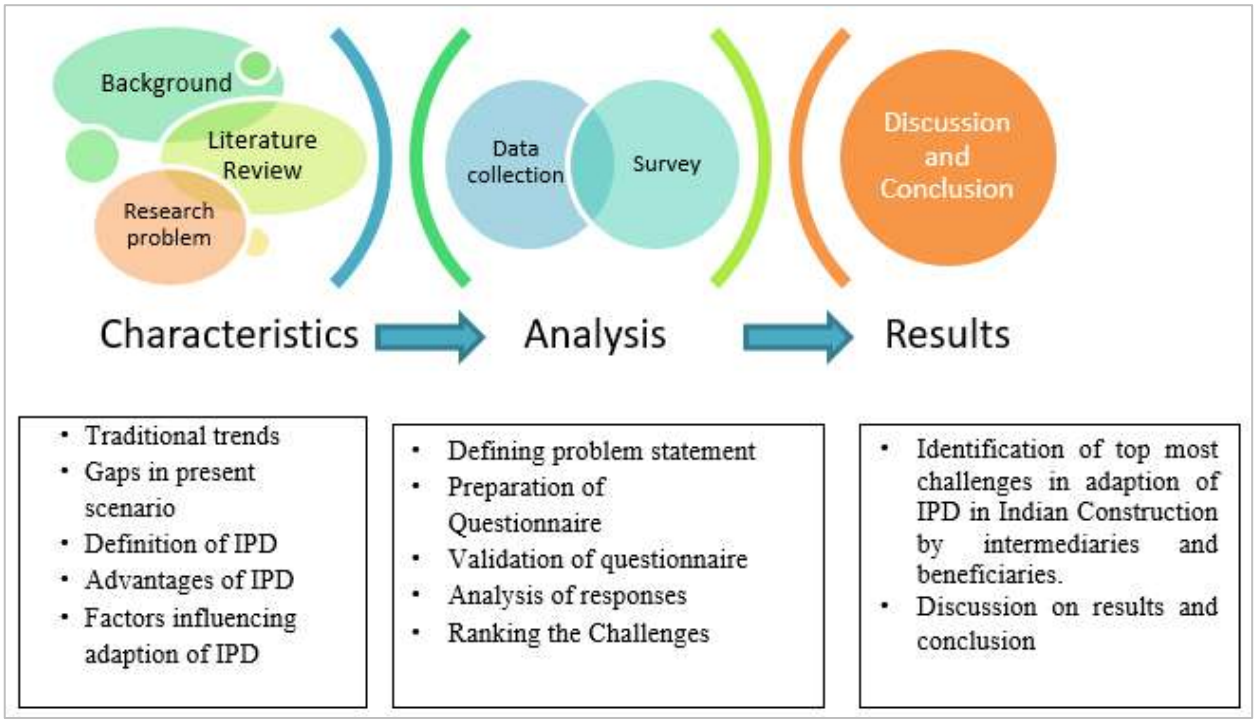

Figure 4. Research methodology

Relative Importance Index (RII) is used to prioritise the factors influencing the challenges to implement IPD.

$$RII = \frac{\sum w}{AN} = \frac{5n_5 + 4n_4 + 3n_3 + 2n_2 + 1n_1}{5N} \quad (1)$$

where

w - weighting given to each factor by the respondent, ranging from 1 to 5.

n_5 - number of respondents rated a factor as Strongly Agree;

n_4 - number of respondents rated a factor as Agree;

n_3 - number of respondents rated a factor as Neutral;

n_2 - number of respondents rated a factor as Disagree

n_1 - number of respondents rated a factor as Strongly Disagree.

A - highest weight (i.e. 5 in the study) and

N - total number of responses.

The RII ranges from 0 to 1. Higher the RII, greater the challenge.

Cronbach's Alpha has been used to measure the internal consistencyy of the instrument and reliability of data. Two-tailed t-Test (two sample unequal variance) at 5% significance level is used for hypothesis testing.

H_0: *There is no difference in perception between the Beneficiaries and Intermediaries on the relative importance of challenges in implementing IPD*

H_1: *There is difference in perception between the Beneficiaries and Intermediaries on the relative importance of challenges in implementing IPD*

4 Results and Discussion

Out of 60 valid responses, 30 belong to beneficiaries group and remaining belong to intermediaries group. The beneficiaries group respondents are primarily clients and the intermediaries consists of designers, contractors and suppliers. Sanitised data set received from all the 60 respondents is checked for reliability using Cronbach's Alpha, which is found to be 0.773. It indicates that the internal consistency of the instrument is good and the data collected using this instrument is reliable to conduct further investigation.

4.1 Overall Analysis

RII of the factors influencing the use of IPD is calculated using Equation (1) based on the responses from all the subjects. The ranking of the factors based on the RII is presented in Figure 5. It can be observed that *Lack of transparency in spending done by the contractor* is rated as the most critical challenge for the implementation of IPD in Indian construction. This can be related to the systemic characteristic of Indian construction sector, which is not highly professional and transparent that leads to lack of trust among project stakeholders. The second most rated factor is *New approach takes time*. This shows the apprehension of the stakeholders to adopt a new approach. There are three factors rated at rank three; they are:

- *Training & Skill enhancement*
- *Lack of IPD awareness among stakeholders*
- *IPD contract types are not tested or understood*

FC	Factors	RII	Rank
F3	**Lack of transparency in spending done by the contractor**	**0.81**	**1**
C7	**New approach takes time**	**0.79**	**2**
C2	**Training & Skill enhancement**	**0.76**	**3**
C1	**Lack of IPD awareness among stakeholders**	**0.76**	**3**
L2	**IPD contract types are not tested or understood**	**0.76**	**3**
T4	**Loss of focus on the aesthetic components of design due to earlier participation of other stakeholders**	**0.73**	**4**
F1	Compensation structure	0.71	5
T6	Early involvement of key participant	0.71	5
O3	Shorter projects cannot spend time on organizational efforts for IPD	0.71	5
L3	Multiparty agreement for entire project lifecycle	0.70	6
F5	Confusion & Misunderstandings regarding accounting of contingency	0.70	6
C6	Inexperience with each other & IPD	0.70	6
T3	Changes in the original design during construction phase	0.70	6
F6	Lenders may demand 'hard pricing' for implementing IPD	0.70	6
C5	Resistant to change	0.69	7

Figure 5. Overall ranking of factors by all the respondents

As the IPD demands high skill levels for implementation, stakeholders feel that they may have to focus on training before embarking on IPD system. Also, IPD is found to be not so familiar with the stakeholders. There is also some concern about the type of contracts (typically multi-party) that are quite different from the contracts used in the traditional delivery systems. It has been observed that there is some hesitations on the use of IPD due to the fact that the early involvement of other stakeholders might have adversarial impact on the design as *Loss of focus on the aesthetic components of design due to earlier participation of other stakeholders* rated as the next big challenge.

Among the least challenging factors *No Dispute resolution clause* is found to be least critical. This may be due to the presence of such dispute resolution clauses in most of the contracts used. In addition, the following factors seems to be of less significance to the stakeholders:

- *Difficult to measure its benefits*
- *Unfamiliarity with BIM*
- *Employer's unwillingness to share consultant in the profits of the project*

This shows that BIM is gaining wider attention and the stakeholders have systems in place for performance measurement of newer project delivery systems. Also, it can be noticed that profit sharing between the consultant and the client is not reported as critical.

It has been attempted to identify the highly important factors within the categories and the results are presented below.

- Financial
  - *Lack of transparency in spending done by the contractor*
  - *Compensation structure*
- Cultural
  - *New approach takes time*
  - *Training & Skill enhancement*
  - *Lack of IPD awareness among stakeholders*
- Legal
  - *IPD contract types are not tested or understood*
  - *Multiparty agreement for entire project lifecycle*
- Technical
  - *Loss of focus on the aesthetic components of design due to earlier participation of other stakeholders*
  - *Early involvement of key participant*
- Others
  - *Shorter projects cannot spend time on organizational efforts for IPD*

4.2 Comparative Analysis

The primary objective of this study is to analyse if there is any significant difference in the perception of beneficiaries and intermediaries on the factors influencing the implementation of IPD. Hence, the RII is computed using the Equation (1) based on the responses from the respective stakeholders and the same along with the ranking is presented in Figure 6. It can be noticed that *Lack of transparency in spending done by the contractor* and *New approach takes time* have been rated as the most critical factors by both the groups. *Resistant to change* is also reported as the top critical challenge by the beneficiaries. While there is an agreement on the top two factors, difference in perception is observed in the next most critical challenge. Beneficiaries reported that *IPD contract types are not tested or understood* in contrast to the preference of the intermediaries i.e. *Lack of IPD awareness among stakeholders* and *Training & Skill enhancement* as the third most critical challenge. This implies that the beneficiaries are more concerned about the project procurement compared to the intermediaries (like designers, contractors & suppliers) are apprehensive about the development of capabilities and capacity building that are related to the cultural aspects (it may be noted that *Resistant to change*, a top rated challenge by beneficiaries is also a cultural issue). Another interesting observation is that technical factors are not figured in the top three critical challenges by both the groups. This may indicate that both the groups are confident about the technical competence.

Please refer to Figure 7 to understand the least preferred factors between the groups. While the RII of the top rated factors are closer (0.80 & 0.82 by beneficiaries & intermediaries respectively), the RII of the least rated factors are 0.57 & 0.65. This can be interpreted as the intermediaries rated the challenges higher compared to the beneficiaries. This prompted to conduct the hypothesis testing to check these differences perceived by the beneficiaries and intermediaries are significant.

4.2.1 Hypothesis Testing

The two-tailed t-Test (two sample unequal variance at 5% significance level) conducted on the means of all the categories resulted in the rejection of H_0 i.e. there is significant difference between the perceptions of the beneficiaries and intermediaries (Please refer to Figure 8 for test results). It was also noticed that the perceptions of the beneficiaries are significantly different from intermediaries on the legal aspects but not on the other three dimensions. Further, a factor level test revealed that only on the following four factors, both the groups significantly differ:

- *Employer's unwillingness to share consultant in the profits of the project* (F2)
- *Disengagement agreement of the parties to implement the project on time* (L7)

It is interesting to note that the above four are from four different categories and the intermediaries rated them as on the higher side of importance compared to the beneficiaries.

5 Summary and Conclusions

IPD is gaining wider attention among the stakeholders of Indian construction. An exploratory study conducted among them revealed that *Lack of transparency in spending done by the contractor* is rated as the most critical challenge for the implementation of IPD in Indian construction and the least challenging one is *No Dispute resolution clause*. The comparative analysis between the beneficiaries and intermediaries showed that there is a significant difference in their perception but they agree on *Lack of transparency in spending done by the contractor* and *New approach takes time.* It is also evident that technical competence is not a major challenge for both the groups. It was also observed that beneficiaries significantly differ from intermediaries on the legal aspects but not on the other three dimensions viz. financial, cultural and technical. The factors on which the groups significantly differ in their perceived challenge in adopting IPD are consistently rated higher by the intermediaries.

As IPD is technology-driven, use of Blockchain and promotion of professionalism can be a possible solutions to overcome the challenges with respect to lack of transparency. In order to address the challenges such *as New approach takes time, Training & Skill enhancement* and *Lack of IPD awareness among stakeholders*, capacity & capability building among the stakeholders can be considered. Having understood the perceived challenges and the differences between these groups, the future work would include formulating strategies for addressing these issues for successful project delivery in order to meet the ambitions targets of Indian construction.

Modelling Traffic Conditions on Fuel Use and Emissions of On-road Construction Equipment

K. Barati[a], X. Shen[a]

[a]School of Civil and Environmental Engineering, The University of New South Wales, Sydney, Australia
E-mail: Khalegh.barati@unsw.edu.au, X.shen@unsw.edu.au

Abstract –

The consumption of fossil fuels by on-road vehicles is a main source of air pollution specifically greenhouse gases (GHGs) worldwide. The construction industry, due to the use of a large number of heavy-duty equipment including haulage trucks, contributes to a significant amount of fuel consumption and consequent emissions production. Due to increasing number of vehicles on the road, traffic condition is becoming one of the main variables having a considerable impact on the fuel use and emissions of such vehicles. There is a lack of comprehensive studies in construction field quantifying the effect of road traffic on fuel use and emissions of construction equipment. This research aims to model the impact of traffic conditions on fuel use and emissions of on-road construction vehicles. The research framework is first developed to present the methodology of data collection and analysis, and then introduce the fuel use and emissions models applied in predicting the effect of traffic conditions. Three variables of driving speed, idling time and equipment stop are identified as representatives of traffic conditions, and their impacts on fuel use and emissions are quantified through conducting statistical analyses on collected field data. The achieved results found that by having more effective traffic management and planning, the fuel cost and consequent emissions can be reduced up to 9% due to the decreasing idling time of equipment. It is also indicated that by lowering the number of equipment stops, up to 0.66 l/100kW fuel is saved and up to 1.7 kg/100kW CO_2 is emitted less per each stop.

1 Introduction

The construction sector plays a significant role in fossil fuels consumption and the production of GHG pollutants. According to the Environmental Protection Agency (EPA), construction sector accounts for 1.7% of total GHG production and 6.8% of all industrial-related emissions which is ranked as the third largest GHG emitter after oil and gas, and chemical manufacturing industries [1, 2]. In addition, it is estimated that construction industry produces more than 100 million tons of carbon dioxides (CO_2) annually, and contributes to around 5% of global CO_2 emissions which is ranked as the third CO_2 emitter per utilized unit of energy after cement and steel production sectors [3]. According to the United Nation Framework Convention on Climate Change (UNFCCC), GHG emissions from construction operations account for around 6.8% of the total emissions produced by all industrial sectors [4]. The majority of fuel used and emissions produced in the construction sector is related to equipment operations. Construction equipment accounts for 45% to 48% of the total vehicular consumed fuel and emitted pollutions of all industries [5, 6]. The machinery is mainly involved in huge earthmoving operations which their emitted pollution is by far more than other vehicles. For example, the pollution production of a middle-sized loader is nearly 500 times more than that of a private car [7, 8]. Based on the report prepared by the EPA's Clean Air Act Advisory Committee (CAAAC), construction sector accounts for 6% of the light-duty vehicles (LDVs) and 17% of the heavy-duty vehicles (HDVs) while producing 32% of nitrogen oxide (NO_x) and 37% of particulate matters (PM) of all mobile source emissions [9]. In the construction projects, equipment operations and materials transportation account for the majority of fuel use and emissions production.

Improving traffic conditions can have a significant effect on decreasing the total amount of pollutions emitted by construction equipment. As an

illustration, if the idling time of construction equipment reduces by 10%, the emission of CO_2 decreases by around 0.8 million tons per year [10]. Furthermore, EPA estimates if the fuel consumed by construction equipment decreases by 10% through lowering the idling times and equipment's stop, around 5% of the entire energy used in the construction sector will be saved resulting in a reduction of 6,700 tons CO_2 production [1, 11]. The Australian Clean Energy Regulator Agency (CERA) predicts that by improving the traffic volumes and having a more effective traffic planning and control, over 3 billion liters fuel can be saved by on-road equipment involved in all industries including construction which approximately 8 million tones CO_2 is emitted less in Australia only [12].

In spite of the significance, there is a lack of comprehensive study on modelling the effect of traffic conditions of fuel use and emissions rate of on-road construction equipment as the primary strategy to improve the fuel efficiency of such vehicles. The current traffic modelling systems mainly have been developed in the transportation field take into consideration just the impact of traffic on small-sized urban vehicles. The main focuses in construction field are on engine attributes, fuel types and mechanical practices to decrease the amount of used fuel and emitted pollutions per specific trip cycle which are costly and not applicable for all equipment.

The main goal of this paper is to model the effect of traffic conditions on fuel use and emissions production of on-road construction equipment. The comprehensive research framework is first developed presenting the methodology of data collection and analysis procedure. The operational level fuel use and emissions models applied in this study for modelling traffic conditions are then briefly introduced. This research continues with developing three variables of driving speed, idling time and equipment's stop representing the road traffic volume. The fuel use and emissions production of equipment at different speeds, idling mode and per each stop are measured in the next step using the developed fuel use and emissions model and equipment's specifications.

2 Background

Traffic management is one of the main challenges of the transportation field covering all moving vehicles. Traffic is a dynamic system which needs to be precisely modelled considering all affecting parameters including operators' driving patterns, road conditions and instantaneous traffic flow rate. It seems impossible to distinguish all factors affecting traffic conditions and model their impacts. Some models focus mainly on the driving pattern of each vehicle driver known as microscopic traffic models, while others concentrate on the average effect of factors at the macroscopic level and do not consider the dynamicity of traffic [13, 14].

As one of the major applications of the traffic models, fuel use and emissions rate of vehicles can be estimated based on the traffic flow. Different studies have been conducted to model the effect of traffic conditions on fuel use and emissions rate at both microscopic and macroscopic levels [15]. Microscopic fuel use and emissions models emphasize the instantaneous measurement of traffic variables plus the vehicle's specifications. The Motor vehicle emission measurement simulator (MOVES) is an example of such models that was developed by the EPA in 2004 to estimate the fuel use and different emissions (CO, NO_x, PM, CO_2, NH_3 and SO_2) of a variety of on-road motor vehicles. This model considers numerous parameters such as vehicle specific power (VSP), and derives second-by-second data from different programs such as US I/M240 and MOBILE6 [16]. MOVES simulator models the traffic conditions and driving cycles considering speed profile and distribution of the operation modes.

On the other hand, the macroscopic models have different inputs of average speed and vehicle group [13]. As an example of this modelling approach, the comprehensive modal emission model (CMEM) was developed by the cooperation of the University of California-riverside and the University of Michigan with the sponsorship of the National Cooperative Highway Research Program (NCHRP) in 1995. The prime objective of designing this model is to estimate fuel use and emissions rate associated with the operation modes of light-duty vehicles. CMEM simulates fuel use rate taking into consideration different readily-available parameters such as operating modes and specific vehicle factors, and calibrated parameters like fuel specifications and catalyst variables [13].

In addition to the traffic controlling and planning, numerous efforts have been devoted by scholars and international agencies to developing fuel use and emissions reduction schemes in the construction field. A number of studies have sought various means of reduction schemes, such as fuel changes, equipment upgrading and operator training. Avetisyan et al. developed a decision model to reduce fuel use and GHG emissions from transportation construction projects. Using the mixed integer programming (MIP), the optimization-based technique minimizes the emissions produced by the

equipment through considering numerous parameters, e.g. machinery availability, compatibility among equipment pieces and operation conditions [3]. Kaboli and Carmichael explored the relationship between the operation cost and produced emissions in the earthmoving activities using queueing technique. They concluded that by reducing emissions produced by machinery, the operation cost would decrease as well. It was also found that the minimal unit cost of emission and project cost are coincident, and this result does not rely on the operation conditions and equipment type [17].

3 Research Framework

As Figure 1 demonstrates, this section presents the methodology adopted in this study to model the effect of traffic conditions on fuel use and emissions of on-road construction vehicles. First, three instruments of the engine data logger, portable emission measurement system (PEMS) and GPS-aided inertial navigation system (GPS-INS) were developed to collect required field data including engine load (EL), fuel use and emissions rate in each second from in-use construction equipment. As shown in Table 1, during seven days of experimentation, eight HDVs with different classes, sizes and year models were tested to cover real working conditions in practice.

After obtaining the field data through experimentation, a data processing and synchronization procedure was performed to create a centralized database of all raw data gathered from the instrument. Database files were first created for storing the data collected from each piece of equipment. Data validation was then conducted to identify potential errors in the raw data. In the next step, the data gathered by instruments were synchronized. Since instruments did not have much delay in recording data, the simultaneous speed of the vehicle measured by both devices was used as a reference for data synchronization. The PEMS data were further processed to match with the data obtained from the other two instruments. One centralized database was then created with all field data of investigated parameters synchronized. The invalid data measured by each of the devices were finally detected and removed together with the corresponding data from other instruments.

Processing and analyzing the real-time obtained data, the fuel use and emissions rate of on-road construction vehicles were then modelled through investigating the effects of operational and engine factors on fuel use and emissions. Figure 2 shows some sample processed data used for modelling fuel use and emissions.

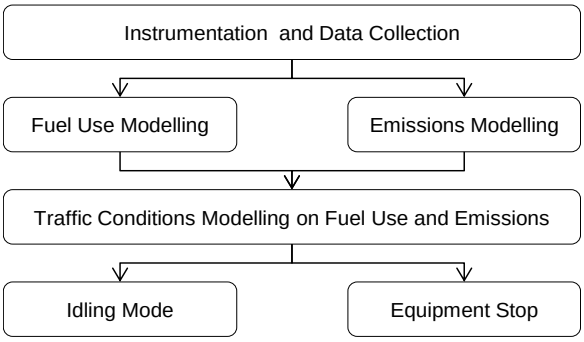

Figure 1. Research framework for modelling the effect of traffic conditions on fuel use and emissions rate of on-road construction equipment

3.1 Fuel Use and Emissions Models

The models developed in this text predict the fuel use and emissions rate of on-road construction equipment at the operation level [18]. There are numerous operational, environmental and engine parameters affecting the fuel use and emissions of equipment, but this study aims to focus on factors having a more significant effect and ignore parameters having a negligible impact. The initial analysis on the gathered raw data indicated that four operational variables of acceleration, speed, road slope and WF are the primary parameters affecting fuel use and emissions. The parameter of WF is defined as the combined weight of equipment (ton) should be carried per 100 kW of engine size [6, 20]. The combined weight refers to the total weight of the vehicle including equipment itself, trailers and payloads. Fuel type is another major factor influencing the fuel use and emissions rate. Different engine attributes also impact the fuel use and emissions including engine size, engine tier and engine age. In this study, the models consider the engine size, and estimate fuel use and emissions per kW of the engine. There are construction equipment pieces with three tiers of IV, V and VI engines in the market, but the tier V engine is currently predominant and is the main focus of this study. Engine age and maintenance conditions vary significantly from vehicle to vehicle and have minor effect of fuel use. Therefore, the parameters of engine age and maintenance have not been considered in this study at this stage. Construction equipment normally uses diesel as the primary fuel globally, and this research develops the models considering diesel fuel.

Table 1. Summary of field experimentation process conducted in this study

Day	Vehicle	Model	Engine size (kW)	Empty Weight (ton)	Payload (ton)	Experimentation Time (min)
Day 1	Six-axle Trident	2014	400	17.7	30.3	235
Day 2	Six-axle Vision	2005	350	17.6	30.9	340
Day 3	Three-axle Granite	2010	345	9.5	13	270

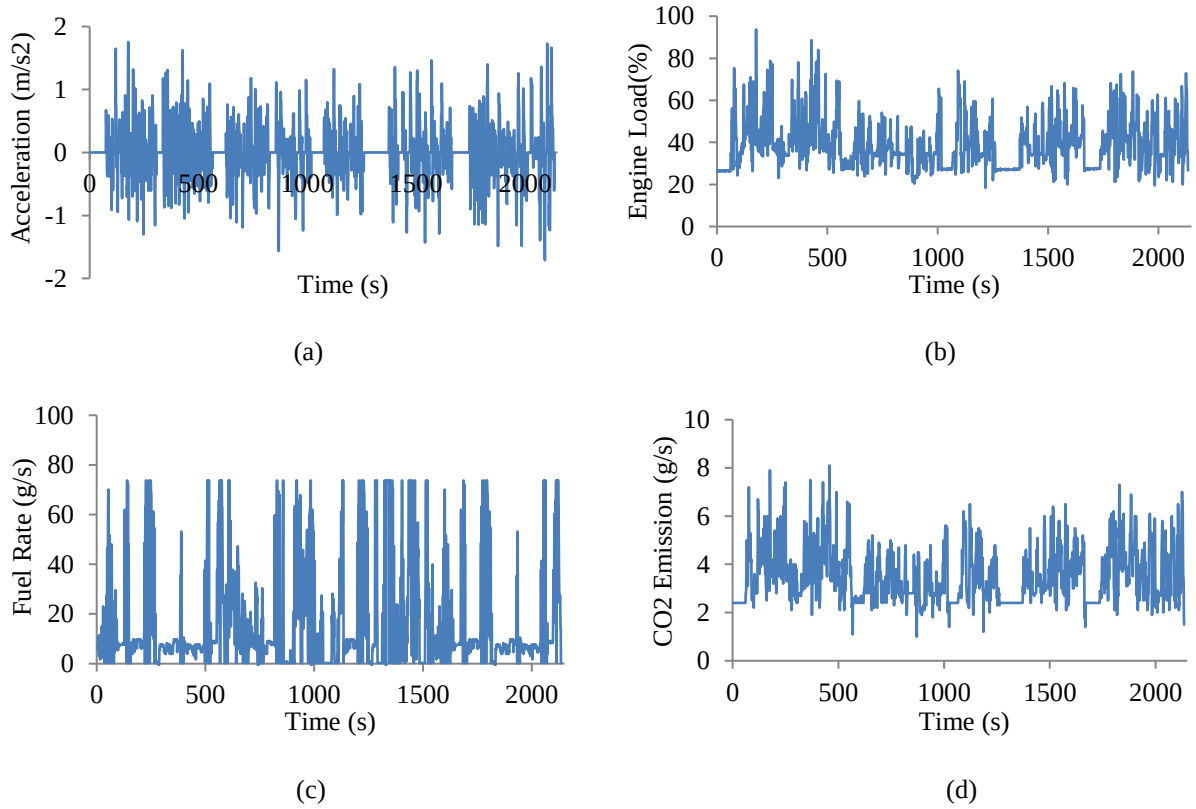

Figure 2. Samples of obtained data analyzed for developing fuel use and emissions model, (a) acceleration rate versus time, (b) engine load versus time, (c) fuel use rate versus time and (d) CO_2 emission rate versus time

In the devised models, EL acts as a critical intermediate factor bridging fuel use and emission rates with affecting operational parameters. Considering the internal specification of the engines, operational and environmental variables impact the engine power, and then engine power effects fuel use and emissions. Therefore, an intermediate parameter must be defined to link operational parameters to fuel use and emissions. Three engine variables of engine load, engine speed and manifold absolute pressure (MAP) were initially introduced as the used power of the engine, but the regression analyses on the collected data indicated that engine load is the best surrogate of the used engine power. Engine load is the percentage of used power of the engine and is defined as the ratio of the used power over the maximum available power of the engine.

The regression statistical method was the theory used in this study to develop the fuel use and emissions models. This method is more flexible compared to the other data analysis techniques. As one of the advantages, it is simple to add or remove some data after conducting an initial analysis. Using regression technique, it seems easier to find the differences among the developed relationships, and compare the results achieved from processing the data of various vehicles. Regression technique has other strong points such as level of familiarity, assumptions and use of multiple variables.

Equation (1) presents the function estimating the EL considering four factors of acceleration, road slope, driving speed and WF. As can be seen, there is a multivariable linear function between operational parameters and EL variable. Also, the constant value (C) shows the EL of equipment in idling mode which is around 20%. The coefficients of investigated factors in the developed EL model are presented in Table 2.

$$EL = (C_{AC}*AC) + (C_{SL}*SL) + (C_{SP}*SP) + C \quad (1)$$

Where:
EL: Engine load of equipment (%)
AC: Acceleration of equipment (km/h.s)
SL: Slope of the road (degree)
SP: Speed of equipment (km/h)
C_{AC}, C_{SL}, and C_{SP}: Coefficients of acceleration, road slope and driving speed parameters given in Table 1,
C: EL of equipment in idle mode which is around 20%.

The conducted ordinary least square (OLS) statistical analyses show there is a direct linear relationship between fuel use and emissions, and EL. The fuel use is around 0.02 l/kWh in idling mode (EL ≈ 20%) reaching approximately 0.12 l/kWh when the engine is fully loaded (EL ≈ 100%). CO_2 is the dominant GHG pollutant emitted by construction equipment and is the main focus of this study. CO_2 emission varies between 45 g/Kwh in idling mode to around 250 g/Kwh in full EL.

4 Modelling Traffic Conditions on Fuel Use and Emissions

Applying the presented fuel use and emission models, this section aims to model the effect of traffic conditions on fuel use and emissions of on-road construction vehicles. As discussed, traffic is a very complex dynamic phenomenon and there are numerous factors affecting traffic flow and its impact on fuel use and emissions. To simplify, three major variables of driving speed, idling time and equipment stop are distinguished and introduced as the representatives of traffic conditions in this study. There are absolutely other variables as the surrogate of traffic conditions, but these three parameters seem the most significant in the construction field. As demonstrated in the developed models, the effect of equipment speed as an operational parameter interrelated with WF has been estimated on fuel use and CO_2 emission. As indicated, by increasing the WF, the effect of speed on fuel use and consequently CO_2 emission linearly rises. In the following, the effect of idling time and stop on fuel use and CO_2 emissions are accurately estimated.

4.1 Fuel Use and Emissions in Idling Mode

Lots of operation times of construction equipment is spent in idling mode. The idling times are mainly due to traffic conditions, poor planning and low compatibility among involved equipment involved in the construction sites. As one of the factors in modelling traffic conditions, idling time of vehicles has considerable influence in fuel consumption and emissions production. It has been estimated if the idling time of construction equipment involved in construction sites decreases by 10%, CO_2 emission reduces approximately 800 million ton per year [1]. In this section, the fuel use and CO_2 emission production in idling mode of construction equipment are first estimated using developed models. Then, the additional fuel use and emissions production due to stop of on-road construction vehicles caused by traffic conditions are calculated.

Table 2. The coefficients of parameters in the EL estimation model

	WF				
Coefficients	2.75	4.5	6.5	13	14.5
C_{AC}	20.3	24.8	29.6	41.7	46.3
C_{SP}	0.20	0.25	0.31	0.42	0.47
C_{SL}	1.8	2.6	3.6	5.1	5.6

Figure 3 presents the fuel use and CO_2 emission rate of on-road construction vehicles in different operation modes. In comparison with other modes, vehicles consume much more fuel and produce much higher emissions in hauling mode due to using more power of the engine. As can be seen, the fuel use and CO_2 emission rate of construction vehicles in idling mode are 0.027 l/kWh and 0.073 kg/kWh respectively showing the high significance of lowering vehicles' idling time to reduce fuel use and emissions production. For example, by reducing the idling time of an equipment piece with the engine size of 400 kW for an hour, 10.8-liter fuel is consumed less resulting around 29 kg reduction in CO_2 production.

Figure 4 illustrates the average percentage of used fuel and emitted CO_2 in different operation modes of on-road construction vehicles. These results were achieved by analyzing collected raw data and using presented fuel use and emissions models. As shown, approximately 9% of used fuel and emissions of construction vehicles is in idling mode. This shows that by having more effective traffic management and project planning, the fuel cost and consequently emissions can be lowered up to 9%.

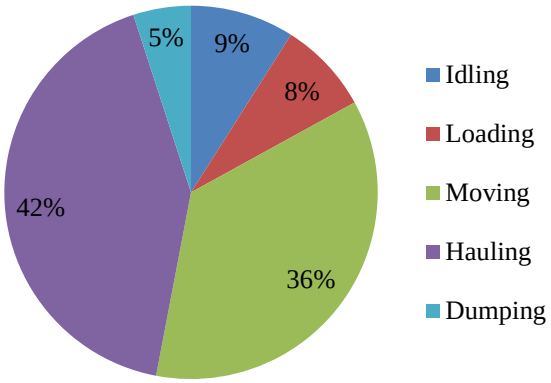

Figure 4. The average percentage of fuel use and CO_2 emission in different operation modes of on-road construction vehicles

4.2 Fuel Penalty and Extra Emissions due to Equipment's Stop

Stops of on-road construction vehicles which are mainly due to congested traffic flows or traffic lights have a considerable impact on the increase of fuel use and emissions. In this step, it is focused to investigate the effect of equipment stop on the fuel consumption and CO_2 production of on-road construction vehicles. Figure 5 indicates the additional fuel use and CO_2 emission due to the equipment's stop.

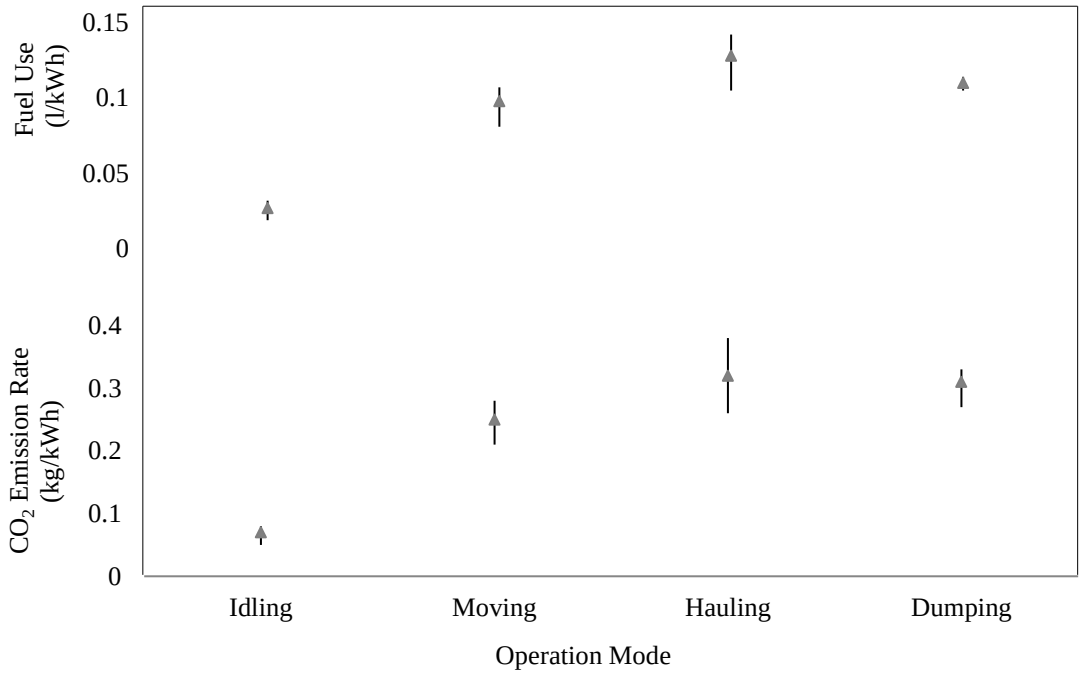

Figure 3. Comparison of fuel use and CO_2 emission of on-road construction vehicles in different operation modes

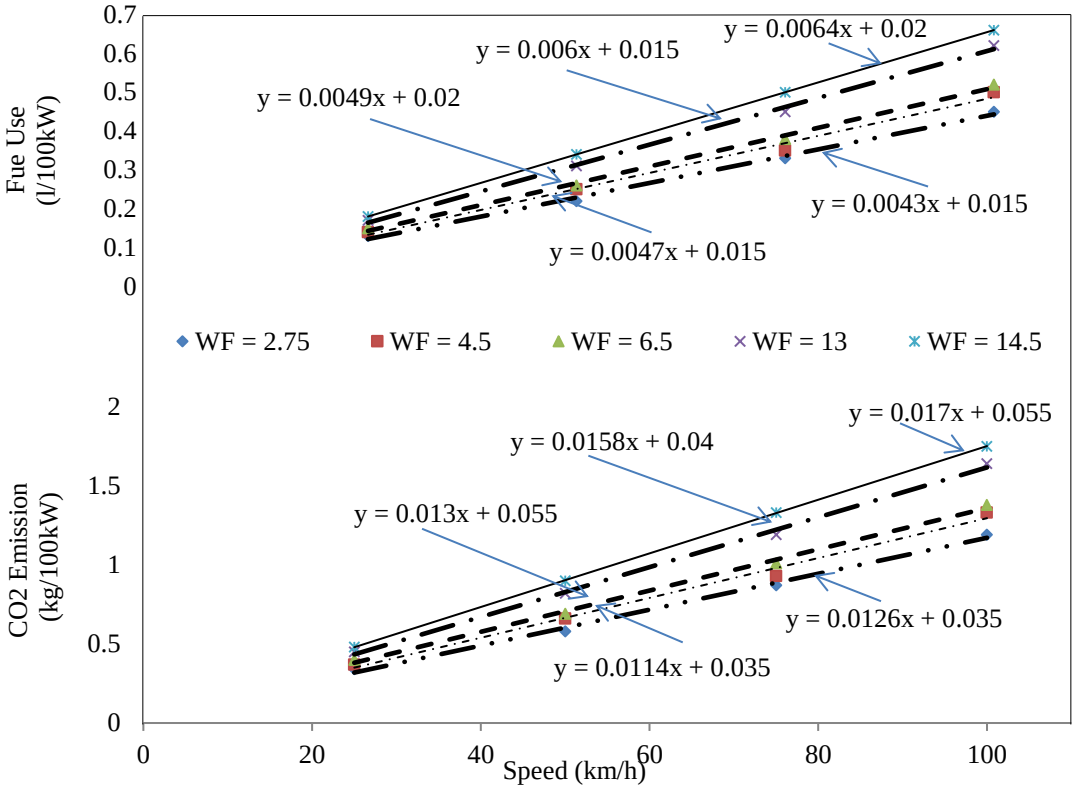

Figure 5. The fuel use and CO_2 emission due to stop of equipment with different WF values

The analyses were undertaken on various experimented equipment pieces. The effect of WF parameter was also taken into consideration in the data analysis process. In the calculations presented in Figure 4, it was assumed that during deceleration step to stop, the gas pedal is not pressed and EL is around 20% (like idling mode). Also, vehicles have three minutes stop, and then they start moving with the acceleration rate of 0.5 km/h.s to reach their previous speed. These assumptions have been made based on conducted observations, and it has been tried to simulate normal stop conditions of construction vehicles.

The equipment's speed and WF are the two main parameters influencing the additional fuel use and emissions in a stop. As shown, there is a highly-correlated direct linear relationship among vehicles' speed, WF and fuel use and emissions production. The additional fuel consumption and CO_2 emission due to stop vary from 0.13 l/100kWh and 0.35 kg/100kWh for the vehicles with the speed of 25 km/h and WF of 2.75 to 0.66 l/100kWh and 1.75 kg/100kWh for equipment with the WF of 14.5 driven with 100km/h speed. It shows the significant effect of vehicles' stop that must be considered by equipment's operators as a reduction scheme to lower fuel use and emissions at the operation level.

5 Conclusions

The construction industry is regarded as one of the major contributors to global energy consumption and GHG emissions due to the large engine size of involved equipment. Despite the significance, there is a lack of comprehensive schemes to indicate the effect of traffic conditions on extra fuel use and emissions production of construction equipment. Such guidelines can be broadly used by traffic planners and equipment operators to decrease the used fuel and emitted pollutions of construction vehicles. This research focused on modeling the effect of traffic conditions on fuel use and emissions of on-road construction equipment by analyzing collected field data and using devised fuel use and emission models.

As three prime parameters for modelling the traffic conditions, the effect of driving speed, idling time and full equipment stop on fuel use and CO_2 emission was investigated. To do so, the fuel use and CO_2 emission production of vehicles in idling operation mode were estimated using devised models. The analysis of raw data indicated that around 9% of used fuel and consequently produced CO_2 emission of construction vehicles are in idling mode showing the importance of lowering idling time

of equipment as a parameter representing traffic conditions. The impact of equipment's full stop on additional fuel use and CO_2 emission was also investigated. The achieved results indicated that by trying to have fewer stops during moving and hauling operation modes, up to 0.66 l/100kW fuel is saved and 1.7 kg/100kW CO_2 is produced less per each stop.

As the future study, this research aims to develop different fuel use and emissions reduction strategies and schemes at operational, equipment and planning level including trailer configuration, equipment's compatibility and engine upgrading to be used machinery manager, project manager and equipment worldwide as guidelines to deliver greater fuel efficiency and more sustainable operations.

Abstract -

Automation in construction is a highly active field of research with promising prospects for more efficient construction processes. This paper presents a novel behavior-based approach for distributed coordination of autonomous tandem rollers. Hereby, a detailed road representation and concepts for tandem roller and paver interaction as well as distributed task assignment are presented. The concept has been tested in a simulated road construction environment on the virtual B10 highway, Germany and compared to real construction data.

Off-Road Robotics, Behavior-Based Control, Multi-Robot Cooperation, Automated Road Construction

1 Introduction

The domain of construction industry strongly benefits from recent developments towards high-performance assistance systems and autonomous machines [1]. Complex construction tasks can be performed with higher efficiency, safety, and quality despite the continuously increasing complexity of the tasks. The area of road construction offers a high potential to profit disproportional from automation because collaborating machines have to be organized according to available time windows, their capabilities, and clearly defined tasks.

The automation of road works raise challenges subjected to the environment, infrastructure, and AI skills of smart machines. For instance, the construction environment changes permanently which challenges a robust and safe robot control. Additionally, the unstructuredness, varying environmental conditions, and fluctuating illumination affect sensor systems negatively. While it is still an open research problem, behavior-based control systems (BBS) present a promising approach to conquer these challenges. They are highly modular and run parallel components with overlapping functionality to increase robustness [2]. Also, swarm robotics are widely studied and there exist various approaches to handle the complex coordination tasks of robot interaction [3].

A prerequisite for robot interaction and collaboration is the availability of communication infrastructure. The project *Autonomous Mobile Machine Communication for Off-Road Applications* (5G-AMMCOA) funded by the German Federal Ministry of Education and Research (BMBF) focuses on the development of mobile 5G-Islands for a local, infrastructure independent communication and its impact on autonomous fleet management.

This paper presents a novel behavior-based control approach for a distributed coordination and task assignment of autonomous tandem rollers in a road construction scenario. Sect. 2 provides an overview to state of the art in autonomous road construction and multi-agent robotic systems. The integrated behavior-based control architecture serving as a base for the presented approach is introduced in Sect. 3. Then, the considered road construction scenario is described in Sect. 4. Sect. 5 introduces the formal description of a road model exploited in the control approach. The corresponding task description for tandem rollers is stated in Sect. 6. A behavior-based, distributed task assignment concept is proposed in Sect. 7. Sect. 8 presents experimental simulation results to evaluate the approach. Finally, Sect. 9 summarizes and concludes.

2 Related Work

In the recent past, there have been various research activities towards the automation of road construction and coordination of machinery. As early as 1998 the GNSS-based assistance system *AutoPave* was developed to map tandem roller trajectories on individual road segments for an improved quality and future automation [4]. Nearly twenty years later advances in automation technology promote the developments towards autonomous road construction. Control concepts have been developed to achieve an autonomous tandem roller navigation that is coordinated with a paver [5] as well as trajectory planning strategies for rolling patterns on asphalt [6]. Design concepts for future tandem rollers envisage machines without a cabin, where a fleet of robots which mimic a manned master machine is operated by a single human [7]. The *SmartSite* project targets real-time path-planning of multi-agent compactors systems [8]. Next to improvements to the overall logistic chain, a focus is directed to sensor data

exchange and adaptation to environmental changes. Subsequently, the project *Road Construction 4.0* builds upon *SmartSite*'s results and aims to further improve the intelligent control of construction processes [9].

Behavior-based and bio-inspired multi-agent systems have been well studied in the past [10]. The ALLIANCE architecture [11] presents a fault tolerant system for heterogeneous robot interaction. Each robot uses a motivational behavior to activate a task and suppress the task assignment of collaborating robots. The authors of [12] suggest a distributed swarm coordination approach which uses hybrid automata for behavior coordination through processing time- and event-based components to coordinate robots. A safety concept for robot collaboration is suggested by [13] and combines dynamic safety contracts with behavior-based control. Hereby, unsafe autonomous operations are limited through a safety cage.

3 Integrated Behavior-Based Control

The integrated behavior-based control (iB2C) architecture ([14], [15]) developed at the Robotics Research Lab (RRLab), TU Kaiserslautern, is used as the underlying software architecture for the presented approach due to its advantages concerning robustness and modularity. An iB2C behavior network consists of three main components (Fig. 1).

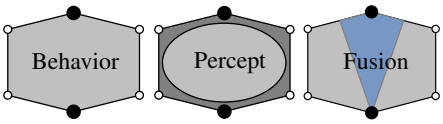

Figure 1. Main components of iB2C [15].

Standard behaviors are applied within a control context. Therefore, the complex tasks are decomposed into rather simple, but yet self-contained sub-tasks that can be implemented by individual behaviors. Thereby, partially overlapping functionality increases the system robustness, while the inherent modularity fosters reuse and extensibility. Similarly, percept behaviors are used to realize perception tasks including the data quality assessment. Competing control (perception) tasks are orchestrated by exploiting predefined fusion behaviors. All behavior components offer the same standardized interface for component coordination. Thereby, the behavior component's activity plays an important role since it represents the relevance of the component in the current system state, which can be externally adjusted via stimulation and inhibition by other modules.

4 Scenario

An important scenario which offers a lot of potential for optimizations in efficiency and quality by exploiting automation is the paving and compaction process of an asphalt layer in road construction. The road is layed out by a paver and compacted by a group of cooperating tandem rollers. To ensure a good compaction result, the rollers have to complete several tasks:

- Right behind the paver, the main compaction occurs. Rollers will compact the asphalt by applying a certain amount of passes, possibly with active drum vibration.
- Further back, rollers finish the surface statically.
- On open sides of the road, a roller has to press the edges with a special edge cutter tool.
- If a top layer is being built, a roller with a chip spreader might have to apply chip.

The process is dynamic, i.e. there is no fixed plan beforehand defining which task will be completed by whom at which time. There are several necessary events which will interfere the process during the day:

- The paver might have to slow down or stop because of a lack of material supply, caused e.g. by a traffic jam or a mixing plant failure.
- Rollers have to refill their water. Since the water tank is usually not moved during the day, the rollers have to travel back some distance to refill.
- Special jobs, like pressing the edges or seams, do not have their own dedicated machine - they are done in between.

5 Road Representation

An automated road compaction process requires a common representation for data exchange. One asphalt paver acts as the primary vehicle and stores road construction data collected during the paving process. The participating pavers collect data about the asphalt area like temperature and compaction. Collaborating rollers gather sensor readings as compaction and temperature to update already existing information. An overview of the road model is depicted in Fig. 2.

A road $\mathcal{R}$ has a set of lanes $\vec{\mathcal{L}}$ corresponding to the number of pavers. A lane $\mathcal{L}_i$ corresponds to the paver with ID i. Additionally, the road has longitudinal seams which connect and delimit lanes. A seam $\mathcal{S}_j$ is shared by

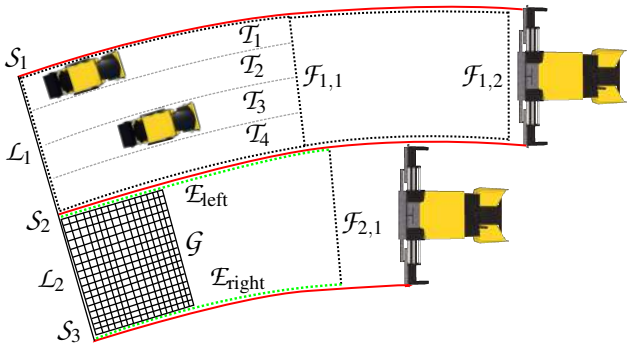

Figure 2. Road $\mathcal{R}$ with lanes $\vec{\mathcal{L}}$, seams $\vec{\mathcal{S}}$, fields $\vec{\mathcal{F}}$, edges $\vec{\mathcal{E}}$, grids $\vec{\mathcal{G}}$, and tracks $\vec{\mathcal{T}}$.

neighboring lanes. Therefore, there exists one additional seam with respect to the number of lanes

$$\mathcal{R} = \left(\vec{\mathcal{S}}, \vec{\mathcal{L}}\right), \text{ where } ||\vec{\mathcal{L}}|| = ||\vec{\mathcal{S}} + 1||. \tag{1}$$

Each road lane $\mathcal{L}_i$ contains a vector of fields $\vec{\mathcal{F}}$. Thereby, each field $\mathcal{F}_{i,k}$ has a maximum length of 25 m. It is defined as a polygon based on the paver's screed points $\vec{\mathcal{P}} = \overrightarrow{(p_{\text{left}}, p_{\text{right}})}$ during paving. Therefore, the field's width varies over time depending on the construction process. Exemplary, the minimum screed length for a BF 800 C paver is 2.55 m and 10 m maximum.

A field $\mathcal{F}_{i,k}$ contains two edges $\mathcal{E}_m$ with $m \in \{\text{left}, \text{right}\}$ and a grid $\mathcal{G}$.

$$\mathcal{F}_{i,k} = \left(\mathcal{E}_{\text{left}}, \mathcal{E}_{\text{right}}, \mathcal{G}\right) \tag{2}$$

Each edge is represented as B-spline which is appended by the respective paver's extending screed outer point p_{left} or respectively p_{right}. An edge is also a part of the corresponding seam $\mathcal{S}_j$.

The grid $\mathcal{G}$ has a resolution of $r = 10$ cm and stores construction relevant data such as the asphalt insertion time or respectively the last sensor update t_{up}, temperature estimation time t_{est}, measured stiffness c in MN/m^2, asphalt temperature T_{asph}, and asphalt temperature estimate T_{est} in °C. The temperature estimate is based on the last temperature measurement by the rollers or paver.

$$\mathcal{G}_{l,w} = \overrightarrow{\left(t_{\text{up}}, t_{\text{est}}, c, T_{\text{asph}}, T_{\text{est}}\right)} \tag{3}$$

The longitudinal grid index l depends on the current field length, while the index w on the respective paver screed width. Each grid $\mathcal{B}$ represents an detailed map of the current road section. Rollers utilize it for path planning under the consideration of the compaction effort, compaction time, temperature, and the current compaction state. Therefore, each field and respectively grid can be converted into a set of tracks $\vec{\mathcal{T}}$. A track $\mathcal{T}_n$ is a planned compaction area of a roller. Therefore the track's width depends on the area covered by a roller's drum or crab steering. For instance, the BW 154 tandem roller class has a drum width of 154 cm while BW 174 has 174 cm respectively. Additionally, the width can be extended through crab steering by 135 cm.

5.1 Temperature Model

A detailed description of asphalt cooling is provided in [16]. The most relevant parameters that influence the cooling behavior are the layer thickness λ, asphalt temperature T_{asph}, wind speed v_{wind}, and ambient temperature T_{amb}. In the previously described road representation, the asphalt layer thickness is provided by the road object $\mathcal{R}$ itself. Hereby, it is differentiated between base course, binder layer, and wearing course. The layer's thickness λ can be set as a parameter depending on the given class. This is also relevant for later compaction, vibration, and chip spreading. As mentioned before, T_{asph} is stored within the lane's grids $\mathcal{G}$. The parameters v_{wind} and T_{amb} are determined externally and set up in advance or measured by additional sensors. To estimate the temperature at time point $t_{\text{est}} = t_{\text{up}} + \Delta t$, which is Δt seconds after the actual measurement sensor measurement time t_{up}, the estimation of the temperature flow $\dot{Q}$ is exploited:

$$\begin{aligned}\dot{Q} = 7.4 + 6.39 \cdot v_{\text{wind}}{}^{\frac{3}{4}} (T_{\text{asph}} - T_{\text{amb}}) + \\ + 53.83 \cdot 10^{-9} \cdot (T_{\text{asph}}^4 - T_{\text{amb}}^4) - 680\end{aligned} \tag{4}$$

It follows

$$T_{\text{est}}\left(T_{\text{asph}}, \lambda, v_{\text{wind}}, T_{\text{amb}}, \Delta t\right) = T_{\text{asph}} - T_{\text{drop}}, \tag{5}$$

where the temperature drop T_{drop} for the duration Δt is

$$T_{\text{drop}} = \frac{\int_0^{\Delta t} \dot{Q}\, \mathrm{d}t}{2640 \cdot \lambda r^2}. \tag{6}$$

Analogous, a maximum time window until a certain temperature is reached can be determined. This is especially relevant for the asphalt compaction planning.

5.2 Asphalt Compaction

The asphalt compaction depends on different factors as asphalt composition and temperature. Furthermore, it can be differentiated between pre-, static and dynamic compaction. Additionally, the machine used for road works influences the compaction process.

Mix proportions are assumed to be constant in the following. This is also a prerequisite of the previously described temperature model, where factors like asphalt density and thermal conductivity are included as constant factors. The current asphalt temperature determines

the compaction effort and defines time frames for compaction. In general compaction should start as early as possible. The effort $\mathrm{Eff}(T)$ depends on the temperature T and is defined as

$$\mathrm{Eff}(T) = \begin{cases} T < 80\,^{\circ}\mathrm{C} & \text{too cold} \\ 80\,^{\circ}\mathrm{C} \leq T < 100\,^{\circ}\mathrm{C} & \text{stop range} \\ 100\,^{\circ}\mathrm{C} \leq T < 140\,^{\circ}\mathrm{C} & \text{optimum} \\ 140\,^{\circ}\mathrm{C} \leq T < 160\,^{\circ}\mathrm{C} & \text{start range} \\ \geq 160\,^{\circ}\mathrm{C} & \text{too hot} \end{cases} \quad (7)$$

Therefore, the duration ΔT_{stop} denotes the time until the asphalt is too cold based on the previously described temperature model.

The road's required number of transitions to achieve a feasible compaction can be estimated beforehand according to the vehicle class. It can be differentiated between static and dynamic compaction. Hereby, static compaction is used to achieve a minimum precompaction (too low compaction value) or for ironing (high compaction value). Dynamic compaction utilizes drum vibration of the roller. Usually, low and high amplitude modes are available. The low amplitude vibration is used for the wearing course and the binder layer, while the high amplitude is used for the road's base course. Additionally, there exist different tandem roller classes as for instance 4t, 7t, or 10t vehicles. Hence, the transition count and compaction amount depends on the roller class. Exemplary data is provided by [17]. In the following, the number of transitions is used to estimate the current compaction.

The optimum compaction speed is inbetween 1 and 2 m/s. This is used for scheduling of tracks based on the compaction priority. The compaction amount and compaction effort define the priority of a track $\mathcal{T}_n$ under the consideration of remaining time. Therefore fields with a low ΔT_{stop} value and low compaction amount c are prioritized high.

6 Road Construction Approach

The general road model of a specific construction site depends mainly on the available pavers. Usually, several rollers of different build types are available. Their usage and usability depends on their properties, the given construction scenario and the task requirements.

6.1 Roller Tasks

Aside from the *compaction* task itself, rollers have several other tasks to fulfill. They have a limited supply of diesel and water, which is consumed meanwhile. Due to the relevance of machine availability, *refueling* is considered as an own task and enables to remain operational even on low supplies. Additionally, resource rerouting may be required. Thereby, a roller *navigates* to a target position. Under certain conditions a roller may be *idle*, e.g during an oversupply. Hereby, it monitors the construction progress and can be requested to rejoin the fleet and actively work on another task.

6.2 Roller Skills

The larger a road construction site, the higher is the probability that there exist unequal rollers which belong to another vehicle classes or are equipped differently. Each roller has some tasks it excels at and some where it is inadequate for. In order to be able to compare rollers, different skills have to be considered. They are described as a percentage of the task feasibility, which influences a later assignment. This guarantees that a roller is able to perform a task in an adequate manner. Exemplary skills are edge compaction, chip spreading, pre-compaction, or narrow curve compaction.

6.3 Compaction Tasks

Road compaction is divided into sub-tasks which are accomplished by the rollers. An initial task is the processing of the *latitudinal seam* which provides a suitable connection to another street segment. Hereby, a roller's drum has an overlap of approximately 20 cm with the hot asphalt while the other part remains on the connected segment. A main tasks is the *track* compaction. It is also related to *longitudinal seam* processing. Each track overlaps with its neighbor for several centimeters in order to achieve an even connection. Additionally, the *ironing* of tracks is important. Final tasks are *edge compaction* and *chip spreading*. While chip spreading is essentially identical in the movement planning to track compaction, edge compaction depends mostly on the type of edge. Usually, edge processing requires a specific tool as a cutter or conical roll mounted on the vehicle. Furthermore, edges need to be driven as accurately as possible. Hence, those tasks are especially dependent on the roller's capabilities.

6.4 Compaction Strategies

The exists a variety of asphalt compaction strategies depending on the number of available rollers. In general, a single roller usually compacts a track, seam, or edge on its own. At the end of each track, a curve is driven towards the center of a seam to create a matrix within the asphalt to improve robustness.

A practical oriented swarm compaction approach is used in the following. Two rollers compact directly behind the paver, while a third roller irons a field behind. If a front roller has to leave the formation, the rear roller can catch up.

6.5 Compaction Errors

The final roads quality depends heavily on the avoidance of compaction errors. A major factor is the road's temperature since the compaction of too hot asphalt damages the surface, while too cold asphalt prevents the completion of compaction, respectively. Furthermore, the application of an unsuited roller class, e.g. too heavy vehicles, can introduce bow waves. Similarly, severe fractures may appear at the rolls edges. Also, shear forces have to be considered and sharp turns on the asphalt prevented. An insufficient bandages sprinkling may cause the material to stick on the rolls. Usually, a damaged section of the road forces a complete reconstruction and has to be prevented by all means. Therefore, error avoidance is explicitly considered during task assignment.

7 Distributed Task Assignment

Road compaction involves many vehicles which have to be coordinated accordingly. The construction process consists of many tasks that are distributed between machines. In contrast to a strict hierarchical procedure, where a master defines every task and the corresponding assignment, human workers follow a more self-determined way of task-fulfillment. In the following, a distributed approach for task assignment is proposed. Here, robots determine their suitability for a task self-directed. Each robot suggests its feasibility for a given task to an inter-robot behavior network which selects the most suited robot.

7.1 Communication of Construction Vehicles

The REACTiON architecture [18] provides a framework for robust and safe off-road navigation of commercial vehicles using a behavior-based approach. REACTiON provides basic perception and localization skills [15], as well as a low-level collision avoidance [19] to the involved robots as tandem rollers, or paver. Furthermore, a behavior-based communication approach adapts transmitted data according to the available bandwidth [20].

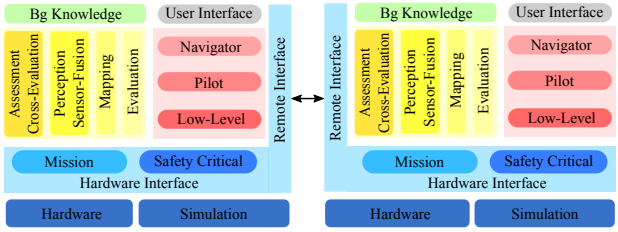

Figure 3. Robot communication using REACTiON remote interfaces.

Robot communication is realized by an extended REACTiON architecture exploiting remote interfaces (Fig. 3). Hereby, a remote interface equals a standard hardware interface. Subsequently, collaborating vehicles and transmitted sensor data can be considered as external sensors. Additionally, higher level information can be exchanged. Therefore, it is possible to span a behavior network across vehicles.

7.2 Paver Road Update and Task Assignment

The paver is the central element of the road construction process. Therefore, it manages the communication of the fleet and creates a mobile 5G-island [21]. As part of the inter-vehicle behavior network, it distributes all road construction and compaction tasks.

Fig. 4 depicts the part of the distributed BBS running on the paver. The *Perception* system provides information about the paver's *Screed* like pre-compaction, temperature, and current screed extension. *Pose* data is used to determine the exact screed location under the consid-

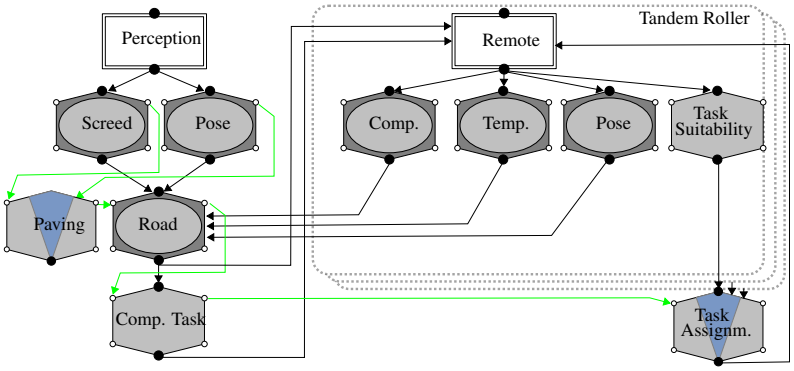

Figure 4. Paver behavior network for road model maintance and task assignment. Tandem rollers connect remotely to the paver and update road information. Task assignment uses a fusion behavior to select a roller.

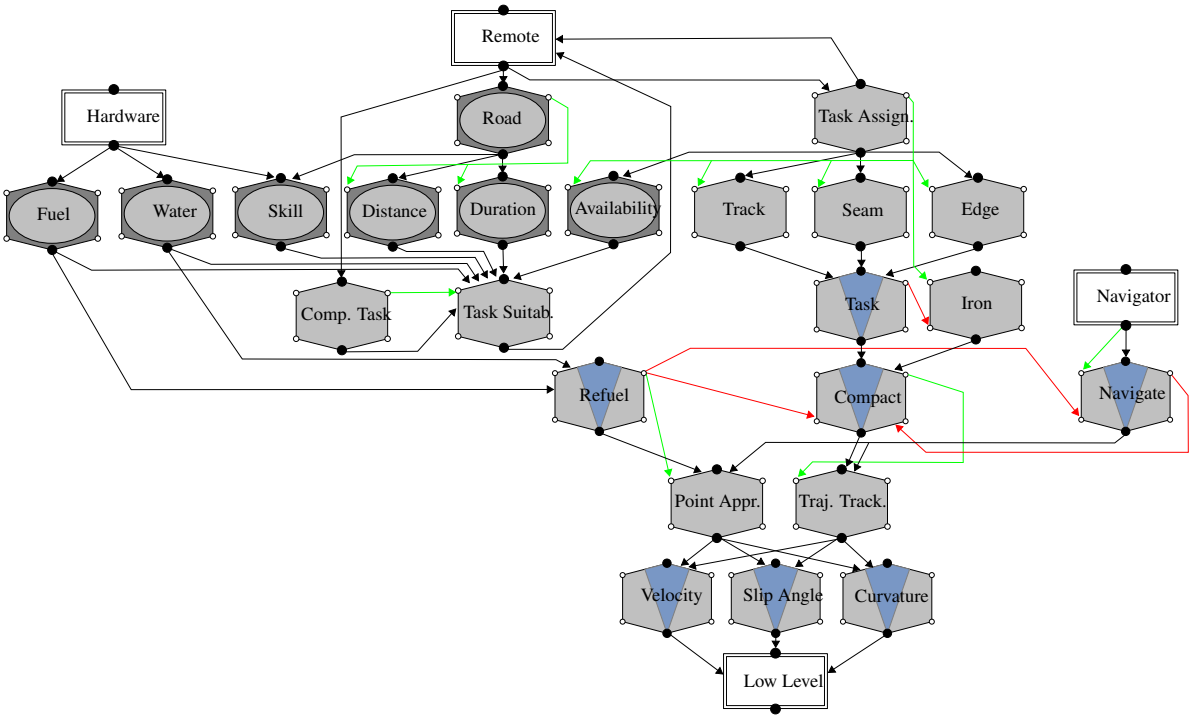

Figure 5. Tandem roller behavior network for road compaction. Properties as fuel, water level, skill, distance to a location, availability, and task duration are considered to determine the individual suitability to execute a task.

eration of localization sensor quality estimates. A *Road* model is maintained during the *Paving* process by successive updates of the paver's screed data. Additionally, collaborating tandem rollers provide road relevant data like the measured *Compaction*, *Temperature*, and the roller's *Pose* through the *Remote* interface. Compaction and temperature data update the temperature information and estimate contained by the road's grid content.

The paver determines the next *Compaction Task* which has to be performed by a roller. Hereby, a priority queue schedules the next task based on the criticality resulting from time constrains, compaction effort, and temperature. The compaction task is sent together with a task identifier to all collaborating rollers through the remote interface. Each roller responds with an estimate about its *Task Suitability* and the roller ID. The suitability is encoded within the behavior's activity and is determined individually by each roller. Thereby, factors as the current task, roller skills, fuel level, distance to the task location, and availability are considered. The *Task Assignment* uses a maximum fusion to select the best suited roller. The winner is acknowledged and adds the task to its task queue.

7.3 Tandem Roller Task Request and Execution

The task assignment among tandem rollers is a distributed process through the connected inter-vehicle behavior network. An extract of the network is depicted in Fig. 5. A roller can fulfill three main actions. It can *Refuel Fuel* or *Water*, *Compact*, or *Navigate*. The latter bases on the output of the *Navigator* interface. The vehicle is idle if there exists no activity in the network. Each of the three tasks provides either a target destination to a *Point Approach* behavior or a spline which is followed using the *Trajectory Tracking* behavior. Both navigation behaviors provide a *Velocity*, *Curvature*, and *Slip Angle* to the *Low Level* control interface.

Each roller retrieves a *Compaction Task* and the updated *Road* model from the *Remote* interface connected to the paver. Thereby, the individual *Task Suitability* is estimated under the consideration of the *Fuel* and *Water* level, as well as its *Skill* for the task based on the *Hardware* information. Additionally, the spatial *Distance* is considered to prefer tasks nearby. Furthermore, the *Duration* of a task and current *Availability* is regarded. This enables a roller to acquire an additional task when it is nearly finished with the current work. The estimate is transmitted and subsequently the *Task Assignment* behavior receives a roller ID for the outstanding task from the paver. The winning roller acknowledges and activates one compaction behavior. Accordingly, either a *Track*, *Edge*, or *Seam* compaction is executed. If there exists no specific *Task*, the roller's *Iron* behavior is active.

8 Experiments

The presented approach was tested in a virtual road construction environment. Simulated tandem rollers compacted a road and assigned tasks based on the construction process and skills. The results were compared to recorded real road construction activities.

The control software was implemented using Finroc, a C++, Java based robot control framework [22]. The scenario was simulated using the Unreal Engine 4 (UE4). Sensors were modeled to behave similar to corresponding real systems [20]. A virtual model of the B10 highway, Germany, served as the test environment, where three BW 174 roller and a BF 800 C operated (Fig. 6). Real construction data was available for comparison.

Figure 6. Road construction test on the simulated B10 highway, Germany.

The paved lane had a width of 7.5 m and length of approximately 1 km. An extract of the road as well as the asphalt cooling behavior is shown in Fig. 7. A comparison of human and robot trajectories can be seen in Fig. 8. In both trials, the lane was separated into 4 tracks. A human operator reversed after approximately 35 m, in contrast to the the autonomous systems with 25 m. The robots stayed strictly in the middle of the track and turned close to the paver. The human drivers navigated more imprecise inbetween the tracks. Additionally, the task separation differed. Real workers operated within different fields, where one roller compacted on all 4 tracks and the other roller stayed more behind. In contrast, the robots equally distributed the tracks of a field which results in a consistently distributed work-load.

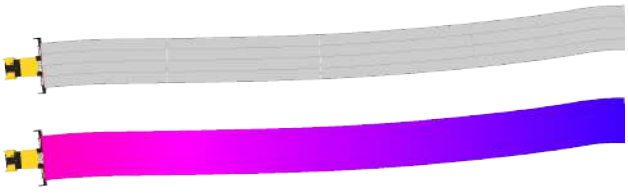

Figure 7. Extract of simulated lane of B10 highway with fields, and tracks. A temperature map shows asphalt cooling from hot (pink, 180 °C) to cold (blue, 80 °C).

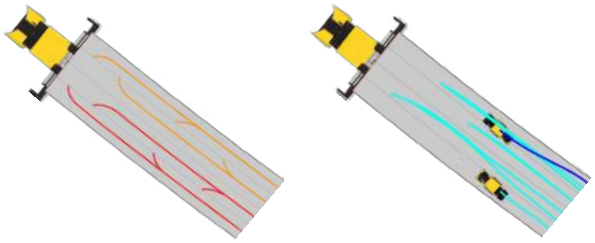

Figure 8. Simulated (orange, red) vs. human (turquoise, blue) trajectories in correlation to paved fields (gray).

9 Conclusion

This paper presented a novel approach for multi-robot collaboration in road construction. It provides an overview to the state of the art in autonomous road construction and multi-robot control. A formal road representation including layout, temperature, and compaction data is proposed. An inter-robot distributed BBS was used for task selection and assignment. Hereby, each roller competes for a task based on the suitability. The design compensates roller failures and distribute tasks accordingly. Finally, the system was tested in simulation and compared to real road construction data.

Future work targets an even more sophisticated road representation, which includes compaction errors as fractures, or bow waves. Additionally, the street model can be improved through considering more factors as different characteristics of mix proportions. Furthermore, varying asphalt supply as well as fluctuating weather conditions like wind or rain can be considered and impact on assignment and quality investigated. Finally, the concept should be tested using the real 5G-AMMCOA demonstrators.

Abstract –

Importance has been placed on improving productivity at construction sites in a recent year, reducing bitterness and repetitive work, and improving the efficiency of inspection and management work. Since buildings usually have a unique shape, efficiency improvement methods used in mass production plants had not been able to be applied, however, due to the recent progress in machine learning and robotics technology, complex works have also been becoming possible gradually. Especially at a construction site where the gross floor area is large, it is necessary to spend a lot of time for checking the status of daily situations and inspection work, and then it is often discussed as an object of efficiency improvement. There are also attempts to autonomously run the rover at a construction site, photograph the surroundings with a camera, automatically check a situation with Building Information Model (BIM), and identify the unusual part. However, the floor surface of the construction site is generally complex shape in many cases, for example reinforcing bars are exposed, it is not easy to run around. Accordingly, we focused on Unmanned Aerial Vehicle (UAV) as a means to move freely without concern the shape of the floor. There are many merits because it is possible to move in any structure as long as it is a small UAV, and it is also possible to grasp states of a high altitude that cannot be reached by a rover. Although autonomous flight of UAV is almost established outdoors, the introduction of indoor autonomous flight has not advanced yet because localization technology and object recognition technology are insufficient, and the risk of damage to people and structures due to collision and fall. There are some UAVs equipped with collision avoidance sensors, and safety is not guaranteed completely. Therefore, in this research, we developed a high safety UAV against collision and falling and conducted experiments on verifying the efficiency of inspection work and the possibility of visualization of acquired data. To ensure strong safety, a balloon type fuselage was manufactured, and collision tests and drop tests were carried out to confirm that it is incredibly safe. Besides, we performed a flight test in the indoor construction site using the UAV and demonstrated that it could be used for inspection work. Furthermore, the walkthrough view was generated from the photographed image for making daily progress management easily. As the results, it was confirmed that some works of walking around the construction site for checking would be reduced, and productivity will be improved. In the near future, we aim to collect data by autonomous flight at night when work is stopped and to create a database of daily information.

Keywords –

Construction management; Inspection; UAV

1 Introduction

The productivity of the construction site has not much changed for decades. Improvement of productivity such as reduction of repetitive work, inspection, and management optimization by cooperation with BIM, becomes an urgent issue. Since the shapes of buildings are usually individual, productivity improvement has been not natural so far. However recent drastic advancement in machine learning technology and robotics technology, even complicated works have also been becoming possible. For example, Shimizu Construction has built a Shimizu Smart Site (Fig. 1[1]) which has been running horizontal slide cranes, column welding robots, arm robot, and horizontal/vertical conveying robot autonomously with artificial intelligence (AI) and internet of things (IoT). The operation status and the work results are recorded and accumulated in real time in the management system integrated with BIM and can be confirmed at any time on the tablet screen, which leads dramatic reduction of work.

Regarding inspection work, it is necessary to spend a lot of time for checking the status of each day and detecting abnormality at construction sites where the total floor area is wide in particular. Typically, a worker is occupied by the inspection work for several hours in a day because pictures taken by a camera at each point including high-place is required. Then it is often cited as an object of efficiency improvement. Thus, there are many attempts to autonomously run a rover at a construction site, photograph and check the surroundings with cameras automatically with the building information model (BIM), and identify the abnormal part[2]. The accuracy of detecting concrete cracks and tile damage by camera imagery has been improved by using AI and machine learning techniques.

However, the floor surface of the construction site is generally in a complex shape in many cases. For instance, since the reinforcing bars are exposed, it has risks and dif-

Figure 1. Shimizu Smart Site

ficulties to walk around. Then we focused on Unmanned Aerial Vehicle (UAV), especially multirotor as a means to survey the site freely without the constraint of the shape of the floor. There are many merits because it is possible to fly any structure as long as it is a sufficiently small UAV, and it also makes possible to grasp the situation of a high altitude that cannot be reached by a rover. Autonomous flight of UAV is generally utilized Global Navigation Satellite System (GNSS), various cameras, Light Detection and Ranging (LIDAR), etc. However, GNSS can only acquire absolute position outdoors, distance accuracy from the camera is low while it is relatively easy to recognize an object, the weight of LIDAR is large while it has high distance accuracy. Although autonomous flight of UAV is usually achieved outdoors, indoor flight has a risk of damage to people and structures due to collision and fall because of the difficulty of localization technology and object recognition technology have not sufficiently developed yet. Carnegie Mellon University[3] and Pennsylvania University[4] are working on research of autonomous flight in GNSS-denied environments, and partially succeed in flying while carrying out localization and obstacle avoidance even in complex shape. Although there are some products equipped with collision avoidance sensors, these are not entirely guaranteed safety. Utilizing UAV for indoor inspection by comparing to BIM is not yet practically sufficient[5] because of the above reasons.

Therefore, in this research, we developed a quite safe multirotor against collisions and falls. Flight experiments were conducted for verifying the efficiency of inspection work and the possibility of visualizing the acquired data. To ensure reliable safety, a balloon-type fuselage was manufactured. Collision and drop tests were carried out to confirm that it was extremely safe. Since it uses injected helium gas, it also has the advantage of increasing the payload weight by buoyancy. Besides, we conducted a flight test in an indoor construction site using the multirotor and demonstrated that it could be used for inspection work. Furthermore, walkthrough view was generated from the photographed imagery which makes daily progress management easy. As a result, it will reduce the amount of walking and checking works, which means productivity considered to be further improved.

Ultimately, we plan to aggregate data by autonomous flight through the night when work is stopped and to create a database of daily information automatically in the future.

2 Method

2.1 Concept

As mentioned in the previous section, general multirotor has the risk of crash and collision, and it is not allowed under current circumstances to use it at the construction site where safety is of utmost importance. Also, if the interior is damaged before completion, time and cost will be wasted. Therefore, in any case, safety must be ensured. As a means to solve this problem, a structure having a spherical frame, a structure hanging from a spherical balloon, a method of mounting an airbag, a structure of extremely lightweight, and a way of making the UAV itself a balloon-type are conceivable. Although the spherical shell structure is lightweight, there is a risk that it may be caught by reinforcing bars or pipes at a construction site, the method of hanging from a spherical balloon is challenging to ensure mobility, the airbag has uncertainty of deployment, lightweight body has a disadvantage that cannot mount a highly accurate sensor.

Therefore we focused on balloon-type multirotor, which can overcome any of the above drawbacks. First, we confirm the flight performance using this balloon-type body. Also, experiment by changing the type of camera installed, and confirm what kind of capturing method is most beneficial to the construction site. The camera to be used is a spherical camera, infrared camera + visible camera, and a high-resolution action camera.

Since the operator must easily check the photographed image, a visualization test is performed by creating a walkthrough view of the work site for validity confirmation. In the future, we will build a system that automatically carries out everything from site photographing by autonomous flight to visualization.

2.2 Balloon-type Multirotor

The figure 2 shows the developed balloon-type multirotor. The position and attitude angles are controlled by the rotational speed of the four propellers attached to the rods. In the center of the body, communication equipment, control equipment, battery, and camera are installed. Depending on the application, the camera can be replaced

with a spherical camera, an infrared camera, an action camera, etc., and its orientation can also be changed.

As shown in the table 1, the outside body is covered with polyvinyl chloride so that both collision safety and buoyancy are acquired by injecting helium gas into the inside. Since it is a prototype, the payload that can be installed at present is as small as 0.3 kg and the flight time is as short as 10 minutes, but these can be improved by the design refinement and the advance of battery performance. The propeller noise is the same as a conventional multirotor, and the flight speed is about the same as a person's walk. Also, video transmission by wireless is also enabled. Because it is very safe against a collision, it also has the advantage that it is possible to take close-up shots when examining walls and ceilings.

Figure 2. Balloon-type Multirotor

Table 1. Specification

Size	$\phi 1.2x0.6$ m
Weight	1.6 kg
Buoyancy of helium gas	−0.3 kg
Endurance	10 min
Speed	1.0 m/s
Membrane	PVC

2.3 Time-Series Spherical Viewer

There are various ways to visualize the acquired data, such as three dimensional model generation by Simultaneous Localization and Mapping (SLAM)[6, 7], Structure from Motion (SfM)[8], a database of images by cooperation with indoor positioning system by Bluetooth beacon or ultra-wideband (UWB), fixed camera images, immersive viewing system with virtual reality (VR) headset using spherical imagery, and so on. However, as the result of our examination and hearing, we found that the walkthrough view of spherical images can be most intuitively operated and the inspection is easy. Therefore, by using commercially available Holobuilder[9], it is possible to browse by moving to the target place simply by clicking the points on the screen or clicking the position on the drawing. Additionally, since images can be saved in chronological order, it is also possible to confirm daily changes, progress, and the cause when an abnormality occurs.

3 Results

The size of the multirotor body is 1.2 m in diameter that is rather large in the present situation, and then the flight experiment was carried out at the site under construction of sufficiently large space (Fig. 3). As a component where inspection is difficult with a general rover, the diagonally below the catwalk near the ceiling was selected as the experimental location.

According to preliminary verification experiments, it was found that the body is very safe against collision and fall, and not damage the object. Additionally, depending on the environment it turned out that the multirotor was liable to disturb the attitude angle by the wind. This is thought to be due to the fact that the shape of the body is ellipsoidal, vortices are likely to occur around the periphery, and the drag coefficient is relatively large. Also, since the inertial efficiency is larger than that of general multirotor, it requires more energy to restore the attitude. The airflow due to convection was confirmed although the influx of wind was also shut out at the experimental site, it was able to stably fly by adequately tuning the attitude control parameter of the multirotor. Typically, when the aircraft is too close to a wall or object, it is likely to be sucked in because the air current is disturbed and the posture is not stable. Nevertheless, such a phenomenon did not occur in this experiment. However, due to the shape of the fuselage and the lack of performance of the propeller, the robustness of attitude stability against a wind more than 1 m/s is not enough at the moment. In the future, it is necessary to improve so that it can maintain stable attitude and position in any wind environment.

Figure 3. Inspection of Catwalk

The figure 4 is an image of a spherical camera (Ricoh Theta V). Because interval shooting is possible, we shot every 4 seconds this time. The resolution of the photo is 5376 x 2688 pix, and the weight of the body is 121 g. As shown in the figure, since the camera is attached to the upper part of the UAV, the lower one third is hidden by the balloon film surface. However, there was no problem

Figure 4. Onboard Spherical Camera

because this purpose is photographing in the upward direction, and further the camera can be attached to the lower part, and then it can be changed according to the purpose.

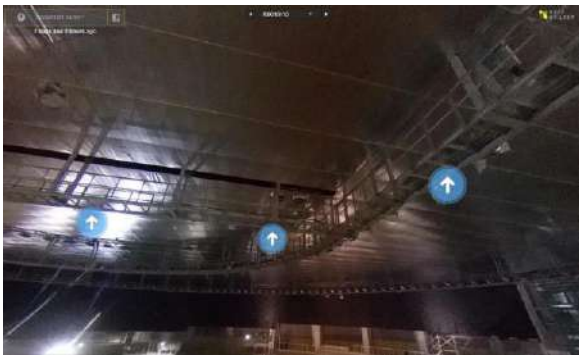

Figure 5. Walkthrough View

The figure 5 shows an example of created walkthrough view from the above spherical camera image using Holobuilder which is on-site image management software. The image can be rotated and scaled quickly, and by clicking the arrow arranged on the picture, it is possible to move to the viewpoint image from the place. By registering the position of the image on the drawing, it becomes possible to view the whole sky ball image at the viewpoint of the desired place. Furthermore, since images can be managed in time series, it is possible to manage daily progress. Also, data is managed on the cloud, and then it can be shared and edited by multiple people. It also has functions such as adding annotations, browsing from mobile devices, and distance measurement. Although it is useful software in visualization, it has a disadvantage that it requires human work such as registration of a position of an image. Recently, the software that can automatically performs localization from a movie and image extraction also appears.

Figure 6. Onboard Action Camera

The figure 6 is a captured image of a motion picture taken by action camera (GoPro Hero 6, 120 g weight). It is possible to take a picture at 4K (3840 x 2160 pix), but this time for the purpose of image processing, we shot at 2.7K (2704 x 1520 pix) using Linear View function with lens distortion removed. The image was very clear, and it was possible to grasp the state of the bolt finely and so on. It was also found out that it was possible to reconstruct the 3D model by SfM from Linear View images. However, position information such as a marker is indispensable for high-precision 3D reconstruction, however, it is not desirable to increase the amount of people's work at the construction site where the environment changes every day. It is a future subject to realize everything automatically and unattended.

The figure 7 is an image by FLIR Duo R (84 g weight) which is a combination of an infrared camera and a visible

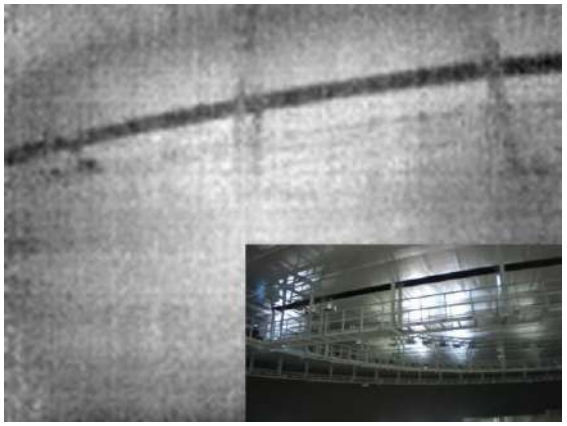

Figure 7. FLIR Infrared & Visible

light camera. As for the resolution, the infrared image is 160 x 120 pix, and the visible light image is 1980 x 1080 pix. Using SfM software such as Pix4D[10], it is possible to paste an infrared image as a texture to a three-dimensional model reconstructed by a visible light image. Researches on abnormality detection using infrared images have been actively conducted for discovering tile deterioration, concrete cracks, or estimate distortion from the temperature of the structure by utilizing artificial intelligence. The resolution of the infrared camera used this time is not sufficient, although it can distinguish a specific temperature difference.

4 Conclusion

We developed highly safe UAV and verified the performance for improvement the productivity of inspection work at a construction site. To ensure reliable safety at any time, a balloon-type multirotor was manufactured. Collision tests and drop tests were carried out to confirm that it was extremely safe. We also conducted a flight test at the construction site of the large indoor space using the multirotor and demonstrated that it could be used for inspection work using the equipped camera.

In the flight experiment of this time, The airflow due to convection was confirmed although the influx of wind was also shut out at the experimental site, stable flight was possible with adequate tuning of the attitude control parameter of the multirotor. However, it easily drifts against the wind and the attitude stability is not sufficient due to its shape of the fuselage. Therefore, future improvement of the robustness against environmental uncertainties is necessary. Also, since the size of the fuselage is slightly big at 1.2 m, it should be miniaturized to a size of less than 80 cm which can pass through the door. Further, since it is not easy to handle helium gas at all times from the viewpoint of cost and operation, it is necessary to improve so that handling can be easily performed with air injection.

Three-dimensional reconstruction by SfM using action camera images is expected, however artificial correction information such as markers is indispensable for highly accurate reconstruction currently. The situation and environment at the site that change every day, it is not desirable to increase the amount of people's work at the site, and it is a future subject to make everything automatic and unattended. Regarding infrared images, if high-resolution cameras are used to make meaningful data, there is a possibility that defects can be found by using machine learning techniques. For the whole sky ball image, we created a walkthrough view to facilitate day-to-day progress management. As the results, it was confirmed that some works of walking around the construction site for checking would be reduced, and productivity will be improved. However, although it is useful software in visualization, it has a disadvantage that it requires human work such as registration of a position of an image. The software that can automatically perform localization and extraction is needed.

In the future, we plan to aggregate data by autonomous flight through the night when work is stopped and to create a database of daily information automatically.

Abstract –

Injuries and fatalities resulting from workplace accidents remain a global concern within the construction industry. While education and training of personnel offer well known approaches for establishing a safe work environment, Serious Games in Virtual Reality (VR) is being increasingly investigated as a complementary approach for learning. They yet have to take full advantage of the inherent data that can be collected about players. This research presents a novel approach for the automated assessment of players' data. The proposed method gathers and processes the data within a serious game for instant personalized feedback. The application focuses on close calls and contact collisions between construction workers and hazards like equipment, harmful substances, or restricted work zones. The results demonstrate the benefits and limitations of safety information previously unavailable, or very hard or impossible to collect. An outlook presents work ahead for practical implementation in existing risk management processes.

Keywords –

accident investigation, close call, construction safety, equipment contact collisions, hazard, human-hazard interaction, risk prevention, serious game, situational awareness, virtual reality, workforce education and training.

1 Introduction

The original inspiration to conduct this research stems from a scientific study on construction accident investigations [1]. It found that approximately 13% of all construction workplace fatalities in the United States relate to too close contact with construction equipment or parts of it (like attached loads) [2]. While construction equipment is dangerous, other industries in engineering suffer from similar problems. As shown in Fig. 1, the location (marked with "x") of 29 coal miners killed while at work between 1984-2004 could only be determined after the tragic loss of their lives. The image depicts detail to the miners who were either remotely operating (72%, indicated by a blank circle) or maintaining (grey shaded circle or square) a continuous miner. The figure is – due to its rarity of pointing out the victim's location – regularly shown in construction safety education classes. However, current learning methods do not engage the trainees in other effective ways of self-experiencing high risk work activities. These often cannot be implemented, especially in field-based safety training where they would endanger one's life [4, 5].

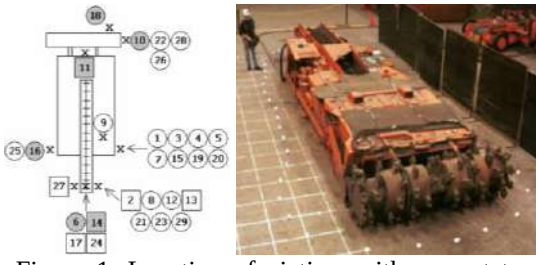

Figure 1. Location of victims with respect to a continuous coal miner (closely related industry) [3]

The novelty of the proposed approach is to provide a safe learning environment where mistakes can be made without suffering the normal consequences. The general hypothesis is that wrong judgement – whether conducted knowingly or not – can be discovered and eliminated by training early on, before it happens at the workplace [6].

Several best practices exist today to mitigate risk in organizations early, starting with a good safety culture and tight safety processes. The layers in the hierarchy of controls, however, still have to take full advantage of data that can be provided by technology during training sessions. Data mining in serious games can offer participants instant personalized feedback.

This research first designed a safe learning process, then a learning platform using serious games in virtual reality (VR). The implementation of a realistic VR environment was supported by the latest, commercially-existing head-mounted display (HMD) units and actual three-dimensional worksite models and schedules (4D) using Building Information Modeling (BIM). Several hazards related to close calls (aka. near misses) and contact collisions between construction workers,

equipment or its parts, harmful substances, and restricted zones were added to the virtual construction scene. Consequentially, close calls and contact collisions were defined based on given occupational safety and health standards. Participants with some construction experience tested the scenario individually while personal safety performance data were collected and analyzed in real-time. Instant quantitative analysis and visual safety performance information became available that is used for personalized feedback and improvement.

2 Background

For years Virtual Reality (VR) has been used for training purposes. A high number of VR applications exist in the fields of military, aviation, and medicine. For example, a serious game (defined 'serious' because of a primary purpose other than pure entertainment) helped to increase the awareness of airplane passengers in case of an emergency situation [7]. Like many studies, it evaluated two user groups (one group using the traditional approach with safety cards, the other using a serious game) based on questionnaires and pre- and exit-interviews. Studies related to construction [4-5,8-12] concluded that VR-based safety awareness training offers more engaging learning environments. Study participants also reported to favor personalized feedback over no feedback (as commonly in lectures, videos, or demonstrations) [5]. Some of the benefits of VR-based safety training are:

- presents trainees with hazards directly and realistically without compromising their own safety;
- holds the attention of trainees better than conventional classroom teaching does;
- gives trainees a measure of control in the environment, thus reinforcing learning; and
- allows trainers to repeat learning content for many participants under the same training conditions.

VR learning scenarios were criticized by some for being unsophisticated and unrealistic compared to the real world experience [12]. A reason is that creating VR scenarios is a very time-consuming task, requiring a lot of attention to fine details [5] such as programming logic, whereas [6,13-14] proposed using BIM to increase the realism level of VR scenes. While using 4D models adds additional return-on-investment to create BIM data (e.g., beyond its use in design/planning tasks or for providing visual walkthroughs), reducing motion sickness for some players, teaching people unaccustomed to computerized environment, creating multi-user environments (incl. training larger groups), and providing options to instantly record and analyze the players' behaviors seem to be challenges for realistic VR-implementations. Known limitations are:

- Although hard- and software technology are rapidly evolving, the investment of developing training materials and virtual construction scenarios is high.
- Several studies [5,10-12] claim that the gained safety knowledge of some trainees may remain at similar levels compared to standard learning approaches.

While some of the issues create needs for additional research, they remain outside the scope of this study (e.g., motion sickness and multi-user environments). This study addresses an effort towards real-time data collection and instant analysis in an immersive serious game for a more detailed construction worker-equipment close call and contact collision assessment.

3 Proposed method

This section explains noteworthy details to the research methodology, its objective and scope definition. As illustrated in Fig. 2, the developed virtual safety learning platform consists of a user (e.g., (un)skilled construction worker), a virtual construction site environment (e.g., 3D content generated from 4D models or open source libraries), scene- or object-related content (e.g., typical sounds), and soft- and hardware technology (e.g., authoring tools and head mounted displays, respectively).

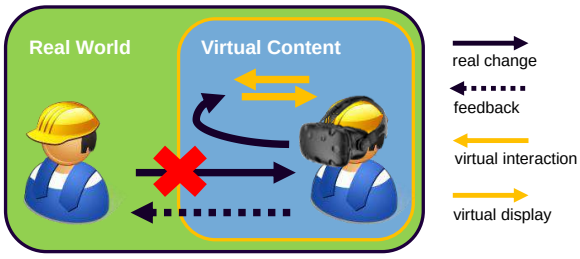

Figure 2. VR safety learning platform [15]

While a person may have previous education and experience (i.e., related to construction safety), advanced tools for automated, in depth, and personalized performance analysis and feedback are not existent in today's practice (research objective). Personal safety skills particularly to close call and contact collision detection and analysis of construction workers to hazardous equipment or restricted work areas will be tested (research scope definition). VR technology is used as it provides a safe work environment (called an experimental testbed) where humans can make mistakes without suffering the losses they would typically experience in the real world. Thus, further processing of any worthwhile information generated in the virtual world (e.g., the location of close calls or contact collisions, their frequency and types) might be applied to improve the working conditions in the real world. Since 4D-models normally exist before construction starts, such information (e.g., relations between 3D objects and

construction sequence) will be used to generate realistic virtual work environments. The following explains how VR is used to advance the analysis and control.

3.1 Visualizing and controlling

VR consists primarily of hard- and software components. While multiple commercial systems exist, this approach used the head mounted display (HMD) HTC Vive Pro (2018 Version) for visualization and control and the game engine Unity3D for authoring content. Although VR raises the immersion effect of the user, it is still challenging to achieve a high realism of VR scenes. Two controllers give a player the opportunity to interact within the virtual construction scene. The lighthouse-system tracks the head-mounted display and controller movements via the emitted infrared rays. A computer combines and finally sends data from the graphics processing unit to the displays of the virtual reality headset. To reduce latency and diminish motion sickness the refresh rate should be close to 90 Hz [14].

3.2 Processing

The second technology which was used is the gaming-engine Unity3D. While the virtual construction scenario is created in Unity3D, it offers programmers many additional functionalities like collision detection or physical handling. To use the HTC Vive tracking system in Unity3D the "steamVR"-plugin" [17] is needed. This plugin contains necessary objects like the "[CameraRig]"-object which handles the communication between the HTC Vive tracking system and the operating computer. The "[CameraRig]"-object has three child-objects: "Controller (left)", "Controller (right)" and "Camera (head)". Both of controller-objects are used to handle the player's input. They visualize the controller's position and rotation in real-time. The "Camera (head)"-object is used to show the direction of the player's view. A player uses the touchpad of the right HTC Vive controller for moving within the VR scene.

3.3 Authoring content and model functions

Construction site models from a real project and additional 3D models (e.g., equipment and materials) from the internal Unity3D Asset Store, online libraries for free share or for purchase, self-modeled models, or other sources served as content to create a serious game which was tested by players. To increase a player's immersion effect, the selection of 3D models plays a pivotal role. Compulsory to the construction scene model were models of a construction worker, a tower crane, a skid steer loader and several smaller construction objects to illustrate two restricted work areas.

Unity3D supports files with .fbx-, .dae-, .3DS-, .dxf- and .obj-extensions [17]. All selected models were converted into the file extension .fbx and made available for further use in Unity3D. They should have the same quality in order to keep the player´s experience, an realistic level. The acceptable number of polygons are preferred, because a higher number influences the computing performance negatively. Once the required models with the supported extension are fetched, they can be imported into the Unity3D-project. While recently announced plugins allow exporting/importing native building information models into Unity3D [17], this research used a self-developed approach [12] to import .IFC models directly. Via drag-and-drop the models can finally be placed into the Unity3D-scene. Within the scene the position, the rotation, and the scale-properties of the models can be adjusted using the inspector-window.

3.3.1 Construction scene

For this research, an existing building project incl. the 3D models (e.g., model of neighboring buildings, detailed site layout plan, pit model and structural model, incl. reinforced concrete walls, columns, and slabs) and the construction schedule served as the main source of information. Fig. 3 shows the resulting scene model.

Figure 3. Construction scene (isometric view)

3.3.2 Construction worker

A 3D-model of a construction worker (Fig. 4) allowed to visualize the movement of the player. The following pseudocode explains the movement in the scene.

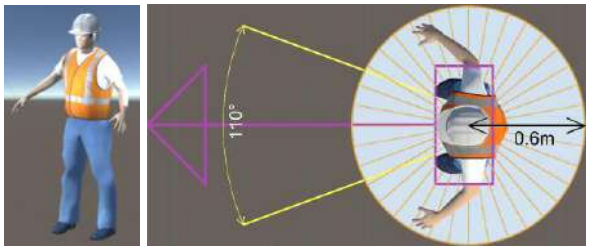

Figure 4. 3D model view of the construction worker with PPE (left); the bounding cylinder field-of-view of head-mounted display (right)

The Start-function initializes the right HTC Vive Pro controller, when the simulation starts. The Update-function checks in every frame whether the worker has pressed the right controller's touchpad. The task of this pseudo C#-script is to move the 3D-model of the worker dependent on the input of the right controller's touchpad.

Pseudocode 1: Movement of the construction worker

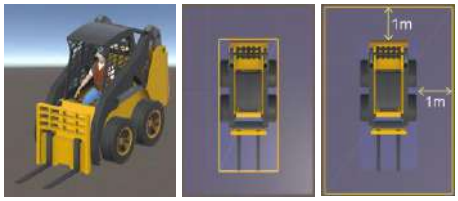
```
Start(){
  rightController.initialize();
}
Update(){
  if(rightController.touchpadTouched)){
    WorkerPosition += touchpadInput * movementScale;
  }
}
```

The developed approach displays two additional items (Fig. 4): (a) an arrow that visualizes the direction of the worker's field-of-view (FOV) in real-time and (b) a circular layer, defined as the safety envelope [6,18]. A player's FOV covers 114° [19] (compared to 110° of the Vive tracking system). The arrow's purpose is to give trainers or by-standers administering or observing a training session an immediate understanding which direction the player is looking at. Data collected to the FOV can further be analyzed, as explained later.

The construction worker's safety envelope has a radius of 0.6 m and represents a typical adult person's shoulder width [5]. This segmentation assists in the counting of the number and the direction of close call or contact collisions. Segments with higher counts thus explain how often and from where the worker collided with hazards.

3.3.3 Equipment

A model of a skid steer loader with operator [17] (Fig. 5) travels (for now) on a pre-scripted path within the scene. The purpose is to cause, and later help analyze model interactions from construction workers and equipment. To add further complexity to the scene, a tower crane with a moving load (Fig. 6) was added to the scene.



(a) (b) (c)

Figure 5. (a) 3D model of skid steer loader and operator, (b) bounding box encompassing all physical elements, and (c) 1 m-safety envelope

Figs. 5b-c further shows two different layers which are important for the close call and contact collision data recording and analysis. The first layer bounds all of the physical parts of the skid steer loader to a box. The second layer represents, according to the ISO 5006 standard, a 1 m-safety envelope to each side of this bounding box [20]. No worker is allowed to enter either area, otherwise a contact collision or a close call, respectively, is called. The crane load is also given a 1.5 m safety envelope.

Figure 6. Model of tower crane and load

3.3.4 Harmful substance, restricted work zone, and other object models

Among the many potential construction hazards are the handling of harmful substances and the prohibited entrance in restricted work zones. A gas bottle and an electric power generator (Fig. 7) were placed in the scene as representative examples. The safety envelope of the gas bottle was set to a 1 m radius. 3 security fences around the generator and a nearby wall formed a restricted work zone of 2.5 m×3 m. Despite shortcut options, no player was allowed to enter either one. The scene also consisted of a recycling container, which each player had to fill with recycling bags.

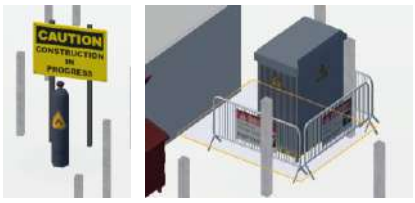


Figure 7. Models of harmful substance (left) and restricted workzone with security barriers and a shortcut option (right)

3.4 Player's mission

Each player was in the role of the construction worker. Equipped with the HMD and controller's touchpad a player traversed through the scene. Their mission was to pick, walk, and finally place 5 recycling bags, one after the other, in a nearby container. Figure 8 shows the construction scene. The gas bottle and the generator with its associated fences were placed in such way that all players had the opportunity of entering their respective safety envelopes. For example, a player may squeeze by the security fences (an obviously shorter, but more dangerous path). While completing their mission, the players further had chances to interact with the skid steer load and crane load.

3.5 Data gathering in VR

3.5.1 Close calls and contact collisions

The second pseudocode shows how to detect a close call or a contact collision between the construction worker's and the crane load's safety envelopes:

Pseudocode 2: Collision detection

```
OnCollisionEnter(){
  If(collision.name == "CraneLoadLayer"){
    CollectDataOfCollision();
    CreateCyanSphereOnGround();
  }
}
```

The OnCollisionEnter-function (provided in Unity3D) detects collisions between two objects: A pseudo C#-script attached to the construction worker's safety envelope layer checks whether it collides with, for example, the crane load's safety envelope layer. If it does, it collects timestamped data of the actual positions and speeds of the construction worker and the crane load. Simultaneously, the CreateCyanSphereOnGround-function sets a cyan colored sphere (a visual marker) at the position of the close call position in the virtual scene.

While placing a visual marker provides real-time feedback for the user (and might be helpful in sensitizing his/her behavior), it might influence the data recording in the remainder time of playing the serious game. For this reason, the option of visualizing the markers right away can be set inactive.

The developed serious game designed 6 different collision types (colors). Fig. 8 shows the visual markers obtained from participant 1 in the construction scene. As explained later in detail, it includes the trajectories of the skid steer load and the crane (both scripted, in blue and red colors, respectively) and the construction worker (participant's actual path, in green color).

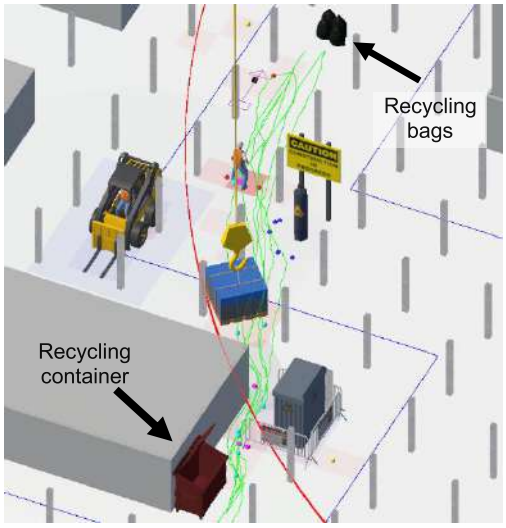

Figure 8. Various types of automatically detected close calls and contact collisions (incl. markers)

A collision point becomes red if the construction worker's safety environment layer collides with the skid steer loader's 1 m safety envelope layer (Fig. 5c). Black cubes are set to the scene's ground if the construction worker's safety envelope collides with the skid steer loader's bound box (0 m) (Fig. 5b). Every type of close call or contact collisions receives its own color (Table 1). This differentiation makes the post analysis between trainer and trainee more effective. For example, a black marker means the player made physical contact with the skid steer loader. While this may result in the real world in life-threating damage, a trainer may give a trainee special responses if such colors appear.

Table 1. Color scheme of close calls & contact collisions

Collision type	Color (Size of safety envelope)	Marker color
Construction worker (0.6m)	Skid steer loader (1m)	**Red**
Construction worker (0.6m)	Skid steer loader (0m)	**Black**
Construction worker (0.6m)	Crane load (1.5m)	**Cyan**
Skid steer loader (1m)	Crane load (1.5m)	**Yellow**
Construction worker (0.6m)	Gas bottle (1m)	**Blue**
Construction worker (0.6m)	Electric generator, Restricted work zone (0m)	**Magenta**

3.5.2 Trajectories

During the entire play time, the trajectories to each moving object are recorded. The blue and green lines, for example, show the trajectories of the skid steer loader and the construction worker, respectively. These can be visualized in real-time while playing or for later analysis (Fig. 8), for example, to reason about collision angle and speeds. The following pseudocode shows how the trajectories of objects are visualized:

Pseudocode 3: Trajectory visualization

```
Update () {
  DrawLine(oldPosition, currentPosition, green, 999);
  oldPosition = currentPosition;
  currentPosition = new Vector3(currentXPosition,
    currentYPosition, currentZPosition);
}
```

The pseudo C#-script is attached to the 3D-model of the construction worker. Its task is drawing the trajectory of the worker first using the internal Untiy3D-library (which offers the DrawLine-function). The function has the input values: 3D-vectors (oldPosition,

currentPosition), a color (green), and a number (999). The latter defines how many seconds the line should be visible. The first 3D-vector defines the start position of the line (oldPosition: the position of the last frame) and the second 3D-vector defines the end position of the line (currentPosition: current frame). Finally a green line between both positions is drawn. The 3D-vector oldPosition is updated in every frame. Analogue thereto a similar pseudo C#-script is attached to the skid steer loader and the crane load (blue and red lines, respectively).

3.5.3 Heat map, statistics and video recording

In order to visualize the location and frequency of close calls, a C#-script generates a heat map after [6,18]. The heat map is divided into equally sized squares (1 m×1 m). Each square changes its saturation from a bright to a dark (red) color as the number of close calls in the square increases. Darker colors probably refer to a location on the virtual construction site that deserves further attention and/or corrective action by responsible safety personnel. Fig.9 shows in an example the different saturation levels. A built-in bird-view camera provides at the end of each serious game a screenshot of the resulting heat map. It can be used for feedback with the player.

Figure 9. Close-up view of heat map: Increasing saturation visualizes higher number of close calls

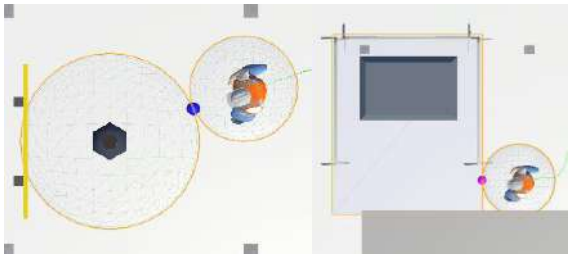
Further functions were scripted to offer detailed insights on the whereabouts and frequency of the recorded close calls. Examples like investigation of angles and speeds were mentioned already. Every gaming session was recorded using virtually placed cameras. Such video material was used occasionally for playback, giving the participant opportunity to explain behavior or simply modify the construction site layout. Although these options exist, they were not explored in this research at this time.

4 Tests and results

The results of testing 3 participants are presented. Every participant was able to choose their own path through the construction scene to complete the task. They were first instructed on the functionality of the VR equipment and told in advance that time to complete the task is of importance. Signs to restricted work areas in the scene and the possibility of oncoming traffic (a skid steer loader and a crane load) were not explained ahead of time.

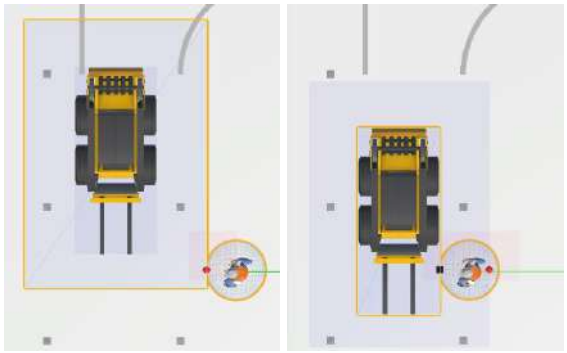
4.1 Close call and contact collision events

Within the developed serious game close calls and contact collisions occurred with static hazards: a participant (without the proper safety experience nor in possession of an adequate training certificate) was getting too close to a gas bottle (blue marker, Fig. 10a) or was entering a restricted work zone (magenta marker, Fig. 10b). The second observation shows a too close human-machine interaction. Red (Fig. 11a) and black markers (Fig. 11b) were left at the close call positions accordingly. Fig. 13 illustrates the third example of a recorded close call between the construction worker and the crane load.



(a) (b)

Figure 10. Construction worker: (a) proximity to gas bottle and (b) entrance in restricted zone



(a) Close call: t_1=120s (b) Collision: t_2=121s

Figure 11. Worker-skid steer loader close call and contact collision at two consecutive timestamps

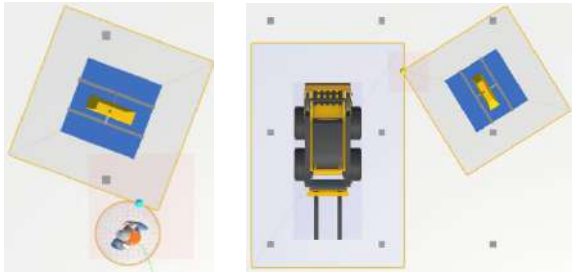


Figure 12. Close calls with crane load: construction worker (left) and skid-steer (right)

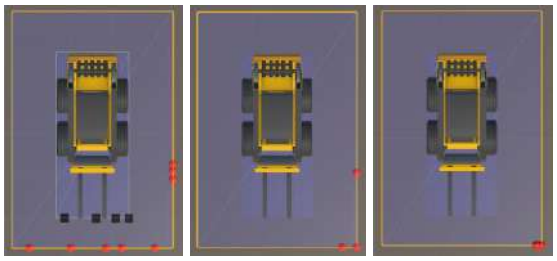
The required time for completion of the same work task by all 3 participants were 193, 298, and 177 seconds. While one might think that the number of close calls might increase with the speed a participant executing the mission, the third participant was the fastest and safest.

Table 2 summarizes the results of the independent tests. Participant 1 had by far the most close calls and was the only one who made contact collisions with the skid steer loader (4). The second participant had less, while the third had the fewest. In brief, the first test participant had 48 close calls within the 3 minutes and 13 seconds needed to complete the mission. In brief, while all participants deserve (additional or first time) safety training, the first participant should attend basic safety education (had 4 contact collisions, entered restricted work areas).

Table 2. Number of close calls

Type	Hazard	Participant			Sum / Avg
		1	2	3	
Crane	Overhead load	20	10	2	32 / 10.6
Skid steer loader	Close call (1m)	8	3	2	13 / 3.3
	Collision (0m)	4	0	0	4 / 1.3
Gas bottle	Proximity (1m)	10	0	0	10 / 3.3
Restricted work zone	Entrance	10	0	0	10 / 3.3

As explained in the introduction section, visuals are important to communicate the cause of close calls or contact collisions. Fig. 13 illustrates the precise location of each of the participants' self-made experiences. It appears that all participants in this study had such events in the front-left of the skid steer loader's driving direction. While this is quite the opposite to the equipment shown in Fig. 1, this in fact due to the scripted path of the skid steer loader (traveling only forward). Had a multi-user environment with a second or third player operating the equipment existed, the result may have looked differently.



(a) Participant 1 (b) Participant 2 (c) Participant 3

Figure 13. Close call & contact collision locations

Data in Fig.14 shows the performance of the first participant over the game time. The large number of crane load swings becomes visible. Future training may point out this important safety issue still very common to many workers on construction sites (and even in this virtual game).

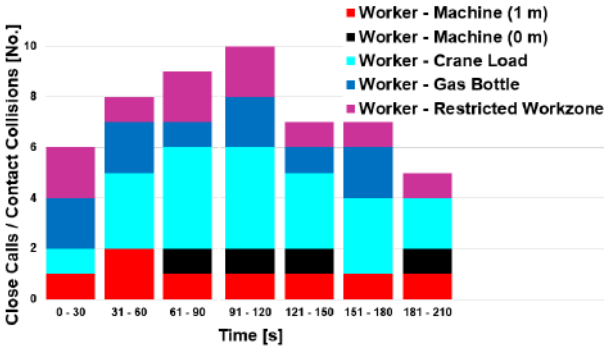


Figure 14. Close call & contact collision numbers

4.2 Heat maps

Heat maps were drawn. Fig. 15 displays the heat map of the first participant. Position and frequency of close calls and contact collision events become visible. While the other participants' heat maps were different, a site safety layout plan always could now be adjusted based on the observed 'hot spots' (arrows pointing to darker red cells). It seems in this situation that the construction worker's path collided with the skid steer loader, crane load, gas bottles and restricted work area. Skid steer loader and crane load had several close call situations as well. While some hot spots were expected (worker passing scripted equipment path), this may still result in decisions towards modifying the internal traffic control plan, for example, the installation of a guided crosswalk.

Figure 15: Heat map to test data of participant 1

5 Discussion and conclusion

Serious games in VR have been around since the late 20th century. They are applied games designed for specific purposes other than pure entertainment, however, so far hardly collect nor analyze data that is readily

available in the game engine. This study developed and tested a serious game in VR that allows a player in a role (construction worker) to immersive into a construction scene (facing hazards). It became possible to record and analyze previously unknown data to close calls and contact collision to human-hazard interactions. Several benefits and limitations were found throughout the study that will help improve further research and development. In particular the difficulty of building realistic and meaningful (multiplayer) VR scenes, the size of the test group, human-behavioral issues, and impact on existing construction workface planning and safety processes (i.e. digital tools of any kind for pre-investigative construction risk analysis and prevention) play important future roles to make any kind of VR education and training an effective tool in construction.

Abstract –

It is well documented that Building Information Modeling (BIM) can significantly improve project performance and productivity. Although the construction phase typically involves in the largest part of financial cost during the project life, insufficient attention has been paid in academia to quantitatively address the impact of BIM on labor productivity. This paper studies the effects of BIM on field pipeline installation productivity using system dynamics modeling. The critical impact factors of BIM on pipeline installation productivity are identified and a system dynamics model is established to map the impact mechanism and quantify the BIM impact on labor productivity. The model is applied to evaluate the pipeline installation productivity of three large scale buildings and their productivity indices are compared. The comparison shows a positive impact of BIM on pipeline installation productivity, resulting in 13~38% of increase in labor productivity dependent on different trades and project phase of BIM application.

Keywords –

Information technology impact; BIM; system dynamic modeling; field productivity

1. Introduction

Labor productivity (LP) is an important index of project performance that reflects the cost conversion efficiency of a project. As reported by the US Bureau of Labor Statistics, the construction LP has been declining in recent years mainly due to the gap between design and construction, relatively low systematic information technology (IT) application and insufficient investment of research and innovation [1]. To improve the LP of the construction industry, significant changes are required in the development of information tools and the formulation of collaborative strategies. Embedding parametric design in a 3D platform, BIM has been proposed to improve construction LP since its emergence. The past decades have seen wide application of BIM in the global construction industry.

One typical example of BIM implementation in construction is to optimize complicated utility pipeline design and coordinate the field installation. There are a large number of utility pipelines with different functions such as water supply, gas supply, electricity circulation, and ventilation in residential and commercial buildings. Design errors and collisions happen frequently in traditional 2D design [3]. Through the application of BIM to arrange pipelines in a 3D space and coordinate on-site installation, the LP of pipeline installation could

be improved from 75~240% [4]. According to statistics in China, the production value of the utility pipeline installation in 2016 is 250 billion USD accounting for 8% of the total value of construction industry. The BIM application in this field has the potential to save substantial resources and generate significant benefits. However, improper BIM application may result in negative effects, such as project shutdown or even engagement of lawsuits and claims [5]. Therefore, study on impact factors and quantify the interaction among these factors is of critical significance to ensure effective BIM implementation. Limited research has been conducted in this field.

The construction activities in the supply chain are closely related and actively interacted, but the interaction between construction tasks is difficult to elaborate in the traditional network diagram due to the nonlinear impact of these activities. System dynamics (SD) is an approach to understanding the nonlinear behavior of complex systems over time using stocks, flows, internal feedback loops, table functions. It can explain system evolution trend and describing the dynamic influence of the internal links. This paper studies the effect of BIM on the LP of complex pipeline installation based on SD modeling. The critical impact factors of BIM on pipeline installation labor productivity （PILP）are identified and a SD model is established. The model is applied to evaluate the PILP of three large scale buildings and the task-level productivity indices are compared.

Table 1. Impact factors of pipeline installation productivity

Impact Factors	Organization	Management	Technical
(1)	Collaboration Degree	Change Orders	Model Precision
(2)	BIM Execution	Quality Control	IFC Application
(3)	BIM Specialist	Plan Compliance	Data Diversity
(4)	Owner’s Support	Risk Control	Localization
(5)	Teams BIM Expertise	RFIs (Requests for Information)	Add-on Development
(6)	Project Delivery Method	Time Delay	Software Function
(7)	BIM Applications	Total Workload	Data Exchange

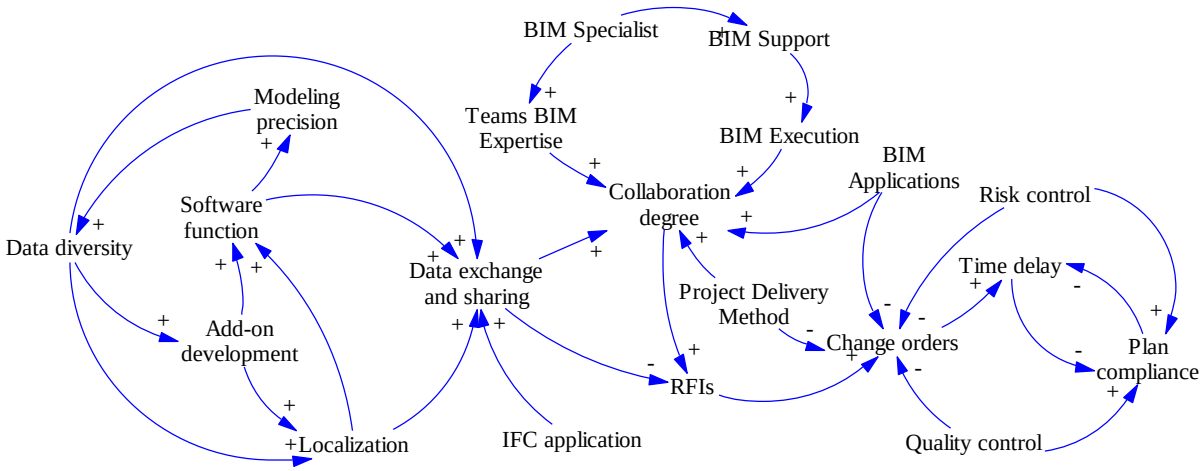

Figure 1. Overall casual loop diagram of impact factors

2. LP impact factor identification

The impact factors of BIM on PILP can be grouped into three primary categories related to the organization, management, and technical aspects of the project, respectively. Within each category, the major factors are identified as listed in Table 1. In total, 21 major impact factors are identified for further system modeling.

3. System dynamics (SD) modeling

In order to study the impact mechanism, a casual loop diagram is developed to qualitatively describe the logical causal relationship between the factors, then a stock and flow diagram is developed to quantitatively illustrate the interrelationship of variables, and the equations for deriving each variable are presented to form a SD model

.3.1 Causal loop diagram

The causal loop diagram describes the feedback structure of a complex system. It reflects the dynamic environment of a causal cycle and visualize relationship between variables and their interaction. By forming a closed feedback loop, the logical causal relationship between the factors are clarified.

The inter-relationship of the impact factors is visualized using a causal loop diagram as shown in Figure 1. By forming a closed feedback loop, the logical causal relationships among the factors impacting the BIM aided pipeline installation productivity are clarified. The factors are with both positive and negative feedbacks and different subsystems interact with each other.

.

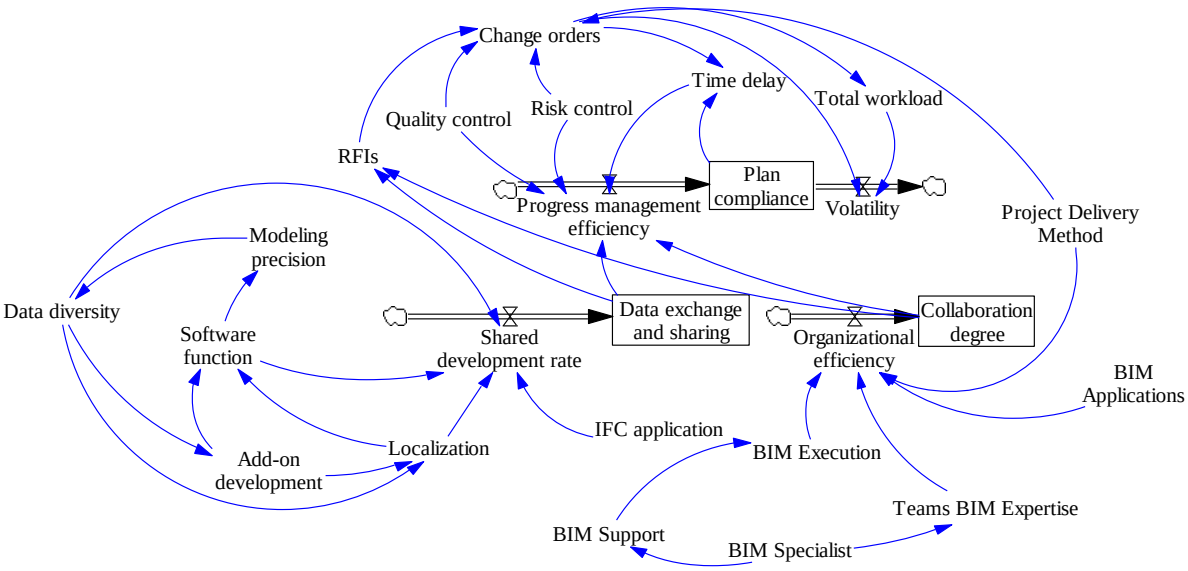

Figure 2. Stock and flow diagram of BIM impact model

3.2. Stock and flow diagram

The causal loop diagram sorts out the model effectively and analyzes the system qualitatively but it is not capable of performing quantitative analysis. The stock and flow diagram is based on the causal loop diagram to distinguish different types of variables, and thus establishing the mathematical relationship between variables. The stock and flow diagram is shown in Figure 2. The plan compliance degree directly reflects the progress control level, and ensures the implementation of the project according to the plan. Engineering changes caused by various factors lead to delay and affect the

degree of plan compliance. Measures such as quality assurance and risk control reduce engineering changes and improve plan-compliance. Data exchange and sharing degree improve the speed and effect of information transmission, enhance communication efficiency, and then increase productivity

3.3 SD Equations

Based on the variable analysis and the stock flow diagram, the level variables (L), rate variables (R) and auxiliary variables (A) that describe quantitative relationship between the impact factors are defined as follow

3.3.1 SD equation of organization subsystem

(1) Collaboration degree equation

The collaboration degree (*CO_DEGREE*) is a level variable whose value is affected by organizational efficiency (ORG_E), DT is time interval. It is defined as

L $CO_DEGREE.K = CO_DEGREE.J + DT * ORG_E$

(2) Organizational efficiency equation

The organizational efficiency (*ORG_E*) is a rate variable whose value is the sum of BIM executive, Teams BIM Expertise, project delivery method mode and BIM applications. It is defined as

R
$$ORG_E = EXCUTION + T_EXPERTISE + D_MODE + APPLICATIONS$$

The teams BIM expertise is a table function of BIM Specialists number and is defined as

A
$$T_EXPERTISE = WITH_LOOKUP(SPECIALISTS)$$

3.3.2 SD equation of technical subsystem

The data exchange and sharing degree (*D_ENJOY*) is a level variable affected by the rate of shared development.

1) Data exchange and sharing degree equation

L $D_ENJOY.K = D_ENJOY.J + DT * DEV_RATE$

2) Shared development rate equation

As a rate variable, the shared development rate (*DEV_RATE*) is the sum of data diversity, localization, software function and the application of IFC standards. It is defined as

R $DEV_{RATE} = D_DIVERSITY + D_LOCAL + FUNCTION + IFC$

The degree of localization (*D_LOCAL*) and software function (*FUNCTION*) are table functions of add-on development (*REDEV*) and are defined as

A $D_LOCAL = D_DIVERSITY + REDEV$

A $FUNCTION = WITH_LOOKUP(REDEV)$

The add-on development (*REDEV*) is a table function of data diversity and is defined as

A $REDEV = WITH_LOOKUP(RICHNESS)$

3.3.3 SD equation of management subsystem

1) Plan compliance degree equation

The plan compliance degree (*D_FOLLOW*) is a level variable whose value is positively related to the BIM based schedule management efficiency (*MAN_E*) and negatively related to the change rate (CHANGE_RATE). It is defined as

L
$$D_FOLLOW.K = D_FOLLOW.J + DT * (MAN_E - CHANGE_RATE)$$

2) Schedule management efficiency equation

The schedule management efficiency (*MAN_E*) is a rate variable that directly impacts the project compliance degree (*D_FOLLOW*). Its value is equal to the sum of risk control level (*M_RISK*) and quality assurance (*M_QUALITY*) minus time delay (*DELAY*) which is the table function of the change orders (*CHANGES*).

R $MAN_E = M_RISK + M_QUALITY - DELAY$

A $DELAY = WITH_LOOKUP(CHANGES)$

The change order (*CHANGES*) is equal to the number of information requests RFI minus the quality assurance (*M_QUALITY*) and the risk control level.

A $CHANGES = RFI - M_QUALITY - M_RISK$

3.3.4 Initial value and variable table function

According to "China Construction Industry Informatization Development report (2015): BIM depth Application and Development") and previous study [3], the initial values of variables are determined. The table function describes the nonlinear relation between some variables whose data source could be historical and literature. Data range is determined by the variation trend and the key points between variables. The interaction effect curve of variables can be obtained by the analysis of VENSIM software，the equation for the variable table function is as follow:

(1) Add-on development equation [30]：

REDEV= =WITH LOOKUP (RICHNES, ([(2000, 0)-(2500, 0.012)], (2000, 0.0101), (2030, 0.0102), (2060, 0.0103), (2090, 0.0104), (2120, 0.0105), (2150, 0.0106), (2180, 0.0107), (2210, 0.0108), (2240, 0.0109), (2270, 0.011)))

(2) Software function equation：

FUNCTION=WITH LOOKUP (REDEV, ([(0，0.4)-(0.011，0.8)], (0，0.4), (0.0102，0.402), (0.0103，0.404), (0.0104,0.406), (0.0105，0.408), (0.0106，0.41), (0.0108，0.412), (0.0109，0.414), (0.011，0.416)))

(3) Time delay equation：

DELAY=WITH LOOKUP (CHANGES, ([(0.08，0.1)-(0.126，0.33)](0.08，0.1), (0.126，0.33)))

(4) BIM level equation：

SPECIALITY=WITH LOOKUP (SPECIALIET, ([(1000, 0.026) -(4000, 0.032)], (1000, 0.026), (1500, 0.028), (2000, 0.03), (2500, 0.032), (3000, 0.034), (3500, 0.036), (4000, 0.038)))

(5) Modeling accuracy equation [29]：

PRECISION=WITH LOOKUP (FUNCTION, ([(0.4, 0.45)-(0.5, 0.6)], (0.4, 0.45), (0.41, 0.47), (0.42, 0.48), (0.43, 0.5), (0.44, 0.52), (0.45, 0.54), (0.46, 0.56), (0.47, 0.58), (0.48,0.6)))

3.4Validation

In order to test the stability of the model, three different time intervals of DT=1, 0.5 and 0. 25 are set in the three subsystem models, respectively. The initial parameter of the model is INITIAL TIME=1, FINAL TIME=15, TIME STEP=1, 0.5, and 0.25. When the interval DT is set to 0.25 and 1, the curves of collaboration degree, schedule compliance degree and data exchange and sharing ability tend to be consistent, so the model is stable to perform sensitivity analysis.

4. Significance evaluation of impact factor

Through sensitivity analysis with initial value of productivity is 0, the significance of the management factor is 0. 56, the technical factor is about0. 29, and the organizational factor is about 0.15. Significance level of each secondary impact factors and overall productivity for 3 subsystems are as follow in Table 2:

5. Case studies

5.1 Background

To evaluate the effects of BIM application, this study compares the installation LP of three cases, a five-star Intercontinental hotel adopted BIM in late construction phrase mainly for facility management, an International Conference Center, which is located next to Continental Hotel, applied BIM from early construction coordination to operation phrase, and the World Trade Square adopted BIM from design review to construction coordination and operation phase. As complexity and size is the most significant factors of projects classification. The three cases are all large-scale with complex pipeline layout, BIM implemented projects and are constructed by contractors with same qualification, such that the installation LP is comparable.

Table 2. Significance level of LP factors

Primary Factor （Significance）	Secondary Factor	Secondary Factor Significance	Significance on Productivity
Organizational Factors （0.15）	BIM Applications	0.284	0.0426
	BIM Execution	0.241	0.0362
	Teams BIM Expertise	0.154	0.0231
	BIM Support	0.148	0.0222
	Project Delivery Method	0.091	0.0136
	BIM Specialists	0.082	0.0123
Management Factors （0.56）	Quality Control	0.324	0.1814

Table 3. Installation LP statistics for three projects

Installation Tasks	HVAC (m^2/man-hr)	Bracket (kg/ man-hr)	Cable trays (m/ man-hr)	Fire control (m/ man-hr)
Intercontinental Hotel	2.60	40.10	1.39	3.70
Conference Center	3.20	45.30	1.70	4.50
World Trade Square	3.60	47.57	1.86	4.74

5.2. Measurement of MEP installation site productivity

The working hours and number of workers are determined according to the records of the weekly reports and construction plan collected from 3 cases. Productivity statics of HVAC (Heating Ventilating and Air Conditioning), bracket, cable trays and fire control pipelines are calculated as

LP=Installed Quantities/Working Time

The results of the LP of the 3 cases are shown in Table 3. Table 3 shows the productivity of the four trades of the three BIM projects. Through field investigation, the conference center and World trade Square showed in higher level of quality control, change orders, BIM Execution and model precision. The installing

productivity statics reflect efficiency of working process including components assembling, connecting, erecting. Compared to the Intercontinental projects, which applied BIM in late construction phrase, early BIM utilized projects, the Conference Center and World Trade Square projects, increased LP between 13% and 38% dependent on different trades

6. Conclusions

In this paper, the critical impact factors of BIM on pipeline installation productivity are identified and a system dynamics model is established to map the impact mechanism and quantify the BIM impact on labor productivity. The model is applied to evaluate the pipeline installation productivity of three large scale buildings and the task-level productivity indices are compared. The comparison shows a positive impact of BIM on pipeline installation productivity, resulting in 13~38% of increase in labor productivity dependent on different trades and project phase of BIM application.

Abstract –
In construction, unanticipated struck-by hazards often arise, which have resulted in a significant number of construction fatalities. To address this problem, many studies have attempted to automate proximity monitoring and struck-by hazard detection using various technologies, such as wireless sensors and computer vision methods. While this technology focuses on understanding what is happening as hazards arise, it is not equipped to detect future hazards. In impending situations, detecting current hazards may not provide enough time for workers to take evasive actions. To address this challenge this study develops a trajectory prediction model for mobile construction resources. Specifically, this study conducts hyper-parameter tuning of a deep neural network, called Social Generative Adversarial Network to develop a prediction model capable of predicting more than five seconds. Further, a test on a real construction operations data follows to validate developed models' trajectory prediction accuracy. As a result, a developed model could achieve promising accuracy: the average displacement error and the final displacement error were 0.78 and 1.27 meters, respectively. The trajectory prediction allows for detecting future hazards, which will support pro-active intervention in hazardous situations. It will ultimately contribute to promoting a safer working environment for construction workers.

Struck-by hazard; Pro-active intervention; Trajectory prediction; Deep neural network; Hyper-parameter tuning

1 Introduction

In construction, mainly due to unstructured and limited workspaces, unanticipated struck-by hazards involving mobile vehicle or equipment often arise, contributing to the significant number of construction fatalities [1]. According to *The Center for Construction Research and Training, United States*, from 2011 to 2015, total 925 struck-by fatalities were reported from construction [2]. The figure accounted for 24% of overall struck-by fatalities in the U.S. and was unmatched by other U.S. industries [2]. Notably, the number of struck-by fatalities rose 34% from 2010 (N=121) to 2015 (N=162) [2].

A critical element of construction safety management is "a proactive, ongoing process to recognize hazards that are present or that could have been anticipated" [3]. However, such continuous monitoring has not been viable in practice as manual observation and inspection is notoriously time-consuming, labor-intensive, and costly [4].

A major research area for this issue is attuned to automating object localization, proximity monitoring, and accordingly struck-by hazard detection. Prior research leveraged various technologies—such as wireless sensors [5-9] and computer vision methods [1, 10-11]—and made a great progress on automation of struck-by hazard detection. It is expected that the successful deployment of such technologies will allow for prompt feedback to involved workers, thereby reducing the chance of an impending collision [1, 5, 10].

However, there remains a critical challenge that has not been tackled yet: how to recognize not only current hazards but also the ones that will be present in the near future for pro-active intervention. All prior works using wireless sensors and computer vision are limited to understand what is happening. That is, these technologies are only capable of detecting current hazards because they depend on current locations of entities of interest. In many cases, however, letting a worker know "now you are in a danger" may not provide enough time for him/her to take a proper evasive action. Therefore, predicting what will happen (i.e., knowing future position of entities and detecting future hazards) is critical in the prevention of potential accidents.

As a preliminary study to address this challenge, this research examines the potential of trajectory prediction for mobile construction resources. To this end, this study develops a trajectory prediction model through hyper-parameter tuning of a deep neural network (DNN), called Social Generative Adversarial Network (GAN) [12], and conducts test on a real construction operations data to

evaluate the developed model's prediction accuracy.

2 Previous Works

Considerable research efforts have been made to automate the struck-by hazard detection in construction. Some studies applied wireless sensors—such as Radio Frequency Identification (RFID) [5-6], Magnetic Field (MF) [7], Global Positioning System (GPS) [8], and Bluetooth Low Energy (BLE) [9]—to instantly detect hazardous proximity between entities of interest. On the other hand, other studies applied deep neural networks (DNNs)-based object detection framework—such as Faster R-CNN [13], R-FCN [14], and YOLO-V3 [1]—for continuous object localization and proximity monitoring.

The previous works have made large strides in automating struck-by hazard detection. However, trajectory prediction and accordingly future hazard detection have not been tackled yet. All prior works using wireless sensors and computer vision are limited to detect current hazards. To provide enough time for workers to take a prompt evasive action, to predict what will happen, namely recognizing future position of entities and detecting future hazards, is required.

One possible solution that can address the above issue is to enable trajectory prediction, which stands for a task to predict a target's future trajectories (a set of future positions) by observing the target's moving pattern. Recently, the trajectory prediction has made a great progress with the advancement of DNNs, such as Long-Short Term Memory (LSTM) [15], Gated Recurrent Unit (GRU) [16], and social pooling layers [17], and Generative Adversarial Network (GAN) [12]. Alahi et al. 2016 [17] first presented social pooling layers-embedded LSTM architecture (called Social LSTM), which showed remarkable progress in trajectory prediction. This work demonstrated the Social LSTM can learn not only each entity's moving pattern, but also social behaviour of human in crowded settings (e.g., collision avoidance). The interconnected use of individual and social features in turn showed a great performance in trajectory prediction: predicted trajectories by the Social LSTM only had 0.72 meter displacement error on average, compared to the ground truth trajectories.

Encouraged by this progress, Gupta et al. 2018 [12] more improved the Social LSTM [17] by using GAN. This work developed unique generator and discriminator by integrating LSTM encoder-decoder and social pooling layers (Figure 1, please refer to Gupta et al. 2018 [12] for detailed information). Consequently, the strict supervision by the discriminator successfully improved the model's prediction performance: the displacement error on average was 0.58 meters.

Despite the promise, applying the trajectory prediction DNN (i.e., Social GAN) to our problem involves another challenge: how to modify the original network so that it can predict longer time-steps. Note that the published Social GAN model has 2.64 s prediction length. To provide a worker in a danger with enough time for evasive action, longer prediction and accordingly more early notice are needed.

3 Research Objective and Framework

With this background, this study conducts hyper-parameter tuning of the Social GAN [12] to develop a trajectory prediction model for mobile construction resources. In essence, the longer prediction is needed for more pro-active hazard detection. This study sets five seconds as the target to predict with the assumption that it would be enough for workers to take prompt evasive actions. Further, tests on real construction operations data are conducted so as to demonstrate the developed model's potential in real-world applications. This study follows the below framework to achieve these aims (Figure 1).

- Data collection: for the purpose of hyper-parameter tuning, ETH [18] and UCY [19] dataset widely used for trajectory prediction are used. In addition, a real construction operations data that captures interactions between construction resources is collected for the test purpose.
- Hyper-parameter tuning: training the Social GAN [12] with multiple hyper-parameter scenarios is conducted to develop trajectory prediction models capable of predicting more than 5 seconds.
- Test on a real construction operations data: the trained models then are tested on a real construction operations data for evaluation.

4 Data Collection

The more extensive data is used for training, the higher performance of a model can be reached. For the hyper-parameter tuning purpose, this study thus benchmarked two sets of human trajectory data, ETH [18] and UCY [19], which are the most widely used dataset in trajectory prediction studies [12,17]. In total, the two datasets captures four different crowded scenes and contains 1,536 human trajectories. The trajectories reflect various human-human interactions, including (i) crossing each other; (ii) collision avoidance, (iii) group forming; and (iv) dispersing [17] (A in Figure 1).

In addition, this study collected a real construction operations data for the purpose of test. UAV captured construction site videos were collected. Of these, the total of 916 sequential frames were sampled that captures interactions between a worker, an excavator, and a wheel loader (B in Figure 1). Each trajectory (i.e., a set of x-y coordinates) of the three entities were manually annotated over the whole frames and a complete

inspection ensured the validity of the annotations.

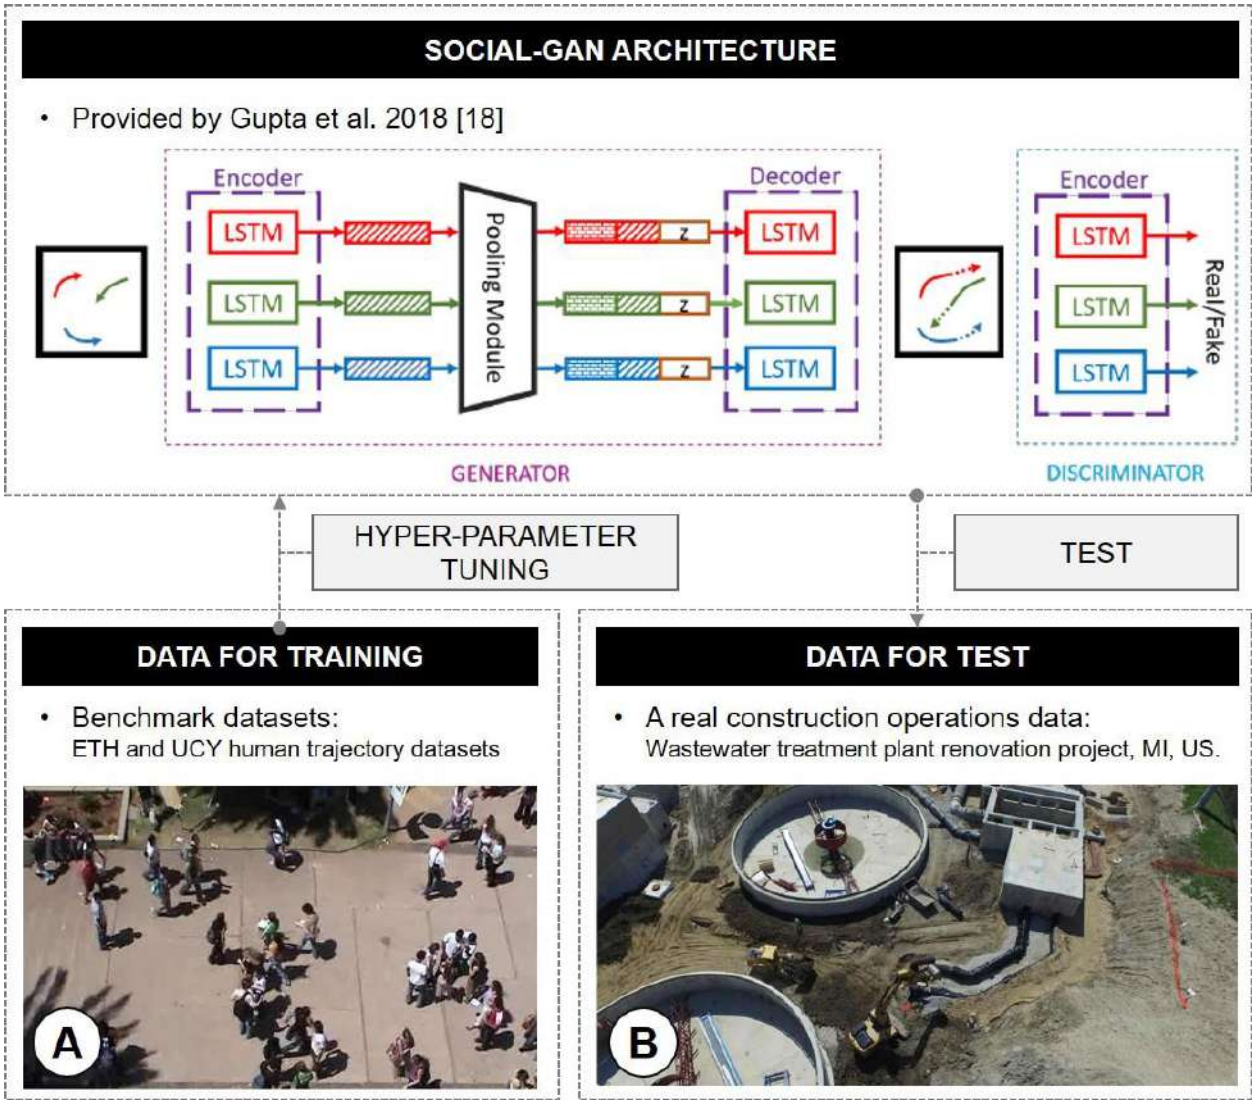

Figure 1. Research framework

5 Hyper-Parameter Tuning

To develop a long-term trajectory prediction model for construction mobile resources, this study conducted hyper-parameter tuning of the Social GAN [12].

The Social GAN has around 40 hyper-parameters that might need to be considered for successful training: batch size, number of iteration, number of epoch, model dimensions, observation length, and prediction length, to name a few. A small change in each hyper-parameter might be able to affect training and a trained model's final performance; however, examining all possible combinations is not viable as training a model with a graphical processing unit (GPU, e.g., Tesla K40c) in general takes more than five days. Hence, this study selected two important hyper-parameters, prediction and observation length, as tuning targets with the following reasons:

- Prediction length: the prediction length is the most important hyper-parameter that literally determines how many time-steps the model will predict. To achieve the prediction model capable of predicting more than five seconds, this study changed the prediction length from the default value (8 time-steps, 2.64 s) to 16 time-steps (5.28 s).
- Observation length: the observation length was selected as the second important hyper-parameter that needs to be tuned. The major input consumed for inferring a set of future trajectory in the Social GAN is a set of observed trajectory. The length of

observation is therefore bound to have a significant impact on a trained model's prediction performance. This work considered seven different observation lengths: from 8 time-steps (2.64 s) to 20 time-steps (6.6 s) with 2 time-steps interval (0.66 s).

Considering the above two hyper-parameters, total seven different tuning scenarios were established and applied in training (Table 1).

Table 1. Hyper-parameter tuning scenarios

Scenarios	Hyper parameter			
	Observation length		Prediction length	
	Time-steps	Seconds	Time-steps	Seconds
#1	8	2.64	16	5.28
#2	10	3.30	16	5.28
#3	12	3.96	16	5.28
#4	14	4.62	16	5.28
#5	16	5.28	16	5.28
#6	18	5.94	16	5.28
#7	20	6.60	16	5.28

6 Test Result and Discussion

To evaluate the trajectory prediction accuracy of the trained models on real construction settings, a test on a real construction operations data is conducted. As evaluation metrics, this study applied average displacement error (ADE) and final displacement error (FDE) that are commonly used metrics in trajectory prediction studies [12,17].

- ADE: average *L2* distance (i.e., mean square error) between ground truth and prediction over all predicted time-steps [12,17].
- FDE: distance between the predicted final destination and the ground truth destination at the end of the prediction period [12,17].

Table 2 summarizes the ADE and FDE of each trained model on the test dataset. Overall, all seven of the trained models showed promising accuracy in this test: the ADEs and FDEs for all the models were less than one meter (avg. ADE=0.88 meters) and 1.6 meters (avg. FDE=1.51 meters), respectively. Given a set of observation, predicting position of far time-step is naturally more challenging than close one. Accordingly, it was shown that the FDEs are 0.6 meters higher than the ADEs on average.

In this test, it was revealed that longer observation length does not necessarily guarantee higher accuracy. Longer observation means that the trajectory of less relevant time-steps are more consumed in the prediction. For example, in the scenario #7, not that all 20 time-steps observation are closely relevant to the future time-steps positions. The first several time-steps observation may have less relevancy to the future trajectory than the last several ones, which can be noises and have a negative impact on the model's prediction performance. In actual, the ADEs and FDEs slightly increased as observation length increased (Table 2).

It turned out that the best model for 16 time-steps prediction (5.28 s) is the one with 8 time-steps (2.64 s) observation (Table 2). This model consumes the shortest observation in the prediction, which however has the highest relevancy to the future trajectory. Consequently, this model outperformed the others and showed the most promising result: ADE=0.78 meters and FDE=1.27 meters (Table 2). Figure 2 illustrates the best model's prediction performance. Note that in this figure, green, blue, red lines stand for predicted trajectory of the worker, wheel loader, and excavator, respectively. And white circles stand for their ground truth position. As shown in Figure 2, the ground truth position of each entity well follows the predicted trajectory in process of time. This fact visually verifies validity of the predicted trajectories.

The developed model also demonstrated that it can continuously update the trajectory prediction at every 0.33 s without significant time-lag. With the use of a GPU (i.e., Tesla K40c), the model predicts three sets of trajectories for 5.28 s (16 time-steps) within 0.12 s. Then, at the next time step, 0.21 s later after completing the previous prediction, it predicts new sets of trajectories with the latest observation. That is, the model can continuously provide trajectory prediction for 5.16 s (5.28 s – 0.12 s) at every 0.33 s.

This test shows the great potential for the developed model in predicting construction mobile resources' trajectories. However, there is still room for further improvement. This study only focuses on hyper-parameter tuning, not considering fine-tuning with augmented construction data. Once an extensive dataset for construction resources' trajectory is available, this work will have another chance that can likely improve the prediction performance.

Table 2. Test result

Scenarios	Observation length	ADE (meters)	FDE (meters)
#1	80	0.78	1.27
#2	100	0.87	1.48
#3	120	0.84	1.42
#4	140	0.89	1.53
#5	160	0.89	1.54
#6	180	0.98	1.80
#7	200	0.91	1.57

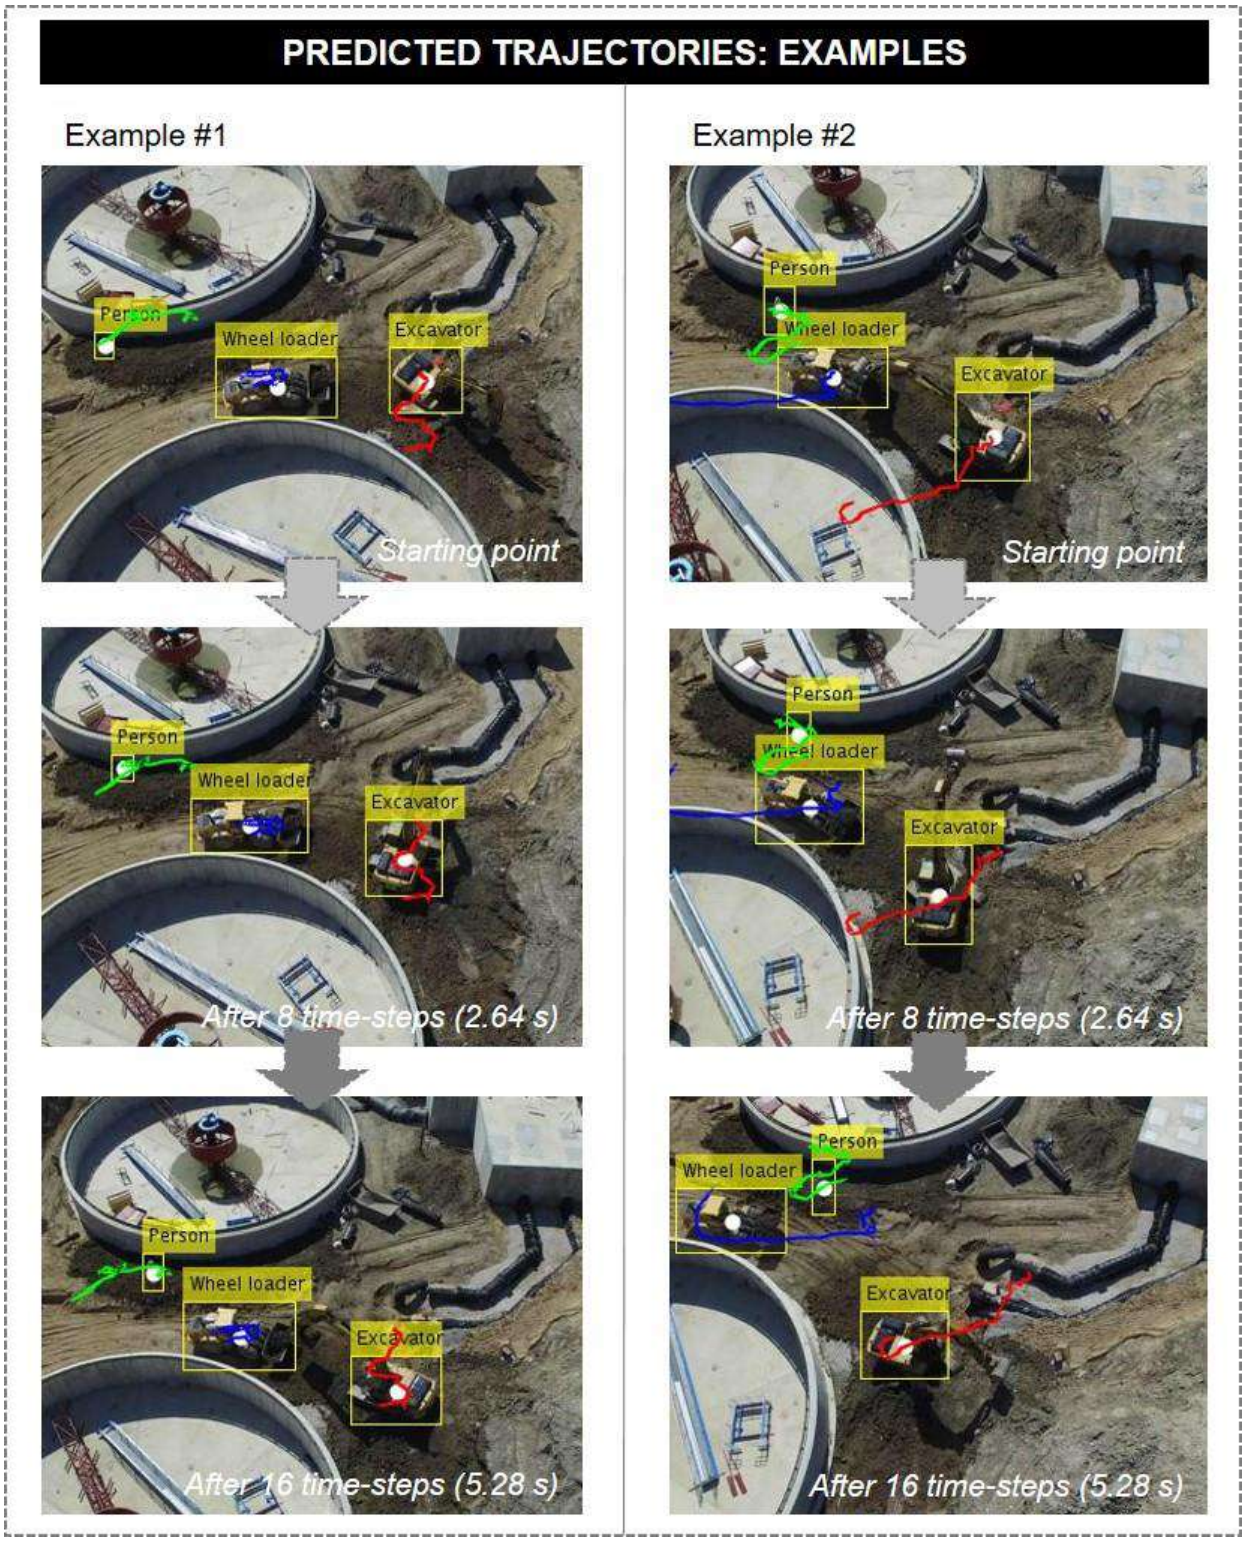

Figure 2. Predicted trajectory vs. ground truth positions

7 Conclusion

To support the pro-active struck-by hazard detection in construction, this study developed a trajectory prediction model for construction mobile resources. Specifically, this study conducted hyper-parameter tuning of a deep neural network, called Social GAN and developed a prediction model capable of predicting target's trajectory more than five seconds.

As a result, the best model (i.e., scenario #1) could achieve promising prediction accuracy: the ADE of 0.78 meters and the FDE of 1.27 meters. However, there still remain critical opportunity to improve the prediction accuracy—such as the fine-tuning with augmented construction training dataset.

With such refinement, an updated model would likely result in a more robust and accurate prediction on real construction operations data. The proposed trajectory prediction allows for detecting hazards that will be present in the near future, which will support pro-active intervention in hazardous situations. It will ultimately contribute to promoting a safer working environment for construction workers.

Abstract –

Construction workers are commonly subjected to ergonomic risks due to manual material handling that requires high levels of energy input over long work hours. Fatigue in musculature is associated with decline in postural stability, motor performance, and altered normal motion patterns, leading to heightened risks of work-related musculoskeletal disorders. Physical fatigue has been previously demonstrated to be a good indicator of injury risks, thus, monitoring and detecting muscle fatigue during strenuous work may be advantageous in mitigating these risks. Currently, few researchers have investigated how physical fatigue and exertion can be continuously monitored for practical use outside laboratory settings. Exercise-induced fatigue has been shown to impact motor control; thus, it can be measured using jerk, the time derivative of acceleration. This paper investigates the application of a machine learning approach, Support Vector Machine (SVM), to automatically recognize jerk changes due to physical exertion. We hypothesized that physical exertion and fatigue will influence motions and thus, can be classified based on jerk values. The motion data of six expert masons were collected using IMU sensors during two bricklaying tasks. The pelvis, upper arms, and thighs jerk values were used to classify inter- and intra-subject rested and exerted states. Our results show that on average, intra-subject classification achieved an accuracy of 94% for a five-course wall building experiment and 80% for a first-course experiment, leading us to conclude that jerk changes due to physical exertion can be detected using wearable sensors and SVMs.

1 Introduction

Construction work is typically physically demanding and can result in a high number of accidents and injuries caused by fatigue. Fatigue can also have a detrimental impact on workers' judgement, productivity, and quality of work. Although accident and injury prevention has become a primary area for improvement within the construction industry, fatigue prevention and detection continue to require manual observation or self-reported subjective assessments. The inherent subjectivity of these methods has prompted the introduction of biomechanical and physiological assessments that quantify fatigue levels, thereby increasing reliability while reducing the time and human resources needed for their implementation. Despite extensive research that confirms the validity of these assessments, they can be cumbersome and or intrusive because they often require that multiple sensors and wires be attached to the worker, or need external devices that work in conjunction to worn devices. These assessments also often require tasks that involve several sequential activities or motions to be manually segmented; this is not only a time-consuming process, but it eliminates the applications of these assessments for real-time feedback and consumer use. The recent advances of inertial measurement units (IMUs) enable the automatic collection of motion data and offer several advantages over the traditional assessments, for example, they are cost-effective, non-intrusive, and wireless. This research investigates the use of support-vector machines (SVM) to automate the monitoring of physical exertion levels using jerk. The detection of high levels of exertion would allow workers to take proactive measures in mitigating adverse effects of fatigue.

2 Background

Physical fatigue refers to a decline in a muscle's ability to exert force as a result of performing a task requiring physical effort [1], [2]. Physical fatigue has been shown to result in increased risks of injury that lead to a variety of musculoskeletal disorders including lower back disorders, tendinitis, and carpal tunnel syndrome [3].

Construction work typically involves prolonged hours of physically demanding tasks, such that workers' muscles can become fatigued, resulting in a reduction in muscle strength.

Currently, there is no standard for a fatigue assessment that is universally accepted in both practical or research settings [4]. Thus, numerous objective and subjective fatigue assessments have been developed for specific industry requirement such as construction, manufacturing, and healthcare. Several work-related studies have developed or used various subjective scales and questionnaires for assessing fatigue or perceived exertion [5]–[7]. Aside from the inherent discrepancies that is expected between one's perceived fatigue and one's true level of fatigue, subjective measures are also cumbersome to implement and are not realistic for use on construction sites [8].

Previous studies have also used physiological measurements to assess the buildup of fatigue, including heart rate, oxygen consumption, and energy expenditure [9]. The downside to physiological measurements is that many factors can reduce their reliability including alcohol consumption, fitness level, and caffeine intake [10]. In laboratory settings, electromyography (EMG) is commonly used to predict muscle activity. Surface EMG (sEMG) can non-invasively assess the development of fatigue over time, however, it has low signal-to-noise ratio and are poorly correlated to fatigue for deep muscles such as at the lower back [11]–[13].

Recent advancements of wearable sensors with processing and communication capabilities, have expanded the applications of existing assessments beyond laboratory settings. Schall et al. assessed the IMU system in field-based occupational settings over an eight-hour work shift and suggested that the IMU system can achieve reasonably good accuracy and repeatability compared to the gold standard, optical motion capture systems [14]. Moreover, the light-weight and portability of wearable IMUs compared to external sensors, make them easy to attach to workers such as on construction vests, gloves, or helmet. IMUs, which combine accelerometers, gyroscopic and magnetic sensors, have been used by researchers to monitor ergonomically safe and unsafe postures during construction activities [15]–[18]. Among inertial sensors, accelerometers have been used extensively for activity recognition and studied with different body locations, number of sensors, classifiers, and feature sets [19]. Valero et al. developed an IMU system to detect unsafe postures of construction workers from motion data [20]. Ryu et al. used a single wrist-worn accelerometer-embedded activity tracker for automated action recognition [21], [22]. However, the use of wearable sensors to monitor physical exertion or fatigue during physically demanding tasks has not been studied extensively.

Physical fatigue and its impact on motor control and jerk has not been widely studied outside of clinical research. One reason is because prior to the advent of IMUs, motion capture systems that collect body segment positions must be differentiated three times in order to obtain jerk, resulting in a low signal-to-noise ratio. Jerk, the time derivative of acceleration, is typically used as a measure of motor control. In the short-term, fatigue can result in reduced motor control and strength capacity [23]. Fatigue is also manifested in increased tremor and changes in the recruitment of muscles, affecting both gross and fine motor skills. During lifting, high jerk values or a sudden change in acceleration can be felt as the change in force on the body and result in biomechanical damages over time. Two studies are notable and relevant to the current research. Maman et al. used IMU-collected motion data during simulated manufacturing tasks to determine acceleration- and jerk-based features that are predictive of fatigue occurrence [24]. Similarly, Zhang et al. used support vector machines (SVMs) to classify the occurrence of lower extremity muscle fatigue of gait [25]. These methods, however, have not assessed the feasibility of using machine learning techniques to recognize changes in jerk values during construction work.

Several methods have been used to classify human movement. Supervised classification techniques include k-Nearest Neighbour (k-NN), Support Vector Machines (SVM), Gaussian Mixture Models (GMM), and Random Forest (RF), and unsupervised classification techniques include k-means, Gaussian mixture models (GMM) and Hidden Markov Model (HMM). The focus of this work is to classify with SVM. Many studies with SVM have been reported in the field of activity recognition, although they do not focus on the study of fatigue.

In our previous work [26], we found that jerk may be used as an indicator of loss of motor control caused by physical exertion. However, the tasks were manually separated to ensure that jerk values were compared between the same action types, for examples, the motion data collected during each lifting action (pick up – transport – lay down) were segmented out from other motions such as spreading mortar. Manual segmentation of the data prevents this method from being used for real-time assessments. In this paper, we conducted two sets of analyses: 1) we tested the feasibility of analyzing jerk values using continuous motion data collected from our previous study to monitor changes in motor control, and 2) we conducted a second experiment that evaluates changes in jerk values between two identical bricklaying tasks following a series of exhausting exercises. Continuously monitoring jerk is investigated in the present study using IMU sensors and SVMs, which have been used extensively to classify human motion patterns and activities [17], [27]. Given that rested and exerted states can create unique jerk signal patterns, machine learning algorithms using motion data may be used to monitor the development of physical exertion in real-time for practical applications.

3 Methodology

3.1 Participants

The experiment was conducted at the Canadian Masonry Design Center (CMDC) indoor training facility in Mississauga, Ontario. Six male bricklayers with an average of 22 years of masonry experience were recruited for the experiment. The participants' mean (SD) stature and body mass were 179.0 (5.0) cm, 89.3 (14.1) kg, respectively. The study was approved by the Office of Research Ethics at the University of Waterloo.

In our previous work, experienced masons displayed statistically significant inter-subject differences between the rested and exerted jerk values over the duration of a bricklaying task. The statistically significant differences between experienced masons was attributed to greater inter-subject similarities compared to unexperienced masons in their learned technique and work pace. In this work, we examine both the inter- and intra-subject differences of experienced workers.

3.2 Instrumentation

The segment kinematics of the participants were collected using a wearable IMU-based motion capture suit, Noitom Perception Neuron [28]. The sampling rate of the IMUs is 125 frames per second. The full-body suit is composed of seventeen IMUs located at the pelvis, sternum, head, and both shoulders, upper arms, lower arms, hands, upper legs, lower legs, and feet. Although not all IMUs were used, all seventeen IMUs were active during the experiment due to the suit configuration. Each IMU sensor is comprised of a three-axis accelerometer, a three-axis gyroscope, and a three-axis magnetometer. Motion data was transmitted between the suit and a laptop via Wi-Fi. The sensor locations are shown in Figure 1.

3.3 Experimental Procedure

In the bricklaying experiment, jerk analysis was carried out on five body segments, namely the pelvis, the dominant and non-dominant upper arms and thighs since lifts involve whole-body work. We hypothesized that the three distinct body segments are suitable for fatigue monitoring since bricklaying requires large ranges of motion, forceful contractions, high precision from the upper and lower limbs, and frequent bending at the torso. IMU sensors have been used to study human motion in several locations. However, some studies have found that the torso is the best location to analyze movements since it reflects major motions and is close to the human body center of mass [29]. The selected body segments may also be the most suitable areas for sensor placement since they are far from external impact and from subject protective equipment.

Prior to the experiment, a calibration session was carried out to allow the Axis Neuron software to detect the placement and orientation of the sensors on the participant. The sensor-to-segment calibration was obtained using three standard postures including the A-pose, T-pose, and S-pose. Two sets of analyses were conducted. First, we tested the feasibility of analyzing jerk values using continuous motion data to monitor changes in motor control with data collected from a previous study which required workers to complete a wall building experiment. Second, we conducted an additional experiment to evaluate changes in jerk values between two identical bricklaying tasks following a series of exhausting exercises. The participants were given an hour break between the two experiments.

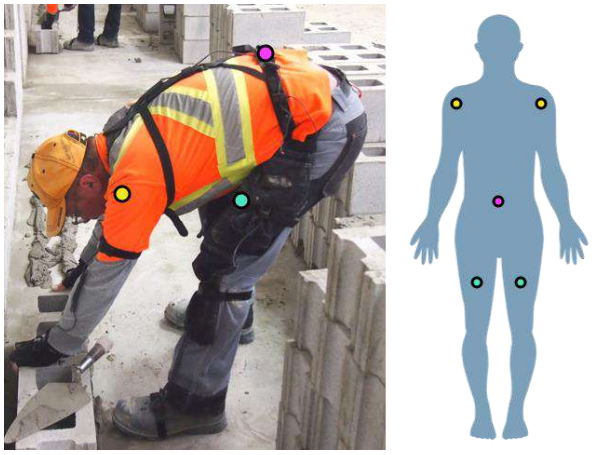

Figure 1. IMU sensor locations

3.4 Wall Building Experiment

To investigate the feasibility of using continuous motion data as an input to train SVM, we first analyzed data from our previous study [26]. Each participant was instructed to complete a pre-built lead wall shown in Figure 2(a), using forty-five concrete masonry units (CMUs) from the second to the sixth course. Each course is defined as a layer of CMUs. The CMUs were Type 1 blocks weighing 16.6 kg as detailed in Table 1. The blocks were placed in three piles approximately one meter away from the pre-built lead wall, and two panels of mortar were placed between the three block piles. The use of mortar and the requirement to meet alignment tolerances reflected field-work conditions. After the experiment, the participants were given a one-hour break before commencing the second experiment. Figure 3 shows the timeline of the tasks completed by the participants and the corresponding level of intensity measured in kg of laid CMU per minute.

Table 1. CMU block properties

Block	Weight [kg]	Dimensions [mm x mm x mm]
Type 1	16.6	390 x 190 x 100
Type 2	23.6	290 x 390 x 190
Type 3	36.1	290 x 390 x 190

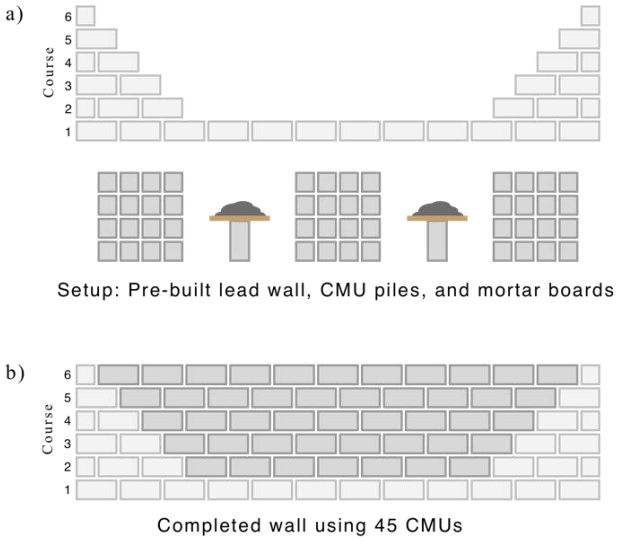

Figure 2. Experimental setup for wall building experiment

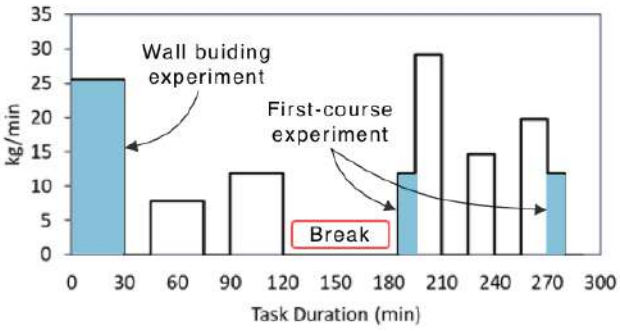

Figure 3. Timeline of task duration and intensity level in kilograms per minute

3.5 First Course Experiment

The purpose of the second experiment was to compare the jerk values of two identical tasks performed before and after an exhausting set of exercises. Each participant was instructed to build the first course of a wall using seven CMUs. The first course was selected because it imposes the greatest loading on the lower back [30]. The CMUs were Type 1 blocks weighing 16.6 kg. The blocks were placed in one pile approximately one meter away from the work space. Figure 4 shows a participant completing the bricklaying task.

After completing the first course, the participants were asked to carry out three bricklaying activities: 1) complete a wall individually using Type 2 CMUs, 2) complete a wall collaboratively using Type 2 CMUs, and 3) complete a wall collaboratively using Type 3 CMUs. In total, each participant carried approximately 1000 kg over an average of 50 minutes to complete all three bricklaying tasks. Lastly, the participants were asked to complete the first course again. Figure 5 shows the experiment sequence schematically.

Figure 4. Experimental setup for first course (top) and series of exhausting bricklaying tasks (bottom)

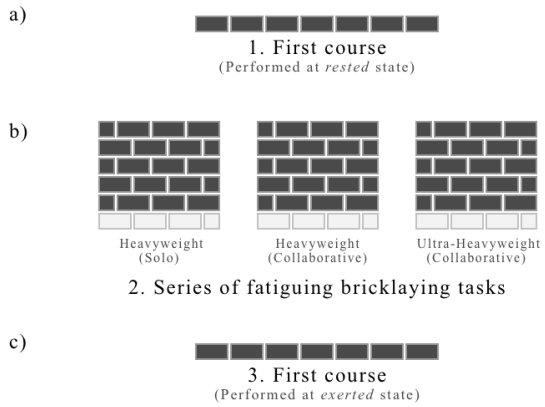

Figure 5. Building sequence for first course experiment

4 Data Analysis

Body segment accelerations collected from the IMU accelerometers were imported into MATLAB for computations. For each of the five IMU sensors, the resultant acceleration data were calculated from the Cartesian components collected from the IMU accelerometers. High frequency noise was removed using a low-pass Butterworth filter with a 10Hz cut-off frequency. Jerk was calculated as the time-derivative of the acceleration magnitude as shown in Table 2.

Table 2. Jerk calculations from Cartesian components of acceleration

	Formula
Acceleration	A_x, A_y, A_z
Resultant acceleration	$R = \sqrt{A_x^2 + A_y^2 + A_z^2}$
Resultant jerk	$J = \frac{dR}{dt}$
Jerk cost	$J = \int_{T_1}^{T_2} \left\|\frac{dR}{dt}\right\|^2 dt$

The classification is performed using predefined MATLAB functions. SVM is a supervised learning algorithm for pattern recognition and classification. Given labelled training data, the algorithm outputs an optimal hyperplane that define decision boundaries which it can then use to categorize new data points. Linear, polynomial, and Gaussian kernels were employed in the SVM classifier. During the wall building experiment, the motion data collected during the second course was labelled as 'rested' and those collected during the sixth course was labelled as 'exerted'. Likewise, during the first course experiment, the motion data collected during the first course completed at the beginning of the task was labelled as 'rested' and those collected at the end of the task was labelled as 'exerted'. Figure 6 shows the schematic to bypass the requirement for manual task segmentation.

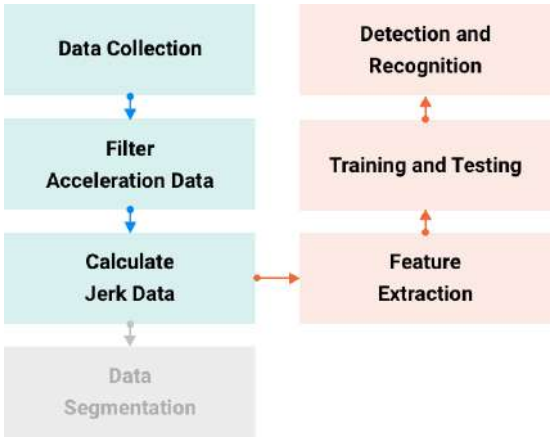

Figure 6. A schematic diagram of data processing for automatic fatigue detection

The selection of a window size has a significant impact on the classification accuracy. Wang et al. [31] conducted tests on different sliding-window sizes for activity recognition and found that accuracy decreases as window size increases. The optimal window size, however, is also dictated by what the classifier is required to classify such that the segment length is adequate to distinguish between unique signal patterns. Using a sliding window approach, multiple window sizes were tested and an overlap size of 50% was used. The window size for optimal recognition was 15 s. Features were extracted from the segmented data and characterised in both the time and frequency domains. The feature set was based solely on jerk measured in g/s and includes the following: 1) mean, the average value of acceleration data over the window; 2) standard deviation of acceleration values over the window; 3) maximum; 4) minimum; 5) jerk cost, an important measure to estimate the energy economy described by the area under squared jerk curve; and 6) dominant frequency – Fast Fourier Transform (FFT) over the window. The classification accuracies are based on all features and for all five body segments.

5 Results & Discussion

In our experiments of classifying rested and exerted states of six subjects, we considered jerk-based features extracted from five IMU sensor body locations, namely

the pelvis, and dominant and non-dominant upper arms and thighs. In the classification stage, we applied several classifiers using MATLAB. On comparing the average classification accuracy, the analysis showed that the SVM classifiers had the highest average value for both experiments, as reported in Table 3 and Table 4. A five-fold cross-validation scheme was used to evaluate the SVM classification algorithms, providing an indication of how well the learner will do when it is repeated using new data. Thus, the reported accuracy is the average accuracy over five iterations.

As expected, the SVM classification results demonstrated a significantly higher intra-subject rested/exerted classification than the inter-subject classification. For the wall completion experiment, the polynomial kernels (94%) performed better than the linear kernel (91%) to identify intra-subject rested/exerted states. For the first course experiment, the linear kernel performed similarly (80%) to the polynomial kernel (79%). The lower classifier accuracy for the first course experiment may be explained by the fact that it was completed following the first experiment. Since a sufficient amount of time is required for muscle recovery following exercise, the participants may not

Table 3. Wall completion experiment – SVM classification accuracy [%], mean, and standard deviation

have fully recovered from the first experiment before moving onto the second experiment. Thus, the participants may have begun the second experiment in an exerted state. The participants might have also recruited an alternate group of muscles for the two collaborative lifting tasks compared to the individual lifting tasks during the first course experiment. Thus, fatigue may have built up for a different group of muscles that were not all utilized in laying the first courses. Another explanation could be that the level of intensity as measured in kilograms per minute could have affected the exertion levels developed by the participants. The intensity level was higher during the wall building experiment compared to the first course experiment; however, the series of fatiguing tasks conducted in between the two sets of first course block laying was higher in intensity.

6 Limitations and Future Work

Conclusions provided in this study should be considered in context of the limitations. First, there was no secondary measure of fatigue, thus we cannot be certain that experiments induced sufficient fatigue. Since we know that the participants had indeed exerted themselves in performing the bricklaying tasks, the classification accuracy reflects the extent to which fatigue was developed. Second, we did not consider masons with other experience levels other than expert masons. Third, due to the fact that physical exertion levels may last for several hours following physical activity, the break in between the first and second experiments may not have been sufficient for the participants to return to a rested state.

The placement of the sensors is of high importance because it can potentially affect the recognition between rested and fatigued states. Thus, future work involves a feature selection method to identify the most significant motion changes after fatigue and determine the optimal number and placements of the sensors to improve the utility of the method.

7 Conclusions

In the construction industry, fatigue can impair workers ability to safely and effectively perform their duties which negatively impacts their well-being, reduces productivity and the quality of their work, and elevates workers' compensation costs. Current workload and fatigue assessment methods, including subjective, physiological, and biomechanical assessments, can be unreliable, cumbersome, or require extensive post processing, which render them impractical for real-time assessment.

This research investigated the use of SVMs to automatically recognize changes in jerk values due to physical exertion. Motion data were collected during two bricklaying activities using IMU sensors to obtain jerk input to SVM classifiers. Inter- and intra-subject classification of rested and exerted states of six expert masons were carried out using the jerk values of the pelvis, upper arms, and thighs.

We found that changes in jerk values due to the development of fatigue can be classified by supervised machine learning techniques. On average, intra-subject classification achieved an accuracy of 94% for the wall building experiment and 80% for the first course experiment. The difference between the classification accuracy for the two experiments may be attributed to differences in task sequence and intensity level resulting in lower classification accuracy in the first-course experiment compared to the wall experiment.

The results lead us to conclude that jerk changes resulting from exertion can be assessed by wearable sensors and SVMs. The investigated method holds promise for continuous monitoring of physical exertion and fatigue which can help in reducing work related musculoskeletal injuries or other fatigue-related risks.

Acknowledgements

We would like to acknowledge the Canadian Masonry Design Centre (CMDC), Mississauga, Ontario, Canada for their considerable help in the data collection effort. Abstract –

Simultaneous evacuation is the most widely used evacuation strategy in buildings. However, there are other evacuation strategies that might lead to safer outcomes if selected appropriately. Different forms of evacuation result from applying time delays to phased evacuation or altering path planning. The best strategy for evacuation depends on the characteristics of the building and the circumstances of the particular emergency. A real-time evacuation path-planning model that identifies the fire hazard and proposes the best strategy of evacuation during the emergency can reduce risk and improve safety. In this paper, a model is proposed to find the safest strategy of evacuation based on the current state of the building and the emergency case. The model focuses on fire emergencies, as they are the dominant cause of fatalities in buildings compared to other types of natural and manmade disasters. The proposed model first defines a risk factor for each compartment based on the location of fire and then calculates the lowest risk path using Dijkstra algorithm. The path-planning runs on the geometric network graph (GNG), which is generated from the IFC file of the building. Furthermore, unexpected events during evacuation, e.g. another source of fire, can force the system to search for another strategy. Herein, a model is designed to monitor the building in real-time and in case of any unexpected event, changes the evacuation plan accordingly. The case study shows that the proposed model for real-time evacuation management can significantly enhance the safety level of evacuation compared to the conventional simultaneous evacuation process.

Evacuation; Dijkstra; Route risk index; Geometric network graph; BIM; IFC; Fire safety

1 Introduction

Decision-making and coordination for evacuation processes are normally managed by a human emergency commander. This person has to comprehend the status of the building, estimate the distribution of the residents, recognize the type and the location of the hazard, decide the best strategy of evacuation and transfer the message to occupants. The procedure gets even more complicated when the commander has to monitor the building and the evacuees during evacuation and improvise solutions for unexpected situations that differ from the forecasted plan. Such complexities in decision making, data interpretation, time constraints, and inevitable human errors highlight the benefits of using automated systems to inform the decision making processes.

Computer simulation can stochastically imitate the course of events during emergencies. Today, crowd simulation approaches make it possible to model the movements and the behaviors of residents during an evacuation. Moreover, the growth pattern of the hazard itself, in cases such as fire, can be modeled and forecasted via software applications and simulators. Such tools enable us to examine a specific building design and evaluate the safety of evacuation processes in that facility. By developing different emergency scenarios and simulating them, a computer-based decision support system can determine the best strategy of evacuation.

However, the main goal of evacuation management process is to facilitate decision making during the emergency event. It is no surprise that the real evacuation process will be different from the simulated event in some aspects. People might escape by different routes, the number and distribution of evacuees could vary, congestion could occur, or a new threat could be added to the original one. These deviations from the simulated scenario need an efficient model that performs path-planning within the tight time limits. During evacuation, there is not sufficient time for running multiple iterations of a fire simulation or a detailed crowd simulation. This highlights the need for a real-time path-planning model that responds to changes in emergency situations and promptly generates new plans that secure the safety of the occupants. For a long time, evaluation of evacuation processes has been measured based on finding plans that result in the shortest exit routes or shortest time of evacuation. However, a successful path-planning model needs to assess and rank the strategies based on the level of safety and the risks to evacuees' lives, and not only the time of evacuation.

The objective of this paper is to present a real-time path planning model for building evacuations during fire

emergency events.

2 Literature Review

The main goal of an evacuation management system is real-time path-planning of escape routes in a building. Path-planning requires a measure based on which the privilege of each specific route can be quantified. In fire emergencies, a combined temperature-smoke risk index measured by heat and smoke detectors has been used to find the optimal evacuation routes. Finally, the optimal routes were transmitted to occupants through smartphone-based devices [1]. The study did not provide enough information about the computational load, the time required for modeling, and how they addressed the challenges of using positioning techniques in indoor spaces. In another research, predictions of stochastic evacuation models were used to generate the optimal evacuation routes in real-time [2]. The framework lacked explicit attention to hazard detection and threat propagation. Dynamic exit signs were proposed for use in a smart emergency management system for tall buildings to guide evacuees towards the safest routes within a proposed geometric architecture [3]. Researchers also used information regarding ignition points, locations of trapped occupants, and locations of firefighters to help firefighters find the optimal route to access trapped person [4].

Real-time path-planning requires accurate and updated information about the physical and functional characteristics of the building. This information is collected and organized in building information model (BIM). BIM can be used to construct a door-to-room connectivity graph that facilitates path-planning in a building [5]. The interoperability of industry foundation classes (IFC) motivated researchers to extract the topological connectivity graph of the building directly from IFC data structure. This approach also uses doors to recognize the connected spaces of the building [6]. The transformation from BIM to a network graph allows the use of graph exploration algorithms for path-planning. Medial Axis Transform algorithm can also be used to produce the geometric topology network (GTN) of a building [7]. Medial axis of a polygon is the collection of all points inside the polygon having more than one closest point on the polygon's boundary.

Traditionally, the main purpose of egress design and path-planning has been to find the shortest path of evacuation. The original problem of finding the shortest path between two points has been solved based on graph exploration methods. Dijkstra algorithm is a graph search algorithm that finds the global shortest path between two nodes of a graph [8]. The cost function of the algorithm in its simplest form is based on the distance between the nodes. A* is another widely used algorithm, but instead of performing a global search, it contains a heuristic function. Similar to Dijkstra, it calculates the cost of traversed paths, while the heuristic leads the search directly towards the goal [9]. Compared to Dijkstra, the computational load of A* is much less and consequently the algorithm is faster. However, the solution is not necessarily globally optimal. In emergency management, Dijkstra has been used to find the shortest rescue path to victims [10]. A combination of BIM and Dijkstra was used for finding optimal evacuation/rescue routes [11].

The quality of evacuation processes has been primarily measured by the time of evacuation. The total evacuation time, average evacuation time of evacuees, and total evacuation time of each evacuee are some examples of this measure. However, real-time management of crowds during emergencies demands that people be guided away from the hazard along the safest possible route. In other words, finding the shortest path cannot necessarily guarantee a safe evacuation.

Route Risk Index (RRI), a risk index designed to quantify the risk of each egress route, was proposed to allow comparison between egress alternatives [12]. This index considers the length of evacuation and proximity to hazards in its calculation. Equation (1) shows the formula of RRI.

$$RRI = \int_{t=0}^{T} \frac{1}{ALET_{p(t)}}\ dt \qquad \text{Equation (1)}$$

where:

$ALET_{p(t)}$ (Available Local Egress Time) is the time it takes for a fire to reach $p_{(t)}$;

$p_{(t)}$ is the location (x,y,z) of an evacuee at time t;

T is total travel time of an evacuee from their starting location to the end of the egress route.

Given Equation (1), the risk of being at point $p_{(t)}$ is equal to 1/ALET, which is integrated over time to determine the risk for the entire evacuation path.

3 Model Development

The flowchart of the proposed model is presented in Figure 1. It is worth noting that since fire emergencies are the most frequent causes of evacuations in buildings, this model focuses on fire as the hazard. In this model, BIM is used to acquire information related to functional and physical characteristics of the facility. The BIM model is transformed to IFC data structure and geometric network graph (GNG) of the building is generated from it. It is assumed that an existing decision support system, such as EvacuSafe [12], already selected the best strategy of evacuation based on the current state of the building and the occupants at the beginning of the emergency. Such decision support system has to conclude based on precise fire simulation and crowd simulation. Here, the main goal

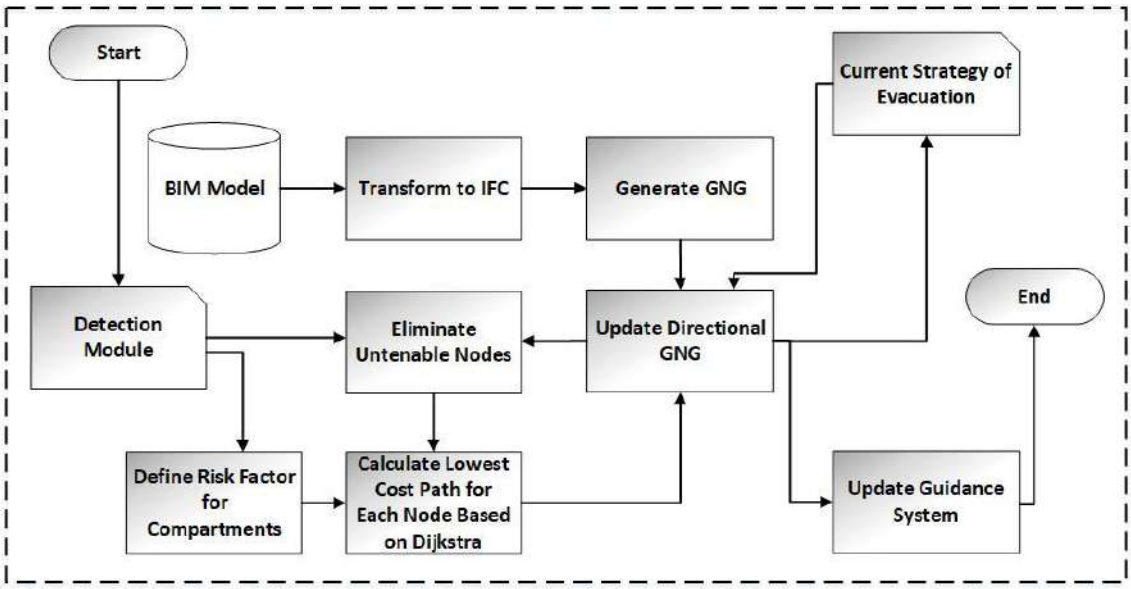

Figure 1. Flowchart of the proposed model

is to update the guidance system during the course of the emergency as the real sequence of events unfold. Fusion of the selected strategy of evacuation with the GNG of the building produces a directional network graph. Once the detection module locates the exact coordinates of the hazard, the associated node in the GNG is eliminated. A risk factor is assigned to all of the compartments/nodes in the building and Dijkstra algorithm is applied to find the updated safest path of evacuation for each node. The guidance system can then be updated.

3.1 GNG

A 3D network graph is required to represent the navigable connections between the spaces in the building. Each node stands for a space and each edge represents a connection between the spaces. This graph also has to contain information about the distances and directions of the pathways.

The graph is defined in continuous 3D space. Each node is positioned at the center of each space (room), and the length of each edge is proportional to the distance between the nodes. In order to generate this graph automatically, two sets of information are required: 1) The data related to the available connections between the spaces; and, 2) The data related to the location of each node in the space and the distance between the nodes. IFC data structure can provide this information and remain independent of a specific BIM file extension, but requires some explanation.

ifcRelSpaceBoundary was first introduced in IFC release 1.5 and was later modified in the 2X release. This entity determines the physical or virtual relationship of each space with its surrounding elements. Two attributes of this entity are *RelatingSpace* and *RelatedBuildingElement*. *RelatedBuildingElement* specifies the elements, including walls, doors or virtual elements that are immediately connected to that space. *ifcDoor* and *ifcVirtualElement* matter here. In this terminology, a virtual element is a delimiter between the rooms or spaces. This element does not exist in the built environment and its only purpose is to allow decomposition of one space into smaller segments. The IFC file is parsed and a query is run to filter the spaces sharing common virtual elements or doors. Therefore, spaces sharing the same element of these two types are connected to each other. Gradually the graph of the entire building is constructed. This graph contains information about the characteristics of all connections between the spaces.

The other element that needs to be extracted is the center of each space. *ifcSpace* has two subtypes of *IfcProductDefinitionShape* and *ifcLocalPlacement*. *ifcLocalPlacement* defines the placement of the element, i.e. space here, in the 3D space. *IfcProductDefinitionShape* describes the physical or topological representation of the product. What matters here is the footprint of the space mirrored on the navigable surface. Each space's boundaries are represented by polylines and composite curves [13]. The type of this mirrored shape on the surface combined with the information related to the coordinates of the boundaries facilitate calculation of the centroid of each space. The combination of the network graph generated from navigable connections between the spaces and the centroids of the spaces generates a GNG in which the length of edges and coordinates of nodes exactly imitates the building dimensions in reality.

3.2 Eliminate Untenable Nodes and Request Updated Path-planning

The GNG prepared in the previous step shows the navigable skeleton of the building. However, it does not present any information regarding the desired movement of the evacuees in the building. An evacuation strategy selection system, such as EvacuSafe, has the ability to select the safest strategy of evacuation based on the first signal from fire alarm system [12]. It positions the location of the hazard and then based on integrated fire and agent based crowd simulations prescribes the safest strategy for evacuation. Merging the best strategy with the GNG generates a directional GNG, which specifies the safest direction of evacuees' movements by inserting arrows on the edges of the GNG.

GNG is only the visual representation of space connections in the building. An adjacency matrix is the mathematical representation of the GNG. An adjacency matrix is an *n-by-n* matrix in which n is equal to the total number of nodes and is filled with 0 and 1 values. A value of 1 indicates that the pair of nodes are connected to each other. In the case of directional graphs, only one element of the pair is marked as 1.

Once a fire case is detected in the building, the fire alarm module sends a signal containing the location of the fire. The node in which the fire is located is eliminated from the directional GNG. As the fire expands, more nodes are eliminated. These changes in the GNG forces recalculation of the safest path for each node. Since this happens during an emergency, there is no time to redo the fire simulation or crowd simulation. As such, another algorithm is required to quickly calculate the risk of available exit paths so that the crowd can be redirected through the safest ones.

3.3 Risk Factor of Compartment
