As the fire is initiated in the building, each spot in the building is subject to a level of risk. Herein, the risk factor is defined based on philosophy of RRI. As mentioned previously, 1/ALET specifies the risk of being present at each spot in the building. This risk factor is distributed based on the time that each space can stay tenable from the evidence of fire. The risk factor provides a basis to know which zones are in higher danger compared to the others. However, ALET has to be computed via fire simulation. Fire simulation is computationally heavy and cannot be performed within the tight time limits of an emergency situation. Therefore, before the emergency occurs, the initiating point of fire has to be placed at all of the compartments of the building in fire simulation, one after the other. The results of simulation reports the ALETs for all of the compartments associated with each initiating point of fire. In this way, each node of the building is assigned by a risk factor. If another fire occurs concurrently in the building, the risk factors add up in each node.

3.4 Dijkstra Algorithm

The Dijkstra algorithm is a widely used graph search algorithm in navigation and robotics. The algorithm can be modified to calculate the cost of each path instead of the number of steps taken. In this research, two factors influence the safety of evacuation. The first is the travel time of the evacuee. The second is the path's proximity to the fire. Proximity is represented by the risk factor RRI. Based on these requirements, the cost function for the traversed path between two nodes is defined in Equation 2 using the Euclidean distance algorithm.

$$f(x) = R \times \frac{\sqrt{(x_2-x_1)^2+(y_2-y_1)^2+(z_2-z_1)^2}}{\bar{V}} \qquad (2)$$

where:

x_1, y_1, z_1 are the coordinates of the start node

x_2, y_2, z_2 are the coordinates of the end node

R is the risk factor of the edge connecting node 1 to node 2

$\bar{V}$ is the average speed of evacuees

Since the risk factors were previously defined for all of the nodes, the risk factor of the edges are calculated based on the average of two connecting nodes.

In Dijkstra, the start node is tagged first. Then, the cost of travel to all the connected nodes is calculated. The node with the smallest value is tagged. Then, the cost of travel to all of its connected nodes are calculated. The cost of unvisited nodes is updated if it is less than their previous cost. This process continues until the end node is met.

Large facilities and high-rise buildings typically have multiple exit doors. Therefore, there are multiple goals in this pathfinding problem. The Dijkstra algorithm is therefore solved for multiple exit goals and the minimum of those is the final solution.

4 Case Study

A hypothetical floor plan is used for implementation of the proposed model. The upper part of Figure 2 shows an isometric view of the three floor building with three stair cases that connect each floor level. The lower part of Figure 2 shows the floor plan, which is standard for each floor. The 3 exit doors are at the bottom of each staircase.

The BIM model of the building is translated to IFC data structure. IFC file is parsed and GNG is extracted. It is assumed that an analysis has been performed and it has been concluded that the best strategy of evacuation is simultaneous evacuation. Simultaneous evacuation is the most prevalent strategy in which all of the occupants are

asked to exit at once.

Based on simultaneous evacuation, the directional graph of the building is generated and shown in Figure 3. Note that the exit doors on the ground level are shown as red circles. The length of each edge is shown in meters, and the risk factor (R) at each node is shown in blue.

In this case, occupants in each compartment on the 2nd and 3rd floors can take all three exits and the staircases are one-way downward. That is why the edges on the 2nd and 3rd floors do not have directional arrow and the edges in the staircases do.

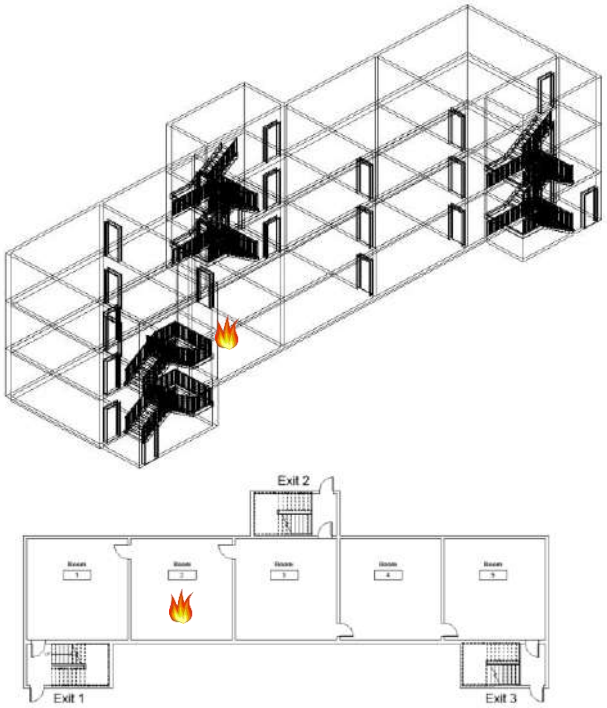

Figure 2. Isometric view and floor plan of the case study

For this research, the widely known Fire Dynamics Simulator (FDS) [14] developed by National Institute of Standards and Technology (NIST) is used to simulate the fire initiation and expansion. It is assumed that the fire-initiating element is a piece of household furniture, represented by a 1 cubic meter block of wood. The early alert of un-tenability or an approaching fire has a threshold defined by the presence of smoke that results in a visibility obstruction of 11%. Due to the computational heaviness of FDS, the fire simulations are run for a large number of scenarios during the evaluation planning stage, i.e. well before the emergency happens. Initiating point of fire is placed in all of the nodes and un-tenability times of the rest of the nodes are calculated. Simulation results are stored for access during an emergency situation.

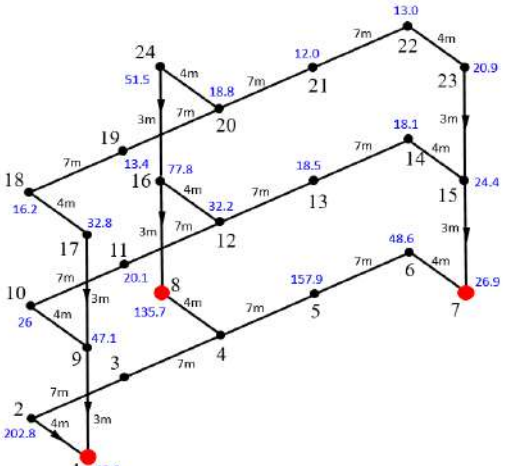

Figure 3. Directional GNG of the building with risk factors

Let's assume that the fire is initiated in node 3 on the first floor and after a specific amount of time, the fire expands. Smoke is quickly detected in node 4. It is prudent at this time to test if simultaneous evacuation is still the best strategy for evacuation.

The un-tenability condition defines ALET in Equation 1. Using this equation, the risk factor of each node is the summation of 1/ALET of the fire initiated in node 3 and node 4. The risk factor of each edge is then defined based on the average risk factor (R) of the nodes at two ends of the edge. The average speed of evacuees is assumed 1.35 (m/s) based on a study on commuters with varying genders and ages [15]. Dijkstra is later run for each node based on the cost function of Equation (2). Table 1 tabulates the result of this calculation. The 'selected route' comprises the path, as labeled in the directional GNG. The lowest cost path for each node is listed. The cost of the *shortest* path is also reported for the purpose of comparison. In 18 of the 24 nodes, the shortest path is the lowest cost path. In six cases, however, the shortest path is not the safest path. These are shown shaded in red.

For example, the lowest cost path from node 12 to an exit goes through nodes 12-13-14-15-7. Its cost is $346.5*10^{-4}$. Note that this path takes occupants to the exit at node 7 and not to the closer node 8 exit, which has a higher cost ($400.2*10^{-4}$) because it is near the fire at nodes 3 and 4. Merging the results in Table 1 with the GNG will result in the directional GNG shown in Figure 4. Note that all of the edges in the graph are now directional.

Table 1. Result of Dijkstra graph search

Node	Selected Route As per Eq.2 (Lowest Cost Path)	Cost of Selected Route ($\times 10^{-4}$)	Cost of Shortest Path ($\times 10^{-4}$)
1	1	0.0	0.0
2	2 1	372.9	372.9
3	3 2 1	Untenable	Untenable
4	4 8	Untenable	Untenable
5	5 6 7	647.5	647.5
6	6 7	112.0	112.0
7	7	0.0	0.0
8	8	0.0	0.0
9	19 1	106.6	106.6
10	10 9 1	214.9	214.9
11	11 10 9 1	334.4	870.2
12	12 13 14 15 7	346.5	400.2
13	13 14 15 7	215.0	746.7
14	14 15 7	120.0	120.0
15	15 7	57.0	57.0
16	16 8	237.3	237.3
17	17 9 1	195.3	195.3
18	18 17 9 1	268.0	268.0
19	19 18 17 9 1	344.7	913.2
20	20 21 22 23 15 7	302.1	485.1
21	21 22 23 15 7	222.2	787.2
22	22 23 15 7	157.6	157.6
23	23 15 7	107.4	107.4
24	24 16 8	380.9	380.9

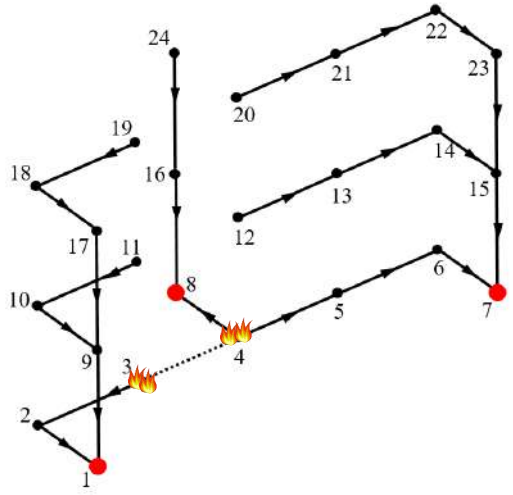

Figure 4. Resulted directional GNG from real-time path-planning model

Figure 4 graphically shows the safest evacuation routes for the current situation. Compared with simultaneous evacuation where evacuees are free to select any route, this graph recommends the evacuees in each node move away from the middle exit. It is interesting how adjacent compartments of 19-20 and 11-12 are directed to take separate egress routes. This emphasizes the point that the shortest exit path is not necessarily the safest or the most efficient option of evacuation.

The graph exploration and cost optimization of the proposed method, which must be performed during evacuation process, took less than 1.0 second on a Core i-7 dual core 2.7 GHz. This quick computation time satisfied the need for an algorithm that could reliably perform during the evacuation process. It was supported by the thorough exploration of emergency scenarios that performed during evacuation planning when the building was first occupied.

5 Conclusion

In this paper a real-time path-planning model for building evacuation was proposed. The model used IFC to automatically generate a GNG of the building. The Dijkstra method was modified and applied for exploration of the lowest cost path. The cost function of Dijkstra was defined based on combination of the proximity to the source of the fire and the length of the escape route. The risk factor representing the proximity to the source of fire was adopted from the RRI concept.

Finally, a hypothetical case study showed that the proposed model can successfully operate within tight time limits of an evacuation process. The result also showed that the conventional notion of "the shortest path is the safest path" may not always be true.

Future work in this research requires a modification to the cost function in order to include other influential factors in path-planning. Incorporating directional bias of the movements, congestion, speed variety in different zones, blockage caused by structural collapse and complexity of the routes can significantly enhance the accuracy and confidence of path-planning, which leads to a safer evacuation process.

Abstract –
This paper presents the initial planning phase results of excavator automation in the SmartBooms research project funded by Business Finland. Automation control is a key factor for the earth construction industry. Automation of excavators enables increased productivity and accurate adjustment of the digging work process, especially in depth control, which results in cost reductions. For design and research of excavator automation, a development platform has been planned using an E85 Bobcat 8.5 t excavator equipped with modified hydraulics and controls. Simulation and software development was selected using Matlab Simulink Realtime Desktop with SimlabIO CAN bus communications and custom code, while additional software development is performed mainly with integration of the robotics simulation software V-rep and Matlab.

1 Introduction

1.1 Development trends of automatic 3D control systems for construction machinery

Over the past few years, the construction machinery, mining, and forest industries have experienced particularly vigorous development in the field of work machines and directly integrated digital processes, and in automation. Finland is currently a pioneer in the world of information modeling and automation in earthworks. The control of earthmoving machinery is based on information models that provide the necessary information for control systems in machines.

Typical automatic 3D control systems at the machinery level are (Tab. 1) for example guidance (the driver moves the machine and manages the machining blade manually on the basis of computer display information); coordinating (the driver moves the machine and manages the machining blade manually with the help of inverse kinematics), guiding (the driver moves the machine and controls some of the movements of the machining blade manually when the system is running automatically on some movements), and autonomous (operating without a driver). In the Nordic countries in particular, guidance, coordinating, and guiding 3D control systems are already widely used in the control of earthmoving machinery.

Table 1. The levels of automation for earthmoving machinery.

Level	Name	Description of the activity
0	No automation	Human operates machine
1	Remote control	Human operates remotely machine
2	Guidance	Operator supported, the operator drives manually machine and blade using computer user-interface to BIM model
3	Coordinated	Tip control, the operator moves the machine and manages the tool blade manually with the help of inverse kinematics
4	Partial automation	Controlling, the operator moves the work machine and manages the part of the tool blade manually while the system drives automatically some of the movements
5	Autonomous	Machine can operate without human driver
6	Autonomous machine swarm	Autonomous operation of work machines, interactivity and collaboration of working machines

The level of automation also depends on the type of machine. In spreader-type machines such as graders, bulldozers, and asphalt spreaders, the control systems are already actively controlling automated movements. In boom-type machines, control is generally still at the guidance level, where the driver manually controls the boom based on the control information displayed by the system. To increase the automation level in control of machines, one of the basic problems and challenges is to take account of changes in the work environment

efficiently and safely. Other machines, vehicles, and people may move into the working area of the machine, or the material to be cut or loaded in excavator work can move unpredictably. Automatic functions always require sensing and control values calculated by the computer. Verifying the condition and correctness of sensing and steering is closely related to the security review of autonomous movements.

An interesting algorithm toolbox and development platform has been introduced by Fraunhofer IOSB [1]. The purpose is to equip a variety of robotic systems with different autonomous capabilities relevant for their intended purpose with minimal adaptation effort.

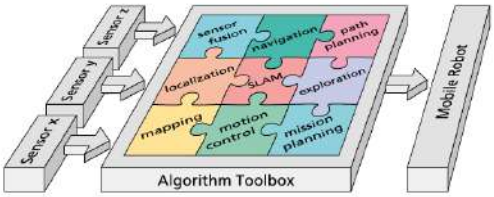

Figure 1. Fraunhofer Algorithm Toolbox for Autonomous Mobile Robots [1].

The puzzle modules of the Toolbox of Fraunhofer are mapping, localization, sensor fusion, motion control, SLAM, navigation, mission planning, exploration and path planning (Fig. 1).

1.2 Automatic control for Excavator

The excavator is a general-purpose machine on construction sites, with a high number of operating hours. The excavator has a lot of end-effectors such as buckets of different sizes, spikes, vibrators, and accessories for pipe installation, drilling, piling, stabilization, etc. The tasks are very versatile and challenging with guidance. The most typical infrastructure construction tasks are ground cutting, loading, material reception, and geometrically challenging ramp work.

The Robotics Institute at Carnegie Mellon University (USA) performed an interesting experiment with an autonomous excavator back in 1998 [2], while LUCIE by Lancaster University [3] is equally well known. The research group behind Carnagie Mellon created a model from the surrounding area and was able to find and fill a truck without the help of a human operator.

In recent years, Komatsu has been one of the most important technology drivers in the construction industry. Komatsu has already introduced an excavator control system. Novatron Ltd is currently marketing a guiding Xsite PRO system, which is the most integrated of commercial systems in the overall process of open information modeling (Open Infra BIM).

Figure 2. Commercial example: the Leica iCON iXE3 Copilot.

Figures 2 and 3 show the automation system of the Swiss Leica, where the guidance system has integrated automatic control of the level of cut of the excavator bucket, based on an angle readings by the machine control model. The Trimble Earthworks system automatically controls the lifting of the main boom according to the model, otherwise the operator manually drives the machine in the guidance model.

Figure 3 Testing the Leica machine automation system at Destia Ltd construction site in Vaala, Finland.

Figure 4. Research project in Japan by Kanamoto Ltd, on a movable humanoid remote robot for remote control.

Figure 5. Control and pilot station for more realistic remote operations.

It is particularly interesting to study and monitor the development of guidance technology in Japan, which is constantly affected by landslides due to earthquakes, typhoons, and sensitive earth material. These conditions are dangerous for workers, which is why Japan has developed and switched to a wide range of remote-controlled earthmoving machinery (Figures 4 and 5). In this case, the operators sit at a safe distance from the work site, in cabins from which they can control the heavy machinery using video connections and machine control systems. Some companies use a human robot in these systems to repeat as accurately as possible the drive movements made by the human operator in a safe cabin. However, Japan is lagging behind northern Europe in the use of information modeling based automation.

The self-propelled or self-contained excavator has been a research and development goal for quite some time. Various test systems have been tested. For example, the excavator introduced by Carnegie Mellon University in 1998 [2] was able to fill a truck platform without driver assistance, based on laser scanning. Automated excavators for construction sites have still not become mainstream, but development activities are now properly ongoing.

1.3 Aim of the research

The aim of the research and paper was to develop and experiment the new robotic development platform to the University of Oulu as well as to introduce the first results how to apply the platform for practical developments and experiments.

2 Automated Excavator Development Platform and the Experiments

The University of Oulu is developing an autonomous excavator in a SmartBooms research project funded by Business Finland. The aim of the SmartBooms project is to research and develop a new, continuously adaptable and automated control method for the boom of working machines through:

1. Developing automated control of the movements of machine and booms.
2. Use of different information models and real-time situation updating by continuous surveying.
3. Modular development enabling wide and versatile development of control applications in the earthmoving, forest, and mining industry, and installation of the control systems at the early manufacturing phase in the machinery factories
4. Applicability to product development of smart boom control systems for earthmoving, forest, and mining working machines.

2.1 Excavator and equipment

Figures 6 and 7 show the Bobcat E85 (8.5 t), which was chosen as the excavator machine by public tender. This excavator size was chosen to fit general construction sites, so it can be tested in a wide range of tasks, including road construction. It was decided to steer away from larger excavators, to make maintenance and handling

easy, while smaller excavators are not well suited to general-purpose digging and there is too little room for fitting the components and sensors needed. The machine needed to undergo a complete overhaul of the hydraulic systems, where valves were retrofitted for precise electrical control. For hydraulic control, a separate control unit was installed. To equip the excavator with a sight, a laser measuring device was installed onto the stick boom of the machine.

Figure 6. The University of Oulu's Smart Bobcat E85 Excavator.

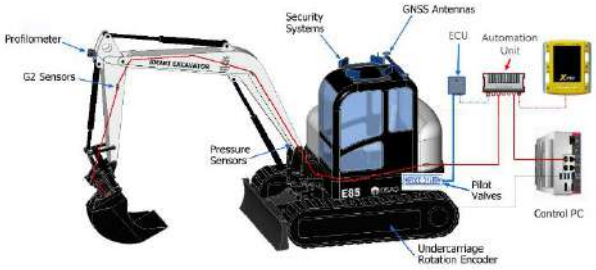

Figure 7. Components of the University of Oulu's Smart Bobcat E85 Excavator.

The basis of the sensory system are newly developed Novatron IMU G2 sensors, which can work up to 200Hz frequency. They provide accurate and precise positioning of the excavator which is good enough for automatic movements. Novatron's G2-type sensors have CAN bus-interfaced sensors. Use of CAN bus decreases the need for wiring and all sensors can be set at the same bus. Sensing accuracies and characteristics of the sensors were tested with the KUKA industrial robot (Figure 8). Dynamic and static features of previous versions of the Novatron sensors were also tested at the University of Oulu [4]. The new G2 sensors are significantly more accurate and reliable than the previous versions of Novatron sensors used widely in earthmoving work.

CAN bus is widely used in the automotive industry and various other industries. It is a low-cost device with less wiring, it works in various electrical environments, and it uses priority according to node ID [5].

Figure 8. G2 sensor testing using a KUKA robot manipulator

For global coordinates, a Trimble GNSS system is used in combination with an Xsite machine control system to provide location data. Communication between Xsite and hydraulic control is by CAN bus, while communication between machine and main level development pc is by both CAN bus and Ethernet proxy.

For safety reasons, it was decided to implement a camera system, most likely in the roof of the excavator. Laser profilometers and stereo sensors are currently selected to fit the excavator to provide data for both security and path planning. In the experiments, a new miniaturized 256x8 pixels line laser profilometer developed at University of Oulu was used.

2.2 Simulation environment

Virtual prototyping and code development testing were first intended to be performed in Matlab only, but it quickly emerged that this was not a reasonable approach, even using a Virtual Reality Toolbox. The Msc.Adams that we have successfully used previously for this purpose [6, 7, 8] was too laborious, lacked programming methods, and was too restricted to be selected. The game engine approach we have used previously in one case [9] is well suited to this task, but is quite a human resource-intensive option. After testing multiple general- and special-purpose virtual simulators, we selected the V-rep robotic simulation tool [10]. The main reasons were a) ease of use, b) light enough to run in normal laptop, and c) reasonable Matlab integration.

For non-commercial and educational use, Coppelia Robotics offers an educational license for The Virtual Robot Experimentation Platform. V-rep is a practical tool for the purpose, since it has many built-in actuators and sensors that are easily modified with scripts. That is why it requires less effort to build a functional environment compared with general tools such as Msc.Adams and Simulink. Model building in the V-rep scene editor is intuitive. Other specialist systems lack significant features such as mesh manipulation, simulation video, and multiple default physics engines. V-rep also has a wide library of miscellaneous robots, vehicles, and objects.

V-rep was chosen as a platform for the prototyping and testing of controls, and sensing of the automated excavator. Simulation parameters and movement are controlled through remote-API with external applications such as Matlab, where an inverse kinematics model and functions to operate actuators and to manipulate sensing data will be built.

With default simulation settings, V-rep simulates the tested scene (Figure 9), which simplifies the dynamic model, as represented in Figure 10, with execution times of around 40 ms for non-threaded scripts and of 10 ms for dynamic handling calculations. Because the calculation time increment is 50 ms, the calculations are somewhat faster than real time and the simulation video is rendered at around 24 frames per second. For the scene shown in Figure 10, one minute of simulation took 55 seconds running in the researcher's basic laptop. Simulation has an option for the lower accuracy and lighter calculations, as well as the customized time increment.

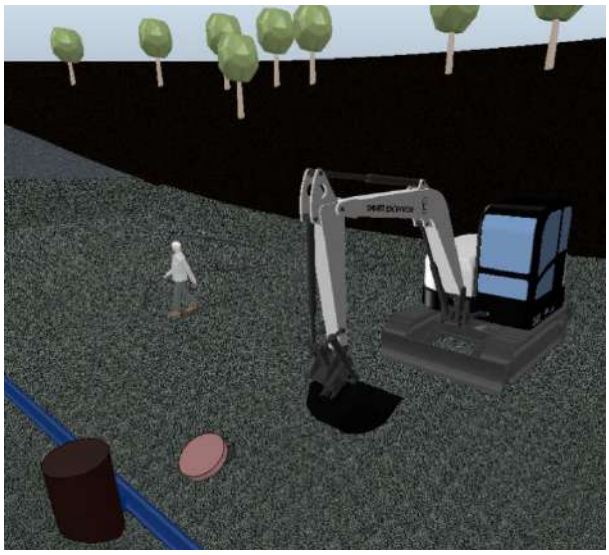

Figure 9. Test scene to study performance of the simulation software.

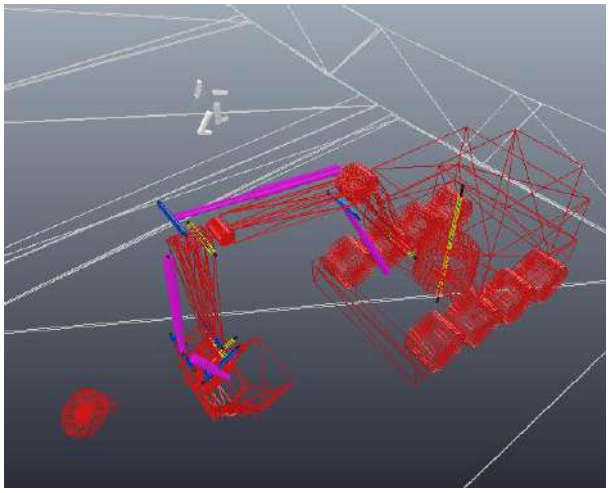

Figure 10. Simplified dynamic model for simulations.

A series of tests were performed using the robotic development platform. In the paper some observations from sensor calibrations, the use of the industrial robot as a reference model for the generation of digging trajectories i.e. control models, the first experiences of V-rep robotic development software as well as some test results of the new type of laser profilometer are reported.

3 Results

In the experiments with KUKA industrial robot, three IMU G2 sensors attached to the robot were used for real-time accurate capturing of boom and bucket movements. Actually, a kinematic sensor calibration of the G2 sensors was successfully performed using the driving paths of the robot as references. The robot was programmed to mimic real excavators digging movements to acquire data of G2 sensors repeatability, angle accuracies and effects of acceleration to the sensors data. Valuable detailed data of sensors abilities were gathered during robot measurements and will be reported later.

The first experiences of the V-rep robotic development software quite positive. The software has a good user-interface with a support of versatile robotic subroutine library, and the programming work was found to be relatively easy to execute. The accuracy and complexity of model details can slow down the real-time calculation of the program.

Experimental field tests and obtained results showed the suitability of the laser profilometer for surface changes monitoring and 3D visualization of a surface from the excavator (Fig. 11). The applied

method seems offer sufficient measurement accuracy in relation to the measurement range in work site. As the main advantages of the method the monitoring does not require expensive measuring equipment. Typical measurement materials and targets on earth construction sites seems to have sufficient reflectivity, color, and brightness of the object surfaces to be captured by the measurement system.

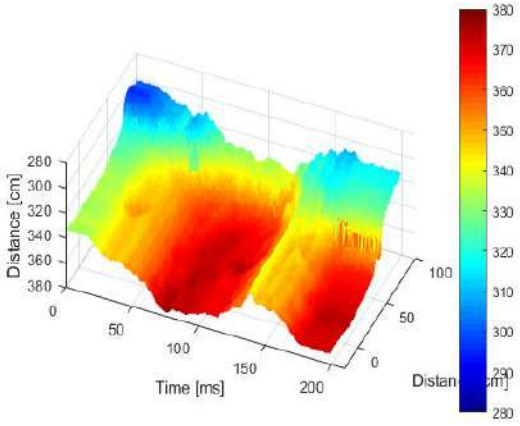

Figure 11. A pit measured by the laser profilometer from the boom of Bobcat excavator.

4 Conclusions

The SmartBooms project has created a simulation test environment and robotic development platform into University of Oulu for the development of autonomous excavation equipment. The simulation environment was a powerful tool for safely testing new concept and control algorithms. The platform utilizes also the selection of newest sensor systems with IMU G2 sensors and a solid state laser measurement system developed at University of Oulu.

The main software chosen for development was Matlab Simulink Realtime with SimlabIO integration to CAN. The main platform software is supported by many different tools, with V-rep used extensively. The physical excavator chosen through public tender is a medium-sized Bobcat E85 equipped with a Novatron Xsite machine control system.

The puzzle modules of the Toolbox of University of Oulu are so far 1) open information modelling, 2) positioning in accurate coordinate system, 3) sensor fusion, 4) motion control for machine rotation and movements of booms and bucket, 5) machine transition and navigation, 6) mission planning and work task creation, 7) path generation and 8) safety assurance.

Our goal in future work is to produce a fully autonomous excavator operating on an earth construction/excavation site according to the parameters given by the designer. In addition, the excavator algorithm must prevent the excavator from undesired and possibly destructive movements. A self-moving machine must always know what to do. The most important facilitator of autonomous control and machine learning, *i.e.* "machine intelligence", is integration into the information modeling process used by the Infra industry.

Abstract –

In a dynamic construction site, sound generated by work activities and equipment operations is one of vital field data indicating construction progress, work performance, and safety issues. However, because of an enormous number of construction work types, accurate sound classification is currently limited. To address this challenge, this study proposes a schedule-based sound classification for establishing dynamic sound training data. With the schedule-based dynamic training method, this system retrieves the types of sounds of daily planned construction activities for flexibly restricting training data types of working sounds and ultimately improving the accuracy of sound classification. To reveal the implications of audio-based construction activity detection and site monitoring frameworks, this study also involves the development of a construction sound library, a hardware system, a sound classification framework, and a web-based visualization method. This proposed method is expected to play a critical role in managing a construction project by supporting site monitoring and progress analysis, and safety surveillance.

1 Introduction

In the construction industry, the lack of appropriate technologies to acquire field data has been a primary obstacle to prevent real-time data collection and analyses. With the rapid development of information technology, the construction industry has been seeking for new field data acquisition and advanced analysis methods to pursue enhanced construction activity monitoring and automated field management. It is critical to allow domain professionals to manage construction activities and operations efficiently with accurate analyses and measurement of field data throughout an entire construction project, because of dynamic and complicated backgrounds of a construction project with various work activities. With the help of previous research studies of field data collection, diverse applications and monitoring technologies such as sensors- and vision-based methods have been investigated to explore their potentials and practicability in the construction industry [1, 2]. Recent studies have also identified the implications of the implementation of the audio-based site monitoring technique [3, 4]. This study states that sound data not only require less data processing weight for a data analysis than one from vision data, but also have no limitation to capture data with an unlimited level of illumination and scope [3]. Because of the diverse types of equipment, materials, and work environment, however, it is not practically feasible to establish a comprehensive sound data library covering all sound types of construction work activities in a site. To ameliorate this challenge, this study aims to establish construction schedule-based sound data training and audio-based site monitoring frameworks that dynamically develop sound training data according to daily planned work activities. This study involves the development of a construction sound library, a dynamic sound data training model, a hardware system, and a web-based sound data map visualization. To assess the proposed approach, this study has the experiment of sound classification with a real construction project schedule and illustrates improved classification accuracies with a confusion matrix.

2 Literature Review

Recent decades, diverse studies explored advanced technologies for construction field data collection and process monitoring using sensors, ultra-wide band, and computer vision-based monitoring [1, 2, 5, 6, 7]. However, vision-based monitoring is somewhat limited in tracking work activities during night time because it requires certain level of illumination and has the restricted range of a vision angle [3]. In addition, video and kinematic data are too heavy to be processed for real-time monitoring. Sound data as a new type of field data requiring less data processing weight have been explored in several studies. The execution of an audio-based approach using the support vector machine has been investigated for construction activity identification of heavy equipment [3]. The frequency domain approach was also applied to identify overlapped sounds generated by different equipment at a construction site [4]. However, these previous studies mostly focus on utilizing and improving a signal analysis, feature extraction, model training, and testing. This study has an objective to enhance sound classification accuracy by providing dynamic sound training data according to planned daily schedule.

3 Research Approach and Methodology

The primary goal of this study is to establish a schedule-based sound data library containing sound data types associated with daily planned construction activities and compare the classification result based on the schedule and that without the schedule. To identify construction activities accurately, the audio-based monitoring system requires a robust sound data library involving diverse types of work activities. Since a construction project schedule entails a detailed daily work plan including types of work activities useful for building the foundation of a site monitoring system, its data can be utilized for pre-identifying daily planned work activities and their sound types, allowing the system to flexibly retrieve sound data from an existing sound data library and establish training datasets accordingly. Figure 1 shows the research process including the establishment of a sound data library, sound classifier training, a construction activity detection framework, and a visualization interface.

To accomplish this objective, this study employs a construction schedule in the XML format extracted from a construction scheduling software. In addition, this system adopts the K-nearest neighbor (KNN) classifier for sound classification based on extracted features of selectively retrieved sound data.

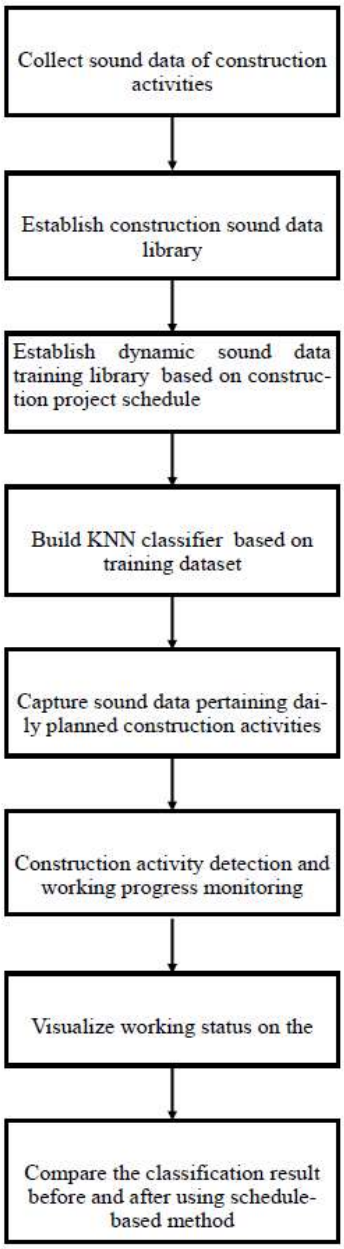

Figure 1. Framework of the methodology

With the customized XML schema, this system extracts XML-based construction schedule data including construction activities, equipment resources, and operation time from the Microsoft project, which is one of the broadly used construction scheduling software. This schedule data are imported into a framework to retrieve corresponding sound data from the established sound data library to build dynamic training datasets. The authors have already developed a sound data library that encompasses more than 100 sound data covering 15 types of construction work activities. Figure 2 shows the

process of the establishment of a dynamic training data library including schedule information retrieval, sound data extraction, and training data development. The retrieved daily schedule information is referred to build a training data library including audio files (.wav) of equipment and work activities by conducting the matching process using the filenames and the semantics of audio data. With the established schedule-based library, the input file containing daily planned work types can be interpreted to extract corresponding audio data and their features that are the imperative resources analyzed by the KNN model.

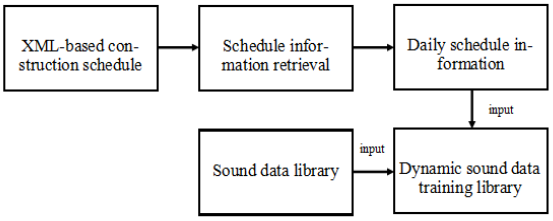

Figure 2. Establishment of dynamic sound data library

3.1 Development of a Sound Data Library

In this study, eight type sound data of construction activities including Excavating, Concrete Mixing, Compacting, Bulldozer, Hammering, Piling, Concrete Pumping and Drilling were recorded from the real bridge construction sites in East Baton Rouge, Louisiana. These sound data are divided into a short segment with bins of 2 seconds long and split into both training and testing sets. Because of the complex background and the dynamic environment of the construction site, recorded sound data of construction activities generally include noise and the classification accuracy is highly dependent on signal to noise ratio [8]. Therefore, a de-noising process is required to enhance raw sound signal data and a noise estimation algorithm [9] is adopted in this research. This algorithm is applied to reduce noise by computing the ratio of power spectrum to minimum power spectrum for each segment. If a ratio is less than one, it should be removed from original signal waves, or it can be regarded as valuable signal. The original and enhanced sound data of compacting and excavating are shown in Figure 3 and 4.

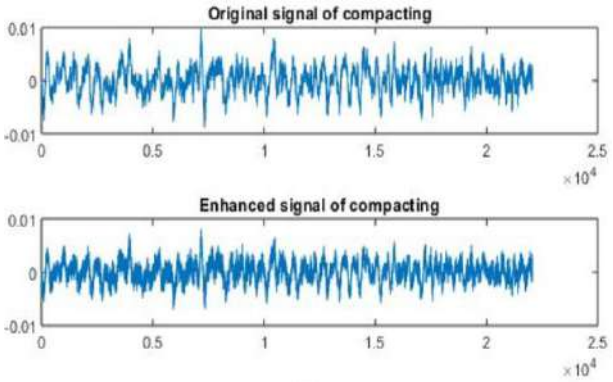

Figure 3. Original and enhanced signal of compacting

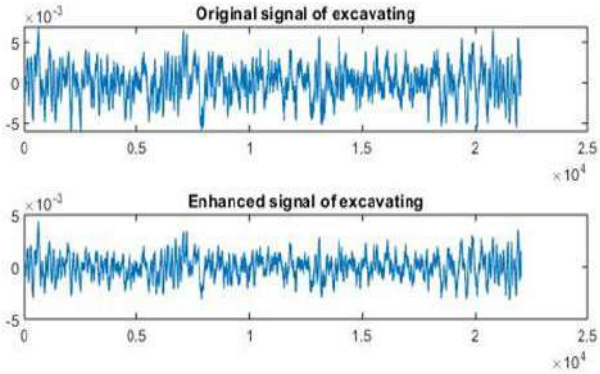

Figure 4. Original and enhanced signal of excavating

3.2 Generation of XML-based Construction Schedule Data and Training Data Library

Table 1 shows the schedule of the bridge construction project in East Baton Rouge, Louisiana, which consists of construction activities, resources, and starting and finishing time. Figure 5 illustrate the XML-based schedule data extracted from the Microsoft Project software.

Table 1. Schedule of Bridge Construction in East Baton Rouge

Construction Activities	Construction Resources	Starting Time	Finishing Time
Earth Works	Mobile excavators	2018-09-07	2018-09-20
Structural Excavation for Minor Structures	Mobile excavators	2018-09-07	2018-09-20
Fabric and Grid Reinforcing	Complete Reinforcement Cages	2018-09-11	2018-09-13
Sheeted Caissons	Pile Drivers (Rammers) and Pulling Tools	2018-09-12	2018-09-13
Sheeted Caissons	Pile Casings (linings)	2018-09-12	2018-09-13
Cast-in-Place Concrete Pile	Ready Mixed Concrete C30	2018-09-14	2018-09-17
Spreading and Compaction	Wheel loaders	2018-09-14	2018-09-20
Reinforcement Bars	Reinforcing Bars	2018-09-18	2018-09-25
Reinforcement Bars	Steel Reinforcement cutters	2018-09-18	2018-09-25
Structural Cast-in-Place Concrete Forming (steel)	Steel Forms	2018-09-26	2018-09-28
Cast-in-Place Concrete C25	Concrete truck mixer / agitator	2018-10-01	2018-10-02
Cast-in-Place Concrete C25	Concrete pumps and equipment	2018-10-01	2018-10-02
Cast-in-Place Concrete C25	Concrete vibrators	2018-10-01	2018-10-02
Cast-in-Place Concrete C25	Ready Mixed Concrete C25	2018-10-01	2018-10-02
Concrete Curing	Coatings for Concrete and Masonry	2018-10-03	2018-10-05

Figure 5. Generated XML based schedule

By referring the project schedule information, this system retrieves project-specific sound data from the pre-developed sound data library to build a dynamic training data library. To evaluate the proposed method, the research team conducted the case study using the following three construction activities in Table 1 scheduled from 2018-09-14 to 2018-09-17: Earth Works, Spreading and Compaction, and Cast-in-Place Concrete Pile. As shown in Figure 6, these schedule data are exported in the XML format from MS Project and imported into the framework to retrieve the associated sound data and generate a daily training library.

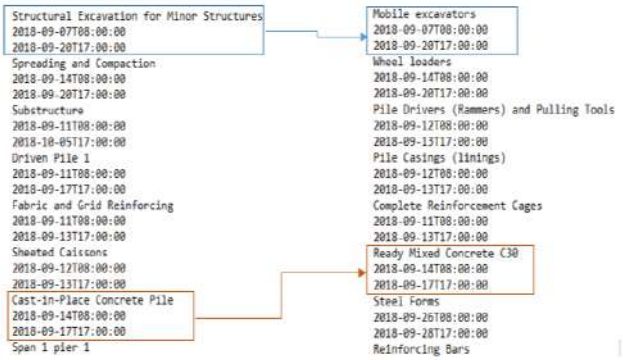

Figure 6. Schedule information retrieval

3.3 Hardware development of an audio sensor-based system

Microphones are the primary devices for capturing and recording sound data and each microphone contains a surface designed to capture audio waves. The internal circuits of a microphone should be powered to generate a sound signal and a wireless system is designed for audio signal receiving combined with the data analysis. Figure 7 shows the hardware design including a microphone, a radio frequency module (RF) including a transmitter and a receiver (nRF24L01), and a multi-track recorder (Zoom F8).

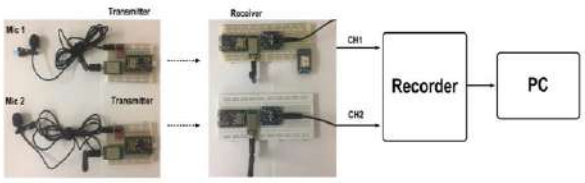

Figure 7. Hardware settings

3.4 Audio Signal Transmission and Analysis

Microphones capture surrounding sounds and transform them into electrical signals that are amplified through pre-amps making that the signals can be readable by micro-controllers. For a real-time sound signal transmission, we utilize a nRF24L01 transceiver module which is widely used in two-way radios, called walkie-talkie. In the current research, even if nRF24L01 modules work as one-way radios, the RF module can be suitable because it has an operating frequency of 2.4 GHz (ISM band) and a multichannel capability (up to 126 channels). Moreover, it can achieve a sample rate of 44 KHz with 1 Mbps data rate.

Within an available network of the RF module generally covering 1.5 miles, transmitters play a role in transferring the data sets to the receivers as shown in Figure 8. Receivers obtain the sound data in the form of digital signals. Microcontrollers select proper channels for the receivers from different channels and the digitized

sound information can be transformed into the analog signal for the 8-channel recorder. The recorder collects the sound data from the multi-channel and transfers the data to a computer for analysis as shown in Figure 9.

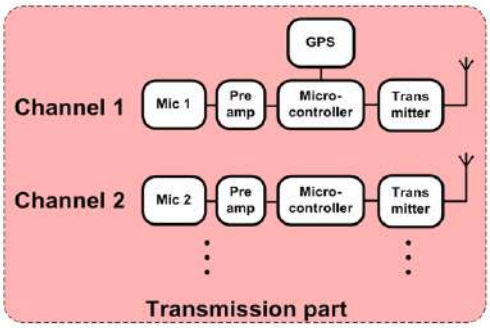

Figure 8. Sound signal transmission

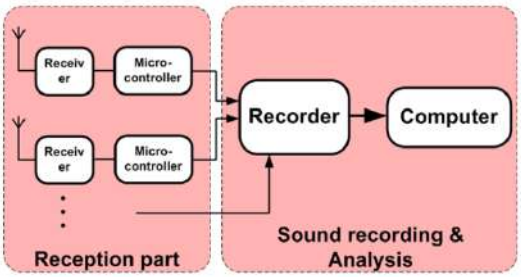

Figure 9. Sound signal receiving and analysis

3.5 Pre-processing Including De-noising, Feature Extraction, and KNN-based Sound Classification

Recorded sound data in a construction site generally contain background noise that negatively affects the accuracy of sound classification and site monitoring. Thus, this system adopts the noise estimation algorithm for de-noising, which reduces noise of a training dataset. This method computes the ratio of power spectrum to minimum power spectrum for each segment and then remove if a ratio is less than one. By using 44.1 kHz sampling frequency, this study utilized 15 distinct sets of features and in our experiments, the K nearest neighbor (KNN) algorithm achieved enough high classification accuracies, while maintaining fast execution. A set of features is required to build the KNN model. To extract the features, sound files were split in frames of 2s, from which the features shown in Table 2 were extracted to fit the KNN model. During training, each sound belongs to a defined construction activity category, as mentioned earlier. During execution, features are extracted from the recorded sound and fed to the KNN algorithm. The predicted category is found by minimizing the expected cost among the nearest neighbors of the current sample that is, by finding the nearest neighbors, shown in figure 10. When testing new audio segments, the output should be one of construction work activities or equipment operations in sound data library mentioned in section 3.1.

Table 2. Selected Sound Features

Symbol	Feature name	Number of features in the set
ZCC	Zero Crossing Count	10
VZCR	Variance of Zero Crossing Rate Ratio	1
HZCRR	High Order Zero Crossing Rate Ratio	1
RMS	Root Mean Square	10
LEF	Low Energy Frame	1
STE	Short Time Energy	1
LSTER	Low Short Time Energy Ratio	1
VLER	Variance of Low-Band Energy Ratio	1
VSFLUX	Variance Spectrum Flux	1
LFRMS	Low-Frequency Root Mean Square	1
LFZCC9	9th-order moment of LFZCC	1
SBC	Sub Band Correlation	5
HOC	High Order Crossing	8
LPC	Linear Predictive Coefficients	7
MFCC	Mel-Frequency Cepstral Coefficients	13
Total		62

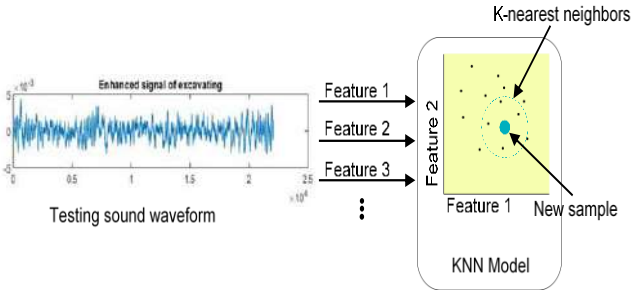

Figure 10. Predicting new sound

3.6 Construction Activity Identification and Accuracy Evaluation

By executing the fitted KNN model with daily dynamic training sound data, this study evaluates the accuracies of sound classifications before and after using the schedule-based approach. 200 short time segments (2s long) audio files of the three selected work activities are split into training and testing datasets evenly: 100 segments are the training dataset and the rest are the testing dataset. To compare the accuracies of the two scenarios without and with the integrated schedule data, the confusion matrices are adopted as illustrated in Figure 11 and 12. The classification accuracy is only 78.6% without the integration of the schedule information and 99.7% with the schedule-based dynamic training data library. These experiments clearly show that a schedule-based dynamic training framework significantly improves the accuracy of construction work sound classification.

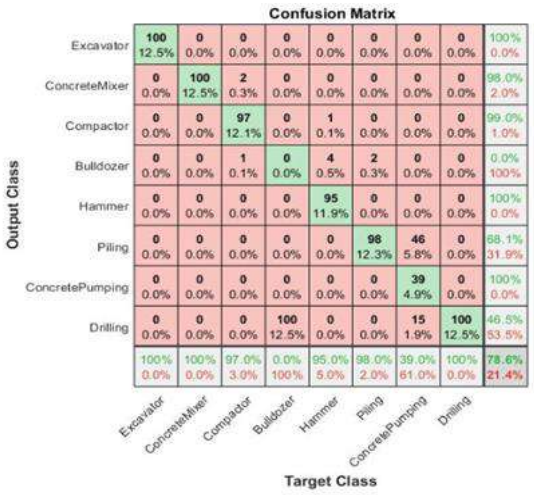

Figure 11. Classification accuracy without schedule information

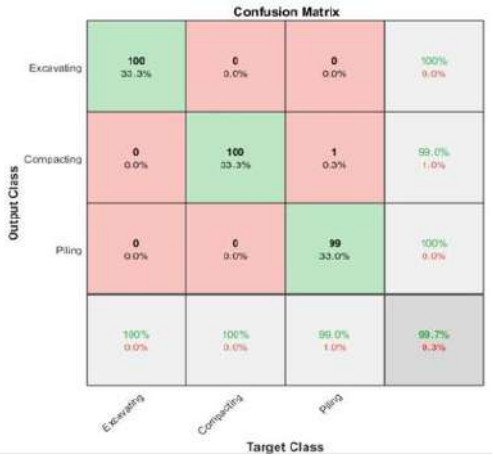

Figure 12. Classification accuracy with dynamic training data library

3.7 Web-based Visualization Map

As a visualization interface, a website has been developed to represent real-time construction work status and progress on different locations. The Web framework has been built with the Python Django framework and Leaflet is used for the base map tiles. Mapbox, ArcGIS and OSM tiles have also been integrated to the website for a better perspective of visualization data. The backend of the website is connected to a PostGreSQL database that is using the cloud Relational Database Service (RDS) from Amazon Web Services (AWS). An additional script written in Python has been used to read data from a JSON file and update the cloud database accordingly. Finally, the website has been deployed using Heroku. The website map representing site locations, job types, and working dates is shown in Figure 13.

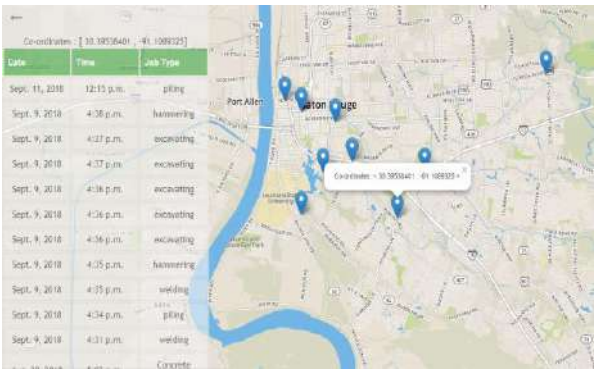

Figure 13. Construction Activity Visualization

4 Conclusion

The sound recognition technology has been adopted in diverse disciplines, but not received much attention in the construction industry. This paper proposes a schedule-based approach to improve the sound classification accuracy for providing robust construction event detection and site monitoring frameworks. As the outcomes show the significantly improved accuracy, this method is expected to be an imperative asset for diverse disciplines to develop an innovative technology that captures, analyses, and visualizes sounds of construction work and equipment in a dynamic and complicated construction site. The research results also involve new knowledge on the implications of sound recognition in the construction industry for accurately identifying working status and progress monitoring without any human effort. However, there are a few limitations identified in this research such as the insufficient size of sound data. The size of the data is not huge enough to validate the result and this research team will keep collecting sound data including various types of work activities for future research. In addition, the identification of heterogeneous sounds occurring simultaneously by using neural network is necessarily to be discussed in the next study and the recognition of sounds that do not belong to any of the categories such as the recognition of idle time will be also investigated. It is expected that the developed theoretical framework will add the innovative scientific knowledge and the new logical theory which pose significant impacts on the workflow optimization, the accurate task-performance measurement, and civil infrastructure construction projects for roads, highways, bridges, and tunnels.

Abstract –

Drawbacks of the absence of the flow view in the conventional construction logistics planning gain more attention. Inefficiency and wastes (e.g., on-site overstock) in the construction logistics caused by adopting an avoidance strategy is recognized. Meanwhile, the unstable labour productivity and periodic planning method cause difficulties for adopting Just-in-Time (JIT) approach in construction. As a real-time control system of a production flow with the ability of rapid and precise acquisition of facts, the Kanban system can be a solution for a pulled production and related logistics. This paper explores how to apply Kanban concept to record the material consumption, report the real-time demand and trigger a material replenishment from off-site to on-site. A methodology of designing and applying Kanban batch in the digital construction logistics with Building Information Modelling (BIM) systems or tools is proposed. A case study of an infrastructure project is carried out to address the functions and performance of a Kanban-triggered material replenishment. The results of the case study show significant savings of site storage area and construction time by applying Kanban concept in the construction logistics.

1 Introduction

For a long time, buffering is a conventional solution to prevent adverse effect of off-site material supply disruptions in the construction field [1,2]. However, it may cause problems, e.g., additional waiting time, an excessive amount of orders, overstock on-site, waste of site capacity as well as difficulty in materials and related equipment maintenance [3]. To reduce buffers and remove wastes from the construction process, lean production approaches such as Just-in-Time (JIT) are considered useful [4,5]. However, the unstable labour productivity and periodic planning method cause difficulties for adopting JIT production in the construction field.

The original Kanban system is well-known as a JIT control system, but its application is not limited to JIT production. The essence of the Kanban system is characterized as a real-time control system of a production flow with the ability of rapid and precise acquisition of facts [6]. A conventional construction logistics plan adopts a short-term demand forecast based on managers' experience and expertise. However, most information systems for construction logistics cannot capture this kind of demand forecasting results because of limited data. Developing the knowledge bases and sophisticated algorithms can help transfer the knowledge in this specific field from the person to the computer. Based on it, real-time analysis, adaptive buffering, proactive scheduling and automated decision-making for construction logistics are realizable. From an operational perspective, the equilibrium of material consumption, on-site stock, and off-site replenishment is essential for construction logistics at the current stage. To address this point, adopting the Kanban concept is helpful for information systems to capture the real-time material consumption amount and replenishment demands precisely and timely.

This paper explores how to apply the Kanban concept to record the material consumption, report the real-time demand and trigger a material replenishment from off-site to on-site. First, a literature review regarding Kanban system and construction logistics planning is conducted to trace back the theoretical foundation. Meanwhile, experiences are drawn from current construction planning practices. Afterwards, a methodology to design and apply Kanban batch in the construction logistics with 4D Building Information Modelling (BIM) systems or tools is elaborated. An infrastructure project is finally studied and simulated to address the functions and performance of a Kanban-triggered material replenishment.

2 Literature Review

2.1 Kanban System

The Toyota Motor Corporation developed the Kanban system with order cards to control production flows because the cost of adopting the computerized system was huge in the 1970s [6]. As the development and maintenance costs of information systems gradually decrease, many manufacturers implemented electronic Kanban systems. Junior and Filho (2010) did a review and classified variations of Kanban systems into systems which follow the original Kanban logic and systems which do not [7]. Systems using the original Kanban logic have the following features:

- Use of two communication signals, i.e., production and transportation signals;
- Pulled production;
- Decentralized control;
- Limited WIP, i.e., finite buffer capacity.

By comparison, variations beyond the original Kanban logic emphasize one or several following aspects:

- Variable maximum inventory level;
- Signal use modification;
- Gathering and using the information;
- Functioning;
- Materials release.

Nowadays, the manufacturing industry has adopted a series of mature production information systems or software packages using original, partially or entirely modified Kanban logic. In the AEC field, Kanban-like or Kanban-type methods are frequently mentioned in lean construction research, addressing the pull concept and visual control of construction workflows. Tserng et al. (2005) proposed a Kanban-like visual control system for project participants to manage construction supply chains [8]. Sacks et al. (2009) introduced Kanban-type pull signals in BIM-based environments to improve the transparency of construction workflows [9]. Dave et al. (2016) adopted control principles from Kanban to fulfil the visual controls in a lean construction management system using BIM [10]. However, most of the Kanban signals applied in construction serves as a visualized process status (e.g., finished, delayed or under construction), rather than the demand-driven, i.e., pull production trigger, which is the essential part of the original Kanban system.

2.2 Construction Logistics Planning

According to current practices, the construction logistics plan is generally made according to construction managers' experience and expertise. It involves an as-designed site-layout, project QTO (Quantity Take-off) and a series of periodic (e.g., daily, weekly, monthly) schedules [11]. It adopted periodic planning of material consumption, and site storage areas are configured according to the periodic consumption. Another essential feature of the current construction logistics planning is that materials and building components are treated as input or constraint of a certain construction task from a construction workflow or schedule [11]. The completion of the target construction task is the highest goal and any shortage of on-site material stock should be avoided. Therefore, problems about excessive amounts of orders, waste of site capacity and difficulty in materials maintenance etc. may occur. Two aspects should be taken into account regarding current construction logistics planning:

1. Uncertainty caused by periodic consumption, i.e., short-term demand forecast based on experience and expertise;
2. Inefficiency and wastes (e.g., on-site overstock) caused by adopting an avoidance strategy to ensure sufficient material resource for construction workflow.

Considering the aspects mentioned above, Last-Planner System (LPS) provides a pull concept using the "Should-Can-Will-Did" pattern and weekly meetings regarding construction workflows and schedules [11]. It helps to correct the deviation between as-planned and as-built progress and to reduce the uncertainty of a short-term demand forecast. Meanwhile, approaches, e.g., Advanced Work Packaging (AWP) and location-based management improve construction scheduling and workface developing [12].

From an operational perspective, the equilibrium of material consumption, on-site stock, and off-site replenishment is essential for the two aspects above. It does not emphasize the robust of the construction workflow itself but requires a clear production flow [13]. Every construction task can be treated as a discrete production, where precise real-time material consumption can be reported as evidence of future demand. It is the essence of the Kanban signal in a pulled production. Compared to LPS or AWP, the Kanban system is more appropriate to deal with material flows rather than construction workflows. The season is that the material flows are not sensitive to on-site discrete production and unstable productivity.

Simulation techniques support the analysis of material and information flows in construction. As Law described, material and information flows for analysing supply chains are suitable to be defined as a simulative system [14]. Modelling and Simulation methods e.g. discrete event simulation (DES) and agent-based simulation (ABS), have been continuously developed in

the field of the construction logistics, to analyse and optimize logistics processes and configurations [15].

The original Kanban system contains complete rules and principles, which companies, e.g., SAP (System Applications and Products) and Oracle already adopted into the ERP (Enterprise Resource Planning) system or supply chain information system. It is also possible to introduce it into BIM-platforms which adopting Industry Foundation Classes (IFC). Building models with higher LOD (Level of Development) can provide abundant detailed information for the construction logistics. For example, LOD 400 contains information required for fabrication, assembly and installation [16]. Meanwhile, 3D visualization with Model View Definitions (MVDs) is helpful for collaborative product development from design to on-site construction. Digital construction sequencing and scheduling techniques and current 4D BIM practices [17] [18] [19] provide a foundation for the adoption of the Kanban signals to report real-time material consumptions. It is essential to not only provide a visual Kanban board or tool with 3D representations but also help change a periodic and centralized construction logistics planning into a real-time demand-driven logistics management.

3 Methodology

3.1 Overview

This paper draws experiences from current construction planning practice, including the long-term planning, short-term periodic scheduling, and site storage planning [12] [17], as shown in Figure 1:

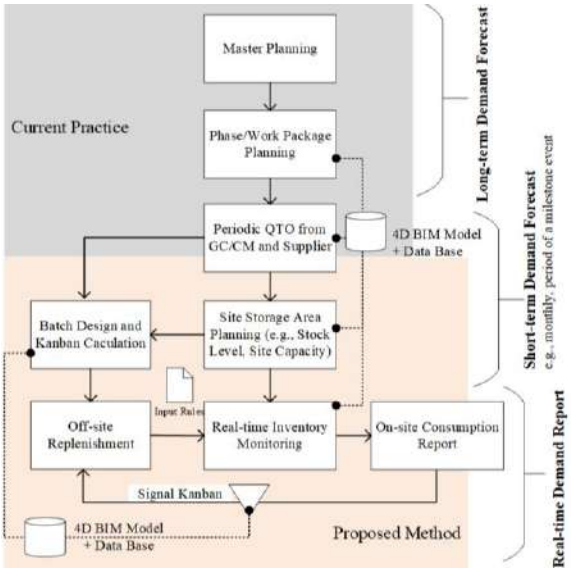

Figure 1. Logistics planning method combined with current construction planning practice

In the proposed method, the following aspects are emphasized:

Long-term demand forecast addresses the project objectives, i.e., overall cost, schedule, and quality goals. It involves mater or milestone planning, phase or work package planning, and project QTO. It follows the conventional construction project management and is conducted in the project early phase.

Short-term demand forecast addresses the periodic planning, i.e., weekly, monthly or within a milestone event's duration. The general contractor, construction manager, trade manager (if any) and suppliers work out periodic QTO documents and Kanban batch size collaboratively. These periodic QTO documents are fundamental for the on-site store area configuration.

Real-time demand report and pulled replenishment adopts the Kanban signal as the trigger of off-site replenishment. Suppliers collect Kanban signals and arrange their production and replenishment activities according to the real demand. Every material batch can be tracked along the whole process using a Kanban barcode or RFID (Radio-frequency identification) and assigned to its area. Therefore, it is possible to achieve a decentralized on-site stock monitoring.

4D BIM provides adequate LOD (level of details) building or construction component models, model-based QTO and related construction processes.

Applying the Kanban signal does not mean JIT production or zero stock. The Kanban signal is adopted as a real-time demand indicator for the off-site replenishment and site stock monitoring. It does not apply for every kind of material resource. The target material type has two features: 1) produced off-site and 2) with a certain level of site stock.

In the following sections, the critical activities in the proposed method to apply the Kanban system in construction logistics will be elaborated: 1) Kanban batch design; 2) site storage area planning and initial Kanban deployment; 3) real-time consumption record, real-time demand report and pulled replenishment.

3.2 Kanban Batch Design

The first step of introducing the Kanban system into construction logistics is to design the Kanban batch size associated with periodic QTO at the short-term demand forecast stage. This paper provides a BIM-enabled example to explain how to work out a consensual periodic QTO and Kanban batch size from both supplying and consuming sides. The collaborative workflow is presented in Figure 2:

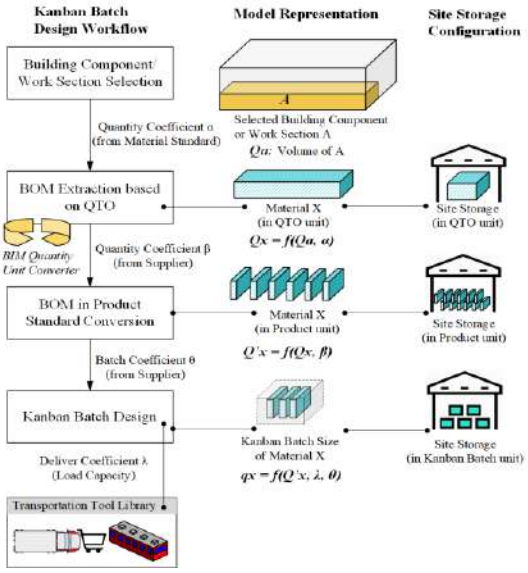

Figure 2. Workflow of Kanban batch design

Building component/work section selection: it depends on the short-term planning objectives, e.g., for a milestone event or a monthly plan. In this example, the building component or work section A is chosen, and its principal material is material X. The QTO extracted from the BIM model provides the volume of A (Qa).

Bill of Material (BOM) extraction based on QTO: according to Qa and quantity coefficient α from the material standard, the quantity of material X (Qx) can be calculated, and a BOM list can also be generated when there is more than one kind of materials.

BOM in product standard conversion: a BIM quantity unit converter (see Figure 3) is applied to convert the unit of quantity of material X from QTO into a product standard or a customized standard, which is provided by suppliers. The contractor can choose BIM objects and submit material quantity information to the calculator as an input, and suppliers can send product information to the server as another input, then a product quantity is worked out as the output.

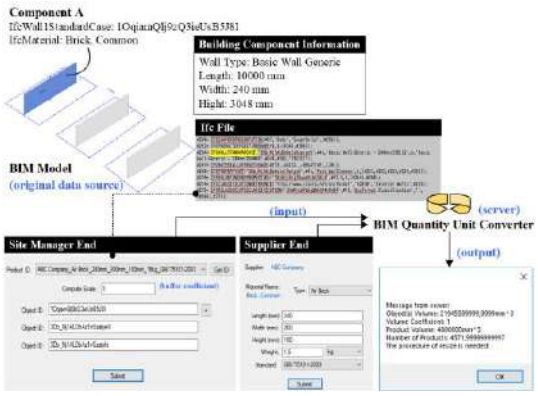

Figure 3. Example of BIM quantity unit converter

Kanban batch design: the Kanban batch size means the least lot size in the pulled material flow, e.g., a container capacity or a customized package capacity. It is the basic unit for consumption reporting, ordering, and material delivery and mainly decided according to suppliers' production (coefficient θ) and transportation (coefficient λ) conditions.

3.3 Site Storage Area Planning and Initial Kanban Deployment

An adequate initial area of site storage is crucial for the execution of the Kanban system. For a certain type of material e.g., material X (see Figure 2), GC/CM or material manager should provide total material consumption quantity (Qc) extracted from QTO and target construction duration (Tc). It is necessary to achieve an agreement about the storage duration (Ts). Besides, the non-uniform coefficient (σ), quantity-to-area convert coefficient (ε) and site utilization factor (μ) should be obtained according to technical standards. The initial area of site storage (see Equation (1)) can be calculated as:

$$S = \frac{Qc * Ts * \sigma}{Tc * \varepsilon * \mu} \quad (1)$$

Meanwhile, the supplier needs to provide the product standard or sufficient design information i.e., the quantity coefficient β (see Figure 2), to convert the initial total stock quantity from the material unit (Qs) into the product unit (Qk) (see Equation (2)). According to the initial value of stock quantity Qk and Kanban batch size qx (see Figure 2), the number of Kanban batches (N) can be further calculated (see Equation (3)):

$$Qk = f(Qs, \beta) = f(\frac{Qc * Ts * \sigma}{Tc}, \beta) \quad (2)$$

$$N = Q's/qx \quad (3)$$

3.4 Real-time Consumption Record, Demand Report and Pulled Replenishment

After the initial Kanban batches of material for the site storage are deployed on the construction site, the real-time material consumption can be recorded, and the discrete demand can be reported using Kanban signals. The information flow is illustrated in Figure 4:

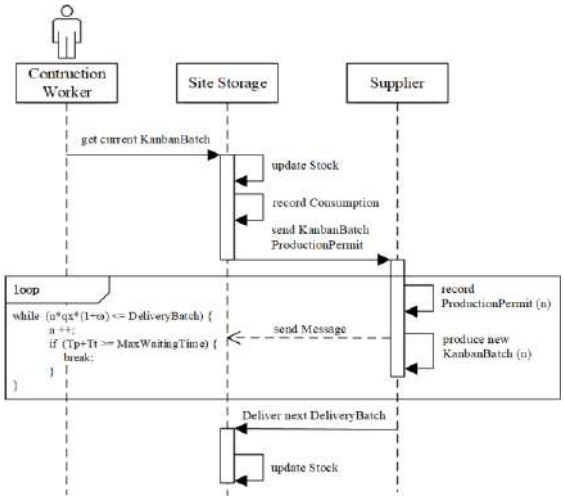

Figure 4. Information flow of real-time consumption record, demand report and pulled replenishment

Getting a KanbanBatch from site storage is a discrete event. When this KanbanBatch is taken out from the on-site storage, a production permit or an order of a new KanbanBatch is released to the supplier. It means that the supplier can know the real-time consumption of required materials. The supplier can collect discrete production orders and produces several new KanbanBatch according to his/her own delivery policy e.g., the minimum size of DeliveryBatch in this example. Meanwhile, the max waiting time of the construction site about the required KanbanBatch should be also taken into account, i.e., the MaxWaitingTime in this example. This paper adopts demand theories from Sugimori et al. (1977) [6] and adapts them into the context of construction logistics. Two discriminants for the loop of recording demands and producing new batches are set up (see Discriminant (4) and (5)):

$$n*qx/(1+\omega) \leq DeliveryBatch \quad (4)$$

$$Tp+Tt \leq MaxWaitingTime \quad (5)$$

Here:
n: number of KanbanBatch production orders;
qx: Kanban size;
ω: buffering coefficient of container/package capacity;
Tp: off-site production time;
Tt: transportation time.

The first discriminant determines how many new Kanban batches should be produced according to the collected demands and the supplier's delivery policy. The second discriminant is a constraint condition of the lead-time, i.e., production time and transportation time. However, the tolerance for lead-time is sensitive to the on-site storage buffer level, material type and flexibility of construction schedule etc., and it should be developed further.

4 Case Study

The aforementioned method is employed for controlling the on-site stock of a river remediation project. The remediation project of Tantou River is located in Shenzhen city, China. It includes six sub-projects: 1) channel improvement; 2) culvert construction; 3) desilting work; 4) sewage interception; 5) spillway tunnel and 6) flood retarding basin improvement. The engineering-procurement-construction (EPC) contractor is Power Construction Corporation of China and Sinohydro Bureau 14 Co., Ltd. manages the project.

We take the section of Furong Road (K0+000 ~ K0+050) in the culver construction sub-project (X0+000.00 ~ X1+192.021) as a case to study how to improve off-site warehousing and on-site stock configuration of culverts' main material i.e., steel bar with the type of HRB400 (16~25). In this case, we focus on applying Kanban signal to capture real-time consumption and adopt a pulled replenishment. It includes on-site storage area planning, initial stock deployment, and Kanban-triggered delivery. A BIM-enabled Kanban batch design is excluded in this case because standardized steel bars are used.

The duration of the target culvert construction section is 116 days and costs 13,862,112.17 in Chinese currency. The size of the culvert is 2.7x3.0 m and built with C25 reinforced concrete, as shown in Figure 5:

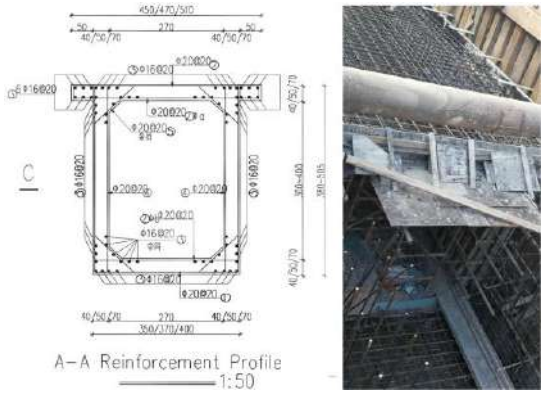

Figure 5. Culvert size and reinforcement profile

For this construction section, an off-site warehouse was set for steel bar storing and a on-site storage area with the size of 8x30 m was planned for weekly consuming. The distance of the off-site warehouse and on-site storage area was 3 km (see Figure 6). There are challenges in the storage and replenishing of steel bars:

- A large amount of steel consumption
- Unstable labor productivity
- Strict construction duration requirement
- Limited on-site storage area because the river flows through residential and commercial sectors

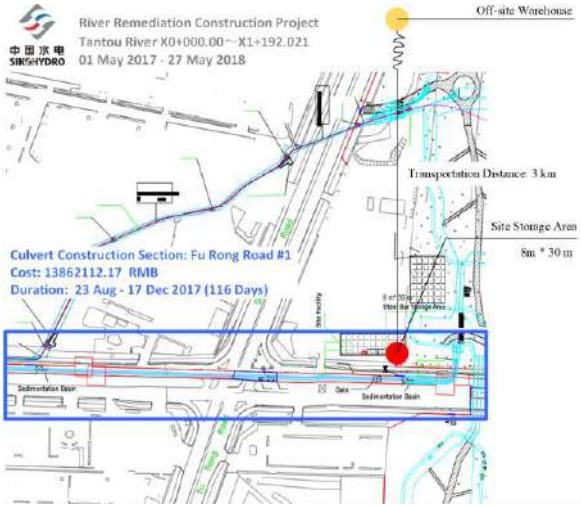

Figure 6. Project information and site layout

The site manager monitored the on-site storage of steel bars, and the replenishing plan of steel bar was delivered weekly from the off-site warehouse to the on-site storage area. Table 1 provides necessary information of steel bar site storage and replenishment. In this construction section, three problems related to site storage occurred and were reported by the site manager:

- Overstock on site in the earlier days
- Site stock shortages in the later days
- Construction delays caused by site stock shortages

Table 1. Steel bar site storage and replenishment plan

Plan Item	Number
Construction duration	60 days
Total quantity	458.83 t
Site storage area	240 m^2
Initial site stock	180 t
Weekly replenish	30 t

To study the periodic on-site storage planning and the influence of the unstable labour productivity, a simulation was conducted. We adopted a distribution triangular (0, 20, 5.01) for the daily consumption of steel bars affected by the labour productivity. It was chosen according to the historical project data. The simulation results are shown in Figure 7:

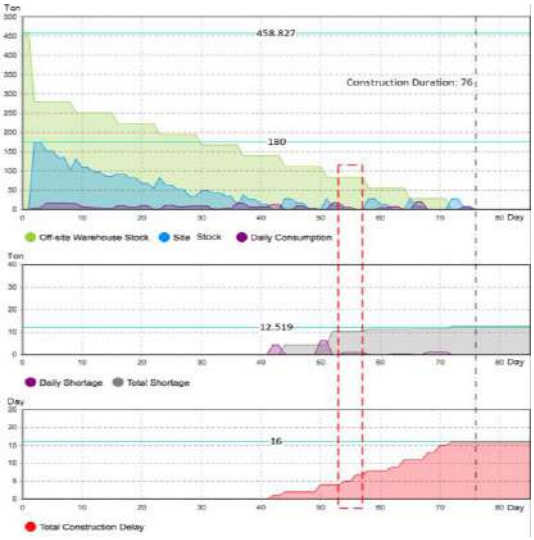

Figure 7. Simulation results of weekly replenishement

The simulation results show a construction delay of 16 days and some steel bar shortages. The results also show that, as the project progresses, even a minor shortage can lead to further delays in construction (outlined with dotted red line in Figure 7). The problem of overstock at the beginning is also obvious according to the simulation results.

To improve this situation, the Kanban signal is applied to report the real-time consumption, and another simulation was conducted. In this case, we treat the off-site warehouse as the supplier. The Kanban size design is simple in this case because standardized steel bars are used. The weight of each 12m long steel bar is 0.0145 t. A bundle with 100 steel bars is set as a package unit and its weight is 1.45 t. The Kanban batch size is designed as 20 bundles with a weight of 29 t. Table 2 shows key parameters of Kanban-triggered on-site storage and material replenishment planning:

Table 2. Parameters of Kanban-triggered replenishment

Parameter	Expression	Value
Site storage area	$S = \frac{Qc*Ts*\sigma}{Tc*\varepsilon*\mu}$	214.12 (m^2)
Initial site stock	$Q's = \frac{Qc*Ts*\sigma}{Tc} * \beta$	144 (t)
Package unit	1 Bundle = 100 steel bar	1.45 (t)
Kanban batch size	qx	29 (t) 20 (bundle)
Initial Kanban stock	N = Q's/qx	5

*Qc = 458.83; Tc = 90; Ts = 30; α = 1.40; ε = 2.5; μ = 0.6; β = 0.8.

The simulation results are shown in Figure 8. We adopt the same distribution for the daily consumption as

the weekly replenishment mode. Because of the real-time consumption report and Kanban-based delivery, all shortages and delays in the weekly replenishment (see Figure 8) mode could be avoided. Meanwhile, the initial site stock is saved from 180 t to 144 t, and the site stock maintains a stable level.

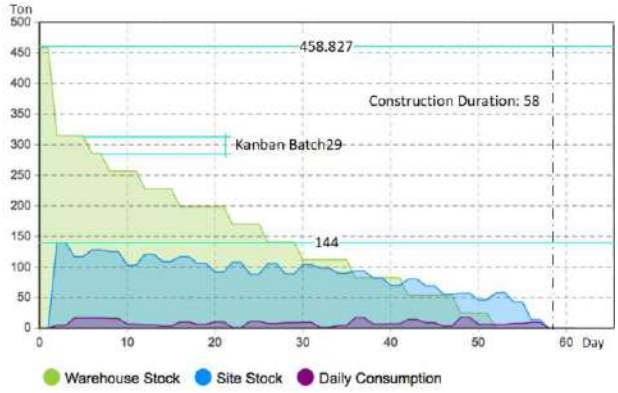

Figure 8. Simulation results of Kanban-triggered Replenishment

To explore the differences between weekly replenishment and Kanban replenishment, a comparison analysis is given in Figure 9.

Figure 9. Comparison of site stock in weekly and Kanban-triggered replenishment modes

Three distributions of steel bar daily consumption are applied: triangular (0, 15, 5.01), triangular (0, 20, 5.01) and triangular (0, 25, 5.01). In the Kanban mode, on-site stocks are stable and the total construction duration is shorter when the daily consumption level is higher. Comparatively, in the weekly replenishment mode, the on-site stock is excessive in the earlier days and insufficient in the later days. The total construction duration can be longer even when an intensive labour input is employed, as additional construction delays occur caused by stock shortages.

5 Discussion

This study was initiated to seek a driving mechanism for efficient construction logistics planning aided by information systems. Besides rethinking of the Kanban system, this paper provided implications for future construction logistics related research:

Essential Role of Digital Collaboration in Construction Logistics: based on the proposed method and the results collected from the case study, it can be stated that digital collaboration between the supplier and the construction manager plays an essential role in the construction logistics planning and monitoring. The construction logistics requires both on-site information and off-site information. Transferring site activities into off-site supply chains is a trend. It is helpful for some types of projects, for example, projects near residential areas. It means accurate and timely off-site information is indispensable for the construction logistics management. Meanwhile, suppliers need more building information for their production schedule and quality control. All these aspects indicate that an efficient digital collaboration in the construction logistics is required. With the development of industry-specialized information technology e.g., BIM and the decrease of information systems costs, it is the time to consider a digital collaboration from both the supply and construction sides. The Kanban batch design, therefore, can be more convenient with the assist of digital collaboration. This kind of digital collaboration in logistics planning can also contribute to a long-term commercial partnership.

Proactive Attitude toward Construction Logistics: there are challenges cause by the unstable labour productivity on-site and it has great effects on the construction logistics. The construction manager of the case study project reported that there were overstocks on-site in the earlier days and site stock shortages in the later days. It indicates the drawbacks of the conventional buffering approach: 1) waste site capacity; 2) ignore the influence of oncoming labour productivity peak. Applying the Kanban concept can improve current situation by collecting real-time consumptions and converting them into demands. It can ease the pressure of stock consuming after a productivity peak by a quick-respond replenishment. When a forecasting procedure of the productivity is applied, a proactive control is possible for the construction logistics. However, it is still a long way to go for a proactive logistics management aided by accurate forecasting.

6 Conclusion

Unlike the manufacturing industry, the unstable labour productivity and periodic planning method cause

barriers for adopting concepts e.g., JIT production in the construction field. The original Kanban system is well-known as a JIT control system, but its application is not limited to JIT production. In this paper, a methodology of designing and applying Kanban batch in the construction logistics with 4D BIM systems or tools was proposed. The Kanban concept was highlighted to record the material consumption, report the real-time demand and trigger a material replenishment from off-site to on-site. A case study of a river remediation project was carried out with a focus on steel bar site consumption and off-site replenishment. The simulation method was carried-out to analyse different scenarios. The simulation results presents significant savings of on-site storage area size and construction time by applying the Kanban concept. Finally, a discussion and implications were provided for future research.

More efforts will be made to integrate theory with practice regarding Kanban in the construction logistics planning and monitoring. Further studies will address complete Kanban application in the construction field and explore the real-time demand forecasting with abundant data from both on-site and off-site sides.

Simulating Wood-framing Wall Panel's Production with Timed Coloured Petri Nets

Fabiano Correa[a]

[a]Department of Construction, University of Sao Paulo, Brazil
E-mail: fabiano.correa@usp.br

Abstract –

The integration of design and construction processes remains, after decades of dedicated research, a great challenge. Even considering the specific context of pre-fabrication and modularization, it was just in recent years, with increasing adoption of Building Information Modeling (BIM) processes, that the challenge, albeit in a virtual environment, begins to be really addressed. With the advent of the Digitization phenomena in Construction, and the advances in Machine Learning techniques to cope with uncertainties of different natures in modelling real processes, it seems that the use of computational tools to simulate off-site production should be reconsidered. In this article, it is adopted an approach in viewing BIM as in a development stage to become an implementation of Product Lifecycle Management (PLM) for Construction. Towards this end, it is identified the lack of representation of the entire dynamics of production processes inside BIM models. The proposition of using Petri Nets with stochastic transitions to represent and simulate those processes are presented, altogether with the use of real RFID data, to adjust the model parameters, collected from a case study with a Brazilian company that pre-fabricate wood-framing houses. The probability distributions are derived based on the Mixture of Gaussians algorithm, and considers parameters of the design of wall panels – so it could be used to extrapolated performance for new designs. Following the presented approach, it is expected that, with more data, the simulation process could be a good feedback to architects in evaluating the impact of its design options in production.

Keywords –

High-level Petri Nets; Building Information Modeling; Simulation; Wood-framing

1 Introduction

In general, architects are not able to exploit design choices and its impact in production processes: they would need to specialize in each existent building system. Design is just one phase of the product development lifecycle, and through it, it will need the expertise of many different professionals. As communication between them is normally scarce and noisy, many opportunities to produce a better product is lost, and problems found later, on construction phase, could be traced back to unaided design decisions.

Computational tools have been developed to aid in this context, but there are still problems, and limitations. Even with the growing importance of information and communication technologies, the integration of design and construction processes remains, after decades of dedicated research [1], a great challenge. The situation is not different when one considers the specific context of pre-fabrication and modularization. It should be expected that in industrialized construction, similar to manufacturing industries, the use of computer-aided systems would be more common. It was just in recent years, with increasing adoption of Building Information Modeling (BIM) processes, that the challenge of integrate the processes of design and construction, albeit in a virtual environment, begins to be really addressed. And because of it, the interest in using pre-fabrication and modularization is rising again [2].

In viewing BIM as in a development stage to become an implementation of Product Lifecycle Management (PLM) for Construction [3], BIM models should resemble the idea of a digital twin, where it is possible to trade working with bits instead of atoms [4]. To use it to give to architects an advanced feedback of the impacts of planned design in production, it would be necessary to build a simulation of the production process in the factory. Although largely employed in other industries, for Construction, simulation have had more success in academic research than large use by the industry [5]. It is natural that with the advent of the Digitization phenomena in Construction, and the advances in Machine Learning techniques to cope with uncertainties of different natures in modelling real processes, it seems that the use of computational tools to simulate off-site production should enter a new cycle of development [5],

and integrate with digital information provided by BIM models.

BIM models are Product Data Models, and lacks the representation of the processes [6]. As so, there is a lack of representation of the entire dynamics of production processes inside BIM models – it is possible to create information about sequential tasks in the model; however, there is few semantic contents to that representation. As an illustration, consider IFC (Industry Foundation Classes) schema for interoperability. There is a growing presence of physical building components in the information model. However, although one could create, from basic entities, and describe construction processes, there will not be an inherent semantic in the representation. There isn't a library of processes to be used "off-the-shelf".

In this article, the proposition of using Petri Nets with timed coloured extension to represent and simulate those processes is presented, altogether with a procedure to use RFID data to adjust the model parameters. Implementation and test were done in a case study with a Brazilian company, which pre-fabricate wood-framing houses. Time representation in a coloured Petri Net is done via delays imposed to each transition. The delays are statistical, based on probability distributions. The probability distributions are derived based on the Mixture of Gaussians algorithm, and considers parameters of the design of wall panels – so it could be used to extrapolated new designs. Each type of wall panel contributes with a normal distribution, which composes the mixture distribution.

In section 2, we briefly present the mathematical formulation of Petri Nets, with extensions for time and colours (tokens are from different kinds in the simulation). Section 3 presents a proposition to derive parameters for mixture of gaussian model of the probability distribution to use in the delay of the Petri Nets. Section 4 presents the experiment that were done with the simulation of the production of wall panels in wood-framing, in a Brazilian company. And finally, section 5 summarizes the presented work, drawing some conclusions about our approach, and indicates future direction of work.

2 Petri Nets for Construction Processes Simulation

The main view about the formalism of what late became known as Petri Nets, and its potential as a model for dynamic systems was conceived in the PhD thesis of Carl Adam Petri [7].

Research in the use of Petri Nets to model asynchronous and concurrent dynamic systems, such as manufacturing systems started to appear in the scientific literature around the 80's. However, for the application of Petri Nets to real world problems, it was necessary to develop many high-level extensions of the traditional Petri Net formalism; for example, to include time, and a way to represent different kind of tokens (coloured).

2.1 Timed Coloured Petri Nets

The concept of Coloured Petri Nets was proposed by Jensen [8], as an high-level Petri Net. Following definition of Viswanadham and Narahari [9], a Coloured Petri Net is defined by the quintuple:

$$N = (P, T, C, I, O) \quad (1)$$

$$P = \{p_1, p_2, p_3, \dots, p_n\}, n > 0 \quad (2)$$

$$T = \{t_1, t_2, t_3, \dots, t_m\}, m > 0 \quad (3)$$

where: P is a finite set of places; T is finite set of transitions; such that $P \cup T \neq \emptyset$ and $P \cap T = \emptyset$.

$C(p)$ and $C(t)$ are the set of colours associated with place $p\ \varepsilon\ P$ and $t\ \varepsilon\ T$.

$$C(p_i) = \{a_{i1}, a_{i2}, \dots, a_{iu_i}\}, i = 1,2, \dots, n\ and\ u_i = |C(p_i)| \quad (4)$$

$$C(t_j) = \{b_{j1}, b_{j2}, \dots, b_{jv_j}\}, j = 1,2, \dots, m\ and\ v_j = |C(t_j)| \quad (5)$$

$I(p,t)\colon C(p) \times C(t) \to \mathbb{N}$ is an input function and $O(p,t)\colon C(p) \times C(t) \to \mathbb{N}$ is an output function.

There is also a token, a mark inside places, to represent the dynamics of the net. One transitions only occurs if there are token in every place connected to it (input set). And if a place is connected to two transitions, and both could fire, a decision should be made.

The concept of time in Coloured Petri Nets (although it could also be inserted in classic Petri Nets) has been implemented as a delay in turning available the tokens generated by a transition. Also, it is possible to employ probability distributions to model uncertainty and randomness in the time of completion of each task.

3 Learning Probability Distributions with Mixture of Gaussians

As there is the necessity to expose some parameters of the model to represent different panel designs, it was chosen to represent the probability distribution as an mixture of Gaussians, in which each Gaussian is attributed to one already monitored production of panel design.

It is expected that, with monitoring many different projects, from houses to buildings, this mixture of Gaussians could capture the intricacies and particularities of products in a company's production line and be

extrapolated to new designs. Then, it could be a source of feedback to the architect based on simulation results, and optimization.

Figure 1 represents graphically how two gaussian distributions could be used to model a multimodal histogram. It is expected that each individual wall panel design would give a specific normal distribution, and that with a large database of production of different designs, for houses and buildings, it should be relevant to predict, based on the estimated mixture of gaussians, future time delays for unseen product design.

The representation of a probability distribution using a mixture of Gaussians as a model, following Figueiredo and Jain [10], is given by:

$$p(y|\theta) = \sum_{m=1}^{k} \alpha_m p(y|\theta_m) \quad (3)$$

$$\alpha_m \geq 0, m = 1, \dots, k, and \sum_{m=1}^{k} \alpha_m = 1 \quad (4)$$

$\theta_m$are the parameters of the model to be find based on data collected.

Traditionally, it is used Expectation-Maximization algorithm to obtain the values of θ, with the formulation presented in (5):

$$\log p(\Upsilon|\theta) = \log \prod_{i=1}^{n} p\left(y^{(i)}|\theta\right) = \sum_{i=1}^{n} \log \sum_{m=1}^{k} \alpha_m p\left(y^{(i)}|\theta_m\right) \quad (5)$$

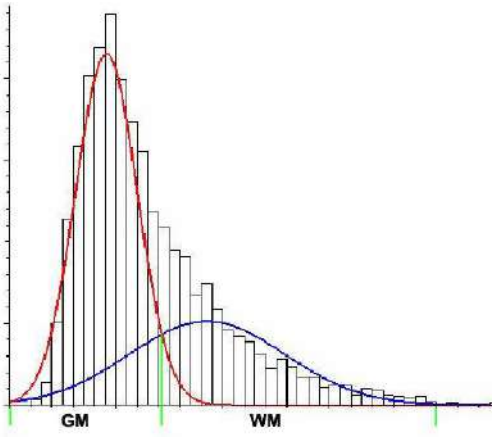

Figure 1. Representation of gaussians distributions derived from a histogram data.

4 Experiments and Results

In the last section, it was demonstrated how to obtain a probability distribution, based on data collected from real process. In our experiments, we do not achieve yet a relevant amount of data to use this methodology. The amount of data acquired is not statistically relevant but was adequate to obtain some estimation of the duration of each activity in the wall panel production, and to test the Petri Nets, and the model of a Mixture of Gaussian probabilistic distribution, as valid representations or models to use in our objective to provide a feedback of the impacts in design of alternative design decisions.

4.1 Production process at a Brazilian company of prefabricated homes in wood-framing

Production plant layout is represented in Figure 2. There are 6 working stations (identified by blue rectangles in the figure and labelled with numbers in white). The numbers represent the processing order.

Their plant is organized as a production line, without buffers. This is known in the factory as “Weinmann line”, after the Weinmann machinery bought by the company, which produces only wall panels. Floor and roof panels are produced manually, and in parallel lines (and are not represented in the figure).

The frame of each panel is composed of studs that are gathered from storage magazines (red rectangle, with an **S** in it), and from special modules (for door and window installation), which are also produced manually in another workstation.

There is a framing machine that reads the digital model and fix one component in the other, until the frame is finished – the red rectangle with the **SA** letters indicate where there is the storage and the other machine that automatically feeds the internal studs to the framing machine.

Workers bring OSB boards from storage (red rectangle with **OSB** in it) and position them with preliminary use of nails. There is another machine that cut electric and hydraulic openings in the OSB board, in both workstations 2 and 4 – represented by a blue rectangle, and a **W** letter in white for the representation of the machine itself.

Transportation between work station 2 and 3 is done by a “butterfly” table mechanism (Figure 3), allowing to work in the other side of the frame, to close it. Work station 4 is movable.

In the workstation 5, two to three workers install Tyvek film in the panel, insert the frame for windows and doors installing (the local where these frames are is represented by the red rectangle with the E letter in it), and put plasterboard – storage of plasterboard are represented by the red rectangle with the **G** letter in it. This work is also carried out in the workstation 6, so they have more space to complete these tasks in two panels.

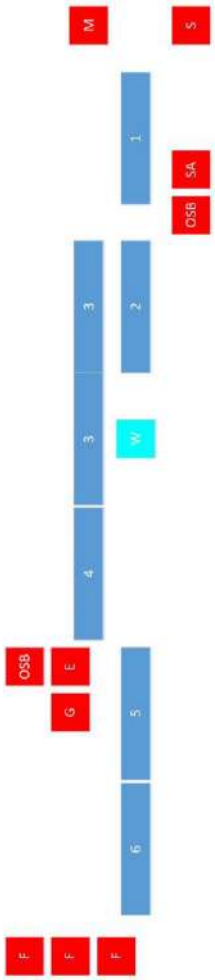

Figure 2. Rough layout of the production plant – not necessarily on scale.

Figure 3. One of the workstations ("butterfly" table) at the production plant.

After completion, the panel is moved by a crane, to temporary storage – represented by three red rectangles with the **F** letter in it.

4.2 RFID Data Collection

As stated by Mullens [11], "[q]uantitative data measuring cycle time variation and its root causes are rarely available". It is important to develop some solution to automatically capture such data. One solution could be an RFID system.

The RFID system employed to temporarily collect data at a Brazilian company was composed by three Sargas Readers from Trimble, and three antennas of 9 Db (one for each reader, although each reader could be used to gather data from two antennas – Figure 4). The maximum workable range between antenna and passive tags were estimated in 1.2 m.

Each panel received two tags, one in each of its lateral studs. The three points of time measure was: 1) immediately after the framing machine (the use of the frame machine is known by the log of the machine); 2) immediately when the panel, turned around, goes back to the main line of production; 3) Between work done in workstations 5 and 6, until the finished panel is elevated to the storage area.

Figure 4. One of the RFID Antennas temporarily installed for data collection in the factory of a Brazilian company.

During two days of collecting production data, it was possible to acquire some information about the dynamics of production for the line in general, and for each panel. However, such amount of data do not have statistic relevance to be used in estimating a global parameter for probability distribution.

It was decided to just attribute some values,

compatible with data collect, to investigate if the proposed solution, Petri Net formalism, given relevant data, could be used as original planned.

4.3 Petri Net Model of Production Line

To build a model representation of the production line of wall panels in wood-framing for the prefabrication of homes in Timed Coloured Petri Net, and to analyze its performance, it was used the software CPN Tools [12].

The resources needed for each activity were modeled by places. There were places for workers, machines, and panels along the production process. A mark in a place means that the resource is available.

The coloured sets extensions allows modelling of different panel designs (they were formatted as coloured sets of the product of an INT – order of production – and a STRING – type of each panel), and the modelling of distinct resources, such as workers and machines (defined as INT).

With the timed extension allowed, every activity in the production line was modelled with time delayed transitions, with a probability distribution composed of a mixture of gaussians. Each arc leaving a transition received a delay of a weighted sum of normal distributions such as (we opted to use only two types of gaussian to simplify, as the extension to the five different wall panels to assemble a house is straightforward):

$$F(x) = \sum_{i=1}^{5} 0.2 * normal(n_i, v_i^2) \quad (6)$$

Places representing the stages of wall panel production demanded a special treatment because an upcoming place should be empty before a previous transition is enabled – so that it not accumulate two panels in the same workstation. As a general and needed solution for this model, it was necessary to create for each pair of consecutive transitions representing work done at workstations, two additional places to avoid accumulation of more than one token in each place – that represents the panels in the workstations (Figure 5). This solution also helped in controlling the sequence of different panels to be produced.

There are 10 activities represented that were already described in previous section (we also give here the average time delays for the two gaussians employed in the simulation):

1. Frame production (time delay: 10 / 11 min);
2. OSB-one side (time delay: 7 / 6 min);
3. Cutting (time delay: 4 / 3 min);
4. Butterfly use (time delay: 4 / 3 min);
5. Electric, HVAC, Cutting, and OSB (time delay: 7 / 6 min);
6. Back to main line (time delay: 3 / 2 min);
7. Cutting-other side (time delay: 4 / 2 min);
8. Door and Windows install, Tyvek (time delay: 32 / 30 min);
9. Plaster board (time delay: 20 / 18 min);
10. To storage (time delay: 6 / 5 min);

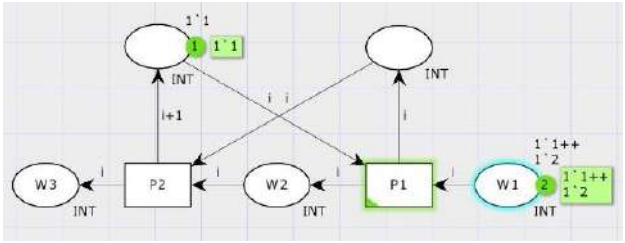

Figure 5. Modelling order of and workstation capability of production.

Figure 6 shows details of the modelling of shared resources in some workstations / activities – the model reproduces the same logic of the layout presented previously: the cutting machine receives a digital design, and it cuts small holes for electric and hydraulic use, and also there is in general one single operator to coordinate movement of wall panels and the machine that do the cutting in two different workstations – in the network. In red are highlighted two workstations (places) where cut, in both faces of the wall panel, occurs and in blue are highlighted two resources (places), operator and machine, that are divided between the workstations.

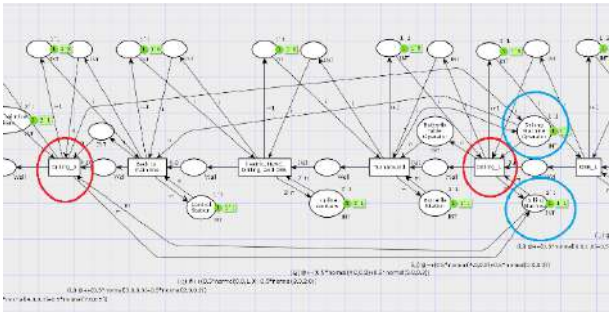

Figure 6. Detail of resources (Drilling Machine and Operator) between different workstations.

Due to the large network obtained, and the lack of space in the article, we opted to give an overview of the topology of the Petri Net, without giving more details (Figure 7).

The bottleneck of the production process is known to be work in the fifth and sixth stations, which is entirely manual, and there are a lot of work to do in it.

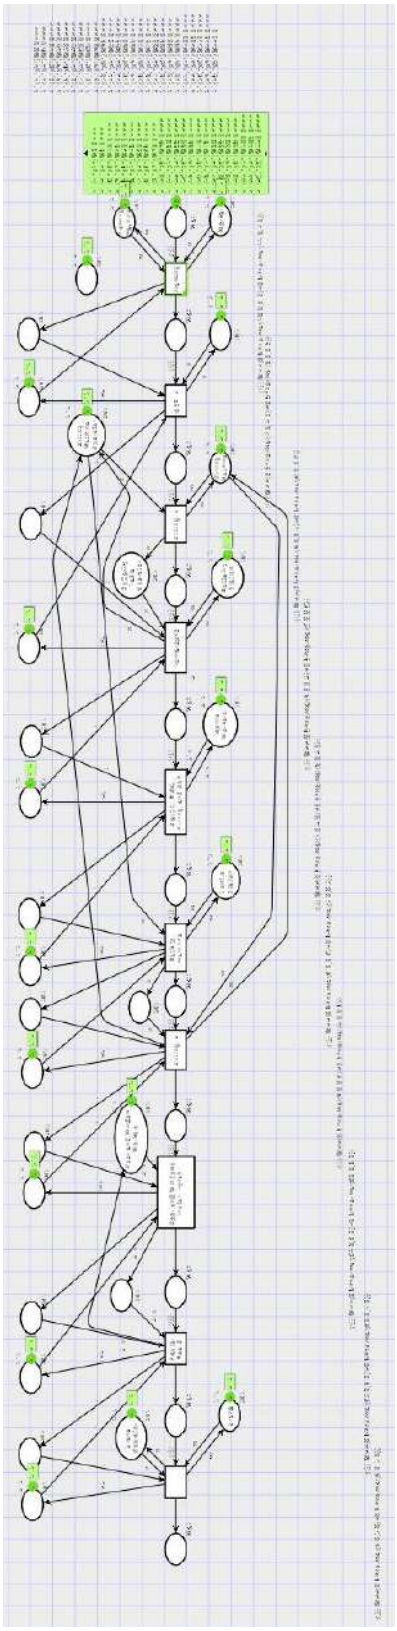

Figure 7. Timed Petri Net representing production of wall panels.

Part of the real dynamics that was not modelled was the movement of workers along different workstations to help its colleagues to keep in the TAKT time. For this, it would be necessary to model agents with decisions, and rewards.

As one example where it happens and is relevant for the dynamics, there is such a case just after the first transition with the operator of the framing machine. He works by itself until the frame is finished. The frame then moves to the next work station, and he also starts to work along two other workers, in fixing OSB boards on the frame. Based on a timed-schedule, he decides when to start a new wall panel, going back to operate the framing machine.

4.4 Results

Our experiment was developed to investigate the Timed Coloured Petri Net, as a formalism, and CPN Tools, as an implementation software, to produce a discrete-event simulation model of the production process. As a result, we could model almost every feature that appears to be relevant to our intent.

However, one behaviour would be of interest, although until the present knowledge of the authors, it is impossible to model it explicitly or directly with Petri Nets: variable time of transitions based on the number of tokens in a place representing resources, i.e., in some occasions, two to three workers are in a specific workstation, and the amount of time to complete the job depends on the size of the workforce at that moment.

The network was simulated with a production programming of 25 wall panels, in two different scenarios. In each scenario, the time delay between the beginning of production process of new panels was delayed by 5 and 10 minutes, respectively.

Table 1. Probability distribution parameters.

	1st Gaussian	2nd Gaussian
Place 1	26 ± 3	20 ± 2
Place 2	9 ± 1	7 ± 0.5
Place 3	4 ± 0.2	3 ± 0.3
Place 4		
Place 5	9 ± 1	8 ± 2
Place 6	3 ± 0.3	2 ± 0.2
Place 7	4 ± 0.3	2 ± 0.5
Place 8	40 ± 3	29 ± 8
Place 9	40 ± 5	38 ± 7
Place 10	6 ± 1	5 ± 1

The production time of each panel throughout the experiment (Table 2) was around the same time obtained in monitoring the production for two days at the plant. Results are exhibited in Table 2.

The registered times in Table 2 refer to the global

clock of the simulation (that starts at zero with the beginning of production of the first wall panel), at the time that each panel is moved to temporary storage. For each scenario, we run the network 5 times, and calculated the average time and its standard deviation.

Table 2. Results from simulating the production plant for two scenarios. The timestamp at the end of the production line is exhibited in the columns.

Type of wall panel	Global clock (s)	
	Scenario 1 (Δ10min)	Scenario 2 (Δ20min)
Type 1	129.6 ± 3.5	130.0 ± 3.4
Type 2	167.2 ± 4.5	169.6 ± 3.2
Type 3	207.7 ± 4.5	208.1 ± 3.0
Type 4	246.4 ± 5.3	246.9 ± 3.3
Type 5	283.8 ± 4.6	286.4 ± 3.6
Type 1	323.1 ± 4.5	324.7 ± 3.8
Type 2	363.0 ± 7.9	363.1 ± 4.4

Verification and validation of results from simulation were done based on comparison with real data collected with RFID system. Even if the collected data is a scarce set, it was verified that the probability distribution applied to the model was able to reproduce compatible times with the observed practice. During the simulation of one entire day of production, 8 hours of work, the behaviour of the model was similar to what was observed in the factory. Thus, it is a promising implementation of a process simulation to be further developed, towards obtain a feedback to architect of design decision on production.

5 Conclusions

The aim of the research present in this paper, was to investigate an adequate formalism to make use of different simulation models that could integrate somehow with digital information provided by BIM models.

It was presented how to use a Timed Coloured Petri Net to represent the off-site production of wall panels for wood-framing houses. The focus was in the specific plant (and processes) of a Brazilian SME. It was also presented a methodology to derive probability distributions from real data of production times collected with RFID systems. However, in the experiment we used guessed values, based on data collected, due to not have collected a representative amount of data until now – two days of data collection, including installation of equipment, and trials with regard to the position of antennas in the factory and tags in the wall panels. Through simulation of the production process, it was possible to derive TAKT time to have a balanced production.

Future goal is to be able to predict production times for new design of wall panels, and thus, to be able to give feedback to architects during design decision making process. Also, it is our intent to install RFID system in the factory, and to automatically monitor the production for one or two months in the near future. We also need to further develop the simulation model, to include stoppage of machinery due to fault, and due to maintenance to obtain a more realistic simulation model.

Abstract –

Recent research efforts have shown that human thermophysiological features could play a crucial role in inferring occupants' thermal comfort, which is required for comfort-aware heating, ventilation, and air conditioning (HVAC) operation. Our previous studies have demonstrated that variations of respiration, a representative human thermophysiological feature, can be non-intrusively quantified by a Doppler radar sensor (DRS). However, in pursuit of enabling human-aware rooms in buildings, in this study we have explored the impact of distance and position of the respiration monitoring system to investigate the potential of DRS systems as a ubiquitous apparatus in the real-world scenarios. Through experimental studies, respiration characteristics were evaluated in different locations and angles relative to the location of the measurement device. The measurements were carried out using a DRS system and a respiratory belt for ground truth data collection. The noise artifacts were reduced by applying the Savitzky-Golay method and Hann window, and respiration was identified by selecting the frequency component with the maximum amplitude in the typical breathing frequency range (0.1 to 0.5 Hz). Our analyses demonstrated that the signal from a cost-effective DRS technology without the use of external amplifiers could cover a range, within 1.0m longitudinally and 0.5m laterally, which is sufficient for an individual sensing given a normal office environment. It was also observed that the use of an external amplifier extends the range of the DRS sensing but at the same time accentuates the noise. Therefore, advanced noise removal methods are needed to increase the range of robust sensing. This study contributes to DRS deployment strategies for realization of comfort-aware systems.

Keywords –

Comfort-aware HVAC operation; Doppler radar; Respiration monitoring

1 Introduction

Studies have demonstrated that accounting for human dynamics in the control logic of Heating, Ventilation, and Air-Conditioning (HVAC) systems has potentials of creating satisfactory indoor environments and improving energy efficiency in buildings [1, 2]. Conventionally, the predicted mean vote (PMV) model, which has been recommended by American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE) [3], has played such a role. However, it has been shown that the generalized human-related factors in the PMV model (the met and clo units for metabolic rate and clothing insulation) could misrepresent actual occupants' dynamics [4, 5] during the operations. For example, Humphreys and Hancock [6] have shown that occupants prefer diverse thermal sensations from cold to hot, which is different from the assumption of the PMV model for thermal satisfaction at neutral state. The objective of the PMV model is to provide thermal conditioning for an environment that majority of occupants find acceptable. Therefore, the predicted thermal comfort by the PMV model, especially when a small number of occupants are present in a space, could deviate from the actual thermal comfort [7]. Hence, recent research efforts have been dedicated to proposing novel methods of adapting actual thermal perception and preferences of occupants to address the aforesaid limitations.

Motivated by the prevalence of the information and communication technologies (ICT), the starting point was the use of electronic surveys [8, 9] to digitize the process of distributing, collecting, and analysing questionnaires and facilitate the data collection process. Hence, large scale occupant comfort voting data have been conveniently collected (e.g., over 10,000 votes were collected within one year [10]), which has contributed to context-aware HVAC operational strategies. This strategy aims to offer personalized comfort zones based on occupants' thermal preferences (hereinafter, this operation is called comfort-aware HVAC operation in this study).

The difficulty of this survey-based approach comes from two aspects: (1) the need for user dedications, and (2) direct comfort quantification. Jazizadeh and Becerik-Gerber [11] have evaluated the participants' dedications in the first data collection process and through a stratified sample selection focused on users that had consistency in providing thermal feedback. Similarly, Kim, et al. [5], have emphasized on the need for users' dedications to create their comfort profiles. It has been also shown that the direct comfort quantification might not fully represent the cause and effect given that occupants' preferences vary under the same thermal conditions [12]. Therefore, when it comes to comfort inference, moderate accuracies (up to 75.0%) have been reported [5, 13]. Accordingly, the integration of physiological attributes in thermal comfort inference has gained attention [14].

Current research efforts are searching for physiological sensing systems (PSS) that can be used in practice to collect human contextual data not only for developing high-performance comfort profiles, but also for realization of comfort-aware HVAC operation. For example, Li, et al. [15] and Ranjan and Scott [16] used an infrared imaging technology for this purpose. Our previous studies have shown that Doppler Radar Sensors (DRSs) have potentials of measuring human thermoregulation states as a non-intrusive apparatus for quantification of respiration [17-19]. However, practical application of this technology calls for investigating the feasibility of the technology under realistic environmental conditions including the distance from the sensor and the direction of signal communication.

Therefore, in this study, we have explored the potential of DRS systems as a ubiquitous measurement method for thermal comfort assessment. In addition to non-intrusiveness, applicability, and sensitivity, ubiquity is one of the core attributes needed for PSS methods to be applied in control loops. Further details on these attributes could be found in the study by Jung and Jazizadeh [20]. In doing so, we conducted two experimental studies. The first focuses on assessing the effective range of a DRS system. To this end, we used two sensing set ups; (1) a minimal DRS setting (without an external amplifier) and (2) a DRS setting with an external amplifier. The subjects were sitting at multiple locations and changed the angle with respect to the DRS, and then their pulmonary activities were measured by the DRS and respiratory belt (the latter for the ground truth). By comparing the respiration extracted by two devices, we assessed the range of a DRS sensor with regard to pulmonary activity measurement. The second experimental study focuses on multi-occupant sensing. As a preliminary attempt, we sought to measure the respiration activity of two occupants in front of a single DRS.

The structure of this paper is as follows. The following section reviews the previous studies that have revealed the potentials of using respiration as a PSS methodology for thermal comfort quantification. Section 3 explains the methodology of this study, and Section 4 presents the results. The paper is concluded with contributions and limitations of this study in Section 6.

2 Previous studies

Thermal comfort is the outcome of diverse mechanisms in the human body and human thermoregulation state demonstrates the response to the ambient environment [21]. Hence, in the indoor comfort research domain, the association between human thermophysiological response and ambient temperature has been investigated for decades.

One of the main contributing mechanisms is the skin blood flow adjustment for heat dissipation regulation. The expansion of blood vessels (i.e., vasodilation) increases the heat dissipation and vice versa (i.e., vasoconstriction). These variations contribute to the skin temperature, that has been used as a well-known physiological parameter for thermal comfort quantification. To this end, given its non-intrusive nature, the infrared imaging technology has been used as a potential apparatus [15, 16]. Moreover, the feasibility of using RGB video images by employing the photoplethysmography (PPG) has been also explored [20, 22].

Another thermophysiological feature that represent thermoregulation mechanism is breathing. ASHRAE [21] mentions that metabolic rate – a collective response of the human body to the ambient environment – can be most accurately quantified by respiration. The inspired air is at ambient temperature and expired air is near the core temperature. In other words, the human body exchange heat with the surrounding environment through respiration. Despite this substantial contribution to the heat exchange between the human body and ambient environment, respiration has not been widely utilized as an attribute in thermal comfort assessment due to the difficulties, associated with its measurements. For example, a spirometer, which is a commonly used apparatus for respiration measurement, requires subjects to blow their breaths into the device, which is not a practical approach for building level measurements.

Leveraging the Doppler effect, a physical phenomenon that causes variation of frequency or wavelength, when the location of wave source or observer is moving, DRSs have been employed as a non-intrusive approach of measuring cardiopulmonary activity (i.e., periodic movements of chest and abdomen area, induced by heart rate and respiration) in the

clinical domain [23]. A DRS transmits a signal and receives a modulated signal representing the frequency and the displacement of the motion which causes the modulation. Motivated by its non-intrusiveness, we have investigated the potentials of using a DRS system as a means of quantifying human thermoregulation states. The implication of this approach is to employ this physiological response as input parameters to operate HVAC systems. The applicability and sensitivity have been demonstrated with two experimental studies for (1) two opposite temperatures (20 and 30ºC) with a 20-min acclimation time [17] and (2) transient thermal conditions (from 20 to 30ºC with no acclimation time) [18]. However, as noted the ubiquity is another critical attribute for practical use of DRS systems. Therefore, in this study, we have sought to explore whether we could use limited sensing nodes to cover a larger area in an indoor space (the primary objective) and multi-occupancy cases (the secondary objective).

These research questions have not been addressed by the previous studies, which focused on cardiopulmonary activity extraction by DRSs at a static location (0.5 m away from a DRS vertically) [24]. The data collection, respiration extraction process, and reason of having the simplest DRS setting are presented in the next section.

3 Methodology

3.1 Non-intrusive respiration extraction by Doppler radar sensors

Using the linear relationship between air volume variations and human chest and abdomen area [25], our thermoregulation state assessment approach extracts the features of pulmonary activities by using DRS systems [17]. The frequency and amplitude of DRS signals represent rates and intensity of breathing. Therefore, in our respiration quantification approach, we could infer thermoregulation states by quantifying the respiration leveraging the aforementioned features. Figure 1 shows the signal characteristics and the resultant breathing index. However, since we are interested in assessing the ubiquity attribute of the DRS systems in this study, we have solely focused on the frequency of respiration in evaluating the feasible range of measurement in quantifying the respiration activities. In doing so, four steps of post-processing methods have been utilized in analyzing the raw DRS signals: (1) applying the Savitzky-Golay smoothing filtering, (2) applying the Hanning window, (3) applying the fast Fourier transform, and (4) identifying the respiration component on the signal. The variations, derived from each step, is presented in Figure 2. The rationale behind using each step is as follows.

- The first step reduces noise and redundancy while preserving the shape and height of waveforms by the local least-squares polynomial approximations [26].
- The second step reduces the amplitude of discontinuities, caused by the digitization, by multiplying an amplitude that changes smoothly and gradually toward zero at the edges (Figure 3). Therefore, the process could result in better frequency resolution. Upon observing such discontinuities in the collected DRS datasets, we chose the Hanning window in consideration of its high applicability to different problems [27].
- The fast Fourier transform (FFT) is applied to convert a time-domain signal into the frequency-domain signal. This process helps the fourth step because the typical frequency range of respiration is often observed with a frequency less than 0.5 Hz [28]. Hence, the respiration activity can be extracted by identifying the signal that has the maximum amplitude within the aforesaid range of frequency [29].

3.2 Experimental setup

We have conducted an experimental study with three male human subjects. Their ages were 26, 31, and 33 and heights were 172, 182, and 183 cm. They declared no cardiopulmonary-related illnesses at the time of the experiment. This study was conducted upon receiving the approval of Virginia Tech's Internal Review Board (IRB) and informed consent was obtained. We used a number of experimental configurations:

1. A basic DRS sensing setup that does not use signal amplification with the first subject
2. A DRS setup that uses signal amplifier with the second subject.
3. The third configuration was focused on multi-occupant sensing, for which the second and third human subjects participated. In this configuration, we used the DRS sensing with signal amplification.

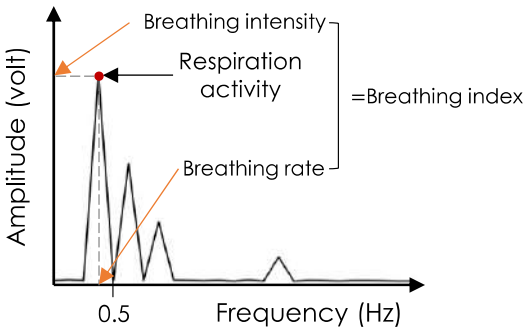

Figure 1. Features of the respiration activity

captured by DRS system.

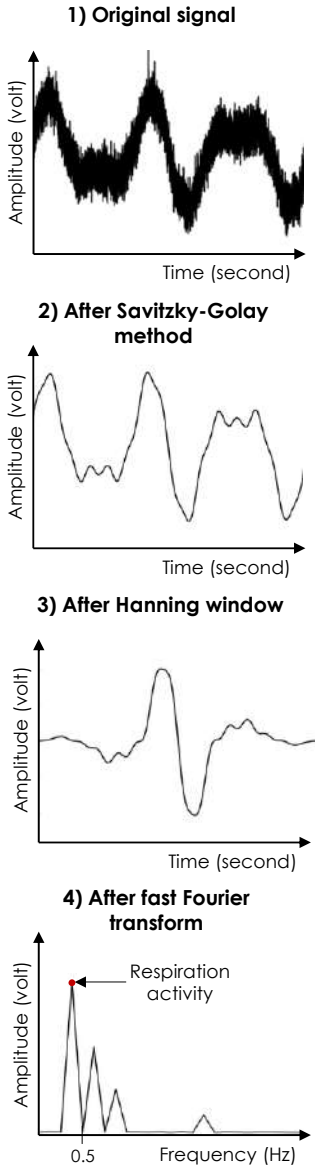

Figure 2. Respiration activity detection by using Doppler radar sensor signal (the signals are schematic representations)

For the sensing set up, we have used an RFBeam K-LC5 product as the DRS sensing system. This senor is a wide-angle sensing system – 34º vertical and 80º of horizontal beamwidths (Figure 4) – with a frequency of 24 GHz in the K-band, which is less occupied by other communication technologies. The sensing system is sensitive to subtle displacement and uses small antenna. As shown in Figure 5, the sensor dimensions are $25\times25\times6mm^3$ [30]. This product includes a built-in low noise amplifier with 10dB gain and needs 5 voltage to power on. For the external amplifier, in the second and third configuration, we used a low-noise preamplifier, SR560. We used 30dB for the amplification factor, which was empirically selected after a tuning process. We also employed a low-band pass filter with the pre-amplifier to reduce the noises caused by higher frequency components. Considering the aforesaid typical frequency of human respiration activities, we employed 3Hz for the low-band pass filtering. For data acquisition, we used a generic data acquisition card from National Instruments (NI6001) and the LabView software with a sampling rate of 1,000 per second.

We placed a DRS on a table as shown in Figure 4. The height was 0.7m (a typical table height) and the subject was sitting naturally and wearing the MLT1132 respiratory belt by ADInstrument. The belt is a transducer that produces a voltage proportional to variations in length of the belt and was used for ground truth data collection.

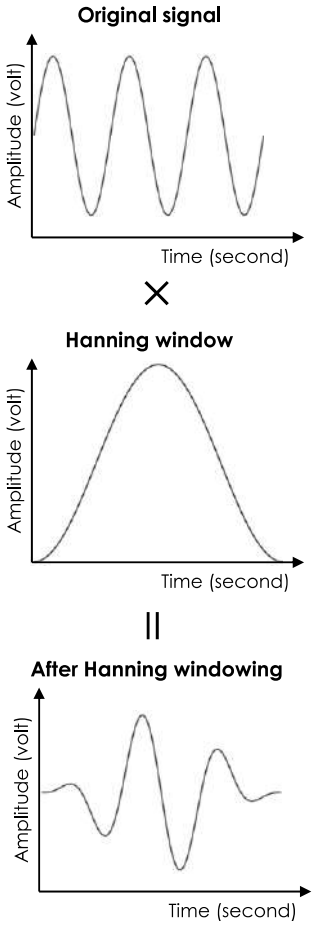

Figure 3. Applying Hanning window

For the first experimental configuration, the subject sat at multiple locations with respect to the location of the sensing system (Figure 6). With the use of external preamplifier, we presumed that a longer distance can be attempted. more distant points were examined: (1) 1.50m longitudinal and 0.50m lateral distance from the sensor and (2) 2.0m longitudinal distance from the sensor at the centreline. These locations have been highlighted with red circles in Figure 6. In each position, the subject faced different angles (from +45, +22.5, 0, –22.5 to –45º). Considering the symmetry of the sensing system, the data collection was conducted only on one side of the sensing system. Considering that DRS measures respiration activity by capturing the periodic movement of chest and abdomen area (moving back and forth), we did not consider the angle beyond ±45º. At each position and angle, we measured the subject's respiration activities for four times (each was 30 seconds of measurement – two minutes in total).

For the multi-occupancy case, which was the third configuration, two subjects were sitting in front of a DRS at 0.50m from the sensor and breathed naturally for 30 seconds.

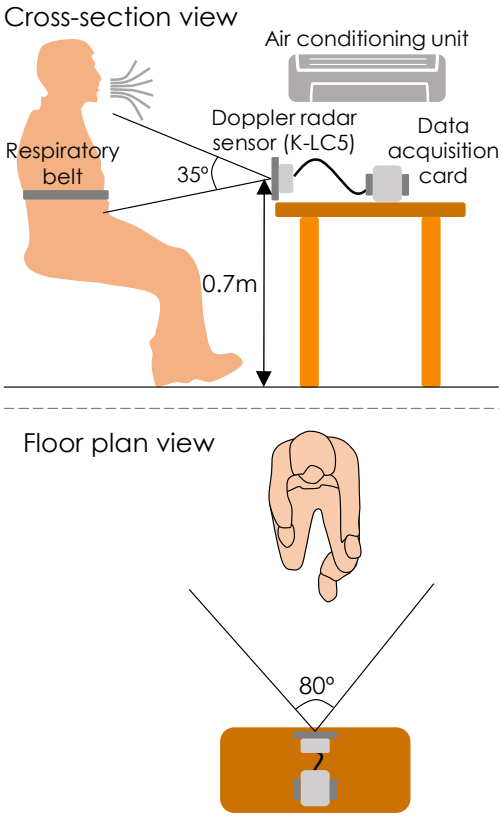

Figure 4. Cross-section and floor-plan view of the experimental set-up

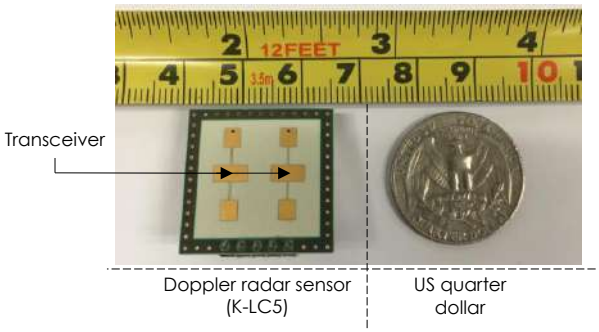

Figure 5. Doppler radar sensor used in this study

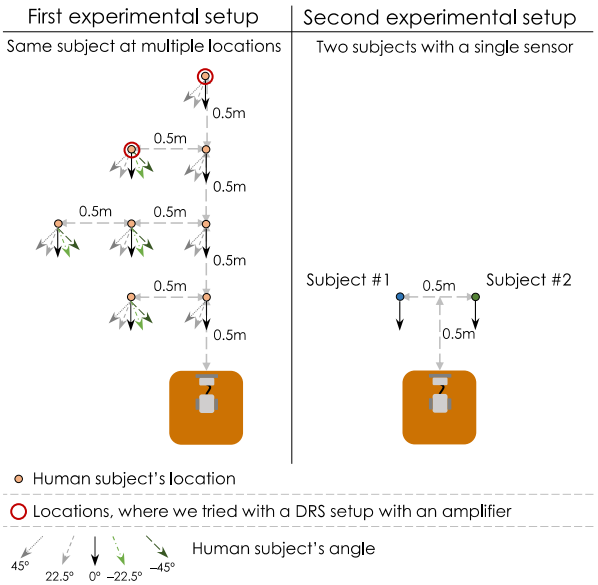

Figure 6. Subjects' locations and angles with respect to the DRS

4 Result

After collecting the raw DRS and respiratory belt data, we employed the aforesaid four steps to extract respiration activities from raw DRS data. Given that the data from belt does not contain noise we only employed the third and fourth steps on the data from that sensor. Due to the use of 30 seconds of measurements (N) with a sampling rate of 1,000 per second (F_s), the frequency resolution of FFT was $0.033Hz$ (F_s/N = 1000/30000 = 2 breathing per minute (BPM)). We compared the respiration rate from the DRS and respiratory belt data and interpreted the results using three indices: (1) there is no gap between the DRS and belt data (good), (2) the gap is equal to or below 4 BPM (moderate), and (3) the gap is more than 4 BPM (poor).

The results are shown in Table 1. Without the use of an external amplifier, the best performance was

observed when the subject was facing the DRS at a distance of 0.5m. In this position, even when the subject's position was shifted at 45 degrees, correct measurements were observed in three out of four cases. In general, as anticipated, in cases the subject was facing the DRS system sitting parallel with the radar antenna plane, the returned signal captures more pronounced movements of the chest and abdomen areas, resulting in a better performance. In addition, in cases that the subject was sitting within the 0.5 m range (both longitudinal and lateral) away from the DRS, the accuracies were fairly acceptable. The discrepancy between the DRS measurements and the ground truth data increases as the range of measurement increases. The cells with light orange color represent the poor performances.

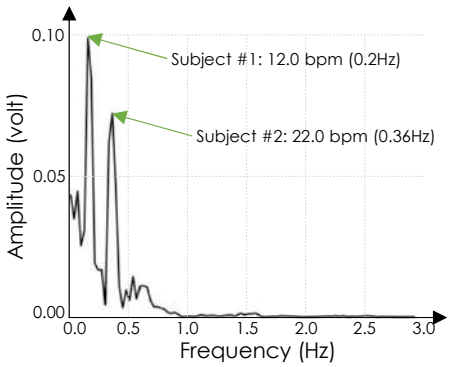

Figure 7. Results from the second experimental study

When the external amplifier was used, we could observe that the accuracy for farther ranges (or longer distances) is improved. For example, the case that the human subject was sitting in 1.0 m range (both longitudinal and lateral) away from the DRS, this DRS setup could identify breathing with fair accuracies, while the first setup fails. Even with the farthest ranges (1.5m longitudinal and 0.5m lateral, and 2.0m longitudinal), respiration activities could be quantified with fair accuracies. However, it has been observed that amplifying the DRS signal might result in lowering the overall accuracy. This is because the amplifier also amplifies the noise in the environment, often caused by subjects' subtle and spontaneous (e.g., yawning) movements.

Lastly, Figure 7 illustrates FFT output of the DRS signal for the third experimental configuration. As this graph shows, within the typical respiration frequencies two peaks are clearly located. Although limited observation, it shows that multi-occupant sensing could be potentially feasible using a single DRS system. However, more experimental studies are required for significant conclusions on multi-occupancy conditions.

5 Conclusion

This study has sought to investigate the ubiquity attribute of a non-intrusive respiration monitoring system, which has the potentials to be integrated into comfort-aware HVAC system operation. Given the recent research trends of exploring potential apparatuses of measuring human-related contextual data, this study provides insight into the feasibility of utilizing DRSs as a cost-effective and ubiquitous measurement system. The results demonstrated that, even by using a simple sensing and data processing set-up, respiration activities could be reasonably captured within the range of 1.0 m longitudinally and 0.5 m laterally. Considering the normal office environments, where occupants normally sit in a distance of 1.0 meter vertically from the computer monitor, this range can sufficiently cover an occupant. Moreover, the size of this sensor is small enough to be placed in a desk without interfering with occupants' activities. It is also noted that having an amplifier could expand the range of a DRS, but the set-up requires more advanced noise cancellation processes for precise respiration activity quantification. We have also preliminarily assessed the potential of sensing multiple people with a DRS with promising result.

One of the requirements for use of DRSs for thermoregulation state quantification is the duration of data acquisition, required for measurements. Due to the low frequency of respiration by nature, its precise measurement requires longer data collection durations. In this study, we used 30 seconds of measurements and, as a consequence, a 2-BPM resolution could be achieved with FFT. For a higher frequency resolution, a longer measurement time is necessary. As noted before, users' unintentional motions could add noise to the DRS signal and having a long measurement time increases a possibility of having noises.

Although this study used a specific product to evaluate the ubiquity attribute of a DRS, it can be used as a baseline for the future studies as we used a minimal hardware and software set-up. Accordingly, as future research, more diverse DRS set-ups can be explored with several scenarios such as expanding the testing area or having multiple DRS systems. Furthermore, the signal processing framework could be further developed. For example, in case of multi-occupancy conditions, a signal separation technique, such as independent component analysis, could be tried when similar breathing rates are captured by multiple occupants. As the results show, the proposed DRS system can also be used in vehicle air-conditioning operations considering its vicinity to the drivers. Accordingly, the outcome of this study will contribute to realization of comfort-aware HVAC operation, assisted with physiological sensing system. Another potential application includes monitoring of construction equipment operators.

Abstract –

Automation of the code compliance checking has been explored extensively, particularly in recent years with the emergence of building information modelling (BIM). Still, automated code compliance checking has not yet been fully realized, as there is no standardized method for rule interpretation and building model preparation for code compliance. Manual verification of design code compliance, meanwhile, requires significant effort and time and is error-prone, while uncertainty and inconsistency in assessment lead to delays in the construction process. In this paper, the development of a prototype to automate municipal bylaw and wall framing code compliance checking for residential building is presented. The building rules have been classified into three groups based on the complexity involved in translation into computer-readable format and complexity in retrieving the required information, and they are represented based on building objects, which makes the regulations easier to understand and assists in translating the regulations into a computer-readable format. By creating a model view based on the required element's parameters extracted from a model for checking purposes, the prototype application offers automated code compliance checking functionality to validate designs based on building code requirements and construction engineering specifications. The implementation of the prototype and its benefits compared to manual checking is demonstrated.

Keywords –

Building Information Modeling (BIM); Automated code compliance checking; Building permit; Building rules

1 Introduction

Technological advancements in the architectural, engineering, and construction (AEC) industry have digitized nearly every stage of the building lifecycle, and this digitization has been a significant advancement in the industry over the past several decades. In this context, building information modelling (BIM) technology has been utilized for a wide variety of applications across the building lifecycle. In particular, automated code compliance checking saw a major leap with the advent of BIM in the late nineties [1]. An automated code compliance checking system is one of the processes for verifying the design in accordance with building codes, regulations, and bylaws. For many years, authorities and researchers have been working on an automated code compliance checking process, yet it is still only a semi-automated process. Many researchers have developed applications for safety, egress, and design checking, but still no application is in use for code compliance checking, even in countries where the BIM model for the design checking process was made mandatory. Many applications have not been updated since they were first developed, and an even fewer number of those have survived. This is partially due to the fact that there is no standardized method for rule interpretation and building model preparation for code compliance.

This research develops a BIM-based automated design checking prototype, in the form of an add-on for Autodesk Revit (i.e., DCheck), for automated checking Edmonton zoning bylaws, lot design for residential houses construction, and wood framing for walls of the residential building in accordance with Alberta building code 2014 part 9. To develop the prototype, the building rules have been classified into three groups based on the complexity involved in translation into computer-readable format and complexity in retrieving the required information, and they are represented based on building objects, which makes the regulations easier to understand and assists in translating the regulations into a computer-readable format.

In the subsequent section, a review of state-of-the-art existing software and plug-in applications with respect to automated compliance checking is presented. Detailed explanations pertaining to the methodology are presented in Section 3. Section 4 illustrates the system architecture of the prototype. A case study is presented as a test-bed to verify the developed prototyped system in Section 5.

Finally, findings are summarized, particularly as they pertain to potential future research.

2 Existing Design Checking Applications

With the use of CAD tools for design purposes by AEC professionals in the 1990s, the automation of design checking has gained more interest among researchers. Exhaustive studies have been performed in automating the building code by many researchers in this field, each exploring different techniques in interpreting the rules from his or her perspective [2]. Typical examples include the development of the following: logic-based approaches for the organization of design standards [3]; computer representation of design standards [4]; and knowledge-based expert systems capable of reviewing building design [5]. An overview of software applications developed by different countries and government authorities for automated compliance of each country's building code is described in the subsection that follows and a summary is presented in Table 1.

2.1 CORENET (Singapore)

In 1995, the Building Construction Authority (BCA) of Singapore initiated CORENET (Construction and Real Estate Network) as a comprehensive network system with a series of IT systems for exchange of information between government agencies and parties involved in construction and real estate [6]. CORENET for approval process provides electronic web-based submission system incorporating in-house building plans (BP) expert system to check 2D plans for any technical irregularities with reference to the building regulations [7]. e-PlanCheck, as part of CORENET, was the first initiative developed for automated code-checking. CORENET consists of three platforms: e-submission, e-PlanCheck, and e-info. E-PlanCheck was used as a pilot project in Norway and New York with replacement of rules required by Norway and by using ICC (International Code Council) codes for New York.

2.2 DesignCheck (Australia)

DesignCheck was developed by Australian authorities for automated building code compliance for Australia, focusing on accessible design regulations [8]. In fact, code checking efforts by Australia involved development in two phases. The first phase was to assess the capabilities of existing rule checking systems to find out which would be the best one for computerization of Australian standards [8]. Both SMC and Express Data Management (EDM) were considered as possible platforms for automated code checking. EDM was considered as the more suitable one because of its ability to provide a publicly accessible definition language to represent building codes. After the first stage of checking for a feasible solution, different domain-specific knowledge can be encoded to EDM rule base and can be applied to check a building model.

2.3 Statsbygg (Norway)

The Norwegian government organization, Statsbygg, acts as the Norwegian government's key advisor in construction, building commissioning, property management and property development [9]. The CORENET e-PlanCheck system has been used for a couple of industry foundation class (IFC) based BIM building projects as an early effort by Norwegian authorities. Multiple platforms, such as e-PlanCheck, SMC (Solibir Model Checker), dRofus, and Express Data Management (EDM) model checkers were also adopted for the purpose of experimenting for finding a better checking system. "HITOS" is a BIM project managed by the Statsbygg government organization and Tromso University since 2005, for which several software applications have been used for modelling architectural, structural, MEP (mechanical, electrical and plumbing), cost estimation, and energy simulation, and an EDM model server was also used for storing and accessing the model data in IFC format [10]. dRofus as rule based system was used for spatial program validation: which acts as a database system used for managing architectural programs, technical functional requirements and equipment's for early stage planning[9]. Solibir model checker (SMC) was used for checking accessible design in the building model. SMC was developed in 2000 in Finland as quality assurance and validation tool.

2.4 International Code Council (ICC) and General Service Administration (GSA) Design Rule Checking (The United States)

GSA, an independent agency of the United States government, issued BIM-guidance in 2006, and starting in 2007, made it mandatory to have a BIM model for validation for all projects seeking permission for spatial planning projects[11]. The application uses the SMC platform and design assessment tool for extending rules, developed by Georgia Institute of Technology. The most interesting initiative in this area is SMARTcode, which was started in 2006 and handled by ICC, a US-based association that develops the master building codes for residential and commercial buildings and most institutional buildings [12]. SMARTcodes is a project for transforming natural language code into computer inter-

pretable format, and a dictionary of the properties found within the building codes have been developed in SMARTcodes. The dictionary is helpful in communication between SMARTcodes model checking system and the IFC building model [22]. The rule interpretation process is the most vital stage in automated code compliance checking, where various technologies have been investigated and employed. With so many technologies there is no standardized way for translating the complete building rules and regulations into computer-readable format. Out of many applications developed the Singapore CORENET project is an early initiative started by a government organization about 23 years ago for checking of 2D building plans submitted online for code compliance. Subsequently, the Solibri company developed an application called Solibri model-checker (SMC) for checking 2D plans around 1999. And even after over two decades since the start of the CORENET project, there has not been much progress in the development of an automated checking process. Solibri is the only commercial software available for checking some aspects of building design like clash detection, and space validation. The applications developed should provide easy way for future updates with change of building rules and regulations and should be user-friendly for continuous use of code compliance. In terms of BIM model preparation, the building models should be developed with BIM technology-enabled software with a certain level of detail (LoD). LoD is details that are included in model objects related to dimensional, special, qualitative, quantitative, and other data to support required purposes. Models should be developed with LoD 300 or more for efficient extraction of information needed for compliance checking process.

It should be noted that previous research classified design rules into four groups, based on the complexity involved in extracting the required information from the BIM model. The present research further considers the complexity of rule translation to classify rules, as the major problem in the process of automated checking is

the rule interpretation, where human-written codes are translated to computer interpretable format. However, building codes are not self-contained and make reference to many other documents. We proposed the strategies of the rule interpretation for each rule category. The translation of the human-readable natural language code into computer interpretable code is complete, only if when the logical representation of regulations gives a clear understanding of the building regulations.

3 Methodology

Figure 1 shows an overview of the process of automated design checking of building code and municipal bylaws for residential buildings. This process can be divided into four main steps [11]: (1) Rule translation, which is the interpretation of natural language building rules into computer-interpretable format; (2) BIM model preparation, which involves the design of the building model in Autodesk Revit software and creating model views from the given BIM model; (3) Rule checking, which involves the checking of the designed model with the encoded rules; and (4) Checking report, where the compliance check result is obtained.

3.1 Rule Translation

The translation of the context and content of the building code and municipal bylaws for residential buildings into a machine-readable format is one important step in the automated rule checking process. Each regulation has a different level of complexity involved in the translation into a machine-readable format. In this research, all the building rules are classified into three groups based on complexity in translation into machine-readable format and also with complexity involved in extracting the required information from the BIM model, These include (1) Easy: These are rules that are classified as easy to translate from natural human-readable language into computer-processable codes and where the information required can be directly extracted from the BIM model; (2) Intermediate: These are rules that are classified as difficult to translate and where the information required needs to be derived. The complexity level of translating these rules into computer-processable codes and getting that information from BIM model involves introducing some new attribute values for defining some properties of building objects for compliance; (3) Difficult: These are rules that are classified as needing to be simplified in order to translate them, and where the information required needs an extended data structure. Some rules need clarification depending on the building design and specifications, and some rules need the building model to be analysed to get the required value to be checked, and the information required from the BIM model is extracted using an extended data structure. Compared with previous studies in which building rules are classified into 4 groups, only based on complexity in extracting the information from BIM model, the proposed three groups make it easier to implement. This classification of building rules facilitates the development of the checking add-on software application in later stages, giving the user a clear understanding of the checking process. The

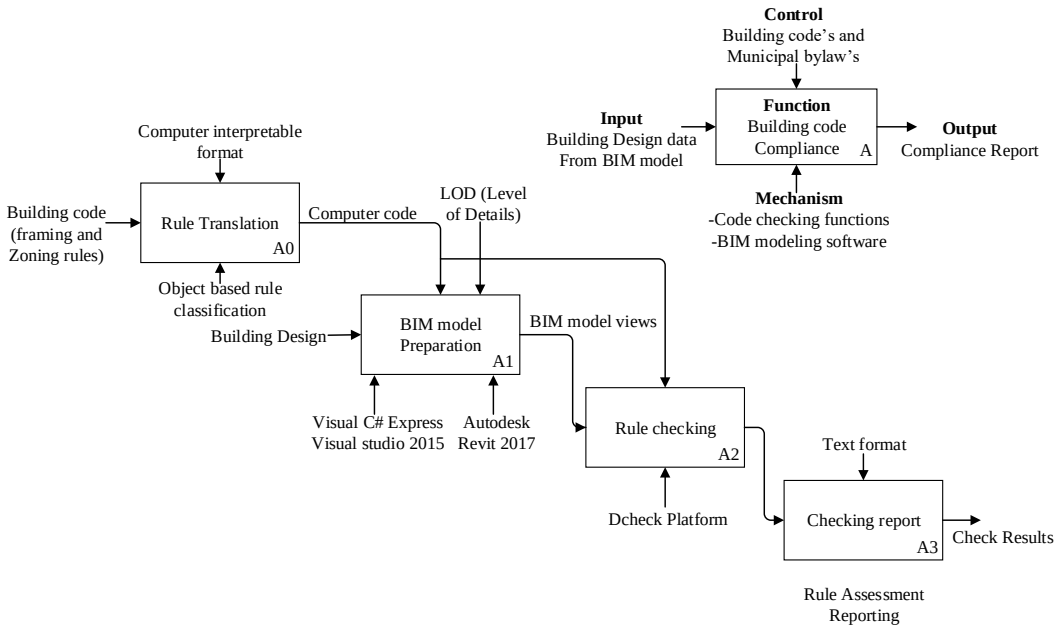

Figure 1. Methodology

representation of building codes based on building objects with conditions to be satisfied, attribute values to be driven from BIM models, and the threshold values to be checked for object-oriented representation, provides a clear understanding of building rules and makes easy for knowing the required parameter value from the model. By using this rule classification, building codes can be efficiently and comprehensively translated into computer interpretable format. In this study, an object-oriented programming language (i.e., C#) is used for compliance checking because of its flexibility and consistency in encoding building rules from the Alberta building code and municipal bylaws related to different zones in accordance with Edmonton municipal bylaws.

3.2 BIM Model Preparation

The BIM model can be defined as a digital representation of physical characteristics, such as architectural designs, and functional characteristics, like structural analysis, energy analysis, or a myriad of other simulations with semantically rich information. Building objects modelled in BIM enabled software's have parametric properties. For example, a wood stud member in the model possess types and properties like dimensions (length, width, depth), material properties, location of element member (XYZ coordinates), and so forth. The building model can be developed with level of details (LoD) above 300 for better extraction of information from a given model. Autodesk Revit provides a way to define and export extensible and interoperable BIM model data with use of Autodesk Revit's API (application program interface). The structure of APIs for exchanging information is object-based, where the geometry and properties of objects, such as name, size, location, finishes, faces and abstract information like cost, quantities, and so forth, can be accessed. In this research, C# language has been used to extract building information for compliance checking from the BIM solution, Autodesk Revit.

3.3 Rule Checking

The fundamental aspect of automated compliance checking is the information exchange from the BIM model to the rule checking platform. The checking platform (i.e. DCheck) applies a set of related rules to a model view. Prior to applying rule checking, syntactic checking of model is needed, to determine that the building model carries the properties, names, objects needed for the complete checking task. With object-based building information extraction, the geometric and functional information of objects, such as faces of building components, vertices, edges, location, and some derived information is extracted for compliance checking. Basically, mapping between the BIM model and the building rules is done by DCheck platform in this step.

3.4 Checking Report

The final step of the automated compliance checking process is to provide the user with a final compliance checking report by notifying the user checking results, such as success or failure and associated reasons and suggestions for failed regulation. This report is displayed to the user in textual format, and those building objects related to the rules which they have failed to satisfy are highlighted in the model, which helps to spot those objects and make corrections. The checking process can be run at any time during the design by the user, so it is easy for the architects or the draftspersons to check models in a parallel manner while designing.

4 Prototype Application

The automated building design checking is implemented as an add-on software application (i.e., DCheck) for the Autodesk Revit software, developed in C# language using Revit API's. Figure 2 shows the architecture of the prototyped Revit-based automated design checking software application. The inputs for the system include: (1) building design of the project and BIM model of the building intended to be constructed containing the architectural and structural framing information; (2) the project applicant information, regarding the applicant, architect's and builder information; and (3) zoning and framing information, regarding site location, plot number, type of wood used for framing and so forth. Criteria for this project are: (1) building code, in this case Alberta building code 2014 part 9, housing and small buildings, containing regulations related to framing of residential building; (2) municipal bylaws, Edmonton zoning bylaws, containing regulations related to different types of zones and residential building; (3) Level of details (LoD), development of model with LoD above 300 serves the required purpose for automation of building rules checking in this prototype.

The core processor of this prototype has main components: (1) object-based representation of building code, where building rules are represented based on the building objects so that required information from building model related to particular building object can be known clearly; (2) BIM model view definition, where required model views of BIM data for compliance checking are extracted; (3) BIM model extension, where some information which cannot be accessed directly from the BIM model needs to be derived and data structure platform extended by DCheck will provide those values; and (4) code compliance with model, where extracted information from the model will be checked

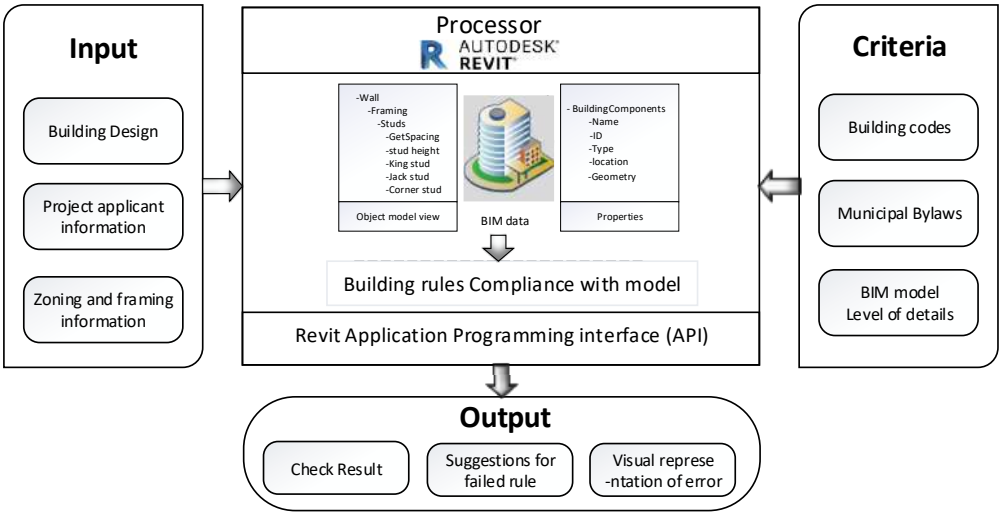

Figure 2. System Architecture

against the already-encoded building rules. These four components are compiled into Autodesk Revit as an add-on through using C# language.

5 Case Study

A residential building design has been modelled in Autodesk Revit as required, with a level of details more than LoD 300 for efficient automated-checking process. Before starting checking, users are required to provide some initial information related to the project, which is the same information house owners or contractors used to provide while submitting 2D CAD drawings for approval.

The building rules are represented based on building objects. The logical representation of rules based on building objects gives a clear understanding and provides an efficient way to accomplish the interpretation of rules into a computer-readable format. Figure 3 gives details about minimum setback distances required for different house types. Building rules from municipal bylaws like "If it is Single Detached Housing: Minimum site/ Lot Dimensions should be, Area: 250.8 m^2. Width: 7.6 m^2. Depth: 30 m^2" and so on are represented in a logical format for better understanding. As an example, the above explained rule related to lot checking can be represented as shown in Eq. (1), which represents two-dimensional matrix with threshold values to be satisfied for each type of house (j) and for different zone types (i). Where i is different residential zones present in city, j is different types of houses built in those residential zones. Finally, if the equation (2) returns the result of 1, then the rules have failed to satisfy, else it is correct.

In the City of Edmonton, there are ten different zones (Z_{bylaw}): Single Detached Residential Zone (RF1),

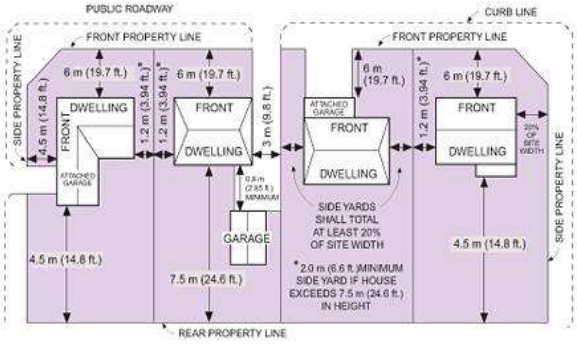

Figure 3. Illustration of Setback Distances Requirements for RF1 Zone (Adopted from City of Edmonton Website [23])

Residential small Lot Zone (RSL), Low Density Infill Zone (RF2), Planned Lot Residential Zone (RPL), Small Scale Infill Development Zone (RF3), Semi-detached Residential Zone (RF4), Residential Mixed Dwelling Zone (RMD), Row Housing Zone, Urban Character Row Housing Zone (UCRH), and Medium Density Multiple Family Zone (RF6). All the residential houses built in these zones are classified as single-detached housing (sdh), semi-detached housing (ssh), duplex housing (dh), limited group homes (lgh), garden suite (gs), secondary suits (ss), or minor home-based business (mhb).

$$i = Z_{bylaw} = \begin{bmatrix} \text{RF1, RF2, RPL, RF3, RF4,} \\ \text{RMD, Row housing zone,} \\ \text{UCHR, RF6.} \end{bmatrix}$$

$$j = HT_{bylaw} = \begin{bmatrix} \text{sdh, ssh, dh, lgh, gs,} \\ \text{ss, mhb.} \end{bmatrix}$$

$$L_{bylaw} \in M_{9X7} = A = \begin{vmatrix} \text{for i} \in 1 \dots 9 \\ \quad \text{for j} \in 1 \dots 7 \\ M_{i,j} \leftarrow [i_j] \end{vmatrix}$$

$$where, \mathrm{A} = \begin{pmatrix} \mathrm{RF1}_{sdh} & \dots & \mathrm{RF1}_{mhb} \\ \vdots & \ddots & \vdots \\ \mathrm{RF6}_{sdh} & \cdots & \mathrm{RF6}_{mhb} \end{pmatrix} \quad (1)$$

$$\text{get the user inputs:} \begin{cases} \sum Z_i = 1\ (i) \\ \sum HT_j = 1\ (j) \end{cases} \rightarrow find\ A(i,j)$$

$$\rightarrow L_{bylaw(i,j)} = \begin{bmatrix} LA^{bylaw} \\ LD^{bylaw} \\ LW^{bylaw} \end{bmatrix}$$

$$\delta_{lot} = \begin{cases} 1 & \text{if } L_{bylaw(i,j)} > L_{BIM} \\ 0 & \text{otherwise} \end{cases} \quad (2)$$

The user needs to provide the project information on housing and zoning type through the main user interface of DCheck add-on application as shown in Figure 4. By running the application for checking municipal bylaws, it provides a textual report related to compliance checking in accordance with municipal bylaws based on building design and user input (see Figure 4). The textual report displays municipal bylaws failed to satisfy with the building objects attribute name, reason for the failure and details about that rules, so that user can easily understand the error in design and make changes as suggested. Once the errors have been corrected, the user can run the checking application again. If there are no further errors in design, it will display a textual report indicating checking successful.

6 Conclusion

This study presents the automated checking of zoning regulations according to the City of Edmonton municipal bylaws related to residential zoning designs and the Alberta Building Code part 9 related to housing and small buildings for light-frame residential buildings in Autodesk Revit. The representation of the building rules based on building objects and the classification of building rules into three groups based on complexity in translation and also in complexity in extracting required information, makes it easier to understand the rules and helps to translate the rules and regulations into computer-readable format. This kind of knowledge formularization makes it easier to understand the regulation and determine the required threshold value to be checked for that building object in the model with specified conditions. This makes it easier for any changes or for the development of add-on software application for a different province or jurisdiction where the building rules are different. Also, the classification of building regulations supports the development of the extended data structure platform in a step-by-step process, which gives the user a clear understanding of the checking process with rules that are incorporated in the add-on application system.

Abstract –

Schedule assessment models were created to ensure the proper development of a schedule. The checks can be categorized into scheduling-related and constructability reviews. Most of the existing automated models are targeted towards two-dimensional schedules, and not nth-dimensional, despite the emergence of building information modelling in the construction industry. The type, method and relations between stored temporal information for activities in nth-dimensional models differ than the typical two-dimensional schedules. Accordingly, this paper presents the adaptation of the existing schedule quality assessment criteria to evaluate nth-dimensional models, utilizing building information modelling and Industry Foundation Classes (IFC). The paper starts with a comprehensive review of previous assessment models, identifying the major checks performed, detailing out the needed activity information and evaluation techniques. The checks are then categorized as quantifiable and qualitative, to differentiate between the measures that can be fully automated and others which would require expert intervention. Afterwards, the paper presents the methodology for attaining the inputs required for the quantitative measures in nD models. The methodology revolves around using IFC, as a standard data model for storing building and construction data. Accordingly, a technological review was conducted of the existing nD modelling software, to view the capabilities and limitations that could affect the development of a schedule assessment model. Initial Algorithms were developed to measure the wellness of schedule properties such as activity duration, criticality levels and accuracy of relationships. These developed algorithms were then verified by testing them versus different schedules with known errors.

Keywords –

4D Modelling; Schedule health assessment; Schedule quality checks; IFC

1 Introduction

According to International Building Information Modelling (BIM) Report 2017 by National BIM Standard, 78% of Canadians think that BIM is the future for managing project information and 67% are currently using BIM in their organization. [1]. The design and construction industry are now transitioning from use of two-dimensional Computer aided designs (CAD) and paper for design to three-dimensional digital models loaded with information. The BIM usage in project is expected to continue growing sharply in coming years [2]. The emergence of BIM in construction industry has allowed for the development of nD models, which combine the 3D spatial information with time, cost, resources, etc. The development of these models has provided enhanced multi-disciplinary and constructability analysis, and more efficient communication of spatial and temporal information between project teams by visualizing the evolution of the construction works throughout the project duration, allowing for the creation of more practical time schedules [3].

The United States Government Accountability Office (GAO) reports that there is a significant relationship between good scheduling practices used early in the project life cycle and the ultimate success of the project [4]. Accordingly, extensive research has been conducted to develop metrics that evaluate the quality of schedules, from various aspects, such as the construction logic, the activity identification, adequacy of estimates durations, enough allocation of resources, ideal cash flow distribution, etc. [5] [6] [7] [8]. Additionally, these metrics have been automated via commercial software [9] [10] [11] [12]. However, despite BIM's growing popularity, these automated schedule assessment models are still configured based upon the review of schedules from the conventional planning tools. In nD models the activities' temporal information and schedule relations are stored in a different database configuration than that in the conventional planning tools (such as Primavera &

Microsoft projects), which is more complex owing to combining the spatial information in the same database. Hence, the current automated schedule assessment models cannot be used to evaluate nD models without adaptation, which is rendering the process of development of these models inefficient.

Consequently, the focus of this paper is to develop the framework that adapts the current schedule assessment metrics of conventional planning tools, to capture information and analyse the schedules directly from nD models. Furthermore, the framework is based upon the Industry Foundation Classes (IFC) format, which is an open and neutral data format, to standardize the information storage and to work with any nD modelling software in the market. IFC is defined using the ISO 10303 suite of specifications for data modelling and exchange, also known as STEP (Standard for the Exchange of Product Data) [13]. This paper presents its method for categorizing previously developed evaluation metrics to identify the potential ones for adaptation. Then, the paper presents the methodology for capturing the selected metrics from nD databases in IFC format, and the corresponding algorithms using Psuedo code. Lastly, the paper verifies the approach via a theoretical case study of a 3-story office building, where faulty schedules were created intentionally to measure the responsiveness of the algorithms.

2 Review of Previous Schedule Assessment Models

The most popular assessment model is that of the United Stated Defence Contract Management Agency (DCMA). They formulated 14 points to assess the schedule quality at both pre-construction and during construction and identified the threshold for each which are presented in Table 1 [14]. For example, to test schedule practicality, they identified metrics as: (1) logic: which stated that only 5% of the activities in the schedule are allow to not have successors nor predecessors, to ensure proper linkage, (2) leads: which stated that activities cannot have a relationship between them with a negative lag, as this leads to improper relationships, (3) hard constraints: which stated that any schedule cannot have more than 5% of its activities with hard constraints, and they tend to disrupt the paths when being misplaced, etc. Currently, these points represent the minimum checks in modern assessment models, with variant thresholds.

Table 1. DCMA 14 Metrics [14]

Metric	Description	Threshold
Logic	Activities without successors/or predecessors	< 5%
Leads	Relationships that have a negative lag	0%
Lags	Relationships that have positive lags	< 5%
Relationship Types	Finish to Start Relationships	>= 90%
Hard Constraints	Activities with Must Finish On/ Must Start On/ Start No Later Than/ Finish No Later Than	< 5%
High Float	Activities with total float greater than 44 WD	< 5%
Negative Float	Activities with total float less than 0	0 %
High Durations	Activities with Duration greater than 44 WD	< 5%
Invalid Dates	Activities with forecast dates earlier than status date or actual dates later than status date	0 %
Resources	Activities without resource loading (money/ hours)	-
Missed Tasks	Activities with actual/forecasted finish dates later than planned finish date	< 5%
Critical Path Test	Test the integrity of the critical path by introducing intentional slippage. If the delay is not proportional to the slippage, then the logic is faulty and is flagged	
Critical Path Length Index (CPLI)	(Critical Path Length + Total Float) / Critical Path Length	>= 0.95

Baseline Execution Index (BEI)	Activities completed within current reporting period / (Activities completed in previous reporting periods + Activities missing their planned finish dates)	>= 0.95

Further metrics were developed in later work after the DCMA to add more analysis for areas as the logic and resources. [8] [15], developed their assessment model, which would check the job logic by: (1) Recognizing pre-defined keywords in the activities' names (2) check for the existence of relationships between each set of keywords. For example, any activity name containing "pouring" must have predecessors with activity names containing "framework" and "rebars", and successors with activity names containing "curing". Furthermore, they developed a set of empirical rules to verify the job logic in any schedule. The empirical rules explained the expected relationship and duration ratios that activities should have with reference to the schedule. For instance, the duration for the curtain wall activities should be around 30% of the project duration, and cannot start until at least 3 floors are done with the framing works. As for resource allocation, their model compared the schedule's productivity rates with that of RS Means, flagging any activities with a deviation of over 30%. Opposing to the DCMA, their system categorized the metrics as obligatory and complementary, where the former must be satisfied, and the later measures the fitness according to a "Schedule Development Index (SDI)". The schedule fitness was considered excellent with SDI ≥800, good with 800>SDI≥500, and acceptable with SDI<500.

[5] [6] [7] developed 75 schedule requirements grouped under 5 categories: (1) General Requirements: which dealt with generic parameters, such as checking for an activity coding structure, defined calendar, etc. (2) Construction Process Requirements: which dealt with job-logic, productivity, activity duration and timing. (3) Schedule mechanics requirements: which dealt with scheduling issues as open-ended activities or relationship types (4) Cost and resource requirements: which dealt with cost and resource loading assignments. (5) Control process requirements: which dealt with validating and evaluating the schedule updates. They used the BEI and CPLI of DCMA, which are shown above in Table 1. Their model was based on user-defined thresholds for each requirement, in which graphs would be developed to display a schedule's performance (rating) under each requirement group according to the defined thresholds, where the rating is a subjective evaluation of the reviewer. The main addition in their assessment model is identifying spatial requirements under "Construction Process requirements" as having a "safe and non-congested work areas." which was done manually.

Similarly, [3] [16] and [17], developed their assessment criteria by reviewing the 4D schedule model created in ArcGIS. However, contrary to the typical metrics, their model focused mainly on the review of the job logic by manual observation of the 4D visualization to check for the adequate activity detailing and proper sequencing. Also, their model ensured that all temporal activities were assigned to at least one spatial object, based their assessment criteria on the manual visualization of 4D schedule to ensure the sequencing and constructability. Such research was based on expert judgement, with loosely defined metrics and was never automated. Till date, there doesn't exist a comprehensive model that combines temporal and spatial metrics for assessing schedule qualities, as that would require moving between more than one software and migrating the data back and forth for multiple iterations which is time-consuming.

3 Model View Definitions for Industry Foundation Classes

IFC schema is constructed of entities (or classes), the relationship between entities, and attributes, which together constitute the IFC model. An IFC model is usually big as it is a representation of all physical and non-physical elements in the project for all types of information (spatial, temporal, etc.) [18]. There are 4 standard methodologies for understanding IFC: (1) ISO 16739 for data sharing in the construction and facility management (2) International Framework for Dictionaries (IFD) ISO 12006-3 (3) Information Delivery Manual (IDM) ISO 29481-1 ISO 29481-2, and (4) Model View Definition (MVD) buildingSMART [19].

Focusing on MVDs, they represent is a subsection of the IFC schema for specific use cases. Meaning that the use of MVDs allows for extracting the necessary information only from IFC and not dealing with the entire model. This allows for faster analysis and less computational efforts. For example, when analysing schedule quality, the required information from IFC is mostly temporal information, and the size and coordinates of the physical components, with no need of material, or structural information. An MVD can help filter this information from an IFC Model. The latest IFC Schema developed by buildingSMART is IFC4 Addendum 2 with two released MVDs: Reference View and Design Transfer View, where the later is more comprehensive than the former and both contain the schedule information [20].

4 Methodology

4.1 Database Creation

Figure 1 displays the 3 steps taken to develop the nD assessment model. Stage 1 deals will the compilation of previous literature, international standards and commercial tools to create a database of 176 metrics. Each metric was tagged to its author, provided with a clear description, displays the suggested threshold (if any).

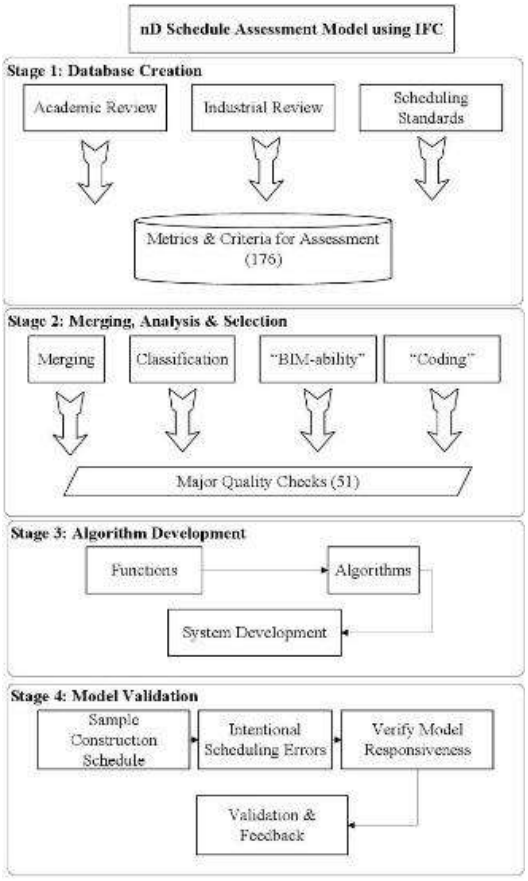

Figure 1. Methodology Procedure

4.2 Merging, Analysis & Selection

The second stage is the analysis of the database (176 metrics) which was conducted on 4 aspects: (1) Merging: to remove any duplicate checks that were suggested by more than one researcher, while maintaining the suggested threshold by each. For example, [14] suggested high duration activities metrics as shown in Table 1. This principle was also used by [8] and [7], but each defined a different threshold in their approaches. This reduced the metrics to 168. (2) Classifying the metrics as (2.1) qualitative: where 26 metrics had no clear threshold defined, and their description indicated manual expert intervention; (2.2) quantitative: where 104 metrics had clear thresholds and evaluation criteria; and (2.3) generic metrics: where 38 of the metrics had very generic description and couldn't be analysed without additional information.

As the target is developing an automated system, the focus was on the quantitative metrics, having clear guidelines for evaluation, which had 83 related to the planning (pre-construction) phase, and 21 related to the progress monitoring (construction) phase. The paper's concentration was on the metrics for the pre-construction phase. Where these were selected for further analysis of their "BIM-ability": a check to verify the existence of the required information in a BIM model exported in an IFC formatted database; and "coding potential": the ability to capture the information using a suitable MVD. This eventually led to selecting 51 metrics for the nD schedule assessment model.

4.3 Algorithm Development

Some of the selected metric required the same information, with the difference of the evaluation criteria and threshold, and hence could use the same algorithm. For example, 2 of the metrics selected were "relationships with lag" and "relationships with lead". Both shared the same evaluation criteria shown in Equation 1, where the metric depended mainly on measuring the ratio between the number of relationships (links # (Lag or Lead)) that had a lag or a lead, to the total number of relationships (Total Links #). hence, both metrics required filtering part of the part of the links with lags or leads. The only difference is the selection, for "lead' links are negative lags and "lag" links are positive lags. Accordingly, both can use the same algorithm. Subsequently, 22 unique algorithms were developed for the 51 metrics. Furthermore, these algorithms shared some global functions that were created as well.

$$Links\ \#\ (Lag\ or\ Lead)\ /\ Total\ Links\ \# \qquad (1)$$

To better explain this approach, Figures 2 and 3 shows the codes for the "total tasks" global function used in the "logic density" algorithm. The logic density is a measure of the soundness (practicality) of a schedule by finding the ratio of the number of relationships developed to the number of activities created. The threshold limit is a minimum of 2.1. To calculate this metric, the "number of links" and the "total number of activities" need to be captured. The "total number of activities' is also required in the "high-duration" metric, where the activities with a duration higher than a specified value are compared to the "total number of activities". The threshold for this measure is a maximum of 5%. Hence, a global function called "total tasks" was created to be used in both algorithms.

Total Tasks:

```
BEGIN FUNCTION TotalTasks(IfcTask,
IfcRelNests)
  ''' INPUT: IfcTask.ID(),
        IfcRelNests.RelatingObject()
        OUTPUT: TotalTasks - A list contaning all
        Tasks'''

  DECLARE LIST: A, B, TotalTasks

   FOR EACH ID IN IfcTask
      ADD IfcTask.ID to List A
    END FOR

    FOR EACH IfcRelNests.RelatingObject[ID]
      ADD IfcRelNests.RelatingObject[ID] to List B
    END FOR

    TotalTasks = List A - List B

    RETURN TotalTasks
END
```

Figure 2 "Total Task" Global Function

Logic Density

Relationships per activity or Relationship ratio or Logic Density = # of Logic links / # Total Tasks

```
BEGIN MAIN LogicDensity (IfcRelSequence,
AllowableValue = 2.1 )
  ''' INPUT: IfcRelSequence.ID()
    DECLARE LIST: TotalTasks
    DECLARE NUMBER: TotalNumberOfTask = 0,
    LogicLinks = 0

     TotalTasks = CALL FUNCTION
TotalTasks(IfcTask, IfcRelNests)
      TotalNumberOfTask = COUNT ID in
      TotalTasks
      TotalNumberOfTask = 100 *
      TotalNumberOfTask

       LogicLinks = COUNT ID in IfcRelSequence

       PRINT CALL FUNCTION
       MeasureCheck(Numerator: LogicLinks,
       Denominator: TotalNumberOfTask, value:
       AllowableValue, Condition: >, MetricName:
       "LogicDensity%=")
END
```

Figure 3. "Logic Density Algorithm"

5 Model Verification

As explained before, the developed algorithms were tested against a hypothetical case study of a 3-storey office building. The 3D model was created using Autodesk Revit. Then was imported to Synchro Pro to develop the nD model. The reason for selecting Synchro Pro over Autodesk Navisworks is because of its extra project management abilities, that enabled the storing of relationships between activities and the assigning of resources and cost loading. Additionally, Synchro Pro supports exporting nD models in IFC format [21].

A baseline schedule was developed for the model, then intentional scheduling errors were placed as alternative scenarios. An example of these errors is changing the activity duration of the foundation works to 60 working days (1,728,000 seconds) and setting the threshold for 44 working days (1,267,200 seconds). The verification was done by breaking down each algorithm into sub-sections and manually calculating the output of each section. Continuing with the "High duration" metric example, Figures 4, 5 and 6 show the breakdown of the algorithm. Step 1 (Figure 4) is to identify the attribute "ID" under "IfcScheduleTimeControl" Class with attribute "ScheduleDuration" greater than 1,267,200 seconds. The model filtered out the ID # 48719 and not # 48701 which was correct. As the # 48701 referred to a WBS level and not an activity. This output verified the functionality of the "Total Tasks" global function and the capturing process. Step 2 & 3 are to find the flagged activity's name, which is stored under "IfcTask" class. Hence, step 2 (Figure 5) is to find the "IfcTask" number under "RelatedObjects" attribute corresponding to the "IfcScheuleTimeControl ID" # 48719 under the "Time for Task" attribute in the "IfcRelAssignsTasks" Class. Lastly, step 3 (Figure 6) is to print out the "Name" attribute for the selected "ID" under "IfcTask" Class.

IfcScheduleTimeControl (41)			
ID	GlobalId	OwnerHistory	ScheduleDuration
48701	3NokVVgsH6aRUs2p$5W5_4	IfcOwnerHistory 5	1814400
48710	3gC0$xPQT7495FmP7p_$Dq	IfcOwnerHistory 5	230400
48719	3MDQqkX_969PX5xnlX79sB	IfcOwnerHistory 5	1728000
48728	0mHop__Yj1OQGrytDRxwnR	IfcOwnerHistory 5	0.00E+00

Figure 4. "High Duration" Metric: Step 1 Output

IfcRelAssignsTasks (41)		
ID	RelatedObjects	TimeForTask
48708	(1) IfcTask 48700	IfcScheduleTimeControl 48701
48717	(1) IfcTask 48709	IfcScheduleTimeControl 48710
48726	(1) IfcTask 48718	IfcScheduleTimeControl 48719
48735	(1) IfcTask 48727	IfcScheduleTimeControl 48728

Figure 5. "High Duration" Metric: Step 2 Output

IfcTask (41)			
ID	Name	TaskId	Description
48700	Office building	1	1
48709	Sub-structure	1.1	1.1
48718	Foundation	1.1.1	1.1.1

Figure 6. "High Duration" Metric: Step 3 Output

6 Limitations & Challenges

Although the use of IFC format allowed for standardization independent from any software application, yet it has presented some challenges as well. The main challenge in this study was the lack of any existing software that exports nD models in IFC format other than Synchro Pro. Moreover, Synchro Pro is based upon IFC2x2 and IFC2x3, earlier schemas than IFC4 which are not as comprehensive as IFC4. Lastly, Synchro uses a specific MVD that does not export all resource and cost assignments and hence any algorithms related to such information could not be verified. Unfortunately, the industry does not have a nD modelling software that is based on IFC4 and can utilize any of the released MVDs.

Another challenge with the use of IFC was the different methodology and definition for certain temporal information. For example, the types of tasks available in IFC are attendance, construction, demolition, dismantle, disposal, installation, logistic, maintenance, move, operation, removal, renovation [22]. However, in Synchro Pro, the activity types were level of effort (LOE), resource dependent, and time dependent. The same applies for the definitions of the milestones. Accordingly, all metrics related to these two aspects could not be verified as well.

7 Conclusion & Future Works

The paper presents a novel schedule assessment model that can evaluate the quality of the construction schedule directly from nD models, without the need to revert to the conventional planning tools. The model starts with developing a database of the assessment criteria developed by previous researchers and commercial software. Then, the criteria were merged and analysed to determine the quantifiable metrics that can be automated. Afterwards, algorithms and global functions were developed to carry out the metrics. The model was then verified via a hypothetical case study of a 3-storey office building.

This work is a genuine contribution to the body of knowledge as it opens the door for the development of new assessment metrics by utilizing the nD abilities. Hence, the future works will focus mainly on exploring such. Additionally, other future works would focus on enhancing the practicality of the developed assessment model such as (1) exploring the development of a specific MVD that would capture only the required information for assessment as the current MVDs have more information that is not used. (2) Extending the evaluation criteria to include controlling metrics that would evaluate the quality of the updated schedules. (3) validating the developed model against a real case study and receiving feedback.

Abstract –

It is difficult to conduct training and evaluate workers' postural performance by using the actual job site environment due to safety concerns. Virtual reality (VR) provides an alternative to create immersive working environments without significant safety concerns. Working on elevated surfaces is a dangerous scenario, which may lead to gait and postural instability and, consequently, a serious fall. Previous studies showed that VR is a promising tool for measuring the impact of height on the postural sway. However, most of these studies used the treadmill as the walking locomotion apparatus in a virtual environment (VE). This paper was focused on natural walking locomotion to reduce the inherent postural perturbations of VR devices. To investigate the impact of virtual height on gait characteristics and keep the level of realism and feeling of presence at their highest, we enhanced the first-person-character model with 'virtual legs'. Afterward, we investigated its effect on the gait parameters of the participants with and without the presence of height. To that end, twelve healthy adults were asked to walk on a virtual loop path once at the ground level and once at the 17th floor of an unfinished structure. By quantitatively comparing the participants' gait pattern results, we observed a decrease in the stride length and increase in the gait duration of the participants exposed to height. At the ground level the use of enhanced model reduced participants' average stride length and height. In other words, in the presence of VR legs, the level of realism significantly increases and thus results in a better virtual gait simulation. The results of this study help us understand users' behaviors when they were exposed to elevated surfaces and establish a firm ground for gait stability analysis for the future height-related VR studies. We expect this developed VR platform can generate reliable results of VR application in more construction safety studies.

Construction safety, virtual reality, virtual legs, extreme height, gait pattern, fall

1 Introduction

According to the annual Bureau of Label Statistics (BLS) report, the construction industry contributed more than 10 percent of all fatal occupational injuries in 2017 [1]. Falling from elevated surfaces accounted for a significant portion of these incidents. According to Hsiao and Simonov [2], the primary stated reasons for falling were slips, trips, and loss of balance based on the worker compensation descriptions and fatality investigation reports. To address the disproportional rate of fall injuries and fatalities, researchers have been focusing on the influential factors affecting postural sway and gait stability. Many of these experiments, especially those related to fear of height and flight, were expensive and dangerous [3]. Therefore, recent studies have been investigating alternative methods to conduct postural stability and fall-related experiments. They found virtual reality (VR) as an alternative solution which "offers the opportunity to bring the complexity of the physical world into the controlled environment of the laboratory [4]."

VR is "a simulation in which computer graphics are used to create a realistic-looking world" [5]. Powerful real-time interaction capability, immersion feeling, and a much more intuitive link between the computer and the user turn this technology into one of the most rapidly growing technological fields. Specifically, there are extensive areas of VR applications ranging from manufacturing design and operation management—things like prototyping, product design, planning, and simulation [6]—to training and rehabilitation [4]. VR provides the users with an immersive environment, a wide range of view, and haptic feedback, delivering a firm platform for experiment designs in a much cheaper and safer way. Despite the inherent instability induction of VR headsets [7], this new technology has been used

in numerous postural stability and fall studies due to its many above-mentioned capabilities [8–12]. Although these studies attempt to utilize VR systems to simulate the destabilizing environment with different kind of stimuli, most of the experiments did not focus on the natural ground walking locomotion in a virtual environment. Furthermore, we did not find any articles concerning the relationship between height exposure and gait stability. Most of the studies in this area have been focusing on the stationary postural sway as the dependent factor. For example, [8] compared the impact of real and virtual height on the postural stability of participants who were standing next to the edge of an elevated surface. However, they did not measure the impact of height on the gait stability of the subjects.

The proposed method of this study for measuring the gait pattern of the participants is to use a virtual environment and first-person character model enhanced with virtual legs to simulate a more realistic gait analysis on narrow, elevated surfaces. By collecting the time series data of the gait patterns from the participants' mounted trackers, this study sought to investigate potential differences between the average and variability of subjects' stride length and height due to elevation and increased realism.

2 Background

2.1 Fall. The leading cause of fatalities in the construction industry is fall, contributing to 38 percent of all fatal injuries happen every day at the construction sites[1]. Numerous research has been conducted recently to find the main reasons behind the disproportional number of fatalities associated with fall [2,13–18]. Slips, trips, and losses of balance are the most common factors contributing to falling [2,13,15]. Hsiao and Simeonov identified loss of balance as the leading cause of fall incidents. They stated that postural regulation of construction workers, especially those who work on elevated surfaces such as roofs or beams, is one of the leading factors in fall injuries and fatalities. Therefore, a closer look at the postural stability and influential factors affecting it can provide valuable insights into the fall-risk assessment.

2.2 Postural stability. Postural stability is defined as "the ability to maintain and control the body center of mass (CoM) within the base of support to prevent falls and complete desired movements [19]." Three central sensory cues for postural stability regulation are visual, vestibular, and somatosensory inputs. Compared to somatosensory and vestibular afferents triggered after the external exposure, visual input is considered a proactive mechanism of balance [2]. Paillard and Noe showed that expertise has a strong relationship with the visual input dependencies for postural regulation [20]. To accurately study the impact of visual input on the postural stability of the construction workers, we need to answer the following two questions: 1. How postural metrics can be measured, and 2. How do individuals respond to different visual perturbations affecting postural sway, especially those associated with height?

2.3 Postural metrics. Based on the definition of postural stability presented earlier, one way of measuring postural metrics is to measure the extent to which the center of the body deviates from the base (feet). Three principal reference planes are describing the anatomical motion of the body, transverse, frontal, and the median plane. The three sway directions namely frontier-posterior, mediolateral, and inferior sway happens respectively on the frontal, medial, and inferior planes. Biomechanical studies use maximum body sway (BS) in the frontier-posterior and mediolateral direction [21,22] and the root mean square of the total body velocity in frontier-posterior, mediolateral, and inferior direction [21] to measure the response of individual to different stimuli. The required data can be obtained by using the force plates or IMU sensors [23]. The other way of measuring the dynamic postural sway responses to external perturbations is to use Maximum Lyapunov exponent (Max LE) [24,25]. Lyapunov exponent directly measures the sensitivity of a dynamical system to minimal perturbations, considered to be a decent indicator of the level of chaos in the system [26]. By utilizing this method, the time series data captured by IMU sensors can then be investigated for any divergence reflecting the response of the dynamic system to the external perturbations. To efficiently find the reasons behind the postural instability of construction workers, identifying workers' responses to diverse types of external visual perturbations is of great importance. Accordingly, numerous studies have been conducted on human subjects to find out the impacts of different perturbations on the postural sway [3,19,27,28]. Interestingly, while postural stability is sensitive to the amplitude of these perturbations, the type of perturbation has far more impact on postural stability than the corresponding amplitude does [19]. Therefore, finding stimulus' characteristics is considered a critical step in fall-prevention techniques. Based on Hsiao and Simeonov critical review, the most significant environmental factors affecting postural stability are elevation, moving visual scenes, depth perception, visual ambiguity, and obstacle detection ability [2]. Since a high number of fatalities are due to falling from elevated surfaces, the current study will focus only on elevation as one of the prominent stimuli on postural stability and consequent loss of balance.

2.4 Elevation, fear of height and VR. The deficit of close visual contact due to the instigating sensory mismatch, and fear-related reactions, especially close to

edges of elevated surfaces, are the two main characteristics of elevation leading to falling [2,29]. In many gaits and postural studies related to elevation and fear of height, pseudo-environment setup and stimuli simulations are the two common procedures to investigate the impact of the factors mentioned above. However, due to versatility of VR tools in generating virtual environment and various visual stimuli, and the unsafe nature of mechanical systems in provoking postural instability, VR systems have been widely used in fear-related behavioral and psychological responses [3,8,12,28,30]. Regenbrecht et al. scrutinized the concept of "presence" and explained that VR is a powerful tool in establishing an immersive environment to convey the feeling of presence to the user [30]. Wallach and Bar-Zvi showed that people suffering from flight phobia could be treated by using VR technology [12]. With an exposure-treatment approach, Rothbaum et al. measured the level of anxiety, avoidance, and attitudes of the participants before and after treatment with VR systems [28]. The outcome of the study showed a significant difference between the self-reported results of anxiety and avoidance of height of participants treated by computer-generated exposure, before and after treatments. In 2012, Celworth et al. compared the impact of height on the postural stability and anxiety level of subjects in a real and virtual environment. They used force plates to measure the center of body frequency and subsequently the stationary balance, and electrodermal activity (EDP) to measure anxiety. By sampling 17 young adults, while minimizing the inherent VR postural instability effect [7], they showed that virtual environment (VE) could simulate the height effect on the mediolateral and anterior-posterior balance of the subjects similar to the real height effect. They concluded that VR could be a useful study and rehabilitation tool for people with balance regulation deficits associated with fear or height. Numerous studies discussed the impact of gait speed and stride length on the overall gait stability and odds of falling in humans [31]. Step and stride length measures the distance between successive points of heel contact of opposite foot and same foot correspondingly. Based on the gait stability studies, the differences between the gait cycle patterns can be good indicators of the overall gait stability performance. During a simple walk the foot will experience periodic movement, which can be represented by the spatiotemporal acceleration and deceleration values. It is assumed that for a stable gait, the acceleration values should be following similar patterns and that the changes are periodically repeated. If there is any irregularity in this cyclic pattern, it indicates that there is an external (e.g., exposure to height) or internal disturbance (e.g., unstable CoM) in the system. Previous research suggests that people have a tendency to reduce their gait stride and speed when they suffer a preexisting fear of falling [32,33]. Interestingly, a higher level of walking disorder parameters--such as gait stride variability--can be affected by the fear of height as well [32].

In the light of foregoing research, the current study will focus on analyzing the time series data obtained in various VR/non-VR scenarios by retrieving the position of the HTC Vive trackers attached to the participants' feet. Furthermore, by quantitatively comparing these time-series data, this paper aims to present the ground walking experiments in VR as a promising tool for time-series data collection in different destabilizing environments, e.g., walking on an unguarded narrow elevated surface. To this end, the first-person character model developed in Unity will be enhanced with the virtual legs, helping the subject to walk on a virtual structural-beam path close to that he would perform in reality. Afterward, the role of VR legs and height in predicting the average value and the variability of gait stride parameters will be studied. By finding differences in gait pattern of the participants across these experiments, further data analysis for obtaining postural sways such as finding MaxLE or maximum BS becomes both possible and promising.

3 Methodology

To compare the impact of height on the gait stability of the 12 volunteer participants, two different experiments were designed (see Figure 1), each with two settings: one with no VR leg, and one with VR leg enhancement (see Table 1). In all the corresponding VR experiments, we attempted to minimize the inherent postural perturbations of VR headsets by simulating a VE as a static visual scene, removing any visual and physical distractions from the virtual environment, and minimizing the VR experiments durations (Horlings et al. 2009). To reduce the VR unfamiliarity, all the participants were instructed to stand, look, and walk for few steps in the VE for 1 minute total. The VR environment was the same environment that they would experience in the other parts of the data collection. After the completion of this part, the participants were equipped with three HTC Vive trackers and an HTC Vive headset. In the first trial, the 'immersed' beam path was presented to the participants while they were able to see their virtual legs. The immersed path consists of a closed triangular polygon constructed by three connected structural beams, with no elevation (figure 1-a). The participants were instructed to walk on the path at a comfortable speed. During this trial and others that followed, the coordinates of the trackers attached to the participants' feet were retrieved with the refresh rate of 60 times per second. The procedure for the second trial was identical to the first trial except that the VR leg

enhancement was not available to the participants. In the third trial, the participants were subjected to height by locating the triangular beam path on the 17th floor of an unfinished building (figure 1-b). The virtual environment remained unchanged save for the height. Similar to the first trial, the participants were able to see their VR legs. In the last trial, the participants were asked to walk again on the same elevated path again. However, the third trial excluded virtual legs from the VR model. In other words, the participants were not able to see their virtual legs as they had been in the first and second trials.

4 Results and Analysis

Gait analysis often includes the spatial and temporal measurement of a gait cycle so that the interesting factors can be inferred by comparing the differences between the measurements. Therefore, the focus of this study was on the gait parameters; namely, average speed, length of step and stride, and their variabilities. As mentioned previously, the x, y, and z coordinates of each tracker (attached to participants' feet) were recorded during each trial. Figure 2 shows a sample gait pattern plotted by using one of the participant's right tracker position dataset. The solid lines showed trials with models enhanced with virtual legs and the dashed lines showed those trials without any enhanced virtual legs. Similarly, those lines accompanied by the astride sign '*' represent trials conducted in the presence of virtual height, while those with no '*' represents trials without the presence of elevation. To study the impact of our two purposed factors—namely, height and virtual legs--we conducted series of two-tailed paired T-tests between relevant groups divided based on the presence of the focused factor. The results of the paired T-test are valid as long as the distribution of the data for each group is normal, and each participant is compared with himself/herself. To test the normality of the data, the Anderson-Darling test was performed for each comparison executed between the two paired groups (Anderson and Darling 1952). For each comparison case, the null hypothesis was not rejected. More specifically, the results of the 'normality tests' showed that the distribution of the paired groups data is normally distributed.

By statistically comparing the gait durations across all scenarios, we found out that (1) LEGS: by enhancing the participants' virtual models with virtual legs, the duration of the ground walking trials increased significantly compared to cases in which the virtual legs

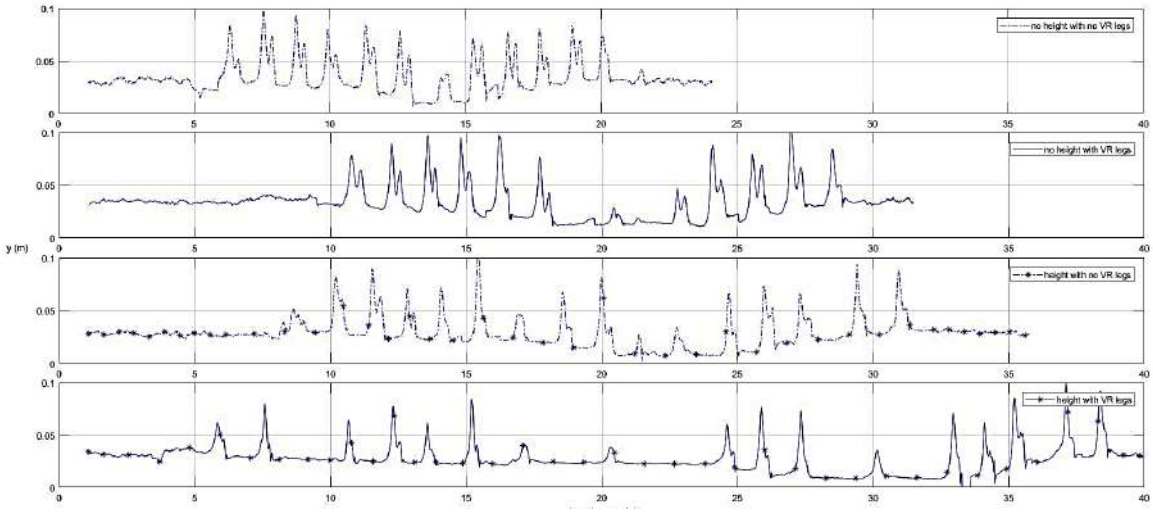

Figure 2. Comparison of the gait patterns of a sample participant during the four trials. The continues lines and those accompanied by the Astrid sign '*' represent the usage of VR legs and the presence of VR height respectively.

were not present (P value= 0.0004). Also, the paired T-test showed that the presence of VR legs noticeably decreased the average gait stride height on the non-elevated walking path. Interestingly, no significant increase in the duration of the trials performed at height was observed while the effect of virtual legs was considered, and (2) HEIGHT: while the participants were able to use their virtual legs in the manifestation of height, the average stride length of the participants decreased significantly (P value= 0.00004). Even without the virtual legs, a similar height effect was detected (P value=0.015). In addition, the duration of the trials performed with (P value=0.03) and without (P value=0.005) virtual legs was noticeably increased once the subjects were exposed to height. No prominent difference in the stride heights was detected with or without the presence of height. However, the stride height variability was meaningfully increased when the participants, equipped with the enhanced model, were subjected to height (P value=0.02).

5 Discussion and Conclusion

By analyzing the data regarding the basic spatiotemporal variables of stride length and speed, we detected a noticeable stride length difference across different scenarios. More precisely, when we focused on height as the influential factor, we observed that the number of strides significantly increased while the average stride length significantly decreased. Hence, these reductions of participants' gait speed and stride length imply that the participants attempted to walk more "carefully." The decrease in gait speed and stride length between ground and elevated walking is in line with Sheik_Nainar and Kaber's findings [34]. Also, Schniepp et al.'s experiment results [35] demonstrated the same bodily reactions from participants subject to destabilizing

environments. The decrease in stride length as a result of participants being asked to walk on the elevated path confirms Schniepp et al.'s previous results, with the only difference being a real elevated path for their experiments as compared to a VR simulation in ours.

Another interesting result was the reduction in the average stride length combined with an increase in both the average stride height and the duration of the trials once the participants had access to the enhanced VR model for the ground walking trials. In other words, with the presence of virtual legs, the participants walked on the path instead of just 'following the path.' This would imply that the use of responsive and real-time tracking virtual legs will increase the level of realism for the participants. However, a similar statistically significant result was not spotted for the elevated walking trials. The average participant's stride length did not decrease significantly (P-value=0.296). This finding perhaps indicates that height was the dominant factor here, reducing the average stride length even without the presence of the virtual legs.

Based on the result of table 2, the stride height variability was significantly affected by height as well (P-value=0.0281). The standard deviation of the stride height was lower for the data obtained from the ground walking trial with the presence of virtual legs compared to those extracted from the elevated path that also included the presence of virtual legs. This higher level of walking disorder parameters can be affected by the fear of height [32]. The thought-provoking part of these findings was that, in the absence of virtual legs, there were no significant variability differences between the two datasets pertaining to ground walking and walking on the height. Whether the cause of this phenomenon was the participants' attempts to place their feet exactly on the beam or the participants' experience of changes in their visual and vestibular systems, we cannot know for sure. However, it is quite apparent that the presence of virtual legs has an impact on the gait parameters, even for the higher level of walking disorder parameters. Therefore, we conclude that walking on the virtual structural beams without being able to look at one's virtual legs is less realistic than when someone walks with virtual legs in view.

Overall, these findings show that VR, along with the advanced virtual models, was successful in inducing the height effect on the basic spatiotemporal variables related to gait. Since these variables are essential to postural sway and gait stability measurements, the finding of the current study could be a good start in designing efficient, height-related experiments for construction workers' posture and gait assessments with fewer safety concerns. In addition, many of these virtual experiments can be integrated with other evolving construction safety studies such as eye-tracking and risk perception [36,37], cultural factors and risk perception [38], and intoxication at construction sites [39].

Abstract –

Falling from elevated surfaces is the main cause of death and injury at construction sites. Based on the Bureau of Labor Statistics (BLS) reports, an average of nearly three workers per day suffer fatal injuries from falling. Studies show that postural instability is the foremost cause of this disproportional falling rate. To study what affects the postural stability of construction workers, we conducted a series of experiments in the virtual reality (VR). Twelve healthy adults—all students at the University of Nebraska-Lincoln—were recruited for this study. During each trial, participants' heart rates and postural sways were measured as the dependent factors. The independent factors included a moving structural beam (MB) coming directly at the participants, the presence of VR, height, the participants' self-judgment of fear, and their level of acrophobia. The former was designed in an attempt to simulate some part of the steel erection procedure, which is one of the key tasks of ironworkers. The results of this study indicate that height increase the postural sway. Self-judged fear significantly was found to decrease postural sway, more specifically the normalized total excursion of the center of pressure (TE), both in the presence and absence of height. Also, participants' heart rates significantly increase once they are confronted by a moving beam in the virtual environment (VE), even though they are informed that the beam will not 'hit' them. The findings of this study can be useful for training novice ironworkers that will be subjected to height and/or steel erection for the first time.

Virtual reality, Postural sway, Height, moving structural beam, Heart rate, Construction safety

1 Introduction

The growing rate of injuries and fatalities due to falling is concerning. In 2017, more than 5147 workers died at job sites, from which 887 were fall-related accidents [1]. Unfortunately, these fall-related losses have reached to the highest level in the 26-year history of the Census of Fatal Occupational Injuries (CFOI)[2]. This fact indicates that current safety procedures, training, and precautions have not adequately limited these types of injuries and fatalities at construction sites.

Therefore, numerous research studies have been conducted to shed lights on the important predictors of falling [3]. Some studies presented risk perception of construction workers as the key driver for these incidents, suggesting that the workers' engagement in unsafe situations results in severe injuries and death [4–6]. These types of studies are valuable in investigating the risk-taking behavior of construction workers [7]. However, the factors affecting postural stability of the workers can address more fall incidents, considering scenarios in which the worker has already executed the task [8].

Postural stability is the result of an association between three main sensory cues, namely, visual, vestibular, and somatosensory systems. The foremost mission of these balance control systems is to maintain the equilibrium of the center of mass of the body against direct or indirect stimuli. Accordingly, to find the root causes of postural instability, first, one needs to discover these provoking factors. Interestingly, from the three sensory cues for postural stability regulation, visual input

is the proactive mechanism of balance, while the other two balance mechanisms of the body, triggered after the external exposure, considered reactive mechanisms. Therefore, the focus of this study would be mainly on the visual inputs as the dominant instigating factors. According to Hsiao and Simeonov, elevation, moving visual scenes, and depth perception are the most commonly visual perturbations affecting balance [8]. Not only these visual perturbations cause instigating mismatch and affect balance, but the exertion of anxiety due to the unsafe nature of these factors, especially those present at construction sites, will influence postural stability as well.

Following this rational, many studies strived to find out the extent to which anxiety (fear) impact postural regulation parameters. Interestingly, the result of these studies demonstrated that the presence of fear, especially in great extents, will negatively impact postural stability [9,10]. Notably, most of these research studies examined fear by utilizing various fear and acrophobia questionnaires. While these 'passive' questionnaires are reliable in measuring the self-judged level of anxiety, however, the need for more 'active' methods in determining the anxiety level of construction workers, subjected to fearful visual perturbations, seems necessary. Methods such as measuring variations in the facial temperature [11] the level of salivary cortisol [12], and heart rate [13] can imply the anxiety level. The latter could be misleading since many activities will impact the heart rate and diminish the reliability of the results. On the other hand, measuring heart rate is simple and inexpensive due to the ubiquity of smartwatches such as Fitbit and Apple watch. Considering the caveats above, this study attempts to investigate if heartrate variability across different trials is significantly affected by provoking visual factors.

2 Point of Departure

The current study will reinvestigate the impact of visual stimuli and fear on the postural stability through the precise and realistic simulation of the environment and virtual body parts (mixed reality). In other words, this research strives to create a virtual environment (VE) of the construction sites, in which participants will be exposed to 1. extreme height and 2. a moving structural beam directed towards participants as a part of the steel erection simulation. Also, the impact of these stimuli on the heart rate of the participant will be measured precisely. To our knowledge, very few studies utilize heart rate for these types of tasks happening at the construction sites.

3 Background

3.1 Impact of height on the visual sensory system. As previously described, one of the most prominent reasons behind slip, trip, and falling is the loss of balance. As such, finding the influential factors which trigger instability in humans, especially those working at great height, is of utmost importance. The integration of the visual, vestibular, and somatosensory sensory systems is essential in maintaining one's postural balance. Some studies suggest that visual sensory system is the dominant system in controlling the human body's postural balance [14] and essential for maintaining balance [15–17]. In addition, the visual sensory system can compensate for the lack of other balance-dependent sensory systems, vestibular and somatosensory, in the presence of visually-induced disturbances. While each sensory system's weight on the postural stability is dependent on the environmental context and goal of the study [16], the importance of visual input as the prominent indicator of postural balance alludes that study of visual perturbations should be researched more extensively. Considering one in three people has visual height intolerance [18], many studies suggest height as an important stimuli in provoking gait instability and susceptibility to falling [19–22]. Studies examining height and fear of falling have reported that the deficit of close visual contact due to the instigating sensory mismatch, and fear-related reactions, especially close to edges of elevated surfaces, are the two main characteristics of falling from an elevated surface [8,23]. Following these findings, the current study aims to explore the aforementioned instigating factors, height, and the corresponding fear, on the postural sway of the participants subjected to virtual height.

3.2 Fear of height. Fear is a bodily response to a danger or hazard in the form of emotional or physical reacts. Sometimes, these responses can be alarming, adversely influencing the humans' health and performance ranging from the reluctance of going to a dentist to changes in the gait and postural stability on elevated surfaces [24,25]. In light of the foregoing, it is important to consider fear and the fear of height (person's level of acrophobia) as leading factors influencing gait and postural stability [26]. Accordingly, in the current study, two questionnaires were presented to the participants, one for generally measuring fear and one for exclusively measuring the level of acrophobia of each subject. Although the focus of this study is on the height-related factors impacting safety, the circular contribution of visuo-vestibular to the fear and anxiety should not be ignored [21]. Coelho and Balaban stated that visuo-vestibular are not only associated with the fear of height, but also with panic and driving. Therefore, along with the acrophobia questionnaire (AQ), the famous James Geer

fear measurement scale [27] has been utilized to pinpoint the potential relationship between any of the aforementioned fear aspects to the changes in the gait and postural stability parameters. Later, it will be shown that those questions related to sharp objects, driving, and auto accident, height, airplane, roller coasters, and death, appropriately predict height while only-height related questions were incapable of addressing postural parameter changes due to height. While these self-judgmental scales possibly show the self-perceived fear, however, the consideration of physiological responses to the experiment trials can be beneficial as well. The number of heartbeats per minute (HBM) is suggested to be a good indicator of the emotional responses to the unexpected thread or danger [13]. Therefore, in this study, the HBM factor was considered to be informative and included in the data collection process.

4 Methodology

4.1 Participants. Based on the flyer approved by the institutional review board (IRB), we recruited 13 students from the University of Nebraska-Lincoln (UNL). Although randomization was considered in the recruiting process, we attempted to selectively recruit an equal number of males and females, so that the potential influential sex factor could be precisely considered. As a result, six females and seven males were selected for of this study. The average age of the volunteers was 29 years old. The participants had no previous falling experience or any problem with standing still.

4.2 Apparatuses and software. To measure the center of pressure (COP) of the participants and consequently calculate the postural sway parameters, the AMTI force plate was utilized, which is capable of accurately calculating COP based on the reaction forces of the plate. Later, by utilizing an in-house code in MATLAB, all the necessary parameters for the postural sway, and heart rate would be imported and calculated. The HTC Vive Pro headset was selected for the immersive virtual environment demonstration. We chose the Vive Pro over other brands since the resolution and display quality of the headset is believed to be higher. As for the game engine software, the Unity3D software [28] was used, so that the creation of the immersive environment and all the VR simulations such as induction of height and the moving structural beam would be easily performed. Finally, to collect the heart rate of the participants, we used a Fitbit Versa. To easily and precisely synchronize the heart rate collection with the other devices, a heart rate collector application was developed in Fitbit studio, so that the start and stop events for each trial could be triggered on the Fitbit Versa remotely from a smartphone.

4.3 Questionnaires. Prior to the experiments, to predict the participants' self-judgment fear scale, the electronic version of James Geer's questionnaire [27] was presented to each participant. In addition, to measure their level of acrophobia, participants were asked to fill out the Cohen acrophobia questionnaire (AQ) as well [29]. As mentioned before, we attempted to find out if the results of these questionnaires can be promising in predicting the physiological responses such as heart rate or postural sway, in different study setups.

4.4 Experiments. The first part of the experiment was designed to help the participants get familiar with the VR environment. The VR environment was the same environment for all parts of the data collection. To potentially improve the feeling of presence in the VR environment, the VR model was enhanced with virtual legs. To ensure that the learning curve effect would be minimal for the participants, prior to conducting the experiment, they were asked to stand, walk, and look at their virtual legs for 1 minute. The force plate was placed on a specific location in an office so that the initial standing position of the participants became the designated location in the virtual environment (VE). In the second part of the experiment, the participants were asked to stand in the center of the force plate and open their legs to the extent to which they are comfortable and most stable. After 5 seconds, the participants were asked to look at their feet once, for 2 seconds, with the least movement possible. This movement will affect the postural stability of the participants; however, they were instructed to perform the same task in the other trials. Therefore, the data collection would be consistent and not biased. This trial finished after 20 seconds. During the trial, the heart rate and COP of the participants were retrieved. After the completion of the first part, the participants were equipped with the VR headset, while they were asked to hold the initial position of their feet on the force plate. In the second trial, the same procedure as the previous trial was undertaken, however, virtually.

The participants were asked to look at their 'virtual feet' in the same way as before. To ensure that the experiment complies with that of the quiet stance postural balance, no subject was allowed to look down more than once. After 20 seconds, a moving structural beam hung from a crane wire, slowly approached the participants. The moving beam's trajectory was in line to the participant's site of view. Before the start of this trial, each participant was informed that the virtual beam will not 'hit' them and will stop 1ft away from their body. This part of the experiment took 10 seconds to finish. The last part of the experiment was almost identical to the second part of the experiment, however, this time the participants were placed on the 17th floor of an unfinished building. The VE, standing beam, moving beam, lighting, shadows, and other virtual scenes were identical to the pervious trial, except the height. Again,

before the start of this trial, all the participants were informed that the moving beam will slowly approach them and will not 'hit' or 'pass through' them. With the last 10 seconds of the moving structural beam approaching the participants, the overall duration of this part was 30 seconds.

5 Results and Analysis

All the data was imported from different text files generated throughout the experiments and then tabulated for statistical analysis. By using the MATLAB statistical toolbox, standard two-tail T-test was performed on the table of experiment results. It is important to note that the normality of the data was tested by performing the Anderson-Darling test [30] and turned out to be valid for this study. For the first part of the analysis, all the data was tabulated for a within-subject design case in which the same subjects perform in all the levels of independent variables. The result of the paired T-tests for such an analysis can be investigated in Table 2. The dependent factors were heart rate and postural parameters. The independent variables were the presence of VR, Height, MB on the ground (no height), and MB at height. Four postural parameters were considered in this research: 1. Total Excursion (TE) of the COP throughout the trial duration, 2. Root-mean-square (RMS) amplitude is representing the variability (standard deviation) of the COP displacement. 3. Maximum absolute amplitude distance of the COP traveled during the trial duration, and 4. Peak-to-Peak (PP) amplitude is expressing the maximum displacement shown between two COP points during the trial. As shown in Table 2, there was a statistically significant difference between the heart rate of the participants subject to the MB on the ground and at height with the P value of 0.00005. Based on the descriptive results, the HRMs of the participants increased by almost 10 percent. Another interesting case was the significant increase in the TE of the participants exposed to VR for the first time. Although prior to the data collection, they experienced VR, the significant increases in all the postural parameters were noticeable.

Table 2. T test's significant level of mean differences between each pair of groups (P values)

	P-values			
	Presence of VR	Height	MB (no Height)	MB (Height)
Heart rate	.190	.554	.00005**	. 00005**
Postural sway (TE)	.004**	.052*	.497	.890

Postural sway (Max)	.057	.156	.112	.694
Postural sway (PP)	.017*	.084	.123	.670

* Sig. at 0.05 level
** Sig. at 0.01 level

Table 3. Descriptive standard two-tail unpaired T-test mean results for HR and RMS based on the participants' sex, fear (selective questions) and AQ

		No height			Height	
	Groups	No VR	VR - No MB	VR – MB	VR - No MB	VR – MB
Sex (HRM)	Male	83.23	82.31*	90.65*	80.74*	89.65
	Female	86.73	99.18*	111.42*	98.26*	105.98
Fear[1] (HRM)	Low[2]	85.98	87.75	98.73	87.83	98.11
	High	83.98	90.93	99.88	88.25	97.51
AQ (HRM)	Low	85.06	88.01	98.18	89.43	94.95
	High	84.90	90.66	100.43	86.65	100.68
Sex (RMS)	Female	. 000217	.000341	.000350*	.000447	.000265*
	Male	.000284	.000530	.001318*	.000588	.000845*
Fear (RMS)	Low	.000249	.000292	.000693	.000275*	.000395
	High	.000251	.000579	.001136	.000784*	.000812
AQ (RMS)	Low	.000199	.000370	.000591	.000336	.000341
	High	.000302	.000501	.001238	.000722	.000865

Besides, Table 2 demonstrates that the mean difference between the TE of the subjects collected during the quiet stance in VR on the ground and their TE during the quiet stance in VR at height was statistically significant with the P value of 0.05. In other words, the TE of the participants increased when they were subjected to height. For each trial, to measure the impact of the participants' self-judged fear values on the heart rate and postural stability, an in-between subject design was performed on the tabulated data. James Geer's fear questionnaire consists of 50 questions collected based on the empirical data and participants' reports [27]. The questions range from auto accidents, being a passenger in an airplane, and height to hypodermic needles, being alone, and crowded places. Since many of these questions may not be strongly correlated to our physiological responses at height, we conducted various test aimed to find out which of these questions best describe the fear of height. Considering Coelho and Balaban's visuo-vestibular study [21], and the result of this study, we find out that "sharp edges", "being a passenger in an airplane", "roller coasters", "death", "heights", "driving a car", and "auto accidents", are strongly in line with the visuo-vestibular predicting factors and leads to statistically significant results in our study. To account for the factor of sex, the participants were divided into two groups of male and female, respectively. The data was then sorted based on

the level of fear reported by the subjects and split into two groups of less fearful and more fearful subjects. The same procedure was undertaken for the AQ factor. The result of the unpaired T-tests on the two groups of the participants can be seen in table 3.

By focusing on the P values of the T-tests on each of the paired groups, the significant mean differences between the groups are recorded in table 3. As reported in this table, in VR with no height and the presence of MB, the male group has a statistically significant lower average HRM compared to the female group. Interestingly, the difference between the RMS of the 'fearful' and 'non-fearful' group was significant (P value = 0.023) for the same scenario, VR with MB and no height. Besides, the presence of height in VR played a key role in differentiating between the RMS of the fearful and non-fearful participants; The participants with more self-reported fear had a higher RMS mean compared to those with less self-reported fear (P-value = 0.046). A similar effect was manifested when the two male and female groups were compared concerning their HR differences during the quiet stance at height. Females had higher HR compared to males. Notably, no statistical difference was spotted between the male and female groups for RMS at height in the absence of MB. However, in the presence of MB at height, the result of T-test indicated that the mean RMS of the females was significantly higher (P value = 0.009) compared to that of males. Another important observation was the inability of AQ values in predicting the differences between the two groups of subjects separated by their levels of acrophobia.

6 Discussion and Conclusion

According to the statistical test results, the presence of a virtual environment has a substantial influence on the postural sway of the participants. Except for postural variability, RMS, almost all the other postural parameters increased for the participants who were experiencing VR for the first time. Based on similar findings of previous studies, the observed increase in the postural sway—due to the exposure to the immersive environment—was predictable [31].

Furthermore, participants were asked to 'normally' look at their feet during the quiet stance in VR with the absence of height. Due to the lower field of view of the VR headsets compared to that of a person without wearing VR headsets, participants' postural balance might have been affected. Streepey et al., pointed out this limitation as a lack of peripheral visual inputs while wearing glasses [32]. Therefore, although the existence of such a factor in the comparison between VR trial cases is unlikely, its potential impact on the presence of VR cannot be rendered negligible. As for the impact of elevated surfaces on balance, the presence of height increased subjects' postural sway. Based on the statistically significant mean differences of the participants' TE, the presence of height factor was able to predict the difference in the means with the P value of 0.05. This finding was also in line with the results of the Cleworth et al., study [33]. They suggested that the virtual height reduces the mediolateral and anterior-posterior balance of subjects similar to the real height. Remarkably, the visual stimuli in the form of a moving object increased participants heartbeat dramatically. With a P value of 0.00005 both with and without the presence of height, the MB significantly increased participants' heart rates. These findings suggest that tasks involving handling of big moving objects, e.g., steel erection, will increase the heart rate of first-time workers exposed to the great extents. This physiological response to big approaching objects should be studied more extensively since the noticeably low P-value magnifies its importance in the context of safety. On the other hand, since the participants were informed that the approaching digital beam would not 'hit' them, no statistically significant mean changes were observed for their postural parameters.

Based on the results of the unpaired T-tests, those fear questions related to driving, height, and sharp objects, derived from James Geer's fear questionnaire, powerfully predict the differences in the RMS in the presence of virtual height. Accordingly, it can be inferred that fear increases RMS, in the presence of virtual height. In other words, standing on elevated surfaces, people with higher self-judged fear values have more postural sway variability compared to those with lower fear values. Adkin et al. showed that fear of height modifies the postural sway [34]. Based on the participants' anxiety rating, they suggested that balance would be affected by the fear of height factor. Similar to our findings, they concluded that both physiological variables, such as postural balance, and psychological factors, such as anxiety, may result in postural instability.

However, to our surprise, the AQ values were not able to address any changes in the postural stability, nor were they able to explain heart rate for different scenarios during quiet stance. One explanation for the incapability of AQ to address mean differences between the corresponding groups might be because this questionnaire was designed to detect abnormalities rather than differences concerning the fear of height. Therefore, since most of the participants did not score high on this questionnaire, then they latent differences regarding fear of height was not noticeable. Following this rationale, a threshold-based categorization should be conducted on the AQ results rather than the AQ mean-based approach. Since the threshold should not be less than 2 (Likert-scale range for AQ is from 1 to 5), so that it can detect people

with acrophobia, and most of our subjects' average AQ score was less than 2, we were not able to categorize with thresholds.

With respect to subjects' gender, at height, female subjects perceived a higher level of anxiety, in the form of HR, compared to male. Also, the average HR of female participants were higher compared to that of male, when they were confronted by the moving structural beam. Another interesting result was the influence of gender on the RMS. With the P values less than 0.05, their RMS values were significantly lower than male in both scenarios with MB. Therefore, regarding bodily responses in the proximity of big moving objects, seemingly, women HR increases more than men and men's RMS increases more than women. Considered as one of the limitations of the current study, prior information regarding VR studies could influence the postural stability of the participants as their uncertainty about the experiments mixes with the expectation of being at height. This unwanted effect potentially explains the differences between the postural stability of male and female groups in VR with the absence of any visual perturbations.

Abstract –

In the Architecture, Engineering and Construction (AEC) field, eye tracking technology is being applied more frequently in cognitive research such as hazard identification. These studies typically use eye tracking in a diagnostic way and pay less attention to the application of virtual environment. However, in virtual environment, eye tracking not only can enhance the study of the cognitive process but also improves the human-computer interaction. Therefore, this paper elaborates on how we use eye tracking devices to track 3D objects in virtual environments diagnostically and interactively. First, we analyze the existing research gaps of using eye tracking in the construction industry. Then, we follow 3D object identification, diagnostic mode and interactive mode to develop a methodology by HTC VIVE device with Pupil Labs HTC Vive Binocular Add-on based on the research gaps. Finally, an example experiment is provided to demonstrate studying hazard identification using eye tracking in construction safety. For analyzing the eye movement data from the participants, we offer the number of confirmations, the scan path and the 3D heatmap of objects in both static and dynamic construction site scenes. This paper provides an approach of applying eye tracking to gather more data in virtual environment for the future cognitive studies and explores the possibility to improve human-computer interaction using eye tracking in the construction industry.

Eye Tracking; Virtual Environment; Human-Computer Interaction; Site Hazard Identification

1 Introduction

The construction industry has been in an era of transformation and reorganization for years. Not only the complexity of construction projects is increasing, but also the technical challenges influence the work on the construction site. A high construction quality is to be guaranteed in even shorter time. Health and safety at work is one of the most important goals of a construction project. However, statistics on accidents at work show that workers on construction sites worldwide are exposed to higher risks than in other industries [1]. The identification of hazards on construction sites is therefore becoming increasingly important. However, hazards cannot be entirely identified on dynamic and complex construction sites since humans cannot simultaneously notice all possible hazards at once. Therefore, actions to increase the safety on construction sites include intensive training and a clear hazard identification. Whether a certain object is identified as hazard can only be determined by intensive testing. It is important, especially on complex construction sites, that hazards are identified as quickly as possible. The availability of different technologies means that these studies can now be evaluated more comprehensively, realistically and detailed.

In existing research, eye tracking is commonly used as a tool to study the cognitive process by collecting the eye movement data at the viewing direction from 2D pictures or real sites, but neglecting which particular object the viewer is looking at. In this way, even the 3D objects in real scenes have no connection with the eye movement data. Jeelani et al. [2] presents a method to facilitate the recognition of objects in the real site. As a post-recognition method, it still does not provide a connection between the eye movement and objects. In these cases, by ignoring the distance between viewer and the viewing object, viewing 3D objects will not provide more information than 2D images.

Combining eye tracking with virtual environment can easily build connection between viewer and the viewing objects. Moreover, the eye movement data collected from a digital model of a construction site can also be made available directly in a virtual environment. Using virtual reality allows a realistic representation of a complex situation on a construction site without exposing the viewer to a real danger [3].

In the context of this paper, an approach to the

systematic use of eye tracking and virtual reality for the analysis of eye movement data is presented. It will be shown how objects can be identified based on available technologies and how the data can be collected automatically. Raw eye movement data automatically generated by eye tracker are not structured, which will cause a big difficulty in data analysis. Table-format eye movement data is used in this approach to help researchers in the construction field read and analyze the data easier. Meanwhile, the data can be evaluated how long a certain object has to be viewed in order to be identified as a hazard by detecting confirmation actions from viewers and to find the scan path (sequence of fixations) of identifying these hazards. These results are a helpful basis for developing more effective markings, e.g. heatmap.

2 Related Work

Research has shown that different frequencies of eye movement give different information [4]. When continuously watching something, this behavior is called fixation; while frequently moving the eyes is considered as saccades. For example, in reading, saccades are for speed reading, while fixations are for comprehension.

Eye tracking is commonly recognized as a process of measuring the gaze direction and collecting data of human's behavior related to eye movement. Specifically, eye tracking is defined as a technique whereby the position of the eye is applied to identify gaze direction of a person at a certain dwell time and the eye movement trajectory [5]. The existing eye tracking applications could be divided into two categories: Diagnosis and Interaction [6].

In the diagnosis of eye tracking, many researchers focus on studying the cognitive process. Salvucci and Goldberg [4] give evidences of utilizing eye tracking in image scanning, driving, arithmetic and analogy. In the computer science area, Bednarik and Tukiainen [7] study program comprehension by tracking the eye movement process of programmers with different experiences reading code. Recently, Meißner and Oll [8] point out eye tracking is widely used in various academic disciplines: information search and decision making, learning, training systems, and expertise.

However, eye tracking technology could not only help studying the cognitive process, but also improve human-computer interaction. Jacob and Karn [6] state the research of human-computer interaction using eye tracking emerged in the 1980s, but the main application is in helping disabled people, e.g. eye typing. Jacob [9] deems that studying cognitive processes only involves recording and follow-up analyzing of eye movement data but has no effect on the computer interface at runtime.

Mine [10] summaries that the fundamental forms of interaction in a virtual world are movement, selection, manipulation and scaling. As one of the fundamental forms of interaction in virtual environments, selection has three steps to follow: indication of object, confirmation of selection and feedback [11].

In the construction industry, the research of studying cognitive process using eye tracking has commenced from the past few years. Among them, the safety awareness for safety training is frequently discussed [2, 12-14]. In addition to studying safety awareness, researchers use eye tracking to study the end-user satisfaction in building design [15], the 2D-construction-drawings interpretation process [16], the architectural features in building design [17] and other applications. Currently, most of the researchers use static images to study safety awareness, which cause problems since the construction site is dynamic [2, 12, 13]. Considering this limitation, Jeelani et al. [2] and Hasanzadeh et al. [13] collect eye movement data from real scenes under construction instead. However, studying cognitive processes on real construction sites has limitations. For example, it is difficult and time-consuming to build or find real sites. Moreover, it is unsafe for the participants to be in the real scene. To address all the problems above, Sacks et al. [3] suggest using virtual reality to demonstrate the construction site. Besides, they underline that using virtual construction sites is feasible, safer and more effective [3].

In summary, there are still gaps in research for the identification of hazards on construction sites:

- A large amount of eye movement data is needed in order to better study the behavior of hazard identification on different construction sites. Using eye tracking in different virtual environments can easily demonstrate different construction sites and generate many eye movement data accordingly.
- Using 2D images to firstly collect the eye movement data and then identify the objects from the images is ineffective. This problem can be solved by having interaction between eye tracker and hazards in the virtual environment.
- Construction sites are hazardous and dynamic. Using virtual environments are always safe to the workers for the cognitive study and fully demonstrate dynamic construction sites at the same time.

3 Methodology

Eye tracking technology is implemented within a virtual environment for the comprehensive study of the identification of hazards on construction sites. This

allows not only for realistic testing but also automated evaluation. The first step is to create virtual and dynamic environments of construction sites with possible hazards. On the one hand, digital planning models are used, which today can already be adopted automatically. On the other hand, special object libraries are integrated for the realization of the construction site equipment. It is important to create dynamic hazards in a virtual scene so that the hazards generated because of the dynamic situations on the construction sites can be demonstrated. The tests can then be carried out based on such virtual environments.

On the device, we use HTC Vive Binocular Add-on provided by Pupil Labs to track the eye movement and attach the Add-on to the VIVE device for tracking eye movement in virtual environment. To make the process of using eye tracking in virtual environment diagnostically and interactively manageable for researchers in the construction industry, the following concepts have been implemented in the Figure 1:

- Systematic calibration of the eye movement by Pupil Labs is for enhancing the ability of object indication based on the eye movement habit of different users.
- Recording the eye movement data with the name and dwell time of objects in certain duration as standardized output.
- Interactive selection of an object as marking a dangerous situation with the help of an external controller.

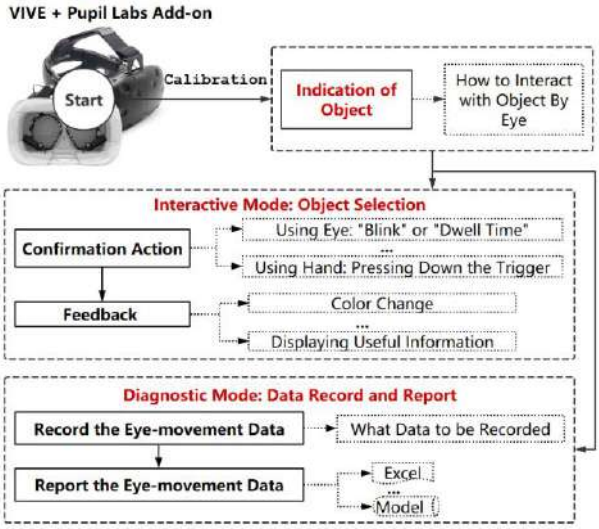

Figure 1. The workflow of methodology

In the following sub-sections, the *Indication of Object*, the *Diagnostic Mode* and the *Interactive Mode* are described in detail.

3.1 Indication of object

In the real world, to touch an object by hand, the distance to the object should be reachable. In order to realize interacting with an object by eyes in distance, we are inspired by Mine's study [10] of using laser beams or spotlights that protrudes from the user's hand and intersects objects in virtual environment. Unlike using the hand as the launch source of a laser pointer, we use the eye. One advantage of using laser pointers to indicate an object is that we can easily change the width of the laser in the virtual environment. By setting the gradient of the laser pointer, we can adjust the visual angle to enhance the accuracy of the particular object we select. Another advantage is that the laser pointer can be invisible in virtual environment by setting its transparency to 100 percent. Therefore, the laser pointer will not affect the eye movement data when studying the identification of hazards.

3.2 Diagnostic Mode: Data Record and Report

In diagnostic mode, recording the eye movement data is essential. To study cognitive processes, the dwell time of an object and process tracking (i.e., scan path) are vital. To avoid missing any important data, we recorded the object data (i.e., object ID, start time, end time and dwell time) line by line based on the eye-movement process. To make those data more intuitive, we put them into a file with a CSV-format file.

Once the laser pointer "hits" an object, we record the object ID to identify the object and the start time to know when the person starts looking at the object. When the laser pointer releases the object, we record the end time to know when the person stops looking at the object and calculate the dwell time. All those data will be outputted as a line in a table-format file. Forming such a table, we know when and how long a person looks at which object, the sequence of eye movement for objects and the individual and total time of an object.

Alternatively, collecting other eye movement data related to an object (e.g. the focusing parts, the position and the shape of the object) could form a file in another format (e.g. OBJ-format and FBX-format) as needed.

3.3 Interactive Mode: Object Selection

As input medium in interactive mode, eye movements as well as other input devices (e.g. mouse, keyboard and controller) are possible. Blink or dwell time can be used as a confirmation action [9]. In addition to using eyes, hand (e.g. pressing down the trigger of controller manually) is another option to confirm in virtual environment. Among these three options, blink as an input medium is difficult to control

[6, 9]. Therefore, in this subsection, we will discuss only the use of dwell time or pressing down the trigger to confirm the selection.

When using the dwell time, the main factor is to select a suitable duration to activate confirmation action. If the duration is too long, the user is forced to wait for a long time to confirm his/her selection. This would be unfriendly and inefficient. Furthermore, it can be difficult to identify the object. The user then looks at such an object for a longer time without wanting to select it. If so, pressing down the trigger might be a better option for a normal user (without disable). In order to allow a short reaction time, the position of the controller should be neglected. Thus, the user does not have to align the object when pressing down the trigger.

If the trigger is used, a late reaction or multiple confirmation may be possible for one-time selection. Therefore, an *isClickRecord* flag is implemented to store the recording of the selection. If the user triggers a manual confirmation, but the identification of the object by the laser pointer has just ended, a false confirmation may occur. In this case, either no or the next object will be selected. However, it is difficult to define the behavior of late reaction. Consequently, we omit the late reaction and record the confirmation action when the user is looking at the object. A multiple selection can simply be ignored, i.e. the *isClickRecord* flag is only set once and cannot be deactivated.

Without feedback, the user cannot know exactly whether the desired object is selected successfully [10]. There are different ways of giving feedback, e.g. changing the color of a selected object or showing a message to the user.

4 Example Application

To show how this methodology address the research gaps mentioned in this paper, an example application as an experiment in construction safety is designed. To introduce the experiment clearer, the *Experimental Procedure*, the *Results* and the *Discussion and Limitations* are provided in the following.

4.1 Experimental Procedure

In this experiment, two different construction-site scenes (shown in Figure 3 and Figure 4) are provided to indicate the simplicity of creating multiple scenes at the same time by the methodology. To differentiate these two scenes, the first scene is considered as a static construction-site scene and the second as dynamic with two moving vehicles. The eye-movement data collected by this method could be analyzed from three angles: *the number of confirmations*, *the scan path* and the *3D heatmap*. To make the process of the experiment intuitive for researchers, the following use case is provided in Figure 2:

- The operator provides some explanation of possible hazards in the construction site to guarantee every participant has basic knowledge about construction safety.
- After calibration, the participant can navigate through two different virtual construction sites (shown in Figure 3 and Figure 4).
- In these two scenes, a task, namely perception of the possible hazards, needs to be accomplished. Once an object is considered as a hazard, the trigger of the controller is used for confirmation.
- Every eye movement and the according confirmation action data will be recorded and reported in a CSV-format file automatically (shown in Figure 5).
- Feedback on feelings about the scenes compared with 2D images and the real construction site.

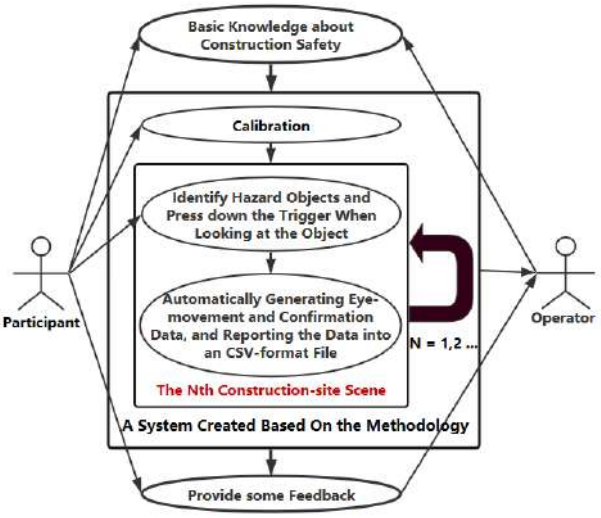

Figure 2. The use case of example application

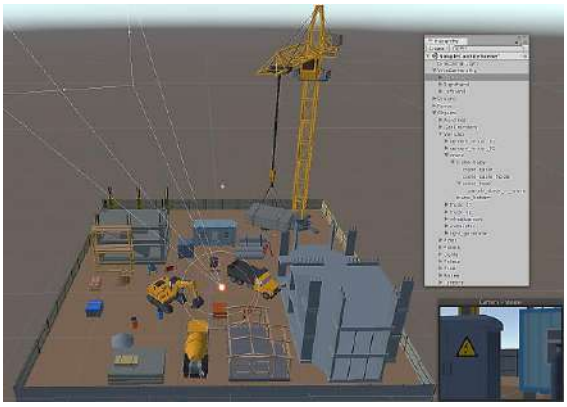

Figure 3. The static construction-site scene

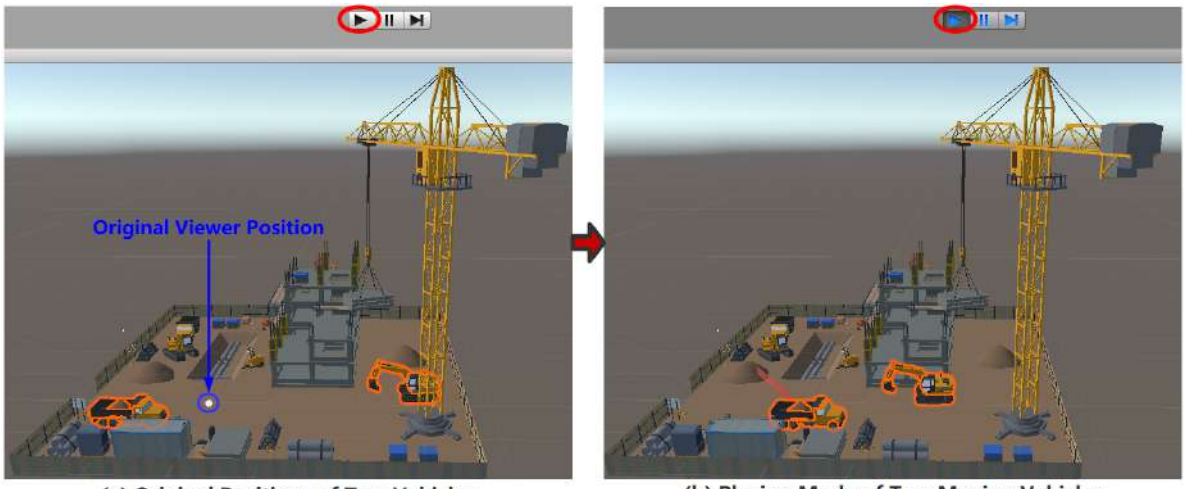

(a) Original Positions of Two Vehicles (b) Playing Mode of Two Moving Vehicles

Figure 4. The dynamic construction site scene

In the static construction-site scene, objects with some possible hazards are reachable from the original viewer position (the position of *Camera* shown in Figure 3).

In the dynamic construction-site scene (see Figure 4), two moving vehicles are hazards with the danger of hitting the participant or the participant being stuck in between. However, without moving, the two vehicles would not be hazards. Therefore, it is important to make one of the scenes dynamic in order to test if the participants can notice hazards on real dynamic construction sites.

Fourteen participants in the range of 20 to 60 years old with basic construction background are invited in the experiment. Since none of the participants had practical construction-site background, the explanation of possible hazards in the construction site (e.g. falls, stuck by objects, electrical hazards, caught-in-between and hazardous materials) was provided to guarantee each participant could find out some hazards in the scenes.

As a confirmation of selection, pressing down the trigger of controller is provided to record the time of confirmation every time the participant selects an object. However, in order to avoid affecting the awareness of the participant, we decided not to provide any feedback to the user during but after the experiment. In this case, the feedback will not affect the cognitive study. After the experiment, the 3D heatmap is generated according to the different dwell time of viewing different objects (see Figure 9). The position of the controller is neglected, but the participants must look at the object when they press down the trigger.

A sample CSV-format file is provided in Figure 5. For each participant, the *ObjectName*, the *StartTime*, the *ConfirmTime*, the *EndTime* and the *TimeDuration(ms)* are recorded based on his/her eye movement behavior and confirmation action. From the table, the number of selected hazards, the scan path of those hazards and the dwell and confirmation time of each hazard are shown.

ObjectName	StartTime	ConfirmTime	EndTime	TimeDuration(ms)
building_01	2019-01-18 14:20:40.36213		2019-01-18 14:20:40.47307	110
wheelbarrow_body	2019-01-18 14:20:40.48507		2019-01-18 14:20:40.57402	88

Figure 5. Data of one participant

4.2 Results

After collecting the eye movement data and the feedback from the fourteen participants, the number of confirmations, scan path and 3D heatmap are offered to demonstrate the data analysis based on the data we collected in the experiment.

4.2.1 Number of Confirmations

After the experiment, we realized that the recorded hazards were not always the participants expected. Since the accuracy of the approach is not high enough yet, it is worthy to calculate the accuracy rate of this approach in this experiment to evaluate the usability of this approach so far for the future cognitive study. In this evaluation, the number of missed, wrong-recorded and well-recorded confirmations with respect to each participant is shown in Figure 6. In the experiment, we did not consider the fences or the ground in the scenes as objects. Therefore, looking at fences, the ground or without objects when pressing down the trigger and a wrong use of the trigger could cause missed-recorded situation. Based on Figure 6, the missed rate and wrong rate overall and separately are calculated, and the corresponding results are in Table 1 and Table 2 to have a better evaluation about the methodology.

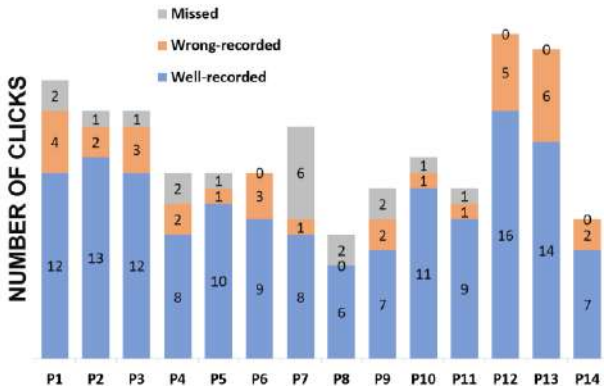

Figure 6. Histogram and table of all the results in both scenes related to confirmation action

Table 1. Rates related to the number of confirmations

Rate	Value (%)
Missed Rate	9.79
Wrong Rate	17.01

Table 2. The sum of the rates of each participant related to the number of confirmations

Participant	$R_M + R_{Wr}$ (%)	Participant	$R_M + R_{Wr}$ (%)
P1	33.33	P8	25.00
P2	18.75	P9	36.36
P3	25.00	P10	15.38
P4	33.33	P11	18.18
P5	16.67	P12	23.81
P6	25.00	P13	30.00
P7	46.67	P14	22.22

Conclusion about the accuracy of the technology cannot be drawn based on the limited number of confirmations. However, based on the rates, there are still room for improving the accuracy of the methodology.

4.2.2 Scan Path

The data collected in the experiment can tell the scan path of each participant. For example, the confirmations shown in Figure 8 were in line 110th, 112th, 113th, 120th and 129th. One sample scan path of the five selected objects is established in Table 3 based on these objects were recorded in chronological order in the data.

Table 3. Sample scan path of confirmations based on the data in Figure 8

Scene	Scan Path
Static	building_01 > fuse_box > gas_cylinder_01 > panelsstack_in_crane > cement_mixer_01_body

The corresponding selected order of the participant could be examined from the static scene (shown in Figure 7).

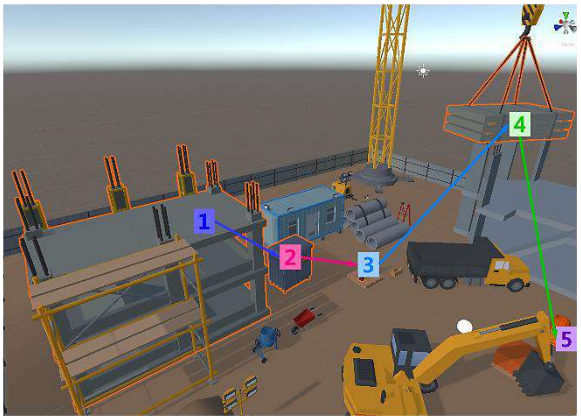

Figure 7. The sample scan path in static scene

Figure 8. Data for scan path in static scene

However, in addition to the lines with confirmation data in Figure 8, the other lines tell the dwell time of each object. To make it intuitively, the concept of heatmap needs to be introduced.

4.2.3 3D Heatmap

Heatmap is frequently used in eye tracking research to visually show the dwell time of eye movement in 2D displays. However, compared to 2D heatmap, 3D heatmap will be more suitable in our approach.

3D heatmap can be generated as well by changing the colours of the objects based on the overall dwell time of each object. Based on the colour bar we designed as an example, a 3D heatmap is shown in Figure 9. By using 3D heatmap, we can visually see the overall dwell time of each object from the participants based on the changed color of those objects.

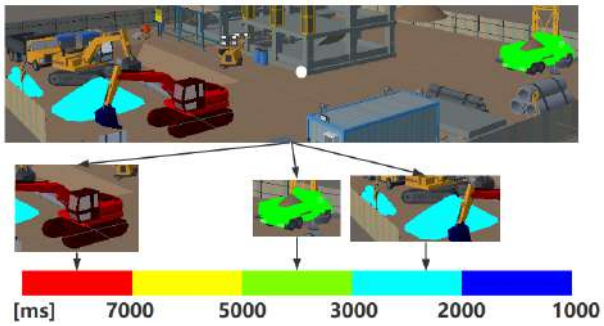

Figure 9. 3D heatmap based on the dwell time in dynamic scene

4.3 Discussion and Limitations

In this experiment, 86% of the participants agreed that standing in a virtual environment is more realistic than watching a 2D image and 100% of them felt safer than standing in the real construction site. However, from the perspective of the participants, the scenes still looked unreal. Based on the Results section, we draw a conclusion that the table data shown in Figure 5 represents human's eye movement to a large extent and can be analyzed in three different angles (i.e., *the number of confirmations*, *the scan path* and *3D heatmap*). Since the number of participants, the number of confirmation action by each participant and the number of construction-site scenes are too low, and none of them had construction-site experience, we cannot simply draw conclusions based on the data we collected. In addition, from the rates shown in Table 1 and Table 2, we know the accuracy of the method still has room for improvement.

Even though this experiment demonstrated how to address the research gaps of combining eye tracking with virtual reality in studying hazard identification as an example, it contains limitations. First, due to only two scenes used in the experiment, the diversity of data is insufficient. Second, the data were analyzed manually. Third, the results of the experiment are not convincing enough based on the inadequate number of participants. Fourth, the accuracy of the eye tracking in virtual environment could be improved by ameliorating the implemented programming algorithms. Fifth, only one possible application is provided in this experiment. Sixth, the dynamic construction-site scene cannot fully represent the dynamic construction site.

5 Conclusion and Outlook

Technological innovations are gradually changing the landscape of the construction industry. Such innovations could improve some remaining industrial issues, e.g. the on-site hazard identification. To study the hazard identification, many researchers use eye tracking technology to collect eye movement data from pictures or real construction sites. However, drawbacks e.g. the poor immersion feelings with pictures and the non-storable real site environment in a one-off project, could occur from these two ways of collecting data. For addressing those drawbacks, we provided an approach to use eye tracking in virtual environment diagnostically and interactively. By this approach, a large amount of different eye movement data could be collected. To verify our method, we conducted an example application using eye tracking in two different construction-site scenes (with static and dynamic objects respectively) to collect different eye-movement data. We analyzed the data quality of the confirmation actions of the experiment participants. We explored how to use the experimental data to generate the scan path and 3D heatmaps.

Future studies should focus more on improving the efficiency of the data collection approach and the accuracy of the collected data on the implementation (e.g. using filtering and smoothing algorithms). Efforts also should be made in digging out more possible applications in the construction industry. Meanwhile, we will focus on building more real and dynamic scenes to improve the immersion feelings and the human-computer interactivity in the demonstration of construction sites. Furthermore, after collecting abundant eye movement data from multiple types of participants in various scenes, studying the cognitive process by data mining would be a better idea to analyze the "big data".

Abstract –

Architectural, Engineering, Construction (AEC) and Facility Management (FM) industry rely on varied expertise to achieve a highly successful project. The industry professionals in these fields require greater level of collaboration in managing the expectation of a project success. When every individual in the team uses different BIM software, it becomes stressful, time consuming and an excessive use of budgeted funds to maintain accurate design model version. It also becomes virtually impossible to controls users, compare versions and analyze different models and data. Consider a large-scale project for example, there are several teams and different professional specializations coming together, all using different BIM software's they have been tasked and making all those interoperate, multiplying the challenges in several folds.

Overall, data is extremely important, and no single firm would want to be held back by the tools they use, nor do they want to maintain various disparate software packages. This paper seeks to find optimal ways in addressing BIM interoperability with emphasis on data exchange not the tools. The study reviews number of top vendors and manufacturers website and solicit their views on BIM interoperability and how those companies deal with the challenges of providing a product that integrate well with competing industry software packages.

Keywords –
Building Information Modelling (BIM); BIM Software; Interoperability; BIM Collaboration; Data exchange

1 Introduction

1.1. Building Information Modeling (BIM)

The National Building Information Model Standard Project Committee defines BIM as "a digital representation of physical and functional characteristics of a facility. A BIM is a shared knowledge resource for information about a facility forming a reliable basis for decisions during its life-cycle; defined as existing from earliest conception to demolition" [1]. A basic premise of BIM is collaboration by different stakeholders at different phases of the lifecycle of a facility to insert, extract, update or modify information in the BIM to support and reflect the roles of that stakeholder. Use of BIM goes beyond the planning and design phase of the project, extending throughout the building lifecycle, supporting processes including cost management, construction management, project management and facility operation.

Participants in the building process are constantly challenged to deliver successful projects despite tight budgets, limited manpower, accelerated schedules, and limited or conflicting information. The significant disciplines such as architectural, structural and MEP designs should be well coordinated, as two things can't take place at the same place and time. Building Information Modeling aids in collision detection at the initial stage, identifying the exact location of discrepancies.

The BIM concept envisages virtual construction of a facility prior to its actual physical construction, in order to reduce uncertainty, improve safety, work out problems, simulate and analyze potential impacts [2]. Sub-contractors from every trade can input critical information into the model before beginning construction, with opportunities to pre-fabricate or pre-assemble some systems off-site. Waste can be minimized on-site, and products delivered on a just-in-time basis rather than being stock-piled on-site [2].

BIM can bridge the information loss associated with handling a project from design team, to construction team and to building owner/operator, by allowing each group to add to and reference back to all information they acquire during their period of contribution to the BIM model. This can yield benefits to the facility owner or operator. For example, a building owner may find evidence of a leak in his building. Rather than exploring the physical building, he may turn to the model and see

that a water valve is located in the suspect location. He could also have in the model the specific valve size, manufacturer, part number, and any other information ever researched in the past, pending adequate computing power [3]. Dynamic information about the building, such as sensor measurements and control signals from the building systems, can also be incorporated within BIM software to support analysis of building operation and maintenance [4].

BIM technology is receiving great attention in the architecture, engineering and construction (AEC) industry, and since it contains a complete set of information of the lifecycle of a structure in the form of a digital model, it is widely projected to be the technology of tomorrow. By being a comprehensive digital database, it is rapidly gaining acceptance as the preferred method of communicating the design professional's intent to the owner and project builders [5]. BIM has been traditionally used for design and its use in the construction phase has also been increasing recently. However, nowadays owners have realized the potential of BIM and insist on inheriting the BIM models for further use. The owner can benefit from the BIM model as an archive of as-built information, for purposes such as Facility Management (FM) decision making tool or repository of materials.

1.2. BIM Interoperability

Architecture, engineering, construction, and facilities management are information intensive industries, and are highly dependent upon effective information technologies. Various software and tools are used to help with the AEC/FM design and management tasks. However, currently the information is passed from one project member to the next by producing paper based or electronic documents which can only be interpreted by people. These members must also re-enter relevant information into their own professional tool. This manual data entry is a non-value adding activity, can often introduce errors into the project, and inhibits the use of better computational tools [6].

With respect to software, the term interoperability is used to describe the capability of different programs to exchange data via a common set of exchange formats, to read and write the same file formats, and to use the same protocols [7]. One common use case for software interoperability is for the customers freedom to switch from one product to another while keeping the data intact after the transfer. This is especially important for use cases where the data will stay in one system for a long time (e.g. in Computer Aided Facility Management - CAFM systems or cloud) to prevent vendor lock-in.

In the AEC industry where, one-off projects teams are assembled across different organizations, disciplines and phases you want the different discipline tools to share information with each other and you want data generated in one phase to be usable without re-entry for the next phase. This is the foundation for openBIM. You cannot have a true openBIM workflow without interoperable software. Interoperability is about freedom to work with the best in any discipline and for them to use the tools they are most comfortable and productive with.

To communicate with each other systems, need to use common data formats and communication protocols. Examples of formats are IFC, XML, JSON, SQL, ASCII and Unicode. Examples of protocols are HTTP, TCP, FTP and IMAP. When systems are able to communicate with each other using these standards they exhibit syntactic interoperability.

For BIM tools to work together we need more than just the ability to transfer information. We need the ability to transfer meaning. What is sent must be the same as what is understood. To achieve this both sides must refer to a common information exchange reference model. We need semantic interoperability. Interoperability between various software applications can be achieved in a number of ways such as: Using software that directly reads the proprietary file format contained in the BIM software application, which will be the case for a suite of software applications developed by one software vendor; using software that incorporates an Application Programming Interface (API), providing a well-developed interface between software from different providers; and using software that supports data exchange standards such as Industry Foundation Classes (IFC) format [8].

2 Industry Foundation Classes (IFC)

BuildingSMART developed Industry Foundation Classes (IFCs) as the open and neutral data format for openBIM with the aim of improving information exchange between software applications [14]. The specification of the IFC standard includes for each major and minor edition:

- the IFC Specification html documentation (including all definitions, schemas, libraries)
- the URL for the IFC EXPRESS long form schema
- the URL for the ifcXML XSD schema

The IFC specification is written using the EXPRESS data definition language, defined as ISO10303-11 by the ISO TC184/SC4 committee. It has the advantage of being compact and well suited to include data validation rules within the data specification.

The ifcXML spec is provided as an XML schema 1.0, as defined by W3C. The ifcXML exchange file structure (the syntax of the IFC data file with suffix ". ifcXML") is the XML document structure. The XML

schema is automatically created from the IFC-EXPRESS source using the "XML representation of EXPRESS schemas and data", defined as ISO10303-28 ed. 2. This ensures that both IFC-EXPRESS and ifcXML handle the same data consistently and that the *.ifc and *. ifcXML data files can be converted bi-directionally.

2.1 IFC Data File Formats and Icons

IFC data exchange has two alternative formats for the exchange of some information content [14]. These formats are:

- IFC format or IFC part 21 Format, which is based on the ISO 10303 -21 standard,
- The ifcXML format, which is based on an XML Schema definition of the IFC product

IFC data files are exchanged between applications using the formats (Table 1) and should be indicated by the published icons:

Table 1 IFC data file exchange format

Icons	Data File Format
.ifc	IFC data file using the STEP physical file structure according to ISO10303-21. The *.ifc file shall validate according to the IFC-EXPRESS specification. This is the default IFC exchange format.
. ifcZIP	IFC data file using the XML document structure. It can be generated directly by the sending application, or from an IFC data file using the conversion following ISO10303-28, the XML representation of EXPRESS schemas and data. IFC data file using the PKzip 2.04g compression algorithm (compatible with e.g. Windows compressed folders, WinZip, zlib, info-zip, etc.). It requires to have a single .ifc or *. ifcXML data file in the main directory of the zip archive.

3 Review of Comparative Building Design and BIM Software

Building design and building information modeling (BIM) software includes computer-aided design (CAD) products used commonly within the architecture and construction industries. Many of these products offer tools and libraries specifically targeted toward architectural design and construction, including mechanical, electrical, and plumbing (MEP) and building information modeling (BIM). Table 2 categorizes BIM software that offers a model-based process for designing and managing buildings and infrastructures, going beyond construction drawings to generate a digital representation of the functional properties of a facility. Other products in this category may be used for a range of CAD purposes beyond architectural design, but their rankings within this grid focus exclusively on their use as a tool in building design. The best products in Table 2 are determined by customer satisfaction (based on user reviews) and market presence (based on products' scale, focus and influence). The list is not meant to be excusive.

Table 2 Comparative Building design and BIM software

Product Name	Features
Revit	Specifically built for Building Information Modelling (BIM), Building design software for consistent model-based approach.
Vectorworks	Tackles complex ideas in 2D and 3D, refine construction details with ease and directly inside files
ARCHICAD	BIM software application for design, document and collaborate on building projects.
SketchUP	Layout, Extension Warehouse and the 3D Warehouse to design everything
Bentley	BIM Application for MicroStation, PowerDraft, and AutoCAD
Navisworks	Reviews integrated models and data with stakeholders to better control project outcomes.
BIM Object	Creates a straight path to the users of any BIM software.
IrisVR	Integrates with Revit, Rhino, SketchUP, and other 3D tools
Trimble Connect	Avenue for designers, builders, owners and operators to collaborate, share and view project information.
AECOsim Building Designer	Single building information modelling (BIM) software application for multi-discipline teams
Tekla BIMsight	Check for clashes, and share information using the same easy-to-use BIM environment.
Virtual Construction	Leverages 2D drawings and 3D BIM models for 4D model-based scheduling and 5D model-based estimating.
Konstru	Cloud-based automation platform that lets you view, edit, clean, synchronize and share model data stemming from a variety of BIM

4 Case Study

Under this section, the paper demonstrated the potentials on interoperability as well as the issues and challenges specific to the selected vendor software's in Table 2. Authors further examined views of how these vendors' deals with challenges of providing product that integrates well with other competing software's. The vendor software products that featured for the case study include;

- Bentley
- Autodesk,
- Graphisoft,
- Vectorworks,
- Konstru, and
- Trimble.

The selection is done in no order of preference. It was solely based on informational purposes and to facilitate the decision-making process for the end-users.

4.1 Bentley

Bentley provide i-models that enable users to access and share information-rich models. This can include competing solutions and varying file formats. i-models act as a container for exchanging information and conveying AECO data to the right people at the right time by breaking down issues with interoperability that have hindered the progress of infrastructure projects. Bentley is fully committed to i-models by recently launching iModel 2.0 Platform which offers a better solution for synchronizing work in infrastructure projects by managing all the change related to a project. Bentley also announced the availability of AECOsim Building Designer CONNECT Edition (Figure 1) which is Bentley's building information modeling (BIM) application designed for building projects of significant size and/or engineering complexity, and which are typically characterized by the challenges of combining vertical construction and horizontal infrastructure (like roads, railways, utilities, etc.). AECOsim Building Designer CONNECT Edition shares a comprehensive modeling environment with all of Bentley's CONNECT Edition applications. Without a comprehensive modeling environment, engineers and architects have had to struggle with complex data exchange, resulting in information loss and repeated translations, or even resort to force-fitting a BIM application beyond its intended use to model geometry, which is lacking in BIM intelligence [15].

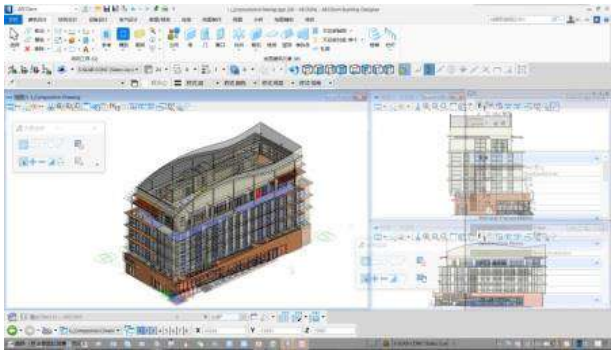

Figure 1: AECOsim Building Designer CONNECT Edition sample

4.2 Autodesk

Autodesk supports interoperability with other BIM vendor software and hardware in a variety of ways. In fact, in 2016, Autodesk and Trimble signed an interoperability agreement to benefit AEC Customers to gain greater flexibility throughout the BIM Project Lifecycle [16]. And, also signed an interoperability agreement with Bentley nearly a decade ago.

- All the BIM products have support for the IFC standard as well as other Industry Standard Formats.
- In addition, Autodesk offer direct reading of Multiple BIM formats with Autodesk Navisworks and cloud-based BIM 360 products. Navisworks is widely regarded as a key BIM interoperability solution on the market today.
- Autodesk provides its IFC software for Revit as a free open source toolkit [17].

Revit software provides certified IFC export and import based on the buildingSMART IFC 2×3 Coordination View data exchange standard. This includes architectural, structural and MEP certifications based on the buildingSMART IFC 2×3 coordination View 2.0 data exchange standard, as of March 2013 and April 2013, respectively. Revit received stage-1 IFC 2×3 Coordination View Certification in June 2006, and full stage-2 certification for Coordination View in May 2007. The IFC for Autodesk Revit 2016 contains up-to-date improvements on the default IFC import and export capabilities of Revit contributed by Autodesk and the Open Source contributors. This application also includes an alternate UI (User Interface) for the export that has extra options from the default.

While this app is not necessary for IFC support, it is recommended that users that depend on the quality of their IFC files download this app and keep it up-to-date, as new enhancements and defect fixes are added, for more information on IFC [18].

Autodesk Software with IFC support: Autodesk Revit LT, Autodesk Navisworks, Autodesk Infraworks, Autodesk BIM 360, Autodesk Robot Structure,

Autodesk Advance Steel, Autodesk Inventor, Autodesk Civil 3D. Examples of initiatives that Autodesk participates in around the world include:

- Support of the U.S General Services Administration (GSA) IFC model view definitions.
- Support of COBie via IFC and xlsx
- Autodesk BIM 360 Docs is designed to help government clients comply with the BIM Level 2 mandate in the UK [19].

Through Application Programming Interfaces (APIs) Autodesk software offerings also provide many ways to work with other BIM vendor's information. For example, when viewing BIM information from other software systems and when using 3D vector file formats for

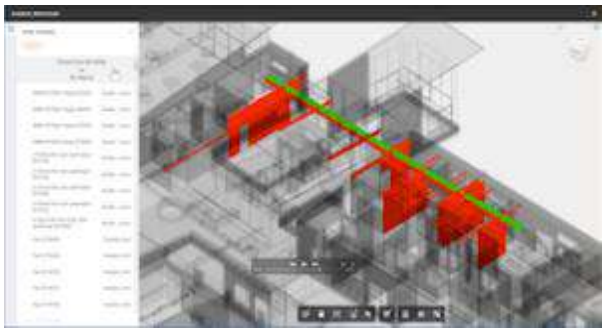

Figure 2. Autodesk BIM 360 Glue on Forge sample

detecting clash/collisions, BIM 360 Glue (Figure 2) supports the many file formats [20]:

4.3 Graphisoft

GRAPHISOFT has been involved in the development of IFC standards since 1996. The latest ARCHICAD version (21) supports the import and export of IFC 4 models including two types of the Model View Definitions, which are developed for multi-disciplinary 3D mode-exchange workflows [21]:

- IFC4 Reference View
- IFC4 Design Transfer View

ARCHICAD continues to support the former 2×3 version of IFC as well. In order to enhance model base communication, ARCHICAD also provides native BIM Collaboration Format (BCF) support in ARCHICAD. There are many other unique solutions in ARCHICAD, such as built-in collision detection, IFC model change detection or custom IFC translators that offers the best in class OPEN BIM workflow for the users (Figure 3).

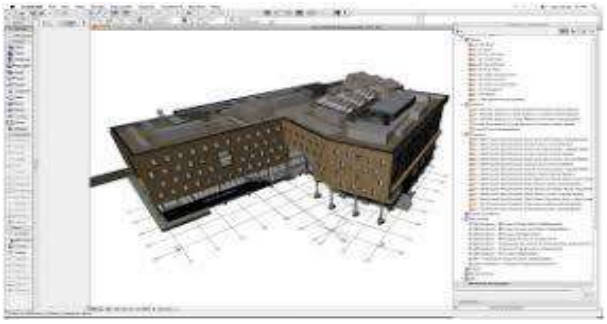

Figure 3. GRAPHISOFT ARCHICAD Sample

4.4 Vectorworks

Vectorworks provides several different methods for sharing data across a large spectrum of workflows and file formats, giving users the ability to select the best option for their needs. For BIM, where geometry and associated information are important, there is the IFC export/import, as well as ODBC. Vectorworks is also the first product to offer import of RVT and RFA files based on the Open Design Alliance (ODA) Teigha BIM software development kit. In addition, important 2D and hybrid 2D/3D workflows can be supported with PDF/3DPDF, DWF and DWG/DXF export and import. For 3D geometry-centric processes and workflows, especially around early design and building product research, Vectorworks supports import and/or export of another dozen or more file formats including 3DM, SKP/COLLADA, 3DS and a multitude of point clouds formats **[22]**.

4.5 Konstru

Konstru, a new product launched in June 2017 is a central interoperability platform that automates the exchange of BIM data between analysis & modeling software tools. Konstru supports all your favorite and most popular design and analysis tools and allows them to communicate with one another.

The product was created by structural engineers and for structural engineers, in order to make this communication possible between BIM software programs. Konstru is a quick plug-in download that allows you to upload your current projects model to their secure cloud. It's possible to exchange BIM data across multiple platforms, make necessary revisions, and visually understand everything that changed.

Konstru has an open API and modern API to allow for people have the flexibility to build their own use cases and develop apps for BIM without much programming language.

4.6 Trimble

Trimble has a philosophy that project team members

should be able to work together smoothly regardless of the tools they use in demonstrated the integrations and interoperability features across multiple solutions:

- **Trimble Connect** — a collaboration environment where everyone involved in a construction project can access and manage project data from other software packages via a cloud platform. For example, a team member using Revit can upload the .RVT file to Trimble Connect for others to view.
- **Tekla Structures** – Tekla Structures has an open approach to BIM. Through IFC, Tekla links with AEC, MEP and increasingly with plant design software. Tekla Structures effectively integrates with other AEC industry software solutions through Tekla Open API, while maintaining the highest levels of data integrity and accuracy [23]. In addition, for anyone working with AutoCAD, those CAD files can be imported and exported into and from Tekla Structures.

Tekla Structural Designer – Tekla Structural Designer was developed specifically with BIM interoperability and collaboration in mind and helps design engineers maximize collaboration with other project parties, including technicians, fabricators and architects. Its unique functionality allows users to integrate the physical design model seamlessly with Tekla Structures or Autodesk® Revit®, and to round-trip without compromising vital design data.

- Most importantly, industry stakeholders, government agencies, educational institutions and users of BIM application must be educated, to fully understand the capabilities and benefits of BIM based collaboration and building lifecycle management.
- Secondly open, vendor independent, practical BIM standards must be adopted in every country.

4.7 Case Study Evaluation Process

BIM tools that works together, ability to transfer meaning, serves as a common information exchange reference model and able to interoperate between various software application formed the basis for the authors evaluation method. Table 3 defines the vendor software products which reads directly the proprietary file format contained in the BIM software application. The authors used the vendors software product that featured for the case study analysis and ranked them against each other to determine a particular software vendor using software that incorporates using an Application Programming Interface (API), providing a well-developed interface between software from different providers. The authors also considered the software that frequently supports data exchange standards such as Industry Foundation Class (IFC) format for the evaluation. The number of meaningful data exchange transfer model/interfaces that each BIM software product could successfully perform among each other were counted. Based on the number of programming interfaces (API) and open standards file formats associated with each software products was assessed. Based on each assessment, paper ranked the software's according to the scale of "LOW to HIGH". "HIGH" indicates a product that can smoothly communicate and transfer data with less effort or difficulty while "LOW" constitute substantial difficulty in exchanging data. To broaden the support base for this analysis, the paper further took into the following considerations; the customer satisfaction – based on user reviews and market presence – based on product scale, focus and influence.

Table 3 Evaluation of BIM Product to support data interoperability

BIM Products / **Project Data Format**	**Bentley**	**Autodesk Revit**	**Vectorworks**	**Graphisoft ArchiCAD**	**Konstru**	**Trimble.**
File Extension	***dgn**	***.rvt**		*.pln	*.vmx	.dwg
Application Programming Interface (API)	i-models	Revit Open .NET API	API + Vectorscript scripting language	Geometric Description Language (GDL)	Open	FC (2x3, 4), IFCZIP
Open Standards						
• Architectural Model	XFM, ODBC	IFC, RVT, DWG, DGN, PLN, NWD	IFC	IFC, DWG, DGN	SAP2000, ETABS	IFC
• Structural	IFC	IFC,	IFC	IFC	IFC	IFC

Mode		CIS/2				
• Civil Engineering	DWG	LandXML, DWG, DGN	DWG	LandXML, DWG	DWG	IFC
• Cost Estimating	CSV, XLSX	XLSX, ODBC	ODBC	ODBC	DWG,IFC	IFC
• COBie Data	PDT	IFC, XLSX	IFC	IFC	XLSX	IFC
• Scheduling Data	P3, MPP	P3, MPP	P3, MPP	P3, MPP		IFC
• Energy Analysis	IFC, gbXML	IFC, gbXML	IFC, gbXML	IFC, gbXML	IFC,	IFC
RANKING	**Medium**	**High**	**Medium**	**Medium**	**Low**	**Low**

5 Challenges

As BIM technology and interoperability continue to evolve, every indication shows that the challenges are less about the technology but more revolves around:

- Contracted deliverables: Engineers are still producing drawings. Even those who would give up drawings in a heartbeat are likely still contractually bound to produce them for the client (usually the architect in design-bid-build contracts) as part of their deliverable. Because of this, they spend more time than is necessary working on 2D drawings. It would be worthwhile spending time on things such as value engineering and identifying potential constructability issues in a 'constructible model' and then simply sharing that model.
- Contracted responsibilities: Often referred to as Level of Development (LOD) 300, contracts typically require that engineers only produce a full set of 2D construction documents that convey the design intent. This approach is very inefficient for the owner as overall project costs can escalate due to RFIs and change management issues during construction.
- Liability. Many engineers are concerned about providing too much detail because if something goes wrong later in the project, they seem to be concerned that it could make them liable.

6 Discussion

The goal of this paper was to provide different approaches to allow for a flexible response to complicated data transfer challenges. The major issues raised in the case study readily focused on project data standards and its interoperability.

Autodesk encourages owners to use their BIM mandates to ask for the data in the native file format of the authoring tool and in IFC format [24]. Autodesk offers both open source and owned its own plug-ins for interoperability. IFC is the most often used but other methods are also useful. For example, autodesk has series of free utilities to facilitate the quality of BIM data exchanges. These consist of classification manager for Revit, COBie toolkit plugin for Revit and a model checking tool for Revit [24].

There are varieties of options, including openBIM, open sources, and host of others but the preferred standard for Bentley would be to ensure cityGML and IFC are adhere to, to deliver and share better engineering – ready models [25].

Most structural analysis programs were written before the emergence of BIM and work around centerline base wire frame model. This becomes extremely difficult if not impossible to find a perfect solution to fit-in nicely with physical modelling solution like Revit and Tekla Structures regardless of how good the link may be. Trimble has developed a structural analysis solution purposely with this problem in mind (Tekla Structural Designer). Tekla Structural Designer has a physical model and a wire frame model working together so the transfer of information and out of BIM environment is made easy [27].

buildingSMART International provides the global marketplace with the openBIM standard IFC format for BIM interoperability. It is the only open, non-proprietary data exchange standard for the building industry that is comprehensive enough to address the many workflows, processes and stakeholders involved in the design, construction and operations of a building over its entire lifecycle. Because it is an International Standards Organization (ISO) standard, like XML and HTML, anyone can build tools to read and/or write IFC data, including BIM authoring, simulation and analysis, viewing and data server platforms. IFC puts the emphasis on the data, not the tools, so important information can be transmitted regardless of source or receiver of the data. This also encourages a healthy, open marketplace for tools to give end users the best technology and value proposition for their investment. Trying to achieve the same level of BIM interoperability by only utilizing proprietary APIs is economically infeasible at the scale necessary to serve so many end users, for so many projects, in so many markets, using so many different tools [27].

There are over 200 software products by 140 plus vendors/developers across the globe that support IFC data exchange for their customers, irrespective of their country of practice. buildingSMART also has a software certification program to verify the technical capability of applications to read and/or write IFC data. This certification program includes IFC2x3 support and has recently started on the new IFC4 standard. To date, 22 different applications, including major market applications from the Nemetschek Group, Trimble and Autodesk, have been certified to exchange IFC2x3 files. Efforts by five vendors, including Vectorworks, are already underway to certify on IFC4 exchanges [28].

7 Recommendation

The market is changing and so are the requirements for managing data throughout the project lifecycle in AEC industry. Digitization and cloud-based services are the trends resonating with all industry players, who want to make data talk to other data platforms. In this regard, stakeholders must embrace the change through:

- digital platforms, and understand the changing context of BIM information,
- organizations need to ensure this information can be interoperable but resolute in order to better connect distributed teams.

Though technical capability of BIM interoperability and other tool interfaces has improved significantly over the past decade, end-user's knowledge and ability to leverage that capability needs to improve as well. Many times, the biggest obstacle to BIM data exchange is the end users' lack of understanding the best practices in their tools for creating good BIMs, neglecting set up of good, consistent data exchange requirements and processes with collaborators and not knowing how to utilize the data exchange commands in their tools for the best results.

Data exchange standard technology also, needs to improve continuously, improving the IFC data exchange transfer results for project teams.

The authors data interface analysis evaluation gives credence to fact that, Autodesk Revit is more versatile BIM tool capable of accommodating a wide variety of design interfaces for data exchanges among other software products, scoring "HIGH" in the rankings in Table 3.

8 Conclusion

From the search and analysis conducted across the interfaces of almost all the software products, each vendor firm is drifting towards cloud services. Autodesk for example, is pushing heavily for cloud services and cloud central model management, so each project team member could readily access changes and updates from their project data irrespective of their location. Based on this paradigm shift, the authors believe cloud is the future for interoperability and collaboration. The could services does not only offer powerful processing potential but also data distribution and accessibility by enabling a connected data environment.

It will be far-fetched to say technology that is holding back BIM interoperability. It is being held back by contractual issues. One simple solution would be to execute more projects as Design-Build projects rather than Design-Bid-Build. That way, it is in everyone's interest to share information to compress construction schedules. Some structural engineers are adopting what is being termed, 'HD BIM' techniques or offering 'Construction Services' as part of their service – this is another way of eliminating some of these contractual issues. Also, in all situations, it would be ideal on all projects to implement a true BIM execution plan that states who will create a model, to what LOD and how it will be utilized.

Digital Terrain Modeling Using AKAZE Features Derived from UAV-Acquired, Nadir and Oblique Images

H. Kim[a], H. Son[a], and C. Kim[a]

[a]Department of Architectural Engineering, Chung-Ang University, South Korea
E-mail: kkhs1127@cau.ac.kr, hjson0908@cau.ac.kr, changwan@cau.ac.kr

Abstract –

During construction, digital terrain models based on images from unmanned aerial vehicles (UAVs) are useful, as they rapidly provide data for objective volume calculations that can be used to monitor in-progress earthworks. As many curved objects are present on construction sites and as construction materials and equipment can provide partial obstructions, nadir images alone is not adequate to generate accurate digital terrain models during the earthwork phase, thus, it is necessary to acquire both nadir and oblique images. However, it is difficult to extract features from oblique images to determine accurate locations using the traditional method from photogrammetry software, the scale-invariant feature transform (SIFT) algorithm. This study proposes a method for generating accurate digital terrain models of construction sites based on the accelerated KAZE (AKAZE) algorithm using a combination of nadir and oblique UAV images. The proposed method consists of the following steps: 1) feature extraction and matching based on the AKAZE algorithm; 2) three-dimensional (3D) point cloud generation based on the results of the feature matching; and 3) digital terrain model generation based on the resulting 3D point cloud and on the GPS information for the corresponding locations of each ground control point (GCP). Validation of the proposed method involves 100 oblique UAV images of the actual construction site's in-progress earthworks. The experimental results indicate that the AKAZE algorithm can be applied to generate an accurate digital terrain model by extracting and matching features to ensure the accuracy of the edges and corners. Based on these results, the proposed method can be expected to provide accurate volume calculations from a generated digital terrain model, which can enable monitoring of the earthwork phase.

1 Introduction

3D digital terrain models are used in fields such as traffic, geology, and archeology, but they are especially common in the construction industry, where they can rapidly provide data for objective volume calculations that can be used to monitor in-progress earthworks. The role of the digital terrain model is regarded as increasing because of the need to periodically monitor the continual terrain changes of the construction site. However, for such digital terrain models to be effectively used in construction project, an approach is needed that can both model the terrain rapidly to provide periodic updates and accurately represent the terrain.

In the construction industry, terrestrial laser-scanning surveys are widely used in digital terrain modeling because of their high accuracy (e.g., [1–3]). However, these surveys' data acquisition is not efficient enough to provide periodic updates because, for each area of the construction site, the laser scanner needs to be moved and installed multiple times before the data can be acquired; this is time consuming and requires at least two people. These surveys also have the disadvantage of being difficult to use on terrain with severe drop-offs and/or inclines. In recent years, digital terrain modeling through the use of photogrammetry based on images from UAVs has gained popularity due to the evolution of UAV technology, which is now possible to improve stability and to allow longer flight time. This approach allows for the fast and easy acquisition of images for a large area, including for terrain with severe variations.

Several researchers have attempted to generate digital terrain models for construction sites using UAV nadir images (e.g., [4,5]) or a combination of UAV and ground images [6]. Previous studies have shown that digital terrain modeling using UAV images has the potential to rapidly generate digital terrain for a large area. However, image-acquisition or -processing methods from other industries are inadequate to be used

in construction site without considering the unique characteristics of construction-site terrain [4–6].

Construction sites often have severe terrain variations, and various construction materials and equipment can partially obstruct terrain in the images. In this environment, using nadir and oblique images together (rather than nadir type alone) increases the vertical accuracy of a digital terrain model [7]. Several UAV manufactures (e.g., Leica Geosystems, Pictometry International, and Microsoft) have developed camera sensors that can acquire both nadir and oblique images from four directions, thus solving the obstruction problem. Accordingly, several researchers (e.g., [8–10]) have attempted to generate digital terrain models using nadir and oblique images in combination. The most commonly used feature-extraction and -matching algorithm in photogrammetry software—SIFT algorithm [12], which is employed in Agisoft's PhotoScan and Pix4D's Pix4Dmapper—is suitable for matching parallel nadir images. This is because the SIFT algorithm performs well when matching two images that have been acquired at different distances [12]; in this scenario, it can extract the features of the edges and corners. On the other hand, the SIFT algorithm has a limited ability to accurately extract features when matching two images that have been acquired from different angles [11]. It is still necessary to consider which feature-extraction and -matching method—when considering construction sites' terrain characteristics—will generate the most accurate digital terrain model from nadir and oblique images.

The aim of this study is to propose a method for using nadir and oblique UAV images to generate accurate digital terrain models of construction sites based on the AKAZE algorithm. This paper is organized as follows. Section 2 reviews the studies on digital terrain modeling based on UAV images in the construction industry. Section 3 introduces the proposed method, and Section 4 provides analysis of the experimental results. Finally, Section 5 describes the conclusions and includes suggestions for future research.

2 Literature Review

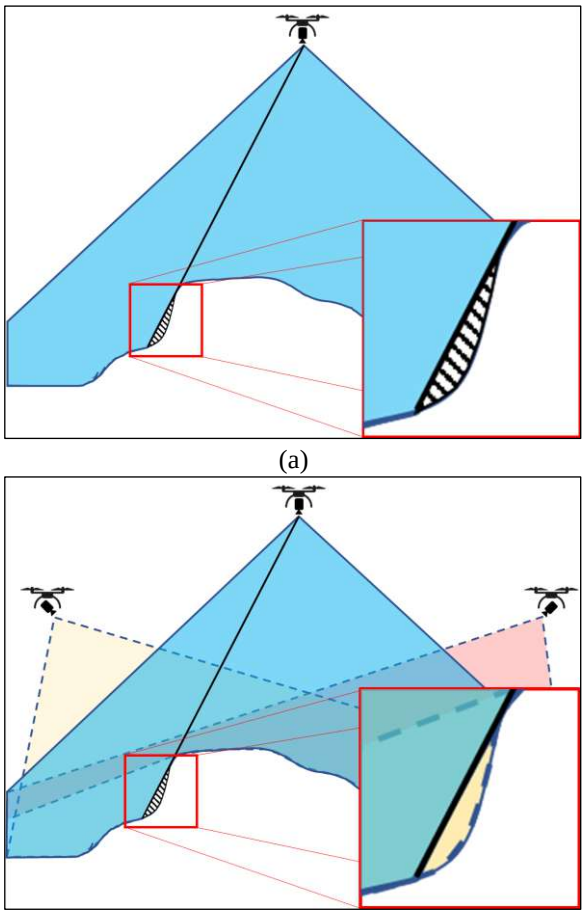
Several researchers (e.g., [4–6]) have attempted to generate digital terrain models for construction sites based on UAV-based nadir image acquisition. Sibert and Teizer [4] and Hugenholtz et al. [5] used UAV flight-plan software provided by manufacturers (e.g., DJI and Intel) in addition to commercial photogrammetry software. The UAV flight-plan software developed by the UAV industry provides the ability to acquire images while maintaining a constant overlap ratio at a certain height. The resulting images can be used to generate digital terrain models using photogrammetry software. Sibert and Teizer [4] used the UAV flight-plan software to collected nadir images from a height of 30 m and then applied commercial photogrammetry software (Agisoft's PhotoScan) to generate a digital terrain model of a construction site. Hugenholtz et al. [5] used AutoGrid's Aeryon Labs flight-plan software to acquire nadir images from a height of 100 m and then applied commercial photogrammetry software (MosaicMill's EnsoMOSAIC) to generate a digital terrain model. In general, commercial photogrammetry software generates digital terrain models based on the SIFT feature-extraction algorithm [12]. Bügler et al. [6] acquired both aerial and ground images and used them to generate a digital terrain model using open-source VisualSFM software [13], which is also based on the SIFT algorithm. The resulting digital terrain model and the activity status of the construction equipment based on video analysis provided information on equipment productivity. In summary, image-acquisition and -processing methods from other industries are inadequate to be used in construction without first considering the characteristics of construction sites' terrain [4–6]). Thus, it is still necessary to consider—based on construction sites' terrain—which method of feature extraction is most appropriate for generating accurate digital terrain models from UAV images.

3 Methodology

3.1 Image Acquisition

In this study, the images were acquired using DJI's UAV Matrice 100 and Zenmuse Z3 camera, with the point-of-interest function from DJI's Ground Station Pro software used to plan the image-acquisition flight. The flight path had a 90% overlap ratio, using angles of −75°, −60°, −45°, and −30°. This resulted in four flight paths. Each flight path followed a hemispherical orbit with a radius of 30 m around the target terrain; in all, 100 images of 4,000 × 3,000 resolution were acquired.

Figure 1 illustrates the difference between regions for rough terrain when using the nadir images alone (Figure 1[a]) and when using nadir and oblique images simultaneously (Figure 1[b]). As shown in Figure 1(a), when using only nadir UAV images for digital terrain modeling, obstructions can be occurred in areas of severe drop-offs and/or inclines [4,5]. On the other hand, as shown in Figure 1(b), when both nadir and oblique images are used, obstructed areas can be revealed.



(a) (b)

Figure 1. Image-acquisition approaches: (a) nadir images alone and (b) both nadir and oblique images

3.2 Image Processing

Nadir and oblique images are based on different distances to the same object, as shown in Figure 2. For this reason, the same object appears on a different scale in these images. Under these conditions, determining accurate locations in all images is important because they affect the accuracy of the resulting digital terrain model. The SIFT algorithm that is often used in commercial photogrammetry software applies the Laplacian of Gaussian method, which uses differences between images (after blurring with a Gaussian filter) to extract the same features of an object that is seen from various scales. Equal-sized masks are used on the images of multiple scales to extract the features that are relevant to determining the edges and corners; this process helps identify the corresponding features for the same objects at various distances. However, the Gaussian filter can result in blurred edges and corners, which makes it difficult to extract accurate locations of features [14].

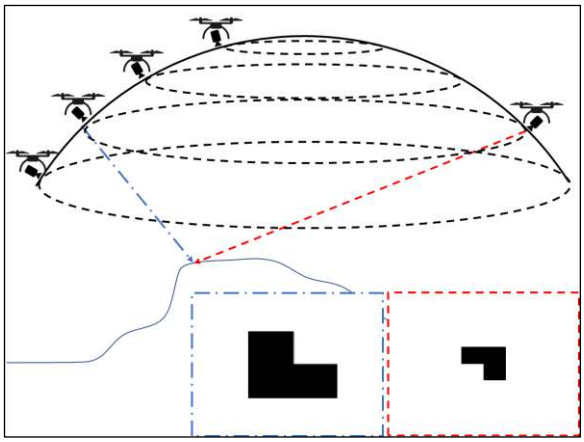


Figure 2. Changes in the scale of the same object in images acquired from different angles

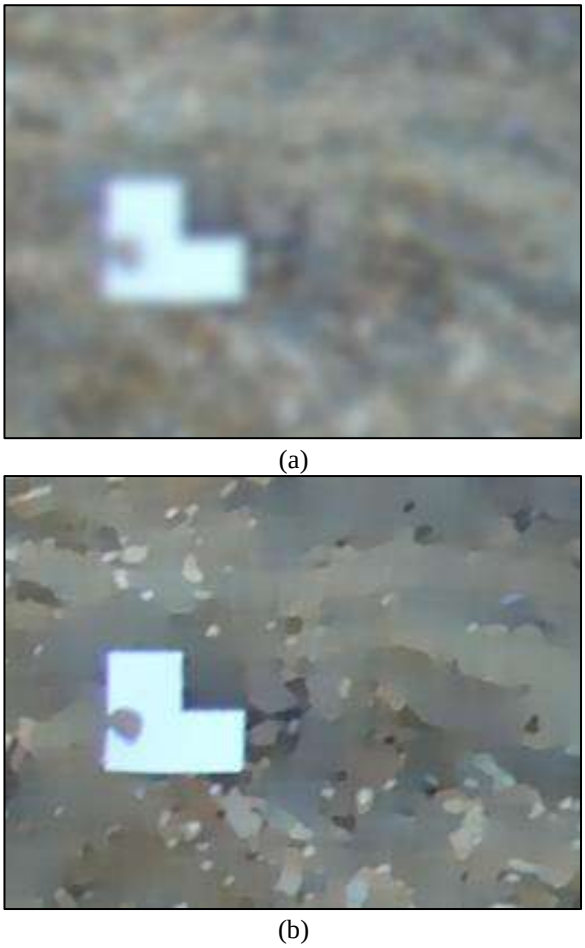
To handle the problem of constructing nonlinear scale space to find the corresponding features for the same object from images obtained at multiple distances, the KAZE algorithm using a nonlinear diffusion filter was proposed by Alcantarilla et al. [14]. The nonlinear diffusion filter is advantageous because the edge information is preserved rather than blurred as it is processed in the Gaussian filter (e.g., [14–16]). Figure 3 shows an image of the GCP placed on the terrain, and the GCP's edges are distinctive in the image.

Figure 3. An example of a UAV image obtained at the actual earthwork site

Figure 4 shows the results of applying the Gaussian filter and the nonlinear diffusion filter, respectively, to Figure 3. Figure 4(a) shows the result of applying the Gaussian filter to construct the scale space in the SIFT

algorithm, and this process blurred edge information from the original image. Figure 4(b) shows an example of applying the nonlinear diffusion filter. During the construction of the scale space, the distinctive edges in the image were retained without sacrificing the object's edges. Unlike the SIFT algorithm, this property leads to the identification of exact position of objects' edges and corners at various scales using such scale spaces [14–16]. This study employed the AKAZE [17] algorithm, which uses the same nonlinear diffusion filter as the KAZE algorithm but improves the processing speed.



(a)

(b)

Figure 4. Example of applying (a) Gaussian filter and (b) nonlinear diffusion filter

3.3 3D Terrain Model Generation

Once the features have been extracted from a pair of images, the features from the same locations are matched using the random sample consensus algorithm and transformed into a 3D point clouds. When the position of the extracted feature is more accurate, so too is its corresponding 3D point. A 3D point cloud is then generated based on the extracted feature-matching results of 100 images. In this process, the SIFT and AKAZE algorithms are applied using OpenCV3.4.0 connected to OpenMVG [18]—open-source photogrammetry software—by applying defualt parameters. Then, the digital terrain model is generated using OpenMVS, which is an open-source method for generating dense point clouds and mesh models from 3D point cloud recalibrated through the bundle-adjustment process; this position of the resulting 3D point cloud is based on the GPS information of the corresponding locations of each GCP.

4 Experiments

This section provides a description of the results for each step of the experiment. The experiment was performed at an actual highway construction site with in-progress earthworks in Asan-si, Chungcheongnam-do, South Korea. The target area for generating the digital terrain model included bumpy terrain. The UAV acquired images of the target area using a hemispherical flight path.

4.1 Performance Measures

To evaluate the accuracy of the generated 3D point cloud, the values of X, Y, and Z at each check point (CP) derived from the dense point cloud are compared with GPS information measured at the site. The dense point cloud generated by registering GPS information corresponding to each GCP location contains CPs to be used for evaluation, which are not used in georeferencing, and the values of X, Y, and Z in each CP can be derived using CloudCompare. The measures used for evaluation are four values of root mean square error (RMSE), which represent the error for each axis and the overall error in the 3D space. The equations for the four measures are as follows.

$$\mathrm{RMSE_x}=\sqrt{\frac{\sum_{i=1}^{n}\left[\left(X_{pi}-X_{qi}\right)^2\right]}{n}} \quad (1)$$

$$\mathrm{RMSE_y}=\sqrt{\frac{\sum_{i=1}^{n}\left[\left(Y_{pi}-Y_{qi}\right)^2\right]}{n}} \quad (2)$$

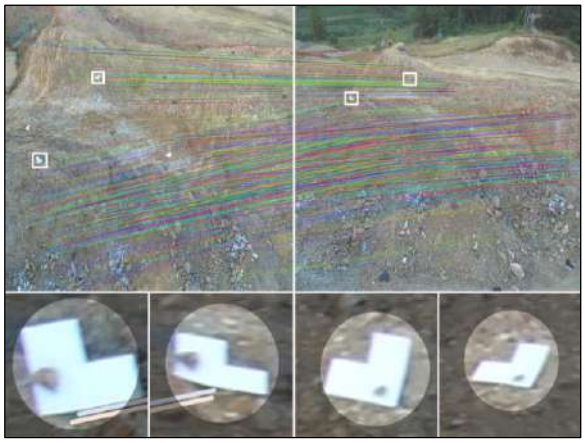
$$\mathrm{RMSE_z}=\sqrt{\frac{\sum_{i=1}^{n}\left[\left(Z_{pi}-Z_{qi}\right)^2\right]}{n}} \quad (3)$$

$$\mathrm{RMSE_{xyz}}=\sqrt{\frac{\sum_{i=1}^{n}\left[\left(X_{pi}-X_{qi}\right)^2+\left(Y_{pi}-Y_{qi}\right)^2+\left(Z_{pi}-Z_{qi}\right)^2\right]}{n}} \quad (4)$$

where n is the number of CPs and X_{pi}, Y_{pi}, and Z_{pi} are the X, Y, and Z coordinates derived from the 3D point cloud for the i_{th} CP. X_{qi}, Y_{qi}, and Z_{qi} are X, Y, and Z coordinates of GPS information for the i_{th} CP measured at the site. A smaller value for each measure means the 3D point cloud is generated closer to the actual site.

4.2 Results and Discussion

The resulting nadir and oblique images produced a digital terrain model through feature extraction and matching; the resulting point cloud was generated based on GPS information for each GCP. Figure 5 compares the results of the matching features for the SIFT and AKAZE algorithms based on two oblique images acquired from the construction site. The point at the end of each line represents the location of the feature.

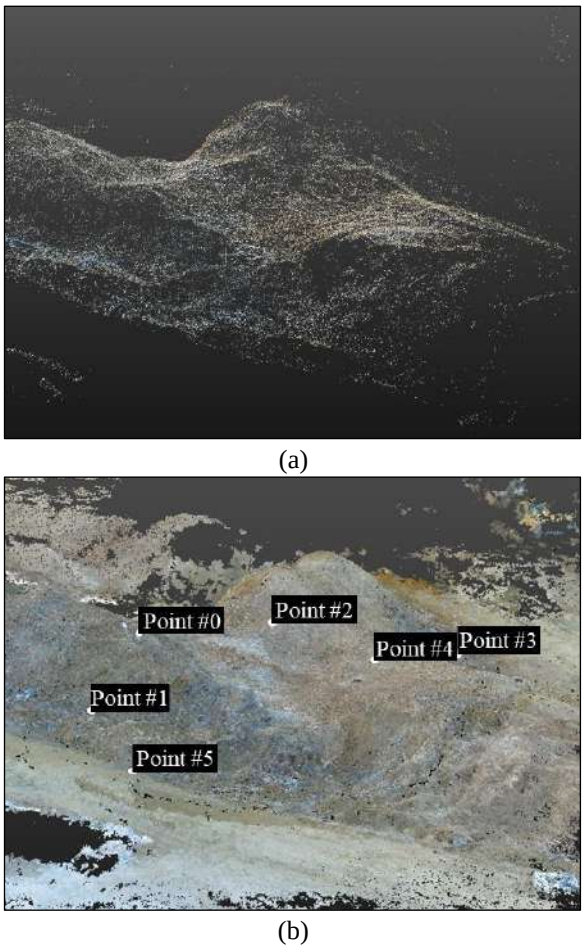


(a)

(b)

Figure 5. Comparison of the feature-extraction and -matching results for (a) the SIFT algorithm and (b) the AKAZE algorithm

The feature-matching result of the AKAZE algorithm in Figure 5(b) was more accurate than the SIFT algorithm in Figure 5(a) in terms of the edges and corners. Figure 6(a) shows a 3D point cloud that was generated using the AKAZE algorithm. The extracted features have two-dimensional location values. Through triangulation based on the camera locations, a single point with a 3D location value can be computed. Finding accurate locations for the edges and corners in each image can reduce errors in the point cloud, thus enabling better matching between pairs of images and improving the accuracy of the resulting digital terrain model. Because the resulting point cloud is generated only using feature matching without GPS information, it is necessary to register GPS information to improve accuracy. Figure 6(b) shows a dense point cloud with GPS information. In Figure 6(b), each pair of a white point and a tag represents where the CP is located.



(a)

(b)

Figure 6. (a) 3D point cloud generated from images using the AKAZE algorithm and (b) dense point cloud based on feature points

Table 1 summarizes the comparison of errors of 3D point cloud generated by the two algorithms. The 3D point cloud generated by applying the AKAZE algorithm showed smaller error values than that generated by applying the SIFT algorithm for all four measures. In other words, the results indicate that a more accurate 3D point cloud was generated when the AKAZE algorithm was applied.

Table 1. Comparison of errors of 3D point cloud generated by various algorithms

Measures (m)	SIFT	AKAZE
$RMSE_x$	0.044	**0.012**
$RMSE_y$	0.116	**0.108**
$RMSE_z$	0.053	**0.038**
$RMSE_{xyz}$	0.053	**0.032**

Figure 7 shows a digital terrain model that is generated from the same dense point cloud from Figure 6. The digital terrain model is then generated, with open-source code (OpenMVS) as the basis for the dense point cloud and the mesh model. The resulting model is based on accurate feature locations, which were extracted using the AKAZE algorithm and which thus are expected to have higher accuracy than those produced using the SIFT algorithm.

Figure 7. Digital terrain model generated using the proposed method

5 Conclusion

In this study, the AKAZE algorithm was employed to generate an accurate digital terrain model from nadir and oblique UAV images. The results indicate that the features extracted using the AKAZE algorithm are more accurate than those extracted using the SIFT algorithm. This difference implies that the proposed method can generate more accurate digital terrain models than can be generated through conventional method. The model generated by the proposed method can be used to provide quantitative measurements, which can be applied for more accurate construction-site volume calculations. Future research will apply the algorithms based on stable affine invariant features and compare the 3D reconstruction performance in terms of accuracy.

Deep-learning for Occupancy Detection Using Doppler Radar and Infrared Thermal Array Sensors

M. Abedi[a], and F. Jazizadeh[b]

[a] Charles Edward Via. Department of Civil and Environmental Engineering, Virginia Tech, US
E-mail: jazizade@vt.edu

Abstract –

An accurate, real-time monitoring of the occupancy state of each space is a necessity for applications such as energy-aware smart buildings. In this paper, we have studied the feasibility of using Doppler Radar Sensors (DRS) and Infrared Thermal Array Sensors (ITA) to build an effective occupancy detection framework. The proposed sensor types are cost-effective and protect the privacy of the occupants. We have utilized Deep Neural Networks (DNN) to analyze the sensor data without any need for specialized feature extraction that is necessary for classical machine learning approaches. The results are indicative of the feasibility and the reliability of using both sensor types for detection of the occupancy state. While a threshold-based approach reached an average accuracy of 84.3% and 86% for the DRS and ITA sensors respectively, DNN models were able to achieve average accuracies of 98.9% and 99.96% for the DRS and ITA sensors respectively, thereby demonstrating the feasibility and success of the proposed framework.

1 Introduction

In the US, residential and commercial buildings are responsible for 39% of the total energy consumption [1]. About 8% of the total electricity consumed in residential and commercial buildings is used for lighting [2]. Heating, Ventilations, and Air Conditioning (HVAC) systems, being responsible for the consumption of 40% of total energy used by the building sector, are also considered to be a major consumer of energy [3]. The combination of these figures underlines the necessity of the notion of energy-aware "smart buildings".

The nature of the relationship between the demand for HVAC and lighting in the environment (e.g. a room) and the state of occupancy of the environment, has given rise to a growing demand for effective occupancy detection technologies. Several smart HVAC control frameworks rely directly on information regarding the occupancy state of the environment for control purposes [4,5]. Occupancy-based control of the lighting system has also been the subject of research studies [6] and has been widely adopted in practice. The potential for energy saving by enabling occupancy-based control of building systems has been estimated to be as high 25% [7] for HVAC systems and 50% [8] for lighting systems.

A necessary condition for the realization of the true potential of occupancy-based smart control of building operations, is the development of accurate and robust sensing frameworks, easily deployable in a variety of environments. Two of the traditional sensing frameworks for detection of occupancy are such technologies as Passive Infrared sensors (PIR) [9], and image-based technologies [10,11]. However, the PIR sensing framework has been known to suffer from high error rates [12]. PIR sensors require an unobstructed view of the occupant to function and their ability to detect the occupant deteriorated with the increase in distance-to-target [13]. Moreover, the ability of PIR sensors to detect the occupant relies on the existence of a temperature contrast between the occupant and the surrounding environment, thereby resulting in a performance loss in warmer room environments [14]. The mechanism of detection of the occupant for PIR sensors relies on measuring the changes in the temperature contrast of the monitored area, as created by movements of the occupant. Thus, the performance of the PIR sensor is predicated on clear occupant movements, rendering the sensor insensitive to more subtle movements by occupants' body parts.

An alternative to PIR sensors is the image-based sensing technology. In particular, video-camera-based occupancy detection frameworks are considered to be an effective alternative to PIR sensors. However, implementation of these technologies is accompanied by considerable privacy concerns. As such, researchers have endeavored to propose alternative sensing technologies to address deficiencies of the traditional approaches while respecting occupant privacy.

One type of sensors that we have evaluated in this

paper with regards to their applicability for occupancy detection purposes are Doppler Radar Sensors (DRS). DRS sensors rely on motion for detection of the state of the occupancy. DRS sensors can detect the existence of the motion by measuring the change in the frequency of the reflected wave as a result of target motion. However, unlike PIR sensors, DRS sensors are capable of detecting subtle movements of the body such as rotation of the occupants' head, movement of the occupants' hands and arms, and even pulmonary activities, thereby resulting in higher accuracy and reliability.

Another sensor type that has been subject to investigation in the present paper is the Infrared Thermal Array (ITA) sensor. While ITA sensors have been prevalently present in the market, until recently there was a gap in the production resolution of these sensors and the users had to choose between an affordable sensor resolution of up to 64 pixels (8×8 or 4×16) or opt for high resolution sensors at an approximate cost of $200 [15] per sensor. However, in early months of 2018, mid-resolution (32×24) ITA sensors (e.g. model name: MLX90640 [16]) at an affordable cost of under $50 have been introduced to the market. These sensors present a unique opportunity for utilization in an occupancy detection framework as the resolution/cost balance has become reasonable enough to allow for such applications. While our original intention was to build a framework that would utilize both sensors simultaneously to reduce individual error-rates, the high accuracy of each individual sensor convinced us to evaluate them separately.

For the proposed sensing setup to be operationally feasible, the framework must be augmented with an effective data analysis algorithm. By defining a binary state of occupancy for the room, the problem of occupancy detection becomes one of binary classification. Within the multitude of well-established classification algorithms, we have opted to utilize a Deep Neural Network (DNN) model for analysis of sensor data. Utilization of DNN models will allow us to obviate the need for feature-extraction step thereby resulting in an autonomous data analysis framework.

2 Literature Review

Given the growing demand for energy-efficient smart buildings, researchers have endeavored to propose a multitude of occupancy monitoring frameworks consisting of various sensor types and data-analysis strategies.

One of the well-studied sensor types for indoor occupancy monitoring are Passive Infrared (PIR) sensors. PIR sensors measure the infrared light emitted from the object and detect the movements of the source of emission. However, these sensors are not sensitive to subtle and slow movements, which diminishes their capacity to perform as a presence sensor. As such, researchers have endeavored to rectify the aforementioned limitation by means of algorithmic developments and augmentation with other sensor types. For instance Pedersen, et al. [17] have augmented PIR sensors with additional noise, CO_2, Volatile Organic Component (VOC), humidity, and temperate sensors to monitor the state of occupancy of a room. In another study, Dodier, et al. [18] have proposed a belief network approach to analyze the data coming from a network of PIR sensors.

Video cameras have also been used for occupancy detection (mostly occupancy counting) and monitoring. For instance, Hoover and Olsen [10] and Fleuret, et al. [19] have used video cameras to enable tracking of occupied spaces within a room. While implementations of camera-based occupancy detection methods have proven to be accurate [20], utilization of cameras is accompanied by privacy considerations. As such, researchers have endeavored to propose sensing frameworks that are both accurate and compliant with privacy expectations.

Doppler Radar Sensors (DRS) have been studied by researchers as an alternative to traditional occupancy detection frameworks. Like PIR sensors, DRS sensors also detect the motions in their field of view, however, their ability to detect very subtle movements such as those created by pulmonary activities, allows DRS sensors to circumvent some of the important limitations of PIR sensors. Lurz, et al. [21] have demonstrated the feasibility of using DRS sensors for occupancy detection in an experiment that emulated human respiration by means of a linear stage at a distance of 2 m from the sensor. Yavari, et al. [22] have used DRS sensors to detect occupancy by relying on extraction of pulmonary and cardiovascular signatures in the DRS signal while the occupant was either at rest or was moving at different activity levels. One limitation of their study was the constant 1.5 m distance between the radar and the occupant. In the present paper, we have sought to extend the investigation of the capability of DRS sensors to measure occupancy throughout the room without preset conditions such as restricting occupant distance from the sensor to enable room-level service. We have used wide-angle DRS sensors, installed at the ceiling to monitor the state of occupancy in a typical office room.

Another sensor type that has presented a potential for occupancy detection is the Infrared Thermal Array Sensor (ITA). Beltran, et al. [7] utilized an ITA sensor with the resolution of 8×8 to monitor room occupancy state and then used the knowledge of occupancy to more efficiently control the HVAC system operations thereby achieving an annual energy saving rate of 25%. The

algorithms utilized in the aforementioned study [7] for the interpretation of the ITA sensor outputs are K-Nearest Neighbor (KNN), Linear Regression, and an Artificial Neural Network. In another study, Tyndall, et al. [23] used an ITA sensor with the resolution of 4×16 to estimate the state of occupancy inside the room. The algorithms used for analysis of data consist of a number of standard classification algorithms such as Support Vector Machine, and KNN [23].

Recent industry advancements have given rise to semi-high resolution ITA sensors at an affordable price of approximately $50 (e.g. MLX90640 [16] with a resolution of 32×24). This development could result in an increased potential for utilization of ITA sensors for non-intrusive occupancy-monitoring applications. As such, in this paper we have evaluated the performance of the MLX90640 [16] sensor for real-time monitoring of the occupancy state in a typical office room environment. Additionally, by implementing a Deep-Learning solution for the analysis of sensor data we have eliminated the feature extraction step, thereby rendering the data analysis step autonomous.

3 Methodology

Presented in this section is the discussion of two aspects of the occupancy detection framework. In the first part we have discussed the overview of the sensing framework. In the subsequent section, the data analysis and occupancy inference approach have been discussed.

3.1 Sensing System Setup and Data Acquisition

As noted, in this study, we have investigated the potential of two distinct sensor types for occupancy detection applications. The first sensor type is the Doppler Radar Sensor (DRS). We have used the RFBeam K-LC3 [24] wide angle doppler transceiver. With dimensions of 25×25 mm and a weight of 5 g the K-LC3 DRS sensor is a cost-effective and practical solution for occupancy detection. Another desirable feature of the selected sensor model is the wide field of view (132º×138º), which allows for coverage of larger areas, compared to other sensor models with narrower fields of view. In Figure 1, the coverage area for the DRS sensor (as well as the ITA sensor) that has been installed in a typical US office room (7.5×4 m) is presented. The sensor is assumed to have been installed on the ceiling with the height of 2.75m (9ft) which is typical in the US. The coverage area has been calculated such that it at least captures the parts of the occupant's body at or under the desk level (0.8 m from the floor), i.e. occupant's hands, lower torso, and legs. As seen in Figure 2., we have installed the DRS sensor on the ceiling close to the air-vent. The DRS sensor has been connected to a SR 560 preamplifier [25] to amplify the output signal by a gain factor of 5×10^4. The amplifier also filters out the frequency content above 1kHz since the frequency content above that threshold is highly unlikely to have been generated due to the motions of the human subject. This sampling rate also helps avoid aliasing error due to possible presence of high-frequency signals associated with the existing equipment in the room (e.g. computer fans and HVAC).

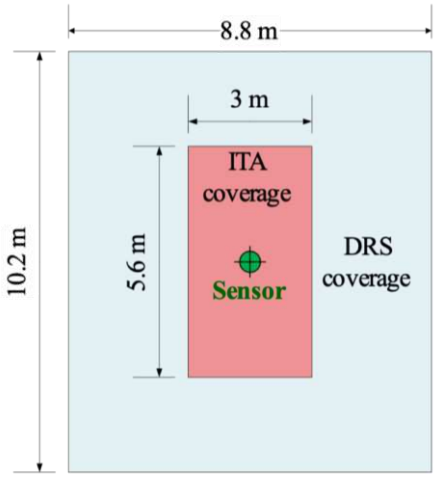

Figure 1. Space covered by each sensor type

Figure 2. Sensors installed (ITA sensor on the left and DRS sensor on the right)

For data acquisition, we used a National Instrument USB-6001 Multifunction I/O Device [26] to record the amplified signal at a sampling rate of 1kHz. The signal was processed through a zero-phase notch filter to remove the frequency harmonic contents, associated with powerline-noise (i.e. 60 Hz, 120 Hz, …). These frequencies in the signal are usually generated due to the existence of AC powerlines (60 Hz) in the vicinity of the setup.

The second sensor type is the MLX90640 [16] Infrared Thermal Array (ITA) sensor. This ITA sensor has a field of view of 110º×75º divided into 32×24 pixels respectively, where each pixel reads the average

temperature of the objects, covered in the view-window of that pixel. We have used a Raspberry Pi 3 [27] computer for data acquisition from the ITA sensor through the I2C serial protocol. We have installed the ITA sensor on the ceiling, close to the air vent as can be seen in Figure 2. The transfer of sensor readings to the on-site computer is done through wire-less connection.

3.2 Occupancy Inference Framework

Each data-point, acquired through our experiments, consists of a 10-second DRS signal @1kHz and a single ITA sensor temperature reading. The DRS data is represented as a time-series and the ITA sensor output is a 2D thermal image. Additionally, each data-point has a binary label (0,1) that determines the state of the occupancy during the 10 second interval associated with each data-point. Through this description, the task of occupancy detection has become one of binary classification (i.e. unoccupied, occupied).

In this study, we have investigated two different occupancy inference methods for the classification problem. In pursuit of an unsupervised method of inference, similar to methods commonly used for PIR sensors, the first approach is a threshold-based decision tree method, that has been used to establish a base-line. Thus, if at any point in time, the DRS time-series exceeds a certain threshold (regardless of the signal amplitude sign), the model will output a positive occupancy state for the room and vice versa. Similarly, if the temperature reading at any of the ITA sensor's output pixels exceeds a certain threshold, the model will output a positive occupancy state for the room and vice versa. The threshold has been selected by using a decision tree of depth 1. The implementation of the decision tree was performed by utilizing the Scikit-Learn [28] library in python 3.65.

As the second class of inference method, we have proposed and evaluated a Deep Neural Network (DNN) solution for the task of occupancy inference based on sensor data. Utilization of a DNN model brings about a number of advantages. Firstly, by utilizing the Deep Learning model, we obviate the need for specialized feature extraction, because the task of feature extraction in a DNN model is performed automatically by the initial layers. Moreover, combining information of fundamentally different nature (in our case a DRS time series and an ITA 2D temperature array) is a relatively effortless task to achieve using DNN models, and it does not require further feature engineering. The structure of the DNN, used for analysis of the DRS time series is as presented in Table 1. Given the high number of trainable parameters in DNNs, there is often a need for a large training data-set to facilitate training and avoid overfitting. However, in some real-world applications such as ours, the size of the data-set is limited. As such, we have opted to use two Dropout layers with a dropout rate of 50% to help avoid overfitting of the model to the training data. The loss function used for training of the model is the 'binary cross-entropy' measure, which is a common choice for binary classification problems.

Table 1. DNN structure for analysis of DRS data with 223,481 trainable parameters.

Layer Type	Layer Size / Drop Rate	Filter Size	Activation Function
Conv1D	128	7	Relu
MaxPool1D	-	2	-
Conv1D	64	6	Relu
MaxPool1D	-	2	-
Conv1D	32	5	Relu
MaxPool1D	-	2	-
Conv1D	16	4	Relu
MaxPool1D	-	2	-
Conv1D	8	4	Relu
MaxPool1D	-	2	-
Flatten	-	-	-
Dropout	50%	-	-
Dense	64	-	Relu
Dropout	50%	-	-
Dense	32	-	Relu
Dense	1	-	Sigmoid

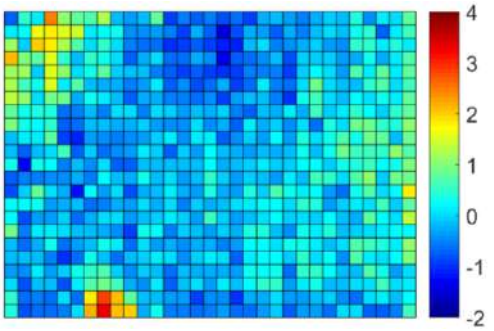
As shown in Table 1, the initial layers consist of relatively large 1D convolutional layers with larger filter sizes. The concatenation of convolutional layers with a shrinking size through the depth results in a phenomenon, through which the first layers are trained to perform generic feature extraction with lesser relevance to the data labels and more relevance to the input data itself. Conversely, the subsequent layers have more and more relevance to the label information. As such, after training the model, one could freeze the initial feature extraction layers, and reuse them for other models, thereby reducing the computational cost of training the new models. This is another helpful feature of DNNs that allows multiple models to share a common body of knowledge. This is an important feature of the model toward generalizability. In occupancy detection, unsupervised models with high accuracy and reliability are preferred.

In Table 2, the structure of the DNN used for analysis of ITA sensor output has been presented. Similar to the previous model, we have utilized Dropout layers to avoid overfitting to the training data. The initial layer of this model can also be used for transfer-learning purposes to obviate the need to re-train feature-extraction layers in a new DNN model. Similarly, the loss function has been chosen to be 'binary cross-entropy'.

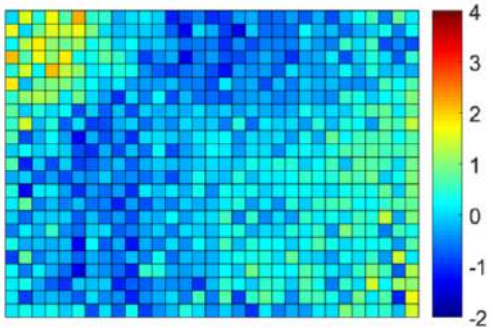
Table 2. DNN structure for analysis of ITA data with 70,433 trainable parameters

Layer Type	Layer Size / Drop Rate	Filter Size	Activation Function
Conv2D	64	(3,3)	Relu
MaxPool2D	-	(2,2)	-
Conv2D	32	(3,3)	Relu
MaxPool2D	-	(2,2)	-
Flatten	-	-	-
Dropout	50%	-	-
Dense	64	-	Relu
Dropout	50%	-	-
Dense	32	-	Relu
Dense	1	-	Sigmoid

Both models have been implemented by utilizing the Keras [29] library with the TensorFlow [30] backend. Before feeding the data to the model, we have subtracted the mean from the ITA sensor readings. This has been done in order to stabilize the model and also to break possible time dependent relationships among data-points, since data-points that have been recorded close to each other could have a similar mean temperature reading. Thus, the ITA readings become temperature differentials rather than actual temperature readings. An example of these readings has been presented in Figure 3.



(a) The room is occupied



(b) The room is unoccupied

Figure 3. Temperature differentials (°C)

As can be seen in Figure 3, in both the occupied and unoccupied case, the upper left corner is warmer than the average. This is due to the presence of a personal computer at the corresponding location, which serves as a thermal noise. In Figure 4 an example of DRS sensor readings has been presented.

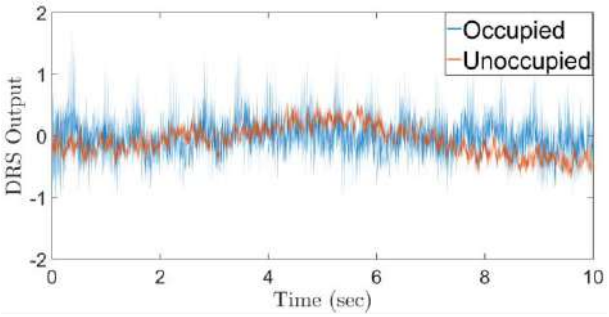


Figure 4. DRS sensor reading

Given that DRS sensor readings for both occupied and unoccupied cases were mostly in the [-1,1] range, no normalization was deemed necessary.

4 Results

In order to train the model to detect the state of occupancy in the environment, we need to provide the model with a data-set that includes both occupied and unoccupied states. The data associated with an unoccupied state, have been collected during the weekend. As for data associated with a positive state of occupancy, the human subject has sat at two different locations within the field of view of the ITA sensor.

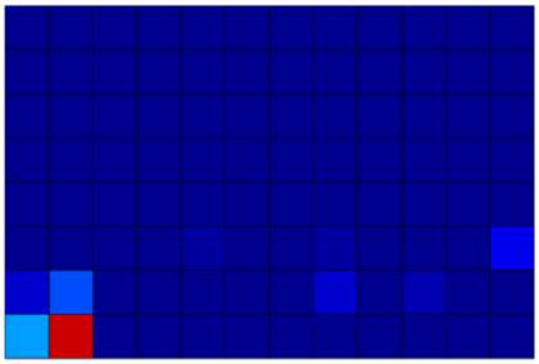
The acquired dataset for this study consists of 1000 data-points, where each data-point contains an ITA sensor reading and 10 seconds of DRS signal (but only one sensor's reading will be given to each model, i.e. either DRS or ITA). In 500 of these cases, the room was unoccupied and in the other 500 cases the room was occupied. The evaluation of the models was performed through a 3-fold cross-validation. As noted, a simplified, threshold-based model was initially used to establish a baseline against which the performance of the DNN model is to be compared. In training of all models, the loss function has penalized equally against both false-positive and false-negative error types. In future studies, the loss function should be modified so as to take into account the relative importance of the two error types for the intended application.

The threshold-based model used to analyze the DRS signal has achieved an average accuracy of 84.3%. By contrast, the DNN model used for the analysis of the DRS signal has achieved an average accuracy of 98.9%. The training process of the model consisted of 10

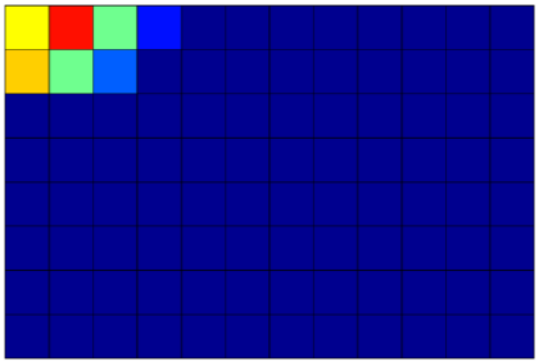
epochs (batch size of 10) with a total elapsed time of 8 minutes on an Intel Xeon E5-1620 V4 CPU [31].

The threshold-based model for the analysis of the ITA sensor resulted in an average accuracy of 86%. By contrast, the DNN model has been able to reach an average accuracy of 99.96%. Training of DNN model used for analysis of ITA sensors consisted of 15 epochs (batch size of 10) with a total elapsed time of 6 seconds on an Intel Xeon E5-1620 V4 CPU [31].

In order to investigate the performance of the DNN model used for analysis of ITA sensor data, we retrieved the activation values of each layer (on the trained model) when the data-point associated with Figure 3.(a) was passed to the model. The filters in a convolutional layer seek to learn a pattern within the input data, and the activation values associated with each filter layer represents the level of a match that exists between a given input data and the pattern that the particular filter has learned. If the pattern of interest for that particular filter exists in certain areas of the data, the activation values for those areas will be higher. In Figure 5, we have presented the activation outputs for two of the filters in the third layer of the DNN model used for analysis of ITA data, i.e. the Conv2D layer with the size of 32.



(a)



(b)

Figure 5. Activation outputs from two filters in the third layer of the DNN model (i.e Conv2D with the layer size of 32)

By comparing Figure 5.(a) with Figure 3.(a), it becomes apparent that the filter associated with these activation values has been trained to exclusively extract the thermal signatures of a human occupant since the activation values are high at the area associated with the location of the occupant. Interestingly, comparison of Figure 5.(b) with Figure 3.(a) reveals that the filter associated with these activation values has been trained to exclusively learn the thermal signature of the environmental noises (in this case the heat emissions from a personal computer in the environment). The mechanism of learning to detect both the noise and the actual occupant-related signatures in the data could be responsible for the high accuracy of the DNN model.

5 Limitations and Future Work

One limitation of this study was the limited size of the train and test data-sets. Moreover, the results are limited to experiments under a single environmental setting (i.e. one room and one occupant). In our future research we will evaluate the potential of the proposed framework under a multitude of experimental settings. Moreover, we will be investigating the potential of the proposed framework to count the number of occupants within each room.

Another line of research which will be the subject of our future studies is the potential to jointly learn from multiple sensor types to achieve synergistic combinations. For instance, in a room with occasionally high thermal noise, the DRS data could help reduce the possible errors in the performance of the ITA-based system. Similarly, if the degree of non-occupant related activities increases to a level that it would affect the performance of the DRS sensor, the information from ITA sensor could compensate for the possible increase in the DRS-based occupancy detection system's error rate.

6 Conclusion

A reliable and accurate occupancy detection framework is in high demand for realization of such applications as smart buildings. In this paper, we have proposed a framework for the detection of indoor occupancy based on cost-effective Doppler Radar Sensors (DRS) and cost-effective high-resolution Infrared Thermal Array Sensors (ITA). We have presented a Deep Neural Network solution for the analysis of the sensor data. We have further evaluated the performance of the framework by conducting real-work experiments in a typical office room. In order to establish a base-line for the performance of the proposed framework, we utilized a simplified threshold-based approach. The threshold-based approach achieved

an average accuracy of 84.3% and 86% for the DRS and ITA sensors respectively. The proposed DNN framework has demonstrated an accuracy of 98.9% via the DRS sensor and 99.96% via the ITA sensor.

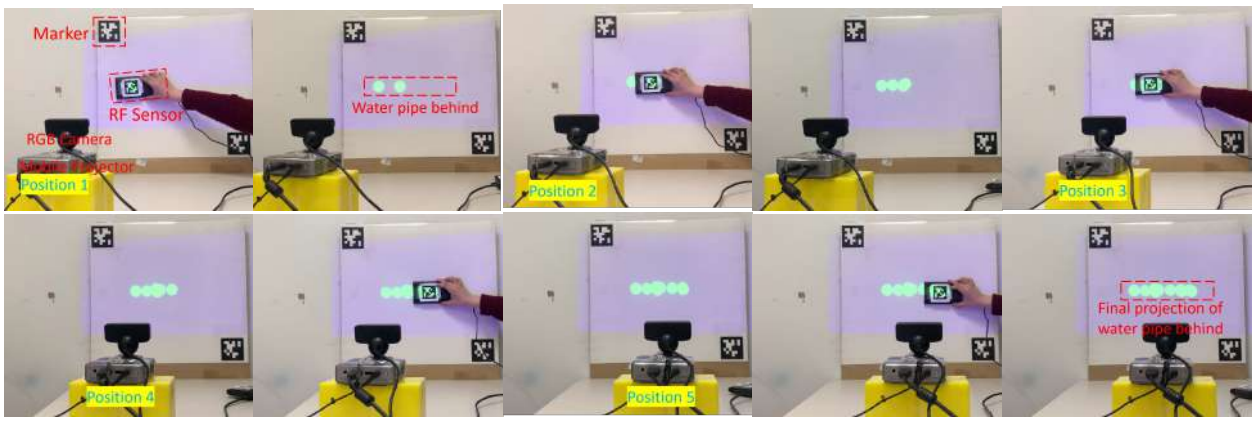

Figure 1. An assistive application of MPAR. An occluded utility is detected and visualized on the fly by projecting the detection results back onto the wall via a moving RF sensor. MPAR enables consistent visualization even after the projector changed its pose. The whole process can be seen in the video at: https://youtu.be/xvNBy$_C$0h3s.

Abstract -

The construction industry has been suffering from both low labor productivity growth and safety issues, due to the increasing project site complexities and the lack of skilled labors. As a potential technical solution, Augmented Reality (AR) has been studied to reduce the cognitive workloads in construction job sites by visualizing task-related information in the direct context of the workspace and operations. Instead of using helmets/goggles that may decrease users' field of views, we advocate mobile projectors for AR (MPAR), and propose a camera-projector system to ensure consistent AR projection even if the projectors may change poses when installed on mobile platforms such as human workers or even construction collaborative robots (co-robot). By obtaining the projector's pose relative to the projection plane (e.g., a wall or panel on construction site) via composing a series of homography transformations in this system, we could determine how to warp virtual information (images or 3D models) for desired projections, no matter whether human observers' head poses are needed. We demonstrate the effectiveness of the method using two construction AR applications: displaying occluded as-planned or as-built facility information behind a mock-up wall.

1 Introduction

The construction industry has been labeled as hazardous [1, 2] and susceptible to casualties and economic losses [3, 4]. Occupational Safety and Health Administration(OSHA) provides statistical data to state that the fatal injury rate in the construction industry is higher than the national average in any other industries in the US [5]. Many research works have been done to improve construction safety. Also, according to McKinsey [6], the construction industry has an intractable productivity problem and there is a large room to improve project efficiency and boost value. Therefore, higher construction productivity has become another pursuit of the construction industry. By blending task-related information directly in real context, AR technology offers the potential to increase construction safety and efficiency with easier access to retrieve on-site information [7]. One trend is integrating AR technology with Building Information Modeling (BIM) [7–11]. Their research works focused on employing AR as a visualization tool to display as-planned BIM information in the context of the real environment in architectural visualization, facility management, construction education, and other construction-related fields. Another trend is to design a mobile augmented reality (MAR) system for architectural, engineering, construction and facility management (AEC/FM), BIM information retrieval and construction education [12–15].

However, conventional AR has several limitations that could be potentially problematic for construction/civil applications. Unlike AR for gaming or education, which is operated in a relatively simple and safe environment, restricted field of view of conventional helmet-based AR will reduce the amount of environmental information available to people [16, 17] and may cause fatal injuries to construction workers. Kawano et al. [18] reported that in their survey of using HoloLens (a pair of head-mounted smart glasses developed and manufactured by Microsoft) to train the construction team during the assembly process, in order to get a full view of the assembly site, workers have to move head instead of moving eyes naturally. Wearing AR devices may also cause distraction and reduce situational awareness, raising concerns about safety [19]. For tablet-based AR, the technology is relatively mature, however, it produces less immersive user experience [20] which could also impede the application of AR technology in the construction field. Also, for many tasks other than monitoring/inspection, workers cannot hold a tablet while working on the tasks.

The objective of this research is to develop a mobile projector-based AR technology to increase the safety and efficiency of the construction industry by enriching the information on the real construction site while avoiding the drawbacks of conventional AR. Our contributions are listed as follows:

- We introduce related projective geometry theory as fundamentals for our method.
- We design MPAR, a camera-projector system that can augment task information directly onto a physical workspace.
- Our MPAR system can be either independent or dependent on the observer's pose.
- We test MPAR in an assistive application that projects positions of occluded utilities behind a wall using an RF-image sensor.

2 Related Work

There have been some researches on introducing AR technology to construction. However, projector-based AR technology that can somehow overcome the drawbacks of conventional AR, has not received much attention. To realize AR technology using a projector, we need to dive into mobile AR technology and other related work, such as projective AR system's math model and pose estimation.

AR in construction. Kamat et al. [21] discussed an HMD/glass-based AR method for assessing the building damage caused by earthquake. Their method superimposes the previously stored building information onto the real structure and computes the difference between the two views. Bae et al. [12] proposed a tablet-based AR system for smartphone users to query 3D virtual information onsite. Their system reconstructs the camera pose by matching feature points of a photo and pre-stored point cloud, thereby obtaining the user's position. Mevza et al. [22] focused on implementing a BIM-based AR system to improve the performance of digital materialization. Their method feeds the mobile AR system with pre-generated AR model converted from BIM.

Projector-based AR. Given the above-mentioned limitations of using conventional AR, we propose to use projector-based AR for our applications. Projector-based AR is not a completely new idea, it has been proposed and used in many areas. For example, assisting human-robot interaction [23], augmenting details for cultural heritage artifacts [24], improving user's gaming experience [25], etc. Benko et al. [26] combined HMD AR display with view-dependent projection to improve user experience. However, their method needs wearable devices, which produces the same problems as we mentioned above. Also, superimposing stereoscopic views onto monoscopic projections is still a challenging work. Our method only focuses on projector-based AR technology so that these problems can be avoided. Lindlbauer et al. [27] developed a framework for combing shape-changing interface with projection mapping, while we assume that our work is performed on a plane of constant shape. Different from all these methods above, our work aims at rendering the 2D frames of objects on the correct position they projected onto the wall.

Methods for Projector-based AR. Since the projector is mobile, we need projector's math model and pose estimation. As Tatsumoto et al. [28] presented in their work, the robot can project the image to any specified location by detecting the marker placed in the environment previously. Chadalavada et al. [29] showcased their work aiming at improving the robot's ability to communicate with human by projecting internal state information through a projector. One important part of their work is to find the relationship between the real world vehicle path and OpenGL frame to render the image. While their work [28, 29] required to calibrate camera-projector system ahead for a precise physical pinhole camera model, our work directly computes the homography transformation matrix between camera and projector to pass the geometry relationship between the two. Boroomand et al. [30] proposed a method that can compensate for distortion of the projected image caused by an uneven projection plane. In order to improve picture projection accuracy, we use two markers of known physical coordinates for precision control.

3 Mobile Projective AR

Our method realizes AR using a camera-projector system to ensure a consistent projection during the process,

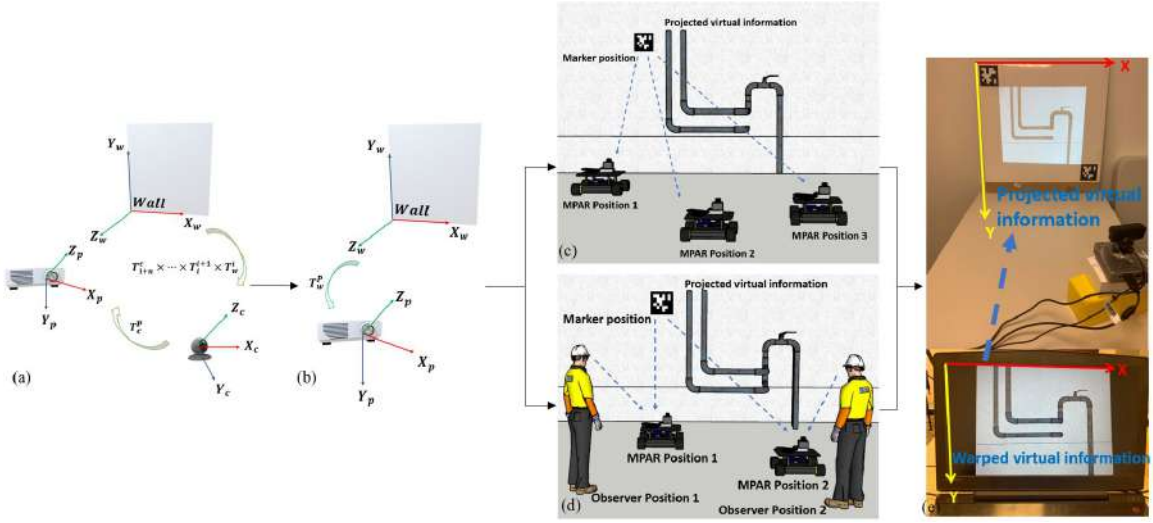

Figure 2. MPAR pipeline. (a) Pose representation and estimation. (b) Composition of projection matrix. (c) observer-independent system. (d) observer-dependent system. (e) Projection of the warped virtual information.

even if the projector might be moved due to various reasons (e.g., to enlarge/move the field of view, to make room for co-workers, etc.). Figure 2 depicts two categories of the MPAR system, one is observer-independent and the other is observer-dependent. The observer-independent MPAR system does not need to know where the observer is (we assume the position of the observer's head represents the position of the observer) while the observer-dependent MPAR system requires for the observer's position. For both systems, we first estimate and represent the pose of the projector in the world coordinate system by passing homography matrices between components in the system; then, according to the projector's pose, the projection matrix from the projector to the target projection plane can be estimated. Therefore, the observer-independent MPAR system could project the excepted virtual information onto the projection plane. For the observer-dependent MPAR system, the observer's location needs to be known before the projection phase. In this section, we will provide a general formulation of our method.

3.1 Pose Representation and Estimation

It is necessary to estimate the pose of the projector relative to the world coordinate system, so we can determine how to warp the virtual information (image or 3D model) for displaying the desired content on the projection plane without geometrical distortion. We developed a camera-projector system to estimate the pose of the projector via vision-based perception. By passing sequential transformations from the world coordinate system via the camera and other possible intermediate coordinate systems to the projector coordinate system, the pose of the projector in the world coordinate system could be calculated. The transformation from a coordinate system to b coordinate system can be represented by a matrix T_a^b. We express the transformation matrix from the world coordinate system to the projector coordinate system as:

$$T_w^p = T_c^p T_N^c \prod_{i=1}^{N-1} T_i^{i+1} T_w^1 \tag{1}$$

Here, w represents the world coordinate system, p represents the projector coordinate system and c represents the camera coordinate system. N is the total number of intermediate coordinate systems. T_i^{i+1} is the transformation from the ith intermediate coordinate system to the $(i+1)$th intermediate coordinate system. To register the position of the MPAR system, either the marker-based method or the markerless method could be used [31, 32]. Markerless AR is usually more flexible than marker-based AR for not requiring marker installation. But there are several reasons that still favor marker-based solution on several circumstances.

Why use markers? First, the markerless technology usually requires abundant visual features in the environment and there is a trade-off between precision and efficiency when applying this method to realistic job sites [33]. Second, our method is effective in indoor environments, no matter whether the projection plane has discriminative visual features or not. While marker-less AR might sometimes lose track for features. Besides, by using markers, it is more reliable to determine the location of the projection plane in the world coordinate system than without markers. Nevertheless, similar to recent works [34, 35] that integrate markers into structure from motion systems,

our on-going work is combining the marker-less solution with marker-based one in MPAR system.

For marker-based AR, the relative pose can be represented by a translational vector and a rotational vector [36]. However, camera calibration is required if poses are represented in this way [32], which may cause inconvenience and complexity, thereby affecting AR application in industry.

To avoid the aforementioned drawbacks, we utilize marker-based AR. Besides, instead of using translational and rotational vectors, we choose to use homography to represent the pose, since all components in the system, such as projection plane, image plane, and makers are planar objects. Homography transformation matrix is an invertible non-singular 3×3 projective matrix which can map the corresponding points from one plane to another plane [37]. Using homography does not require camera calibration. Therefore, the pose of the projector in the world coordinate system can be represented in the form of homography:

$$H_w^p = H_c^p H_N^c \prod_{i=1}^{N-1} H_i^{i+1} H_w^1 \tag{2}$$

where we represent homography transformation between a and b coordinate systems as H_a^b. Given the pose of the projector in world coordinate system, if $\mathbf{x}_w$ are the homogeneous coordinates of a point on the projection plane in world coordinate system, then the coordinates on the projector's image plane should be:

$$\mathbf{x}_p = H_w^p \mathbf{x}_w \tag{3}$$

According to H_w^p, virtual information which needs to be projected can be converted to a warped image. By sending the warped image to the projector, the virtual information can be projected to the correct locations in the world coordinate system.

3.2 Observer-Independent MPAR

In the multi-person collaborative site, the projected information will be shared by multiple workers and designers, so the projected information should not change with the position of one person. Therefore, the previously proposed methodology, equation 3 could be used for the displaying purpose.

3.3 Observer-Dependent MPAR

In contrast to observer-independent MPAR, the projected content of an observer-dependent MPAR system is related to the observer's position. This feature is important when the worker or designer on the site is moving while observing a 3D virtual model. To establish an observer-dependent MPAR system, either static projector(s) or mobile projector(s) can be used.

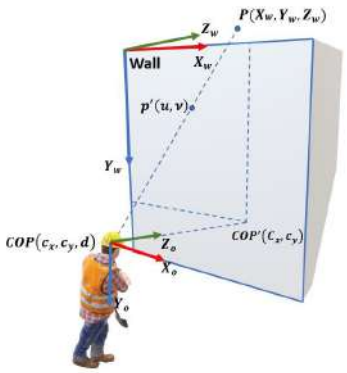

Figure 3. Illustration for computing a projected point in the observer-dependent MPAR.

For the observer-dependent MPAR system using static projectors, the pose of the projector relative to the world coordinate is known. Therefore, the virtual information can be projected directly without computing the series of homography transformation matrices. We can only focus on the impact of human location on the overall system. Equation 4 links the three-dimensional coordinates of the object to the corresponding projected two-dimensional coordinates by the observer's location.

$$s \begin{bmatrix} u \\ v \\ 1 \end{bmatrix} = \underbrace{\begin{bmatrix} d & 0 & c_x & 0 \\ 0 & d & c_y & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix}}_{\text{projective}} \underbrace{\begin{bmatrix} 1 & 0 & 0 & -c_x \\ 0 & 1 & 0 & -c_y \\ 0 & 0 & 1 & d \\ 0 & 0 & 0 & 1 \end{bmatrix}}_{\text{world to observer}} \begin{bmatrix} X_w \\ Y_w \\ Z_w \\ 1 \end{bmatrix} \tag{4}$$

Figure 3 establishes the world coordinate system and the observer coordinate system. The observer's location COP, the virtual point's location P and its projection on the wall P' have also been defined. For proper projection, we first convert the coordinates of the object from the world coordinate system to the observer coordinate system. For this conversion, since the corresponding coordinate axes of the two coordinate systems have the same direction, the rotation matrix is a 3×3 identify matrix; the translation vector is $(-c_x, -c_y, d)$, related to the observer's location. To apply the transformation matrix to the homogeneous coordinates of $P(X_w, Y_w, Z_w)$, the rotation and translation matrix should be combined as the world to observer matrix in equation 4. Then the object's coordinates $P'(u, v, 1)$ in the world coordinate system plane can be obtained by multiplying the projective matrix in equation 4. s is a scaling factor.

The observer-dependent MPAR system using mobile projectors is complicated and comprehensive in taking

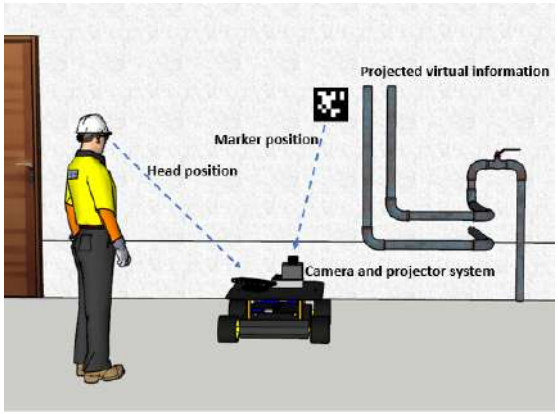

Figure 4. Illustration of observer-dependent MPAR.

both observer's location and projectors' mobility into consideration. The methodology of this system can be realized as a combination of the aforementioned methodologies. Figure 4 shows the schematic of the observer-dependent MPAR system. Knowing the position of the observer (COP), the coordinates of the virtual point being projected onto the projection plane P' can be calculated by equation 4. Then according to equation 3, coordinates of P' on the warped image can be calculated.

4 Applications

It is important that designers and workers can see building/facility information in the exact location during the construction process. For example, in the maintenance or inspection process, workers can evaluate the quality of the building by comparing the appearance of the on-site building with the as-designed building information projected onto the site. Based on the aforementioned MPAR methodology, our first task is to project as-designed building/facility information to where they are located.

Our task 2 is to detect the object behind the wall, visualize and save the detected RF signal based on the framework of MPAR methodology. In practice, workers can set up the markers in an unknown construction site for renovation work. After settling down the MPAR system, they should be able to employ the Walabot to detect the hidden objects and visualize them in real time. Moreover, they can save the detected signal to BIM database for future information retrieval. Task 2 is a prototype for such work, and its result can be seen in Figure 1.

Since in last section, we have provided a general formulation of our proposed method, in this section, we will show two applications which realize our method.

4.1 Projection of As-Designed Building Information

Some assumptions should be made before the implementation of task 1. First, it is reasonable that we have access to as-designed building information and its location in the world coordinate system. Also, since our pose estimation method is based on detecting optical markers, the projection area is within the control range defined by markers, so the physical coordinates of the building information that our task can project need to be within the control area.

System Setup. For computing homography matrix, AprilTag, a robust visual fiducial system [38] is utilized to detect correspondences in two coordinate systems [39, 40]. By placing markers on the wall, the world coordinate can be defined. As Figure 5 shows, a RGB camera is fixed on the ultra short throw projector. Also, a laptop is utilized as a mobile workstation for computing homographies and displaying the virtual information.

Related Transformations:

Wall to Camera. For this part, we first set up the two markers on the wall, as can be seen in Figure 5, to define the world coordinate system, which is a 2D coordinate system on the wall plane. Then we measure the physical coordinates of four corners for each marker. Also, the on-board camera captures an image which contains the two markers. The image coordinates of eight corners can be automatically measured. Then the homography from world coordinate system to the camera's image coordinate system H_w^c can be calculated using Direct Linear Transformation (DLT).

Camera to Projector. In addition to capturing the physical markers on the wall, the RGB camera is also set up to capture the projected marker. An image of a marker is sent to the projector to make it being projected on the wall. Then the RGB camera takes an image of the projected marker on the wall. The corners of the projected marker are automatically measured in the captured image and the input image. According to the corresponding corners, homography from camera's image coordinate system to projector's image coordinate system H_c^p can be calculated.

Wall to Projector. After obtaining H_w^c and H_c^p, H_w^p can be calculated according to equation 2. Then the warped image sent to the projector can be obtained according to equation 3.

Result. As we can see in Figure 5, suppose the plumbing is located in the control area defined by the markers, though the projector is moving, the projected information remains at the same specified location.

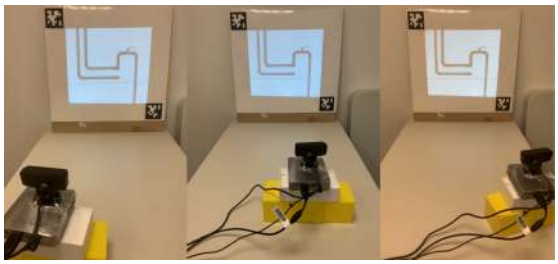

Figure 5. Observer-Independent MPAR for as-designed building information

4.2 Projection of Occluded Building Information

Specific Image Warping Representation. Unlike the previous application, which needs to find homography transformation from world coordinate system to projector coordinate system, this application aims to project the sensed RF image to the correct location on the wall. Therefore, homography from the sensed image coordinate system to the projector's image coordinate system H_i^p needs to be calculated:

$$H_i^p = H_c^p H_s^c H_i^s \tag{5}$$

H_c^p, H_s^c, H_i^s represent the homography transformation from camera's image to projector's image, Walabot sensor's coordinate system to camera's image and sensed RF image to Walabot sensor's coordinate system respectively. To better visualize the detected RF image, we rendered a circle, centered on the location of object being detected, on the 21×21 pixel sensed RF image. According to H_i^p, we could warp the RF image such that it can be projected properly on the projection plane.

Since the projector's pose is changing during the projection process, we should warp the image of the previous frame to align with the projector's pose of the current frame and fuse all images together to get a global image for projection.

System Setup. In addition to the camera-projector system used in the previous application, Walabot, a handheld 3D-imaging device was utilized for detecting the RF signal of the object behind the mock wall. Since it is difficult to directly detect the pose of the Walabot sensor plane, we attached a marker on the Walabot to detect its position.

Related Transformations:

Image to Sensor. The homography transformation matrix H_i^s is pre-defined since we specified the physical sensing arena in the sensor coordinate system and image size in the digital image coordinate system. We can calculate H_i^s by using the corresponding four corners in both two coordinate systems.

Sensor to Camera. To compute the transformation matrix between the sensor coordinate system and the projector coordinate system, we attached an optical marker on the opposite side of the sensor plane, whose center coincides with the surface's center in z axis, as can be seen in Figure 1. By capturing the four corners of the marker, we could compute the homography H_t^c between the tag and the RGB camera. For the transformation between the sensor plane and the marker plane, we can easily measure the the thickness of Walabot, which represents the translational vector between sensor plane and tag plane. Since homography transformation matrix does not contain the translational information explicitly, we need to use affine matrix for geometry transformation. By decomposing the homography transformation matrix H_t^c with the RGB camera's intrinsic matrix, we can obtain the affine matrix which contains the rotational and translational information between the tag and the camera; adding the translational vector allows us to get the affine transformation matrix between sensor plane and the RGB camera. Then we can compose the homograhpy matrix H_s^c with the camera's intrinsic matrix.

Camera to Projector. This part of implementation is the same as the previous application.

With these homogaphy matrices obtained, we could calculate the homography transformation between project the warped image of each frame onto the projection plane properly.

Two Frame Image Fusion. Since the projector is moving during the scanning process, we need to fuse the previous frame image to the current frame image such that H_i^p is always representing the current homography transformation matrix between image coordinate system and projector coordinate system. The homography between two frames can be calculated by solving DLT problem using the optical markers' points captured by the RGB camera in two frames. After knowing the homography transformation matrix between two frames, we can warp the previous image using equation 3 and fuse it with the current image.

Result. By sending the fused image to the projector, we can visualize the water pipe behind the mock wall. As can be seen in Figure 1, our result shows that even the projector's pose changed during the scanning process, our system could still augment the occluded water pipe consistently.

5 Conclusions

In this paper, we proposed MPAR, a camera-projector AR system which ensures a consistent projection even when the device might be moving during the AR process. In our two applications, by composing a series of homographies modeling poses between components in the system, it is possible to warp the virtual information in the projector coordinate system and display it on the projection plane as desired.

Limitations and Discussions. There are some limitations in our proposed method. Limited by the image brightness of the projector, the result of our method might be affected by the sunlight outdoors. Also, since our method uses optical markers for detecting feature points, it might cause extra workload for setting up these markers. The method might even become invalid in a large-scale scenario due to the inability to detect the markers.

Another limitation is that our MPAR system does not provide an as immersive environment as helmets/goggles (see-through based AR). Yet we believe that the restricted field of views will cause safety concerns for the construction industry, which could be a more serious problem compared to the less immersive user experience.

Future Work. Some future work needs to be done to produce a more general and reliable MPAR system. One work is to calibrate the projector to obtain the intrinsic matrix, thus we could know the pose of the projector as long as we know the extrinsic matrix of the projector. This frees us from acquiring the image of the projected marker. Also, we believe that by projecting the virtual information on uneven surfaces using 3D cameras, the MPAR system could be applied to more scenarios. Another important work we need to conduct is quantitative evaluation. It is important to evaluate how accurate our method is, and we should also explore some possible factors that might affect the accuracy of our method.

Abstract –

Over the last few decades, the investments in more complicated construction projects, involving multiple disciplines and different teams, have increased the need for more complex communication means. The purpose of communication methods is to ensure higher levels of coordination between project participants (owners, architects, engineers, contractors, suppliers, etc.). Adequate communication brings many benefits to a project, such as improved team performance due to information exchange, increased knowledge of other participants' skills or their availability. Building Information Modelling (BIM) has the ability to aggregate information on construction projects and facilitate the design, construction, and facility management processes. Therefore, including BIM classes in construction management education is of utmost importance for the success of students. Moreover, introducing cloud collaboration to these classes helps students better understand the collaborative aspect of the construction industry. The purpose of this paper is to study the benefits of Autodesk Next Gen BIM 360 brought to a graduate BIM class. Students of this class were divided into groups and asked to model the different disciplines of a project using Autodesk Revit© while collaborating the project on Next Gen BIM 360. At the end of the semester, students reported the benefits and drawbacks of Next Gen BIM 360. The benefits included the ease of use of the platform, better communication of ideas and concerns using Next Gen BIM 360 cloud services, real-time collaboration opportunities, and model coordination on the cloud.

Keywords –

BIM; Next Gen BIM 360; Collaboration; Construction; Education

1 Introduction

The construction industry is very dependent on information exchange between project stakeholders, as communication is imperative for the success of construction projects. The structure of the industry is very much fragmented, and it involves numerous data-intensive processes through the lifespan of projects [1]. Typically, massive amounts of data which need to be continuously updated and synchronized are generated across the entire lifecycle to achieve better project outcomes [2]. Seeing as construction projects comprise complex activities interconnected with these vast amounts of data, collaboration between team members is highly essential to ensure successful completion of these projects. However, seamless collaboration and information exchange continue to be a challenge for the industry despite great efforts dedicated to understanding and improving these processes [3]. With the advancements in information technology, the construction industry has gradually shifted towards more collaborative working practices based on BIM. Collaboration is a process of teamwork and information dispersion through communicating, coordinating, networking, and exchanging in order to maximize the group effort of the project stakeholders [4].

In recent years, collaboration technologies have evolved through research efforts to increase the efficiency of information communication. The utilization of cloud-based technologies to realize the integration of all project phases has increasingly grown to be a widespread practice in project management, making the communication of more cumbersome information probable [4]. Through the use of these collaborative technologies, long-distance communication is made possible, and project stakeholders are not confined to an actual workstation next to each other. Consequently, collaboration, communication, and teamwork skills are ever more crucial in the construction workforce today [5]. Thus, there is an opportunity for institutions of higher learning

to incorporate collaborative learning into their curricula in order to equip students with essential employability skills and to also enhance their engagement in the classroom. This paper explores the use of Autodesk Next Gen BIM 360 as a collaborative learning platform in construction management education to enhance the learning experience of students.

2 Literature Review

2.1 BIM in Education

BIM is an intelligent three-dimensional model-based process capable of combining the dispersed information shared between project stakeholders [6]. For this reason, BIM has been customarily implemented on construction projects to address several of the problems confronting the industry such as budget overruns, contingencies in schedule forecasts, safety, and overall quality of the project [7]. In the last few years, BIM has been used as a collaborative platform in projects to magnify the quota of data shared between the various parties involved in construction. Taking into account the high potentials of BIM and the several advantages to its implementation on construction projects, the technology can be employed as an educational tool in institutions of higher learning. For instance, construction jobsites can be virtually incorporated into classrooms with computer-generated models hosted in virtual environments that simulate design and construction processes. With BIM-based instructional techniques, educators are capable of equipping students in the architecture, engineering, construction, and operations (AECO) fields with the required skills and abilities necessary to complete construction tasks successfully, by eliminating inadequacies from the lack of practical exposure to real-time jobsite situations [8]. Computer and information technologies significantly impact the skills and educational successes of students as they foster collaboration between instructors and students, ultimately enhancing problem-solving and inquiry skills in the students [9].

Additionally, some government protocols require that public construction projects are commissioned with BIM, leading to a rise in demand of BIM specialists in the construction workforce. As a result, several approaches to encourage institutions of higher learning to integrate BIM into the curricula of both undergraduate and graduate courses [10, 11, 12]. Research has shown that BIM can be implemented as an instructional tool for a variety of construction activities such as the operation of construction machinery, occupational health and safety, logistics planning, jobsite training, and project coordination and visualization [13, 1, 14, 15, 9].

2.2 Collaborative Learning

As established, BIM processes are multidisciplinary and require seamless collaboration and information exchange between all project stakeholders. In the construction, context collaboration can be defined as a harmonious team-based setting in which every member understands and values the contribution of others, as well as their role and responsibilities [16]. However, there is often the problem of ensuring the various disciplines, trades and companies collaborate amicably which poses an obstacle to channeling the full potentials of BIM [17]. Several researchers have tackled the issues facing BIM-enabled projects in maintaining collaboration through the lens of technology, while others consider the issue to be that of human behavior [17, 18]. Following the human behavior school of thought, the integration of collaboration philosophies into BIM courses in institutions of higher learning has been suggested as a practical solution to hostile teamwork situations in the industry [18, 19]. In the context of construction management education, collaboration can be defined as a shared, interactive process that requires the involvement of two or more participants, working collectively to attain results not easily achievable individualistically [20]. This process is commonly referred to as collaborative learning.

Collaborative learning often incorporates team-based, project-based, and problem-based learning methods in which students work together in small teams to achieve a common objective [15]. Collaborative projects characteristically simulate actual construction projects and processes with the goal of solving problems more efficiently in order to ensure better outcomes [21]. During the process, students are trained to be good listeners to their team members, as well as to regard the ideas of others with respect and uphold equivalent decision-making authority [22]. Several collaborative learning platforms can be utilized in classrooms to make the learning, designing and executing process easier [5]. Three-dimensional modeling platforms and information communication technologies can be employed to impart a clearer understanding and visualization of designs and models, and to improve communication among the students [18]. For the purpose of this study, Autodesk Next Gen BIM 360 was the platform used to facilitate collaborative learning in a construction management program.

2.3 Autodesk Next Gen BIM 360

Autodesk BIM 360 is as a cloud service that aims to connect the construction project lifecycle. BIM 360 improves construction project delivery processes by providing the tools required to evoke informed-decision making as the platform emphasizes the importance of

well-structured data that is continuously kept up-to-date [23]. BIM 360 is an inclusive project management program intended for the construction industry. Since its introduction into the industry in 2010, the portfolio expanded as a group of products designed to support construction workflows from pre-construction through handover and operations through the BIM 360 Docs, BIM 360 Glue, BIM 360 Field, and BIM 360 Plan services [24]. However, each of these services fundamentally functions as isolated products, creating a non-unified platform for communicating and sharing information.

However, at present, the BIM 360 platform has evolved from a set of separate solutions to a construction management platform that offers a more integrated, workflow-focused, "one-product" experience, called the Next Gen BIM 360. The Next Gen BIM 360 platform features a single, common data platform that allows easy access to all project information from anywhere in BIM 360 [24]. Drawings, models, and files uploaded during the design phase can be carried into the construction phase to support requests for information (RFIs), submittals, inspections and more. The platform also features a powerful insight and analytics layer that includes interactive dashboards and reporting, for informed decision making and predictive analysis. The services included in the Next Gen BIM 360 portfolio are Document Management, Design Collaboration, Model Coordination, Field Management, Project Management, and Cost Management [24].

The cloud-based platform endeavors to optimize project delivery schedules and budget while ensuring that industry standards, safety regulations, and project specifications are adhered to. The software empowers managers by allowing them to coordinate staff actions, implement workable schedules, improve communication between teams and companies, resolve issues and non-conformities; all of these in a digitalized environment with real-time information. One of the significant advantages of Next Gen BIM 360 is the fact that the software is flexible enough to accommodate different sizes and scopes of construction projects, which is one of the prime reasons for choosing the platform as a collaborative learning platform for this study.

3 Methodology

3.1 Use of Autodesk Next Gen BIM 360 in the Classroom

For the purpose of this study, the data collected is based on a sampling of students enrolled in the M.E. Rinker, Sr. School of Construction Management at the University of Florida (UF). The Construction Information Systems class offered by the Center for Advanced Construction Information Modeling (CACIM) was the class selected for the implementation of this study, which is a graduate level class covering virtual design and construction (VDC) technologies. The first eight sessions of the class demonstrate modeling concepts in Autodesk Revit®, where students are asked to complete architectural, structural, and mechanical models of a medium-scale commercial building. The remaining eight sessions of the class expound on the use of BIM for scheduling, estimating, point layouts, and visualization. In addition to the class assignments, students are expected to complete a team project which entails developing BIM models using original blueprints of educational buildings.

Since the Fall 2016 semester, the Autodesk BIM 360 has been incorporated in the class for collaboration; however, in the Fall 2018 semester, the class transitioned to the Next Gen BIM 360 platform. The study was conducted over two semesters, with participants from the Fall 2018 and Spring 2019 semesters. The breakdown of the sample size is shown in Table 1 with 47 students participating in this study. Using the Next Gen 360 platform, specifically the Document Management, Design Collaboration, Model Coordination, and Project Management modules, students had the chance to explore the multi-disciplinary coordination, clash detection, BIM data, and document management functionalities of the platform. Most importantly, the different team members were able to co-author BIM models on a single Revit® file. At the end of the semester, students were asked to evaluate the usefulness of the Next Gen BIM 360 platform, and rate their experience using the tools to collaborate and communicate.

Table 1. Study sample size

Semester	Number of Study Participants
Fall 2018	18
Spring 2019	29

3.2 Workflow

One of the class deliverables is a final project in which the class is divided into groups of four or five. Each group was given a set of two-dimensional drawings and asked to model the architectural, structural, and mechanical components of the building.

The first task for the students was to upload the drawings to Next Gen BIM 360 Document Management. In Document Management, students were able to organize the drawings into folders, and create templates that can automatically detect the sheets' numbers and names. Moreover, Document Management can

automatically detect sections and callouts on the drawings, and create hyperlinks to facilitate the navigation of large sets of drawings.

The next task required of the team project was to initiate the project on the cloud using Next Gen BIM 360 Design Collaboration. Students also created worksets to control the level of permission and the ownership of elements in the model. This facilitated the modeling process as students had the ability to grant or deny editing requests placed by other team members, which guaranteed the correct placement of the elements in the model.

During the modeling process, students also used Next Gen BIM 360 Project Management to communicate issues and RFIs. Students were able to place pushpins on the drawings and submit RFIs to the class instructor related to the drawings. Once the RFI is reviewed by the instructor, all team members were able to see the response. The Issues functionality was also used for communication among team members themselves.

Finally, before the final submission of the model, students used Next Gen BIM 360 Model Coordination. Model Coordination automatically creates clash detection tests from the models saved on the cloud. Moreover, similar clashes are grouped to facilitate the review process. Students used these clash groups to coordinate the model better and resolve clashes between the different disciplines of the project.

During the semester, a questionnaire was developed and distributed to the class. The questionnaire was a short survey that asked the following questions:

1. What did you like best about the Autodesk Next Gen BIM 360 tools?
2. What did you dislike about the Autodesk Next Gen BIM 360 tools?
3. How would you rate your experience using the Autodesk Next Gen BIM 360 tools on a scale of 1 to 5, 5 being best?

4 Results and Discussion

4.1 Benefits of Autodesk Next Gen BIM 360

At the end of the semester, students were asked to evaluate the usefulness of Next Gen BIM 360, and discuss how it enhanced their construction management education. Based on the responses of the study participants, the benefits of the Autodesk Next Gen BIM 360 tools can be categorized into six as shown in Table 2, all of which center on enhanced collaboration and communication.

Table 2. Responses of students to the benefits of Autodesk Next Gen BIM 360

Benefits	Frequency n = 47	Percentage of total
Ease of use	40	85%
Real-time collaboration	45	96%
Single data repository	38	81%
Central project collaboration	47	100%
Design review	41	87%
Model coordination	40	85%

The percentages of the responses of the participants in summarized in Figure 1.

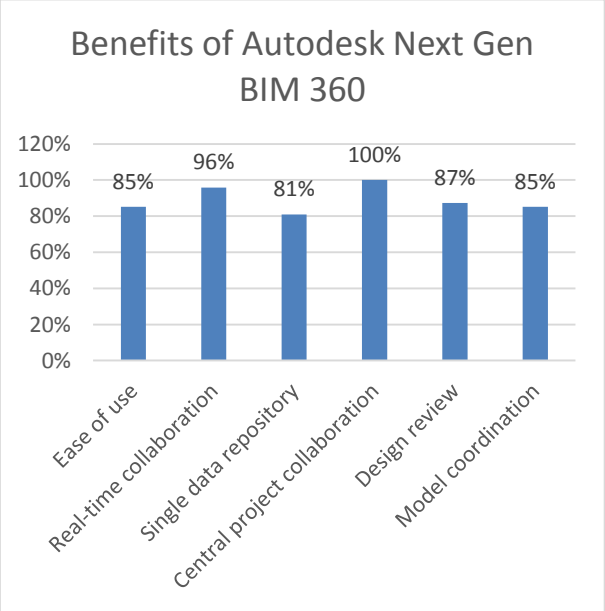

Figure 1. Benefits of Autodesk Next Gen BIM 360

4.1.1 Ease of Use

The Next Gen BIM 360 platform is a user-friendly platform that did not require any extensive knowledge of cloud-based services. Some of the feedback from the students regarding the ease of use of the platform include:

- The platform is relatively easy to use and is getting more and more integrated as a coordination tool.
- The simplicity of use for people with little or no computer knowledge.
- The easy access to the website and ease of use was a big benefit.

4.1.2 Real-Time Collaboration

With the Next Gen BIM 360 platform, students were able to work remotely and still collaborate with their team members from their different locations. Some of the feedback from the students regarding the benefit of long-distance collaboration include:

- It is perfect for working remotely from home.
- It fostered a connection with team members even though we worked mostly from different locations.
- Next Gen BIM 360 enabled real-time updating of models and documents.

4.1.3 Single Data Repository

The Next Gen BIM 360 platform now centralizes all project data in a single data repository connecting all workflows from design to construction to operations. Some of the feedback from the students regarding the single data repository feature of the platform include:

- It is an excellent depository to compile all the project information in one place.
- Having relevant project information readily accessible in the cloud was helpful.
- A significant benefit is having information available in the cloud and having the ability to collaborate with others in the cloud.
- The concept of a single bank of all the project information and to have a well-structured process in place for checking, reviewing and approving the information is appreciated.
- Autodesk Next Gen BIM 360 improves sharing and storing of documented files.
- One centralized location where all project information is kept was essential.

4.1.4 Central Project Communication

With the Next Gen BIM 360 platform, communication with other team members can be easily achieved in the BIM 360 environment without the need for email. Some of the feedback from the students regarding the benefit of central project communication include:

- Communication was improved by BIM 360.
- BIM 360 solved countless communication errors between all the members of the team.

4.1.5 Design Review

Using the Document Management Module, students could create markups on design sheets, make comments as well as publish both the mark-ups and comments for other team members to see and respond accordingly. Also, Document Management made it easy to publish design sets by converting models into individual two-dimensional sheets that could be measured and calibrated. Some of the feedback from the students regarding the benefit of design review include:

- Being able to make markups and issues and share them with team members, as well as keep a record of them.
- Creating mark-ups and issues on the sheets is a significant benefit.
- Easy to upload 3D models with sheet generated files easily extracted sheets.
- Title block data is automatically scanned and extracted when uploading pdf files and also comes with an automatic zoom of sheet title, sheet numbers, and sheet names.
- Having the ability to review and analyze the information is a powerful tool.

4.1.6 Model Coordination

With the Model Coordination module, students were able to automate the BIM coordination process, making it quicker to identify and resolve problems between the different disciplines. Some of the feedback from the students regarding the model coordination feature include:

- It is a great collaboration tool that makes problem-solving much easier through model coordination processes.
- The ability to coordinate and solve problems much sooner than usual without using BIM 360.
- It is excellent for viewing models as it quickly highlights any problems or clashes.
- The comparison tool is useful for visualizing model changes.
- It sped up the review process by almost half the time.

4.2 Drawbacks of Autodesk Next Gen BIM 360

As with all emerging software, the Autodesk Next Gen BIM 360 is not without a few technical difficulties that can be improved. The students were also asked to evaluate the limitations of the Next Gen BIM 360 platform. Based on the responses of the study participants, the top five drawbacks of the Autodesk Next Gen BIM 360 tools is shown in Table 3.

Table 3. Responses of students to the limitations of Autodesk Next Gen BIM 360

Benefits	Frequency n = 47	Percentage of total
Slow speed	47	100%
Time consuming to sort documents	30	64%
Issues cannot be assigned to more than one person	40	85%
Problematic issues tracking	25	53%
Working with worksets is delicate	40	85%

The analysis of the responses indicated that:

- Out of the 47 respondents, 100% mentioned the slow upload and download speed to and from the cloud platform as a significant limitation.
- In the Document Management module, 64% of the respondents indicated the lack of a feature that highlights the most recently updated documents as a limitation, as it makes it time-consuming to sort through several sheets.
- The inability of users to assign an issue to more than one person at a time was indicated by 85% of the respondents as a limitation.
- Of the 47 respondents, 53% stated that the issues tracking functionality in the Model Coordination module is problematic.
- Of the 47 respondents, 85% stated that working with worksets in the Design Collaboration module is delicate as a team member can change the properties of elements assigned to worksets of other team members without permission.

4.3 Experience using the Autodesk Next Gen BIM 360 Platform

The last question of the questionnaire was designed to evaluate the experience the students had with using the Autodesk Next Gen BIM 360 Platform. The experience of the students were rated on a Likert scale ranging from poor to excellent. The results of the responses to this question are summarized in Table 4. Out of the 47 respondents, 4% indicated that they had a moderate experience using the Autodesk Next Gen BIM 360 tools, 21% indicated that they had a good experience using the platform, while 75% of the students stated that they had an excellent experience using the Autodesk Next Gen BIM 360 platform.

Table 4. Frequency and percentages of the experience of participants

Experience using Autodesk Next Gen BIM 360	Frequency n = 47	Percentage of total
Very poor	0	0%
Poor	0	0%
Moderate	2	4%
Good	10	21%
Excellent	35	75%

5 Conclusion

With construction projects becoming more complex and multidisciplinary, the amount of information exchanged between project stakeholders has increased the need for more advanced collaboration and communication technologies. BIM and cloud-based collaborative platforms can aggregate the dispersed information and enhance communication between project stakeholders. In addition to their use in the construction industry, collaborative platforms can also be employed in education to improve the learning experience of construction management students.

This paper explored the use of Autodesk Next Gen BIM 360 as a collaborative learning platform in a Construction Information Systems graduate class. In Fall 2018, 18 students reported the benefits of Next Gen BIM 360 and how it helped them collaborate and communicate with their team members for successful completion of their final project. The students highlighted the ease of use, real-time collaboration opportunities, single data repository, central project communication, design review capabilities, and model coordination as significant benefits of Next Gen BIM 360. However, the platform is not without a few technical difficulties that must be improved upon for a better experience.

Abstract –

Remoteness, although a subjective concept, has indispensable consequences. It can support decision-makers in quantifying risks and feasibilities of developing newly discovered mineral deposits, resilience planning and evaluation of accessibility challenges of remote communities, or support agency budget allocations for much-needed services. Developing a remoteness index typically involves merging spatial and temporal data from a variety of incompatible sources such as topographical, census, and travel cost and duration. This paper presents a novel method for generating a measure of remoteness for any geographical location based on the nighttime satellite imagery. This continuous measure, herein referred to as Nighttime Remoteness Index (NIRI), is generated using machine learning-based models that link the intensity and statistical features of nighttime lights to remoteness; the predictive model is trained and validated using the nighttime satellite imagery and the Accessibility Remoteness Index for Australia (ARIA). This method does not require local data; hence, it is not limited by political jurisdictions or geographic boundaries. The NIRI is developed by using multivariate adaptive regression splines, and support vector machines regressions, after examining several other machine learning techniques. The NIRI maps of Australia and North America are developed based on the validated models.

Remoteness; Accessibility; Resource Projects; Resilience; Nighttime Satellite Imagery; Machine Learning; GeoTIFF

1 Introduction

Remoteness is a relative term. It is defined as "situated far from the main centers of population; distant" [1]. Remote could be used to refer to the fringes of a megacity that have sparse access to public transit or medical aid or to an uninhabited corner of the earth that has rarely seen human activity. Remoteness can be highly subjective, and its labeling can be controversial as it might have social, economic, technical, or political implications associated with it. These challenges may result in inherent biases that can hamper the objective measurement of remoteness.

The quantification of remoteness can assist decision makers in many domains, including 1) risk quantification for construction and industrial projects; 2) the resiliency assessment for communities and their underlying infrastructure; 3) policy making and research regarding resource allocation, public projects, and accessibility to essential services.

First, quantifying remoteness helps in risk assessments of large construction projects. The choice of location is particularly crucial for industrial projects due to their specific demands for skilled labor, material, and equipment [2]. The prevalence of remote projects is on the rise due to several factors. For natural resources projects, the depletion of conventional and accessible deposits has urged explorations in ever distant areas. Infrastructure projects are proposed to connect inaccessible communities and emerging markets to population hubs and open waters. Renewable energy projects such as hydroelectric dams and wind farms are built to harness clean but distant potentials. Quantifying the remoteness risk is an important step in assessing the overall risk of such projects, and in determining their development feasibility. Remote projects suffer from cost overrun, schedule slippage, and operability problems respectively 30%, 29%, and 70% more [3]. The distance to economic hubs represents access challenges to skilled trades and determines the safety and productivity implications of shift rotations that have employees work for several weeks followed by weeks-long leaves. Remoteness also affects access to raw materials, the most suitable modes of transportation, and access to markets or downstream treatments for the products of such remote projects. In this context, remoteness is a measure of vulnerability in adhering to the schedule and budget that make such developments economically feasible.

Second, with ever-growing implications of climate

change and extreme weather effects, understanding remoteness is crucial in creating expert systems for resiliency assessment and planning for remote communities and infrastructures. Physical remoteness is an inherent quality of cities, townships, and communities and plays a major role in assessing their resiliency and vulnerability [4]. A quantification of remoteness can benefit mitigation strategies and response plans for natural disasters. For example, remoteness can function as an input to regional multi-severity casualty estimations [5] or similar vulnerability functions.

Third, accessibility is the inverse of remoteness and while distinct in their perspective, the two are highly correlated [6]. Accessibility reflects the proximity to population centers that have the capacity to provide healthcare, education, and other essential services. Quantifying remoteness and accessibility is essential in policy making and budget allocation for public projects, including public health, education, and infrastructure projects. For example, a measure of remoteness was used to guide the eradication of malaria in Lao People's Democratic Republic. The study's success prompted its extension for achieving similar disease eradication goals and improving overall health in Vanuatu, and the Solomon Islands [7].

Approaches to the development of remoteness and accessibility indices are data intensive, mostly based on census and transportation data that takes a long time to collect and require specific strategies based on the range of their policy implications. Therefore, their applicability and scope are usually limited to certain spatial or temporal contexts due to the restricting nature of their input data and its level of aggregation. For example, an index developed to facilitate policy making on a national level may not be valid at the community level due to the loss of resolution. Remoteness indices are also typically developed for a specific jurisdiction, ranging from local to national, but rarely crossing national borders due to data ownership and compatibility. Even adjoining countries have difficulty comparing accessibility indices since there exists no standard method for their development.

As such, a *universal continuous remoteness index*, developed from a readily available source of data, that is applicable to different geographical, spatial, and temporal contexts can be utilized in a multitude of situations and be of utmost value.

1.1 Objective and Scope

Nighttime satellite imagery is an independent and readily available data source, and it can be used to understand the distribution and the growth of populations over time. The objective of this paper is to examine the potential of nighttime satellite imagery to measure remoteness and to build a continuous remoteness index that can be calculated for any location, and for any time.

Sections 2 and 3 review the related efforts on quantifying remoteness and elaborate on the nighttime satellite data used for the development of the remoteness index introduced in this work. Section 4 discusses the methodology used to develop the proposed nighttime remoteness index (NIRI), while sections 5 and 6 discuss the results, their validity, and finally the conclusions.

2 Approaches to Quantifying Remoteness

The proximity of human settlements to economic hubs is an important factor for countries with large land masses and only moderate populations as they strive to provide essential services to their residents. Two such countries are Canada and Australia who rank 222nd and 228th respectively out of 233 countries with respect to population density in 2018 [8].

Australia is a global leader in the study of proximity for practical purposes. One of the earliest of such studies was an index to distinguish the remoteness of rural areas created by associating population data with grid sections of the national map [9]. The index was based on the distance of the center of each grid to the center of the nearest populated grid. A contour map was drawn reflecting discrete categories of remoteness and accessibility. The remoteness index was later upgraded and named as the Australian rural, remote & metropolitan areas (RRMA) classification [6]. Both indices were criticized due to the subjectivity and the effect of the grid layouts on the index values assigned to specific regions.

In 1998, the continuous Accessibility Remoteness Index for Australia (ARIA) was created using census data to define population centers [10]. Travel times were incorporated in ARIA by overlaying the ground transportation network of roads and highways. This allowed the index to classify a region's accessibility to general practitioners, pharmacies, cardiovascular services, scientific grants, and urban infrastructure. As the index is linked to government funding policies, there was some concern about the fairness and reliability of some of the classifications. Although ARIA was calculated as a nominal index, the published version summarized it as discrete contour maps comprising five remoteness categories. In this way, the impact of moving a line could appear tremendous for communities on or near those boundaries.

A set of indices for remoteness and accessibility was developed for Canadian townships to measure and compare their accessibility to health, retail, and financial services [6]. It largely followed the ARIA methodology but instead of using the driving distance, the indices were scaled by the most affordable mode of transportation to reach the fundamental services. This accounted for the lack of year-round road networks and the local practices

of using travel modes that better suited the region.

3 Nighttime Satellite Imagery

Satellite images are breathtaking and pique our imagination. They contain immense data and have great potential to provide us with valuable information. At first glance, the images can estimate electrification rates if coupled with population data [14]. More generally, they serve as a proxy for human development. Images can be compared over time to understand growth patterns in locations around the world [14].

Economic growth can be seen as the expansion of lighted centers, reductions in the dark spaces between centers, and as the increased intensity of lights in highly urbanized centers. Where reliable statistical data are unavailable, using nighttime imagery to estimate economic indicators [15] and socio-economic factors has proved accurate and effective [16].

Development can also be viewed as a measure of economic equality. With this perspective, the Night Light Development Index (NLDI) [16] measures the intensity of nighttime lights and their distribution and forms a Gini coefficient versus the distribution of the population. In effect, the resulting Gini coefficient interprets the comparative wealth of the neighborhoods without the use of monetary measures of wealth. Significant correlations were found between the NLDI and other data-intensive development factors such as the Human Development Index (HDI), Human Security Index (HSI), and electrification rates. While NLDI provides a spatial depiction of development in a country, it does not reflect an area's proximity to developed centers.

Shifts in economic activity have also been identified using nighttime imagery. The discovery of minerals in one area in Madagascar was made evident by the dramatic appearance and growth of nighttime lights in the area over a period of 5 years. The lights resulted from the development of mining facilities, local commerce, and communities to support workers. The mine was also identified to be the cause of the dimming of light intensity and slowed economic activity at a town further away [17].

Although the use of satellite nighttime imagery has many successes, some shortcomings have been discovered. In mapping global economic activities, satellite nighttime imagery methods were unable to account for activity that did not generate light, such as agriculture [19]. Along the same theme, regional cultural or operational practices, such as restricting the use of outdoor lights at night, can affect the results if the analysts are not aware of local practices. Although nighttime satellite lights are a reliable source for comparative analysis within similar regions, methods to validate findings are helpful in identifying such shortcomings.

4 Nighttime Remoteness Index (NIRI)

This work uses machine learning techniques to develop a predictive model linking the intensity and statistical features of the nighttime satellite data to remoteness. A model is trained to map a feature vector extracted from the nighttime satellite data (i.e., the predictor, or the independent variable) to the ARIA remoteness values (i.e., the target, or the dependent variable). The predictions of this model are further used to develop a continuous remoteness index, herein referred to as the nighttime satellite imagery (NIRI) for any given geographical location. NIRI maps the degree of remoteness to a nominal scale between 0 to 100, with

0 being the least remote, and 100 being the most remote point in the spatial context where NIRI is developed. The NIRI is independent of national boundaries and the data collection and integration challenges often related to local jurisdictions. Using the satellite data available for different time periods, NIRI can be automatically adjusted to reflect remoteness for a given temporal context, and it can be utilized to study changes in remoteness over time.

The majority of work was done in R programing language by taking advantage of Raster library. The maps are developed using ArcGIS® software. The following sections respectively elaborate on 1) the nature and the format of the input nighttime data; 2) the feature engineering and the choices regarding the mathematical representation of the input data in formulating the predictor variables; 3) calculating the target variable; 4) the predictive modeling process, mapping the predictors to target variables; and 5) the generation of NIRI based on the prediction results.

4.1 Predictor Variable: Nighttime Satellite Imagery

National Oceanic and Atmospheric Administration's National Geophysical Data Center (NOAA) published nighttime satellite imagery data annually from 1992 to 2013. Two data sets are available. The average lights data are calculated as the average readings during the year. Readings affected by clouds, moonlight, sunlight, aurora, and glare are excluded. The average stable lights data are further adjusted to exclude temporary light effects caused by, for example, wildfires and visual background noise. The data are available in 8-bit quantized georeferenced tagged image file format (GeoTIFF) as 30-arc-second resolution maps from -180 to 180 degrees Longitude and -65 to 75 degrees Latitude. GeoTIFF is an image file embedded with metadata, such as the reference coordinate system and pixel resolution, and spatial or georeferenced data in the form of pixel parameters [20] [20].

4.2 Feature Engineering

For any location on the map, a feature vector is generated for the purpose of training and testing the predictive models; a series of statistical features and summary statistics are extracted from the nighttime satellite data and in the neighborhood of a given location. This neighborhood is defined by a radius, the size of which can have important implications on the final index. The perceived remoteness of a location will vary depending on the region size and the distance in the context of major construction projects. For example, a site located more than 200km from a populated area can be considered remote in North America but perceived as relatively less remote in Africa [3]. A continuous remoteness index shall be sensitive to absolute distance from populated areas.

Therefore, this paper uses multiple neighborhood sizes to calculate the feature vector; individual feature vectors are calculated for four different influence radii of 100km, 300km, 500km, and 1000km, and they are concatenated together. The feature extraction process is further adjusted to reflect the proximity of open waters, ensuring that the model is expressive to the coastlines. This is intended to take into account the effect of open waters on the summary statistics of a given location; for example, while two locations may have similar readings on the nighttime satellite data, their corresponding remoteness indices can differ based on proximity to open waters.

4.3 Target Variable

In the next step, the target variables are calculated. Because Australia has established a robust and long-term record of indexing remoteness and accessibility, ARIA was used for this purpose. ARIA is published as contour maps, dividing Australia into five classes based on the measure of remoteness (see Figure 1) [11]. For any location, the target variable can be considered as either, first, the remoteness class (e.g., "very remote", that can be extracted from the ARIA map), or second, the actual nominal value of remoteness (ranging from 0 to 15 in the case of ARIA). The former formulates a classification problem that links the predictor variable (i.e., readings from the nighttime satellite images, see section 4.2) to their corresponding class of remoteness. This does not allow for introducing a continuous index that accounts for the gradient changes in remoteness. The latter choice results in a regression problem; and hence, allows the development of NIRI as a continuous index. However, nominal ARIA values are only known for the classes' borders from the overall map. The latter was used in this paper.

4.4 Predictive Modeling

The feature vectors and the target variables are passed to a machine learning model; several algorithms from regression-based modeling techniques were used for the purpose of predicting the target variable using the predictors, including the linear regression, the multivariate adaptive regression splines (MARSplines), the support vector machines regression (SVR), and the k-nearest-neighbor regression. Several validity tests were performed on the prediction results including the stratified random resampling and a non-random geographic split test. The residuals were carefully investigated to avoid overfitting and modal behaviors.

Moreover, an iterative model tuning campaign was carried forward to optimize the behavior of the models based on various definitions of cost parameters.

4.5 NIRI Development

The predictive models map the intensity and the statistical features of the nighttime data to the ARIA index. In this step, the model predictions are normalized across the geographical context for which the NIRI maps are being developed (e.g., across the entire map of Australia). The normalization allows for the resulted NIRI to specify the remoteness of any point at a value between 0 and 100, reflecting the relative remoteness of that location within its spatial context. This also allows for comparison of NIRI values between geographical locations, and it makes NIRI applicable to all regions.

When expanding the use of NIRI to other regions, the index shall be normalized based on the context of the region in question. It must be separately developed for countries with major cultural and geographic differences. This is due to the different mechanism of illuminating cities and population settlements across the globe, the geographic and cultural differences, among others [17].

5 Validation and Discussion

To train and test the predictive models, more than 7000 data points were selected on the region borders of the ARIA map (i.e., where the nominal value of remoteness is known). The feature vectors were calculated for all these locations using the process described in section 4.2.

The accuracy of the models is established by performing several validity tests, including the geospatial half split test; the ARIA map is split in two halves; the models are trained on one half, and they are used to predict the remoteness values in the other half. The best performing model is used to predict remoteness and develop the NIRI maps based on the normalization steps described in Section 4.5.

5.1 Results

Among the trained models, the SVR achieved the highest coefficient of determination, R^2=0.94 while, MARSplines produced similar results with R^2=0.93. Both models performed reliably in terms of the residuals. The non-random geographic split test, using Eastern Australia data to train and Western Australia data to test posed the highest challenge to coefficients of determination, however, it resulted in R^2=0.85 and R^2=0.84 for SVR and MARSplines, respectively. The SVR produced slightly less normally distributed residuals for the geographic split test in comparison to MARSplines, and hence, MARSplines is less prone to overfitting and more appropriate for these data. Therefore, MARSplines is chosen as the best performing model and is used hereafter to create the NIRI maps using the procedure described in section 4.5.

Figure 2 and 3 show the NIRI maps of Australia and North America, generated using MARSplines model and the nighttime satellite data of 2011. Figure 4 shows the superimposition of NIRI contours (iso-remote lines), on the average stable lights of North America for 2011. NIRI envelopes the light clusters normal to the direction of remoteness gradient from population centers to remote areas with great accuracy.

5.2 Discussion

The spacing of the corresponding grid to build the index determines the resolution of the ultimate NIRI map and has an immediate effect on its accuracy as well as the computation time. The triangulation error increases as the resolution of the grid increases, subjecting the corresponding maps to both random and systematic errors. More importantly, larger grids mean that each point represents a larger area. This increases the occurrence of index locations that do not represent their areas. To examine the sensitivity of the grid size on the accuracy of the map, analysis was performed to identify the potential systematic and random impacts on the results. Figure 5 plots the average and standard deviation of NIRI for a region in the southeast of Australia encompassing Sydney and Melbourne for four grid sizes ranging from 0.2 to 1.2 degrees. The random error disappears as the average and the standard deviation of the index start to converge in grid sizes below 0.8 degrees. Therefore, depending on the size of the coverage area, the desired resolution, and the computational power available, a grid size of 0.8 degrees or smaller produces reliable results.

Because NIRI is a continuous index, it allows establishing remoteness contours at any interval and for any region. Once the models are built to link the nighttime satellite imagery to remoteness as the target variable based on Australia data, the same models can be used to compute NIRI for other regions of the world. This extends the use of the index to a variety of applications. Once the model is run, the relative remoteness difference between any two points can be measured for risk assessment and other purposes.

NIRI can be used to better understand and quantify the resiliency of communities and their underlying infrastructure. In the case of infrastructure resiliency, NIRI can be used as an additional factor to improve mitigation strategies for natural disasters [21]. Combining an understanding of remoteness and accessibility with casualty estimations can optimize the use of the limited resources in the face of natural disasters such as earthquakes, tsunamis, and hurricanes.

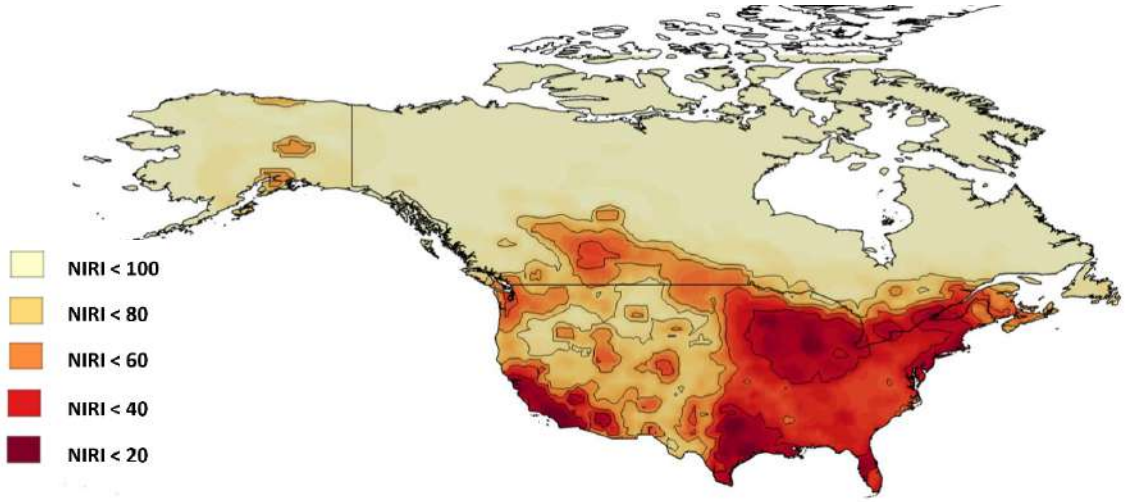

Figure 3: NIRI Map of North America for 2011

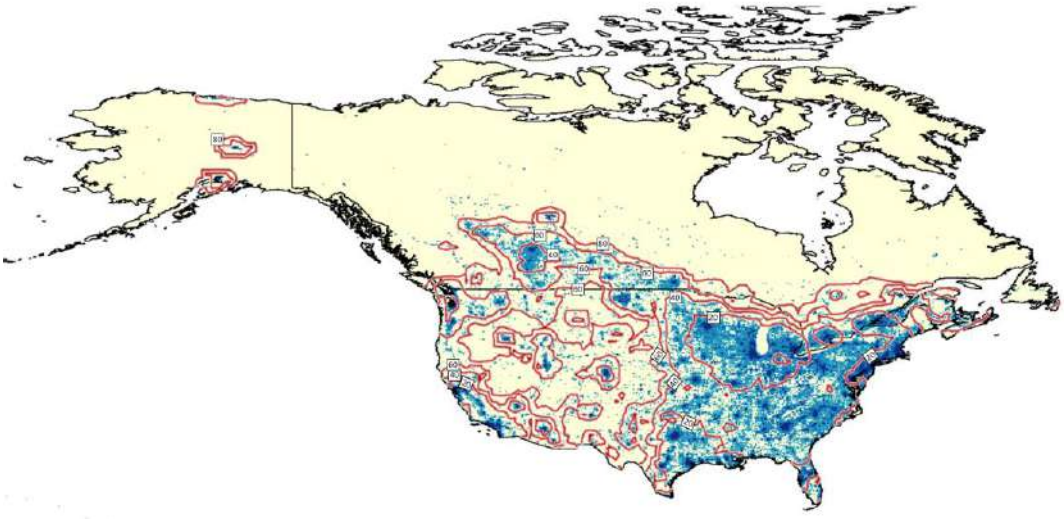

Figure 4: NIRI Contours (Iso-Remoteness Lines) Superimposed on Average Stable Nighttime Lights of North America for 2011

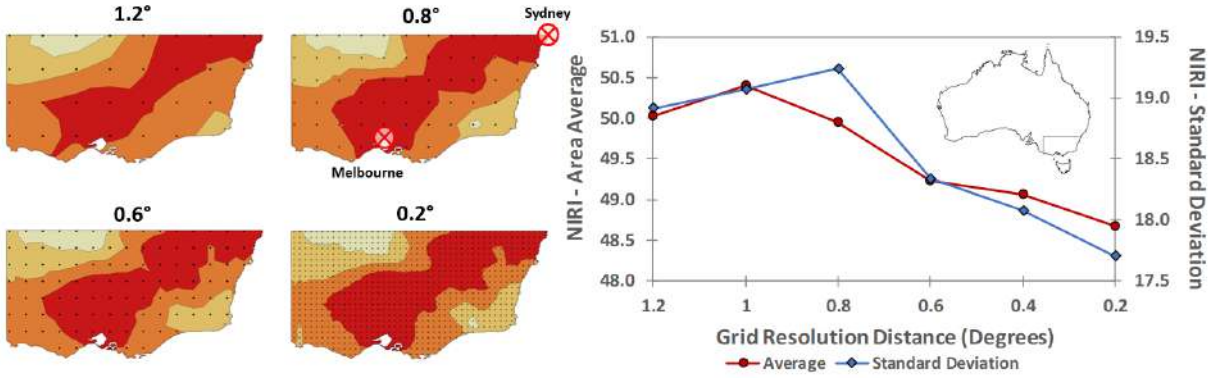

Figure 5: Grid Spacing Sensitivity Analysis Results

Regional remoteness indices were directly utilized in vulnerability analysis of road networks for south east Australia [22], such frameworks and programs can be expanded to any other part of the world by utilizing NIRI. Several models are proposed to forecast damage and severity for seismic events. For instance, NIRI can be a direct input to regional multi-severity casualty estimations [5] and Earthquake vulnerability functions [23] to calibrate those models for physical location characteristics. Previous studies have linked remoteness to both resiliency and vulnerability of communities and proposed adaptation pathways to consequences of climate change and extreme weather events to those communities [4]. NIRI can quantify remoteness for implementation of such strategies.

Moreover, NIRI can help in research applications at a variety of economic and social sciences' fronts. Satellite data in general [24], and nighttime satellite imagery in particular [15~19] have been effectively used in several studies to explore various economic outcomes including poverty. Separate studies have established links between the prevalence of poverty and remoteness characteristics of communities [25]. NIRI can be utilized effectively as an input to such models to better understand similar phenomena.

6 Conclusions

Remoteness is hard to measure, yet it is a crucial factor in determining the success and feasibility of large international projects and assessing the resiliency and vulnerabilities of remote communities. The existing means of quantifying remoteness require extensive data collection and are based on the integration of multiple data sources. A global measure of remoteness is needed that is not limited in terms of its applicability to different geographical contexts and time periods. This paper proposes a novel method that exploits the readily available nighttime satellite data for developing a continuous measure of remoteness that is not limited to local jurisdictions or certain borders. While most research on nighttime satellite imagery has been focused on the characteristics of illuminated clusters and its relationship with human development, this paper links the lack of such light clusters to remoteness.

In this study, the nighttime satellite imagery proved to accurately predict a multidimensional composite index of remoteness. The nighttime data is used as a predictor of remoteness and to create a continuous remoteness index, NIRI, that describes remoteness and its directional gradient with great accuracy for a variety of risk and resiliency assessment tasks.

NIRI can be developed across different regions and as well in time. Although this paper only used 2011 data to establish the predictive model, the index can be developed using nighttime satellite imagery of other points in time. This allows NIRI to measure the changes of remoteness not only across regions but also across time.

Acknowledgments

We benefited from comments of Murray Pearson and Nick Mason in formulizing the index to best suit practical risk assessment procedures of large construction projects. The project is funded by Hatch Ltd. and Natural Sciences and Engineering Research Council (NSERC) of Canada grant CRDPH 491877-15.

Abstract –

The type and quantities of formwork system are necessary information for construction process of a concrete-framed building and the solution to this problem usually lays on the shoulders of specialized consulting firms or contractor's engineering department. These calculations are generally performed using available procedures and guidelines. The conventional formwork design process is manual and time-consuming, which requires considerable experience and attention to details. The emergence of building information modeling (BIM) in the AEC industry has allowed automation of many time-consuming tasks through application of object-oriented 3D modeling. In this project, a system was developed to automate formwork design process for the concrete-framed buildings. This method first extracts required data for the formwork design from the building information model of the project, which includes concrete elements' dimensions, quantities, and spatial information. It then applies formwork design rules and a database of modular formworks to determine dimensions and type of the formwork for each element. This system demonstrated promising performance in automation of formwork design in two test models.

Keywords –

Formwork design; Construction; Automation; Building Information Modelling; Reinforced Concrete

1 Introduction

Formworks are auxiliary structure made of wood, metal or composite materials; which serve to temporarily maintain shape, geometric dimensions, position in space, surface texture, and solidity of the structures that are made of shapeless or bulk materials, namely fresh concrete [1]. Formwork (also called shuttering) systems typically consist of forming elements, supporting structures, and fasteners [2]. After hardening of the concrete, formwork elements are usually removed (called detachable formwork), but there are also permanent formwork systems which are not removed and become a part of the main structure [3]. Both of these systems are widely used in modern concrete construction [1], but the removable formworks are more common and are classified based on their function, design, and material. Formwork systems for various structural members are slightly different from each other. For example, column formworks include struts whereas props are used for beams and slabs construction [1].

Traditional timber formwork systems are known for ease of fabrication and installation, and economical benefits in small construction. Aluminum and steel formworks usually cost more than wooden systems and are used in large-scale and high-precision construction. Moreover, these formworks can be used multiple times and they are more efficient for fast installation and removal of formwork, which in turn reduce the cost of form working after each use [3].

Conventional formwork design is a time-consuming and heuristic process, and is often based on the skill and experience of the engineers [4], and strength and the quantity are the main parameters in the design of a formwork system [2, 3]. A well-designed formwork system contributes to the quality, and timely and cost-effective construction of a reinforced-framed concrete building [1, 3]. Designing of a concrete structure and its formwork system are usually carried out separately, where the structural engineers design the concrete structure, and then the contractor designs a formwork for each element based on the dimensions and geometry of that component [5]. Therefore, development of automated formwork design tools would assist site engineers with the process of determining a suitable formwork system.

Earlier research efforts summarized best practices for design of a formwork system and proposed step-by-step guides and specific tables to speed up the process of formwork design [6]. Later, a Fuzzy logic-based model was proposed to assist site engineers in selection of a suitable vertical formwork system [7]. In addition, a

mathematical formwork design method integrated with formwork operation layout planning demonstrated promising performance in high-rise building construction [8].

The multifaceted capabilities of the BIM have encouraged the use of this platform in the design and planning of on-site construction processes. The abilities of BIM to generate, store, share, and reuse information of building components are useful for repetitive tasks such as document generation, visualization, and quantification [9]. Application of BIM for different analysis, such as construction energy analysis [16], planning of construction processes [17, 18], and cost estimation [19], could reduce human errors of manual processes. Therefore, later efforts employed building information modelling to improve formwork design and planning processes. For example, a rule-based model was developed to assess the constructability of the horizontal formworks [10]. A cascade method was proposed which extracts required data (such as quantity take-off and construction phases) from the BIM model and uses them to design a formwork system for the project [5]. Industry Foundation Classes (IFC) schema was employed to optimize formwork design of concrete walls in building construction [11]. Later, a method was proposed to increase the proportion of the modular forms to increase formwork efficiency [12].

In addition to the formwork design, BIM-based data could be used to estimate labor productivity in formwork operations [13], and to determine required consumption of formwork systems [20]. These research efforts, however, did not present customizable approaches. In particular, most of these systems used a certain type of modular formwork system and did not search among various modular alternatives, and also did not investigate traditional timber formwork systems.

This paper presents a customizable system which was developed using a visual programming environment to extract data of cast-in-place concrete elements form BIM model and then designs a formwork system using a database of modular formworks from different suppliers. Upon the user request, this system is able to design traditional timber formwork for the concrete elements.

2 Methods

The workflow of this method is presented in Figure 1. It extracts certain attributes of the cast-in-place concrete elements, which are identified based on the corresponding codes, such as type and reference level. Then the system calculates pressure of the concrete based on the dimensions of each element. Afterwards, the system selects formwork elements based on the preference of the user between modular and wooden formwork systems. It should be noted that the system is only able to process prismatic elements rectangular cross-sections. Following subsections discuss the modules of this system.

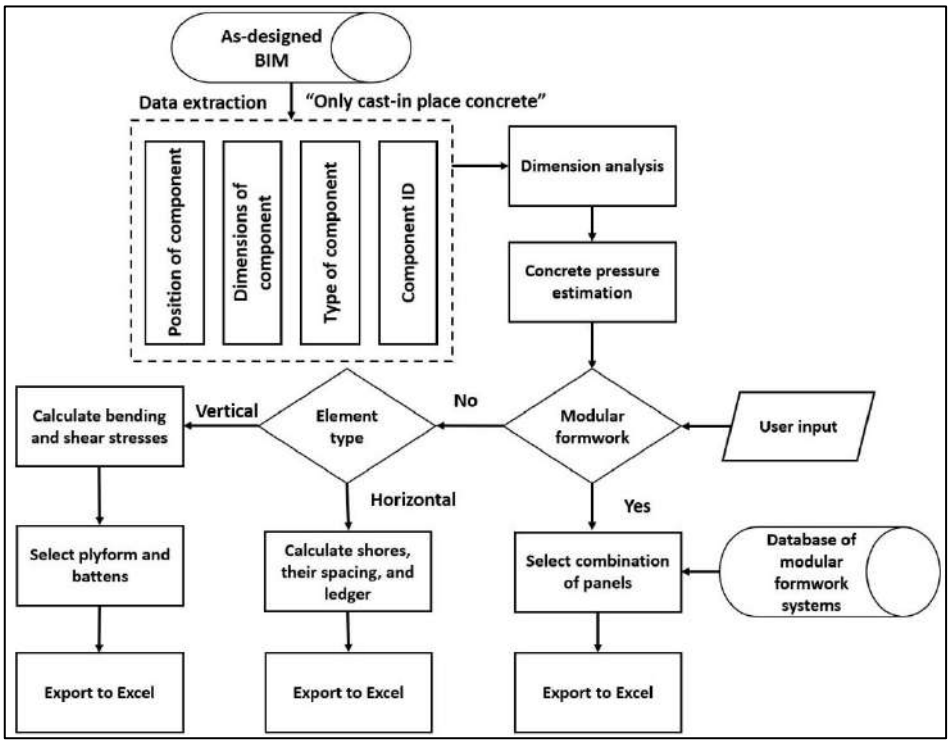

Figure 1. Workflow of the proposed system

2.1 Data Extraction

Dynamo environment [14] was used to automate the data extraction process. Dynamo is a visual programming and open-source platform for automated interaction with BIM models, which has the ability to extract various attributes of building elements.

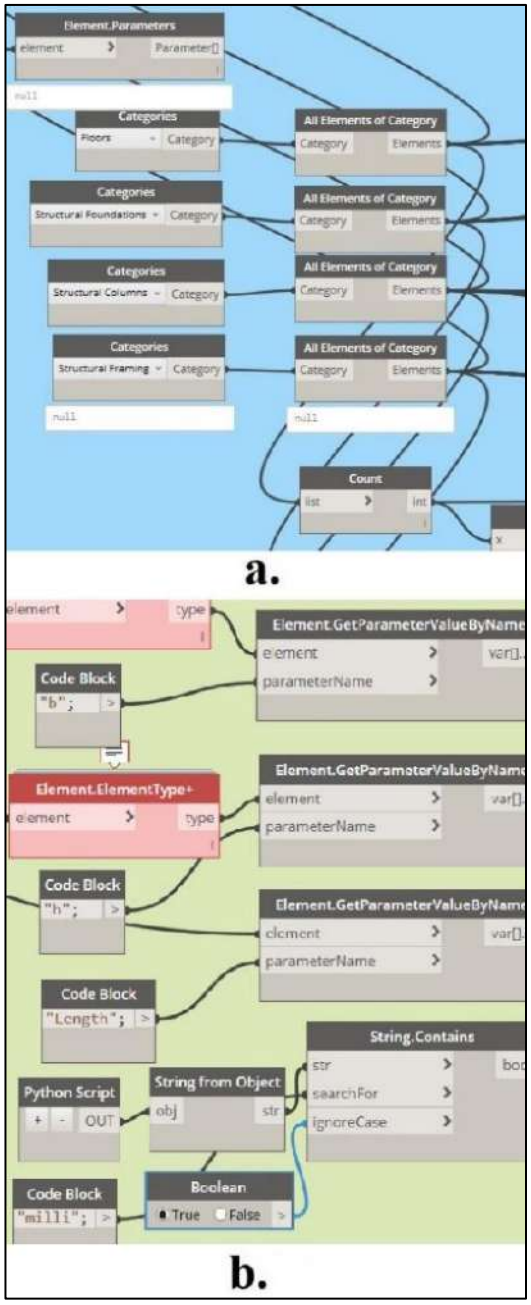

Figure 2. Data extraction using Dynamo functions: a) selection of elements of interest; b) selection of the target attributes

This module extracts the following data for each concrete element: dimensions (width, depth, height), ID (e.g. gridlines), type (e.g. column, beam, slab, foundation), and its level. Figure 2.a depicts a small part of this script which uses "Categories" and "All Elements of Category" to select all elements in the target categories, and then "Code Block" and "Element.GetParameterByValueName" are employed to extract the attributes of interest. For example, Figure 2.b shows a part of the script used the extract dimension of the columns.

2.2 Concrete Pressure Estimation

2.2.1 Vertical Load Estimation

There are two main types of vertical loads: 1) Dead loads include weight of fresh concrete, rebars, and the formwork; 2) Live loads consist of the weight of equipment, workers, and other related items. Based on the guidelines in ACI 347R-14 [15], the live load should not be less than 2.4 kPa (assuming no motorized cart is used) and the unfactored combined load (dead + live) should be more than 4.8 kPa (6.0 kPa in case of using motorized carts).

2.2.2 Lateral Pressure Estimation

Lateral concrete pressure depends on the dimension of concrete elements. The lateral pressure exerted on the formwork walls (see Figure 3), which was estimated based on the guidelines provided in ACI 347R-14 [15]. The lateral pressure of the fresh concrete depends on a few main factors, namely slump and temperature of the concrete and rate of concrete pouring. Two conditions were implemented in this system which should be selected by the user based on the properties of the concrete and pouring conditions. Equation 1 should be used for high slump concretes (greater than 17.8 cm) and concretes with deep vibration (greater than 122 cm), which simply calculates the equivalent hydrostatic pressure of the concrete. The lateral pressure for other cases is calculated using Equation 2. These equations were implemented in the Dynamo environment using "Python Script" node, which enables development of customized functions within the Dynamo platform.

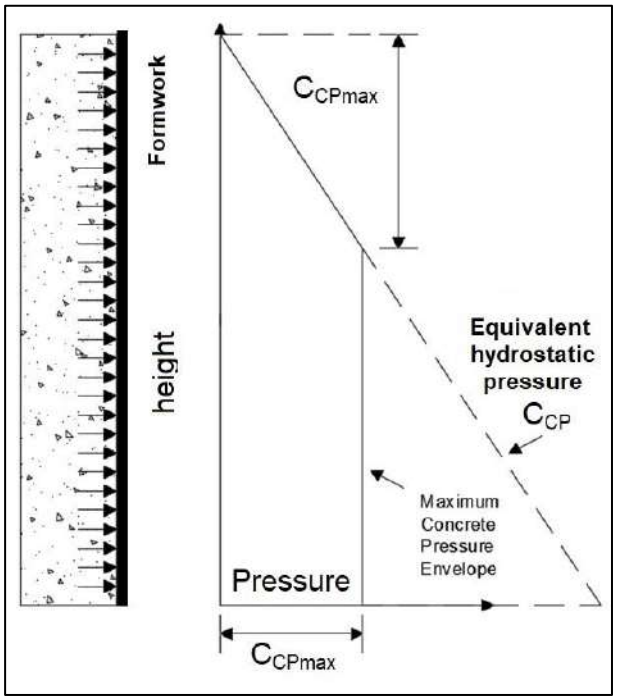

Figure 3. Schematic view of the lateral concrete pressure [15]

$$C_{CP} = \text{wh} = \rho gh \quad (1)$$

$$C_{CPmax} = C_c C_w [150 + \frac{900R}{T}] \quad (2)$$

Where C_{CP} is the equivalent hydrostatic pressure, w is unit weight of fresh concrete, h is the height of the element, C_{CPmax} is the maximum concrete pressure, C_C is chemistry coefficient, C_W is unit weight coefficient, R is the rate of placement ft/h (m/h), and T is the temperature of fresh concrete °F (°C).

2.3 Modular Formwork Design

Lists of modular formwork systems from four manufacturers were created. These lists include name of the manufacturer, admissible load (Kg/sq.m), width, and length of the available panels by each manufacturer (see Figure 4). Selection of formwork panels for concrete elements is carried out by a special "Python Script" node, which requires a number of inputs, including the name of the manufacturer, admissible load of the formwork panels in kg/sq.m, list of available panel dimensions for that formwork system, and the dimensions of concrete element.

When the system analyzes a vertical element (e.g. columns), the length corresponds with the vertical axis, and 0 to +0.30 m tolerance is accepted for this dimension. The same tolerance is applied for the side formworks of horizontal elements, namely beams. If there are more than one manufacturer for an element, then the program will eventually select the type that has appeared the most in all of the solutions. It is also possible to include unit cost of each type; thus, the system determines the lowest cost option.

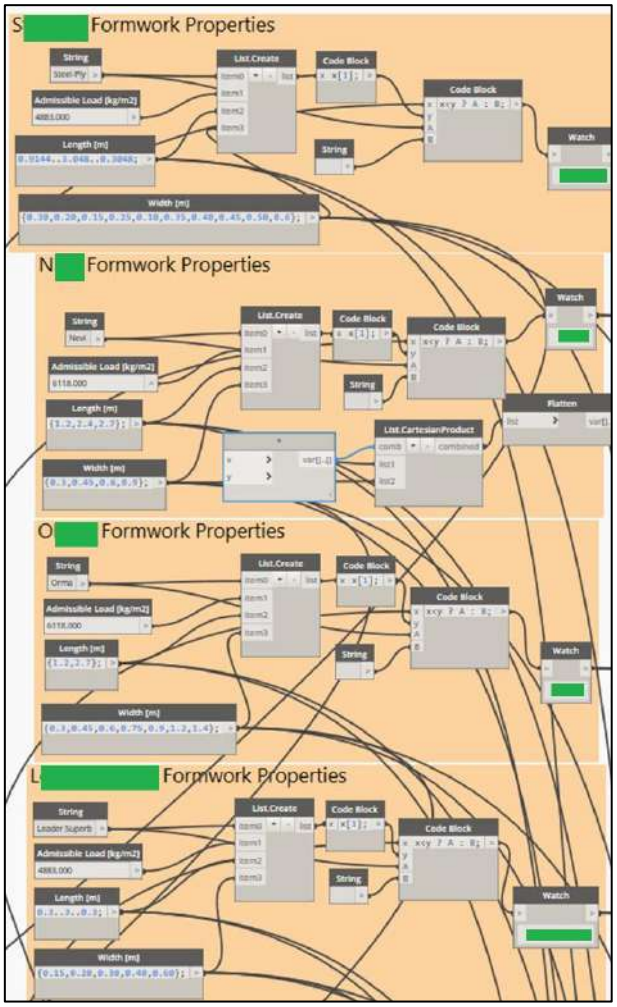

Figure 4. Lists of formwork systems from four manufacturers (names are covered)

The system identifies width (w in Figure 5) and length (l in Figure 5) as the smaller and larger dimensions of each formwork surface, respectively. The panel selection process iterates over the list of available dimensions from the manufacturers lists (using for loops) to find combinations that completely cover each formwork surface. It should be mentioned that this algorithm only uses panels from a same manufacturer to create a combination. This process is illustrated in Figure 5.

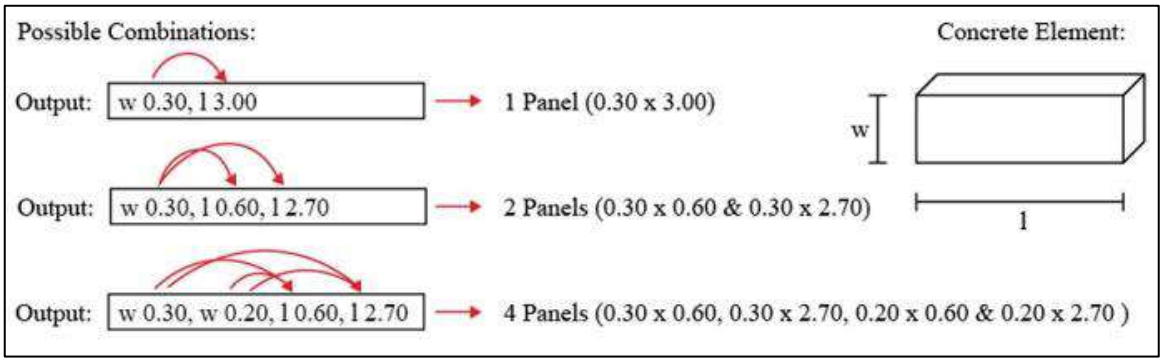

Figure 5. A sample workflow for selection of a panel combination

2.4 Conventional Timber Formwork Design

If the user chooses timber formwork option, the system calculates formwork elements based on whether they are vertical or horizontal.

2.4.1 Vertical Elements

The lateral concrete pressure acts against the plyform, which is supported with vertical wood battens laid flat. The plyform panels must transfer lateral pressure to the adjacent vertical wood battens. There are different types of wooden formwork products with different mechanical and physical (e.g. moisture content) properties, and dimensions, but a small number of options was used in this prototype. The plyform must have adequate strength to transfer the pressure with supports spacing up to 18 cm. The main criteria for selection of the plyform and battens is to pass the allowable bending and shear stresses. The calculations were implemented according to the design procedures available in [3].

In this approach, the system starts with a plyform with the smallest thickness, and if it fails, then it tries the next thickness until it reaches the allowable stresses. The same approach is used for the battens.

2.4.2 Horizontal Elements

This part of the system calculates three main items: shore spacing for the bottom part, ledger spacing, and shore design. These calculations were implemented according to the procedures provided in [1].

The shore spacing is calculated based on the bending due to the vertical loads and the bending capacity of the bottom surfaced two sides (S2S) lumber. The ledger spacing is also calculated based on allowable stress of the selected (surfaced on 4 sides) S4S ledgers and the stresses due to concrete load. Then based on the spacing of the shores, the applied load on each shore is calculated and compared against the allowable load of the unbraced shores.

2.5 Exporting Results

At the end, generated results are organized and exported to MS Excel for presentation. This process is implemented using a series of nodes, namely "Excel.WriteToFile" function. This way, the system arranges formwork information in a tabular format with all the necessary parameters such as element ID, level, family type, dimensions, and the proposed panel combinations and manufacturer.

3 Case Study

A five-story and four-story reinforced concrete-framed buildings were modelled in the Autodesk Revit environment. Isolated footings were used for foundation and beams and slabs were used for the flooring systems. Figure 6 depicts a 3D view of the five-story building model.

Figure 6. A 3D view of the test model

Figure 7 presents a sample of the results generated for modular formwork in the Excel environment. All the mentioned properties are organized and presented for the user.

b.

Figure 7. Sample tabular output: a) sample columns; b) sample beams

In addition, these formwork data can be imported in the Revit environment and saved as a parameter for the corresponding case-in-place concrete objects, and then be visualized for each element. Figure 8 displays a sample of a formwork combination added to the BIM model in Revit environment.

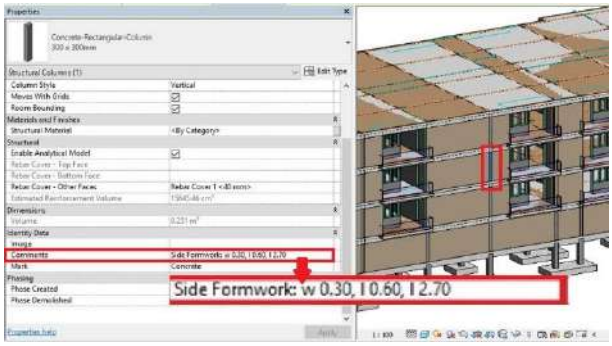

Figure 8. Sample of a formwork combination added to the BIM model

The system was also tested in designing of a conventional timber formwork. For this purpose, a simple BIM model, containing four columns and four beams, was used. Figure 9 shows the result for one of the column formwork designs (the results are drawn manually).

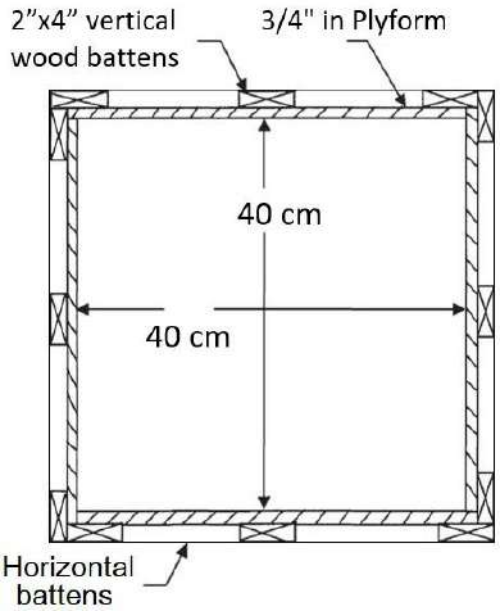

Figure 9. Cross-section of the wooden formwork for a 40x40 cm column

The results of this method and its modules was assessed to validate its performance. First, the outputs of the data extraction part were compared against the BIM models, where no difference was found. Second, the concrete pressure estimation correctly estimated vertical and lateral pressures. Next, selected panel combinations were validated, in which the system was able to provide a sufficient combination for each element; however, the results do not necessarily represent an optimized combination. Because this system does not consider form working state of other concrete elements and the availability of formworks. Moreover, performance of

this system is limited to prismatic elements with rectangular cross-sections and further expansion is needed to analyze curved elements and the concrete components with irregular shapes and openings.

4 Conclusion

Formwork systems are essential part of cast-in-place concrete construction and automated design of formwork systems could improve this design process by saving time, and enhanced visualization and documentation. This research paper proposed a BIM-based decision support system to design modular and conventional wooden formwork systems for concrete-framed buildings. This system was implemented in the Dynamo platform, which extracts required data of cast-in-place concrete elements, and then calculates concrete pressure on the formwork surfaces. It finally tries different panel combinations to obtain a sufficient combination for each concrete element. This system demonstrated promising performance to facilitate formwork design processes in concrete construction, and the same data extraction and analysis could be used to develop automated tools for similar problems. The future research will focus on the analysis of irregular shapes, and also will investigates optimization of the formwork systems by considering overlapping and succeeding formwork activities.

Abstract –

Construction sites require many efforts to be well organized due to the complicated tasks and various construction machines. Recently, computer vision technology has gained success in the construction research field. By deploying single or multiple cameras, we can extract construction information from videos and then help the project manager to understand what happened in real-time. This paper presents a method of checking construction machine status automatically by cameras. We assume that the camera is installed in a high position, which provides clear views for the whole site. This research focuses on extracting the machine information from videos, comparing with construction schedule and feedbacking to project manager for further decision making. In the preliminary stage, a deep learning detector has been employed for detecting active construction machines. Meanwhile, a construction image dataset has been organized for training deep learning models precisely and robustly. This dataset also helps to promote this method to generalized construction scenarios. Comparing the number of active machines of video and the expected number of machines from the schedule, the project manager will get real-time feedback and alerts when missing construction machines. In the future steps, we will develop a method to understand construction activities from videos and highlight important activities automatically. Once the reliable method has been developed, it will benefit the project manager to monitor construction sites from an easier way.

Keywords –

Construction Machine; Computer Vision; Deep Learning

1 Introduction

Construction machines have participated the most of construction activities, and they are essential for any construction processes [1]. Properly using and monitoring of machines contributes to the economy, speed, and quality of projects. It is difficult to track the working machine status, especially in a large construction site. The traditional way of monitoring construction machine is employing a worker to record the information and report to project manager each day. Manually checking of machines is tedious, time-consuming, error-prone, and not safe [2].

Furthermore, the recorded information cannot be feedbacked to the project manager for making a real-time decision. Recently, computer vision technology has succeeded in medical imaging, human-computer interaction and autonomous driving [3]. This technology also shows great potential in construction management. In this paper, we present a method of automatically checking construction machines from the video stream.

By deploying the camera in a high position of construction sites, such as the crane boom and existing high-rise buildings, the camera captures the entire footprint of construction sites. In this research, we have developed a method to extract machine active status from the video stream and comparing the number of active machines with the project schedule. The deep learning detection algorithm YOLOv3[4] has been employed to extract machine category and position from videos. A construction image dataset has been built with the purpose of training deep learning models. Until now, 5,000 images have been collected and manually labeled for construction object detection. This dataset will be kept developing in order to train deep learning detectors and make these methods generalized in more construction scenarios. Then the expected number of active machines can be extracted from project schedules. The comparison results will be summarized in the active chart and feedback to project managers in real-time.

This method benefits project managers and enables them to monitor construction machine status more

directly. If any machine is missing when compared with the planned schedule, the project manager will be notified immediately and they can coordination among construction crews to figure out the problem. The machine active information can be recorded every day for documentation purpose. In the future, we will focus on how to understand construction activates from videos, highlight essential moments for project managers, and help them control the project schedules. A user interface will be designed to display essential information and enable users to search their interested information.

2 Literature Review

In this section, recent studies on object detection methods are reviewed. Then, applications of computer vision technology in construction management are presented. At the end, the evaluation criteria which are widely used has been introduced.

2.1 Development of Object Detection

Object detection refers to detecting instances of semantic objects of certain classes from digital images and videos [5]. The sliding-window paradigm has a successful history in classic object detection, which applies classifier on dense image grid. Viola and Jones [6] have introduced boosted detectors into face recognition. The HOG (Histograms of oriented gradients) [7] provides effective features to pedestrian detection. DPMs [8] are based on part-based deformable models and had achieved the best performance on PASCAL VOC dataset [9] before the introduction of deep learning models.

Recently, the Convolutional Neural Networks (CNNs) methods become the dominant in object detection. The CNNs detector has two categories, which are two-stage detector and one-stage detector. In two-stage detectors, the first stage generates a bunch of candidate regions which may contains expected instances, and the second stage employs classifier to filter all instances into categories. R-CNN [10] has adopted AlexNet [11] and SVM [12] into the second stage and achieved higher performance on VOC dataset. R-CNN has been enhanced in boost precision and speed recently [13], [14].One-stage detectors do not have the first stage of generating candidate regions.

One-stage detectors, such as YOLO and SSD [15], have excellent performance in speed. Recent researches have shown the two-stage detectors perform better in accuracy than one-stage detectors, while one-stage detectors are much fast. Although, recent work shows that two-stage detectors can be faster by reducing the input image resolution and proposal regions [16], one-stage detectors are the better choice for real-time applications. All object detection methods have faced a large class imbalance problem in training, which means these detectors evaluated thousands of candidate regions per image but only a few of them contain objects. The focal loss [17] has been introduced to figure out this problem and allow us training deep learning detectors effectively.

2.2 Applications in Construction

There are many researches and applications that have been developed in construction management with the assisting of computer vision technology. The applications can be categorized as productivity estimation and safety control. For productivity estimation, Weerasinghe and Ruwanpura [18] tracked construction resources with the purpose of reducing waste. Rezazadeh and Brenda [2] have developed an automated method to detect dirt-loading cycles in earth moving tasks. Xiao and Zhu [19] have compared fifteen tracking algorithms in construction scenarios in order to identify the most efficient algorithm. Yang et al. [20] have employed Gaussian background subtraction to detect crane jibs and then make sure the crane operates in good environment.

Construction has become one of the most unsafe industries because of the high risks exist. According to previous study [21], there was more than 2500 annual deaths accompanied in construction sector from 1994 to 2014 in China. Computer vision technology is able to help safety management from comprehensive ways [22]. Han and Lee [23] have developed a system to detect workers and machines. This system protect workers from potential collisions from video streams. Deploying multiple cameras in construction sites can reconstruction 3D clouds of workers, which tracks worker motion precisely [24]

2.3 Evaluation Criteria

Evaluation criteria is important to estimate detectors. Precision and recall are the most common criteria for object detection [25]. Precision refers to the fraction of correct instances among all retrieved instances, while recall means the fraction of correct instances among total ground truth instances. Figure 1. shows the definition of True Positive (TP), False Positive (FP), False Negative (FN), and True Negative (TN). The precision and recall can be then defined as follows.

$$Precision = \frac{TP}{TP+FP} \quad (1)$$

$$Recall = \frac{TP}{TP+FN} \quad (2)$$

Mean average precision (mAP) is another metric that measures the performance of CNN detectors [26]. mAP is the average of maximum precisions at different recalls. The average precision can be calculate as the

average of precisions in 11 recall levels, which from 0.0 to 1. The formula has been defined as follow. The mean average precision is the average of AP in each object class. In this study, we will use mAP to evaluate the deep learning detector.

$$AP = \frac{1}{11}\sum_{r\in\{0.0,0.1,\ldots,1\}} AP_r \quad (3)$$

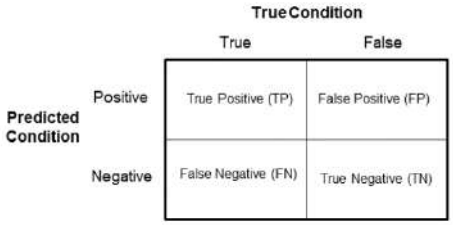

Figure 1. Definition of true positive, false positive, false negative, and true negative

3 Methodology

Figure 2. illustrates the overview of the methodology of machine status checking pipeline. There are four main parts of this method, which are building the dataset, training YOLOv3, detection and visualization, and feedback. In this section, we will introduce each part in details.

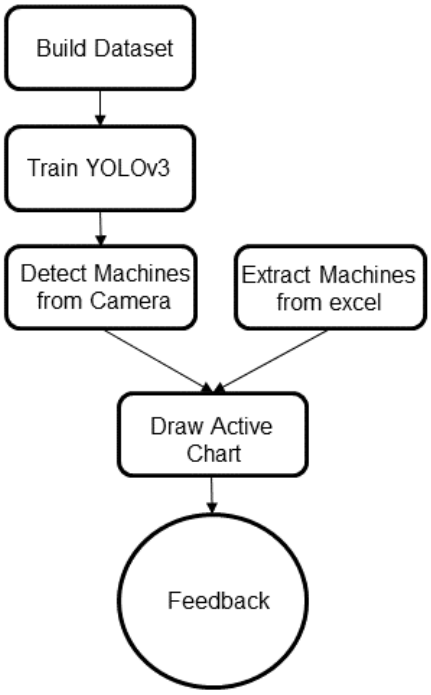

Figure 2. Overview of methodology

3.1 Build Dataset

The biggest challenge for deep learning detection is the limited data. The sufficiently large number of data helps the deep learning model robust and generalized. Since the proposed method will employ the deep learning detector and there not exists construction detection dataset, we have worked on building a new construction image dataset, which contains common construction machines. Over 200 construction videos, which come from YouTube channels, real construction projects, and other datasets, have been collected. 5000 images have been extracted and manually labeled to build this dataset. The entire dataset is divided into training set and testing set, while 80% of images in training set and 20% of images in testing set. In this dataset, there are four types of construction equipment, which are truck, excavator, loader, and backhoe. It shows that 22% of instances in our dataset contain have the size smaller than 5% of the whole image, while 25% of instances have the larger size than the 60% of the entire image. This distribution shows our dataset has both close-up equipment images and bird-view images. A large number of images helps to train deep learning models and generalize into common construction scenarios.

3.2 Training YOLOv3

YOLOv3 is a one-stage state-of-art detector with extremely fast speed. YOLOv3 has shown excellent in COCO dataset [26] with the mAP of 0.553. In this study, the image input size is 416x416 and this algorithm can process 30 images in one second. Compared with some two-stage detectors, the performance of YOLOv3 is slightly low, but the speed is much faster and that is important for real-time applications. The construction detection dataset from the previous step is used for training YOLOv3, which takes 12 hours for the training process. The mAP of YOLOv3 on our testing set is 0.87 from an overall view, where the AP is 0.71 in the truck category, 0.93 in excavator category, 0.91 in loader category, and 0.93 in backhoe category. The validation result shows YOLOv3 fits well in our dataset and could be used in other construction videos.

3.3 Detection and Visualization

This part refers to three steps of methodology in Figure 2, which are detecting machines from the camera, extracting machines from excel and drawing the active chart. In the detection stage, the image stream captured from cameras will be put into YOLOv3 model in real time. The detected images with bounding box will show to users for visualizing the object detection (Figure 3). The detection performance directly effects the overall performance of the entire system. The detected

information, which includes the number of each category of machines, sent to the next step for drawing the active chart.

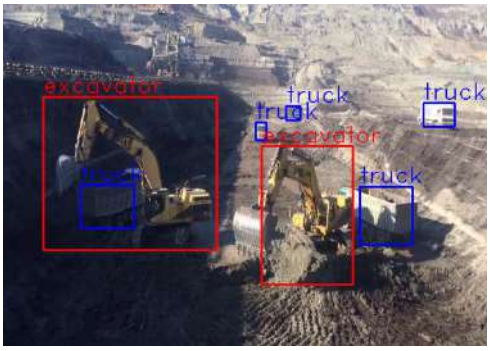

Figure 3. An example of detected images

The excel file of project schedule has been parsed to extract the machine numbers during this time. The information extracted from an excel schedule can be specific to one hour by one hour. The active chart will be drawn to visualize the number of machines active from the camera and construction schedule. Figure 4 shows an example of active chart, which is monitoring excavators and trucks. In the active chart, the jet colormap represents the number of machines, and the horizontal axis represents the time.

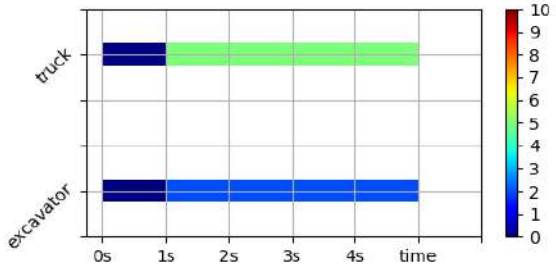

Figure 4. Active chart of describing machine amount

3.4 Feedback

The active chart shows the real-time machine status in construction sites. In each hour or few minutes, the checking system summarizes the active machine chart in this term and saves in local files. The system will notify users with a short sentence, such as "2 trucks and 1 excavator are missed at 14:00pm", when there is a mismatch of detected and scheduled information. The historical information of missing equipment will also be recorded including the timestamp, machine category, missing numbers to local files. This feedback process supports the project manager to document construction activities and active machine status. These files saved with original videos for further purpose. This system expected to help project managers generate construction logs for documentation purpose.

4 Results and Discussion

The construction machine checking system has implemented by Python and C language. All training and detection process was running on an NVIDIA 1080Ti GPU. The testing video has the duration of one hour, which recorded the earthmoving activity. The monitoring object is excavator and trucks. The expected machine number has been manually set up in the excel file, and the number changes every ten minutes. The detection result updated 25 times in each second and the active chart updated by seconds.

To evaluate our system, we use success rate (SR) to describe the performance. Construction sites are slowly moving, and we decided to check the machine numbers in every minute. If the detected machine number is the same as the ground truth from this frame and the feedback information is correct, it will give a positive sign in this minute. Otherwise, it will give a negative sign in this minute. The SR is calculated as Equation 4. The test precision is 95%, which means the machine checking system succeeded 57 times in one-hour test video.

$$SR = \frac{\sum Positive\ Sign}{60} \quad (4)$$

In this study, it found that deep learning detection is robust when well-developed image dataset provided. In computer vision community, there exists some detection dataset such as VOC and COCO. These dataset helps researchers to evaluate new algorithms and applications. It is necessary to build a public image dataset in construction research field, which will benefit the whole community. Since deep learning methods have huge potential in the construction automation field. Detecting all construction objects from images allows us to understand what happened in sites. For project managers, filtering useful information and visualize help them to monitor construction activities and decide in real-time.

Visualization is another concern in construction management. Effective visualization improves the sites communication and help experts understand what happened in construction sites. Since construction sites are always disordered, managers cannot extract useful information directly even with the assistance of cameras, visualized information provided key information to managers to support real-time decision making. Visualization in construction provides an efficient way to training junior workers and engineers.

5 Conclusion

This paper presents a system of checking construction machines automatically from video streams and construction schedule. Cameras deployed in construction sites provide clear views for the whole site and activities. The machine checking system extracts machine information from videos by using deep learning detector YOLOv3. Then it compares detected results and expected number from schedule excel file to feedback to project manager for further decision making. In order to train a general model, a construction image dataset has been built in this study.

In the future steps, the authors will work on developing a method to understand construction activities from videos and highlight important activities automatically. In addition, the authors will keep expanding the construction image dataset.

Abstract –

Laser scanning-based techniques have been applied for checking the dimensional tolerances of concrete elements. Several studies utilized Terrestrial Laser Scanning (TLS) for measuring concrete floor waviness. The results of those efforts have shown that accurate floor waviness information can be obtained using TLS. Unmanned Aerial Vehicles (UAVs) mounted with cameras and 3D laser scanning sensors, referred to as Airborne Laser Scanning (ALS) hereafter, have versatile applications in construction, such as surveying, progress control, 3D modelling and inspections. As-built data collection for dimensional quality assessment can be a potential application of such technology. In particular, the application of ALS for assessing the waviness of concrete slabs warrants further exploration. This study presents the results of a comparative analysis of floor waviness measurement results obtained using ALS and TLS-based technologies. Continuous Wavelet Transform (CWT) is applied to the depth map derived from both point cloud datasets to obtain waviness information. Comparable results are obtained for the CWT scales of 30, 60 and 75. Detailed discussions on how the results can be improved are presented. The analysis of the accuracy of results obtained using ALS advances its application in the field of dimensional quality assessment.

Keywords –

TLS, ALS, Continuous wavelet transform, Depth map, Point cloud, Dimensional quality control, tolerance compliance

1 Introduction

The geometric dimensions of as-built concrete elements often fail to comply with the tolerances specified in the as-designed plans [1]. The factors that contribute toward such discrepancies include lack of attention to details included in the project specifications, low accuracy and precision issues that occur during the construction of elements, and the misinterpretation of information provided in the project specifications. Consequently, increasing tolerance accumulation may affect the aesthetics of concrete elements, affects the correct placement of adjacent concrete elements and negatively affects the structural health of components in severe cases [2]. Construction quality control inspectors collect data related to the quality of on-going construction for effectively designing solutions to correct any defects or discrepancies that are present on concrete surfaces. Thus, dimensional quality assessment ensures that constructed elements accurately reflect the dimensions and locations specified in the contract documents. For concrete floors, this is one of the most significant processes constituting the overall construction process. For instance, constructed floors that do not meet appropriate flatness and waviness requirements negatively affect the operation of Very Narrow Aisle (VNA) trucks in warehouses. Furthermore, the undesired waviness present on the floor surface can affect the racking height of such vehicles, and consequently, the static lean which ultimately may cause these vehicles roll over [3–5].

Existing methods commonly used in the industry such as the Straightedge Method, the F-number method (ASTM E1155)[6] and the Waviness Index (WI) method (ASTM 1486) share the common drawback as they yield sparse as-built measurements. In addition, the data collection process is time and labor intensive, given that the floor surface area in warehouse construction projects easily exceed 4,000 m^2 [3–5]. The method proposed in [3] utilizes a framework that uses lidar-based point clouds and the Continuous Wavelet Transform (CWT) to overcome these disadvantages and provides a novel framework for measuring floor waviness. This framework was further developed to process 2D as built information in the form of depth maps, as opposed to 1D survey lines derived from TLS-based point clouds to impart waviness information of newly constructed concrete slabs. This study focuses on performing a comparative analysis of the floor waviness

results obtained using point cloud data collected with a TLS and a lidar sensor mounted UAV. The method of comparison presented in this study uses waviness detection results from TLS point clouds as ground truths, and relies on recall and precision rates to determine the accuracy of waviness results obtained using ALS point clouds.

2 Related Work

Lidar technology has a wide range of applications in the civil engineering industry, such as quantifying erosion rates and surface deformation [7], to landslide inventorying and assessing hazards [8], structural health monitoring [9–12], road roughness quantification [13–17] and survey and maintenance of historic buildings [18–20]. In the construction industry, lidar is primarily used for as-built documentation that supports progress tracking [3]–[7], facility management [8]–[13], dimensional quality control [3–5,32–34] in construction projects. In the area of dimensional quality control, lidar technology is commonly used for acquiring as-built data, owing to its ability to capture millions of points with mm-level accuracy. The acquired data is processed with the help of a multitude of algorithms, based on the desired applications. Few of the applications include assessing the flatness of the exterior facades using a color map derived from TLS point clouds [35], visualizing the elevation differences across a floor using elevation map generated from point cloud data [36] and assessing the dimensional compliance of concrete elements using BIM and TLS-based point cloud data [37]. Lidar-based point clouds, with the application of the Continuous Wavelet Transform (CWT), were also used in the assessment of floor waviness in [3,4]. The study in [3] demonstrated the efficacy of applying the two-dimensional CWT (2D CWT) to lidar-based point cloud data for assessing the waviness of concrete surfaces. The comparative analysis between results obtained using the framework and those obtained using the Waviness Index (WI) method showed that the framework accurately identifies regions on the floor where surface waviness of different characteristics exist. The framework utilized TLS-derived point cloud data for assessing the surface waviness of concrete floors.

Unmanned Aircraft Systems (UAVs) are exponentially gaining popularity for collecting as-built data from construction sites. UAVs mounted with photographic cameras, thermal cameras and lidar sensors or “pucks” have been widely used for survey data collection. Compared to TLS, UAV-mounted lidar sensors are capable of collecting data from large survey areas in a non-intrusive manner with limited occlusions [38,39]. For instance, a person standing in front of the laser scanner can create a larger obstruction during data collection using TLS, compared to ALS. Moreover, using TLS for collecting as-built data from working surfaces may hinder on-going operations and may interrupt workers on the surface. Thus, the objective of this paper is to compare the results of floor waviness obtained using point clouds derived from TLS and ALS. The framework proposed in [3,5] will be used for obtaining surface waviness results.

3 Analysis

3.1 Data Collection and Preprocessing

The data was collected from a newly constructed floor of a lecture hall under the Magruder Hall Expansion project in Corvallis, OR. Figure 1. shows the region of interest, and its surface area was approximately 140 m2. The Leica P40 scanner was setup in two locations across the floor. After registering the two scans, the spatial resolution of the output point cloud was approximately 5 mm within a range of 10 m. The Riegl miniVUX was used for obtaining the ALS point cloud. The UAV mounted with the lidar sensor was flown at a constant height of approximately 60 m above the surface of the ground, making two passes over the area of interest. It is assumed that the beam divergence is constant throughout the flight. The spatial resolution of the output point cloud collected from the UAV system was approximately 5 cm.

Figure 1. The region of interest is marked in orange.

3.2 Data Processing

The framework developed in [3] was used to process the data obtained from TLS and ALS. The obtained point clouds from the TLS and ALS systems were imported into a commercial point cloud processing software to remove scans corresponding to workers

working on the floor and various construction debris. A depth map is developed using triangulation-based linear interpolation on a grid with regular intervals of 1 cm. This process generated a map showing z-coordinates at each query point, where each query point is represented by the intersection of lines on the x-y plane of the grid. CWT, using the Mexican Hat wavelet as the mother wavelet, was applied to the depth map at different scales. To simplify the analysis, only five scales were chosen for the CWT: 15, 30, 45, 60 and 75. The five scales correspond to the five undulation periods in the WI method: 2, 4, 6, 8 and 10 ft, respectively. The correspondence between the WI index values and the CWT scales are shown in Table 1.

Table 1**.** Waviness Index values and corresponding continuous wavelet transform scales [3][4]

Characteristic period (T) [cm]	CWT scale (a)	Waviness Index (k values)
61	15	1
121.9	30	2
182.9	45	3
243.8	60	4
304.8	75	5

3.3 CWT Results

The surface waviness results obtained for the TLS- and ALS-based point clouds, for scales 15, 30, 45, 60 and 75, are shown in Figure 2, Figure 3, Figure 4, Figure 5 and Figure **6**, respectively. The peaks detected for the CWT responses for these five scales are presented.

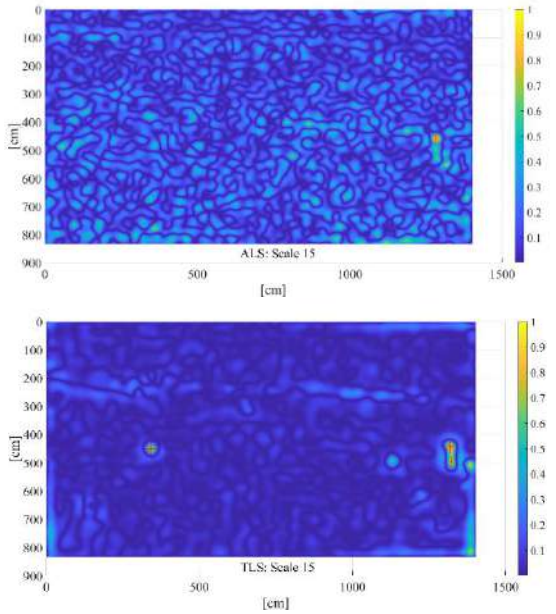

Figure 2. The results of the CWT analysis at scale 15 with peak detection (red asterisk) for the ALS (top) and TLS point clouds (bottom)

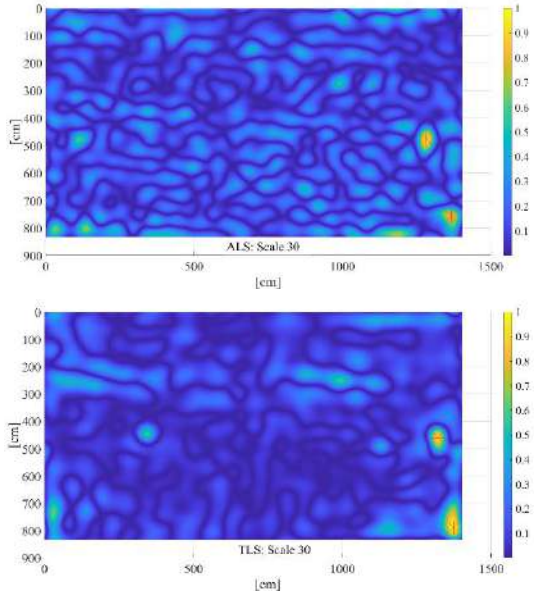

Figure 3. The results of the CWT analysis at scale 30 with peak detection (red asterisk) for the ALS (top) and TLS point clouds (bottom)

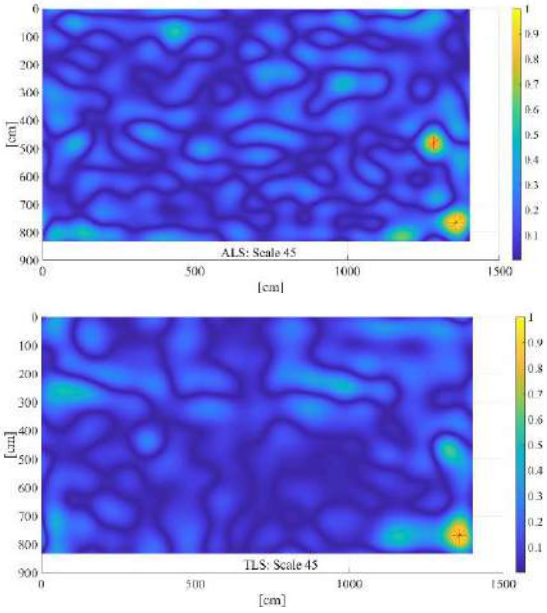

Figure 4. The results of the CWT analysis at scale 45 with peak detection (red asterisk) for the ALS (top) and TLS point clouds (bottom)

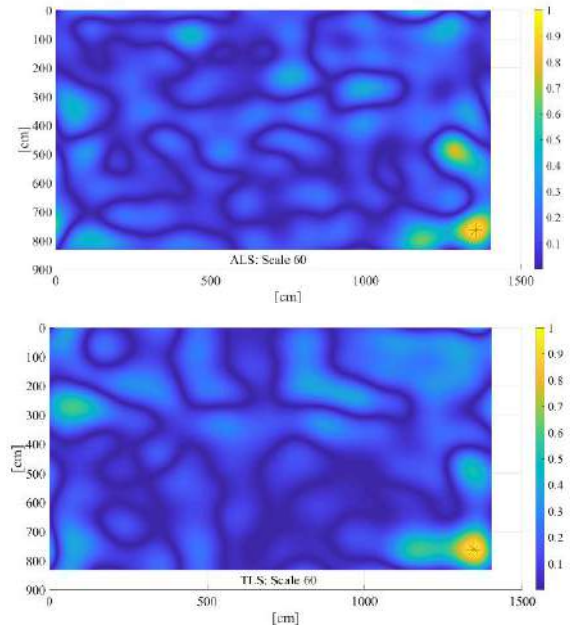

Figure 5. The results of the CWT analysis at scale 60 with peak detection (red asterisk) for the ALS (top) and TLS point clouds (bottom)

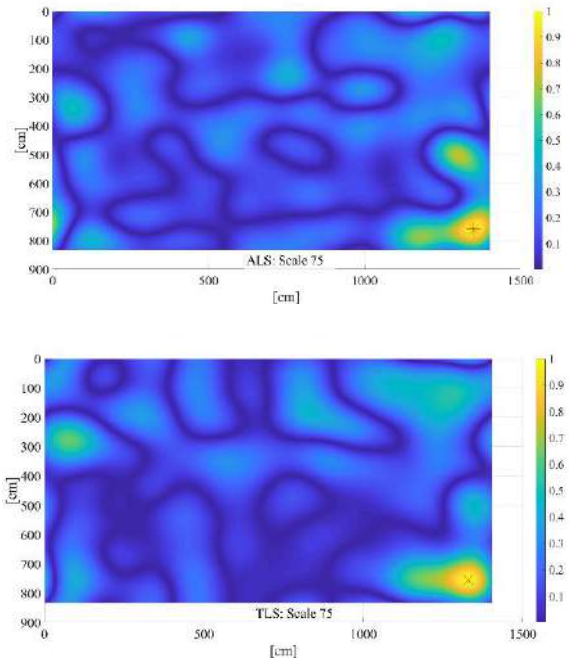

Figure 6. The results of the CWT analysis at scale 75 with peak detection (red asterisk) for the ALS (top) and TLS point clouds (bottom)

As shown in Figure 2, Figure 3, Figure 4,Figure 5, and Figure **6**, peak responses for the CWT coefficient values lie 10% below the maximum value. The location of these peak responses for each of the five scales are used for our analysis.

The waviness results obtained from the TLS-based point clouds are used as ground truth for measuring the performance of the ALS-based point clouds for generating the waviness results. The convention of true positives (TP), true negatives (TN), false positives (FP) and false negatives (FN) that applies to the peak detection problem in our study is shown in Table 2. The number of true positives, true negatives, false positives and false negatives are shown in Table 3.

Table 2. Convention of the true positive, true negative, false positive and false negative for peak detection

	Peak present (TLS)	**Peak absent (TLS)**
Peak detected (ALS)	TP	FP
Peak not detected (ALS)	FN	TN

Table 3. Total number of true positives (TP), true negatives (TN), false positives (FP) and false negatives (FN)

Scales	**TP**	**TN**	**FP**	**FN**	**Actual number of peaks (TLS based)**
15	1	0	0	2	3
30	2	0	0	0	2
45	1	0	1	0	1
60	1	0	0	0	1
75	1	0	0	0	1

In the TLS based results, for scale 15, the ground truth shows that there are 3 peaks that correspond to undulations having a characteristic period of 61 cm. Only one of those peaks are detected in the waviness results derived from the ALS point cloud. For scale 30, two peaks that correspond to the characteristic period of 121.9 cm were detected in both the TLS and ALS based results. At scale 45, one peak corresponding to 182.9 cm was obtained in the TLS and two peaks in the ALS based results. Similarly, for scales 60 and 75, 1 peak corresponding to the characteristic period of 304.8 cm was detected in both the TLS and ALS based results. Table 4 shows the correspondence between the waviness detection results obtained using TLS and ALS using precision and recall rates for the five scales selected in this study.

Table 4**.** Recall, precision and accuracy rates

Scales	**15**	**30**	**45**	**60**	**75**
Recall	33%	100%	100%	100%	100%
Precision	100%	100%	50%	100%	100%

Accuracy	33%	100%	100%	100%	100%
F-Score	0.5	1	0.67	1	1

The surface waviness results for scales 60 and 75 using the TLS and ALS based point clouds are comparable. For scale 45, a false positive was detected near [1283 cm, 481 cm]. The same region near the TLS was inspected and no peak was found. The CWT response at that region for the ALS based results was 0.8816, and 0.1674 for the TLS. This discrepancy might be attributed to the difference in the z-values shown in the depth maps of the TLS and ALS point clouds. The TLS based depth map shows the elevation at [1283 cm, 481 cm] to be approximately 2.8 cm and the ALS based depth map shows 1.75 cm. Although the TLS and ALS scans were collected almost simultaneously, there were workers actively working on the work surface. This may be due to dynamic changes resulting from moving objects or debris on the floor surface. Another reason may be due to the low resolution of the ALS point cloud. For scale 15, the results are not comparable to each other. A possible reason could be that using TLS-based high-resolution point cloud helped detect undulations of a lower characteristic period (61 cm) accurately. The lower resolution ALS-based point cloud may have failed to capture those undulations. While generating the depth map, the z-coordinates are smoothed out to a higher degree if there were fewer neighbouring points present around the query points.

4 Discussions and Conclusions

The efficacy of using ALS-derived point clouds for detecting surface waviness of concrete floors was examined. Using the UAV mounted with lidar can help quality control inspectors to non-intrusively collect as-built point cloud from concrete slabs. The analysis of the CWT results show that the surface waviness detection results are not comparable for scales 15 and 45. The analysis showed comparable results for detecting the undulations corresponding to scales of 30, 60 and 75. In summary, one of the possible reasons for discrepancies in the two results is the difference in the resolution of both point clouds. The resolution of the TLS based point cloud was approximately 10 times better than that of the ALS based point cloud. The other reason could be due to the misalignment of both point clouds. The targets placed on the ground were visible in the TLS data, but were not clearly visible in the ALS point clouds. Two solutions are proposed: 1) Flying the UAV closer to the ground: The lower the aircraft flies, the smaller the lidar footprint diameter will be, which results in a higher density of points per scanning area. Decreasing the lidar footprint is essential for detecting small changes in elevation across the surfaces. A good option would be flying under 15 m. 2) Increase the number of passes: An increase in the number of passes will improve the resolution quality of the point cloud.

Future work will focus on examining the number of passes required to obtain a point cloud resolution that is comparable to that obtained using a TLS. In addition, the impact of the altitude difference for obtaining the desired resolution and capturing the small changes in elevation across the floor will be examined. Furthermore, the differences in the z-coordinates of the depth map resulting from the application of other interpolation methods will be evaluated.

5 Acknowledgements

The authors would like to thank Chase Simpson from Oregon State University and Jake Dafni from the NHERI RAPID Experimental Facility at the University of Washington for their help in collecting the data using the UAV and for preprocessing the data. The authors would also like to thank John M. Doty, the project manager, Scott Cach and the Fortis team for their help and cooperation throughout the data collection process.

Abstract –

Remote building information modeling (BIM) model review collaboration is the trend in the architecture, engineering, and construction (AEC) industry. Virtual communication environment is a key factor in a successful collaboration. However, the proper environment has yet to be fully revealed. Therefore, this study aims to identify the effective environment. We identified the environment with three main types and then proposed and developed the corresponding environment namely BIM-based, PC-based virtual BIM reviewer (VBR), and VR-based VBR. A user test has been conducted to evaluate their performance and task loading in finding issues and reaching consensus. In the test, the participants were asked to find four kinds of issues and determine the top five issues and their solutions. The result shows that in finding issues, the average of issues they found in BIM-based, PC-based VBR, and VR-based VBR are 6.57, 9.77, and 9.91. The performance of PC-based VBR and VR-based VBR are no significant difference ($\alpha = 0.461462$) but both of them are significantly better than BIM-based ($\alpha = 0.000339$ and 0.004431). However, the averages of task loading in finding issues are 899.50, 813.84, 807.00 with no significant difference. In reaching consensus, the averages of seconds they used are 740.67, 682.93, and 724.40 with no significant difference. However, the averages of task loading in both of PC-based VBR ($\mu = 721.00$) and VR-based VBR ($\mu = 718.10$) are significantly lower than BIM-based ($\mu = 867.00, \alpha = 0.009610$ and 0.013879). In overall, both PC-based VBR and VR-based VBR have better performance in finding issues and lower task loading in reaching consensus.

Remote collaboration; Virtual communication environment; BIM model review

1 Introduction

The beginning of remote collaboration can be considered starting from the offshoring and outsourcing of services that emerged in the late 1980s and early 1990s [1]. With the rapid development of information and communications technology reduces the barriers of remote collaboration, remote collaboration has become the trend in many industries. In the AEC industry, there are also many construction teams consist of engineers and architects located in different regions or countries requires remote collaboration. For instance, the Oakland Bay Bridge is manufacturing in China and fabricating in the United States [2], Taiwan High Speed Rail Project consists of many experts from different countries including Taiwan, Britain, Denmark, India, and other countries [3], and Taiwan Taoyuan International Airport Terminal 3 is also a remote collaboration example that is joint contracted by Taiwan, Britain, and Hong Kong companies.

BIM is a novel approach in the AEC industry [4]. The concept of BIM is being a data center that integrates geometric and functional information during the building life-cycle. The information will be represented in a visualized 3D model for project participants to use. BIM supports strong spatial cognition and abundant information that can reveal most the of design issues in the early design stage through BIM model review, which is a repeated design process reviews visualized information model from various aspects, such as design, construction, specification, and safety, to decipher a proper solution [5].

Remote BIM model review collaboration is the trend in the AEC industry [6]. However, the existing common virtual communication environments, such as Skype, Hangout, Join.me, Zoom, Sococo, etc., can only help users review BIM models with a shared screen-view controlled by one of the users. This is easy to build the virtual communication environment but hard to provide the senses of teamwork and immersive exploration.

Without both of them will reduce the effectiveness of remote BIM model review collaboration. Some researchers mention that virtual avatar [7-10] and virtual reality [11] will solve these problems, but they are more focused on finding issues rather than reaching the consensus of final solutions. Although we know the communication environment is a key factor in a successful collaboration [12]. However, the proper communication environment has yet to be fully revealed.

2 Research Goals

This study aims to identify effective communication environments for BIM model review collaboration with following goals: (1) identify the main types of virtual communication environment; (2) propose and develop these communication environments; (3) evaluate their performance and task loading in finding issues and reaching consensus.

3 Virtual Communication Environment

In this study, we classified virtual communication environment types by two factors: the flexibility of exploration and the degree of immersive. The flexibility of exploration consists of passive exploration and proactive exploration. The degree of immersive consists of semi-immersive and full-immersive. Therefore, we have four kinds of type: (1) Type I: a passive exploration with semi-immersive; (2) Type II: a passive exploration with full-immersive; (3) Type III: a proactive exploration with semi-immersive; and (4) Type IV: a proactive exploration with full-immersive. Four types of virtual communication environment are listed in Table 1.

Table 1. The types of virtual communication environment

		The flexibility of exploration	
		Passive	Proactive
The degree of immersive	Semi-	Type I	Type III
	Full-	Type II	Type IV

In the existing common approaches to implementing these four types. It often uses screen-sharing-based to implement passive exploration and virtual-avatar-based to implement proactive exploration. Regard to the semi-immersive and full-immersive will often be implemented on PC devices and VR devices respectively. However, Type II is not reasonable and will not be practiced due to the dizziness issue. If users fully immersive themselves into a virtual environment but the view is controlled by others, it will cause serious dizziness to them. Moreover, in the existing VR technology, most of them already provide a virtual avatar for each user no matter it is visible or not. Therefore, this study will only focus on discussing Type I, III, and IV. We proposed and developed three environments to the Type I, III, and IV namely BIM-based, PC-based VBR [13], and VR-based VBR [13] respectively. The reviewing tool, conference tool, display device, control device, etc. they used are listed in Table 2.

Table 2. The implementation of the three main types

	BIM-based	PC-based VBR	VR-based VBR
Reviewing tool	Revit 2016	VBR (PC)	VBR (VR)
Conferencing tool	Sococo	Sococo	Sococo
Exploration type	Screen-sharing	Virtual-avatar	Virtual-avatar
Display device	Screen	Screen	VR goggles
Control device	Keyboard and mouse	Keyboard and mouse	VR controllers and VR goggles
Communication device	Microphone and headphone	Microphone and headphone	Microphone and headphone

3.1 BIM-based Environment

The BIM-based environment allows users to review BIM models by a reviewing tool, Revit 2016. Users can navigate and manipulate the models in Revit 2016 by keyboard and mouse. They can communicate with each other through a conferencing tool, Sococo. They will use microphones, headphones, and screen-sharing in Sococo. Users using the BIM-based environment is shown in Figure 1.

Figure 1. Users using the BIM-based environment

3.2 PC-based VBR Environment

The PC-based VBR environment allows users to review BIM models by a reviewing tool, VBR (PC). Users can navigate and manipulate the models in VBR (PC) by keyboard and mouse. They can communicate with each other through a conferencing tool, Sococo. They will only use microphones and headphones in Sococo. They do not use the screen-sharing through Sococo since they can directly interact with each other in a virtual environment through VBR (PC) by their own avatars. Users using the PC-based VBR environment is shown in Figure 2.

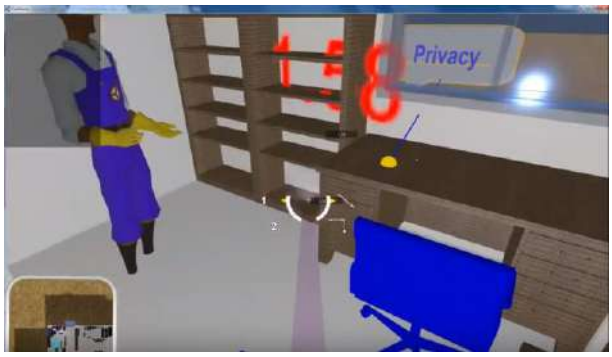

Figure 2. Users using the PC-based VBR environment

3.3 VR-based VBR Environment

The VR-based VBR environment allows users to review BIM models by a reviewing tool, VBR (VR). Users can navigate and manipulate the models in VBR (VR) by VR goggles and controllers. They can communicate with each other through a conferencing tool, Sococo. They will also only use microphones and headphones in Sococo and directly interact with each other in a virtual environment through VBR (VR) with their own avatars. Users using the VR-based VBR environment is shown in Figure 3.

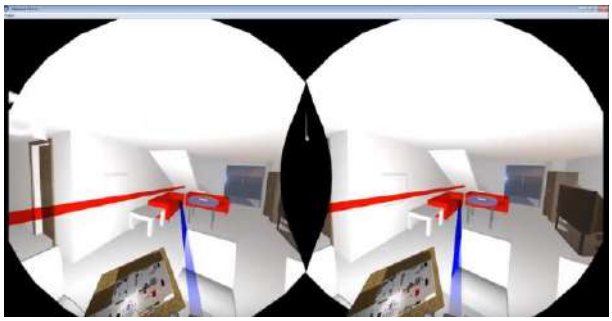

Figure 3. Users using the VR-based VBR environment

4 Evaluation

This study designed a Space Feasibility Inspection test to evaluate the performance and task loading of BIM-based, PC-based VBR, and VR-based VBR in finding issues and reaching consensus. We used Revit 2016 to build an example BIM model with four kinds of issues: usability, safety, privacy, and others. This model is a common living space including one living room, one dining room, one kitchen, one bathroom, one study room, one bedroom with bathroom, and one balcony. One example of the usability issue is that the height below the stair is too short that users are not comfortable to use the sofa. One example of the safety issue is that the table and the chair are too close to the fence. Once someone climbs on, he will be exposed to the falling danger. One example of the privacy issue is that the sliding door window would be better to have a curtain for privacy. Regarding other issues, one example of other issues is a construction problem. It is better to locate both bathrooms next to each other. So it will only require one piping space.

There are four phases in this test. The pre-phase has 3 minutes for demographics questionnaire. Then, the first phase is finding issues. It has 5 minutes for explanation and practicing, 12 minutes for finding issues, and 5 minutes for task loading questionnaire. After the first phase, the second phase is reaching consensus. It has 5 minutes for explanation and practicing, 12 minutes for reaching consensus, and 5 minutes for task loading questionnaire. Finally, the post-phase has 5 minutes for overall post-questionnaire and 8 minutes for an interview discussion. The flow-chart of this experiment is listed in Table 3.

Table 3. The procedure of user test

Phase	Description	Time (Minutes)
Pre-phase	Demographics questionnaire	3
1st phase: Finding issues	Explanation and practicing	5
	Finding issues	12
	Task loading questionnaire	5
2nd phase: Reaching consensus	Explanation and practicing	5
	Reaching consensus	12
	Task loading questionnaire	5
Post-phase	Post-questionnaire	5
	Interview discussion	8

In this test, we random recruited 90 participants and separate them into 45 groups, each environment has 15 groups and each group has 2 participants. The participants know each other before they come to the experiment to prevent the communication barriers caused by they are not familiar with each other.

At the beginning of this experiment, two participants and two research assistants meet in the same room. While all members arrive, one participant and one research assistant will go to room A. The others will go to room B. They do the same thing in the two different rooms. In the pre-phase, the research assistants will guide the participants to fill out the demographics questionnaires.

Next, the research assistant will explain the control manners of reviewing tools (Revit 2016 / VBR) and the task (finding issues) in the first phase within 5 minutes. Participant has 12 minutes to find issues as many as possible. After 12 minutes, the research assistants will guide the participants to fill out task loading questionnaires of finding issues.

Then, the research assistants will guide the participants to use a conferencing tool (Sococo) to communicate with each other. After 5 minutes of practicing, they were asked to list the top 5 issues they want to solve and also negotiate the proper solution within 12 minutes. They are also required to fill out the task loading questionnaires of reaching consensus.

Finally, they will turn off the conferring tool and fill out the overall post-questionnaires. After that, the research assistants will ask questions we designed and other questions related to the participants' 1st phase and the 2nd phase behaviors.

5 Results and Discussions

In the test, we measured (1) the average issues they found in finding issues (Table 4); (2) the average task loading in finding issues (Table 5); (3) the average time they used in reaching consensus (Table 6); and (4) the average task loading in reaching consensus (Table 7).

In the finding issues phase, the performance of PC-based VBR ($\boldsymbol{\mu = 9.77}$) and VR-based VBR ($\boldsymbol{\mu = 9.91}$) are no significant difference ($\boldsymbol{\alpha = 0.461462}$) but both of them are significantly better than BIM-based ($\boldsymbol{\mu = 6.57, \alpha = 0.000339 \text{ and } 0.004431}$). We further compared the performance in usability, safety, privacy, and other aspects of PC-based VBR and VR-based VBR. The results show that PC-based VBR is better in safety and privacy issues. VR-based VBR is better in usability and other issues. It may be caused by that VR-based VBR supports full-immersive experience enhancing participants more focus on simulating whether space is convenient for use. Regarding the averages of task loading in finding issues are 899.50, 813.84, 807.00 with no significant difference. We further compared the task loading in mental demand, physical demand, temporal demand, performance, effort, and frustration. All of them are no significant differences in mental demand and frustration. VR-based VBR has the greatest loading in physical demand ($\boldsymbol{\mu = 94.17}$) and is significantly higher than BIM-based ($\boldsymbol{\mu = 31.17, \alpha = 0.012771}$) and PC-based VBR ($\boldsymbol{\mu = 41.67, \alpha = 0.033628}$). But VR-based VBR has the lowest loading in performance ($\boldsymbol{\mu = 104.00}$) and is significantly lower than BIM-based ($\boldsymbol{\mu = 177.67, \alpha = 0.001412}$) and PC-based VBR ($\boldsymbol{\mu = 158.50, \alpha = 0.023266}$). VR-based VBR also has the lowest loading in effort ($\boldsymbol{\mu = 114.00}$) and is significantly lower than BIM-based ($\boldsymbol{\mu = 189.33, \alpha = 0.001212}$) and PC-based VBR ($\boldsymbol{\mu = 158.00, \alpha = 0.023981}$). The loading in temporal demand decreases from BIM-based to PC-based VBR and then to VR-based VBR. Among them, BIM-based and VR-based VBR have significant differences ($\boldsymbol{\alpha = 0.008672}$).

Table 4. The average issues they found in finding issues

Finding issues	BIM-based	PC-based VBR	VR-based VBR
Usability	3.83	4.77	5.77
Safety	1.40	2.70	1.97
Privacy	0.97	1.53	1.30
Other	0.37	0.77	0.87
Overall	6.57	9.77	9.91

Table 5. The average task loading in finding issues

Task loading in finding issues	BIM-based	PC-based VBR	VR-based VBR
Mental demand	247.17	236.67	269.83
Physical demand	31.17	41.67	94.17
Temporal demand	176.67	138.50	106.17
Performance	177.67	158.50	104.00
Effort	189.33	158.00	114.00
Frustration	77.50	80.50	118.83
Overall	899.50	813.84	807.00

In reaching consensus, the averages of seconds they used are 740.67, 682.93, and 724.40 with no significant difference. However, the averages of task loading in both of PC-based VBR ($\boldsymbol{\mu = 721.00}$) and VR-based VBR ($\boldsymbol{\mu = 718.10}$) are significantly lower than BIM-based ($\boldsymbol{\mu = 867.00, \alpha = 0.009610 \text{ and } 0.013879}$). We further compared the task loading in mental demand, physical demand, temporal demand, performance, effort, and frustration. All of them are no significant

differences in effort and frustration. PC-based VBR has the lowest loading in mental demand ($\boldsymbol{\mu = 185.67}$) and is significantly lower than BIM-based ($\boldsymbol{\mu = 249.83, \alpha = 0.017308}$). PC-based VBR also has the lowest loading in physical demand ($\boldsymbol{\mu = 47.17}$) and is significantly lower than VR-based VBR ($\boldsymbol{\mu = 88.00, \alpha = 0.032764}$). VR-based VBR has the lowest loading in temporal demand ($\boldsymbol{\mu = 138.33}$) and is significantly lower than BIM-based ($\boldsymbol{\mu = 220.83, \alpha = 0.008720}$) and PC-based VBR ($\boldsymbol{\mu = 212.33, \alpha = 0.015529}$). VR-based VBR also has the lowest loading in performance ($\boldsymbol{\mu = 99.50}$) and is significantly lower than BIM-based ($\boldsymbol{\mu = 147.00, \alpha = 0.032007}$).

Table 6. The time they used in reaching consensus

	BIM-based	PC-based VBR	VR-based VBR
Seconds	740.67	682.93	724.40

Table 7. The task loading in reaching consensus

Task loading in reaching consensus	BIM-based	PC-based VBR	VR-based VBR
Mental demand	249.83	185.67	227.97
Physical demand	74.17	47.17	88.00
Temporal demand	220.83	212.33	138.33
Performance	147.00	111.83	99.50
Effort	142.50	128.67	125.63
Frustration	32.67	35.33	38.67
Overall	867.00	721.00	718.10

To sum up, both PC-based VBR and VR-based VBR have better performance in finding issues and lower task loading in reaching consensus. In addition, we found that VR-based VBR has the lowest loading in temporal demand no matter in 1st phase or 2nd phase. It may be caused by that participants already immersive themselves into the virtual environment. They can use less time to adapt and realize the example BIM model and then use more time to conduct the tasks we assigned.

6 Conclusions

This study aims to identify effective communication environments for remote BIM model review collaboration. We identified and implemented three kinds of virtual communication environment: BIM-based, PC-based VBR, and VR-based VBR from two factors: the flexibility of exploration and the degree of immersive. A user test with 90 participants was conducted for evaluating their performance and task loading in finding issues and reaching consensus. The result shows that in finding issues, PC-based VBR ($\mu = 9.77, \boldsymbol{\alpha = 0.000339}$) and VR-based VBR ($\mu = 9.91, \boldsymbol{\alpha = 0.004431}$) are significantly greater than BIM-based ($\mu = 6.57$). Among them, PC-based VBR is better in finding safety and privacy issues and VR-based VBR is better in finding usability and other issues. The averages of task loading in finding issues are no significant difference in overall. However, VR-based VBR has the lowest loading in temporal demand, performance, and effort but has the highest loading in mental demand, physical demand, and frustration. The result shows that in reaching consensus, PC-based VBR and VR-based VBR can use less time to reach consensus than BIM-based but are no significant difference. However, the averages of task loading in both of PC-based VBR ($\mu = 721.00$) and VR-based VBR ($\mu = 718.10$) are significantly lower than BIM-based ($\mu = 867.00, \alpha = 0.009610$ and 0.013879). PC-based VBR has the lowest loading in mental demand and physical demand. In overall, both PC-based VBR and VR-based VBR have better performance in finding issues and lower task loading in reaching consensus.

Abstract –

This paper presents largely severe natural disasters had happened in Japan, and efforts to unmanned construction until now. First, problems in responses to post-disaster restoration and reconstruction are reported. Secondly, are described demonstration of ultra-long-distance unmanned construction and the requirements for the deployment. Thirdly, this paper presents research and development on autonomous crawler carrier. Finally, concluding remarks and further works are reported. In addition, are proposed levels of promising applicability of robots in responses to post-disaster restoration and reconstruction.

Keywords –

Post-disaster, Unmanned construction system, Situational Awareness, Ultra-long-distance, Autonomous crawler carrier

1 Introduction

Japan is located in the Circum-Pacific Mobile Belt and Japanese archipelago, which are formed on the complex crusts. Accordingly, we are always facing and fearing natural disasters such as typhoons, unexpected strong and sudden tempest, and then deadly flash floods, earthquakes, volcanic activity, slope failures, landslides, avalanche of earth, fire of petrochemical complex, nuclear power station accident, and so on. Largely severe natural disasters have recently occurred in Japan are listed below.

(1) The 1995 Hanshin-Awaji Earthquake,
(2) The 2004 Mid Niigata Prefecture Earthquake,
(3) The 2011 off the Pacific coast of Tohoku Earthquake with the Fukushima daiichi nuclear power station accident,
(4) The 2016 Kumamoto Earthquakes, and
(5) The 2018 Hokkaido Eastern Iburi Earthquake.

Now, we need consider countermeasures against largely severe natural disasters. When facing dangerous situations in post-disaster restoration and reconstruction, in order to avoid any secondary disasters, we inevitably demand unmanned construction.

This paper reports efforts to unmanned construction for post-disaster restoration and reconstruction, which have been and are being discussed in the disaster and accident sub-committee, construction robot committee, JSCE in Japan. As for post-disaster restoration and reconstruction, this sub-committee plays a role in:

(1) Finding out applicability of unmanned construction system,
(2) Analysis of examples of the unmanned construction systems responded to natural disasters and accidents,
(3) Investigating advanced technology applicable to develop future unmanned construction systems,
(4) Guidance to put the future unmanned construction systems in practice,
(5) Informing the public widely of the achievements of these, and utilizing them to society, and
(6) Proposal of levels of promising applicability and objectives of research and development on construction robots.

The discussions in this sub-committee here will make it possible for researchers, engineers, and users to have a shared awareness of efficiency index and applicability level, performance to be the goal, state-of-the-art to be attained, and so forth, in responses to post-disaster restoration and reconstruction. Moreover, it will contribute to the research and development on robotics for post-disaster restoration and reconstruction.

This paper is organized as follows. First, this paper presents problems that we have to face when conducting unmanned construction. Secondly, this paper reports issues and future directions pertaining to ultra-long-distance remote-control unmanned construction system.

Thirdly, efforts to research and development on autonomous crawler carrier are described. Finally, are reported concluding remarks, further works, and proposal of the promising applicability in levels of responses to post-disaster restoration and reconstruction.

2 Problems

In response to post-disaster restoration and reconstruction, construction machines are often remotely controlled to remove earth and rocks at the steep slope on the left and at the ridge of steep cliff on the right as shown in Figure 1. As mentioned above, when facing dangerous situations, in order to avoid any secondary disasters, we inevitably demand unmanned construction system.

Figure 1. Works at the ridge of steep cliff and at the steep slope

Handling joysticks to operate construction machines, either directly or remotely, is an inherently eye-hand coordination task. The eye-hand coordination task means to control eye movements with hand movements, as processing the situational views to handle joysticks. Considering unmanned operation, however, the operators handle their joystick controllers to operate construction machines remotely in narrow field of views produced by camera-monitor system at the control room. Problems here include machine operability, difficulty in a task at hand, performances limited by bearings of operators in their behavioural frameworks, and continuous or intermittent mental workload on them. The continuous or intermittent mental workload might be caused by communication with latency, narrow field of view, different reference frames without realistic sensation, and so forth. Although, the operators have to make a decision instantaneously on do's and don'ts in their operations, it is sometimes difficult to ensure line-of-sight for location and movement direction of their machines, positions of and clearance from surroundings of the machine and the target. Then they have to mentally translation, rotation and scaling between different frames of references in Figure 2.

As shown in Figure 3, however,

(1) Just by images from on-board cameras, it is difficult to grasp shape of work target,

(2) Just by images from fixed cameras, it is almost impossible to understand the whole of situations on site, and so,

(3) It is required to have functions to adjust coordinates of the entire of work site.

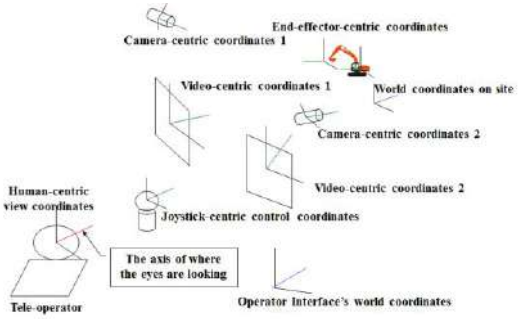

Figure 2. Different reference frames

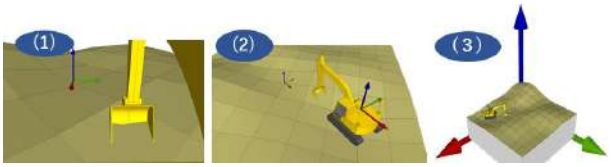

Figure 3. Images from camera

Therefore, the unmanned construction requires that operators indispensably acquire extensive trainings and broad experiences on problem-solving skills pertaining to:

(1) Different viewpoint control,
(2) Spatial locations and positioning,
(3) Figuring out and completing the given task at a hand in real-time manner.
(4) Endurance of continuous or intermittent workload
(5) Scale ambiguity
(6) Rate of motion, and
(7) Loss of peripheral vision with retention of central vision, which is liable to result in a constricted circular tunnel-like field of vision.

The skilled operators are imperative for the unmanned construction operation. In Japan, however, there are very few skilled operators, and most of them are aged people.

Therefore, it is very important and significant to provide the operators with physical cues related to behaviour of construction machines, in order to compensate for their realistic sensations, which operators would feel when directly operating their machines, and to increase their consciously and situationally spatial awareness, which enable them to infer and understand the present and future surroundings of remotely controlled machines and watch oneself in their work space.

3 Ultra-long-distance Remote-control Unmanned Construction

When the 2011 off the Pacific coast of Tohoku Earthquake occurred, the Ministry of Land, Infrastructure, Transport and Tourism of Japan (hereafter called MLIT) conducted demonstration tests on ultra-long-distance remote-controlled operation of unmanned construction machines, in March of that year, at the foothills of Mt. Unzen. This demonstration tests aim to prepare for future large-scale volcanic disasters [1], [2]. Figure 4 shows Demonstration tests network. The experiment yard is shown in Figure 5, and the mobile relay station in Figure 6.

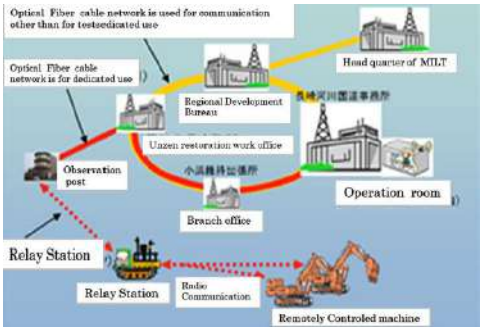

Figure 4. Demonstration tests network in ultra-long-distance remote-controlled operation of unmanned construction machines

Figure 5. Experiment yard for demonstration tests

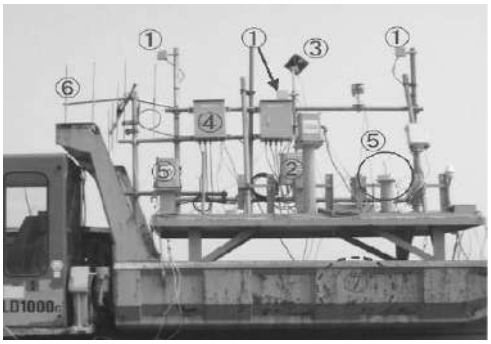

Figure 6. Mobile relay station for demonstration tests

The devices shown in Figure 6 are explained as follows:

① Directional patch antenna for wireless LAN (IEEE802.11),
② Wireless LAN (IEEE802.11) master unit 5GHZ,
③ 25GHZ low power radio device,
④ RS232C 422-LAN converter,
⑤ Specified low power radio station (429MHz),
⑥ Public broadband communication antenna, and
⑦ Public broadband communication device.

Communication latency, and image degradation in ultra-long-distance remote-control machines might make it difficult to figure out and complete the given task at a hand in real-time. And then it is easily conceivable to decrease the work efficiency. Moreover, the machines are highly liable to collide with each other.

The purposes of the demonstration tests are described below.

(1) Evaluation of capability (e.g., data-carrying capacity, latency) of various communication methods as follows:
  1) Long-distance communication (from control room to relay station on site), and
  2) Local communication on site.

(2) Analysis of operating environment and operator's bearings related to:
  1) Influence by communication latency, and image degradation,
  2) Maintenance of construction machines (refuelling, maintenance, etc.), and
  3) Operator's skill (operating envelope, proficiency, etc.).

(3) Comparison and verification experiments with respect to:
  1) Operator's proficiency (skilled, unskilled) and
  2) Operational envelope limited by image communication latency and degradation.

The demonstration tests used actual construction machines and an optical fibre cable network for the first time in Japan, and demonstrated the applicability of remote-control operation technologies to ultra-long-distance unmanned construction machines. The machines here were remotely operated from a remote-control room 30 km away. Are also demonstrated that the communication system, combined with wireless mesh LAN, simultaneously transmitted high-definition 1 Mbps images from 20 cameras. Then hydraulic excavators could be operated with a high degree of accuracy. In addition, are verified the transmission capabilities of alternative long-distance communication such as public broadband communications, long-distance wireless LANs, satellite communications, etc. in this demonstration tests.

3.1 Operator's Qualification

Operators with different level proficiency (e.g., skilled, unskilled) participate in this comparison

and verification experiments, which have been done in demonstration tests. These experiments conducted are outlined in the following subsections

3.1.1 Climbing Over a Large Bump

Each of the skilled and unskilled operators remotely controls a backhoe with 1.2 m^2 bucket for one-cycle of a series of the following operations as shown in Figure 5.
(1) Level down a fill with two meters in height and the inclined part 45 degrees, and
(2) Build a runway and climb the fill
Operators' hacks learned from the above operations are summarized below.
(1) It was observed that the unskilled operator's cycle time runs 1.9 times longer than the skilled operator's one.
(2) When not using a camera car, the difference between the two has spread to 2.3 times.
(3) On the other hand, in case of boarding operations, the unskilled operator's cycle time runs 1.8 times longer than the skilled operator's one
(4) Putting the cycle time of boarding operation equal to one, the unskilled operator took a work time to complete the task from 2.0 to 3.6 times of the one.

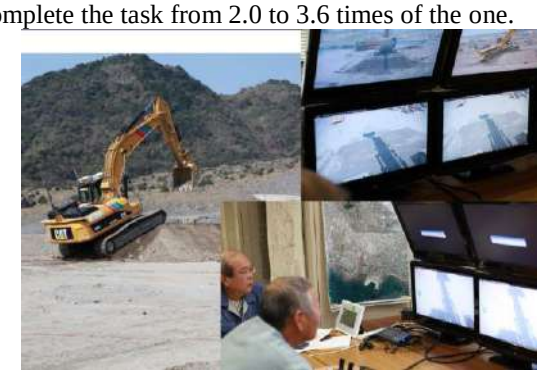

Figure 5. Climbing over a large bump

3.1.2 Travelling as Avoiding Obstacles

The three colored corns are installed in a 40 m interval of running path. In addition, three concrete blocks are placed at the running path. The backhoe zigzags between the three colored corns. The backhoe is planned to stop and scoops the three objects of concretes in the middle of running. The experiment shows the following results.
(1) The unskilled operator's cycle time runs 1.5 times longer than the skilled operator's one.
(2) In case of boarding operations, the unskilled operator's cycle time runs 1.7 times longer than the skilled operator's one.
(3) If image latency occurred, the difference between the two has decreased.

3.1.3 Pseud-refueling Operation

Aiming to unmanned maintenance, pseud-refueling works by remotely controlling a backhoe was conducted as shown in Figure 6 and Figure 7. It could be seen from this experiment that
(1) If and when camera images of the refueling hose and the refueling neck are intersecting perpendicularly, it becomes easier to position the refueling hose and to adjust its height direction, and
(2) Although it is required to improve the filler neck, the current method in this experiment could be more than enough put it in practice.

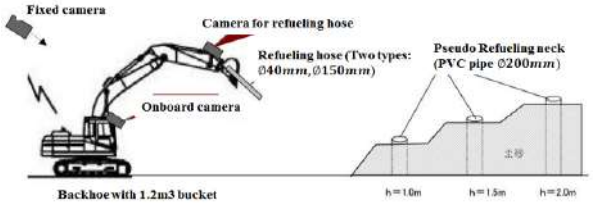

Figure 6. Image of pseud-refueling operation

Figure 7. Pseud-refueling scene

3.2 Operational Envelope Limited by Image Communication Latency and Degradation

Concerns about ultra-long-distance communication are latency and degradation of images, and presence or absence of camera cars. As arbitrarily changing conditions of images from monitors, the skilled operator has remotely operated a backhoe with a hydraulic breaker as shown in Figure 8.

Figure 8. Backhoe with a hydraulic breaker

This aims to confirm influences and operability of remote control to the following works.
(1) Travelling, grasping and placing boulders, and turning by the backhoe.
(2) Crushing boulders by the hydraulic breaker.

Accordingly, it was were confirmed that allowable delay time was less than 1.5 seconds in rough works and one second in precise works.

3.3 Lesson Learned from Demonstration

The lesson learned from these demonstration tests are outlined below.

3.3.1 Availability of Wireless LAN Method （IEEE802.11j）

The confirmed availabilities of wireless LAN method are listed below.
(1) Time delay of operational data with video communication via optical fiber network and wireless LAN is less than 1 second even if the communication distance is more than 80km.
(2) High resolution of six images per one channel of wireless LAN can be transmitted simultaneously and stably.
(3) The transmission delay long-distance wireless LAN is less than about 1 second. Communication intermittent might be occurred under the condition of the large amount of data transmission (e.g.,1.5 Mbps), that's why dropping frames of image data transmitted might happen. If the number of cameras is less, that is, volume of data transmitted is less, it might be available.
(4) The transmission amount of wireless LAN is large, but the communication sneak performance is poor.
(5) Image transmission capability
The wireless LAN is able to stably transmit 6 images per channel in case of quick changes (one image: 1.5~3.0 Mbps/30 fps), and 10 images per channel (one image: 1.0~1.5 Mbps/30 fps) in case of little changes.

3.3.2 Communication within Construction Site

In case of usage of wireless LAN and specified low power radio, it is limited to about 10 units of construction machines, in order to prevent communication interference. In this demonstration, both the image system signal and the operation system signal could be handled without hindrance. When using wireless LAN (IEEE802.11j) and specified low power radio, the each reaching distances was about 230 m. It might be promising to use low-latency type codec in wireless LAN method in future.

3.3.3 Possibility of Public Broadband Communication

The public broadband communication shows superior communication sneak performance with about 70 degrees at location where there are impenetrable hills, buildings and the like. According to narrowness of the bandwidth, image degradation, dropping frames of image, and so on, it is difficult to concurrently use image system signal. Boom or arm of backhoe might cut radio waves off sometimes. The communication sneak performance might be valid at a place with poor visibility.

3.3.4 Long-distance Communication Method

Allowable limit of transmission delay to operators is up to about 2 seconds. In ultra-long-distance communication method more than 30 km, the transmission delay is less than 0.8 seconds. When combining wireless LAN (one channel/IEEE802.11j) and optical fiber, transmission delay of operation data was less than 100 msec.

Although optical fiber communication is applicable to unmanned construction, it is necessary to carefully consider the usage environment and conditions.

3.3.5 Inmarsat Satellite Communication System

The transmission capacity is 64 kbps, and the 8-second delay occurred. If and when the usage is limited to emergency applications with fewer amount of data, it is likely that this system works well for control system.

3.3.6 Startup of Communication and Unmanned Construction Systems

To sum up the participants' opinions, it might take four days to arrange the orders and shipping pertaining to equipment such as remote-control room, relay stations, allocations of unmanned construction machines, and forth. Moreover, it might take one day to set up them, and moreover one day to take their test runs. Considering examination of new technologies, however, it shall take ten days to do so.

4 Efforts to Post-disaster Reconstruction at Aso Bridge District

4.1 Efforts Up till Now [3]

The 2016 Kumamoto Earthquakes are in a series of earthquakes, which are a foreshock earthquake observed at 21:26 on April 14, 2016 with a magnitude 6.5 at a depth of about 11 kilo meters, and then main shock earthquake with a magnitude 7.3 observed at 1:25 on April 16, 2016 with a magnitude 7.3 at a depth of about 12 kilo meters.

It was heavily damaged around the centre of Mashiki, where the earthquakes with a Japanese scale, that is seismic intensity of 7 (hereinafter called Shindo) occurred two times. Moreover, earthquakes with more than Shindo 1 were observed 4,481 times as of April 13,

2016, including seven earthquakes more than Shindo 6 lower.

After the earthquakes, 172 deformations of river embankments such as cracks and subsidence were confirmed in relatively larger river system under control of MLIT. Approaching the verge of rainy season, urgent restoration works were required without a moment's delay

MLIT has carried out urgent restoration works 24 hours a day on 11 relatively larger deformation points in 172 damaged points of river embankments, and worked it out and accomplished the restorations on May 9 before the rainy season in 2016. In addition, considering causes of the damages, methods of restoration and monitoring on the situation of restoration, full-scale restoration works have been done on 52 points required to restore and accomplished by the end of May before rainy season in 2017.

Slope failures and landslide by these earthquakes shredded major transportation routes and then it was transport impossible everywhere. These damages made it difficult to rescue and transport emergency supplies, and moreover to take measures for livelihood rehabilitation. Accordingly, MLIT had urgently restored roads within about 1 week after the disasters, which had been essential for lifesaving and indispensable to transport relief supplies.

The scale of the large-scale landslide at Aso bridge district run up about length 700 meters and about width 200 meters, and the sediment discharge was estimated about 500,000 cubic meters. Many crown cracks and terrace scarps occurred on the head of the landslide. Since the post failure ground surface was steep slope, there was a danger of further collapse caused by rainfall or aftershock.

Since it was the most important task to avoid any secondary disaster under the above circumstance, the latest unmanned construction technologies, which are leveraged the knowledge and results obtained from the demonstration tests as mentioned before, were introduced into the rehabilitation works, as monitoring and sensing movement of the post failure ground surface and the surrounding.

The works commenced on May, 2016. Firstly, as considering what kind of works are possible in the landslide area, building approaching path to the crown of the landslide started in order to construct retaining embankment.

Since sediment in the area destructed by landslide had high soil moisture content, it was forced to move forward to consolidate the surface and subbase of the approaching path as stirring and mixing soil amendment and additive in situ. Subsequently, a full-fledged construction of retaining embankment could commence in July of that year, where was utilized unmanned construction system with multiplexing of connected devices with high-speed and wide-bandwidth data transmission as shown in Figure 9. This unmanned construction system made it possible to remotely operate up to 14 construction machines at the same time and to build retaining embankment. Moreover, this system enabled us to do rounding and remove large boulders at the crown of the landslide, and to remove soil at the post ground surface. Accordingly, urgent construction works could be completed to avoid secondary disaster.

Figure 9. Bird's eye view of unmanned construction conducted at Aso bridge district

Because the danger of secondary disaster is reduced, currently, manned works have been and are being implemented to build permanent fix works such as protection net and inserting rebar.

5 Research and Development on Autonomous Crawler Carrier

5.1 Supposition and Purpose

To achieves a less burden on operators mentally, we have been and are doing research and development on autonomous crawler carrier utilized for material haulage. It is supposed that autonomous construction machines might cause new mental strain on operators, such that, as expecting nothing happens, waiting for something might happen. Then, it is worth providing operators with infographics pertaining to construction machine's behaviour. The infographics include figures, evaluation indexes and messages as to operability, safety and productivity. The infographics give operators opportunity to prognosticate something that might happen.

5.2 Experiments at the institute of technology

Experiments as to operability of a crawler carrier and driving performance of the autonomous crawler carrier developed were conducted at the institute of technology, Kumagaigumi, Co., Ltd. Objectives of the experiments are as follows:

(1) Comparison of operabilities between boarding operation and remote-control of a crawler carrier, and

(2) Confirmation of driving performance of the autonomous crawler carrier developed.

5.3 Field test on at Aso bridge district

The field test on autonomous operation of crawler carrier to haul soil removed at the mountainside was conducted. These crawler carrier was remotely controlled at loading and unloading spots and automatically run through the haulage road.

Examples of the infographics shows the following hazards latent in the haulage road:

(1) Many impacts and free-falls in Figure 10 show the surface of the haulage route is rough and uneven;

(2) Figure 11 shows sudden acceleration occurred uphill and rapid deceleration downhill and both sudden acceleration and rapid deceleration at the waypoint of turnaround, and

(3) Attitude of machine body, however, was stable as shown in Figure 12.

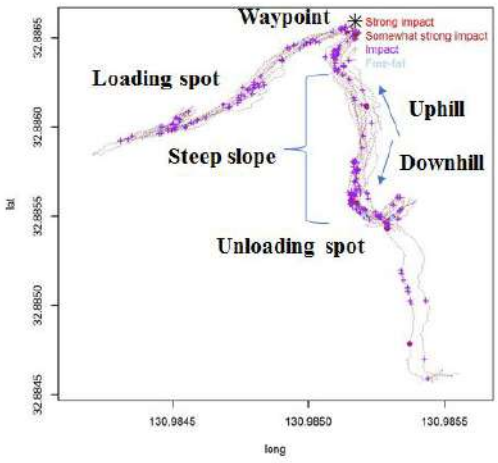

Figure 10. Impact and free fall latent spots occurred in the haulage road

These infographics are visualizing the spatiotemporal behavior of the autonomous crawler carrier, and help the operators to prognosticate hazards. These infographics could enhance their spatial awareness, which would be able to provide the operators with the opportunities to reflect on their own bearings as facing their own works at hand, to reduce likely stress in remote-control operations of construction machines. Furthermore, it would be possible to take timely and quickly correct actions based on detailed visibility of appearances and motions of the autonomous crawler carrier in a whole unmanned construction process.

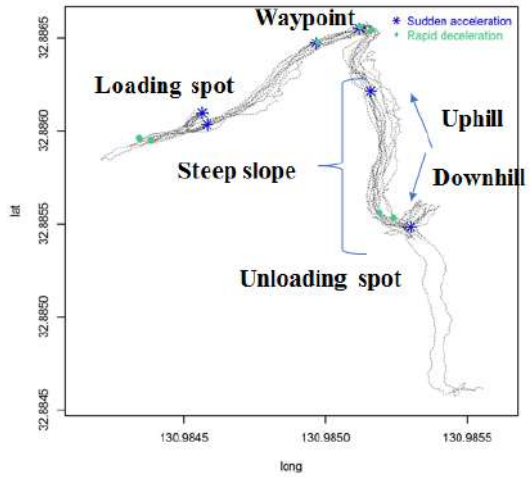

Figure 11. Sudden acceleration and rapid deceleration spots occurred in the haulage road

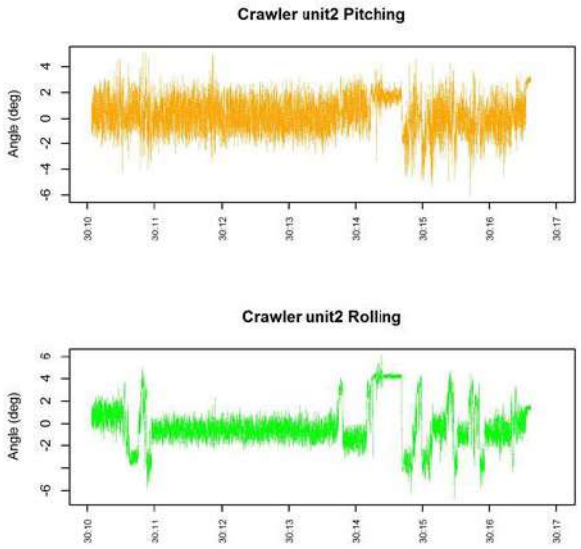

Figure 12. Attitude of machine body

6 Remarks, Further Works and Proposal

This paper presents largely severe natural disasters happened in Japan until now, problems in responses to post-disaster restoration and reconstruction, demonstration tests of ultra-long-distance unmanned construction and the requirements for the deployment, the research and development on autonomous crawler carrier.

Considering the participants' opinions, tasks to be resolved for practical use are listed below.
(1) Unmanned refueling, lubricant oil supply, and machinery maintenance.
(2) Preventive maintenance techniques for inspection and maintenance.
(3) To ensure durability of on-board communication devices.
(4) Autonomous system adjustments such as setup of devices, change of IP address, and so on.
(5) Operator training system to develop skilled operators.
(6) To build communication system suitable for peculiarities of post-disaster restoration and reconstruction site.
(7) Procurement management of construction machines and devices suitable for unmanned construction.

Providing operators with perpendicularly intersecting images of objects, it will become easier to position the object and to adjust its height direction. More arbitrary viewpoints on the monitor, however, are liable to increase new mental workload to memorize and understand simultaneously. It is desirable to develop functions that enable operator to easily accommodate mentally translation, rotation and scaling between different frames of references.

Although automation of construction machines will decrease mental workload on operators, it will produce new mental workloads to carefully watch unexpected occurrences of unsafe events, and cooperative states of several autonomous machines. It is desirable to develop service planning and executing diagram and functions to control complement of remote-control machines, autonomous machines and computer devices operating together for construction.

In future, when unmanned construction system would be deployed in various kinds of remotely dexterous operation in close proximity to other, for examples, approaching to the target (e.g., inspection, repair, monitoring another one), positioning or repositioning dangerous materials, connecting an object with other, grasping and stacking sandbags or gabions, inserting nozzle into a fuel filler port for replenishment, and so on. Then, it is desirable to find the better way to control micro manipulation by remote-control operation.

Finally, following discussions on construction robots at the disaster and accident sub-committee, we propose the following levels of promising applicability of robots in responses to post-disaster restoration and reconstruction.
Level 1: It could be remotely controlled to monitor and investigate within disaster-stricken location.
Level 2: It could propel oneself within disaster-stricken location to complete simple works.
Level 3: It could propel oneself within disaster-stricken location and then remotely controlled to complete complex works. and
Level 4: In combination of autonomous and remote-control operations, it could smoothly complete sophisticate works.

Considering these levels, we are going to do research and development on the further tasks to be resolved.

Abstract –

Automated vehicles (AV) are undergoing development at a remarkable pace and have the potential to revolutionize the existing transportation system. The ASCE [1] evaluated the United States' infrastructure as a D+ grade. Moreover, they predicted radical infrastructure investment gaps in the surface transportation sector in the upcoming years. Some new urbanized regions might require new highways. Meanwhile, many other highways are reaching the end of their service life and will need significant repairs or even replacement. However, this seems to be unrealistic to happen until having a high market penetration of Fully Connected and Autonomous vehicles on the road to benefit from the capacity expansion benefits. Regarding the funding related issues of highway construction in the U.S. and the emergence of AVs, having a better understanding of the future's traffic status is a must. This study investigates the impact of autonomous vehicles on Florida's district five of I-95 highway traffic including three counties: Flagler, Volusia, and Brevard. This research is the first study to develop a fusion model considering the impact of both traffic flow and capacity adjustments based on the literature review to forecast the traffic from 2020 to 2040 by considering the increasing AV market penetration. The proposed approach provides a more realistic plan for government agencies and private investors, and as a result, significant savings financially and resource-wise can be achieved. The findings of the study confirm that autonomous vehicles will increase traffic flow and capacity, and the increase in flow is higher than the increase in capacity.

Keywords –

Autonomous Vehicles; Traffic Flow and Capacity; Long-term Planning; Highway

1 Introduction

Civil infrastructure systems are an integrated system of engineered systems and people within an ecological context. It is critical to keep resiliency of these complex systems in mind during their design, operation, and maintenance to ensure their efficient operation. Differing perspectives are required to understand the system dynamics of such complex systems correctly to achieve effective and stable operation. Highway Infrastructures constitute an economically vital form of transportation infrastructure. They have the potential to contribute to the productivity and economic growth of states economies. ASCE gave U.S. infrastructure a D+ in 2017. They also predicted radical investment gaps in the highway sector. Mobility is the lifeblood of our cities and a crucial aspect of urban life. U.S. automobile incidents are mostly related to human errors and the US petroleum use for road transportation corresponds to approximately 60% of the total U.S. petroleum consumption. Moreover, the average commuter gets delayed 38 hours per year due to traffic congestion. By revolutionizing the nature of personal mobility and removing the need for passengers to be in the car at all times, AVs have the potential to dramatically affect roadway usage and the built environment to yield urban spaces that are safer, more efficient, and attractive. As a result, there is a possibility that the highways that are under construction or soon their construction will commence could be obsolete by the time that they become operational due to the impact of the autonomous vehicles on effective road-capacity and shared mobility travel behavior. However, the chance of occurrence of this scenario is slim before having a high market penetration of fully Connected Autonomous Vehicles (CAVs) on the road to fully take advantage of the capacity expansion benefits.

Then again, the number of trips increases substantially due to various disruptive forces such as the increased population, increased urbanization, increased vehicle miles traveled (VMT) for AV cars as a result of easier trips, and, new consumers such as children, disabled and senior people. Truck-related travels also have a pivotal role in transportation planning as their impact on the transportation system could also be significant which in turn would affect the overall infrastructure costs. There is a positive relationship between the size of the economy and truck VMT. The size of the U.S. economy is expected to double from 2017 to 2045 which will lead to the continuous expansion of truck VMT reflecting increased productivity and population.

Even though several studies have investigated the impacts of Connected and Autonomous Vehicles (CAVs) adoption on travel behavior, much remains to be explored regarding the different ways in which upcoming disruptive forces such as CAVs, urbanization, and, the increasing population could affect the highway infrastructure level of service and their respective cost and benefit streams for the stakeholders. Considering the impact that these forces can have on the societies' quality of life, postponing decision making and quantifying their impact to the time when a significant number of CAVs are operating, and higher urbanization occurs, would be most likely too late for any remedial actions. CAVs in all likelihood will have the most significant and earliest impacts on highway capacity and traffic volume. The number of trips increases substantially due to the mentioned disruptive forces. Impact of increased congestion on the economy decreases the reliability of transportation facilities, increases vehicle operation cost, increases environmental and safety costs, and, deteriorates the roadway conditions. In this study, first, appropriate scenarios based on the literature review are devised and used to project the traffic flow. Then, the capacities of the selected highways are adjusted by considering the market penetration of AVs. Lastly, it is shown that which highways will operate under, at, or over capacity. The output of this study will eventually help long-term planning for infrastructures in Florida. Moreover, this study can be used by policymakers and researchers as an input in disaster management and planning for resilient communities.

2 Literature Review

This study applies a data-driven model to examine the impact of AVs on Florida's district five I95 highway traffic, analyzing the effect under different scenarios considering the increasing AV market penetration. The market penetration of the AVs and the corresponding travel consequences in future are of great interest to researchers and companies. Also, if AVs enter new vehicle markets in the 2020s, it will be the 2040s or 2050s before most vehicles can be Connected and autonomous driving of level four and five [16]. The market penetration assumptions used in this study is based on the literature review [15] and is summarized in Table 1. Two pessimistic and optimistic market penetration scenarios are defined for each specific time being studied in this modeling based on the [15].

Table 1. Optimistic and pessimistic CAV market penetration

2020		2025	
Pessimistic	Optimistic	Pessimistic	Optimistic
0%	10%	10%	20%
2030		2035	
Pessimistic	Optimistic	Pessimistic	Optimistic
15%	30%	30%	40%
2040			
Pessimistic	Optimistic		
35%	45%		

Highways' characteristics should improve to increase its capacity to be able to adjust CAVs in the traffic system [7]. Studies revealed that the capacity of the network could grow two to four time more than current capacity, based on the CAV fleet size [7, 22]. Improvements in the network capacity are the result of the enhanced reliability of travel time, the precision of CAV controls and the communication features [27]. [19] estimated that decreased headways could nearly double or triple roadway capacity. VMT increase concerning road capacity is 30% to 60% (short-term) and 60% to 100% (long-term). [23] also predicted that vehicle-to-vehicle (V2V) coordination of adaptive cruise control could improve capacity by 21% with 50% of all vehicles using this technology, or up to 80% capacity expansion with a 100% coordinated vehicle fleet based on empirical examination.

Due to the new category of users, vehicle automation can improve the mobility of currently underserved populations, namely, those with travel restrictive medical conditions, and seniors. Speculation based studies by different authors show that AVs would add some trips to the traffic network by providing mobility for disabled people and children [27]. [3] speculated that level four vehicles (fully automated) would considerably increase the number of trips because it provides mobility for those groups which are not able to drive using conventional vehicles. AVs could be especially transformative for one group of people in particular: those who are physically incapable of driving. [19] estimated 10% to 14%, [8] estimated

14%, Brown et al. estimated (40%), and [10] estimated 10% to 20% increase in VMT due to the new categories of users. CAV can also increase empty vehicle travel while dropping off or Picking up travelers, or during waiting to be called. It is argued that it is more reasonable for a car to drive around than to pay parking charges [24]. Furthermore, experts predict that there will be an increase in goods delivery by AVs on the roads as well.

Regarding the ownership, total travel effects will depend on the extent that households move from owning to sharing vehicles. Changes to shared mobility lead to a decrease in overall vehicle travel. It is not clear that AVs increase or reduce total vehicle travel. Lovejoy, [14] predicted that Households tend to significantly decrease their vehicle travel, by 25-75%, when they move from owning a vehicle to sharing it. Regarding safety, it is claimed that because human error is the reason for 90% of crashes. Autonomous vehicles full adoption will decrease crash rates and costs associated with insurance companies by 90% [9].

3 Methodology

The research includes the application of input-output modeling technique to conduct a traffic analysis on I-95 Highway in district five of Florida Department of transportation, counties of Flagler, Volusia, and Brevard. Weighting method is used to have a normalized Annual Average Daily Traffic (AADT) for all the segments of each county calculated by FDOT Hybrid model from 2020 to 2040, recently developed by the forecasting engineering team. In this study, the sections of the FDOT final report in 2015 are being used. There are 38 stations in total defined for the Highway I-95 in District five. Each station has information regarding the state road no., start, and end of the segment, length, level of service and so forth. [11] used systems dynamics modeling to generate three scenarios that describe the possible negative and positive outcomes of the broad adoption of AVs. They defined three scenarios to predict the future's impact of AV adoption on traffic. Likely profits include cheaper and safer travel by car, with enhanced mobility for those who do not have access. They also consider the ownership behavior of the passengers. Figure 1 illustrates the summary of the parameters used in this research for adjusting traffic volume and capacity. In this study, the optimistic and pessimistic thresholds are chosen to be used as special cases due to the suggested model by [15] regarding the AV market penetration. In the modeling procedure, the traffic capacity is adjusted by the method proposed by [17]. The inputs and outputs of this study presented in Table 2. The inputs data include the FDOT's traffic-related data and the literature information to build the fusion model regarding the various studies in this modeling. Moreover, this study includes six outputs as shown in Table 2.

Table 2. Inputs and outputs of the model

Inputs	
FDOT's Inputs	Traffic Flow Forecast Data (Average Annual Daily Traffic)
	Traffic Capacity information
Literature's input	Impacts of AV on Traffic Flow and Capacity

Outputs	
Outputs 1	Fusion Model, Defined Scenarios base on the impacts of AV on Traffic
Outputs 2	Impact of New categories of users on V/C Ratio
Outputs 3	Impact of Shared or Private Ownership on V/C Ratio
Outputs 4	Impact of Time Gaps-Capacity on V/C Ratio
Outputs 5	Impact of Behavioral Scenarios (Base-Disruptive-Adaptive) on V/C Ratio
Outputs 6	Impact of Construction scenarios on V/C Ratio

This study uses the input-output modeling technique to conduct a series of scenario analysis. Scenario analysis is the process of evaluating potential future events through the consideration of feasible alternatives, though, not equally likely, states of the world. Figure 1 shows the assumptions regarding different scenarios of the model based on the literature review that accounts for adjustments for traffic flow and capacity.

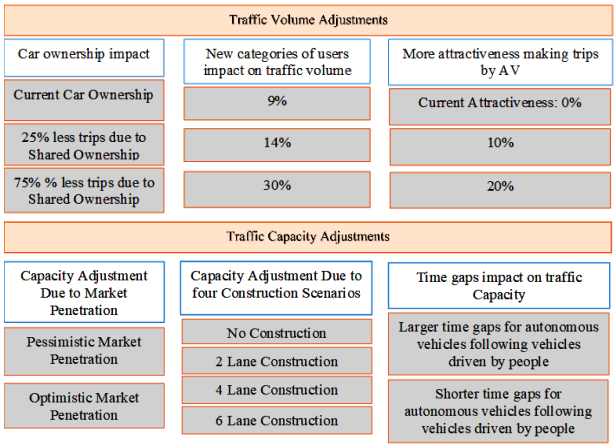

Figure 1. Traffic volume and capacity parameters

assumptions in this study.

4 Results

There are five pivotal aspects related to volume/capacity ratio (V/C) discussed in this section. Namely, the impact of new categories, the shift of the ownership, large and short time gaps, three different behavioral scenarios, and constructing of new lanes based on the Volume/Capacity (V/C) ratio.

Table 3 shows the assumptions and traffic information data regarding the study of the impact of various new categories of users on volume/capacity ratio. This study assumes a pessimistic market penetration of autonomous vehicles. Moreover, the impact of shared ownership and the attractiveness of having more trips by AV is not considered.

Table 3. Information regarding the data and the assumptions used in Figure. 2

County	Brevard County
I-95 segment #	15
Market penetration	Pessimistic
Variable under study	Impact of New categories of users
Variable's impact 1	0%
Variable's impact 2	9%
Variable's impact 3	14%
Variable's impact 4	30%
Impact of Shared or private ownership	0%
Impact of More attractiveness of making trips by AV	0%

The impact of new categories of user increase from 3% in 2025 to 18% in 2040 considering four different scenarios on the V/C ratio is depicted in Figure 2. The results show that the difference between the V/C ratio increases between different scenarios as the time passes. It is evident that higher percentage new user scenarios (more evident for the 30% scenario) start departing from the baseline earlier. The growing distance between the scenarios shows that there is a critical need for federal government to pass limiting laws (Licencing) to manage the probable new users efficiently to avoid lower service level and high congestion level. Furthermore, this study did not consider the children under 18, a tech-savvy market that mobility service start-ups are already tapping, in the calculations which have the potential to worsen the traffic congestion.

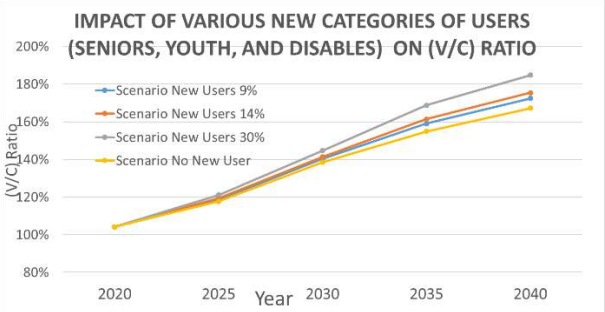

Figure 2. Impact of new categories of users on (V/C) ratio.

Table 4 shows the assumptions and traffic information data regarding the study of the impact of shared and private on volume/capacity ratio. This study assumes an optimistic market penetration of autonomous vehicles. Moreover, the impact of shared ownership and the attractiveness of having more trips by AV is not considered.

Table 4. Information regarding the data and the assumptions used in Fig. 3

County	Brevard County
I-95 segment #	15
Market penetration	Optimistic
Variable under study	Impact of Shared Ownership
Variable's impact 1	0%
Variable's impact 2	25%
Variable's impact 3	75%
Impact of New categories of users	0%
More attractiveness of making trips by AV impact	0%

Figure 3 shows the crucial impact of the shift of the ownership from private cars to shared mobility on the service level of the highway. It can be inferred that shared ownership can significantly increase the service level of the highway and delay the overflow of the highway. For instance, %75 shared ownership would delay the overflow of the highway by six years. CAVs are a naturally attractive type of transportation. The results from figure 3 stresses the importance of planning to encourage people using different kinds of shared mobility as the primary transportation means.

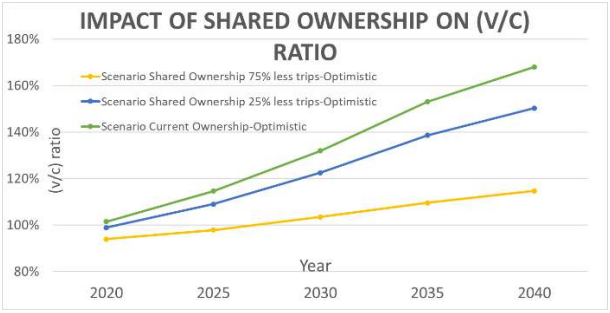

Figure 3. Impact of various shared car ownership on (V/C) ratio.

Table 5 shows the assumptions and traffic information data regarding the study of the impact of larger and shorter time gaps for autonomous vehicles following vehicles driven by people on volume/capacity ratio. This study assumes both pessimistic and optimistic market penetration of autonomous vehicles. Moreover, the impact of shared ownership and the attractiveness of having more trips by AV is also included.

Table 5. Information regarding the data and the assumptions used in Fig. 4

County	Brevard County
I-95 segment #	15
Market penetration	Pessimistic & Optimistic
Variable under study	Impact of Time Gaps of AV Following Vehicles driven by People
Variable's impact 1	Shorter Time Gaps in Optimistic Scenario
Variable's impact 2	Larger Time Gaps in Optimistic Scenario
Variable's impact 3	Shorter Time Gaps in Pessimistic Scenario
Variable's impact 4	Larger Time Gaps in Pessimistic Scenario
Impact of New categories of users	14%
Impact of Shared or private ownership	25%
Impact of More attractiveness of making trips by AV	20%

Figure 4 depicts the impact of large and short time gaps on the capacity regarding both optimistic and pessimistic market penetration. The mentioned time gap can have a 20% impact on (V/C) ratio in 2040. Automated technologies allow shorter headways between the vehicles, which in turn have the potential to increase the capacity of the freeway network and reduce traffic delays significantly. But it is important to remember that small market penetration rates of automated vehicles do not lead to noticeable capacity increase. The potential benefits are likely to be realized at higher penetration into the traffic mix. As a result, it is a crucial variable to consider in modeling for further studies.

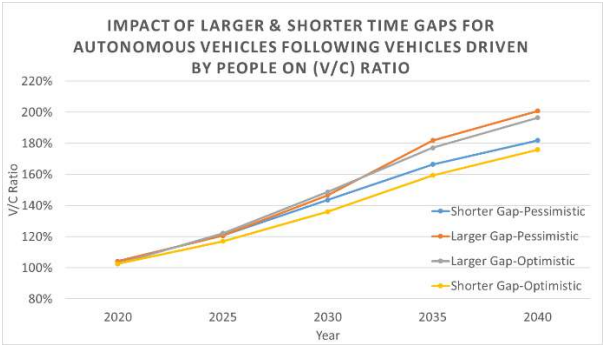

Figure 4. Impact of large and short time gaps for autonomous vehicles following vehicles driven by people on capacity.

Table 6 shows the assumptions and traffic information data regarding the study of the impact of different behavioral scenarios on the volume/capacity ratio. This study assumes an optimistic market penetration of autonomous vehicles. Moreover, the effect of variously shared ownership, the attractiveness of having more trips by AV and the new categories of users is considered.

Table 6. Information regarding the data and the assumptions used in Fig. 5

County	Flagler County
I-95 segment #	5
Market penetration	Optimistic
Variable under study	Behavioral Scenarios
Impact of Time Gap regarding the capacity adjustments	Shorter Time Gaps

Variable's impact 1, **Baseline Scenario**	Variable's impact 2, **Adaptive Scenario**	Variable's impact 3, **Disruptive Scenario**	
9%	9%	30%	New users
0%	75%	0%	Shared or private ownership
0%	0%	20%	More attractiveness

Figure 5 illustrates the impact of three different

behavioral scenarios of the future on the (V/C) ratios. As shown in that figure, the gap between the disruptive scenario and the adaptive or baseline scenario exceeds as passing the time. The gap between the scenarios is showing a critical issue of how proper planning and taking essential measures ahead regarding the adaptive scenario can delay or even enhance the traffic status. Figure 6 shows the threshold (Maximum and Minimum) range of the possible scenario of the future.

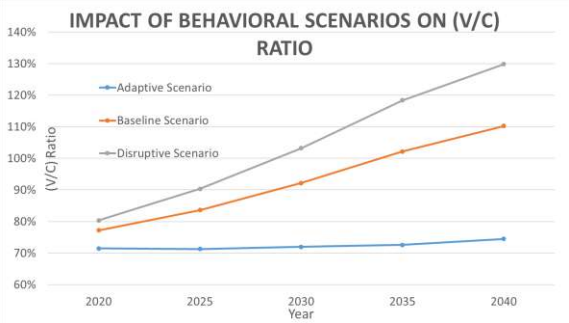

Figure 5. Impact of different behavioral scenarios on (V/C) ratio.

Table 7 shows the assumptions and traffic information data regarding the study of the impact of construction scenarios on the volume/capacity ratio. This study assumes an optimistic market penetration of autonomous vehicles. Moreover, the effect of variously shared ownership, the attractiveness of having more trips by AV and the new categories of users is considered.

Table 7. Information regarding the data and the assumptions used in Fig. 6

County	Brevard County
I-95 segment #	15
Market penetration	Optimistic
Variable under study	Impact of Construction Scenarios
Variable's impact 1	No Lane Construction
Variable's impact 2	2 Lane Construction%
Variable's impact 3	4 Lane Construction%
Variable's impact 4	6 Lane Construction
Impact of New categories of users	14%
Impact of Shared or private ownership	25%
Impact of More attractiveness of making trips by AV	20%

Figure 6 illustrates the impact of constructing new lanes on the (V/C) ratio. As shown, in 2030 there is a need to build two new lanes to have under capacity status, but if instead, four lanes are constructed, the issue will be solved until 2040. It is evident that as the number of lanes increases the impact on the V/C ratio decreases. In other words, the first extra two lanes would provide more utility compared to the next extra lanes. This figure can also be used as a tool to find the optimized time of adding more lanes to the highway not to face congestion issues.

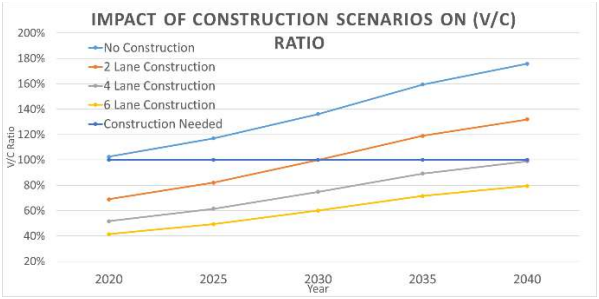

Figure 6. Impact of construction scenarios on (V/C) ratio.

5 Conclusion

This study presents a comprehensive analysis of finding the impact of connected and autonomous vehicles on traffic flow and capacity. This research is develops a fusion model considering the impact of both traffic flow and capacity adjustments based on the literature review. This research not only contributes to the body of knowledge in the transportation field by conducting a comprehensive study to develop a fusion model considering the impact of both traffic flow and capacity adjustments based on the literature review for the highways, but also has important practical applications in managing the investment measures of government agencies and private investors. The insight into the upcoming highway construction needs, with a focus on understanding the disruptive impact of CAVs on highways' performance provided by this study, would improve the resiliency of transportation systems. The findings of the study confirm that connected and autonomous vehicles will increase both traffic flow and capacity, and the increase in flow is higher than the increase in capacity. Shared ownership of passenger vehicles has been found to mitigate the traffic flow. The growth in projected demand for AVs will not be accommodated by a similar increase in the capacity that currently exists, resulting in even greater congestion of the market penetration of AVs. The time to plan the infrastructure necessary for smooth deployment of AVs and avoid congestion due to the projected traffic flow is passing. Meanwhile, the proposed approach provides a more realistic plan for

government agencies and private investors, and as a result, significant savings financially and resource-wise can be achieved. Based on the preliminary results presented in this paper, it can be concluded that federal and local governments should take a proactive approach and began to act. It is a critical issue to think ahead and plan to use limited resources efficiently. Researchers can further investigate the impact of the involved parameters on the emerging technologies to address the upcoming challenges. The directions for future research includes considering the impact of urbanization in dense cities around the world. Some States, due to their logistics and critical location, are subject to facing hurricanes, wildfires, heat waves and other natural disasters, especially regarding the severe climate change predictions, studying the impact of this parameter on the necessary highway infrastructure for the emergency evacuation situations is a must. Moreover, assessing AV impact's sensitivity to different shared use, Public Transportation behavior and urban sprawl growth are also required in better realizing the impact of AVs on the highways' service level.

Abstract –

Temporary bridges are indeed of need after a critical disaster due to the connectivity and efficient assembly. However, the conventional structural design of these temporary bridges may be limited by the construction requirements. In this study, a new type of structural connectors is developed and beneficial for more effectively assembling ability of temporary bridges. In this development, a construction-oriented design procedure is initiated from a conceptual design and verified by an in-house, small-scale model. This conceptual connector is then modified and analyzed by sophisticated software and finally fabricated for the full-scale use. This design has a bolt-free feature and allows rotational assembly workability. The structural analysis and virtual 3D simulation are conducted to numerically verify the state-of-the-practice connector. The results from the numerical simulation imply the possibility to employ the proposed connector for a temporary bridge.

Keywords –

Bolt-free connectors; Rotational assembly workability; Temporary bridges; Construction-oriented design procedure

1 Introduction

A temporary bridge is indeed of need after a critical disaster because this structure resolves the disruptive transportation of residents and associated resources. In past, the temporary bridge designed by Yeh's team [1] was built up much faster than a commonly used temporary bridge, i.e., a culvert bridge. As analyzed from the construction video in Figure 1. Construction video of a temporary bridge. and in Table 1. Analysis of the temporary bridge construction., the erection of a glass-fiber-reinforced-polymer (GFRP) girder module costed a lot of time and human resources. The construction of the temporary bridge required five workers to adjust the orientation and alignment of this bridge module for assembly and connection. In addition, the workers had to stay at the end of the incomplete bridge structure and to accomplish the assembly, raising a concern about the worker safety. The connection between each bridge module required hundreds of bolts, resulting in tremendous manpower demands. Thus, this task should be improved by a more efficient assembly approach.

Figure 1. Construction video of a temporary bridge.

Table 1. Analysis of the temporary bridge construction.

Structural component	Task	Time[min.]/ labors/difficu-lty [1-10]
Steel segment A	Assembly	15/16/3
Steel segment B	Assembly	15/16/3
Steel segment C	Assembly	15/16/3
H-tower	Assembly	20/14/3
GFRP segment 1	Assembly	20/10/4
GFRP segment 2	Assembly	20/10/4
GFRP segment 3	Assembly	20/10/4
GFRP segment 4	Assembly	20/10/4

GFRP segment 5	Assembly	20/10/4
Steel segment A	Erection	10/7/4
Steel segment B	Erection	10/7/4
Steel segment C	Erection	10/7/4
Steel bridge panel	Installation	30/6/3
H-tower	Erection	20/15/6
GFRP 1	Erection	15/16/8
GFRP 1	Steel cable fastening	15/18/4
GFRP 2	Erection	20/16/8
GFRP 2	Steel cable fastening	20/18/4
GFRP 3	Erection	25/16/8
GFRP 3	Steel cable fastening	20/18/4
GFRP 4	Erection	30/16/8
GFRP 4	Steel cable fastening	20/18/4
GFRP 5	Erection	30/16/10
GFRP bridge panel	Installation	120/6/3

To achieve effective construction, some structural connectors featuring quick assembly and reduced manpower demands were developed. In 1994, the ATLSS system was developed to automate the beam-to-column assembly [2]. This system consisted of a quick-assembly connector and a cable-driven Stewart platform equipped on a crane. Due to expensively required equipment, the ATLSS system needed to be improved with respect to economic feasibility for the construction industry nowadays [3]. In contrast, ConXtech was a technique that provided structural connectors for quick assembly with specific constraints [4]. The ConXtech protected workers from potential risks because the working time on the assembly of structural components (e.g., workers staying at a high position) was reduced. Similarly, Kim *et al.* developed an automated beam-to-column assembly method by integrating special connectors, guiding ropes, and two developed guiding machines [5]. In addition, Liang *et al.* developed a self-rotating hook block that allowed assembling a steel beam to a steel column based on Quicon [6] connection design [7]. All these developments are directed to expedite assembly process without inducing risky manpower in construction.

In this research, the objective is to develop and design a new construction-oriented structural connector for a temporary bridge. In this development, a construction-oriented design procedure is initiated from a conceptual design and verified by an in-house, small-scale model. This conceptual connector is then modified and analyzed by sophisticated software and finally fabricated for the full-scale use. This design has a bolt-free feature and allows rotational assembly workability. The structural analysis and virtual 3D simulation are conducted to numerically verify the state-of-the-practice connector.

2 Construction-oriented structural connector design

A construction-oriented design workflow for the structural connector is proposed in this section. The workflow was iteratively improving the connector design based on a design concept described in the section as well. The section also elaborates the geometry formation.

2.1 Design workflow

Five steps were identified in the workflow in Figure 2. The design workflow for a structural connector. Step 1 is to target a structural component to redesign. The temporary bridge was constructed by connecting bridge segments. We planned to redesign the original connectors between bridge segments for quick bridge assembly. In the Step 2, by taking advantage of existing machineries we proposed possible construction methods. In the research, we aimed to use a mobile crane to assemble a temporary bridge. The following is Step 3 creating an original connector design based on the selected construction method. Finally Step 4 iteratively refines the design by the results of 3D simulation, 3D printed prototype, and finite element analysis.

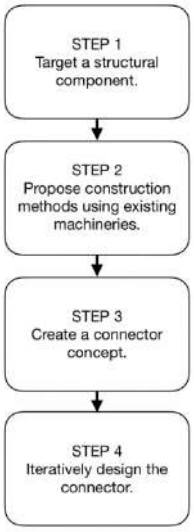

Figure 2. The design workflow for a structural connector.

2.2 Conceptual connectors and requirements

The initial connection concept was formed by a connecting mechanism and an erection method (see Figure 3. The initial connection concept). The connecting mechanism was a gravity-triggered assembly with a designed connector. When the attached connector is adjusted to the designed position a structural component applies the self-weight to finish the connection. Afterwards, the bridge segment would be temporarily fixed for workers finalizing the rest connections. The erection method was that a mobile crane lifts one end of the structural component, transports the component to where the attached connector was being placed at the designed position, and finally the crane releases the load to trigger the assembly of two structural components. Moreover, the structural behavior of the structural connector was also considered in the connection concept. The connection design must resist two axial forces, a torsional force, and a shear force. Additionally, the designed connector was attached onto the top of the connecting face of the bridge segment, and a pin-hole connection was at the bottom of the connecting face. Therefore, the designed connector and the pin-hole connection can resist negative moments and positive moments respectively.

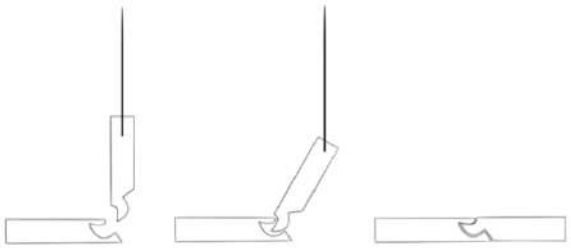

Figure 3. The initial connection concept.

2.3 Connector geometry

The workability, the strength, and the manufacturability are three major factors influencing each generation of the connector design. Because there is no definite approach to consider all major factors in a design iteration, we refined the connector design by means of divide-and-conquer approach in each design iteration. For example, although the initial connection concept met the requirements of the workability and the strength, the connection remained a challenge of producing the female connector. Therefore, for this challenge, we only focused on the production of the connector, not on the workability and the strength. We reformed the connector geometry, and the connector became the assembly of producible pieces as Figure *4*. The reformed connector. Testing the workability of connector design can be easily executed by virtual 3D simulation with physics engine and 3D printing technology. In a macro perspective, the virtual 3D simulation can simulate the assembly of the bridge segment with the designed connector. The virtual simulation helps the designer obtain the big picture of the connector application in temporary bridge construction. In contrast, the 3D printing technology can identify the problems of production from a micro perspective. Take the study for example, the tolerance and the 3D model to produce could be adjusted by taking the 3D printed prototype as a reference. The structural behavior of the designed connector can be efficiently analyzed by Finite Element Method. The manufacturability verification of the designed connector is taking the technical constraints of manufacture into the design consideration.

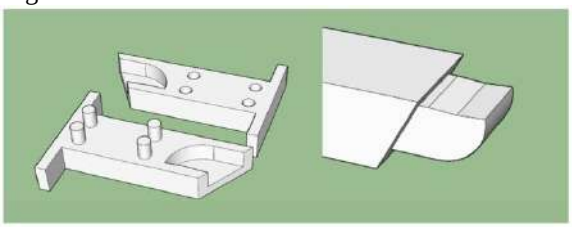

Figure 4. The reformed connector.

3 Results

This section shows the finalized connector design and two feasibility tests including a virtual assembly simulation and a structural analysis.

3.1 Finalized connector design

The final design of the connection was formed by a male connector and a female connector (see Figure 5. The finalized connector design (a) male connector, (b)

female connector). Each of both was constituted of two same designed plates and an end plate. When connecting to the female connector the joint at the top of the male connector attaches onto the groove on the top of the female connector. As a result, the male connector may rotate about the joint and then complete the connection.

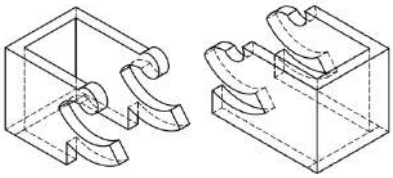

Figure 5. The finalized connector design (a) male connector, (b) female connector.

3.2 Virtual assembly simulation

We simulated the connection process in a virtual environment (see Figure 6. The virtual assembly simulation). A designed connector was attached to the bridge segment. The assembly simulation only tested the designed connection while there would be five other pin-hole connections between two bridge segments in an actual case. The simulation indicated that the alignment of the bridge segment directly influenced the operation to succeed the connection. Once the female connector and the male connector were not placed on the same plane, the connection would be stuck until the male connector was adjusted to be on the same plane of the female connector.

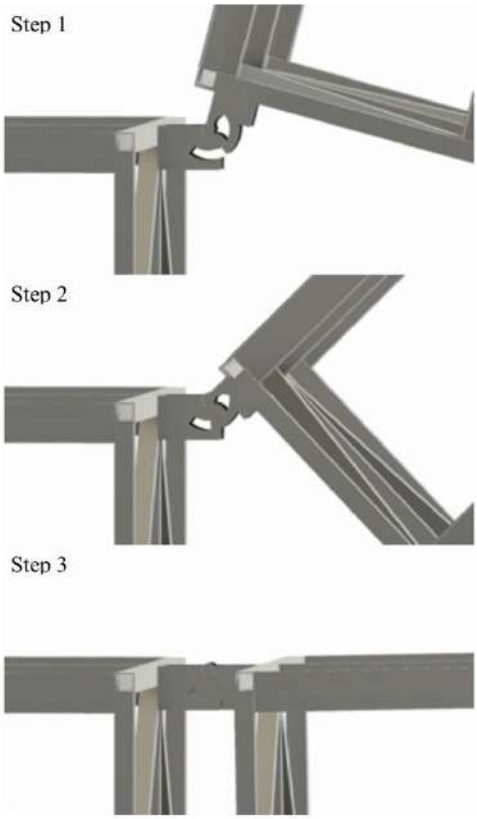

Figure 6. The virtual assembly simulation.

3.3 Results of structural analysis

We conducted four structural analyses using finite element method. Each analysis applied the designed load of the connection between bridge segments and defined the end plate of the female connector as a fixed end. The results showed the Von Mises stress.

(1) The compression test result in Figure 7. The compression test result represented that the weakest occurred at the upper part of the connection.

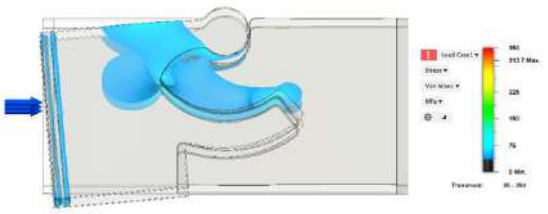

Figure 7. The compression test result.

(2) The tension test result in Figure 8. The tension test result showed that the weakest area occurred around the turning point of two discontinuous curves.

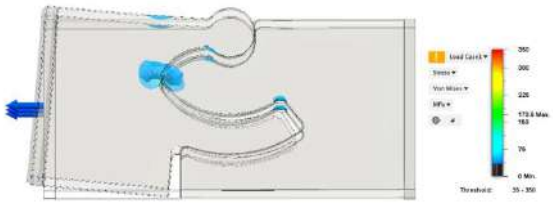

Figure 8. The tension test result.

(3) The torsion test result in Figure 9. The torsion test result showed perfect resistant to the designed torsion.

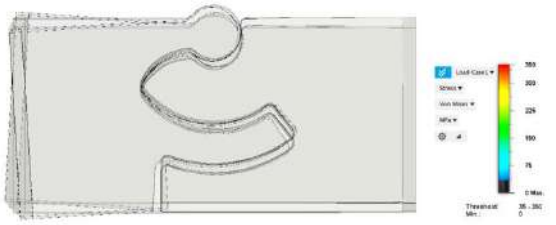

Figure 9. The torsion test result.

(4) The shear test result in Figure 10. The shear test result represented that the joint was weakest part when applying the designed load on the top surface of the male connector.

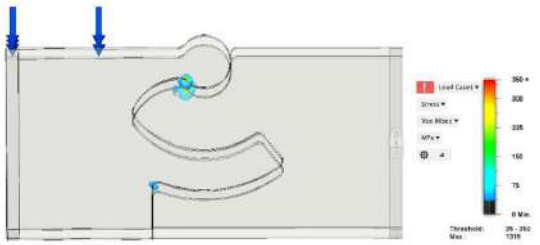

Figure 10. The shear test result.

4 Conclusion

This study proposed and designed a new type of structural connectors featuring bolt-free and rotational-assembly connection. This connector was derived from a conceptual design in the viewpoint of construction convenience and fabricated through a 3D printer. The workability of this connector was numerically and experimentally verified using a 3D manipulation platform and a small-scale model, respectively. Before turning this connector for the real-world use, the productivity and mechanics were also discussed and analyzed. Therefore, this new type of structural connectors was ready for a temporary bridge and will be experimentally evaluated in the future study.

Abstract -

Robots need to perceive beyond lines of sight, e.g., to avoid cutting water pipes or electric wires when drilling holes on a wall. Recent off-the-shelf radio frequency (RF) imaging sensors ease the process of 3D sensing inside or through walls. Yet unlike optical images, RF images are difficult to understand by a human. Meanwhile, in practice, RF components are often subject to hardware imperfections, resulting in distorted RF images, whose quality could be far from the claimed specifications. Thus, we introduce several challenging geometric and semantic perception tasks on such signals, including object and material recognition, fine-grained property classification and pose estimation. Since detailed forward modeling of such sensors is sometimes difficult, due to hidden or inaccessible system parameters, onboard processing procedures and limited access to raw RF waveform, we tackled the above tasks by supervised machine learning. We collected a large dataset of RF images of utility objects through a mock wall as the input of our algorithm, and the corresponding optical images were taken from the other side of the wall simultaneously as the ground truth. We designed three learning algorithms based on nearest neighbors or neural networks, and report their performances on the dataset. Our experiments showed reasonable results for semantic perception tasks yet unsatisfactory results for geometric ones, calling for more efforts in this research direction.

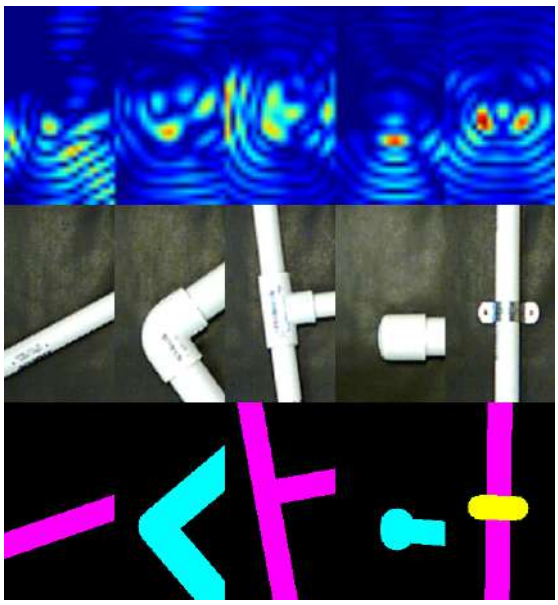

Figure 1. Overview of our problem. The first row are Walabot-returned 3D radar images (sliced at 1cm-depth for visualization) through a wooden board over the device. The second row are photos taken from the opposite side of the wooden board over Walabot. The third row are visualizations of geometric and semantic information of PVC pipe components estimated by our method. Different classification results are best viewed in color.

1 Introduction

It is often necessary to detect or even recognize the occluded objects on job sites for safety reasons. Ground penetrating radar (GPR) system has been applied for subsurface object detection. For example, GPR system can be used to survey the geological information on the construction site to predict potential construction safety hazards [1]. Signal detected by GPR can also be fused with other data. Li et al. [2] proposed a method to survey and visualize underground utilities by integrating the pre-processed GIS data with GPR signal, whose location is determined by RTK GPS.

Besides GPR, through-wall imaging techniques are widely used in fields such as fire protection, hostage rescue, flaw detection, and building construction. It is especially useful to estimate the content and structure beyond line-of-sight during maintenance and renovation. Abdel et al. [3] reviewed the state-of-the-art techniques of location and condition assessment for underground water pipelines. By employing radio frequency (RF) sensors, a through-wall imaging system can extract information through obstructions, which is impossible by using conventional line-of-

*Chen Feng is the corresponding author.

sight sensors, such as optical cameras or LIDAR.

With the development of RF sensors and signal processing algorithms, many through-wall imaging techniques have been proposed. Ahmad et al. [4] provided a method of digital beam-forming to capture 3D images behind a single uniform wall. Zhuge et al. [5] have created a real-time 3D near-field imaging algorithm with the application of Fast Fourier Transform (FFT) for 2-D multiple-input-multiple-output (MIMO) sensor array. By implementing their methods, a 3D image of object reflectivity can be formed with high accuracy and computational efficiency. In 2017, Karanam et al. [6] used WiFi router and WLAN card mounted on two UAVs to get the 3D image of an area surrounded by brick walls. These techniques are well designed in the phase of signal processing and imaging, with clearly defined forward sensor models and wave propagation model. Besides, to get higher resolution images, their antenna arrays are relatively large. In Zhuge's method, the self-designed antenna array is 0.54 m wide along both azimuth and elevation directions [5], and in Ahmad's method, their simulated antenna array can reach 2.4m [4]. Such large antenna arrays are less portable for mobile robotics applications. Also, as far as we are aware of, not much research has been done for multi-class object recognition from through-wall images.

As we mentioned before, through-wall imaging techniques benefit from increasingly accessible inexpensive off-the-shelf RF sensors. Walabot, a portable UWB-based (ultra-wideband) sensor developed by Vayyar Imaging Ltd, can provide API for users to capture 3D RF images. It has about the same size as a cell phone, drawing power and sending data through a single USB cable. Thus it can be easily incorporated in mobile robotic applications. However, due to commercial reasons, some key parameters of the Walabot sensor model are unknown to users, so detailed forward modeling of the sensor's physical process and its calibration is either impractical or cost-inefficient. Besides, the small aperture size causes low ambiguity resolution, resulting in ripple-like artifacts in the signal, as shown in the top of Figure 1. In practice, RF components are often subject to hardware imperfections (e.g., the phase noise of oscillators and mixers, nonlinear distortion from RF amplifiers, mutual coupling between antennas [7, 8]), resulting in distorted RF images, whose quality is far from the claimed specifications in user manuals. This distortion may be more severe for low-cost RF imaging systems [9]. Therefore, objects are difficult to be recognized intuitively by humans from these 3D images.

Fortunately, with the help of machine learning, some categorical and geometric information of objects could still be restored from raw 3D images, such as material, size, shape, and pose, etc. Moreover, these utility objects, such as PVC (polyvinyl chloride) pipe components, have important fine-grain attributes including thickness and contents (full of water or empty). They are all crucial for the aforementioned construction applications. The bottom of Figure 1 illustrates several results of our method based on the Convolutional Neural Network (CNN).

We highlight the contribution of our paper as follows:

- We introduce several challenging geometric and semantic tasks for better understanding and utilizing RF-based through-wall images, including materials recognition, fine-grained property classification and pose estimation.
- We propose to use machine learning methods to address the above tasks while bypassing detailed RF sensor modeling and electromagnetic wave propagation modeling that is sometimes inaccessible to end users, which showed promising results.
- We develop methods for efficiently collecting a large number and variety of through-wall images using an off-the-shelf RF sensor, with ground truth automatically generated from machine vision.
- We will make our dataset publicly available to stimulate more research in this direction.

2 Related Work

As previously mentioned, there are many research works aimed at image formation from RF signals. However, another branch of research is focused on extracting information from radar images or even raw signals. Among those, there are some works on RF object recognition and pose estimation, which is closely related to this paper.

Object Recognition. Yeo et al. [10] trained a random forest classifier for object recognition using handcrafted statistical features from raw signals. Their method has been tested for object classification, transparent material classification, and body part classification. Their method reaches over 90% accuracy on all three tasks. However, their method was not implemented with obstructions between the sensor and targets. Avrahami et al. [11] developed an activity recognition method through a cashier's counter, using a Walabot sensor, which is the same sensor used in our paper. Their method projects the 3D images sensed by Walabot to 2D plane, then extracts handcrafted statistical features for classification. By using an SVM classifier, their method reaches 90.5% accuracy. Zhao et al. [12] used RF signals reflected from a person's body to recognize one's emotion by extracting the person's heartbeats. Their method reaches comparable accuracy to on-body ECG monitors. All these above methods need handcrafted feature extractions. Wang et al. [13] proposed a method for gesture recognition using Google Soli [14], based on deep learning. However, Soli is a dedicated and customized millimeter wave radar system, which operates at a much higher frequency than Walabot, thus has a

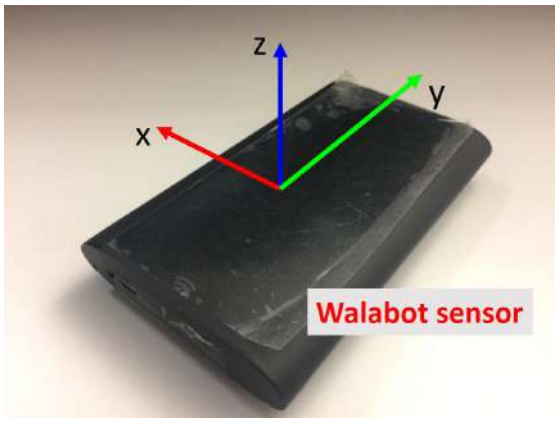

Figure 2. Walabot Coordinate System. The z axis is towards the object being detected.

higher spatial resolution. Also, there were no obstructions between the sensor and the target in their work.

Pose Estimation. Pose estimation from optical sensors has been studied for a long time [15–17]. However, pose estimation from RF sensors currently has not attracted a lot of research attention. Adib et al. has done a lot of work on pose estimation using RF sensors. In 2014, Adib et al. [18] proposed a 3D motion tracking system, WiTrack, which can track the 3D motion of a human, and estimate the direction of a pointing hand. Then they [19] presented the RF-Capture system, which can track the limbs of a human body. Most recent research on pose estimation from RF signal is from Zhao et al. [20]. In this paper, they create a deep neural network approach that estimates human 2D poses through the wall. Our work is inspired by this line of research, yet our focus is on construction robotics applications that require a different set of semantic and geometric perception tasks.

3 Method

3.1 Sensor Introduction

Walabot is an ultra-wideband MIMO array that operates at frequency 3.3-10 GHz. The model used in this research has 18 antennas. The coordinate system is defined as illustrated in Figure 2. The sensing arena used in our experiment is -5 to 5 cm in x direction, -9 to 9 cm in y direction and 1 to 10 cm in z direction. The resolution is set to 0.5 cm. In this case, the raw 3D image sensed by Walabot is a tensor of dimension $37 \times 21 \times 19$.

3.2 Dataset Design

Our dataset is designed for two tasks. The first task is material-based classification and pose estimation for linear objects. In this task, we set 5 classes of objects made from different materials. They are all common in-wall structures, including cable, wooden stud, steel pipe, PVC pipe, and background. The pose estimation task is designed only for 3 classes of straight objects: cable, wooden stud, and steel pipe. For PVC pipes, multiple shapes of pipe components are considered, and their pose estimation is designed in the second task.

The second task is more fine-grained compared to the first one, which focuses only on PVC pipes. This task contains multi-label classification and pose estimation. The PVC pipe components are classified from three aspects:

- **Thickness.** We use two types of PVC pipes in our experiment, one is 1/2" thick, the other is 1" thick. We use binary labels on these two types of pipe.
- **Content.** The PVC pipes are either full of water or empty, which is another binary classification problem.
- **Shape.** The PVC pipe components in the sensing arena are classified as 5 shapes: straight, elbow, tee, end and strap. Different shapes of objects have different ways of pose parameterization, as Figure 3 shows. It is worth to mention that, for straight components, two translational parameters x and y are enough to characterize the pose. For other types of components, two translational parameters x, y and one rotational parameter θ are used to characterize the pose. The specifications of our dataset are listed in the experimental part. For straight components, the pose is described by the coordinates of the foot of the perpendicular from the original point to the line. For elbow components, the pose is described by the coordinates of the intersecting point of the two pipes, and the angle of the angular bisector. For tee components, the pose is described by the coordinates of the intersecting point, and the angle of the pipe which constitute the vertical part of letter T. For end component, the pose is described by the coordinates of the center of the cap, and the angle of the ray away from the cap. For the strap component, the pose is described by the coordinates of the strap and the angle of the perpendicular line. The pose of the straight components also applies in task 1.

Note that we currently ignore situations when multiple objects appear simultaneously in the sensing arena, and only focus on RF images of a clean background, which is not very uncommon in practices.

3.3 Data Collection

Figure 4 shows our data collection system. The wooden board here serves as the mock wall's shell. Walabot is

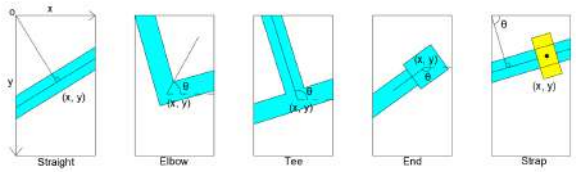

Figure 3. The definition of pose for 5 shapes of PVC pipe components.

placed right under the wooden board. Objects are placed on the upper surface of the wooden board with different poses against a black background. The camera takes photos of the objects, and synchronously, Walabot records the data it sensed from below the board. The photos are warped to the cross-section of the upper surface and the sensing arena using a homography prior to any processing. This allows us to also employ the cross-modal data annotation strategy like in [20]. But we do not need a pre-trained deep neural network to get the object poses from a camera. Instead, we developed a simple marker-based approach to track object poses from a camera, which is very robust under our controlled lab environment. This method is based on estimating the skeletons of color tapes. Figure 5 shows the procedure of pose estimation from color tapes.

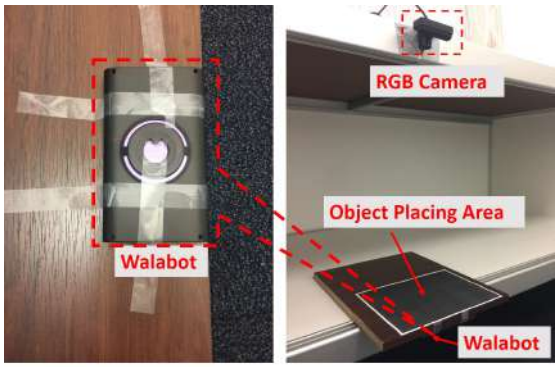

Figure 4. Cross-modal Data Collection System. RGB camera is placed above the object placing area with a black background while Walabot is placed under the object placing area (on the other side of the wooden board). Therefore, RF signals and images of the object can be collected simultaneously. The left image shows the bottom view of the Walabot in the right image.

Color Statistics. The tape is placed against the background, then the mean RGB value of pixels on the color tape and standard deviation of the distances of pixels on the color tape to the mean RGB value is calculated respectively.

Find Color Tape. For each pixel on the image taken by the camera, calculate the distance to the mean RGB value. If the distance is less than a certain threshold times the standard deviation, this pixel is classified as that color. In this case, the mask of color tape is created. Small holes on the mask are closed by morphological operations.

Figure 5. Ground truth pose generation. From left to right: Warped image, detected red mask, detected green mask, green and red tape skeletons estimation. The pose of corresponding objects can be calculated according to the skeleton of color tapes.

Skeleton Extraction. For the color tape mask image, detect line segments using LSD [21]. Merge the two longest line segments by averaging their closest end points. The merged new line segment is regarded as the skeleton of the color tape. The pose of the object is then calculated according to the new segment.

3.4 Baseline and Proposed Methods

To show the superiority of our proposed CNN-based method, we compared it with two baseline methods based on K-Nearest Neighbors (KNN) and Multi-Layer Perceptron (MLP) in all classification tasks respectively. The two baseline methods need hand-craft features, which come from Principal Component Analysis (PCA). Unlike the two baseline methods, our proposed CNN-based method does not need hand-craft features. Instead, the features are learned by the neural network.

PCA+KNN: We stretch the 37×21×19 tensor to a 14763 dimension vector. We use PCA to reduce its dimension to 5. Then a KNN classifier is applied to these 5-dimensional vectors.

PCA+MLP: We use PCA to reduce the tensor to 10 dimensions. There are 3 hidden layers in our MLP classifier with 20, 40 and 20 neurons respectively. The number of neurons in the output layer depends on the classification task.

CNN: Our CNN-based method has a share-weight structure. The input tensor is treated as a 19-channel image. After 5 interleaved 3×3 convolution layers and 2×2 max pooling layers, the tensor is reduced to a 512-dimension vector. Then this vector is sent to different sub-networks for different purposes. In task 1, the vector

is sent to a classification sub-net which predict the materials and a regression sub-net which estimate the poses of straight objects. In task 2, the vector is sent to three classification sub-nets which predict the thickness, content, and shape of the object, and a regression sub-net which estimates the poses of different PVC pipe components. The total loss function is the weighted sum of the losses of each sub-net. The total loss functions for the two tasks are formulated as following (**w** is the set of learnable network parameters):

Task 1:

$$J(\mathbf{w}) = -\frac{1}{N}\sum_{i=1}^{N}(\sum_{c=1}^{5} \underbrace{y_c^{(i)} \log \hat{p}_c^{(i)}}_{\textbf{classification loss}} + C_i\lambda_0 \underbrace{\|\mathbf{x}_i - \hat{\mathbf{x}}_i\|^2}_{\textbf{translational loss}}) \tag{1}$$

Task 2:

$$\begin{aligned} J(\mathbf{w}) = -\frac{1}{N}\sum_{i=1}^{N}(\sum_{l=1}^{3}\sum_{c=1}^{K_l} \underbrace{{}^{l}y_c^{(i)} \log {}^{l}\hat{p}_c^{(i)}}_{\textbf{classification loss}} \\ + \lambda_0 \underbrace{\|\mathbf{x}_i - \hat{\mathbf{x}}_i\|^2}_{\textbf{translational loss}} + C_i\lambda_1 \underbrace{D(\theta_i, \hat{\theta}_i)^2}_{\textbf{rotational loss}}) \end{aligned} \tag{2}$$

Here, c represents different classes; N is the number of training samples; y, $\mathbf{x}$, and θ are the ground truth values for label, translational vector, and rotational angle respectively; $\hat{p}$, $\hat{\mathbf{x}}$, and $\hat{\theta}$ are the predicted values for class probability, translational vector, and rotational angle respectively, which are functions of $\mathbf{w}$. λ_0 and λ_1 are weight coefficients of the translational and rotational loss, and both of them are hyperparameters. In task 1, $C_i = 0$ when the ith sample is "no object" or PVC pipe, in other cases, $C_i = 1$. In task 2, $C_i = 0$ when the shape of the ith sample is straight, in other cases, $C_i = 1$. We use circular distance for angular loss, since θ is in [-π, π), the loss should be their shortest distance on a circle. $D(\theta, \hat{\theta}) = |\theta - \hat{\theta}|$, when $|\theta - \hat{\theta}| < \pi$. $D(\theta, \hat{\theta}) = 2\pi - |\theta - \hat{\theta}|$, when $|\theta - \hat{\theta}| >= \pi$.

4 Experiments

For both of the two tasks, our CNN based method is trained 500 epochs with batch size of 10. λ_0 and λ_1 are both set to 10. We choose Adam optimizer with learning rate 0.0001. The confusion matrix and accuracy are calculated to evaluate the performance of classification. Root Mean Square Error (RMSE) is used to characterize the accuracy of pose estimation. Compared to the two baseline methods, PCA+KNN and PCA+MLP, our CNN based method shows better performance in overall accuracy for all experiments. Furthermore, the CNN based method is more efficient than the PCA+KNN method, without storing training data for prediction.

4.1 Material Classification and Pose Estimation

Figure 6 shows the classification result of task 1. Bkg., Cb., S.P., W.S., P.P. represent background, cable, steel pipe, wooden stud and PVC pipe respectively. The overall accuracy of our CNN based method far exceeds the other two methods, especially for the classification result of Cb.. Classification accuracy on all 5 classes exceeds 95%. For pose estimation, Figure 10 shows that our CNN-based method can achieve the overall error around 1.3 cm in both x and y directions on relatively large experimental objects. The translational error of pose estimation for straight objects in our experiment is 1.8 cm. For all types of objects, steel pipes have the highest pose estimation accuracy, due to their high reflectivity to RF waves.

4.2 Thickness, Content, Shape Classification and Pose Estimation

Figure 7, 8, 9 show our thickness, content and shape classification results for task 2 respectively.

In the thickness classification experiment, our CNN based method outperforms the other two methods, with an overall 0.90 accuracy, while the accuracy of the PCA+KNN method and PCA+MLP method is 0.66 and 0.75 respectively.

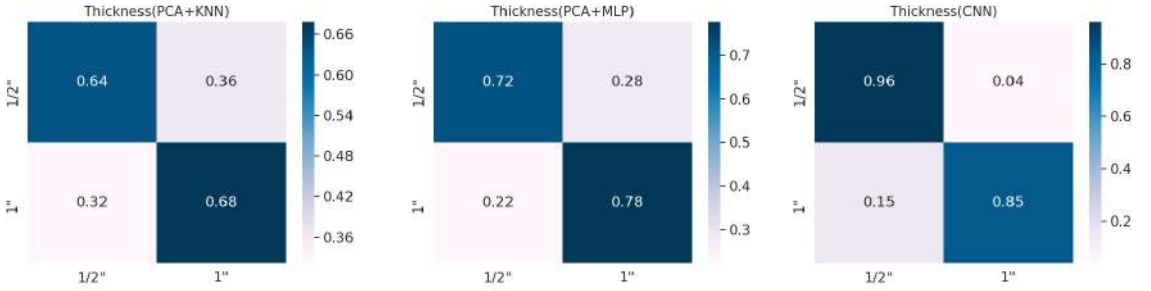
For content classification, our PCA+MLP baseline method has overall 0.92 accuracy, slightly lower than the CNN based method, whose overall accuracy is 0.98. The relatively high accuracy of the CNN based method showcases that our algorithm is quite suitable for content classification. Besides, the high reflectivity of water makes the signals very distinguishable between full and empty PVC pipes.

However, even using the CNN-based method, our experimental result of the overall accuracy of the shape classification is not satisfying, compared to material, content and thickness classification, with only 0.82 of accuracy overall. We think it might be caused by noise generated during the scanning process. Either pre-processing the RF signals to filter out noise or using larger training dataset might improve our experimental result.

Figure 11 shows the result of the pose estimation for the 5 shapes of PVC pipe components. Notice that straight shaped object does not need any rotational parameter to represent its pose, thus the rotational error ϵ_θ is not estimated in our experiment result. The overall error in x axis and y axis is 1.0 cm and 1.5 cm respectively. The translational error is 1.8 cm and the rotational error is 47.6 degree. Note that for all shapes of objects, error in x-axis is always smaller than the error in y-axis, which could be due to the arrangement of antennas of the sensor. Compared to translational error, rotational error is very large. The source of error could come from the noise of

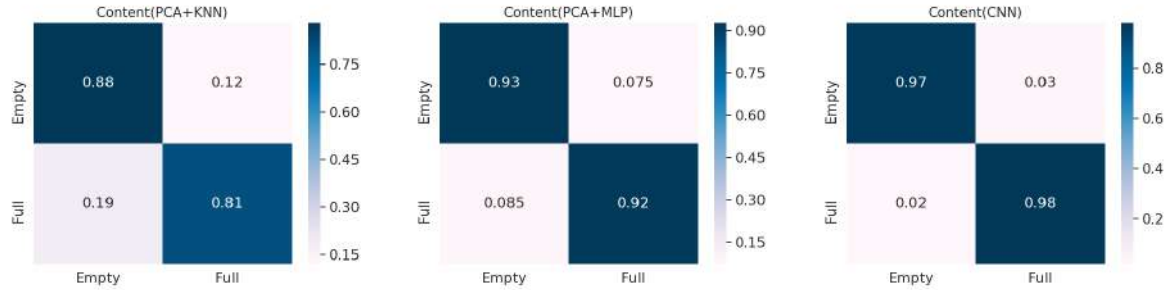
Overall Accuracy: 0.78 Overall Accuracy: 0.85 Overall Accuracy: 0.98

Figure 6. Material Classification Confusion Matrix. 120, 119, 120, 120, 402 training data for Bkg., Cb., S.P., W.S., P.P. (background, cable, steel pipe, wooden stud ,and PVC pipe), respectively.



Overall Accuracy: 0.66 Overall Accuracy: 0.75 Overall Accuracy: 0.90

Figure 7. Thickness Classification Confusion Matrix. 200 and 202 training data for 1/2" thick and 1" thick PVC pipe respectively.



Overall Accuracy: 0.85 Overall Accuracy: 0.92 Overall Accuracy: 0.98

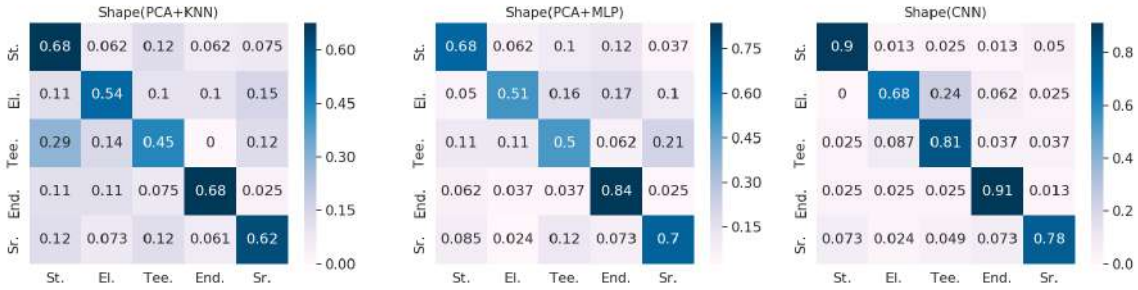
Figure 8. Content Classification Confusion Matrix. 200 and 201 training data for PVC pipes empty of water and filled with water respectively.

the signal, or the sensor's non-sensitivity to rotation.

5 Conclusions

In this paper, we explored the feasibility of using a CNN-based method for through-wall object recognition and pose estimation. With the CNN-based method, we could achieve very high performance on material, thickness, content classification for common in-wall structures. Our proposed method shows a large potential of application in construction industry.

Limitations and Discussions. However, there are some limitations in our proposed method. For the shape classification of five different PVC pipes, the overall accuracy is not satisfying, which calls for more efforts in this research direction. As discussed in the experimental part, we would



Overall Accuracy: 0.59 Overall Accuracy: 0.64 Overall Accuracy: 0.82

Figure 9. Shape Classification Confusion Matrix. 80 training data for shape Sr., End., Tee., El. respectively, and 82 training data for St..

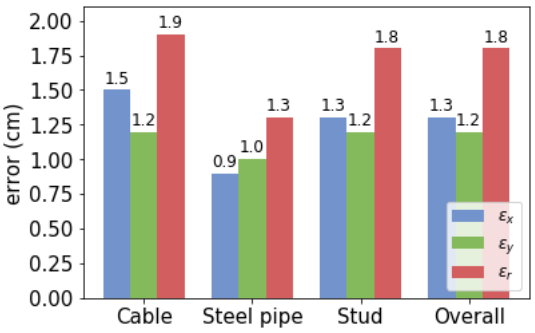


Figure 10. Pose estimation accuracy for Task 1. ϵ_x is the RMSE in x-axis, and ϵ_y is the RMSE in y-axis. Translational error $\epsilon_r = \sqrt{\epsilon_x^2 + \epsilon_y^2}$.

test two possible solutions, filtering out noise or using a larger dataset, to improve the shape classification result in the future.

Future Work. One future work we are aiming towards is a useful application that can generate a detailed plumbing map behind a wall. We believe by generating such plumbing map, the designers and workers can retrieve the object information in the wall more easily.

Abstract –

Many project managers and researchers have emphasized the importance of considering uncertainty in the scheduling of EPC projects, and perform stochastic analysis when preparing a schedule to reflect uncertainties of duration for project activities. In this case, the uncertainty of the individual activity duration is treated as probabilistic variables, and this probability should be estimated based on previous project experience and data. To use past project data for probabilistic schedule analysis of planned schedules, the schedule information of past project should be stored and managed systematically, and the analysis should be based on the relevant past project data. Existing schedule analysis tools are focused on the analysis process, and there is a lack of consideration on how to manage and apply the past project data needed for the schedule analysis. Therefore, this paper proposes a system framework that enables probabilistic schedule analysis, which automatically supports the process of identifying and allocating corresponding past project activities for estimating activity durations of a planned schedule. We propose a data model and system framework that reflects defined issues and the requirements. The framework is composed of 4 modules: As-built schedule data storage module, a planned schedule input module, a historical data allocation module, and uncertainty analysis module. It is expected that the proposed system framework will contribute to overcoming the difficulties of data management for collection and planned schedule analysis in practice.

Keywords –

Schedule Analysis; Probabilistic Analysis; Uncertainty; System Framework; Data Model

1 Introduction

In the construction industry, many mega-projects are delivered in the form of EPC contracts. In the early stages of the EPC project development, the project scope is unclear, because the EPC contractors are responsible for the design, procurement, and construction phases. This implies the uncertainty of the management factor such as cost and schedule is much larger than other construction projects. In particular, scheduling is critical for successful project management when considering the size, participants, and scope of EPC project [1,2], and the scheduling for initial project planning should be done with careful consideration of the uncertainty.

Many project managers and researchers have emphasized the importance of uncertainty considerations in the scheduling of EPC projects [3,4], and perform stochastic analysis when preparing a schedule to reflect uncertainties of duration for project activities. For scheduling of EPC project schedule, a planned schedule is prepared, which consists of hundreds, or even thousands, of activities. In this case, the uncertainty of the individual activity duration is treated as probabilistic variables, and this probability should be estimated based on previous project experience and data [5,6].

To use past project data for probabilistic schedule analysis of planned schedules, the schedule information of past project should be stored and managed systematically, and the analysis should be based on the relevant past project data. The reliability of the schedule analysis depends on the appropriateness of the utilized data and should select relevant information of past project activities should be selected to corresponding activities of the planned schedule. In this process, it is difficult to allocate the appropriate past information on the planned schedule due to the unclear project scope at the initial stage of the project, the difficulty of activity identification from a past project, inconsistency in resource and productivity to be put into each activity of EPC projects. Such problems indicate that the process of applying past project data to the probabilistic schedule analysis is a process that requires multiple

decision-making, and it is impossible to allocate the past data to all activities of planned schedule in the same way.

To support the process of managing past project data and probabilistic schedule analysis, various methodologies and software have been developed and utilized for project scheduling. However, existing tools are focused on the analysis process, and there is a lack of consideration on how to manage and apply the past project data needed for the schedule analysis.

Therefore, this paper proposes a system framework that enables probabilistic schedule analysis, which automatically supports the process of identifying and allocating corresponding past project activities for estimating activity durations of a planned schedule. First, we investigated the precedent methods and studies for probabilistic schedule analysis to define challenging issues of project schedule analysis and the system requirements. And we propose a data model and system framework that reflects defined issues and the requirements.

2 Literature Review

In this chapter, the authors review uncertainty analysis technique to identify required data structure of the system and previous approaches about data structure for schedule data management.

2.1 Required data structure for uncertainty information

To deal with uncertainty of activity duration quantitatively, a probabilistic approach was generally used for schedule analysis. Monte-Carlo Simulation (MCS) is the most popular tool for probabilistic analysis. In case of scheduling, MCS is possible to be performed by considering activity duration as a random variable. During each iteration in the MCS process, values of random variables are determined from a specific range, probability distribution in other words [7]. Therefore, the reliability of result from uncertainty analysis depends on how to estimate the probability distribution of each activity.

According to previous studies and project management body of knowledge (PMBOK), which is recognized as a fundamental rule of project management around the world, if historical data exists sufficiently, high accuracy duration estimation is possible [5]. However, most of the researches [6,8–10] apply probability distribution to activity by expert judgment like three-point distribution due to lack of data availability. Therefore, for reliable results of analysis, it is an important issue how to develop data structure which is able to enhance data availability.

2.2 Previous Efforts for Improving Data Availability

Generally, a schedule includes work breakdown structure (WBS) information which has a hierarchical structure. Therefore, how to develop standard WBS has been an important topic in the area of construction data management. The approach for developing standard structure of WBS was based on the expectation that it could allocate the past performance information to the planned schedule of the new project if a company manages all projects with single standard WBS. Although the hierarchical structure has advantages in terms of management in practice, it has disadvantages such as difficulty in representing various perspectives and levels of detail [11]. To overcome these limitations, facet-classification model with facet concept emerged [12], and work package model was also proposed, which is improved based on the facet-classification model. Work package model expresses the structure of information divided into Where, What, How, and Who. Cho et al. [11] proposed a 5W1H model by improving abovementioned concepts.

These efforts can be categorized as a project-

Table 1. Comparisons of project-oriented data structure and activity-oriented data structure

Contents	Previous Approach	Proposed Approach
Concept	Project-oriented data structure	Activity-oriented data structure
Description	If the schedules based on a standard data structure, duration data can be allocated to new schedule just by collecting past project schedules.	Add past performance to the database through separate tasks after project execution
Advantage	If the standard is appropriate, no extra effort is required to collect and allocate schedule data.	-Flexible configuration of the purpose and type of data -Little effort is required to accumulate new data after initial database construction.
Disadvantage	If the characteristics of the each project are significantly different, there is difficulty in establishing the standard.	-The allocation process is cumbersome.

oriented data structure. In other words, previous researches try to establish a data model which is possible to utilize when a project schedule is created based on the fixed data structure. However, it is hard to ensure applicability in project schedule management practice with the project-oriented concept. Due to the different characteristics of every individual project, especially in case of mega-project, a more detailed breakdown of WBS or work package makes it hard to establish a standard data structure for multiple projects. To address the issues, this research proposes activity-oriented data structure to manage and to allocate historical data efficiently. Table 1 summarizes advantage and disadvantage of both approaches.

3 Data Model

Data for probabilistic schedule analysis can be acquired from past project schedule which contains actual data. However, data collection for certain purpose cannot be performed without purpose-built designed data model. The fact that the project manager has some past schedule files does not mean he or she can analyze schedule with historical data. So systemically structured database is essential to manage and allocate historical data to the planned schedule. A data model is an abstract model to represent data relationship and flow so that the reader can understand actual data better. The main objective of the data model is to enhance understanding of data structure and to provide access to the appropriate source to improve accessibility [13,14].

Fig. 1 shows developed logical entity relationship diagram of the proposed data model to represent activity-oriented data structure. Project and activity table in the figure indicate as-built schedules information. Resource table does not mean the type of resource, but the resource that has performed the actual project. Therefore, even if the same welder has two different activities, it would have two different resource ID. Information in the resource table is limited to labour in this research.

The duration information and the productivity information table on the right side of the figure indicate the storage type of data with a specific purpose. For example, if the A/G filed pipeline welding is to accumulate data on productivity, it is generated by assigning one data code to the Duration Information table. Whenever the information in the data-resource table is accumulated one by one, the values of productivity information such as the number of data, mean or max value of data are continuously changed. The tables in blue dotted line on figure represents the link of accumulated data to activity or resource information. These two tables are filled with information by the user's direct information allocation. However, when the work package information operates to allocate other data and activities, the query is configured so that no data is inserted to facilitate later retrieval.

Also, activity, resource and each information table have attributes to the work package. The name of these attributes may vary depending on the user or project. This is because the way and perspective of managing projects differ by person, project, or company. Through this database development, it directly supports the as-built schedule data storage module and the historical data allocation module of the system framework.

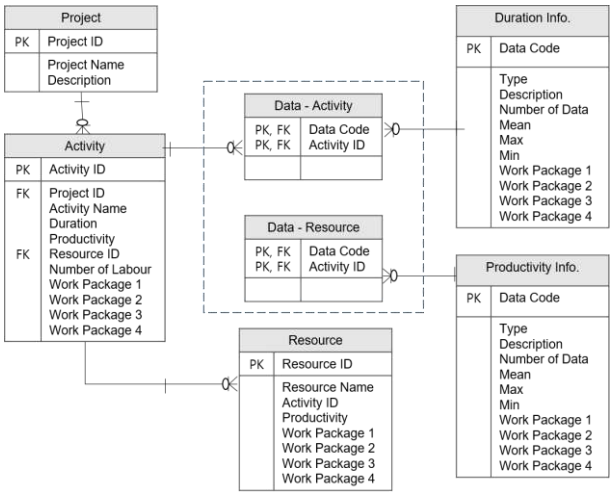

Figure 1. Proposed Data Model

4 System Framework

This chapter introduces the system framework to manage historical schedule data and to analyze the planned schedule with stored data. Each content of the system framework will be described respectively with modules and use case of the system. The prerequisite for using the system is that both as-built schedules and the planned schedule should use the same work package. The work package, which is meant here, is a high-level facet, such as a discipline (e.g. civil, architecture, mechanics) and phase (e.g. engineering, procurement, construction), so that even if the characteristics of the project are different, it can be shared by various projects. The work package is the basis for enhancing the usability of the storage and allocation modules to be described in the following chapters. Fig 2 shows the system framework developed in this research and each module of the system.

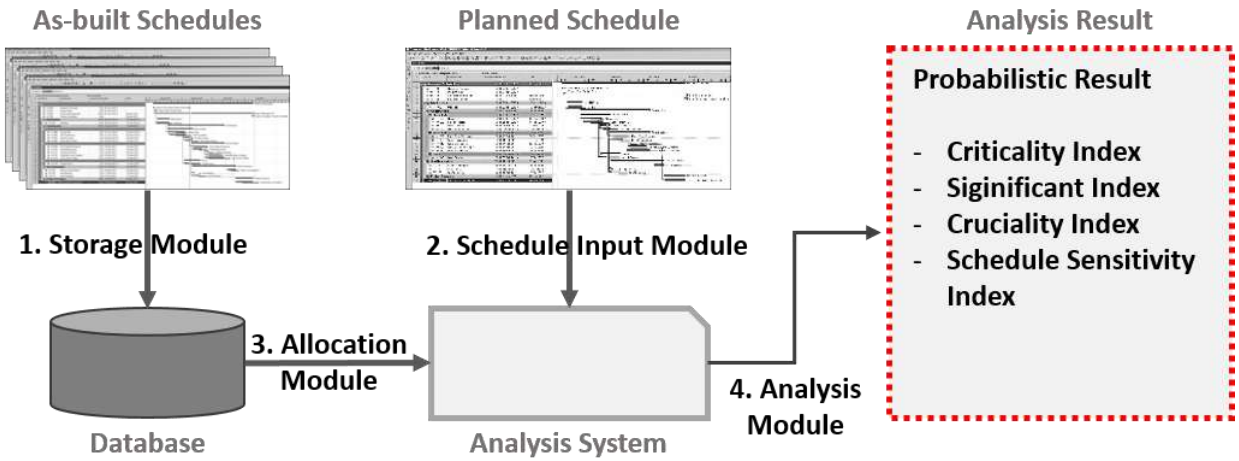

Figure 2. System framework for probabilistic schedule analysis

4.1 As-built Schedule Data Storage Module

After the project finished, the project manager has to store as-built schedule in the system. Storage module supports this process based on the data model developed in the previous chapter. In this module, the user stores the tasks of the as-built schedule in the database. In this process, the related data codes are retrieved through the work package and are selected. At this point, the user needs to decide whether to save the activity in duration table or to save in productivity table. For example, some activity or procurement tasks in engineering are often difficult to estimate for reliable productivity. Therefore, the reliability of the database can be improved by making such a selection directly by the user.

4.2 Planned Scheduled Input Module

In general, the EPC project schedule is developed and managed in Primavera or MS project. Therefore, to enhance a practical application, the system has to include a module that enables a connection with the existing schedule management system. Planned schedules generally include the following four information: activity, dependency, resource, and resource allocation. Both Primavera and MS project provides an ability to export this information as excel format. And we can easily convert excel to CSV (comma-separated variables) format. Based on imported these 4 CSV files, the system creates a simulation model of the project. This simulation model generation automation process is a modification of research in Jung et al. [15].

4.3 Historical Data Allocation Module

Although the planned schedule is input in the system, it doesn't mean appropriate historical data is allocated to each activity in the planned schedule. Therefore, users have to retrieve relevant historical data in as-built schedules. Utilizing the attributes of the work package of the previously defined data model, users can find the data codes associated with each activity of the planned schedule. Data codes can be used to search for past related activities and to use the entire or some data inherent in the data code for the analysis.

After allocating historical data for activities of the planned schedule, the system is ready for MCS. It means that system can generate a probability distribution from historical data. From statistics information of historical data, the system can generate cumulative distribution(CDF) function, inverse cumulative distribution function(ICDF) in order. By entering a random number in the range between 0 and 1 into ICDF, a value according to the probability distribution can be obtained.

4.4 Uncertainty Analysis Module

Through the process described in the first three chapters mentioned above, the planned schedule entered into the system is ready to be analyzed based on historical data. When MCS is performed, virtual schedules are generated by the number of times of simulation. The statistics of these schedules can be used to create an indicator of how the activity's uncertainty affects the schedule planned schedule. There are following four popular indicators in previous researches: criticality index, significant index, cruciality index and schedule sensitivity index [16–18]. Based on the theoretical concept and the system framework, it is

possible to provide these indicators to the user as simulation results.

5 Conclusions

This research proposed a system framework that supports the process of storing information on past schedules in a database and linking them with planned schedules. Also, this study proposed a required data model for the proposed approach. It is expected that the proposed system framework will contribute to overcoming the difficulties of data management for planned schedule analysis in practice.

There are still following limitations in the proposed framework. Most of them depend on heuristic tasks in the storage module and an allocation module. For the usability of the proposed system framework, future study is needed to explore the possibility of automation and implementation. Also, since the system is not yet implemented, the applicability and effectiveness of the proposed system framework should be validated after developing and testing a system prototype.

Abstract –

In the operations and maintenance (O&M) stage of a building, thermal comfort and acoustic comfort are essential for the health and productivity of occupants. There are many complaints about the indoor human comfort in office buildings due to inappropriate indoor temperature or noise. Building information modeling (BIM) technology is an efficient means for helping facility managers to capture complete information from the design and construction stages and deliver this valuable information to the operation stage. In addition, WELL building standard is a performance-based system for monitoring, measuring, and certifying metrics of the environment of buildings that impact human wellbeing and health. It is potential that leveraging environment condition data and BIM data to improve the indoor human comfort level based on WELL building standard. However, there is a lack of study on improving the indoor human comfort level using BIM technology and WELL building standard.

Therefore, this study proposes the methodology of applying BIM technology and WELL standard to improve the thermal comfort and acoustic comfort. BIM provides geometric and semantic information for different BIM engineering analysis software to simulate comfort zones in office buildings. Ontology engineering approach is adopted to establish the knowledge and relationship among observation data from sensor network, occupant behavior, indoor human comfort index, and indoor human comfort situation. Ontology can address the information interoperability among these different domains. In addition, an illustrative example is studied to verify the feasibility of the proposed methodology. The results indicate the methodology can be applied to evaluate the indoor human comfort based on thermal comfort and acoustic comfort index. Finally, some recommendations are given to facility managers to improve the indoor human comfort level.

Keywords –

Acoustic Comfort; Building Information Modeling; Ontology Approach; Thermal Comfort; WELL Building Standard

1 Introduction

The physical factors related to human comfort in office buildings includes temperature, acoustics, air quality, layout and lighting [1]. Thermal comfort is essential for the places where people work and live. 11% of the office buildings met the acceptable criteria based on a survey in USA in 2006 [2]. Six essential variables influence the thermal comfort of human beings, such as radiant temperature, metabolic rate, humidity, dry bulb temperature, air speed, and clothing or other insulation [2]. Moreover, other psychological parameters also have a large role in affecting the level of thermal comfort, for example, individual expectations. People feel different comfortable levels when they are in the same condition. It means thermal comfort is subjective. Currently, a new standard, WELL building standard [3], supports an approach combining many strategies to handle the occupant issues related to thermal comfort.

The sound in the building environment, especially in open plan offices, is the major source of complains from occupants [4]. The noise and sound have a big influence on occupants' working motivation [5], behavior, and intellectual performance [6], which indicates that the optimization of the sound has a high priority. The speaking in acoustic aspect in the office is a complicated case and it is relevant to human comfort and working efficiency. Not only physical properties and acoustic descriptor, but also the condition of environments can determine the acoustic comfort. The objective of WELL building standard is to enhance the satisfaction, social interaction, and productivity, by

reducing exterior noise intrusion and indoor noise level [3].

Based on many studies [4] [5], acoustic comfort and thermal comfort are of importance in the office buildings. When the acoustic in the room cannot meet the criteria of acoustic standard, it has bad influence on the people's satisfaction, the emotion, and physical activities. However, a methodology to study the indoor human comfort in the operations and maintenance (O&M) stage is lacking. Moreover, they rarely studied the trade-off between thermal comfort and acoustic comfort.

Currently, a new technology can be applied to simulate the indoor building environment, building information modelling (BIM). BIM is defined as "a digital representation of the building process and is used to facilitate the exchange and interoperability of information in digital format" [7]. BIM can be used to monitor the indoor thermal condition and acoustic condition combining with sensor technology, which are useful for the automated evaluation and analysis of human comfort based on WELL standard. BIM supports different types of engineering analyses (e.g. thermal comfort and acoustic comfort analysis), which are helpful for improving the building operations in terms of human comfort [8]. BIM can improve data interoperability and collaboration between different participants and different engineering software to facilitate the human comfort analysis process [8].

The human knowledge can be conveted to a machine-readable knowledge in explicit format using ontology [9]. Ontology contains three main aspects, classes (entities/ concepts), properties or attributes of the classes or entities, and the relationships between entities or attributes. A knowledge base consists of the ontology combining with classes, properties and relationships. Ontology enables people to reuse the existing knowledge in different domains, and ontology also provide prototyping and sufficient details of knowledge in many domains [10]. Some researchers have leveraged ontology approaches to solve the information interoperability problem in the AEC/FM industry, such as Chen et al. [11] developed an ontology-based method and addressed the information interoperability between facility management and BIM. Moreover, an ontotology method is developed by Adeleke & Moodley [12], which aimed to monitor and control the indoor environment for a real case in Durban, South Africa.

This paper focuses on the problem of improving indoor human comfort, especially in acoustic and thermal comforts. This study explored the trade-off between acoustic comfort and thermal comfort. It leveraged BIM technology and ontology approach to improve the indoor human comfort level. In Section 3, a novel methodology to analyse the thermal comfort and acoustic comfort is proposed based on BIM and ontology engineering. The final recommendations in Section 4 will benefit the renovation and decoration of office buildings.

2 Research Background and Related Work

2.1 Indoor Human Comfort Standard

Currently, there are many standards related to indoor human comfort. Standards; EN-ISO 7730: 2005 [13], ASHRAE55-2013 [14], Fanger's Model of thermal comfort is a refer of EN 15251: 2007 [15]. However, only physiological reactions are considered in the Fanger's model for the physical aspects in the indoor environment. Thermal comfort means the level of satisfaction when people feel the heating level of the indoor or outdoor environment. Thermal comfort in various levels of humidity and temperature in different seasons is defined in ISO 7730:2005 standard [13].

Based on thermal comfort checklist [13], there are serval indexes for thermal comfort assessment are includes in the thermal comfort checklist, such as metabolic rate, humidity, air temperature, air movement, radiant temperature, and changes to the environment. EN 15251:2007 standard [15] entitled "Indoor Environmental Input Parameters for Design and Assessment of Energy Performance of Buildings". Thermal environment, acoustics, indoor air quality, and lighting are designed for indoor conditions and for setting limits, which ensures the Energy Performance of Buildings Directive do not compromise the comfort of occupants in the pursuit of energy reduction.

The new section "Open plan offices" of the standard ISO 3382 [16] "Measurement of room acoustic parameters" was released in 2012. It describes innovative measures for the acoustic condition qualification with a high correlation of the sound environment in the subjective perception. The third section of ISO 3382 summarized that the distance dependent qualities are the suitable acoustic measurement in open offices, for example, sound pressure level, spatial decay rate, and distraction distance.

However, these standards are not comprehensive to evaluate the indoor human comfort. WELL building standard is a performance-based system for monitoring, measuring, and certifying metrics of the environment of buildings that impact human wellbeing and health [3].

The WELL building standard seven aspects of wellness, i.e., Air, Light, Comfort , Nourishment, Water, Fitness, and Mind [3]. The development of WELL Certified™ leads to a good environment of buildings and helps people to enhance the sleep, mood, fitness, nutrition, performance and comfort of the occupants. WELL building standard aims to implement technologies, programs, and strategies and encourage the active lifestyles, healthy as well as reducing the opportunity of appearance of harmful pollutants and chemicals [3].

2.2 Study on Thermal Comfort and Acoustic Comfort

Noise is an unpleasant aspect of the indoor or outdoor environment as the commonly experienced. The influence of noise on human comfort w studied in many years. Physiological responses to acoustic stimulation studied by Candas and Dufour [17] showed that the vasoconstriction is affected by high noise level, and it may increase the metabolic rate of human and muscle tension. Santos and Gunnarsen [18] claimed that two or more parameters of indoor environment are relevant to the optimal levels of human comfort. They studied the trade-off between temperature and noise considering the parameters of the window opening or draft. The outcomes show that the decrease of 1 °C in operative temperature has the same effect of decreasing of approximate 7 dB in noise level. They claimed that the noise from HVAC system can reduce occupants' willingness to lower the temperature in a warm environment. Another finding, that the change in noise level of 3.9 dB has the same effect on human comfort when changing 1 °C in operative temperature (in a range of 23 – 29 °C), was proposed by Clausen & Carrick [19].

Moreover, many researchers have studied on the comfort-based control of HVAC system. A neural network was applied to come up with a thermal comfort based on HVAC system control in study Liang and Du [20]. A predictive thermal comfort model is introduced to the controlling using HAVC systems by Freire, Oliveira [21]. However, people paid little on the negative effects of HVAC system in acoustic comfort level. Some survey results were described by Reffat and Harkness [22], and they found that acoustic comfort has the equal importance of thermal comfort for the occupants in office buildings. Many occupants have to suffer from the noise from HVAC system, because the mechanical system is unavoidable and the reinstalling of HVAC system costs high. Frontczak and Wargocki [23] studied on multiple sensations and they found that the acoustic comfort and thermal comfort are the most essential parameters for human sensations.

The control of acoustic and thermal comfort affects to the multiple comforts, and people have studied this topic for many years. Even though people studied the acoustic performance, the coverage of room ceiling and the effect of HVAC system, such as Machner [24]. They indicated the different materials of ceiling have different influence on the acoustic comfort and thermal comfort. A few of researchers studied the trade-off between thermal comfort and acoustic comfort. The big problem is that there is lack of study on the trade-off between acoustic and thermal comfort for the design and control of HVAC system.

3 Methodology

3.1 Proposed Methodology

This study has drawn from various research areas, including BIM engineering software, WELL building standard, wireless sensor network for indoor human comfort management, and ontology engineering. The methodology includes the following four aspects:

(1) The geometric and semantic information from BIM models is used for indoor human comfort simulation and analysis.

(2) The various sensing networks and sensing devices are applied to monitor the indoor environment.

(3) BIM engineering software are implemented to simulate the indoor thermal comfort zones and acoustic comfort zones.

(4) Ontology approach is adopted to prototype the knowledge of indoor human comfort management and occupant behavior interaction. Ontology approach is also applied to provide information from sensor network for indoor human comfort management.

The information process of the proposed methodology for indoor human comfort analysis is illustrated in Figure 1. In the process, the geometric information of BIM models is extracted into CAD files, such as .dwg files, .dxf files, and .sat files. These files are available for BIM engineering analysis software, including Autodesk CFD and COMSOL Multiphysics [25].

When using these two software for indoor comfort evaluation, the first step is to identify materials of building structures and main components, because different materials have different influences on thermal comfort and acoustic comfort [24]. For example, the noise level from HVAC system when the ceiling is made of baffle is higher than the noise level from HVAC system when the ceiling is made of master matrix. Similarly, the materials of wall, floor, furniture, door, and window are identified.

In the second step, the space function of each room are determined based on usage situation. The sensor data obtained from ontology schema of indoor human comfort, for instance, temperature setting in HVAC system, and noise from outside, are as the parameter input and boundary setting of BIM engineering analysis software.

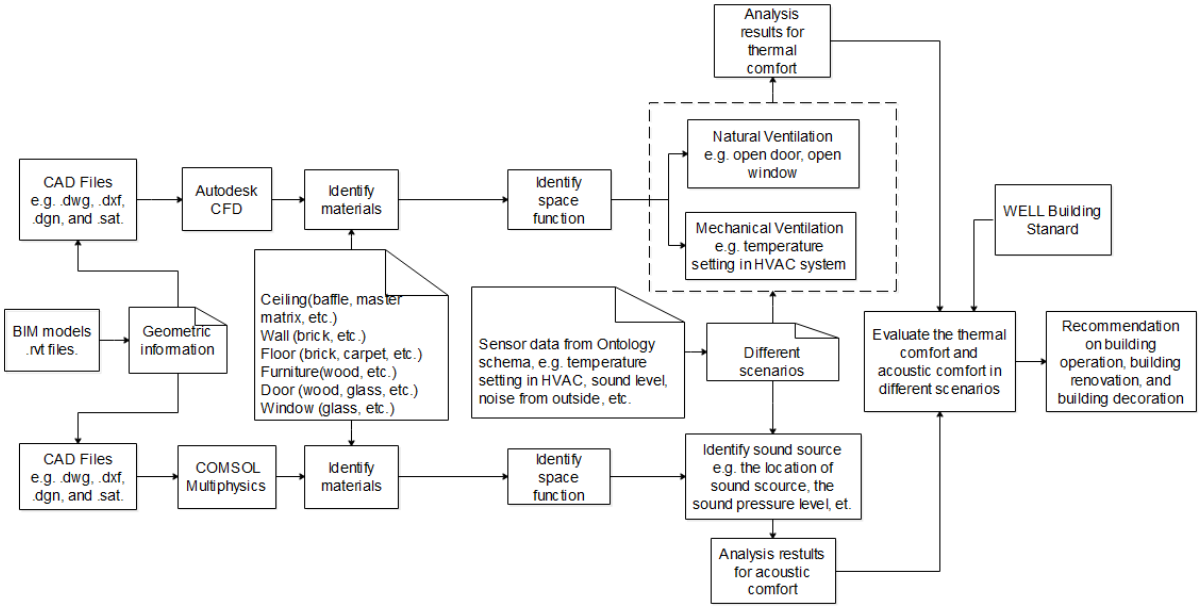

Figure 1. The information process of proposed methodology for indoor human comfort analysis

In the third analysis step, several scenarios (natural ventilation or mechanical ventilation, door open or window open, exterior noise or internally generated noise) are determined to simulate the thermal comfort and acoustic comfort. The simulation results are analysed to evaluate the indoor human comfort level based on WELL Standard. Finally, some recommendations are given for facility managers to improve building operations, building renovation, and building decoration.

3.2 Criteria of Thermal Comfort and Acoustic Comfort

In this paper, the criteria of thermal comfort and acoustic comfort in WELL standard are studied based on [14, 26], and the Indoor Air Quality Certification Scheme in Hong Kong [27]. Table 1 illustrates the requirement of acoustic comfort index based on WELL standard, while Table 2 shows the requirement of thermal comfort index.

Table 1. The requirement of acoustic comfort index

Index	The Requirement of Index	Standard
Exterior noise intrusion	Average sound pressure level from outside noise intrusion <50 dBA.	WELL Standard
Internally generated noise	Open office spaces and lobbies < 40 dBA; Enclosed offices < 35 dBA; Conference rooms and breakout rooms: <30 dBA	WELL Standard
Reverberation time	Conference rooms: 0.6 s Open workspaces: 0.5 s	WELL Standard
Sound masking	Open workspaces: 45 - 48 dBA. Enclosed offices: 40 - 42 dBA	WELL Standard

Table 2. The requirement of thermal comfort index

Index	The Requirement of Index	Standard
Ventilation effectiveness	CO_2 < 800 ppm	WELL Standard
Air flush	Indoor temperature > 15 °C Relative humidity < 60%.	WELL Standard
Humidity control	30% <Relative humidity < 50%	WELL Standard
Air quality monitoring and feedback	20 < Indoor temperature < 25.5; 40 < Relative humidity < 70 Air speed < 0.3 m/s; CO_2 < 800 ppm CO < 1.7 ppm; PM 10 < 20 ug/m3 NO2 <40 ug/m3; O3 < 50 ug/m3	Indoor Air Quality Certification Scheme 2003
Ventilated thermal environment	Air speed > 0.2 m/s, 1.0 met < Metabolic rates < 1.3 met; 0.5 clo < Clothing insulation < 1.0 clo	ASHRAE Standard 55-2013 Section 5.3

Natural thermal adaptation	Clothing insulation < 0.7 clo 1.0 met < Metabolic rates < 1.3 met 0.5 clo < Clothing insulation (Icl) < 1.0 clo 10°C < Outdoor temperature < 33.5 °C 19 °C < Floor surface temperatures< 29 °C	ASHRAE Standard 55-2013 Section 5.4

3.3 Ontology Implementation

This paper adopts ontology approach to represent the main concept of indoor human comfort management, as shown in Figure 2. The developed ontology provides representation support for the actions/ activities of the occupant, the observations of sensors in the indoor environment and the description of building environment [28]. The observations of sensor give the measurement values of sensor in certain properties (e.g., air quality, sound level, humidity, temperature, and CO_2 concentrations) of the environment. While the description of environment provides data or information such as features in the office buildings, types (e.g., type of ceilings), and quantities (e.g., number of windows), etc. Figure 2 illustrates the main concepts of the developed of indoor human comfort ontology.

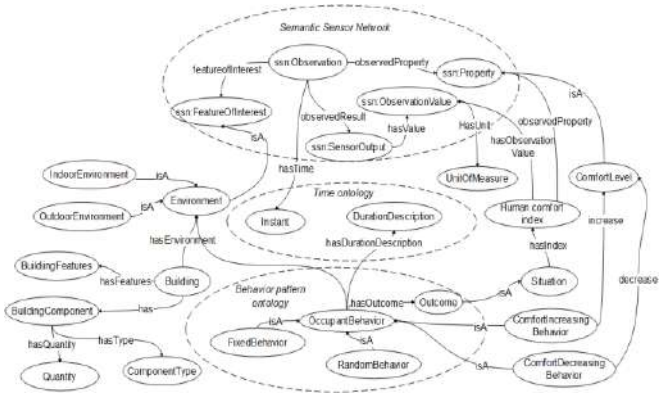

Figure 2. The main concepts of the developed indoor human comfort ontology

In the ontology schema, reasoning-based ontology can automatically determine the indoor acoustic comfort index and thermal comfort index. Sensor data is used to evaluate the proposed ontology, and the condition date can be queried from ontology for analysing the human comfort situations and determine control actions. This ontology schema enables the support for data representation and ontology reasoning on both occupant actions and the observations of sensor for indoor human comfort analysis. The ontology also represents the semantic indoor human comfort index regarding to thermal comfort and acoustic comfort.

The Unified Modelling Language (UML) diagram can represent the information in the proposed ontology schema. The office includes the space and the occupant. The office has two situations: occupied and empty. The number of occupants is one important factor to evaluate the human comfort. In order to monitor the environment condition of the office space, the temperature sensor, humidity sensor, CO_2 sensor, and sound sensor to monitor the value of each comfort index. The space has quantity of sensors, semantic type of various sensors, and different units of sensor values. For example, there are five temperature sensors in one specific office and the unit of temperature is " °C ". Similarly, there is one sound sensor in this office. The parameter of the sound sensor is acoustic pressure level and the value of acoustic pressure level is 35 dB. The UML diagram of data representation for sensors is illustrated in Figure 3, as follows.

Based on the ontology approach, the adequate sensor measurements for indoor human comfort are represented in the proposed ontology schema. It provides representation and reasoning services to analyse indoor human comfort situations based on measurements and WELL building standard. It determines human actions/ behavior to reduce the influence from bad environment. In the case, we will evaluate the proposed indoor human comfort ontology to test sensor data and query it for different situations relevant to each of scenarios.

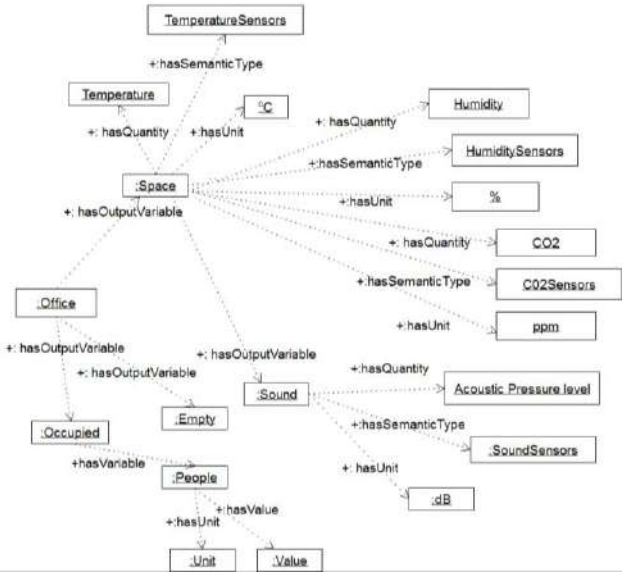

Figure 3. The data representation of sensor information for human comfort management

3.4 Using BIM Authoring Software to Evaluate Indoor Human Comfort

Different BIM-based engineering analysis software are incorporated in the proposed framework in order to

evaluate and improve indoor human comfort level based on WELL standard. For example, Autodesk CFD can be applied for indoor thermal analysis, and COMSOL Multiphysics is used for noise impact assessment. Specifically, the application procedure of using BIM-based engineering analysis software to evaluate and improve indoor thermal comfort and acoustic comfort in buildings is illustrated as follows.

(1) The inputs include geometric information (e.g. length, area) and semantic information (e.g. quantity, materials) from BIM models.

(2) The inputs include real-time data (e.g., temperature, humidity, CO_2, noise from outside) obtained from ontology schema of sensor network.

(3) Reports and code from other resources, such as building operation records, are used to set different scenarios for simulation and evaluation.

(4) The inputs are used in BIM engineering software for different types of engineering analysis (such as acoustic impact analysis and indoor thermal analysis). For example, the indoor noise, layout of one room, material of ceiling and wall can be used in COMSOL Multiphysics to simulate indoor acoustic comfort zone.

4 Illustrative Example

4.1 Case Background

In order to validate the proposed methodology, two conference rooms in the academic building of HKUST are used as the example to illustrate the methodology. The layout of two conference rooms is shown in Figure 4. The ceiling is made of baffle and the wall is made of concrete. X door, Y door, Z door and one wall of right room are made of glass, indicated in Figure 4. The left room is open office space and right room is enclosed offices.

Assume there are eight people speaking around two tables (highlighted in blue in Figure 4) in left room in this case. The sound source is internally generated noise, defined from the surface of two tables. The parameter setting in COMSOL Multiphysics is as follows: walls of two rooms are sound hard boundary. The density of air is 1.25 kg/m3 and the speed of sound is 343 m/s. The sound frequency of internally generated noise is 90HZ. The glass doors are open.

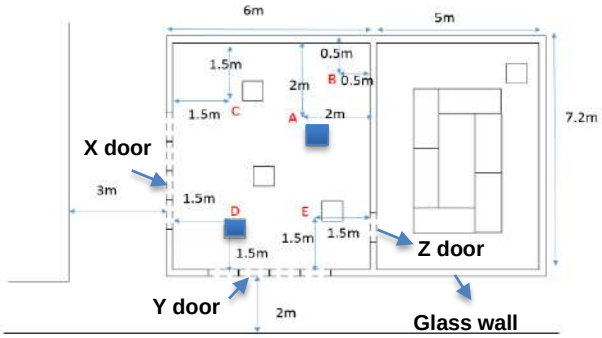

Figure 4. The layout of two conference rooms

The BIM model of two conference rooms is built using Autodesk Revit 2018, as shown in Figure 5. According to the methodology in Figure 1, the BIM model is successfully transferred into COMSOL Multiphyiscs software for acoustic comfort simulation.

Figure 5. BIM model in Revit

4.2 Simulation Results

The sound simulation result is illustrated in Figure 6a and Figure 6b. The sound pressure level in left room ranges from 45 dB to 55 dB. The sound pressure level in right room is less than 40 dB. Based on WELL standard, open office lobbies and spaces are occupied regularly and/or contain workstations, and the noise criteria in maximum level is 40 dB [3]. The maximum noise criteria of the enclosed offices is 35 dB [3]. Therefore, the sound pressure level in these two conference rooms are higher than the maximum noise criteria. People feel very noisy when there are eight people speaking. The glass door should be closed if they have meeting in left room. Otherwise, the bad influence will affect the normal work in near offices and the lobby.

Apart from the acoustic effect of people speaking, in order to validate acoustic comfort and thermal comfort without people in different situations, two scenarios are designed: (1) HVAC system is on and (2) HVAC system is off. Sensing devices are used to detect the thermal comfort and acoustic comfort index in four testing points, A, B, C, and D. The values of comfort index in four testing points are obtained from the designed ontology schema, and the values are shown in Table 3.

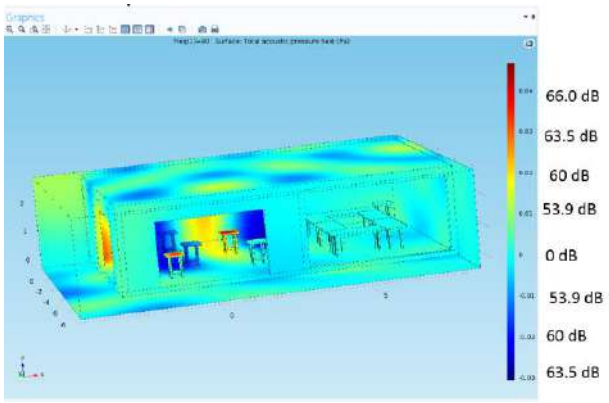

Figure 6a. The overall sound simulation results

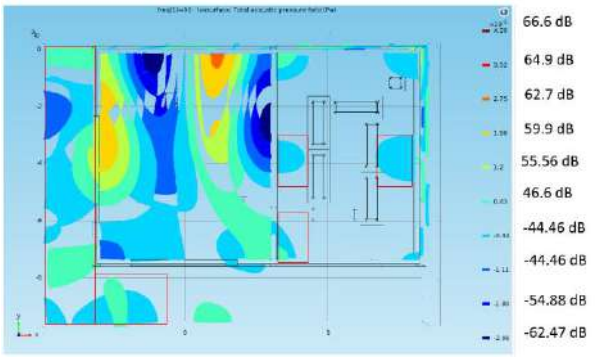

Figure 6b. The plan view of sound simulation results

According to thermal comfort index in Table 2, when temperature is more than 20 °C and less than 25.5 °C, relative humidity is 30% to 50%, and CO_2 is below 800 ppm, occupants feel comfortable [3].

When the HVAC system is off, temperature values in four testing points (A, B, C, and D) are slightly higher than 25 °C, which is near the maximum value. Humidity is 62.2% to 63.2% and CO_2 is from 542 ppm to 651 ppm. Humidity is higher than the acceptable level, and CO_2 is within the acceptable limits. The exterior noise is around 42.3 to 45.2 dB, which is higher than the maximum criteria of 40. Therefore, in this situation, occupants feel a little hot, moist and a bit noisy.

Table 3. The value of thermal comfort index

Testing point	**A**	**B**	**C**	**D**
Index	HVAC System Off			
Temperature (°C)	25.3	25.1	25.1	25.5
Humidity (%)	62.8	63.2	62.9	62.2
CO_2 (ppm)	544	651	561	542
Sound pressure level (dB)	43.6	45.2	42.5	42.3

Index	HVAC System On				
Temperature (^{o}C)	22.6	21.5	22.4	23.5	↓
Humidity (%)	50.5	50.6	47.2	45.6	↓
CO_2 (ppm)	533	533	537	521	↓
Sound pressure level (dB)	50.5	50.6	47.2	45.6	↑

When the HVAC system is on with setting the outlet temperature 20 ^{o}C, the indoor temperature decreases to 21.5~23.5 ^{o}C. Simultaneously, the humidity reduces to 45.6~50.6% located in acceptable area and CO_2 concentration decreases to 521~537 ppm. This indicates occupants would feel more comfortable than the former situation. However, the noise from HVAC system though baffle ceiling increases the sound pressure level by 3~7dB. If occupants prefer to reducing the temperature level rather than reducing noise level, they would feel more comfortable when the HVAC is on. Otherwise, they would feel more comfortable when the HVAC is off.

5 Conclusions

Thermal comfort and acoustic comfort are essential for the productivity and health of occupants in the O&M stage of a building. This paper leverages the advantages of BIM technology and ontology engineering approach to study indoor human comfort. A novel methodology is proposed to analyse the thermal comfort and acoustic comfort based on BIM technology and WELL Building Standard.

The process of methodology is explained in detail in this paper. BIM provides geometric and semantic information and information interoperability function for different engineering analysis software to simulate comfort zones in office buildings. In addition, ontology schema is developed to represent the knowledge of sensor observation domain and indoor human comfort managemnt domain. Ontology approach addresses the information interoperability problem between sensor data and indoor human comfort management. Finally, an illustrative example is studied to verify the feasibility of the proposed methodology. The results indicate that the methodology can be successfully applied to evaluate the indoor thermal comfort and acoustic comfort based on BIM and ontology approach.

Abstract –

A vehicle-mounted video camera, which is one of low-cost off-the-shelf devices, can be used economically for pavement crack monitoring. The pavement frames obtained by the video camera can be merged to form a mosaic image, from which road distress information can be extracted. However, quality of crack detection in the frames is different from one another. The different level of crack detection quality should be considered for accurate construction of crack mosaic. This paper proposes a new pavement crack mosaicking method based on quality of crack detection in each frame. A convolutional neural network is suggested as a way to evaluate the quality of crack detection in the video frames. The proposed method showed a promising mosaicking performance compared to other existing methods.

Convolutional Neural Network; Crack Detection Quality; Pavement Crack Mosaicking; Vehicle-mounted Camera

1 Introduction

Cracking is an important factor in evaluating pavement surface condition [1]. A crack can allow water to enter the pavement and cause potholes to develop. Because potholes can damage vehicles [2], it is crucial to perform pavement monitoring and timely maintenance [3]. Pioneering studies were conducted for automatic crack detection in 1990s [4,5,6]. Ever since, various inspection devices have been used for automatic pavement crack detection research, including a ground penetrating radar (GPR) [7], an unmanned aerial vehicle (UAV) [8], laser scanners [9], infrared spectrometers [10], and a red green blue depth (RGB-D) sensor [11]. Low-cost off-the-shelf devices have also been used for pavement crack detection research; examples include smartphones [12,13,14] and vehicle-mounted cameras [15,16,17].

There are several advantages to using a vehicle-mounted video camera, which is one of the low-cost off-the-shelf devices, for pavement monitoring. By using a device already installed in a general vehicle, it is not necessary to purchase an additional experimental device for data acquisition. Obtaining data with multiple vehicles can allow large areas to be observed in a short time. A pavement that is too long to be covered by a single image can be observed by making a mosaic from successive video frames [18,19]. However, quality of crack detection is different frame by frame. For generation of the mosaic from video data, the different level of crack detection quality should be considered.

In this paper, we propose a new pavement crack mosaicking method based on crack detection quality in images. A convolutional neural network plays a major role to evaluate the crack detection quality of each frame. The methodology and experiments are explained in Chapters 2 and 3, respectively, followed by conclusions in Chapter 4.

2 Proposed Methodology

Convolutional neural network (CNN), which has shown encouraging performance in recent years [20], was used for image data processing in this paper. An encoder-decoder network based on ResNet [21], which is the winner of ImageNet Large Scale Visual Recognition Challenge 2015 (ILSVRC2015), was used for the pixel-wise crack detection; the network was the preprocessing step for this study. An input image size for the crack detection network was 1920 x 1080. Input images were collected from a vehicle-mounted camera. The dataset consisted of 427 and 100 images for training and testing, respectively. Ground truth crack binary images were made by manual labelling. Pre-trained weights learned with ImageNet data were used as the initial weights of the crack detection network.

2.1 Crack Detection Quality Prediction

The core of the proposed method is a crack detection quality prediction network (CDQ-Net). The CDQ-Net calculates a crack detection quality (CDQ) of each frame. An f1-score calculated by the crack detection network is considered as the CDQ of a frame. The CDQ-Net consists of convolutional layers, a global average pooling layer, and fully connected layers. Raw input images (2560 x 1440) obtained from a vehicle-mounted camera included non-road area. By eliminating the non-road area, the amount of computation could be reduced. On the raw input images, only the road area were extracted to result in the image size of 1536 x 540. At the convolutional layers, the filter size and the stride were 7 x 7 and 4, respectively.

The motivation why the CDQ-Net is a shallow network and includes a big filter size and stride is as follows. Most of crack shapes are thin lines, which are expected to be more related to low-level features than high-level features. Low-level features are easy to be generated by a shallow network. The vehicle-mounted camera has a high resolution (2560 x 1440) compared with many applications with ImageNet (256 x 256). If a 3 x 3 filter is used, as in a typical CNN model, it may be difficult to capture a long line feature such as cracks. A relatively larger filter sizes and strides can be appropriate for the purpose of this study.

To avoid overfitting problems, batch normalization is adopted right after each convolution and before activation. The activation function is ReLU [22]. Dropout at 50% was applied to each fully connected layer. The number of channels in each convolutional layer is determined to be similar to ResNet [21]. The number of channels in the first convolutional layer is 64 and the number of channels in the second convolutional layer is 128. In the same way as above, the number of channels in a convolutional layer is twice the number of channels in the previous convolutional layer. Except for the last fully connected layer, each fully connected layer has the same number of neurons as the number of channels in the last convolutional layer. The number of neurons of the last fully connected layer is 1 because the output of the CDQ-Net should be a single scalar value.

2.2 Pavement Crack Mosaicking

Mosaicking pavement crack information from consecutive video frames was conducted in the following steps. A CDQ of each frame was calculated by the CDQ-Net. A crack probability, which is the output just before binarization, was obtained for each pixel of a frame through the crack detection network. An example of a crack probability image is shown in Figure 1. The crack probability image, which is an oblique-view image, was transformed into a top-view image. Consecutive crack probability images were then overlapped based on the geometric relationships, which is explained in the next paragraph. Crack probabilities of overlapped pixels corresponding to a specific pixel location were weighted averaged according to the CDQ of each frame. The weighted averaged crack probability is the crack probability of the mosaic. Next, a binary crack mosaic image was derived from the crack probability mosaic image based on a specific threshold value. The optimal threshold value was to maximize a mean of f1-scores for binary crack detection of multiple mosaic images. An example of a pavement crack mosaic is shown in Figure 2.

The geometric relationship between two consecutive frames was calculated in the following steps. Oblique-view frames obtained by a vehicle-mounted camera were first transformed into top-view frames. A top-view frame included lane markings on both sides. The center curve in the previous top-view frame was then estimated based on the lane markings. Geometric relationship candidates between the two consecutive frames were derived according to the position and tangential angle of the center curve. The optimal geometric relationship was finally selected when the mean squared intensity difference between the two consecutive frames was minimum.

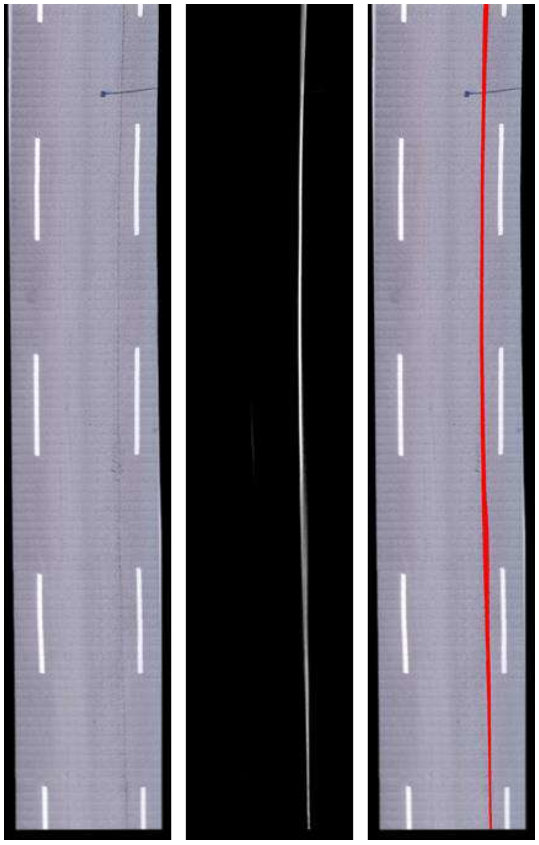

Figure 2. An example of pavement crack mosaicking (from left to right: pavement mosaic, weighted averaged crack probability mosaic, and binary crack mosaic)

3 Experiments and Results

The experimental environment was as follows. All of the image data were obtained by a dash-board camera Qrontech LK-919 QAD. The fps (frames per second) was 30 and the resolution was 2560 x 1440. Experiments were performed in a desktop with GeForce GTX 1080 Ti GPU and Intel Core i7-7700 CPU. The operating system of the desktop was Ubuntu 16.04.

3.1 Crack Detection Quality Prediction

The number of convolutional layers and the number of fully connected layers were changed to find the optimal CDQ-Net structure. The image dataset consisted of 270, 66, and 83 images for training, validation, and testing, respectively. Ground truth binary crack images were made by manual labelling. A CDQ of each frame was calculated through the crack detection network. Epochs were 500 for a majority of the CDQ-Nets, but larger epochs were used when the value of the loss function did not converge sufficiently in the validation process. Batch size was fixed to 4. The network with the lowest MAE (Mean Absolute Error) was chosen as the optimal CDQ-Net. The optimal CDQ-Net consisted of four convolutional layers and one fully connected layer. The experimental results are summarized in Table 1.

Table 1. MAE and epochs of various CDQ-Net structures: MAE (Epochs)

No. of convolutional layers \ No. of fully connected layers	1	2	3
2	8.61% (2000)	11.01% (1000)	9.99% (3000)
3	10.30% (500)	8.59% (1000)	10.98% (2000)
4	8.26% (500)	8.59% (500)	8.95% (1500)
5	10.11% (500)	10.01% (500)	10.72% (500)

The proposed CNN model was compared with a representative CNN model, the ResNet, in terms of its capability to predict the CDS. For the direct comparison, the experimental environment was set to the same conditions. Pre-trained weights learned with ImageNet data were used as the initial weights of ResNet50 [21]. In terms of MAE and duration for training, CDQ-Net's performance was superior to ResNet50. The experimental results are summarized in Table 2.

Table 2. MAE and duration on CDQ-Net and ResNet50

Performance	CDQ-Net	ResNet50
MAE (Epochs)	8.26% (500)	9.23% (1000)
Duration (Unit)	0.39 (hours)	9.77 (hours)

3.2 Pavement Crack Mosaicking

The proposed method for pavement crack mosaicking was tested using LOOCV (Leave-One-Out Cross-Validation) [23]. In the LOOCV, one mosaic image was selected for testing, while the others were selected for the determination of the optimal threshold value. The threshold value was selected to binarize each pixel of the test mosaic image into crack or non-crack category. Based on the ground truth images, the performance was measured by the f1-score. This process was repeated for every mosaic image of the dataset. In the end, the f1-scores were averaged to provide a scalar value of

performance.

The performance of the proposed method was compared with two intuitively obvious methods: overwriting and accumulating. The overwriting method is to use the crack information of the new frame to its fullest extent, ignoring the crack information of the existing mosaic. The accumulating method is to conserve every crack information of the existing mosaic to result in the OR operation with the new information. The two methods were measured by the average f1-score.

The experimental dataset for pavement crack mosaicking consisted of five videos. Each video has 90 frames. The ground truth binary crack mosaic images were made by manual labelling. In terms of f1-score for crack detection, the performance of the proposed pavement crack mosaicking method was superior to the other mosaicking methods. The experimental results are summarized in Table 3. Examples of pavement crack mosaicking results are shown in Figure 3.

Table 3. Performance of the crack mosaicking methods

Mosaicking method	Precision	Recall	F1-score
CDQ	0.5175	0.6748	0.5838
Overwriting	0.8251	0.2634	0.3969
Accumulating	0.3427	0.8543	0.4870

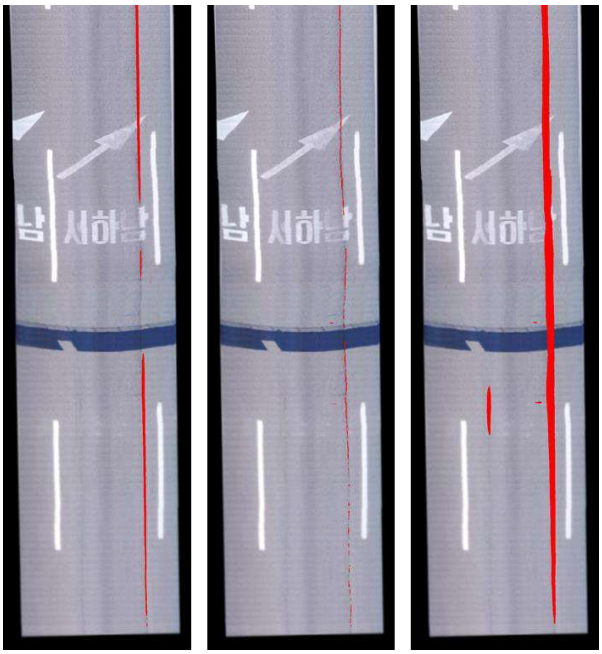

Figure 3. Examples of pavement crack mosaicking results (from left to right: CDQ based method, overwriting method, and accumulating method)

4 Conclusions

This paper presented the pavement crack mosaicking method based on crack detection quality. The proposed network, which is to predict a crack detection quality of each frame, performed better than ResNet50. The proposed pavement crack mosaicking method, which is based on the crack detection quality of each frame, showed better performance than the two intuitively obvious methods: overwriting and accumulating. The proposed method, when strengthened by a large number of crack image data, is expected to produce a significantly improved mosaic map of pavement cracks.

Abstract –
Monitoring the progress of a large construction site manually is a challenging task for managers. By collecting visual data of the site, many monitoring tasks can be automated using machine vision techniques. In this work, we study a new method of collecting site data, which is through crane camera images used to create 3D point clouds. The technology is cost-effective and enables automatic capturing and transmission of on-site data. To automatically extract buildings from the as-built point clouds, we present VBUILT, which uses 3D convex hull volumes to identify building clusters. Experimental results on 40 point clouds collected over four months on a large construction site show that the proposed algorithm can identify building clusters with 100% accuracy.

Keywords –
Building extraction, crane cameras, convex hull, progress monitoring

1 Introduction

Machine vision is revolutionizing the construction industry by allowing real-time and autonomous inspection of construction projects to replace laborious and error-prone manual methods. We can now capture as-built information in the form of 3D point clouds, which can be used for construction progress monitoring [1]-[3], quality control [4], structural damage assessment [5]-[6], heavy equipment planning [7] and safety management [8]-[9].

Point clouds are typically acquired using light detection and ranging (LiDAR) due to their high accuracy. However, laser scanners are not suited to capturing large spaces due to the high number of scans required. In fact, the time, cost and labour needed for accurately capturing an entire construction site using a laser scanner would be prohibitive. Large areas are surveyed using Airborne LiDAR, which includes the significant expense of a piloted airplane carrying specialist laser scanning equipment [10]. Besides, Airborne LiDAR produces a distant view of the site that is not suited for close-range analysis.

An alternative is the use of photogrammetric point clouds. For a large construction site, these can be created from images captured using cameras mounted on Unmanned Aerial Vehicles (UAVs) (a.k.a. drones). But UAVs have a few limitations, such as the need for flight permissions [11], image quality deterioration due to vibrations caused by weather and the difficulties in camera pose estimation with the continuous position changes of the UAV [12].

In this paper, we study a promising new approach to capture as-built information of a construction site, which is the use of photogrammetric point clouds created from crane camera images. Crane cameras offer the advantage that they are already present on construction sites and no flight permissions are required as in the case of UAVs. Their installation and operation is low-cost and convenient.

The crane camera solution used in this work was developed by Pix4D [13]. The 3D point clouds are created automatically every day and stored on the cloud. In this work, we analyse data collected on a large construction site in Finland.

We focus specifically on the problem of automatically extracting buildings from the construction site point clouds. Removing the non-building elements from a multi-building point cloud can enhance alignment with the BIM model for progress measurement, but this is beyond the scope of this paper. Our work builds on the workflow reported in the literature for automatic building extraction from airborne LiDAR data.

Our contributions are as follows:

- To the best of our knowledge, we are the first to study the potential of point clouds generated from crane cameras for automated progress monitoring.
- This is also the first work that addresses the

problem of automatic building extraction on a multi-building construction site.
- We introduce the use of 3D convex hull volumes to identify buildings on the point cloud.

The rest of the paper is organized as follows: Section 2 discusses related work on automatic building extraction, crane cameras and convex 3D hulls. Section 3 describes the crane camera data collection. Section 4 describes the VBUILT algorithm. Section 5 presents the results and discussion. Section 6 lays out the conclusions and future work.

2 Related Work

An illustrative example of the automatic building extraction workflow for airborne laser scanning (ALS) point clouds was presented by Sampath and Shan [14]. They performed ground extraction using a slope-based 1D bi-directional filter. Then, they applied a region-growing algorithm to cluster individual buildings. They set the dimensions of the moving window to incrementally more than twice the point spacing, which in a LiDAR point cloud differs in the across and along scan directions. They also set a minimum point count threshold to identify non-building clusters. Wu et al. [15] fused LiDAR data with image data to extract the boundary lines of buildings. They used a triangulated irregular network (TIN) progressive densification filtering method to extract ground points. Widyaningrum et al. [16] used a generalization of the convex hull called the alpha-concave hull [17] to do two-dimensional boundary tracing.

An excellent review of building extraction techniques for ALS point clouds is presented in [18] which categorizes all the reported techniques into three categories: i) 2D building outline extraction; ii) 3D model reconstruction of buildings and iii) 3D roof contour extraction.

Our problem differs from the reported works in a number of ways. First, we intend to extract the actual as-built point cloud of a specific building, rather than to construct a 3D model from 2D segments. Secondly, a region-growing algorithm such as the one used in [14] discards non-building clusters based on point count. That is, from the points that remain after ground extraction, those clusters that have less than a certain number of points are discarded as being possibly vehicles or trees. This method is not suitable for construction sites, where non-building clusters (corresponding to large equipment, for example) may also have a high point count. Thirdly, the reported works do not perform building identification. Our problem requires that after extraction, the buildings be labeled. Fourthly, our data is a photogrammetric point cloud obtained from crane camera images.

Additionally, we choose to use a variation of RANdom SAmple Consensus (RANSAC) called M-estimator SAmple and Consensus (MSAC) for separating ground and non-ground points. This algorithm was proposed by [19], who showed that changing the cost function of RANSAC to score inliers on how well they fit the data improves the robust estimation with no additional computational burden.

A recent work [20] used crane camera images for updating the 3D crane workspace on a construction site. However, the crane camera images were used to modify a laser-scanned point cloud, which had to be manually captured. Point clouds generated automatically from the crane camera images were not considered.

Another recent work [21] used the area of 3D convex hulls to automatically map discontinuity persistence on rock masses. However, to the best of our knowledge, the use of 3D convex hull volumes for building extraction has not been reported.

3 Data collection and description

The data was collected on the site of the Tripla project located in Helsinki, Finland, which includes a shopping centre, hotel, housing and offices. The total area of the site is 183,000 floor square meters. Our focus in this work is on three buildings of the site, whose as-designed model along with the building labels is shown in Figure 1(a). Two independent cameras were mounted on the jib of a tower crane. Images were taken automatically when the crane would begin operation and then transferred to the Pix4D Cloud, where they were converted to 2D maps and 3D models.

The dataset consists of 40 as-built point clouds corresponding to weekdays spanning August 17th, 2018 to November 23rd, 2018. The as-built point cloud for day 40 is shown in Figure 1(b). Twenty point clouds contain building A only (due to B and C not being captured by the crane cameras), while twenty others contain multiple buildings as described in Table 1.

Table 1. Description of point cloud data

Available data	No. of point clouds
Single-building data (A only)	20
Multi-building data	
A,B only	1
A,C only	10
A, B and C	9

By default, the point clouds are georeferenced, with an average point density of the order of 1000 points/m^3, except for point cloud 40, which has an average point

density of 37,233 points/m^3. However, for 13 point clouds between August 29th, 2018 and September 17th, 2018, the image geotags were not detected and thus the output coordinate system was arbitrarily set. Therefore, the point cloud could not be scaled and the resulting point density is of the order of 3 points/m^3. We subsequently refer to these point clouds as 'non-georeferenced'.

Figure 2(a) shows the front-view of Building A. The holes in the data are due to the portion of the building being out of the field-of-view of the camera. Figure 2(b) shows the top view of the building, which shows the formwork being laid. This is the clearest data of the building available.

4 Building extraction using VBUILT

In this section, we explain the VBUILT algorithm. Our objective is to extract the 3D point cloud of a specific building on the site to be used for further analysis, such as construction progress tracking.

Our solution is to extract the ground plane using MSAC, then cluster the non-ground point cloud based on Euclidean distance, followed by an analysis of the 3D convex hull volumes of each cluster.

Figure 2. Manually extracted point cloud of building A: (a) front-view and (b) top-view

4.1 MSAC-based ground extraction

Let the set of construction site point clouds be $S=\{S_1, S_2, \ldots S_D\}$, where D=40 and each point cloud $S_i=\{s_1, s_2, \ldots s_N\}$, $S_i \in R^3$. First, we downsample the point cloud for faster processing using grid average downsampling, which merges points within a 3D grid by averaging their locations and colours.

Next, we need to separate the ground and non-ground points. For this, we implement the MSAC algorithm using the in-built MATLAB function *pcfitplane*, which we explain subsequently. We specify three parameters for the MSAC algorithm:

- the reference vector ($\mathbf{n_r}$) (the *orientation constraint*).
- the maximum absolute angular distance (denoted as θ_{max}) between the normal vector of the plane hypothesis ($\mathbf{n_h}$) and the reference vector.
- the threshold d_{max}, which is the maximum distance between an inlier point and the fitted plane.

For ground plane extraction, $\mathbf{n_r}$ should be set normal to the xy plane. Then, the algorithm checks if the angular distance between $\mathbf{n_r}$ and $\mathbf{n_h}$ (denoted as θ) is less than θ_{max}. If not, the plane hypothesis is discarded and a new one is considered. Otherwise, the MSAC algorithm proceeds to calculate the following cost function:

$$C^j = \sum_{i=1}^{N} \rho_i \quad (1)$$

where j is the iteration number and the robust error term ρ is defined as follows:

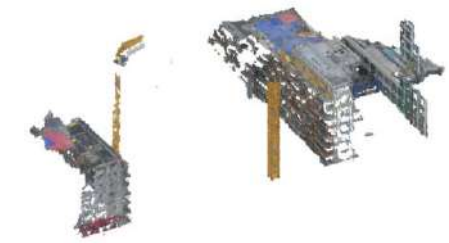
$$\rho = \begin{cases} |d| & if\ |d| < d_{max} \\ d_{max} & if\ |d| \geq d_{max} \end{cases} \quad (2)$$

If C_{j+1} is less than C_j, the $(j+1)_{th}$ model is taken as the best model found so far. Every time the best model is updated, the maximum number of iterations is set to k, which is defined as follows:

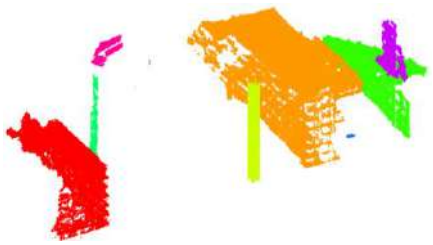
$$k = \frac{log(1-p)}{log(1-w^n)} \quad (3)$$

where p is the desired confidence level (set to 0.99 as per standard practice) that at least one point in the plane hypothesis is an inlier, w is the probability that a single point is an inlier and n is the number of points needed to define the model (which for a plane, as in our case, is 3).

For the georeferenced point clouds, θ_{max} and d_{max} were selected as 5° and 5 m, respectively, based on the intuition that the ground plane is only slightly inclined with respect to the xy plane. For the non-georeferenced point clouds, due to the smaller point cloud density, d_{max} was set to a higher value (40).



(a)



(b)

Figure 3. (a) Ground removed using MSAC; (b) Euclidean-distance based clusters

Note that the ground in the as-built point cloud contains many more points than the top floors of the buildings, thus yielding more inliers and a smaller cost (see Equation (1)). This is why the top floors are not mistaken for the ground by the algorithm.

Once the ground plane is identified, we remove the portion of the point cloud below it by checking the dot product of each point with the plane. If the dot product is negative, the point is below the plane. In other words, for a point $s_i=(x_i, y_i, z_i)$ and the ground plane parameters a_g, b_g, c_g and d_g, if $a_g x_i + b_g y_i + c_g z_i + d_g < 0$, then s_i is a below-ground point and is removed. Finally, the ground plane is removed from the point cloud. Figure 3(a) illustrates the ground-removal for Day 40.

4.2 Euclidean distance-based clustering

With the ground and below-ground points removed, the task now is to cluster the point cloud. We do this using a Euclidean distance criterion. For every point $s_i=(x_i, y_i, z_i)$ and $s_j=(x_j, y_j, z_j)$, the Euclidean distance between the points is as follows:

$$d_{ij} = \sqrt{(x_i - x_j)^2 + (y_i - y_j)^2 + (z_i - z_j)^2} \quad (4)$$

If d_{ij} is less than a distance threshold δ, then s_i and s_j are in the same cluster. We set δ =1 (and δ =5 for the non-georeferenced point clouds) as a reasonable estimate of the separation between intracluster and extracluster points. We refer to the clusters as the set C^d. The results of the clustering are shown in Figure 3(b).

4.3 Building identification using convex hull volumes

A convex hull of a set of points is the smallest convex set that contains all the points. In this paper, we describe the creation of a 3D convex hull based on the Quickhull algorithm, upon which the MATLAB function *convhull* is based. Note that *convhull* uses a more robust (albeit proprietary) strategy for coping with imprecision than the approach outlined in Section 4 of the original Quickhull paper [22], but otherwise the implementation is standard.

Starting with a 3D set of points, Quickhull first builds an initial hull from four points. Ideally, this tetrahedron should be maximal, which can be accomplished by first finding the maximum and minimum points along the X, Y and Z axes, then finding the furthest point from the line segment made by the first two points, then finding the furthest point from the plane made by the first three points. Once the initial hull is created, the point from the remaining set (not used in the initial hull) which is farthest from the hull is set as the *eye point*. Those faces of the hull that lie above the

eye point (as determined by a simple plane test) are called visible faces, while those that lie below it are non-visible faces. The edges that connect visible with non-visible faces together constitute the horizon. To determine the horizon, a flood-fill approach is used. The algorithm starts from a visible face, and then travels across an edge to a neighbouring face. If the neighbouring face is also visible, the algorithm travels further across an edge until a non-visible face is encountered, at which point the offending edge is marked as being part of the horizon. Then, the algorithm returns to the last visible face and continues traveling across another edge. This process continues until the algorithm returns to the original visible face. Once all the horizon edges are found, the eye point is connected to it and thus the hull is extended. This process continues till no face remains with a point outside it.

Our use of convex hull volumes is based on the intuition that buildings are typically more voluminous than non-buildings on a construction site, especially a large site such as the one we are considering. As we shall demonstrate, this intuition is supported by our dataset. For example, Table 2 shows the convex hull volumes for C^{40}.

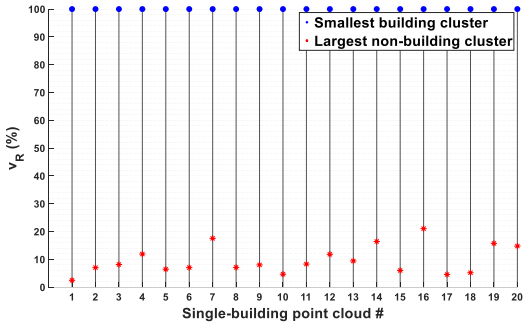
Table 2. Convex hull volumes of clusters

Cluster #	Convex hull Volume	Cluster-type (Manually labeled)
1	749.2316	Building
2	318.9671	Building
3	169.1460	Building
4	10.4517	Non-building
5	7.2664	Non-building
6	3.9378	Non-building
7	3.7009	Non-building
8	0.1131	Non-building
9	0.1000	Non-building
10	0.1000	Non-building

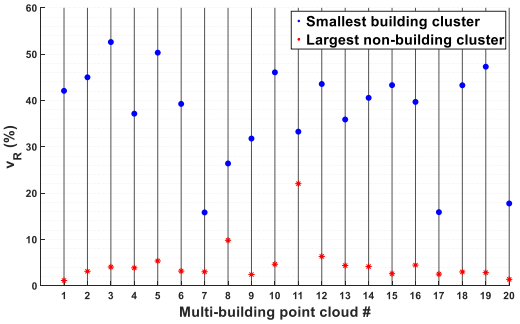
Note that the building clusters are much larger than the non-building clusters. This motivates us to define a quantity called the *relative volume* (v_R) as follows:

$$(v_R{}^i)_d = \frac{(v_{abs}{}^i)_d}{(v_{max})_d} * 100 \qquad (5)$$

where $v_{abs}{}^i$ is the convex hull volume for cluster i and v_{max} is the largest convex hull volume for the set of clusters under consideration (i.e. for day d). Figure 4 shows the smallest building cluster and the largest non-building cluster for each day based on the v_R values of the clusters. The figure shows a considerable separation between building and non-building clusters. As Figure 4(a) shows, for the single-building data, the building cluster is always the largest and maintains a significantly higher v_R value than the largest non-building cluster for each day. In fact, the mean of the relative volumes of the largest non-building clusters is 9.68%. For the case of multi-building point clouds (Figure 4(b)), the mean of the relative volumes of the largest non-building clusters is 4.72%, while that of the smallest building cluster is 37.35%.



(a)



(b)

Figure 4. Comparison of smallest building cluster and largest non-building cluster for (a) single-building point clouds and (b) multi-building point clouds

Based on these insights, we outline the following strategy for extracting the building clusters:

- For the single-building data, the cluster with the largest v_R value is the building.
- For the multi-building data, a cluster with v_R less than 15% is a non-building cluster. Additionally, we impose the maximum possible buildings on the site (3 in our case) as a constraint.

The algorithm finally divides the point cloud into

two sets, *BuildingClusters* and *NonBuildingClusters*. The results are presented in the next section.

In order to label the extracted buildings, we consider the relative v_R values of the three buildings, but this approach is not fully demonstrable due to some limitations in our dataset, as is discussed in the next section.

5 Results and discussion

5.1 Classification: building vs non-building clusters

We define the classification accuracy as being 100% for a particular day if the set *BuildingClusters* contains the actual buildings available on the original construction site point cloud. The achieved accuracy is 100% for all 40 point clouds, i.e. building and non-building clusters are successfully separated for the entire dataset. Figure 5 shows the building-only point cloud obtained for day 40.

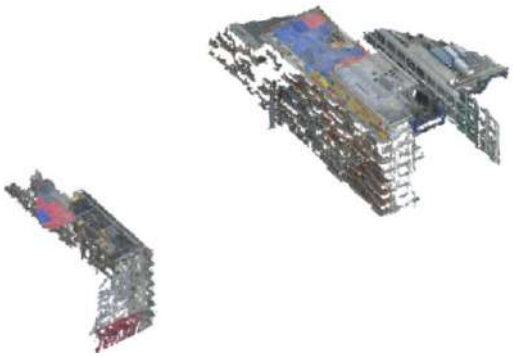


Figure 5. Building-only point cloud for day 40

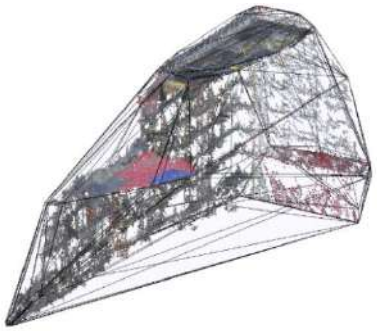
5.2 Building labeling

In our dataset, building A always has the largest v_R value and it can therefore be labeled with 100% accuracy for the entire dataset. However, only a small segment of buildings B and C is captured by the crane cameras. The size of these segments varies inconsistently due to the varying positions of the crane cameras. Thus, a volume comparison cannot be consistently applied to these buildings until they are captured more completely. In other words, more complete data is required to label these buildings according to their relative v_R values.

5.3 Departure from convexity: effect of the *α-radius*

A convex hull is a specific case of an *alpha shape*, which is a polytope with a parameter called the *α-radius* that defines how tightly the boundary fits around the shape [23]. A convex hull results when the α-radius is infinity. In our specific case, using the convex hulls was more suitable due to the nature of a convex hull to "wrap around" the object, thus ignoring false cavities in the point cloud clusters resulting from the crane camera not capturing a portion of the site. An alpha shape, on the other hand, tends to "wrap into" the cavities of the point cloud clusters, resulting in a smaller boundary volume that does not approximate the actual volume of the building well. This is illustrated in Figure 6. We suggest this phenomenon might generalize to any point cloud with missing regions being subjected to boundary volume analysis. Additionally, using convex hull volumes obviates the need to find a suitable alpha radius, as was done in [24] for example.



(a)

(b)

Figure 6. Illustration of (a) convex hull (*α-radius*=∞) and (b) alpha shape with lower radius

5.4 Crane cluster outlier

Figure 4(b) shows that for multi-building point cloud

11, the largest non-building cluster has a v_R value of 22%, which is a clear outlier. Visualizing this cluster shows that the large volume comes from the presence of a crane in the cluster, as is shown in Figure 7. When we manually remove this crane from the cluster, the v_R value of the cluster reduces to 4.44%. Note that the maximum building number constraint we imposed deals with this outlier effectively, which is why this cluster is correctly classified as a non-building cluster despite being above the 15% v_R threshold.

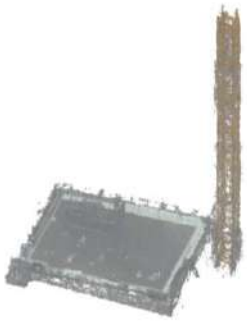


Figure 7. Outlier cluster for multi-building point cloud 11 (day 29/40) with v_R=22%

6 Conclusions and future work

Crane cameras are a convenient and cost-effective alternative to laser scanners and UAVs for visually capturing an entire construction site. In this work, we did a preliminary study on the potential of crane camera point clouds for automatic progress monitoring. We addressed the problem of automatically extracting buildings from the crane camera point clouds. We presented an algorithm called VBUILT which is based on the intuition that building clusters have larger 3D convex hull volumes than non-building clusters. We found that our dataset supports this intuition, showing a large separation between the relative volumes of building and non-building clusters. By utilizing this separation, VBUILT was able to correctly identify the building clusters for all 40 point clouds in the dataset. We also successfully labeled one building which is captured relatively well by the crane cameras, but would require better data of the other buildings to demonstrate the effectiveness of the relative volume strategy for multi-building labeling.

An important insight from our work was that convex hull volumes capture the volumes of building clusters with missing regions more effectively than alpha shapes with lower radii due to the tendency of the latter to wrap into the empty regions of the cloud. We thus recommend the consideration of the convex hull over alpha shapes for such volume-based analyses of incomplete point clouds.

The algorithm successfully dealt with an outlier non-building cluster by imposing a maximum building number constraint. However, in order to prevent such outliers altogether, an automatic crane removal algorithm can be developed in future work, possibly by leveraging on the high slenderness ratio and the uniform colour of the cranes.

The proposed algorithm worked successfully with both georeferenced and non-georeferenced point clouds, the latter constituting about 32% of our dataset. In future work, we will study why georeferencing fails for some point clouds and how we can address the problem.

The point clouds generated from crane cameras give a good overview of the site and high quality views of the top portions of the buildings where the laying of formwork and rebar can be observed. Thus, in future work, we intend to use the building point clouds obtained through VBUILT to infer the progress of formwork and rebar. Also, the crane camera point clouds contain holes in the building façade regions. More studies are needed to truly gauge the effectiveness of this portion of the point clouds for progress monitoring. Therefore, in the future, we intend to match the building-only point cloud with the as-designed Building Information Model (BIM) of the site to study the extent to which progress and deviations can be measured.

Abstract –
Robotics, mass timber, and parametric design are all key technologies that are underutilized in construction. To fully take advantage of these new technologies requires a rethinking of the entire process from design to construction. The Greenbuild Pavilion represents a new construction workflow, in which a digital parametric model is communicated directly to a robot fabricator. The robot, equipped with various tools, can manipulate dimensional lumber into complex geometries with industrial precision. This workflow has the potential to drastically improve the sustainability, quality, cost, and time of construction.

1 Introduction

Perkins + Will's Building Technology Lab was able to leverage its previous research into mass timber and robotic fabrication, combining expertise across offices in a year-long effort. Hakim Hasan, from Perkins+Will Boston, and Anish Reddy, from the Los Angeles office, fabricated a pavilion in modules (using 2,451 individual pieces of wood and 10,828 nails) over 54 hours at Autodesk's Technology Center in Boston. It was then shipped to Chicago and assembled at the Greenbuild Expo, where it stole the show with its curved geometry and massive scale, topping out at 4.26 meters tall and 6 meters wide.

The success of the pavilion marks a major step forward for sustainable applications of robotics. Because it is a post-and-beam mass timber structure, the pavilion's workflow could be applied to a structure as tall as 18 stories. The use of wood allows for a renewable, widely-available material to displace steel or concrete and reduce a building's carbon footprint. The use of robotics allows for buildings to be delivered faster and more precisely. Moving forward, Perkins + Will seeks to implement these workflows into its projects, ensuring a better final product for its customers.

1.1.1 Problem Statement:

Robotics, mass timber, and parametric design are all key technologies that are underutilized in construction. To fully take advantage of these new technologies requires a rethinking of the entire process from design to construction.

Cross-laminated timber (CLT) has become more popular in recent years, with most innovation (led by companies like Katerra[1]) centering around providing orthogonal modules that can be prefabricated off-site and quickly assembled on-site. The International Code Council recently adopted new language for 2020 that would permit high-rise construction with CLT (and other related mass timber assemblies) up to 18 stories. These developments feed into a burgeoning demand for sustainable, efficient, and dense structures in the current real estate market.

Robotic fabrication has the potential to allow more complex assemblies with mass timber than are typically produced in a factory. Recent research into robotic fabrication with wood has focused on dome structures (ICDE/ITKE Research Pavilion 2015[2]) or typical balloon framing (DFAB House[3]), which do not translate easily the high-rise industry. For robotics to become economically viable in construction, it must take advantage of economies of scale and be able to produce mass timber assemblies.

2 The Robotic Setup

The robotic setup is a 6-axis ABB IRB 4600-40/2.55 mounted on an ABB IRBT 4004 external linear track yielding 7 degrees of freedom. The robot is operated at a speed of 2 metres per second and has a Maximum reach of 2.55m from the base of the robot, and when mounted

on the external linear axis, the range is extended across 9 meters with a position repeatability RP of 0.06 mm and a path repeatability of 0.28mm.

2.1.1 The Tools

5 tools are equipped with ATI automatic tool changers allowing for the robot to quickly switch from one to the other. The changeable tools are mounted to a shared base to allow for easy repositioning. These tools include:

- A custom-made spring-actuated suction gripper for gripping wood with a max payload of 20kg.
- A Modified Fasco Lignoloc Coil Nailer shooting a magazine of 150 wooden nails. (Tool Not Used throughout the entire Process)
- A Modified Dewalt Pneumatic Nail gun with a 300-nail magazine shooting 63.5mm nails
- An Air-cooled milling spindle equipped with a 12.7mm end mill with a max rpm of 24000.
- A Modified Dewalt Circular Saw with 177.8mm Diameter Blade

An alignment slide constructed to serve as a constant reference obtaining the physical gripping center of each piece of lumber. A Schunk pneumatic gripper with stepped grips was floor mounted to function as a work holding as each Lumber is processed. Using the suction gripper, there were limitations to the weight and imprecisions for vertical placing of members as there is a 1.5 mm of movement due to the spring actuation. The circular saw was limited in the max perpendicular cutting depth of 63.5mm. When using the pneumatic nail gun, in order to have a successful fire meant that the nozzle has to be fully pressed up against and perpendicular to the lumber.

2.1.2 The Robot Work Cell

The work envelope measures 4.26 meters wide by 12.22 meters long and is enclosed by 2.43 meters tall polycarbonate walls seen in Figure 2. Laid out in a linear fashion, the cell has two doors positioned at opposite ends, the first being for material loading and unloading to and from the cell and the other for general access. Each door is tied into a safety control system of the robot and activates an emergency stop if faults during robot operation. Inside of the cell starting from the loading door on the right, is a pallet positioning marker located on the floor to indicate the approximate placement of the pallet of boards. This allows the operator to quickly and accurately position the pallet in place. Next to the pallet is the lumber alignment slide where every piece of lumber picked by the robot is dropped on the slide and re-picked from its centre. Positioned next to the slide, all the robot end effectors are resting in their appropriate holders and all mounted to a shared base. The work holding is fastened to the floor next to the tools with a transparent Plexiglas wall acting as a barrier to protect the tools from dust and other objects during the milling and mitering process. Next to the work holding is the build platform where the pieces of lumber are placed and the build-up process occurs. The platform measures 1.5 meters by 4.5 meters dictating the maximum building area of the robot. At the end and outside of the cell is the operator viewing and control desk.

Figure 2

2.1.3 Selecting the Wood Grade

There were a series of investigations in attempt to select the right species and grade for the robotic process. Out of all the various species available at the local Boston lumberyards, Douglas fir was the preferred choice in terms of surface finish and density but it was prohibitive due to its relatively high cost. Our solution was to side on a low cost approach using the lowest grade Spruce-Pine-Fir (SPF) framing lumber as it is readily available and is a popular construction material. Our robotic setup was constructed to tend both 2x4 (38.1 x 88.9mm) and 2x6 (38.1 x 139.7mm) dimensional lumber at a maximum length of 1.21 meters, however we limited the design to using only 2x4 (38.1 x 88.9mm) Lumbers with a maximum length of 1.21 meters and a minimum of 0.3 meters.

2.2 Design Scripting

Various surface-based forms were explored within the 10’x20’ envelope of the booth at the exposition, with the basic theme of a Core (two Columns and a Beam) and Shell (Ground Floor, Upper Floor, Exterior Wall, Interior Surface). Grasshopper was used to divide the surfaces, modeled in Rhinoceros 3d into its individual elements and generate.

Figure 1
Rendering of Design

A nailing pattern needed to connect them. The application of textures to the digital model was also automated using the Human plugin for Grasshopper. Wood textures were mapped to each individual piece along its length (slightly shifted each time to maintain a natural feel. Primary parameters of Grasshopper Shell geometry script, used to divide the surface into its individual elements:

- Board Thickness
- Board Width
- Maximum Board Length
- Minimum Board Length

Using the Grasshopper Core geometry script, surfaces of Core are divided into curve Contours every Board Thickness along the y axis. Contours are divided into point Nodes (limited to Maximum Board Length). Nodes are connected by lines of Primary Rails. Rectangular profiles matching the Board Thickness and Board Width are extruded along the resulting linear Input data provided by the design outputs are sorted by type and subsequently by assembly. These inputs are:

- Lumber Geometry (Optional)
- Lumber Center Plane
- Lumber Center Lines
- Lumber Left and Right Miter Lines
- Dowel Points
- Lumber Lengths
- Nail Points

geometry and mitered at intersections. Lumber Geometry is organized by build order.

Primary parameters of Grasshopper Core nail script, used to generate a nailing pattern:

- Nail Offset from Ends
- Nail Offset from Center
- Nail Spacing

Using the Grasshopper Shell nailing script, two Nail Endpoints are identified for every Primary Rail, moved by the Nail Offset from Ends along the length from both endpoints. Two nails are offset by the Nail Spacing diagonally from the Nail Endpoint and assigned to each Primary Rail. Two nails are offset at the opposite diagonal (to avoid conflicts between layers) from the Nail Endpoint and assigned to the Primary Rails in the next layer. Two Nail CenterPoint are identified for every Primary Rail, moved by the Nail Offset from center both ways along the length from the CenterPoint. Two nails are offset by the Nail Spacing diagonally from the Nail CenterPoint and assigned to each Primary Rail. Two nails are offset at the opposite diagonal (to avoid conflicts between layers) from the Nail CenterPoint and assigned to the Primary Rails in the next layer finally, all nails are assigned to geometry and organized by build order as NailPoints.

2.3 Robotic Process

A program script was developed that converts outputs from the design script into a fabrication process and outputting robot-readable commands for its execution. The Software used for these processes are; Rhinoceros 3d (modelling), Grasshopper (scripting), Machina Plugin (robot communication), and ABB Robot Studio (simulation). An accurate 3d model of the robot cell was created for a visual understanding of the workspace of the robot.

OBJECTIVE:	ROBOT SUBROUTINE:	IMAGE:
1. Get Lumber From Pallet	- Pick Up Suction Gripper - Turn On Vacuum - Pick Lumber from Pallet*	2. Align Lumber	- Place Lumber on Slide - Release Vacuum - Apply Vacuum - Pick Lumber from Slide*	3. Clamp Lumber	- Open Work Holding - Place Lumber in Work Holding - Close Work Holding - Release Vacuum - Return Suction Gripper	4. Miter Lumber	- Pick Up Circular Saw - Turn On Circular Saw - Miter Left and Right Ends* - Turn Off Circular Saw - Return Circular Saw	5. Mill Dowel Hole	- Pick Up Milling Spindle - Turn On Milling Spindle - Mill Dowel Hole* - Turn Off Milling Spindle - Return Milling Spindle	6. Get Lumber from Clamp	- Pick Up Suction Gripper - Turn On Vacuum - Move to Work Holding - Open Work Holding	7. Place Lumber on Platform	- Place Lumber on Platform* - Release Vacuum - Return Suction Gripper	8. Nail Lumber	- Pick Up Nail Gun - Nail Lumber* - Return Nail Gun	
* Subroutines with variable target parameters

The first part of the script generates 3 stacks of lumber on a pallet. The stacks are 1 foot, 2 feet, and 4 feet in length from which the robot will pick each piece of lumber from. The output design data is then oriented and centered to build platform, this gives the viewer a visual understanding of the geometry which will be built. A series of sub routines were programmed outlining the overall fabrication process. This is depicted in Figure 2.

2.4 Manual Assembly

Apart from the maximum 1.5m x 4.5m x 1.4m build volume on the platform, transportation, manual handling, and assembly logistics were factored which limited the size of what each module could be. These constraints are that no module should be heavier than 200 lbs., its two smallest dimension not exceed 4 feet and 7 feet, and its longest length not greater than 16ft. This ensured that every module fabricated by the robot could be lifted by two people onto flat dollies loaded into a moving truck and erected on site without any heavy machinery involved. Every module was fabricated with ½ inch dowel holes that corresponded with its neighbouring module this aided in precisely aligning modules together and then subsequently fastened with screws for additional security. This simple modular technique was created to allow for non-skilled labour to easily assemble complex components with basic hand tools.

2.5 Results

The parametric workflow was critical to managing the complex data of the 2,154 individual pieces. The relational nature of the digital model allowed for this large amount of data to be flexible, changing as real-world tests affirmed or rejected our initial assumptions. In the robotic script, Machina was a useful tool to seamlessly compile fabrication instructions from Grasshopper into robot-readable code, simulate robot movement in ABB Robot Studio and subsequently sending that data in real time to the robot for execution. This allowed for real-time modifications to the design as changes arise.

2.5.1 Fabrication with Robots

Despite the automated nature of this process, there were a few manual processes involved prior to fabrication and post fabrication. The 800 boards supplied from the lumber yard came in 2.43 meter lengths and required cutting them down to 1.2, 0.6, and 0.3 meter lengths using a standard chop saw. With two people involved, the time to process all 800 boards was approximately 7.5 hours. These lumber pieces had to be stacked in a pile on pallets and place in the robot cell for retrieval by the robot.

2.5.2 Jointing and Planing

In initial testing, the lumber was jointed and face planed to ensure a squared rectangular profile and a smooth surface finish. This made all boards, regardless of their natural inconsistencies, uniform and guaranteed proper suction when being gripped by the suction gripper. The jointing and face planing of all 800 boards would have been time consuming and labour intensive, taking over 42 hours to complete. This approach was abandoned and instead the focus was to engineer a more robust gripping system to accommodate for the natural inconsistencies of the unprocessed wood. Special webbed suction cups from Schmalz were used that would then compartmentalize the suction over the surface of the Lumber for better adhesion. In tandem an air ejection system had to be integrated to release the boards when being placed due to the high suction (101 kPa) generated by the vacuum pump.

Figure 4

2.5.3 Quality Control

A visual inspection of the Lumbers were done when stacking them on pallets. Features that would disqualify a Lumber from being placed on the stack are significant warping, large splits, and loose knots. Splits and knots that run through or around the centre top face of the Lumber tends to create a leak in the vacuum cups and is likely to fall when being handled by the robot. Warped Lumbers however can be used in the process by cutting them down to 1 foot lengths, but unless factored in, it can affect the consistent aggregation of Lumbers. After

quality controlling all 800 boards the unusable percentage was a surprising 2.25 percent, less than anticipated.

2.5.4 Calibration

In order to utilize the high precision of the industrial robot, every tool was carefully measured in and calibrated of optimal performance. Each tool's TCP (Tool Center Point) was measured in with an accuracy of 0.01mm-0.03mm. Starting with the suction gripper, it went through a series of iterations varying the suction cup types, gripping vacuum pressure, and quick release mechanisms. As for the Fasco Lignoloc nailer, it was working normally when running at a reduced robot speed of 250mm/s but stopped working when attempting to run at 700mm/s. This was mainly because the air flow rate we were supplying was too low for the speed we were moving. This cause a rupture inside the tool rendering it unsuitable to continue use in the process. Pressed with time, we had to resort to using the standard Dewalt nailer with steel nails. The initial approach to cutting the ends of each lumber was using a milling spindle. This was to allow the flexibility of cutting beyond straight miters. The process was too slow and there was no need to cut the ends other than straight miters. The milling spindle however was appropriately used to position the dowel holes. Mitering the ends of the boards was done with a ripping blade on the circular saw. The maximum speed of cut was 90mm/s while still have a good cut finish.

2.5.5 Speed of Fabrication

Every portion of the fabrication was gradually sped up to its maximum capabilities without affecting performance or quality. On average the processing of each board takes 1 minute 20 seconds from the point of picking up the board to nailing it in place. For a total of 2,154 members, total fabrication time amounted to 54 hours.

2.5.6 Assembly Evaluation

Laser scanning was used to verify the constructed geometry against the design model. The robotically-constructed modules were accurate to 1mm precision, while the completed assembly, done by hand, were accurate to within 75mm. This further advances the notion that robotic fabrication should extend into the assembly process, allowing its inherent precision to carry through to the constructed building. Figure 3

Figure 3

Comparison of laser scan of constructed pavilion (wood texture) and digital design model (in red). All geometry was verified to be within a 75mm tolerance.

2.6 Conclusions

The success of the pavilion marks a major step forward for sustainable applications of robotics. Because it is a post-and-beam mass timber structure, the pavilion's workflow could be applied to a structure as tall as 18 stories.

The use of wood allows for a renewable, widely-available material to displace steel or concrete and reduce a building's carbon footprint. The use of robotics allows the resulting assemblies to be infinitely varied and optimized with millimetre precision. The direct nature of communication between a digital model and a robot allows for a seamless translation from an imagined design to constructed reality. Moving forward, Perkins + Will seeks to implement these workflows into its projects, ensuring a better final product for its clients.

2.7 Future Research

Future research will seek to build on this workflow and seek ways to implement them into real projects. Because of the experimental nature of the project, the workflow was somewhat imprecise. Wood is a natural material and no two pieces of lumber are alike. The project used generous tolerances to finish within the deadline.

There are two ways this research can continue: non-structural elements and structural elements. Non-structural elements would generally use the same workflow, with adaptations for specific forms and connection types. Structural elements, however, must be built to more exacting standards, and will most likely

require sensors feeding data back to the digital model, allowing the model to adapt to the shape of the actual lumber given. Machine learning could be used to optimize nailing patterns by understanding and analyzing the grain of the wood.

Abstract –

This paper is sharing an on-going project about the design of a software package, tentatively coined as RS4B, for the builders of modularized construction. The shortage of labour resources and safety awareness issues have become the emerging problems in the construction industry. As the price of robots gradually decreases within these years, it is a promising direction to integrate robotic technology with the construction process to bring better productivity. However, shifting the long-term labour-based process to the robot-based process is not a simple task. Therefore, this research designed an assisted software package for filling the gap between the conventional process and robotic process. Four kinds of software were proposed in this research with their required functions and user interfaces design. With such an assisting tool, builders of modular home manufacturing will be able to extract information from the existing BIM model and transfer the information for the robot control.

Keywords –

Modular homes; Industrial robots; Robotic construction

1 Introduction

This research focuses on the design of an assisting software package for robotic modular home manufacturing. A modular home is a building that produced using factory-built modules instead of site-built [1, 2]. It is an innovative method that uses large, three-dimensional, and off-site manufactured modules to build a home [3]. Within these years, the modular home building has been widely utilized in North America, especially residential buildings, due to its high efficiency and low construction cost [4]. Although advance in the process can bring improvements to the industry, such a construction method has no significant improvement in productivity [5]. It is because the modular home manufacturing process still relies on labour works. The entire process may cost 202 labour hours in average for a single modular, including subassembly, module-built, interior work, and wrapping and shipping [6].

As the elevation of labour shortage and safety awareness, it is critical for builders to develop advanced construction methods for reducing the usage of labours. According to the Canadian Federation of Independent Business (CFIB)'s report, construction industries holds the second highest job vacancies rate (3.6%) in the first quarter of 2018 in Canada [7]. The severe shortage issue can bring serious issues to construction productivities. Besides, construction safety is another increasing issue in the industry. During 2014 to 2016, fatalities happened in the construction industry account for 23.81% of all industries in Canada [8]. Therefore, it is an urgent and promising direction for the industry to reduce the requirement of human involvements.

Recently, studies have been conducted for implementing the industrial robot into the manufacturing process of buildings for dealing with the labour shortage issue meanwhile increasing the productivity of the process. However, shifting the long-lasting labour-based process to robot-based is not a simple task. There are still challenges and constraints remain unsolved before implementing into the industry, such as insufficient education program for basic robot control training, no research environments for the development of new construction method, and lack of well-developed assisting software. Therefore, this research proposes the design of an assisting software package for filling the gap between conventional construction to robotic construction. The following section will include a literature review for identifying both the opportunities and challenges of utilizing industrial robots into the building industry, the research objective, and the design of the software package respectively.

2 Robots in Modularized Construction

As the growth of robot technology and decreasing of robot price, it is a promising direction to develop robotic and internet of things (IOTs) solutions to reduce labours in the job site, and meanwhile increasing the productivity of the construction industry. According to Statista - The Statistics Portal, the price of industrial robots drops 28% in the past ten years [9]. Industrial robots, such as robot arms, have been widely utilized in the manufacturing industry for complex, repetitive, and tedious tasks for years [10]. However, in the field of construction, the application of industrial robots is now infancy and still has a long way to go. In fact, in 2017, 83% of construction companies had not implemented robots into their working process [11].

Recently, research about robotic construction has been conducted for reducing the gap between labour-based and robot-based process. For instance, Khoshnevis used additive manufacturing process for large-scale construction [12]. Skibniewski and Hendrickson identified the benefits of using robots for the on-site surface finishing work [13]. The "In-situ Fabricator" was developed by ETH Zürich for the rebar work of a double-curved concrete wall [14, 15]. García de Soto et al. conducted an experiment for comparing the productivity performance of ETH Zürich's robotic method with the conventional process [16]. The results showed that robotic construction method could have higher productivity when facing a complex wall.

Although utilizing robots for repetitive building tasks has been proven for having higher efficiency than conventional methods [17], there are still challenges for implementing such technologies into the building manufacturing process. This research concluded three major issues should be overcome.

- **Thousands of components:** Unlike the manufacturing industry, the building contains thousands of components for assembly. Therefore, how to breakdown the original design to manufacturable components with considering the capacity of robots may be one of the most critical issues. The robotic assembly plan should be well organized and designed for such a huge number of components.
- **Complex building regulations:** In the industry of construction, the most important but difficult task is to meet the building regulations, such as structural regulations, connection regulations, or shipment regulations. Some of the regulation is hard for the robot. An assembly planner which is able to check if the design fits the regulation automatically is thus important.
- **Numerous unique robot motions:** The building component is more complicated than other mechanical components. The robot may need to place different types of studs for different types of frames, nailing or wielding for connection, and installing different kinds of objects like windows, doors, or Mechanical, Electrical, Plumbing (MEP) systems. Therefore, a well-designed robotic motion planner with intelligent algorithms which can automatically generate related robotic motions should be developed.

3 Research Objectives

This research aims to propose a blueprint of an assisting software package, tentatively coined as Robot Studio for Builders (RS4B). RS4B is designed to extract the information from the existing building information model (BIM), and transfer the information for robot control. Such a software package should be able to deal with the large amounts of building components meanwhile considering the building regulations and the robot motions simultaneously. The design of the RS4B will list the functions of the tool and propose a prototype of the user interface.

4 Design of RS4B

This research designed a software package for assisting the builder to link the original design (BIM) with robot controls. The package contains four software: *BIM Exporter*, *Assembly Planner*, *Robot Simulator*, and *Motion Planner*. With the four software, builders are supposed to be able to breakdown the buildings into the modular, panel, and assembly components. Such software is expected to be an assisting tool for the future building industry with robot-assisted workflow. The following subsections will describe the designed function and user interface of each software respectively.

4.1 BIM Exporter

BIM Exporter is designed to subsect the entire building into components, extract the geometrical information and generate the robot-manufacturable models of the building component. It should assist the builder to retrieve the geometric information of building components from the complete building information models. The software will help dissect the digitized 3D models and export the building components to be manufactured by robots. *BIM exporter* should divide a BIM model into building components such as walls, roofs, floors, and stairs, with their geometric properties. The exported data will be linked with the original BIM model to assist the builders to figure out where the building component in the BIM model.

Figure 1 illustrates the design of the main interface

of BIM Exporter. Four major functions will be included in the software. (1) BIM model import: The users will import common BIM models such as Autodesk Revit (.rvt), Bentley Microstation (.dgn), Graphisoft ArchiCAD (.pln), and other models in IFC format (.ifc). The software should be able to read the file and import to the associated database. The imported BIM model will be represented on the user-interface. (2) Components breakdown: *BIM Exporter* will subsect the whole building into components. The users can view the breakdown details for each component. They are able to click the component in the breakdown structure to see the isolated 3D view of the component. (3) Components classification: *BIM Exporter* will intelligently classify the objects by type and size. The similar objects can be manufactured by similar robotics working packages. With the classification, the users are easier to export similar objects as groups to reduce the efforts for the following steps. (4) Geometric information extraction: *BIM Exporter* will extract the geometric information for all the building components to be assembled by robots. The models are stored in a cloud database which allows better management and flexible usage in the following steps.

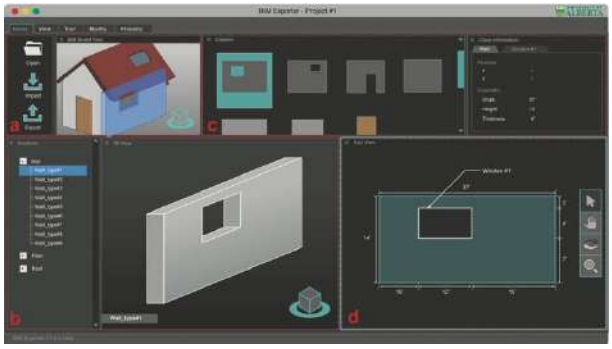

Figure 1. The designed interface of *BIM Exporter*. (a) imported BIM model (b) breakdown structure and isolated 3D view (c) classifications and their detailed information (d) geometric information of the component.

4.2 Assembly Planner

Assembly Planner aims to assist the builders to plan the assembly details of each component exported by *BIM Exporter* for robot manufacture. The assembly details include the frame layouts of each component, the temporary supporting layout for robot assembly, and the optimal sequence of assembly. The software should have an intelligent algorithm to automatically generate the suggested assembly sequences by considering the building regulations, geometrical constraints, and physical limitations.

Figure 2 illustrates the preliminary design of the main interface. Five major functions will be included in the software. (1) Components import: The users can import the building components to be manufactured by robots. The components' breakdown structure will be displayed in the left-hand side. (2) Regulations import: The users can import the regulations and the association between components and regulations will be linked. After regulations import, the software would be able to generate the default framing layout automatically considering the building regulations. (3) Components framing layout: *Assembly Planner* should allow the users to refine the default framing layout through framing toolkits. Different type of components requires different elements for framing. They can replace the different dimension of elements to satisfy the required structural strength and under the geometrical constraints. (4) Temporary supporting layout: The users can also plan the temporary supporting layout. The temporary supporting will be placed by robot arm before assembly. The physics limitations will be considered to ensure the support can keep the frame stable during assembly. (5) Assembly sequence planning: *Assembly Planner* should provide an intelligent algorithm to plan the manufacture in an efficient assembly sequence. The users can also refine the sequence by adding any other consideration and determining the weighting to reflect different scenarios.

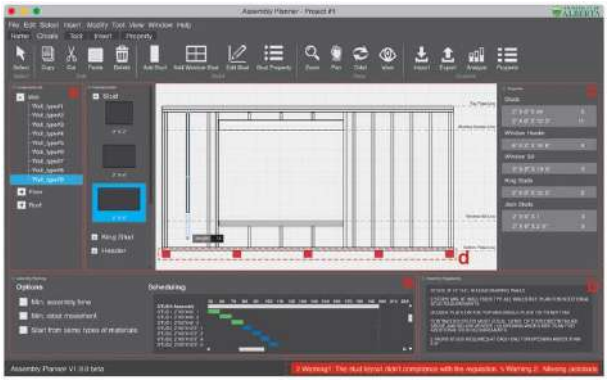

Figure 2. The designed interface of Assembly Planner. (a) components to be manufactured (b) regulations import (c) framing toolkits (d) temporary supporting layout (e) sequence planning.

4.3 Robot Simulator

Robot Simulator should provide the detailed simulation for the entire work sequence of robots, including material preparation, move, assemble as well as the working layout. In the robotic development or application, the simulator is often used to simulate a

robot's movement without depending on the actual machine. With the simulator, the builders can optimize the work sequence of robots without wasting time and cost. In some commercial simulator, it even allows the simulated movement to be directly transferred onto the physical robot without modifications.

Figure 3 illustrates the design of the main interface. The interface contains six major functions. (1) Assembly layout and schedule import: *Robot Simulator* allows the users to directly import the assembly layout and work schedule created by *Assembly Planner*. The builders can import the 3D models with detailed geometry properties, the temporary support layout, and the assembly schedule. (2) Animation-based robot programming: The software allows the users to drive the robot using time-based animation tools. The users can operate the robot through keyframing motion, velocity and acceleration tuning, motion blending, and more. The operations can be exported as either animation files or robot commands codes. (3) Built-in robot models: *Robot Simulator* provides several built-in robot models for the users. The robot's rig and post-processors, external axes, configurations, and I/Os are all extensible. With the flexibility of robot models, the users can control most brands of industrial robots in the simulator. (4) Inverse Kinematic/ Forward Kinematic robot control: The users are allowed to manipulate the robot through either Forward or Inverse Kinematic method. (5) Collisions and singularities warning: The collisions and singularities will automatically detect through an embedded algorithm. Whenever the collision or singularity is detected, the simulator will highlight on the model to warn the users. (6) Robot commands export: The software can output the operation able robot code after the users sets the movement of the robot. The real robot can directly be actuated without further programming by inputting the exported code from Robot Simulator.

Figure 3. The designed interface of Robot Simulator. (a) assembly layout and schedule import (b) animation-based robot programming (c) built-in robot models (d) FK/IK robot control (e) collisions and singularities warning (f) robot commands export.

4.4 Motion Planner

Motion Planner aims at autonomously optimizing the robotic movement to a more efficient assembly process. Motion planning is the process of breaking down the robot trajectories into discrete motions that considers both the constraints of surroundings and the limitations of the robots. Robots have been widely implemented in the manufacturing industry for high-repetitive tasks. Since building components usually consist of complex and large elements, it is essential to have an intelligent motion plan for the manipulators to interact with the surroundings safely and efficiently finish the task.

Figure 4 illustrates the design of the main interface. Six major functions are included in the software. (1) Back-end algorithm: An algorithm with features of inverse kinematics, collision detection, and singularity avoidance which considers the working space, joints limits, and speed of actuators will be utilized. Through implementing artificial intelligence, the developed algorithm can autonomously optimize the paths generated from the *Robot Simulator*. (2) Front-end fine-tune panel: The software will offer a fine-tune panel for the users to adjust the auto-generated paths. The users can change the manipulation time, add the path constraints, and modify the workspace's specifications. (3) Robot trajectories generation: The software will illustrate the image of the simulation in action with motion planning on the user-interface. This feature details the configuration of joints and links of the robot, which enables the users to check the designed movement through an intuitive way. (4) Data recording and visualization: The flexion and extension angle of the robot's joints will be recorded. The data streams can display the time-graph of each joint as well as combined to form x/y-graphs. The users can easily use those graphs for assistant them to fine-tune the planning result. (5) Connection with real robots: The optimized robot movements can directly export and output as the real robot's commands. *Motion Planner* provides the robot codes for KUKA and ABB, two major robot arms solutions globally. The user can also add the preferred robot language, such as Python, Pascal, C#/.NET, and more, through the open-sourced development environment. (6) Extensible functions: The software is designed with modularity. The users are allowed to reconfigure the interface, create the planning templates, integrate external sensors, and so on. The users can easily optimize the robot's motions by using the designed features as well as customized settings.

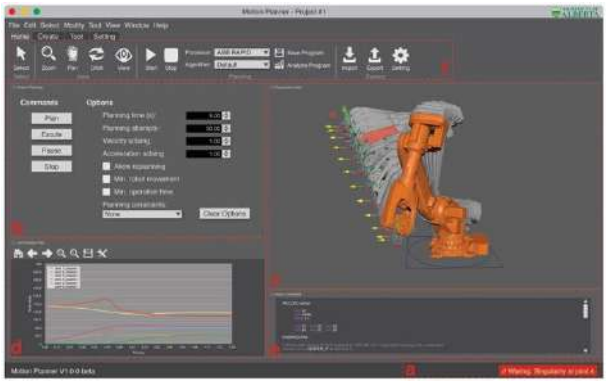

Figure 4. The designed interface of Motion Planner. (a) back-end algorithm; (b) front-end fine- tune panel (c) robot trajectories generation (d) data recording and visualization (e) connection with real robot (f) extensible functions.

RS4B is designed mainly for helping the builder to link the original design to the robotic control. The builder can follow the step-by-step process to discrete the building components, generate the assembly plan, and actuate the robots. With the help of such a software package, the builder who usually has insufficient knowledge and skills might be able to fast and easily implement robots into the manufacturing process.

5 Conclusion

This paper shared an on-going project of developing a robotic software package for the modular home builder. This research designed a four-software package for reducing the threshold of linking the conventional process and robotic manufacturing. The package includes a BIM exporter, an assembly planner, a robot simulator, and a robot motion planner. With such a package, the builder will be able to link the BIM design with robot control thus realizing the robotic process. However, two more details also need to be figure out before realizing the robotic process. One is the development of building design policy for robotic manufacturing. The design policy should also be improved with the consideration of robotic manufacturing to fit the capacity of robots for increasing both efficiency and productivity of the process. The other one is the design of the robotic factory. It may include the design of the robot gripper, the workstation, the assembly line layout, and the circulation. This research will consider these two tasks as the future works. The robotic process is estimated to be realized within the following five years. Implementing robots for modular homebuilding can be expected as the first step to lead the whole industry toward robotic construction.

Abstract –

In this paper, we present a set of enabling technologies developed for the KUKA Innovation Award to facilitate Human Robot collaboration targeted for the architecture, engineering and construction (AEC) sector. Critically, little progress has been made in the usability of user interfaces for industrial robots [1]. We targeted our investigation explicitly towards human-robot collaboration (HRC) in wood based prefabrication production. Although wood is a sustainable material with abundant processing possibilities, it is also a material system where process knowledge remains critically important, making highly automated workflows unfeasible and inefficient.

We propose an interactive fabrication process where a user such as a construction worker could wear an augmented reality head mounted display (ARHMD) as an interface to plan robotic trajectories, influence production sequencing, and view superimposed diagnostic feedback. We describe necessary system components including a robotic workcell consisting of a KUKA LBR iiwa, flexFELLOW mobile platform, a Robotiq 2-finger gripper and a custom platform and material feeding station. In addition, we describe a communication framework and set of protocols connecting a CAD digital design environment, a user interface (UI) for Microsoft HoloLens, a ROS server for backend path planning and coordination, and a 3D graphical web interface for downstream visualization of construction status. We conclude with an outlook on enabling technologies for human-robot collaboration in construction, and the importance of increasing digital integration and accessibility in characteristic production workflows through accessible and intuitive digital interfaces.

Human-robot Collaboration; Timber Construction Prefabrication; Robotic Fabrication; Augmented Reality; Digitalized Construction; Hardware-Software Interoperability

1 Introduction

The construction industry stands to benefit tremendously by increased digitization and automation [2,3]. Extensive progress has been made, primarily in research contexts, in the development of nonstandard material systems enabled through digital and computational workflows connected to physical and precise production equipment including industrial robots. However, there still remains a lack of transfer of these developments into typical production chains and construction processes.

Though there are many factors which have hindered the importation of robotics into construction, one reason is the need for human level dexterity and cognition due to the unstructured nature of construction tasks. In prefabrication workflows, where production occurs in a more structured setting, there is still often a need for human intervention in response to material inconsistencies. Existing timber construction methods and construction systems rely on the expertise, craftsmanship, and dexterity of human workers, favouring a "human-in-the-loop" production chain over highly automated production. Thus one way to increase efficiency and productivity is to facilitate collaborative human and robot workflows, where digital mechanisms and enabling interfaces can orchestrate safe exchanges of tasks.

1.1 Research Aim

Thus the aim of the project is to develop a set of technologies to facilitate an interactive human-robot collaborative workflow for the construction industry: where a user such as a construction worker with limited background knowledge in robotic programming, can interact with a robot system through an augmented reality (AR) interface. To investigate this question, a proof-of-concept fabrication system for human-robot

collaboration is developed. In the developed workflow, production and assembly tasks alternate between a human user and the robot system in the construction of an architecture scale non-standard wooden construction system. Additional communication mechanisms increase interoperability with secondary devices and monitoring platforms.

2 Context

2.1 Challenges in Adapting Robotics in Construction

Much has been written about the construction industry's reluctance to embrace both digitalization and robotic technologies. Reasons given include the compartmentalization of the construction industry [4], interoperability of software for different services, and lack of accessibility of robotic technology as barriers for application. A standard fabrication systems including the well-known six axis industrial arm, developed for the domain of manufacturing, is additionally known to be ill suited for unstructured environments such as a construction site. In addition, historically, robots developed with specific use for the construction industry were primarily focused on narrowly automating single tasks, rather than automating many different tasks within a singular production workflow [5].

Though redesigning building systems for the contingencies and constraints of automation through integrated co-design processes is one long term solution, this project focused in particular on HRC as a means to accelerate automation of the construction industry in the short term.

2.2 Human-Robot Collaboration

Human-robot collaboration as defined in TS/ISO 15066:2016 is an operation where a human worker and a purposely designed robot system can perform tasks in a defined collaborative space concurrently during a production operation. From a technical point of view, this definition means mainly that the motor drives are powered (moving or in safe operational stop) and brakes are not applied even when the robot or its workpiece is in close proximity or even in a physical contact with a human.

However, manufacturing applications with standard industrial robotic arms pose serious danger to human workers and have to be equipped with additional safety components for a safe HRC which decrease the flexibility of the system and increase the setup costs. To overcome this problem an entirely new type of industrial robot arm and controller emerged in past years that can limit the collision forces and thus prevent harm to human body in the event of a contact. Though collaborative robots were developed initially with different target applications and domains, their safety in proximity to humans makes it possible to implement them in fundamental research where collaborative workflows are necessary. Construction sites, which are inherently unstructured, and existing construction systems that rely on human cognition and expertise, make the AEC sector an ideal domain for human robot collaboration.

While the issue of safety is an elementary part of HRC it is only one layer of behaviors needed for successful collaboration [6]. From a broader perspective collaboration does not involve only physical behavior of the involved agents but also their cognitive states [7] as well as optimal form of human-robot communication frameworks.

In this context, the proposed system focuses mainly on the design of appropriate interfaces between a human operator and the robot system resulting in a higher level of behavioral cooperation while limiting physical human-robot interaction. The system also involves only simple cognitive functionality and focuses more on increased integration and interoperability through a set of digital mechanisms connecting design and production.

Similarly, the topic of safety is addressed by others [8,9] and it is not focused in this paper.

2.2.1 Automation in Timber Construction

There are various reasons for the recent rapid advancement and relevance of HRC within the construction industry. The two main reasons are:

- The need to address the growing demand of product customization instead of standardized mass-production.
- Importance of increasing competitiveness of small and medium-sized enterprises (SMEs) that must usually rapidly adapt production to new products in small batches.

Typical construction industry projects can be characterized as a one-of-a-kind production with a fragmented supply chain (i.e. many different contractors involved) that are being fabricated mainly on-site [10]. In Germany, where this project was based, in particular more than 88% of the construction market is formed by companies with up to 19 employees. Timber construction and carpentry companies in Germany have those numbers even higher with more than 96% of the companies having up to 19 employees [11].

Timber construction has however several key features and differences that increase the chances of the industry to adopt novel automation strategies. Those features are especially:

- High level of off-site prefabrication in a controlled

environment
- Short required technological brakes during the production (e.g. glue setting)
- Easy to machine and assemble materials

2.2.2 HRC in Timber Construction

The Level of Automation (LoA) in timber construction is relatively high in the earlier stages of the prefabrication chain where the material is being shaped and trimmed by various CNC and power tools. On the other hand, the subsequent assembly stages that require higher flexibility and human knowledge are still largely manual.

Standard automation strategies developed as a result of flow production demands are not suitable for the dynamic batch and job production within timber construction prefabrication which requires flexibility. HRC applied towards prefabrication presents an opportunity to increase the automation and productivity of timber prefabrication by combining the human knowledge and dexterity (e.g. screw fastening) with the advantages of industrial robots (e.g. precise positioning).

2.3 User Interfaces for Fabrication and Construction

User interfaces (UIs) for industrial robots have hardly made as much progress as UIs in other comparable industries [12]. Thus increasing the ability for non-expert users to interact with a robot was a key motivation for this project, and a key feature which could arguably allow robots to more readily infiltrate the construction industry.

It has already been demonstrated in previous work that well designed human-machine interfaces (HMIs) and background computational coordination have potential for coordinating multiple users in complex building processes; within HMI research just-in-time instructions provided through wearable devices could provide the necessary instructions for non-expert users to engage successfully with robots towards the production and assembly of architecture-scale structures [13].

The advantage of using AR, in addition to screen based interfaces, lies in the ability to overlay digital information over the real-world environment where and when necessary while interacting in real-time using physical and virtual controls. In addition, production statistics and information, assembly sequences as well as machine feedback and control can become more accessible with less training, less preparation time and pre-programming, and also capable of real time updates in response to detected system changes.

State-of-the-art ARHMDs have obvious traits which prohibit their deployment as a universal device for all interface needs, in particular their high cost, short battery life, and limited field-of-view, making it advantageous to develop compatible secondary screen based interfaces.

2.4 AR Applications in the AEC Sector

Several projects have investigated the use of AR in the architectural context. Already in the mid 90´s researcher visualized invisible infrastructure like load bearing columns and their structural analysis using a head worn display [14]. In more recent research, Fazel and Izadi used a head mounted display to guide the manual construction of complex architectural freeform modules [15]. Object interaction and projection-based AR was used to design and robotically transform a seemingly random material system out of melting wax [16]. Newly available plugins developed for computer-aided design (CAD) environments, including Fologram [17], suggest increased opportunities for AR displays as devices which can enable direct three-dimensional feedback superimposed on reality from a digital CAD model.

At the time of submission, limited research has been conducted using AR together with robotic manipulators for the domain of AEC. Fazal and Izadi state in their conclusion that the use of AR can be beneficial for controlling robotic systems [ibid.]. We saw a gap of research where multiple hardware and software technologies could be combined into one system, fabrication workflow, and experience, particularly addressing the need to for robotic interfaces to be compatible with customizable one-off production processes.

3 Methods

3.1 Robotic Workcell and Fabrication Setup

The hardware includes the LBR iiwa robot mounted on a flexFELLOW trolley, a Robotiq 2-finger gripper as an end-effector, a custom-built wood magazine for standard wood stock, a Microsoft HoloLens ARHMD, and a Bosch cordless impact driver for screwing.

The final structure is divided into fabricable building groups called in the context of this research “sub-assemblies”. The fabrication of each sub-assembly takes place on top of an assembly pedestal (Fig. 1). During the exhibition, the robot is moved manually along the pedestal to enable increased reach, though improving robot localization would be a next step in development. Each completed sub-assembly is moved by hand into its predefined position within the final structure, where it is connected to its neighbours with screws.

Figure 1. Robotic workcell and demonstration setup with the assembly pedestal.

3.1.1 Construction System and Computational Process

Though the wooden beams have standardized lengths for simplified implementation in an exhibition setting, the proof-of-concept construction system has the important characteristic of unique rather than standard positions of all the elements, necessitating precise positioning and digital integration. This initial design geometry is generated in CAD software Rhinoceros utilizing a generative design tool and visual scripting language Grasshopper.

Several additional software environments are used for their relative strengths; thus it is critical to establish conventions for interoperability between multiple software environments. To meet this aim, each element in the initial design file and database is given a unique identifier, indicating its assembly number, row and column position.

The driving system principles for the collaborative process are that users execute tasks requiring process knowledge and dexterity, while the robot is used for precise positioning. The HoloLens is deployed as the main HMI and control layer through which this user can plan, dispatch and manipulate robotic path planning in real-time, while also getting live feedback about the current construction status and the state of the robotic system. After selecting a part for fabrication, the path is previewed in the HoloLens. On dispatch, the robot takes an element from the magazine, places it precisely according to the digital model, and then holds the part until the user fasten parts together with screws.

3.1.2 ROS Engine and Communication Network

The core of the system is built using the Robot Operating System (ROS) [18] framework that provides the required communication layer. The ROS server is responsible to manage the CAD geometry, receive and publish robot positions and targets, collect robotic status data, keep track of the fabrication progress, plan robotic paths, and receive commands from the ARHMD and forward them for execution.

The core ROS server achieves this functionality with several features:

- A digital twin of the system that manages system states and real-time environment data
- Path planner based on the ROS package MoveIt! [19]
- Set of ROS nodes that serve as a bridge between the ROS environment and the Java environment of the KUKA Sunrise controller. The bridge nodes are responsible for sending planned actions and receiving real-time robot and gripper data using Google Protocol Buffers (Protobuf).
- Websocket server based on the rosbridge_suite ROS package that provides communication with the components of the system outside of the ROS environment (ARHMD, web-browsers etc.).

Additional important components outside of the ROS framework are:

- MongoDB database for storing the symbolic representation of the CAD geometry.
- Web server that serves as a graphical web interface using the Autodesk Forge Viewer APIs for supervisory visualization of the system data-
- Microsoft HoloLens ARHMD running a user interface build with Unity 3D.
- Rhinoceros+Grasshopper generative design environment able to stream the CAD data in real-time.
- A robot controller running the KUKA Sunrise.OS stack allowing the operation of the KUKA LBR iiwa manipulator.

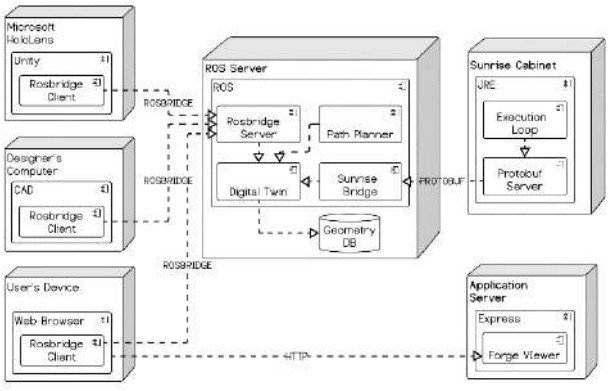

Figure 2. System deployment diagram.

3.1.3 Path Planning

The ROS-based motion planning framework MoveIt! is used for path planning (Fig. 3). Using this framework, it is possible to develop advanced pick-and-place behaviors to be able to precisely position the building elements. These behaviors consider the parameter space of the grasping position of the elements to further enlarge the workspace of the manipulator. By using the current state of the system and its limitations (e.g. arm joint limits) and the known position and shape of the already assembled structure it is possible to plan a collision-free path of the arm. The actual sequence of joint values is calculated using the RRT-Connect [20] single-query algorithm, proving to be a good compromise between the quality of the result and the speed of the calculation for holonomic robotic manipulators with 7DOF.

The "plan" button, selected through the ARHMD, triggers a regeneration and preview of a valid robotic motion. After the user's confirmation, the planned path is sent to the robot controller for execution as a discrete set of joint values.

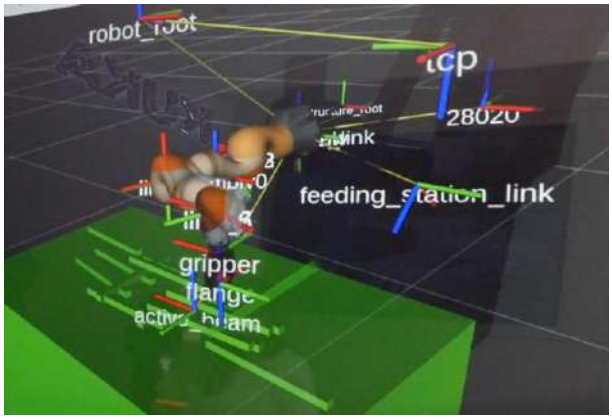

Figure 3. MoveIt! path planning scene with collision meshes visualized with the ROS 3D visualizer Rviz.

3.2 AR Interface

The Microsoft HoloLens ARHMD is used for its built-in stable simultaneous localization and mapping (SLAM) capability as well as for its self-contained nature (i.e. not needing a physical connection to an external device). The Unity 3D game engine is used to develop the AR interface for its integration and compatibility with the Microsoft HoloLens. The interface is kept rudimental and integrates the HoloLens gesture-based input system, by which the user can select and interact with the virtual superimposed content. This feature allows the user to use the UI elements such as virtual toggles and buttons. The robot main actions can be triggered through buttons, labelled as "PLAN" and "EXECUTE", virtually anchored above the selected element that is highlighted yellow (Fig. 4). The "PLAN" button triggers a generation of a robotic path while the "EXECUTE" button triggers the planned movement by uploading a sequence of joint values to the robot controller through the ROS server for execution. If the robot already performs a movement in the time of an upload of a new path the current movement is interrupted, and the newer path is executed instead.

In this UI system diagnostics about the robotic system can also be selectively previewed or overlaid directly on 3D objects including the robot or the production pedestal. The live torques on each axis for example can be displayed.

Lastly a static heads-up display (HUD) is designed in the top part of the AR field of view that displays the more abstract system data and as well as general information such as the overall construction progress percentage or the number of the current sub-assembly.

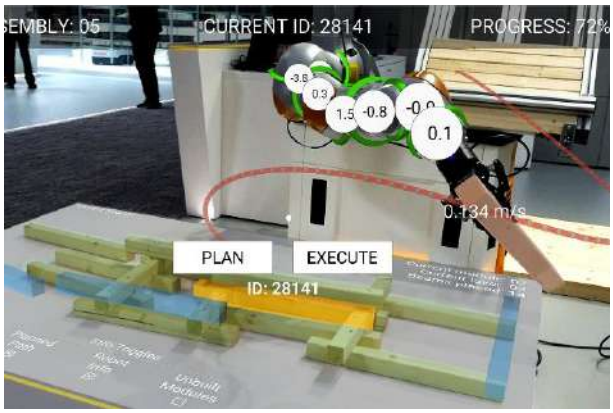

Figure 4. AR view visualizing buttons for selecting, planning, and executing robotic instructions as well as superimposed diagnostic feedback data.

3.2.1 Display Pipeline for Web Visualization

It is well-known that project management is a key component of any complex building process, and multiple concurrent production, finishing, and logistic processes ultimately affect project timelines and need to be considered simultaneously. To provide a scalable solution for unidirectional process supervision, a web user interface is integrated into the overall system communication system. This web interface additionally serves to complement some of the shortcomings of AR, in particular, its higher price and limited battery life are disadvantages which limit the deployment of AR as a universal interface for all needs. The web viewer application was developed using NODE.js and Autodesk Forge Viewer APIs. The application can be executed in any modern web browser and thus it creates

a ubiquitous and low-cost solution.

The core of the web application is a geometric scene loaded and displayed in a local web browser client utilizing the Autodesk Forge Viewer API and the WebGL cross-browser JavaScript library three.js. The preloaded scene view already has the robot model as well as the full fabrication model with naming conventions. In this preloaded model, each wooden strut element exists twice, once in its fabrication position and once in its final position. After initialization and loading events, the client browser references a json file that describes what had been already assembled and subsequently updates the scene accordingly. At the same time the browser establishes a TCP/IP communication through the WebSocket protocol to the previously described rosbridge_suite running on the ROS server. The client browser subsequently subscribes to various ROS topics and starts updating the scene. On a successful part place event, the visibility of the geometry in the scene changes from hidden to visible. Any remote user is therefore able to observe the actual fabrication updates and system data in real-time.

4 Results and Discussion

This project and exhibition successfully established a set of tools for facilitating human and robot collaboration in wood construction through enabling AR interfaces. In additional, critical system components in communication protocols were established and verified, including a communication workflow connecting multiple customizable CAD design environments to ROS through common developed data structures. Arguably, one of the core contributions of the project is the achievement of interoperability between multiple software platforms and hardware devices, particularly in the communication between ROS and the Microsoft HoloLens, which had been achieved in precedent projects only in a limited way. The project also demonstrated and achieved a process specific interface for robotic control, and demonstrated increased digital integration by propagating fabrication data downstream into secondary platforms and digital representations.

The advantages of untethered and therefore unrestricted movement and the easy marker less localization setup was extremely advantageous in the environment of a live demonstration on the Hannover fair. The limited battery life of around two hours, plus the reduced computational power of the HoloLens required an extra amount of effort for optimizing the performance which is for a proof of concept project hindrance. Furthermore, the inside-out tracking principle of the HoloLens is based on a spatial mesh mapping of the environment in combination with the data from the on-board inertial measurement unit (IMU). The highly dynamic environment of the ever-changing visitor crowd on the fair was causing an interference in localization resulting in a positional drift that impaired the AR-experience. However, with the rapid development of the AR technologies, these difficulties will arguably be eliminated in future AR-Devices.

While RRT-Connect proved to be a very robust and versatile planning algorithm for the application, its random sample-based nature sometimes resulted in an unsuccessful path when the solution space got smaller. Thus using it in isolation does not circumvent the need to make good kinematic decisions about where the robot should be placed relative to the workbench, to ensure that a viable path will be found. Furthermore, the lack of a well-defined cost function for the robot path proved to be an obstacle for the reproducibility of the robot movements as well as for planning an optimized movement.

4.1 Next Steps

This exhibit was not evaluated by the same metrics by which an interface would be evaluated in the context of HMI research: whereby efficiencies of production workflows with and without the HoloLens could be compared quantitatively. However, it was possible to gain qualitative feedback by visitors who came to the exhibit, predominately users who have extensive experience with programming robots. A next step towards evaluating the usability of the interface would be to test a novice user to interact with a defined objective, where the success of the interface could be measured by whether or not the user could accomplish a predetermined objective without supervision.

The technical implementation could have been improved by more robust localization of the HoloLens: users walking in front the interface was enough for the on-board SLAM to lose its position. A viable option would be the integration of a low frequency external outside-in localization system in parallel that would allow to correct the positional drift or a marker based optical approach that can be additionally used to automatically synchronize the position of the workpiece and the robot arm in a common world coordinate system of the HoloLens.

The presented system also clearly lacked higher cognitive functionality. Simple cognitive cooperation patterns such as joint attention could be highly beneficial in making the HRC scenario more efficient as well as rendering the robot more approachable and lifelike. Without such cognitive features it is hard to imagine that the robot system would become a real co-worker to its human counterpart.

In addition, any of the failures that happened during the course of the exhibition can be attributed to an error in communication, resulting in an incorrect system state,

or digital twin model, in one of the environments. These errors could be circumvented by increasing the ability for the human user to enter into the system when an unexpected error occurred. For example, if a part was not loaded in the magazine and was therefore not actually placed.

4.2 Outlook

This project proposed and investigated enabling interactive and interface technologies which can facilitate a more rapid advancement and utilization of robotic fabrication in building prefabrication production chains by increasing accessibility, digital integration, and usability. Simultaneously, the limitations of the project, particularly the limited reach and payload of the KUKA LBR iiwa, point to other technological developments which could accelerate robotic building production processes. In particular, there is a need for collaborative robots designed for the domain of AEC, with specifications including increased reachability, higher payloads, as well as locomotion systems for moving on a difficult terrain.

4.3 Acknowledgements

This project was executed as a demonstrator for the research project: Human-Robot Collaboration in Timber Construction at the Institute for Computational Design and Construction (ICD) at the University of Stuttgart, with funding provided by Forschungsinitiative Zukunft Bau, Bundesinstitut für Bau-, Stadt- und Raumforschung (BBSR). Additional researchers on this project included Oliver David Krieg.

This project was additionally developed as a finalist application for the KUKA Innovation Award 2018 competition. The organizer provided the robotic workcell, on a donation basis, as well as travel funding and a training for researchers.

Additional funding was obtained by Autodesk to support the use of Forge APIs for web based services. The work conceptually built upon the ITECH master's thesis at the University of Stuttgart by Benedikt Wannemacher, *Augmented Manufacturing* from 2017. His continued research was supported in parallel at the chair for Experimentelles und Digitales Entwerfen und Konstruieren under the direction of Professor Philipp Eversmann.

Student researchers, Samuel Leder and Rebeca Duque Estrada, supported the project.

Abstract –

Recent surveys among construction firms found, a majority has a hard time filling craft worker/hourly positions and salaried jobs. Among the ways they are trying to create more is in-house training. However, existing learning methods have been lagging effectiveness or are outdated. New approaches, like mobile virtual reality, are being investigated. In this paper, the authors describe their approach to a low cost virtual reality training that offers personalized feedback for trainees or workers. The developed approach utilizes elements of gamification for motivational purposes. While the training requirements were gathered in dialogue with leading companies in the construction and engineering industry sectors, the research conducted focused on prototyping and testing the novel learning concept. As a result, the authors developed a mobile virtual reality application that utilizes the Google Daydream SDK that runs on Google Cardboard, Samsung Gear VR, Oculus Go or compatible other inexpensive devices. The application was tested and evaluated by industry representatives. An outlook provides the path forward in research and development.

Keywords –

digitalization, construction safety, personalized feedback, virtual reality, virtual trainings, workforce education and training.

1 Introduction

The construction and engineering industries face several major hurdles at this time. While construction workplace accidents account for a significant number of fatalities and injuries [1] that consequentially lead to a loss in productivity, engineering in general faces another problem: a severe shortage of skilled labor [2].

Over the past decades, researchers and practitioners have attempted to understand and mitigate the underlying precursors of accidents in construction [3,4]; with some success the accident rates dropped until they recently started rising again [5]. Among other ways, hazard recognition is one of the first steps in effective safety management [6-8]. However, results on the effectiveness across the globe have shown that up to 50% of construction hazards remain unrecognized despite that training and certification are provided [6-12]. Among the contributing factors for such poor hazard awareness are worker's paying attention on their task, ignoring predominantly some types of hazards, and having low capabilities in "visual search". Latter means the initial detection and then identification of hazards is a very challenging human task [13]. It is particularly difficult considering that construction sites are very complex and dynamic, where one worker's attention to all the present details can often be overwhelming.

Examples of such work environments are building and industrial construction sites or larger vs. smaller work spaces. No or no recent training, no or unclear tool box meetings before work begins, imprecise work station preparation, and inadequate site conditions or staffing are some of the most common reasons that challenge worksite safety behavior. The recent example of a partial refinery explosion shows, unsafe work preparation, unclear instructions, or using the wrong tools for the wrong task can result in a tragedy [14].

The objective of this study is to leverage mobile virtual reality construction training. The preliminary research effort designed training in two virtual environments: hazard detection in a virtual building construction site and a flange training scenario in a virtual training center of a chemical plant operation. The next section presents a brief background on safety training and flange coupling. This is followed by an explanation of the virtual gaming environment that was created and tested. Results are shown and an outlook of future work is presented.

2 Background

Safety is a major concern in the construction industry. Besides numerous other approaches on hazard awareness, training has one of the highest positive impact factors in reducing fatalities. In the literature as well as in the praxis exist several different teaching formats, such as self-, hands-on-, supervised- learning. Generally, the level of awareness aimed at implies knowledge on possible hazards and safety regulations. These are strictly defined in most countries, like in Germany by the BG Bau [15],

an official organization responsible for establishing and enforcing construction safety rules.

While workers in the chemical industry are constantly confronted with the installation or maintenance of piping and the respective connections, these works can only be executed once normed guidelines and instructions are followed [16-17]. Problems arise or continue to exist if no or only limited trainings for executing work tasks are provided. This may happen less in the chemical industry because training has been part in their core business processes. The fragmented construction industry though has a continuous problem with adequate workforce training.. There, knowledge on safety and health is hardly ever refreshed in greater depth once primary education as an apprentice has ended [5]. For this reason, several researchers started investigating new methods, particularly on using Virtual Environments (VE's) for hazard awareness [6,18-19,20]. Although a full scientific validation of VE for safety education and training is a very challenging task considering that mature practical solutions seem far to be reached, all of these approaches claim that VE will provide safe and more effective training, at reduced time and cost. An additional example is, the right way to work with flange connections in the chemical industry is typically taught on a single day and is usually viewed by the trainers and trainees as a basic training. But especially larger diameter flange connections can challenge work crews, so that an adaptive VR training and instruction guide could help workers build confidence and provide readily available knowledge in handling the materials and the necessary tools.

3 Requirements and general setup

As mentioned in the introduction, this paper focuses on testing the limits of mobile virtual reality for two different scenarios with very specific requirements. To avoid the accumulation of inert knowledge, the authors want to use immersive virtual reality technology to enhance the experience for the trainee. This offers a safe way to confront the trainees with realistic representations of hazards without exposing them to real dangers.

One of the most relevant requirements, in context of this paper, is the ability to use the trainings on mobile virtual reality devices. Mobile VR devices like the Oculus Go cost around 200 €, with more advanced hardware (Lenovo Mirage Solo, Oculus Quest, etc.) costing around 400 €. This is significantly less than an equally usable stationary VR setup, which costs anywhere from 2000 to 4000€. Low cost and ease of use are centerpieces of mobile VR hardware. These advantages seem highly appreciated by training organizations or departments who need to equip higher numbers of training staff with such technology.

The aim is to offer explorative, immersive experiences at minimal costs. Both virtual trainings aim at a maximum of 15 minutes working time.

As with most virtual surroundings, the visualization of the desired scenes must be believable with a realistic scale between the user and her/his surroundings. As photorealism in the virtual reality cannot be achieved with the limited computing performance of existing mobile devices, the focus is on creating a visually-sound context for the training scenarios.

The first virtual construction safety awareness training orients itself on the regularities from the German Social Accident Insurance (DGUV) and its subdivision for the building trades (BG Bau) [15]. The second scenario is the virtual flange training, which is based on German norms and guidelines for the handling of flange connections [16].

3.1 Virtual safety awareness training

The objective of the scenario was to provide a scene that must show a realistic and valid construction site. Embedded in the scene are typical hazards that can and must be avoided in the real world. To accommodate the scene for regular use in training and to offer some variety, the total amount of hazards must exceed the number of hazards in each session, with an automated, random selection applied at the start of the training. Hazards must be identifiable by the user, preferably by pointing at them and then selecting them with the controller. Head mounted devices (HMD) provide such instruments that even allow for data gathering and post-analysis which and when a hazard was selected.

The user must have full locomotion in the scene to reach all parts of the virtual construction site. When coming closer than the typical safe distance for a particular non-identified hazard – granted the user has line-of-sight – the user needs to be informed that the concerning hazards was not detected and is therefore marked as failure. The safe distance of each hazard depends on the type of hazard and should be automatically applied.

The virtual construction safety awareness training application must record user- and session-specific datasets consisting of the current scene configuration (number of randomly selected hidden hazards with their IDs) and the user's actions in the scene (total time, full completion yes/no, total number of corrected hazards, specific listing of the hazards, their status and association with German safety training regulations). The exact documents considered for the creation of hazards must be at least BG Bau A021 (fire safety), A062 (flammable substances), A064 (pressured gas tanks), B100-1 (work-at-height), B132-1 (ladders), B161-1 (load handling), B172 (electrical equipment), B173 (mobile generators), B181 (excavators) and B202 (hand tools) and each

hidden hazard must specify the associated document for later analysis.

3.2 Virtual flange training

The virtual flange training's purpose is to teach and train both patterns of valid screw-fastening on flange-couplings (cf. DIN 1591-4) for novices and experienced work crews. The training must be flexible enough to train on a variety of flange couplings ranging from small (8 screws, DN20) to big (24 screws, DN400).

The virtual flange training is supposed to offer two separate modes. The first mode aims at teaching novices the usage of both the standard crosswise and the alternative pattern of fastening the flange's screws (Fig. 1). In this teaching mode, each step taken should be marked as either correct or incorrect to provide immediate feedback. The trainee must be able to access help functions to learn about the general guideline for the chosen approach [16] and optionally which screw to fasten next. In this training environment, the trainee should not be able to move around freely but be allowed to concentrate on the task at hand. Therefore, the flange should be placed floating in a frontal view to mimic the depiction in the guidelines.

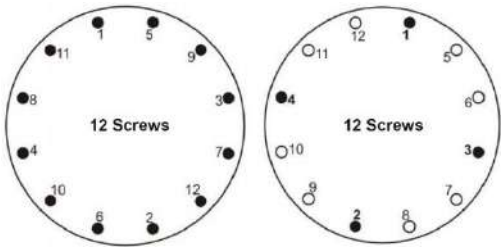

Figure 1. Standard crosswise pattern (left) and alternative pattern (right) [16]

The second "open training" scenario should offer less help, free locomotion and a realistic scenario with a flange connection of two pipes stacked vertically. This should force the trainee to change her/his position and viewing angle similarly to the movement necessary in the real world. The immersion of the trainee in the scene was improved and an option to use the controller in a movement like a ratchet was offered optionally.

The virtual flange training application must record user- and session-specific datasets consisting of the current configuration (e.g., number of screws, choice of training mode, method of fastening), the total amount of time till full completion, the achieved score and the total amount, type and time of occurrence of errors made during the training. Before each training session, the trainee was made aware of the recording, putting her/him under pressure to concentrate on quality and timely completion of the assigned tasks. The different kinds of errors that can occur in this scenario are described in Table 1.

Table 1. Registered events in the flange training application

No.	Error Description
1	User specified the wrong torque number
2	Selected screw was already fastened in the current turn
3	Selected screw is not opposing to the last
4	Selected screw is not one of the two screws orthogonal to the axis connecting the first two screws
5	Wrong sequence in the last step of the standard cross-wise pattern (i.e. not clockwise)
6	Wrong starting point in the last step of the alternative pattern
7	Wrong sequence in the last step of the alternative pattern (i.e. not clockwise)
8	Wrong combination of method and nominal diameter

4 Prototypical implementation

For the preliminary evaluation, the authors implemented two mobile virtual reality applications using the Unity3D Engine and a Samsung S8 in a Google Daydream Headset with its accompanying controller. To run the application on Google Cardboard, Samsung Gear VR, Oculus Go or compatible devices, the Google Daydream SDK was used. In each scenario, the rotational head tracking enables the trainee to look around in the scene, while interaction and movement via virtual teleportation as locomotion method is handled with the controller.

4.1 Virtual safety awareness training

The authors created a virtual construction site in the Unity3D Editor (Fig. 2, top), which has over 70 possible hazards from which each training set is drawn. When looking directly at the controller, tooltips (Fig. 2, bottom) show up to inform the user about the total time in the scene, the amount of found and left hidden hazards in the scene and the button's functions (identify hazard and teleportation).

For each training session, a new set of hazards is selected from the "hazard pool" and all non-selected hazards are "non-existent" in this very training session. The algorithm for the process is displayed in Table 2. As the number of implemented hazards is known (70) and the amount of targeted hazards per scene is known (between 10 and 25), all that is needed to set up an individual scene is a random number *i* to generate. The goal for the trainee is to find all hazards in the construction site, but no further assistance (i.e., highlighting when hovering over objects in the scene) is given.

Table 2. Algorithm for the construction safety training

Step	Description
1	Generate a random number *i* between 10 and 25
2	Generate “”"-many random numbers between 1 and 70 with no doublets allowed
3	Hide all hazards
4	Show all hazards where the generated numbers match the hazard’sIDs

Fig. 3 shows screenshots taken from the user’s perspective when looking at unsafely stacked cable spools and an unsecured falling hazard (Fig. 3, left). When the user identifies the hazard via point&click using the controller, the hazards is resolved, and the desired (safe or healthy) situation is revealed (Fig. 3, right).

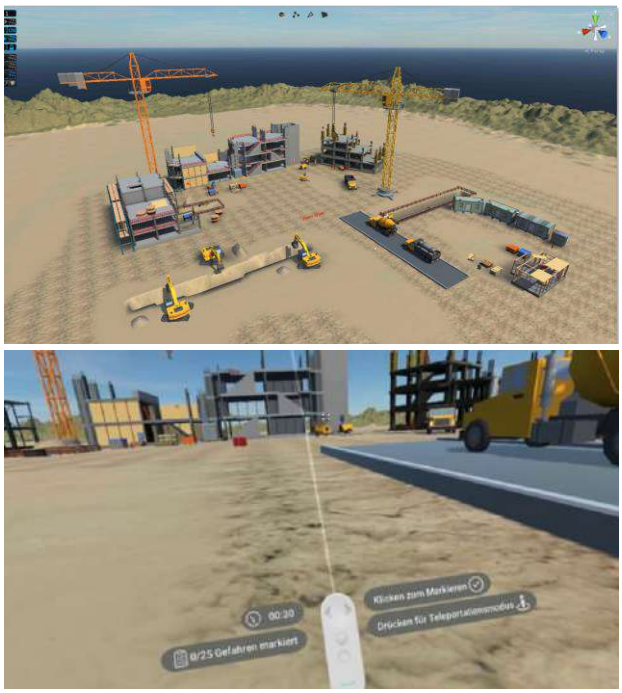

Figure 2. Screenshots with overview over the created construction scene (top) and the user’s perspective using the application (bottom)

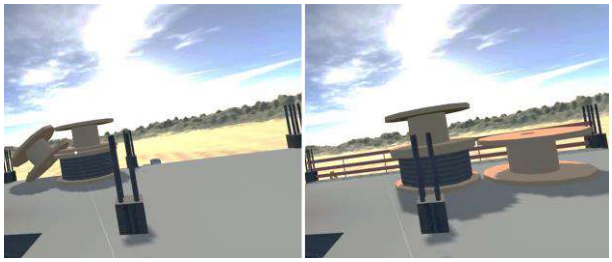

Figure 3. Close calls with crane load: contruction worker (left) and skid-steer loader (right)

4.2 Virtual flange training

The virtual flange training must implement both methods (standard and alternative) of fastening flange connections specified in the German Industrial Standard (DIN 1591-4). For that matter two different algorithms were implemented in C# and used in the training scenes to check a trainee’s input. Table 3 shows the algorithm for the standard method. In short, the standard pattern consists of three rounds with different torque figure. In each round a set of four screws is fastened, starting with two opposing screws and going to the pair of screws that are orthogonal to the first two. This crosswise pattern continues until all screws are fastened with the current torque figure. After a full pass of all three steps, the guideline specifies an “unlimited” amount of clockwise repetitions until each screw passes with 100% torque. In our algorithm a single pass is sufficient.

Table 3. Algorithm for the standard method in the flange training application

Step	Description
1	Start with 30%, 60% and 100% torque
2	Select random screw (< current max. torque)
3	Select opposing screw to the first screw
4	Select one of the two screws orthogonal to the axis connecting the first two screws
5	Select opposing screw to the third screw
6	Repeat steps 2-5 until no screw is left < current max torque
7	Repeat with next torque level starting at step 1
8	Select each screw, starting at screw one and following a clockwise path

Table 4. Algorithm for the alternative method in the flange training application

Step	Description
1	Start with 20%, 60% and 105% torque
2	Select random screw (< current max. torque)
3	Select opposing screw to the first screw
4	Select one of the two screws orthogonal to the axis connecting the first two screws
5	Select opposing screw to the third screw
6	Repeat with next torque level starting at step 1
7	Select each screw, starting at screw one and following a clockwise path

Table 4 shows the algorithm for the alternative method. It is important to note that the DIN-standard specifies the alternative method invalid for nominal flange diameters of less than 200 mm. In consequence to that, once a “smaller” training flange is selected and the alternative method is used, the current try is considered a failure. The alternative method is basically a single

crosswise pattern with different torque figures, followed by clockwise fastening with the highest torque figure. Analogue to the standard pattern, the theoretically unlimited number of repetitions until the final torque figure is met is reduced to exactly one in the algorithm.

Each algorithm can be used in each of the two training modes. As the novice mode is supposed to offer a great amount of support functions, the authors created the scene and Graphical User Interface (GUI) as seen in Fig. 4. The user starts at the trainee position (Fig. 4, No. 1) with a frontal view of a flange connection (Fig. 4, No. 2) of a specified size. The score panel shows the current number of correct steps and the score for this session (Fig. 4, No. 3). In the option and help menu (Fig. 4, No. 4) the user can switch between help for individual methods and switch on the help and instruction panel (Fig. 4, No. 5). In the scene configuration menu (Fig. 4, No. 6) the user can set up the size of the flange, the preferred method and the optional "manual ratcheting". Locomotion is disabled in this mode, so that the trainee is surrounded by (optional) information, with her/his task in front.

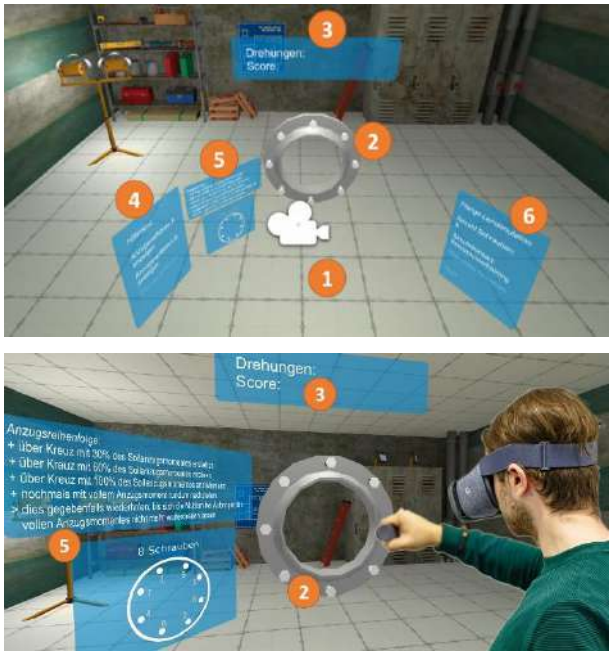

Figure 4. Screenshots with overview over the created scene (top) and the user's perspective (image overlay) using the application (bottom)

Instead of the strict nature and learning-based novice mode, the open training mode offers free locomotion (identical to the construction site scene) and more naturally placed interaction elements. The trainee starts at a standard position (Fig. 5, No. 1), with the task in front of him. The vertical piping elements with the flange connection needs to be fastened (Fig. 5, No. 2). It can be configured with the scene configuration menu (Fig. 5, No. 4), just as the frontal flange view in the novice scene. The idea behind this is, that when handling the flange connection of rather large piping, the task becomes harder, as the exactly opposing screw is not that easy to find. The score panel for the current session is fixed to the opposing wall (Fig. 5, No. 3).

The task in this scene is to choose a flange size, start wrenching and use either the standard or the alternative pattern to fulfill the task. Once the route for a particular method is set after choosing the 5th screw, every error lessens the score.

Figure 5. Screenshots with overview over the created scene for the open training

5 Results to demonstration and testing

The prototypical applications were demonstrated at an interdisciplinary internal workshop for experts for digitalization of learning environments and didactics in engineering at the Ruhr-University Bochum, Germany. Many of the attendees had long-term construction or engineering industry experience. They were asked about their opinion after testing either or both of the applications.

On the positive side, the experts mentioned the ease of use due to the nature of the light headsets and the easy way to understand locomotion. The comic-like graphics were easy to understand too and offered not much distraction, while being clear enough to offer orientation and recognition.

Concerning the construction site safety training the experts suggested, instead of revealing the ideal solution for each found hazard, the trainee could be asked to choose from several different suggested solutions. This would offer a better possibility to verify the trainee's deeper understanding.

Data gathered from three exemplary users show what kind of insight instructors can get, when preparing feedback based on virtual trainings. Table 5 lists some of the gathered data, with hazards subdivided by their according BG Bau rules like A021 or B100-1. As one can see, user 1 seems to be at ease with the recognition of hazards in a construction environment with a good time and full completion. Users 2 and 3 did not finish on time, but user 3 found all but one hazard. As the full XML data log contains timestamps for all events, a graphical

timeline could reconstruct the events within the training. That would reveal that User 3 was as fast as User 1, but didn't look up to check the load hanging from the crane till the time ran out.

In both applications, the experts found the trainings to be interesting and challenging, while the technical representation left some things to be desired. To address these concerns, performance enhancing measures will need to take place before a larger survey can be conducted. Also, future participants will need to get a precise introduction to the applications and tasks, as the applications are not self-explanatory enough and the overpowering nature of VR to first-time users might hinder this further.

Table 5. Data collected from three exemplary users in the construction hazard awareness training

	Participant

6 Conclusion and outlook

This study described a novel approach towards a low-cost virtual reality training that offers individual feedback for trainees or workers. The approach utilized elements of gamification for motivational purposes. With requirements gathered in dialogue with industry leading companies and based on research conducted at the Ruhr-University Bochum the concept at hand successfully created and tested a prototype. While the results are preliminary the authors have shown the complexity of creating virtual reality experiences based on existing safety-related regulations.

In case of the presented applications, the far smaller scenes of the virtual flange training contains more complex interaction elements. Its dynamic algorithms also offer a varying degree of difficulty.

In the rather large construction site scene, the algorithms are based on many elements and regulations. A simple hit or miss strategy which was particularly easy to implement might be enhanced in the future by providing immediate feedback on the hazard type. Similarly, allowing false positive errors might strengthen a trainee's attention to be careful about selections.

In brief, our future work will combine the presented approaches for work place safety and actual work tasks. This will enhance the experience with further interactive elements like dynamic non-player characters and vehicles. The idea is to offer a holistic construction site representation with varying tasks to perform, to lessen the impact of the acclimation time users usually need to accept and cope with their immergence into a virtual environment. Another research topic in this context is the increase or decrease of learning quality due to the immersion in virtual reality. As the applications were created with Unity 3D, a reference group will test the same applications and 3D contents in a non-immersive standard PC configuration. Structured may replace opinion-based surveys.

Abstract –

Crane simulations are necessary for selecting a proper type of crane for an erection task in a construction project. However, simulating the motion of a specific crane is hardly realized because modelling a specific crane is complex. Thus, by taking advantage of a robot arm with multiple degrees of freedom, our goal is to simulate any type of retractable crane and boom crane virtually. The developed simulation process can help identify constraints of the robot arm and transform the configuration between the robot arm and a selected crane. In the experiment, by applying the developed simulation process we used a virtual robot arm to simulate a virtual retractable crane in one of the tasks of crane operator exam. The comparison of the endpoint paths of the crane and the robot arm showed the feasibility of the method. Furthermore, the method can be applied to the real robot arm for selecting a proper type of crane for the erection tasks. The erection tasks can also be easily simulated physically with a robot arm in a scaled construction site.

Keywords –

Simulation, Extreme point, Robot arm, Crane

1. Introduction

1.1. Background

In recent years, various types of cranes are used in all walks of life, especially mobile crane has high mobility and a wide range of operation suitable for many sites. Research discussed the boom control of mobile cranes, such as Autonomous Beam Assembly System [1] or Crane Operation [2] so on and so forth.

However, due to the complex kinematics and low mobility of the crane, the crane operation is difficult. There are lots of restrictions including the size of the site, the safety of the area around the site, crane rental etc. Therefore, in the past, the 3D model technology was used to simulate in advance and observe the movement behavior of the crane in the virtual space as a reference for decision-making. [3] In this paper, the method of using a virtual robot arm to simulate the extreme points motion of a crane is presented.

1.2. Crane Simulators

With the rapid development of visualization technology, many 3D simulation tools have been developed. However, these simulations in the virtual environment are limited by the software and cannot fully consider all the influencing factors, resulting in errors between the simulated objects and the reality. Especially in the erection tasks, the movement of the hanging object will be affected by complex natural factors, so the simulation results may not be accurate.

This study focuses on the use of a virtual robot arm as a tool to simulate the extreme points of crane. There are four advantages of this method. First, the researchers are able to accurately simulate any point and path. Second, the method could simplify the process for researchers to operate the crane and make research more efficient. Third, the axis of horizontal rotation and elevation are combined into one single axis. The last but not the least, the results of these simulations can be observed by actually operating the robot arm to observe the physical changes of the hanging object.

1.3. Research goal

We use the robot arm in the virtual environment to simulate the extreme point motion of the crane. This method enables operators to simulate the endpoint path of the crane before actually operating the crane. Different

from the direct simulation of the crane, the robot arm can achieve high simulation accuracy and clearly record the coordinates of each endpoint in the path, freely control the speed of movement, and the simulated movement can be actually implemented in the robot arm. This information can be used as a reference for operator decisions.

Notation
k: The ratio of maximum length of robot arm and crane boom
μ: The distance between the hoist of crane to the origin in coordinates system
R_{max} : The maximum length of robot arm.
r_{max} : The maximum length of crane boom.
r_i: The initial length of crane boom
θ_i: The initial azimuthal angle (horizontal rotation angle) of crane boom
ϕ_i: The initial polar angle of crane boom
r_T: The terminal length of crane boom
θ_T : The terminal azimuthal angle (horizontal rotation angle)
ϕ_T: The terminal polar angle
Δr: The change of length of crane boom
$\Delta\theta$: The change of azimuthal angle (horizontal rotation angle)
$\Delta\phi$: The change of polar angle
PTP: Point-To-Point form
$i(x_i, y_i, z_i)$: The initial 3D Cartesian coordinates (input of robot arm)
$T(x_T, y_T, z_T)$: The terminal 3D Cartesian coordinates (input of robot arm)

2. Methodology

After analyzing the relationship between a crane and a robot arm, the methodology is organized as follow:

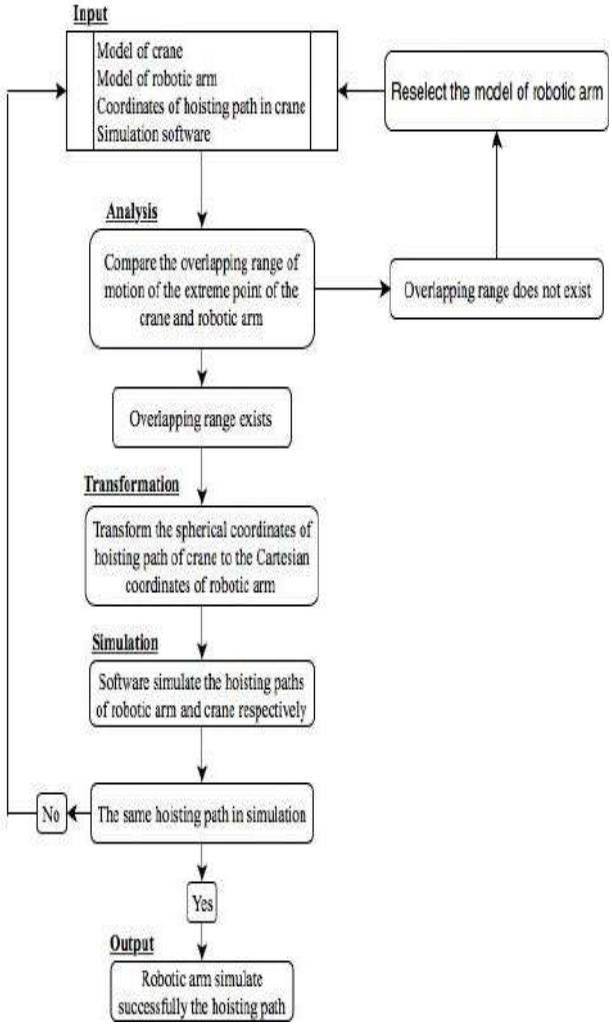
2.1. Operation process for simulation

We developed an operation process, that included input, analysis, transformation, simulation, output five parts to determine whether hoisting paths between robot arm and crane were the same or different for the developed simulation.

2.1.1. Simulation steps

First, we input the model of a crane and a robot arm, the coordinates of hoisting path in crane. Second, we calculate the effective simulation range of the crane and the robotic arm to ensure that the simulation path is feasible. After that, the 3D Cartesian coordinates input data of robot arm are collected. Third, simulation software is used to test the result whether the paths of the crane and the robot arm are the same. Finally, if the hoisting path in the simulation is the same as the crane, the robot arm simulates complete. Otherwise, the method restarts and repeats the steps repeats.

Figure 1. Simulation process



2.2. Constraint identification and assumptions

Six constraints are identified and eight assumptions regarding geometry and numerical calculation are established in this section.

2.2.1. Constraint identification

Robot arm

The upper sheave of the robot arm must be perpendicular to the ground. The form of extension and retraction of robot arm are not the same as the crane. Furthermore, one robot arm only simulates one mobile crane at each time.

Crane

The crane has two angles to be considered. The first one is the range of the elevation angle of crane: $\mathbf{0°} \leq \boldsymbol{\phi} \leq \boldsymbol{\phi_{max}}$(determined by the model of the crane). The other one is the range of the horizontal rotation angle of crane: $\mathbf{0°} \leq \boldsymbol{\theta} \leq \mathbf{360°}$.

2.2.2. Assumptions

Crane

Only mobile crane situation is considered. The pivot of the crane is fixed at the origin. The hook and cable of the crane are ignored. The factors of natural environment such as wind and personal factors such as the experience in operating crane are ignored. Moreover, any two of values of ϕ, θ, r change at the same time at most.

Both robot arm and crane

Robot base rotation center and pivot of crane's boom are the origins in the coordinates system. The swinging of extreme points of the crane and the swinging of the crane do not be considered. Furthermore, the motion of extreme points of the crane and the robot arm are analyzed since the extreme point is the main point we focus. Regarding the problem of the deformation of the boom and the robot arm, we assume that the deformation caused by the weight of the object can be ignored.

2.3. Configuration transformation

We derived the configuration transformation model between a retractable crane and a robot arm from their kinematic model. It consists of two parts. The first part is proportional scaling, that the virtual robot arm and crane are the same length of simulation to find their effective range of motion. In the second part, the endpoint motion of the crane is simplified into a triangular coordinate relationship, and the conversion formula is obtained by using the trig function and polar coordinate:

2.3.1. Proportional scaling

According to the model information provided by the government, the simulation condition of the equivalent ratio can be achieved through proportional conversion. The variational constant (1) is obtained by using the longest distance that can be reached by the lifting arm of the crane and the longest distance that can be reached by each axis of the robot arm at the initial Angle.

$$k = \frac{R_{max}}{r_{max}} \tag{1}$$

2.3.2. Conversion formula

The relationship between the rotation Angle of each axis of the robot arm and its motion posture in space is calculated based on forward and inverse kinematics [4]. As a tool to simulate the endpoint's path of the crane, we ensure that the A5 axis remains horizontal and that the changes in the intermediate axes are not considered. Therefore, the motion posture of the robot arm is simplified into a trig function to take the starting point and ending point of the motion of the robot arm. And it is necessary to consider that the pivot of crane and Rotation is different.

The spatial coordinates of x, y and z in the simulated environment are obtained by the transformation between the polar coordinate system and Cartesian coordinate system. As shown in figure 2, formula (2), (3) and (4) are used to calculate the initial point $i(x_i, y_i, z_i)$ of the robot arm movement in the 3D simulated environment.

$$x_i = k(r_i \sin\phi_i - \mu)\cos\theta_i \tag{2}$$
$$y_i = k(r_i \sin\phi_i - \mu)\sin\theta_i \tag{3}$$
$$z_i = kr_i \cos\phi_i \tag{4}$$

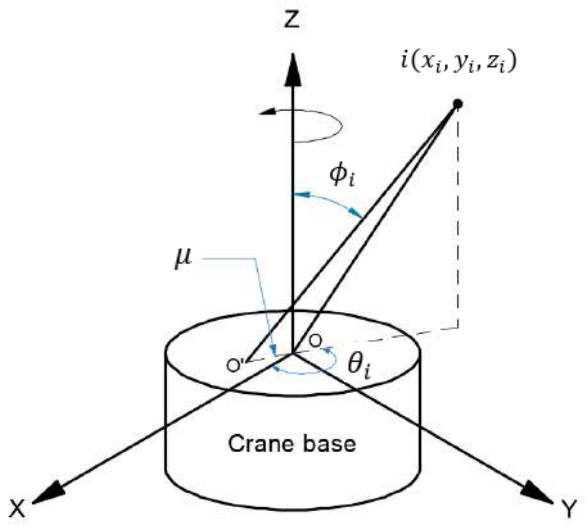


Figure 2. The initial point of the simulation

After obtaining each coordinate in the simulated space, formulas (5), (6) and (7) are used to calculate the length of the mechanical arm, horizontal rotation Angle and elevation Angle.

$$r_T = (r_i + \Delta r) \tag{5}$$
$$\theta_T = (\theta_i + \Delta\theta) \tag{6}$$
$$\phi_T = (\phi_i + \Delta\phi) \tag{7}$$

As shown in figure 3, equations (8), (9) and (10) can be used to calculate the extreme point to be simulated by the virtual robot arm.

$$x_T = kr_T \sin\phi_T \cos\theta_T \quad (8)$$
$$y_T = kr_T \sin\phi_T \sin\theta_T \quad (9)$$
$$z_T = kr_T \cos\phi_T \quad (10)$$

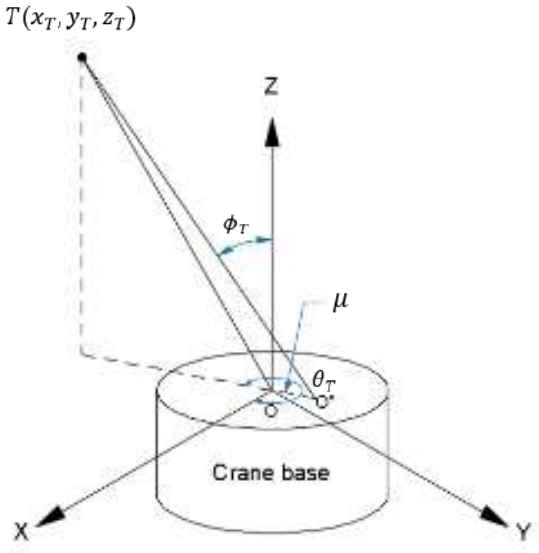

Figure 3. The end point of the simulation

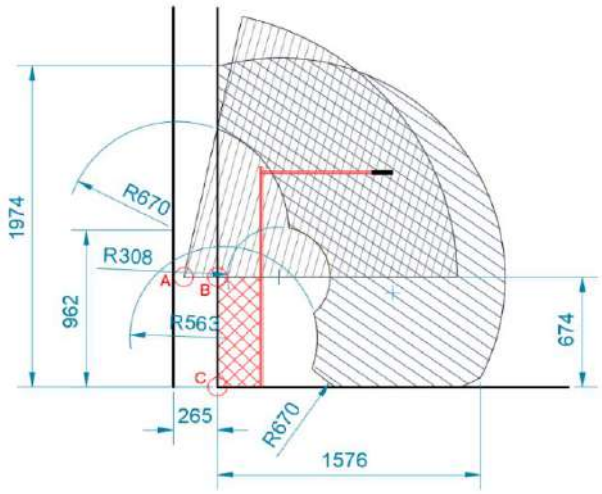
Figure 4. 2D Effective simulation range



Point A: The pivot of crane
Point B: The center of Rotation
Point C: The simulated pivot of virtual robot arm
Red Area: The shape of a robot arm

Considering the crane and robot arm can rotate horizontally, 3D graphics software is used to display a complete 3D effective simulation range, as shown in figure 5.

3. Results

3.1. Analysis of crane and robot arm

At the present research stage, we combine the horizontal rotation of the crane and the pivot of the crane as a single pivot in the virtual robot arm for subsequent simulation to find out the effective simulation range between the virtual robot arm and the crane. Finally, the crane operator exam is taken as an example to verify the accuracy of the virtual robot arm simulating the motion of the crane extreme points.

We first analyze the motion path of the robot arm and the crane, and then compare them together. First, we assume that the robot arm is always horizontal and does not rotate at the A5 axis, and the motion range of the robot arm is not lower than the ground plane. For the crane part, it has two different Pivot Points and the height of the crane itself must be considered. The length of the crane arm is then converted to the ratio, and the effective simulation range of the two is calculated by 2D drawing software. According to figure 4, the inclined area at two different angles is shown. The sector is the movable range of the lifting arm of the mobile crane model RT-100, and the other irregular block is the movable range of the robot arm model KR16s.

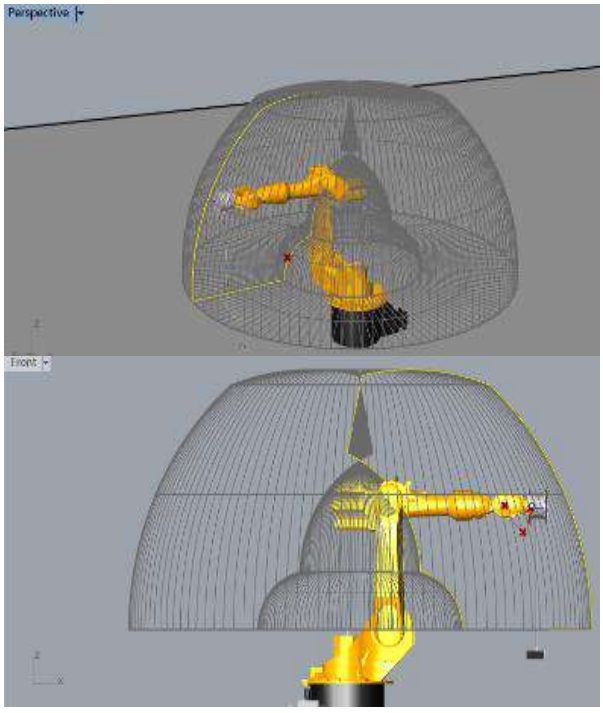


Figure 5. 3D Effective simulation range

3.2. Calculation process and simulation

According to the driving test of a mobile crane in Taiwan, we used the operation test path of the crane in the game engine, and recorded the extreme points of the boom in the space of the Coordinate points. In addition to the path, we also operate according to some examination regulations, including the following:

1. The crane is fixed in the rotation center.
2. The starting point of the crane is at point S, and the hanging object is about 2 meters high from the ground.
3. During the operation, follow the running path, pass the obstacles in sequence and return to the starting point.
4. During hoisting, the hanging object should not touch the ground.

Simulation results of crane operating model RT100 in the game engine are shown in figure 6. The red line in the space represents the route of the technical examination for the crane driver's license.

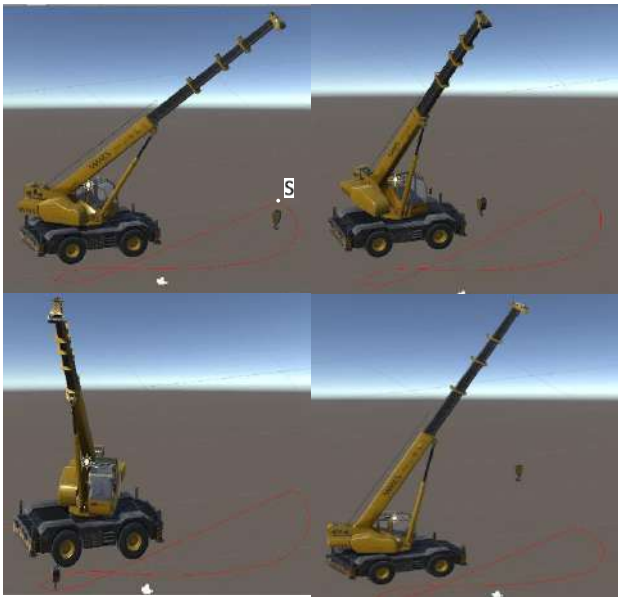

Figure 6. The crane simulates the process of the path

Next, move these Coordinate points as the crane simulates to another 3D software that can simulate a robot arm. In figure 7, you can see that the simulated path consists of red points. Some Coordinate points may appear in an area that cannot be simulated, and we can use scaling to adjust the range to be simulated. During the simulation process, it is necessary to ensure that the pose of the end of the virtual robot arm is the same as the crane. We also record the points that the end of the virtual robot arm passes through.

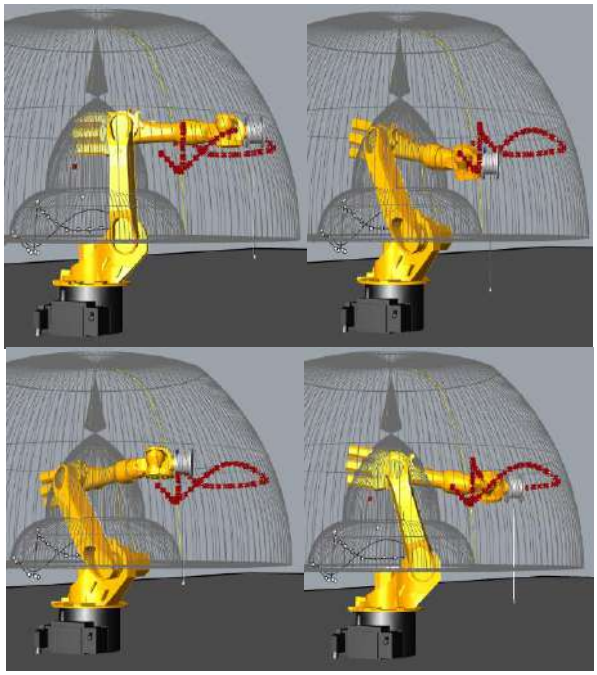

Figure 7. The virtual robot arm simulates the process of the path

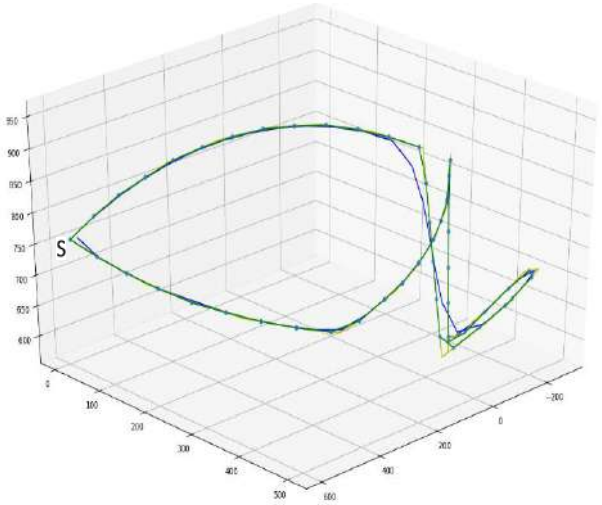

Figure 8. Comparison of simulated path results

We tested two different ways of simulations. The first is to use a curve made up of points as the simulation path, while the other is to use a straight line made up of points. In figure 8, we compare the simulated paths using 50 points. The yellow line represents the path of the crane. The blue lines represent curved paths of points, while green lines represent straight paths of points. Next, we increase the number of points on the straight path to 100

and compare again, as shown in figure 9.The red line represents the results of the robot arm simulation.

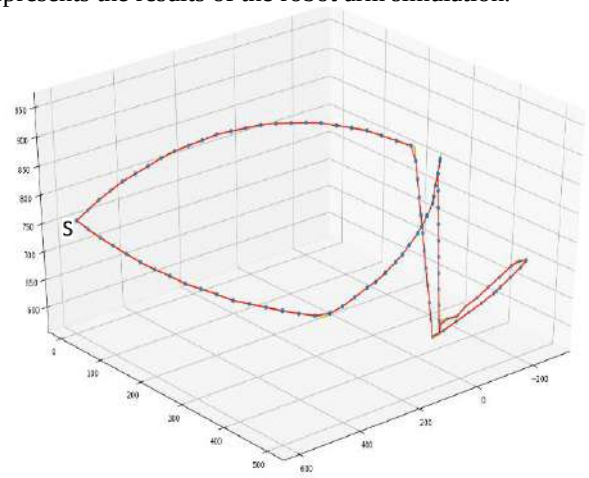

Figure 9. Increase the number of points to simulate

For the 2D plane, we compared the curves, straight lines, and lines with 100 points of simulation paths.

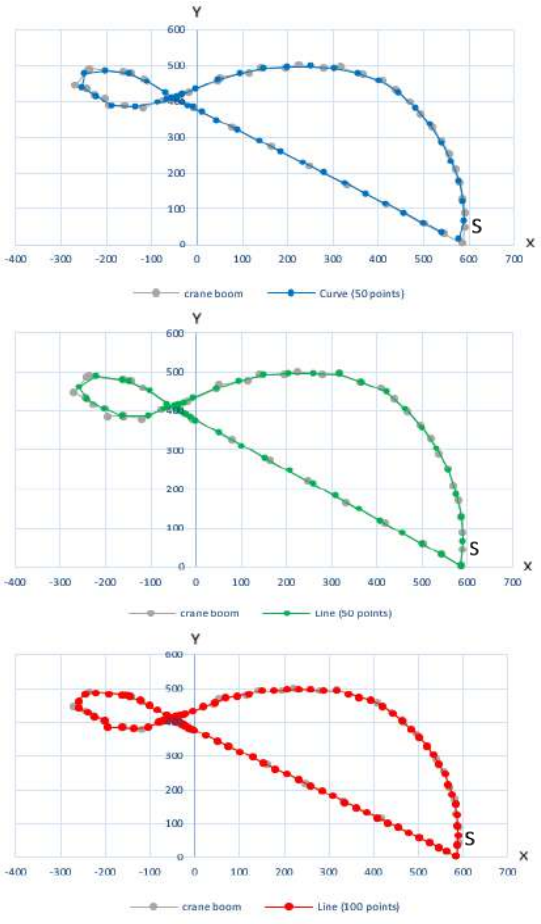

Figure 10 and figure 11 are the X-Y plane and the X-Z plane, respectively.

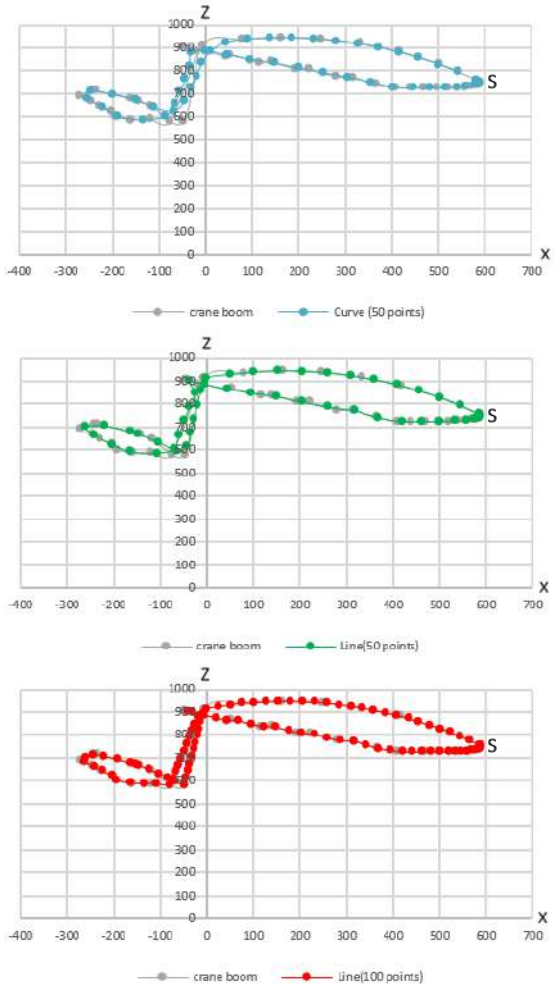

Figure 10. Comparison of coordinate point paths in X-Y plane

Figure 11 Comparison of coordinate point paths in X-Z plane

4. Discussion

We obtained the effective simulation range based on the motion limit of the crane model rt-100 and the robot arm model K 16 RS and found that some coordinate points of the crane extreme points converted from UNITY could not be simulated by the robot arm. The reason is that we are scaling with the longest length, resulting in some points near the shortest length to be outside the effective range. In order to focus on the virtual robot arm to simulate the movement of the extreme point of the crane, the coordinates are all within the range of simulation through scaling.

During the simulation of extreme point paths, we

observed several things. If the same number of coordinate points are used for simulation, the curve path will produce a large error, while the line path will be more accurate. And when the number of simulation points is increased to 100, the accuracy of the path simulated by the robot arm can be improved. At the same time, we find that even if the number of simulation points is increased to 100, there will still be some errors when the extreme points path of the crane suddenly changes. For example, when the extreme points of a crane crashes or falls suddenly or shifts up and down. However, in the real hoisting operation, the speed of the crane movement will affect the swinging posture of the suspension. [5] Therefore, in order to simulate the real crane movement with the robot arm, the speed must also be considered. In this study, the path of the crane extreme points is analysed. Future study will discuss the time factor.

5. Conclusion and future works

Selecting an improper type of crane for a construction project may significantly increase the erection cost. In order to select a proper type of crane, crane simulation is one of the effective methods. However, simulating multiple types of crane requires multiple types of crane models which are always lacking. We developed a simulation method with a 6-degree-of-freedom robot arm using the developed process. The simulation processes include the identification of simulation constraints and the configuration transformation between a robot arm and the crane. One of the erection tasks selected from the crane operator exam was applied to the simulations with a virtual crane and a virtual robot arm respectively. Despite the kinematic constraints for the robot arm simulating the crane, the motion paths of the extreme points of the crane and the arm are highly similar. Only with the same robot arm, the application of the method can simulate the retractable crane and the boom crane regardless of its size and detailed specification. In future work, we will take into account the problem of boom deformation and test configuration transformation with actual mobile crane and robot arm operating on site and in R-lab. In addition, we will find general configuration transformation to test the situation of the movement of the crane and the swing of hook in all crane models.

Abstract –

The purpose of this paper is to classify the level of formation of the bid price by using the type of uncertainty inherent in the bid document as a variable. To this end, the research examined the factors of the project related to the bid price presented in the previous study. Next, the pre-bid clarification document, which can be used to check the uncertainty of the bid documents, is used as a surrogate variable. Through these input variables, this research implemented two kinds of models using four algorithms: one predicts the level of bid price with uncertainty of bid document and the other predicts the level of bid price without uncertainty of bid documents. As a result, the model that predicts the level of the bid price reflecting the uncertainty of the bid document shows about 24 percent better performance than the model that predicts the bid price without reflecting the uncertainty of the bid document.

1 Introduction

Contracts for construction projects are made through competitive bidding. Bidding is a method of concluding a contract with a bidder who offers the most favourable content, that is, generally the lowest price, by letting multiple bidders submit applications with their price. Therefore, the most important issue for the bidder is how much the bid price should be presented [12]. This is because the bid price affects the likelihood that the bidder will be able to obtain a satisfactory profit from the project, as well as the likelihood that the bidder will be able to win the project.

Since the construction contract is concluded by contracting to implement the construction object through mutually agreed price based on the information given prior to the contract, which means bid document, the price required for the implementation of the construction object is also based on the bid document. Since the bid document can be operative as a contract document after the contract is concluded, bidders will thoroughly review the bid document from the bidding stage. In other words, the bid document serves as a substantive basis document for the bidders to calculate the bid price.

The bid document is a fundamental and essential communication tool between the client and the bidder. If the content of the bid document is uncertain, the intention of the construction object may become ambiguous and cause a mistake during construction phase [8], which may lead to construction rework, disputes and claims.

Understanding the uncertainty of the bid document can therefore enhance mutual communication among stakeholders and ultimately encourage the clients (i.e., owners) to improve the quality of the bid document [9]. In the United States, a system is in place to address such uncertainties in the bid document through a system that encourages bidders to inquire to their owners during the pre-bid clarification on the uncertainties inherent in the bid document and responds to them.

Bid price may be expressed in many ways, but generally it can be expressed as follows:

$$B_i = C_i(1 + M_i) \quad (1)$$

C_i means the total project cost of the project that bidder i expects, and M_i means the markups that bidder i internally reflect by analysing the project's uncertainty, or risk [1]. In other words, the result M_i reflecting the uncertainty in the bidding stage is included in the bid price B_i, which cause increase of total bid price. Conversely, if the uncertainty decreases, the bid price is determined at a lower level. In particular, a project that eliminates the uncertainty of bid document through the

pre-bid clarification procedure has been studied to form a bid price at a level more stable than the other projects [14].

Risk management is carried out throughout the lifecycle of the project, but initial preemptive risk management is crucial in that risk management at the bidding stages minimizes the damage that will occur at the later stages of the project [8]. Failure of risk analysis at the bidding stage is one of the root causes of project failure, which can cause significant damage to bidders and construction industry as well as project failure [15].

However, due to the many uncertain factors to be considered in predicting risk, it is difficult for bidders to offer bid prices that simultaneously satisfy satisfactory profits and the likelihood of winning a project [10]. In particular, there is a growing need to eliminate risks at the bidding stage of larger construction projects that involve relatively more uncertainty [18]. This uncertainty ultimately increases the price of the project [16], but due to the difficulty in figuring out the level of risk within a limited amount of time during the bidding process of the construction project, bidders have difficulties in determining the bid price as well as difficulty in deciding whether to participate in the bid [7].

For this reason, in practice, rather than predicting a reasonable level of risk in deciding whether to participate in a bidding for a construction project, it relies on subjective factors such as experience, speculation, and intuition. In other words, there is a need for a decision support tool that can be utilized by practitioners who have difficulties in accurate price predicting due to many factors affecting the bid price.

Therefore, this study considers uncertainty that can be observed in pre-bid clarification document as surrogate variable (i.e. proxy variable) in order to measure uncertainty in bid document and compares the level of performance of the bid price prediction between the model including that proxy variable and the model without it.

2 Theoretical Backgrounds

2.1 Risk Management of Construction Project

According to the PMBOK (Project Management Body Of Knowledge), risk management research can be said to consist of 1) Risk Identification, 2) Risk Assessment, and 3) Risk Plan and Control. Risk assessment can be defined as an estimate of the potential impact of an uncertain factor on a project based on an understanding of this uncertainty [4]. However, due to the difficulty of considering too many variables to be considered, and too much time to be taken into account, risk assessment studies in practice as well as in risk assessment remain qualitative [2]. Although the most important prerequisite for quantitative analysis is to obtain real data [22], existing risk management studies have mainly focused on higher-level risk factors, and these studies have the problem that it is difficult to identify the results through actual data.

2.2 Factors Affecting Bid Price in Preliminary Studies

Construction projects can be divided into building, transportation, and various types of plant depending on the characteristics of the construction object. Among them, although construction and transportation are relatively different in size (e.g., construction (20.2%), transportation (25.6%)), the difference is not significant. In previous risk management research, rather than dividing building and transportation, there was a considerable case in which the risks of construction projects were covered in a comprehensive manner.

However, since the data analyzed by this study is the transportation project data, the risk factor list is extracted from the total of 5 studies including the study using the transportation project data in the preceding research. Seven variables were selected by matching whether the variables corresponded to the same or inclusive relation.

In this study, 5 prior risk management studies were used to extract risk factors for model input variable selection. Risk factors extracted from each study were presented in Table 1.

Table 1. Risk factors from literature review

No.	Risk Factors
1 (Chan and Au 2009)	Poor employer's reputation to honor payment on time; Amount of liquidated damages being higher than expected; Poor financial capability of the employer; Very tight contract period; Non-ideal project cash flow; Large portion of works subcontracted to nominated subcontractors; Low intensity of work; High degree of difficulty; Onerous contract conditions and rigid specifications; Possibility to have public objections
2 (El-Mashaleh 2012)	Project type; Project size; Quality of bid documents; Terms of payment; The contract includes an "adjustment for changes in cost" sub-clause; Cash flow requirements of the project; Availability of labor required for the project; Availability

	of materials required for the project
3 (Agnieszka and Edyta 2013)	Availability of equipment required for the project; Promote the reputation of the firm; Improve the experience of firm's personnel; Increase the possibility of building a long-term relationship with the client; Identity of the client; Financial capability of the client; Reputation of the client regarding his commitment of making timely payments; Influence of the client in making recommendations in the construction market; Reputation of the consultant regarding his independence in making "fair determinations" between the contracting parties; Amount of work currently at hand; Current financial standing of the firm; Availability of other projects in the market
4 (Dominic and Simon 2014)	Type of work; Past experience with similar projects; Contract documents; Owner's reputation; Value of the project; Need of work; Current involvement in other projects; Size of the project; Profits from similar past projects; Time of project duration; Criteria of bid selection
5 (Delaney 2018)	Location of the project; Time for the preparation of the bid; Possible subcontractors; Necessity for specialized equipment; Degree of complexity of works

The variables extracted from previous studies are as follows (Table 2).

Table 2. Factors affecting bid price in preliminary studies

No.	Factors
1	Number of bidders
2	Working days
3	Engineer's estimate
4	Project location
5	Bid preparation days
6	Project type

In Chapter 5, these variables are included in the training dataset in Model 1 and 2 so that both can predict the volatility level of the bid price.

2.3 Pre-Bid Clarification Document

Bidders are provided with bid document by which they obtain the desired construction object at the bidding stage. Bidders will carefully examine the bid document from the bid announcement date to the start date of the bid, and then determine the bid price. In this way, the bid document describes the criteria and procedures for the design, construction method, material, and quality inspection to complete the construction object. Since the bid documents themselves are contractually valid, bid documents may be used as a basis for making important judgments when claims and disputes arise in the future. If the risk factors included in the bid document cannot be reviewed in advance, it may become a factor of future project costs. Therefore, it is very important to analyse the uncertainty of bid documents in terms of risk management [14].

If the bidders believe that there is a problem due to uncertain contents of the bid documents during the pre-bid clarification process, they can ask the owner to review the contents. In other words, pre-bid clarification is a process in which a bidder inquires to the owner if the content of the bid document provided by the owner (e.g., construction contract, design document such as plans, special conditions of construction contract) is unclear [14]. The owner who receives the query from the bidder generally has an obligation to respond within a fixed period. If the query determines that there is a problem with the bid document, he or she will issue an amendment document, which is called addendum, instead of simply responding. Thus, the elimination of uncertainty in bid documents through pre-bid clarification can reduce the occurrence of abnormally low bidding prices and winning prices [19], the New York State Office of General Service, [17]) proposed the policy making process of inquiry and response process of Pre-bid clarification document in the bidding system of construction project as follows:

PRE-BID INQUIRY & RESPONSE POLICY

Background

The pre-bid inquiry and response process is important and beneficial for both the bidder and OGS. It helps to ensure more accurate contractor estimates and bids and fewer ambiguities. Providing consistent responses to prospective bidders also helps to avoid or minimize contract change orders, claims and disputes.

Therefore, considering that the risks presented in the pre-bid clarification documents address uncertainties arising from all kinds of bid documents, the pre-bid clarification document is used as a proxy for uncertainty of bid document in the bidding phase of the project. In the pre-bid clarification document, the following is a table summarizing the five common types of contents that affect the bid price. In Chapter 5, the variables that

can be extracted according to these types (Table 2) are constructed and reflected in Model 2 and compared with Model 1.

Table 3. Types affecting bid price in pre-bid clarification document

No.	Type and example
1	BI 1. Discrepancy (Mutual contradiction) ***Example (Unsolved)*** ***Inquiry #34:*** *Comparing Layout drawing L-1 (pg 17) with pavement elevation plan C-1 (pg 37), the dimensions of the Alhambra Ave EB on-ramp (right) are not the same. Please clarify or re-issue correct drawings.* ***Response #2:*** *Please bid per current documents.*
2	BI 2. Error ***Example (Solved)*** ***Inquiry #10:*** *Please check the State Quantity regarding Bid item 35 Rubber HMA – GAP?* ***Response #2:*** *Quantities have been verified. Bid per current contract documents.*
3	BI 3. Omittance ***Example (Solved)*** ***Inquiry #4:*** *The Special Specifications require the installation of some plants and the irrigation. The irrigation plans shows two truck standpipe. It is safe to assume that there no water at this location either water must be truck or water must be developed.* ***Response #3:*** *Correct, the contractor is responsible for bringing water to the site. Water cannot be developed at the site, such as installing a well to capture underground water.*
4	BI 4. Insufficient information ***Example (Unsolved)*** ***Inquiry #58:*** *`?* ***Response #2:*** *Please bid per current contract documents.*
5	BI 5. Alternative information ***Example (Unsolved)*** ***Inquiry #113:*** *We are requesting clarification on the requirements for Uniaxial Geogrid specified under Section 88–1.02R Uniaxial Geogrid. Specification requires a punched and drawn polypropylene uniaxial geogrid with minimum ultimate tensile strength of 7600 lb/ft. Review of available uniaxial geogrid products indicates no manufacturer supplies polypropylene uniaxial geogrid. We are requesting Caltrans to allow uniaxial geogrid with minimum ultimate tensile strength of 7600 lb/ft meeting the requirement of Section 88–1.02D(1) and geogrid shall have a regular and defined open area with an open area of 50 to 90 percent. Geogrid shall be manufactured from high tenacity polyester (PET) or high density polyethylene (HDPE).* ***Response #2:*** *Any proposal not specifically identified in the bid documents will only be considered by the Engineer after contract award. Please bid per the current contract documents.*

3 Machine Learning

Machine learning can be roughly divided into two types, one is prediction method that derives regression equation as statistical analysis, and the other is classification method which determines the category of data. The bid price volatility level classification model that predicts the level of actual bid price after learning data by using machine learning needs a proper classification algorithm. In this study, four classification algorithms were used for the model: Decision Tree (Tree), Support Vector Machine (SVM), K-Nearest Neighbor (KNN), and Neural Net (NN).

The classification algorithm using Tree algorithm is a methodology commonly used in machine learning. It aims at generating a model that predicts the level of an output variable based on several input variables. Tree generally has merit that it can be understood only by a brief description. In addition, compared with other techniques, there is no need to process the data, so the data pre-processing procedure is simple, and the processing speed is fast, so that it can be applied stably to a large dataset. However, the Tree model is very sensitive to the initial settings, which can lead to different results each time [13]. In addition to this, there is a disadvantage that it is difficult to solve a complicated classification problem such as XOR operation with the Tree algorithm.

SVM is one of a kind of machine learning and is a supervised learning model for pattern recognition and data analysis. It is mainly used for classification. Given a set of data belonging to either of the two levels, the SVM algorithm creates a non-stochastic binary linear classification model that determines to which level new data belongs based on a given set of data [20]. The SVM algorithm finds the boundary with the largest width. SVM can be used in nonlinear classification as well as linear classification. In order to perform nonlinear classification, it is necessary to map the given data to the high dimensional feature space. In order to this efficiently, a kernel trick is used. The learning effect of SVM is known to be very good among classification algorithms, and it is useful for classification of proteins in the field of medicine.

KNN is one of the representative classification algorithm used in machine learning. It categorizes data into a principle that weights neighbors' contributions so that the closer the neighbors contribute more to the average than the farther neighbors. For example, the most common weighting scheme is to give each neighbor a weight of *1/d* when d is the distance to the neighbor. This principle allows KNN to classify data effectively, but it can be very sensitive to the local structure of the data. This is called 'Majority Voting', and this phenomenon occurs when the level distribution is biased. In other words, more frequent levels of data tend to dominate the prediction of new data because more frequent levels of data tend to be the majority of

the K Nearest Neighbors [11].

The NN algorithm, also known as the Artificial Neural Network, is a classification algorithm that can be useful for learning highly complex data. The main advantage of the NN algorithm is that it can learn from the observed data and produce the desired approximate function. In order to utilize this NN algorithm, it is necessary to set the connection pattern between the neurons of the other layers, the learning process of updating the weight of the connection, and the activation function of converting the weight input of the neuron into the activation output. The NN algorithm belongs to Deep Learning among the machine learning. It can solve complex problems such as XOR problem, and it is generally known that it has high performance in classification.

4 Data

In order to classify the bid price volatility level through the analysis of the bid data, this study selected the public construction project in transportation ordered by Caltrans, California, USA as analysis data.

There are various types of private standard contracts used worldwide, such as the International Federation of Consulting Engineers (FIDIC), Joint Contracts Tribunal (JCT), New Engineering Contract (NEC), and American Institute of Architects (AIA). In Caltrans' case, Federal-Aid Construction Contracts (FHWA-1273) is used as the standard contract terms when they carry out a general project. Unlike private projects, the contract conditions of these public projects are used without any modification of special conditions in most cases. This means that the construction project from Caltrans uses a bid document that does not deviate significantly from the standard. These standardized contracts and the bid documents that contain them will not only reduce the influence of numerous factors affecting the bid price, but also the nature of the bid documents, as described in the scope of this study, it is believed to be effective in examining the impact of uncertainty in the bid documents on the risk measurement indicators.

The California State Department of Transportation is a very large ordering organization in the United States, and it has about 450 civil engineering works each year based on its strong economic power. According to the State Transportation By The Numbers: A Compendium of State Summaries, a statistical survey conducted by the US Department of Transportation, the California State of California is a large administrative area that accounts for about 4.3 percent of the US territory. 281,617 km of roads and 8,521 km of trains, (US Department of Transportation 2015). The US State Department of Transportation is investing $ 1.7 billion annually in infrastructure to reorganize aging facilities and build new facilities, accounting for about 10 percent of the US Department of Transportation's overall budget, the largest figure in the nation's 50 states. Therefore, the California Department of Transportation has thousands of standardized construction project data that have been carried out to facilitate data collection and analysis. However, due to the long experience of ordering and project management knowledge, the uncertainty of bid documents of the California State Department of Transportation is estimated to be relatively small compared to other ordering organizations. If the uncertainty of these bid documents decreases, I think it may be a little difficult to see the relationship and its effectiveness.

In addition, the California State Department of Transportation's bidding process includes a Pre-bid clarification process that eliminates the uncertainty of the bid documents through the bid question and answer process. In addition to the Pre-bid clarification document generated during this process, and that the data are in accordance with the purpose and characteristics of this study.

5 Datamining: Modelling

There are two models to be implemented in this study:

- Model 1: Implemented with input variables NOT including uncertainty of bid document related
- Model 2: Implemented with input variables including uncertainty of bid document related

Therefore, this Chapter deals with specifying the input, output, and output variable classes required to implement these two models.

5.1 Input Variables

The input variables to be used in the model consisted of the variables related to the bid price derived from the preliminary studies and the variables related to the uncertainty of the bid document (Table 4).

Table 4. Model input variables

Model	Input variable
1	▪ Number of bidders ▪ Working days ▪ Engineer's estimate ▪ Project location ▪ Bid preparation days ▪ Project type
2	▪ Number of bidders ▪ Working days

- Engineer's estimate
- Project location
- Bid preparation days
- Project type
- Number of unsolved BI. 1
- Number of unsolved BI. 2
- Number of unsolved BI. 3
- Number of unsolved BI. 4
- Number of unsolved BI. 5
- Number of unsolved BI Total
- Solved ratio
- Number of addenda

5.2 Output Variable and Class Designation

The output variable of the model should be a risk measure of the bid price. In this study, the following two risk measures were used: Bid Average Risk and Bid Range Risk.

5.2.1 Bid Average Risk

Bid Average Risk is the ratio of the average price which can be considered the agreed bidding price to the project's base price (engineer's estimate), which measures the risk and can be expressed as follows:

$$Bid\ Average\ Risk = \frac{Average\ Bid\ Price}{Engineer's\ Estimate} \quad (2)$$

For example, if the bid price of project A and B are both \$10 billion and each average bid price of project A and B is \$10 billion and \$13 billion, the Bid Average Risk of Project A and B are 1.1 and 1.3 respectively. And for project B, bidders are expecting more risk.

5.2.2 Bid Range Risk

Bid Range Risk refers to the difference between the maximum bid price and minimum bid price as a result of the bid compared to the engineer's estimate, and it can be expressed as follows:

$$Bid\ Range\ Risk = \frac{Max\ Bid\ Price - Min\ Bid\ Price}{Engineer's\ Estimate} \quad (3)$$

Since the difference between the maximum and minimum bid price is also affected by the project size, the risk cannot be determined simply by measuring difference between the maximum and minimum bid prices. For example, in a project with \$10 billion and a project with \$1 billion of engineer's estimate, the difference between max and min bid price is all the same at \$2 billion, but the difference between the uncertainties of the two projects cannot be considered same.

Therefore, it is appropriate to compare the difference between max and min bid price against the project's base price, in this study, which is regarded as engineer's estimate.

5.2.3 Output Variable and Class Designation

According to the above discussion, the output variables of Models 1 and 2 are shown in Table 5.

Table 5. Model output variables

Model	Output variable
1	▪ Bid Average Risk ▪ Bid Range Risk
2	▪ Bid Average Risk ▪ Bid Range Risk

The classification model predicts the class divided by a certain criterion rather than the value of these output variables themselves. For this purpose, the level of each output variable is specified and their classes are designated based on a certain criterion (Table 6).

Table 6. Class designation

Output variable	Class	Range	Ratio
Bid Average Risk	++	≥ 1.1	25%
	+	≥ 1.0 and < 1.1	27%
	-	≥ 0.9 and < 1.0	26%
	--	< 0.9	22
Bid Range Risk	++++	≥ 0.27	25%
	+++	≥ 0.2 and < 0.27	23%
	++	≥ 0.13 and < 0.2	24%
	+	< 0.31	28%

6 Results

This Chapter discusses the implementation of the models in accordance with Chapter 5. The following table shows the accuracy of the algorithms and output variables of Models 1 and 2 (Table 7), where the accuracy is a predicted ratio of the total data, and the expression is as follows:

$$\text{Accuracy (\%)} = \frac{Number\ of\ correct\ predictions}{Total\ number\ of\ predictions} \quad (4)$$

Table 7. Accuracy of classification models by algorithms

Algorithm	Accuracy (%)			
	Model 1		Model 2	
	Bid Average Risk	Bid Range Risk	Bid Average Risk	Bid Range Risk

Tree	31.5	34.3	61.7	60.6
SVM	34.6	40.5	59.5	60.5
KNN	32.8	36.1	58.4	56.1
NN	37.5	42.5	63.9	65.8

First, according to the Table 7, it was showed that the prediction accuracy of the model slightly differs according to the algorithm. The NN showed the highest accuracy in all cases, followed by SVM, KNN, and Tree, although with a few exceptions.

Second, the bigger difference is between Model 1 and Model 2. In Model 1, mean accuracy is somewhat low at 36.22%. In Model 2, which includes variables related to uncertainty of bid documents, mean accuracy is 60.81% as shown in Table 7.

Third, there was a difference in the accuracy depending on the output variables. Except for only two cases in Model 1 and Model 2, both models showed better performance in predicting Bid Range Risk than Bid Average Risk.

7 Conclusion

Although it is important to manage risk at the initial stage of the construction project, that is, at the bid stage, there are many cases where it fails to calculate the appropriate bid price because it is not done properly. In particular, the bid document is one of the important risk factors in the bid phase because it contains many uncertainties in the document due to the characteristics of the one - time construction project. However, since it is difficult to analyze all of the uncertain risk factors affecting the bid price in a short time, in business, it relies on the experience of practitioners or experts in predicting bid prices, and many studies have focused on qualitative solutions to risk management. Quantitative solutions are also based on statistical techniques based on virtual data or expert questionnaires rather than based on actual bid data, which has limitations in verification. In other words, there is a lack of empirical analysis of the effect between the uncertainty of the bid document and the actual bid price.

In order to meet both the need for decision support tools that can be used to calculate the final bid price in business and the academics' need for risk management research based on actual bid data, this research has developed a model to classify the bid price volatility level for the project bid data. The bid price volatility to be considered in this paper means the average of the bid price and the range of the bid price over the engineer's estimate. In order to reflect the uncertainty of bid documents, which were previously regarded as uncontrollable risk, the research sought to improve the accuracy of the classification model by using pre-bid clarification document as a proxy variable.

First, variables that can be obtained from the bid data were extracted and variables with high contribution were chosen by analyzing 13 previous researches related to risk factors. After that, 14 variables were identified as input variables in the model through the numeralization or categorization of the variable data.

Pre-bid clarification document analysis showed that the project with high uncertainty of bid documents formed a relatively higher average of bid prices than those without, and the range of bid prices was relatively broad. This confirms that the uncertainty of the bid document affects the bid price.

In order to examine whether the information related to the uncertainty of the bid documents gives better results in terms of accuracy in classifying the level of volatility of bid prices, a classification model that includes 8 variables related to uncertainty of bid documents and a classification model that does not include those variables were developed and accuracy of both models were compared. As a result of the analysis, the model that reflects the uncertainty of the bid documents showed accuracy of 63.9% for the average bid price and 65.8% for the range in bid price volatility level classification, whereas the model that does not reflect the uncertainty of the bid documents showed accuracy of 37.5% for the average bid price and 42.5% for the range in bid price volatility level classification. Consequently, it is confirmed that the result is better when the information related to the uncertainty of the bid document is reflected.

This study ultimately has the following contributions. In the bidder 's view, the bid price should be calculated to increase the likelihood of winning the project and to guarantee the profit of the project within the limited bid preparation time. The bidder will have the opportunity to fix or strategically change their bid price by comparing their bid price with the bid price average and range of the current project predicted through the cases of the past projects. In other words, the results of this study can be used as a more reasonable decision support tool that bidders can use when determining the bid price based on actual bid data. In addition, from the view of the owner, it can be expected that unnecessary design change and increase of project cost will be reduced by contracting with the bid price which fully reflects the result of the risk analysis including uncertainty of the bid price. Moreover, the bid document is a document that the owner provides to the bidder. The result of this study that the uncertainty of the bid document affects the bid price suggests the positive effect of providing bid document with high quality.

Although the actual bid price is calculated on the basis of the actual bid documents containing the contents for the purpose of construction, there has been

a limit to the difficulty in analyzing the actual bid data as the risk management research conducted based on the higher level of qualitative risk factors. This study has significance in that variables were obtained from the actual bid data, and implies that the level of risk management research has deepened to the detail level based on the actual bid documents by reflecting uncertainty of bid document through pre-bid clarification document as a proxy variable, consequently providing the foundation of research that can make more effective risk management risk studies.

Abstract –

A construction contract facilitates payments through the supply chain by integrating people, activities, and events throughout the project period through obligations, permissions, and prohibitions in its terms and conditions. The management of payments is a manual process and is more difficult in the case of construction projects as different stakeholders at different levels of the project organizational structure are bound by different contracts. Moreover, payments are strongly affected by the lack of clarity in the definitions of the obligations, responsibilities, and liabilities of various stakeholders in construction contracts. This intensifies disputes and causes delays in construction payments leading to additional expenditure, cash flow problems, and lack of trust. Therefore, to address these problems, we propose a methodology to automate construction payments by formalizing them into smart contracts and executing on a decentralized blockchain based framework. We formalize the payment logic that binds the prohibitions and liabilities associated with financial commitments, such as interim payments on completion of tasks in a construction project, and convert it into a computer-executable code. A framework based on blockchain is used to host this smart contract and to automate actions such as the triggering of payments after achieving consensus among the relevant project stakeholders. This framework also address the conditions required for the security of information in construction projects, such as confidentiality and information integrity in a multi-party environment. The proposed framework is demonstrated through a case-based scenario.

Keywords – Blockchain; Smart Contracts; Construction Projects; Interim Payments

1 Introduction

Construction projects often suffer from payment problems. Due to the adversarial working relationships of different stakeholders, and the complexity and uncertainty of the construction environment in Hong Kong construction projects, the outstanding payment amount was reported to be over HK$20 billion in 2015[1]. The solution to payment problems in construction projects greatly depend on the execution of construction contracts, which regulates the behaviour of the stakeholders by holding them accountable through commitments, prohibitions, obligations, and liabilities. It is the foundation for information management, claims, and payments, and therefore is a key to successful project completion. However, the execution of construction contracts is a complex process and faces many challenges, such as delays in payment [2]. A contract is said to have been breached or halted in cases such as defaulting on payment due to lack of funds or disputes on unsatisfactory quality of work. These problems escalate due to the ambiguity of language in the identifying responsibility, authority, and prohibitions described in the contracts. Moreover, the process of contract management is slow due to the fact that consensus among stakeholders is required for decision making. Achievement of consensus is preceded by several levels of approval from the stakeholders from various organizations, and therefore an immutable audit trail must be kept in order to prevent any disputes in the future. Previous research proposed measures to improve construction contract management. For example, standard construction contracts have been proposed by many countries and regions as references for contract formalization for specific types of construction projects, such as the FIDIC contract [3]. However, standard construction contracts focus on the improvement of the contract structure and are still difficult to interpret by individuals who are not lawyers by profession. To simplify contract management, e-contracts have been proposed. E-contracts are created by analysing relationships between the contract participants and contractual information, followed by modelling traditional textual contract in xml format [4]. However,

current applications of e-contracts are mainly found in electronics trade, where the complexity of relationships between parties, obligations, and activities is simpler compared to that in construction contracts. Therefore, a framework that improves the current state of construction contract management by addressing the challenges due to complexities and inherent nature of the construction industry is required. In this paper, we propose a blockchain based framework to facilitate semi-automatic contract execution and consensus achievement for the construction industry. Blockchain was selected for the proposed framework because it possesses the following characteristics: (1) information sharing among multiple parties; (2) information updating among multiple parties; (3) verification/approval at several levels [5].

The general architecture of blockchain is comprised essentially of a shared ledger. Every participant in a blockchain stores a local copy of this ledger in his/her database. The integrity of information in each local copy is maintained as they can be altered only upon achieving consensus by the majority of the participants. Information security and integrity is ensured through cryptographic techniques and consensus mechanisms. In general, there are three types of blockchain - public blockchain, private blockchain, and permissioned blockchain. A public blockchain network is open for anyone to join and host information. The BOPTI project utilized Ethereum, a well-known public blockchain platform, to issue their cryptocurrency, attracting customers through the reward mechanism [6]. Unlike public blockchains, private blockchains have a closed network and is owned by one controller. For example, it is especially useful for a closed network of banks. The private blockchain system has been used to store construction-related transactions by SiteSense software [7]. However, the construction industry may require access control mechanisms to allow or reject participants joining certain transactions. Therefore, a permissioned blockchain is most suitable for construction projects. In a permissioned blockchain, participants can join by invitation and require access rights to read or write from the blockchain, therefore adapting to the intrinsic feature of decentralization in the construction industry and the complexity of construction contracts. Thus, we propose a permissioned blockchain based framework to formalize and execute smart contracts. Our methodology includes contract formalization and a framework for automated contract execution. The methodology is supported by a case-based scenario that demonstrates its key features and advantages, such as information integrity, security, and transparency.

2 Methodology

In this study, a framework is proposed to automate payments in construction projects by formalizing construction contracts into smart contracts. The contract is executed on a blockchain based decentralized framework which supports the achievement of consensus for decision making based on the conditions of the smart contract. The methodology is divided into two parts - (1) contract formalization and (2) contract execution.

2.1 Contract Formalization

In this section, we describe our methodology for converting construction contracts into smart contracts for automatic interim payment. Construction contracts (such as HKGCC [9]) were studied to identify the general concepts of construction contracts, such as parties and activities and the logic relating them. Based on this study, data representation for smart construction contracts and the formalization of logic was done. The methodology for contract formalization as follows:

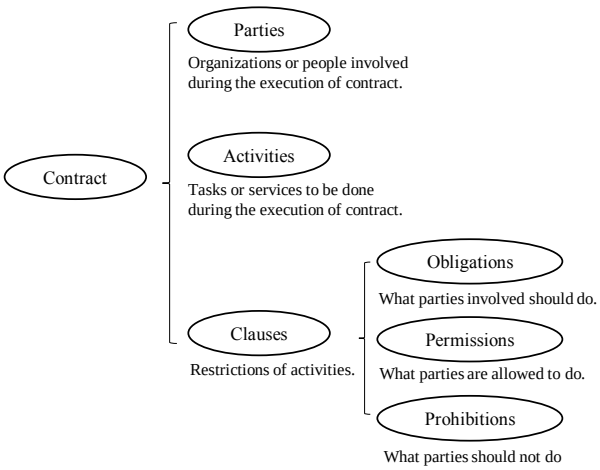

Figure 1. General structure of a construction contract

1) As shown in Figure 1, data representation for smart construction contracts was developed. Contract clauses were analyzed and key concepts were extracted, such as parties, activities, triggering events, conditions, actions, and resultant events.
2) Construction contracts were studied to identify and formalize the logic for executing smart contracts. For example, the relationship among parties and the sequence in which they are supposed to execute their responsibilities were identified. The parties involved in a construction contract for interim payment are

the contractor, inspector, quantity surveyor, engineer, and employer.

During the payment process, the obligation of a contractor is to submit an application with supplementary documents and to the initiate interim payment procedure. The inspector is supposed to check the correctness of all quantities claimed by the contractor followed by the quantity surveyor who is responsible for checking the correctness of the valuation in the payment claim and so on as shown in Figure 2.

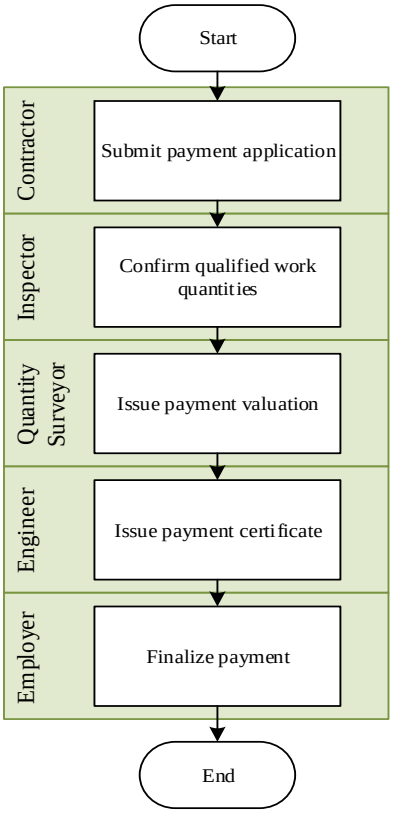

Figure 2. The sequence of activities and participants for interim payment

At the end of this process, interim payment should be triggered. This logic was converted into pseudocode and then into executable code using JavaScript. The conversion process is illustrated with an example scenario in Section 4.

2.2 Automated Contract Execution

The execution of the smart contract is done through a permissioned blockchain based framework and has two parts – (1) A automated consensus process based on pre-defined conditions of the smart contract and (2) a manual process which requires an input from the authorized stakeholder. In a blockchain based framework, information is stored in the two data models – one is for recording transactions which represents the action done by the authorized stakeholder, called the ledger, and another data model, called the asset model, is for checking and recording current values of construction data assets such as tasks and payments. All the project participants store the same construction information in their local asset data models and ledgers. The asset model is based on the transactions recorded in the ledger. The ledger is the actual backbone of blockchain which is an unmodifiable cryptographically linked storage structure, and therefore is a trusted source of information.

At the beginning of the contract execution process, a project participant, for example a contractor in this case, submits a request for payment. When the transaction of payment application is received by the following project participant which is the inspector in this case, the process of automatically achieving consensus begins. The incoming data is stored locally with every participant in a pre-defined data model, from where it is evaluated by the smart contract. Smart contracts are executed automatically to check pre-defined conditions of standard prohibitions and obligations (as discussed in Section 2.1). These pre-defined conditions check the validity of the incoming request by assessing information such as price, quantity of material, and other construction information against information such as historical records of payment and variations, stored in their local asset model. Consensus is achieved when all participants either approve or disapprove the proposed request according to the results of executing the smart contract on their local systems. After consensus on the correctness of a transaction is achieved, the transaction is added to the blockchain. This transaction contains information on who approved what (for example, who approved the payment application, quantity checking, and quality inspection results and so on), along with a timestamp, and is digitally signed by all the participants. Meanwhile, the asset model is be updated according to the transaction, which becomes the reference for validating later transactions. After this, the control is passed for manual input to the next project participant (which is quantity surveyor, as shown in Figure 3). It is to be noted that there is manual and automated consensus at each level of approval. During the manual approval part, the authorized participant has the right of approval or refusal based on existing information from the local asset model. The approver may also check other information manually, such as through on-site inspection, and may use his/her professional judgement to make a decision. After that, the decision is manually inputted by approver. The execution progresses through a series of manual inputs and automatic consensuses till the end of the approval process is reached. At every

stage, actions on construction data are recorded by transaction models in the blockchain ledger, which is unalterable. Therefore, at a later stage such information can be used for audit trail for identifying a defaulting participant or the responsible person for a project delay.

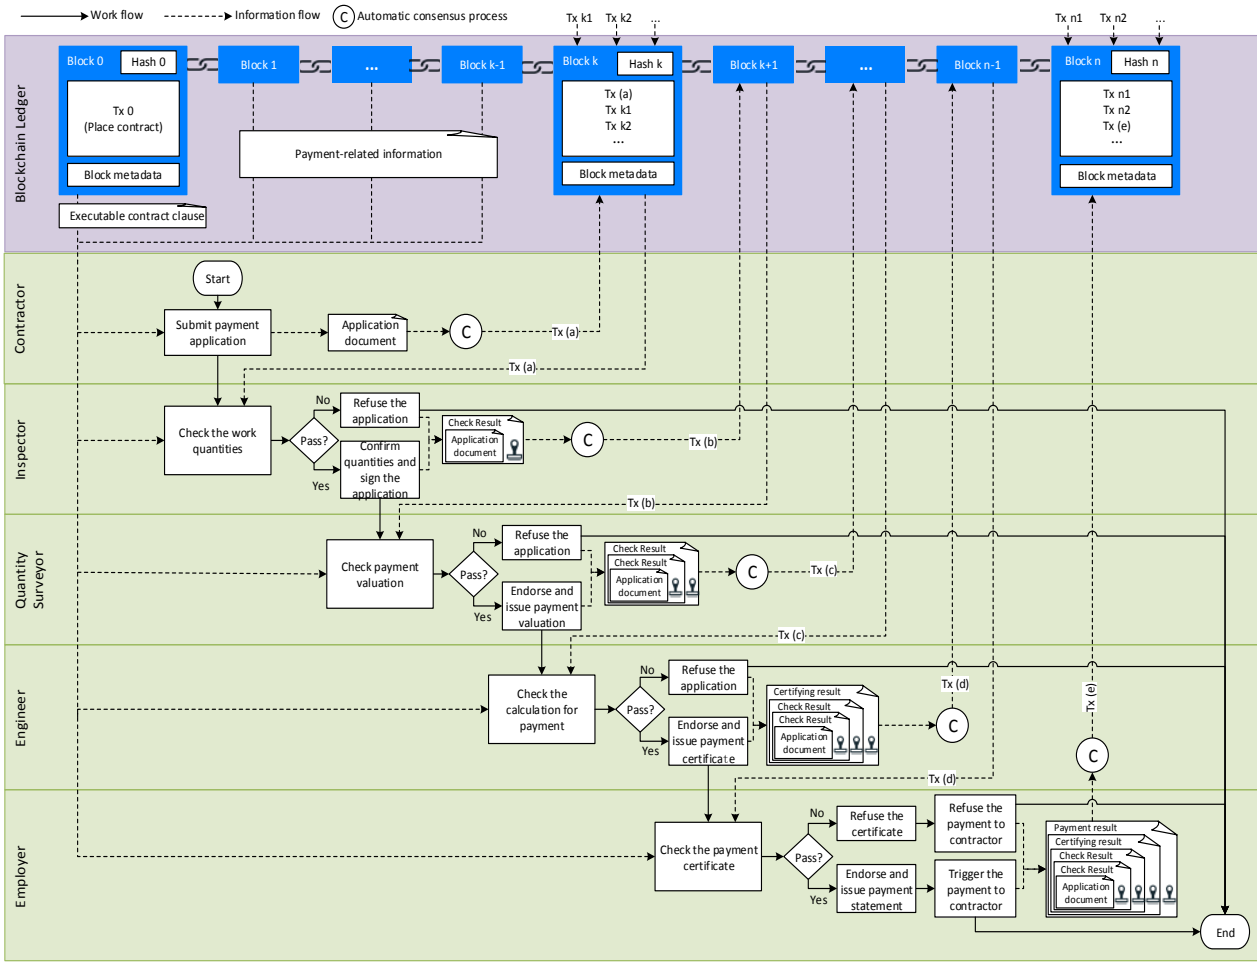

Figure 3. The semi-automatic blockchain based framework for interim payment

3 Contract Security Protection

In this section, we discuss the security related features of the proposed framework, which allows participants to come to a common consensus with verified endorsement in a secure fashion, without having to meet face-to-face. To do this, the framework implements blockchain based cryptographic protocols for the authenticity of participants and authenticity of data during transfer, and data confidentiality. This means that it ensures that only authorized participants are allowed to exchange information, that data is not altered during transmission between two participants, and sensitive project information is kept private. The proposed cryptographic protocol and hash functions ensure authenticity of the participants and authenticity of data during transfer. The private-key public-key is a type of asymmetric encryption where plain data is encrypted with a key, but is decrypted with its respective key pair. Hashing

however facilitates robust one-way encryption of plain text into encrypted text. Hash functions are collision free, which means that for a particular plain text, there a unique corresponding encrypted text. In our framework, in order to securely achieve endorsement and consensus, a participant, say A calculates the hash value of a message to be exchanged. After that, A signs (encrypts) the hash value of the message with a private key that is only known to him, as shown below.

$$signature_A = \mathrm{Pr}_{\mathrm{k_A}}(hash(message)) \quad (1)$$

The participant A, then broadcasts the concatenation of the original message and signature in the format, "$Encrypted(message \,||\, signature_A)$" to

every other participant on the blockchain framework. The participants at the receiving end can confirm that the message has been sent by A only if they can decrypt the signature with the corresponding publicly available key of A. Furthermore, the message is be confirmed to be unaltered during transfer, if calculation of the $hash(message)$ performed at the receiver's end is the same as that sent as a part of $signature_A$ by the sender, A. It is to be noted that this is done only to ensure the authenticity of the participants and data during transfer having nothing to do with data confidentiality. Data confidentially is implemented by separately encrypting the message itself in the first place with a different key available only to the project participants. Thus, only the parties within the permissioned blockchain network have the key to decrypt the message after they have ensured the authenticity of the users and data during transfer.

4 Example Scenario

In this section, an example scenario is demonstrated for describing the feasibility and key properties of the proposed methodology. Hyperledger [10] is used to set up the permissioned blockchain network for the involved parties in a construction project. The example scenario is based on the clauses related to interim payment from the General Conditions of Contract for Term Contracts for Civil Engineering Works in Hong Kong (HKGCC) [9]. Different parties have different obligations and responsibilities in the interim payment process (shown in Figure 2). These responsibilities and obligations are guided by clauses of HKGCC (as shown in step 1 of Figure 4) which have been transformed into machine executable logic to realize interim payments.

Contract execution is demonstrated in Figure 5. The contractor initiates the payment process with a manual input comprising information such as payment application ID, total payable amount, tasks and material quantity and passes control to the automatic consensus process (designated by "C" in Figure 5). The first consensus process checks the condition such as whether the claim is submitted or not. If successful, a transaction (as shown by Tx(a)) is written to the blockchain ledger. As can be seen from the data representation of the transaction, information such as price and quantity of materials, submission time and the record of associated parties are recorded and are immutable. Therefore, in a subsequent transaction at any time in the future, information from this transaction can be drawn by the smart contract. For example, as shown in Figure 5, checking the quantity of material is one of the checks for achieving consensus at a particular stage of approval. This check is designed (in the smart contract) to pull quantity data from the transactions (Tx(a) in this case) stored in the blockchain ledger. Since this framework allows standards checks to be performed against the data stored in the blockchain, it can be assured that these checks are always evaluated against authentic data. There is no scope for altering this data even by hacking into the system. If such attempts are made, a trail of the same will be left in the blockchain (due to use of cryptographic protocols such as Merkle Tree in the inherent design of blockchain).

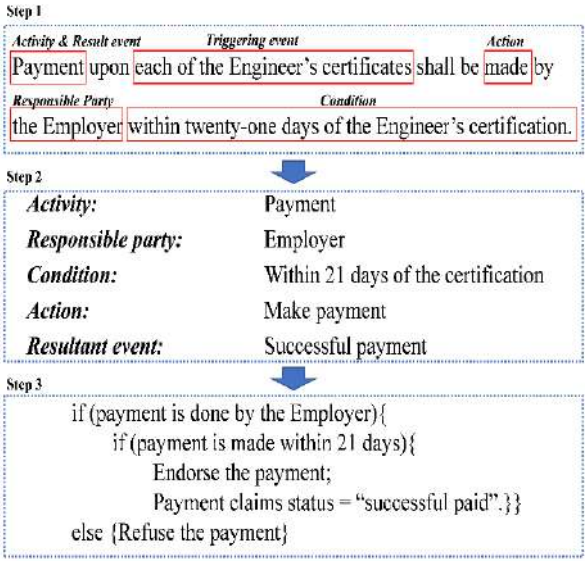

Figure 4. An example illustrating formalization and representation of smart contracts

5 Conclusion

Construction contracts regulate the behavior of the stakeholders in a construction project. Effective construction contract management protects the interests of all stakeholders, decreases the possibility of construction delay, and ensures smooth construction progress. In this research, a blockchain-based smart construction contract framework is proposed for semi-automatic execution of construction contracts for interim payments. A data representation for a smart contract is developed based on traditional textual contracts. This representation models contractual conditions into obligations, prohibitions, and actions, which can be read and executed automatically. By leveraging blockchain technology, a framework for executing this smart contract is developed which caters to the requirements of sequential approval process in a decentralized environment, such as that of the construction industry. A customized semi-automatic consensus mechanism is developed to facilitate interim payments through the blockchain framework. This mechanism regulates the sequence and conditions of

approval by stakeholders such as engineer, architect, and owner by automatically providing them with necessary information at the time of approval. It furthermore removes the scope of fraudulent approval by individual stakeholders as the consensus mechanism sends the result of individual approval to all the stakeholders on the platform.

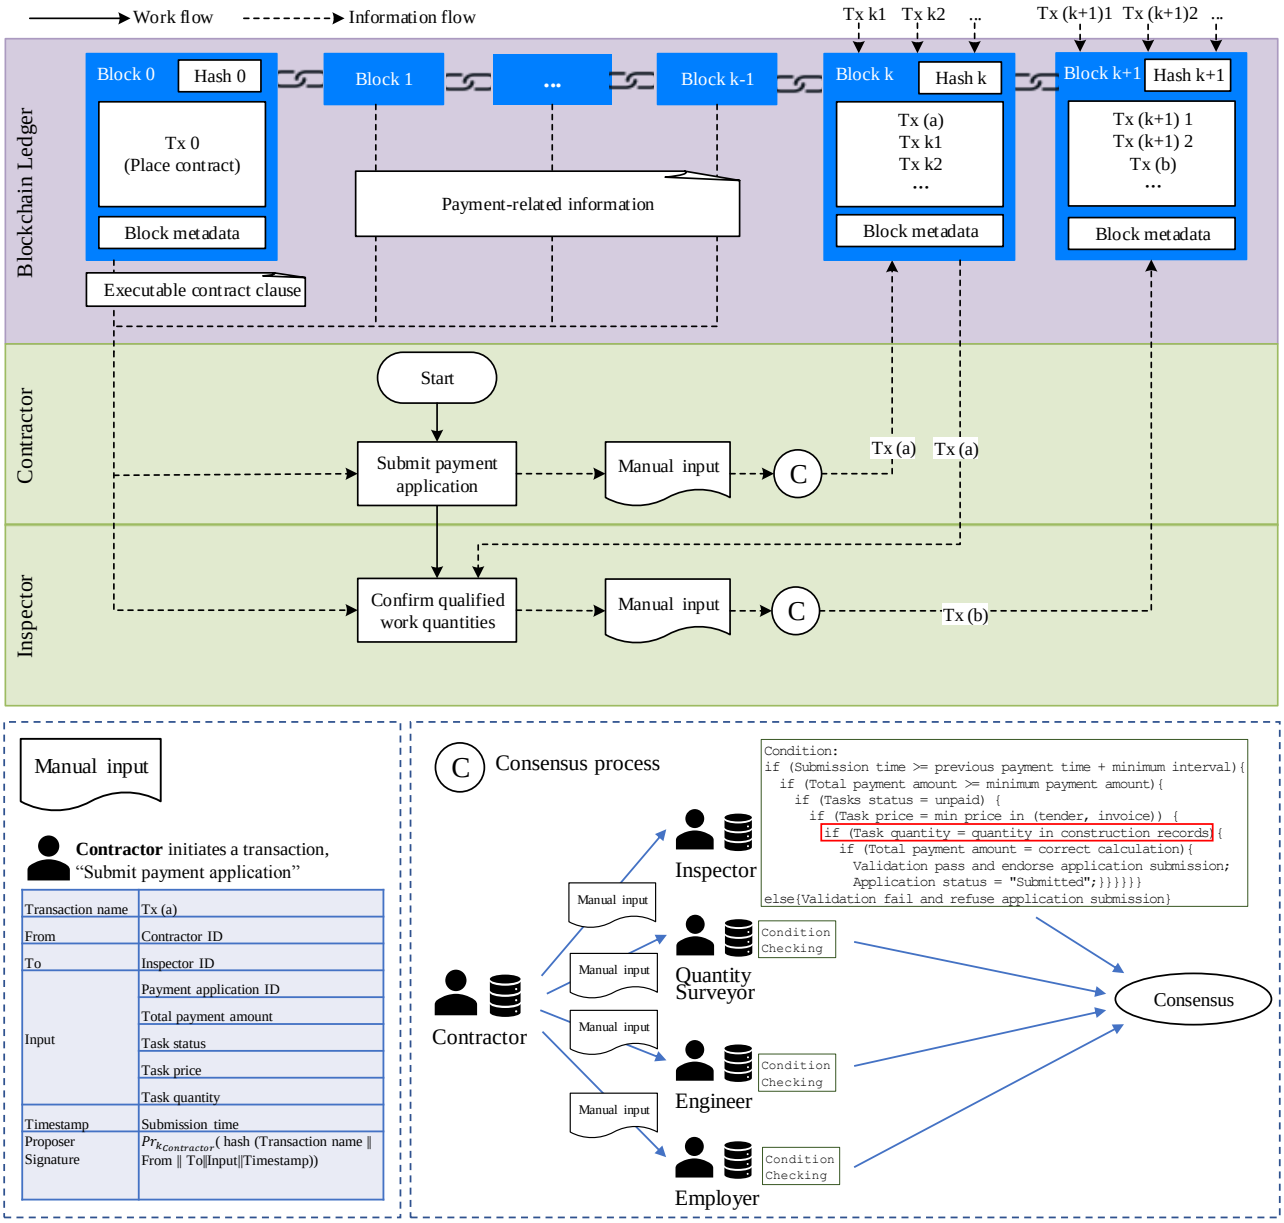

Figure 5. The example scenario illustrating blockchain-based smart contract for interim payments

All these stakeholders thereupon automatically check that result against certain pre-set rules, on their individual machines and communicate back their decisions across the group. Therefore, an approval is legitimized only when it has the collective endorsement from all the stakeholders. The record of this approval is thereupon stored on the blockchain ledger, which is inherently immutable, and therefore is secure against malicious alteration. Along with this, the proposed framework implicitly deploys cybersecurity measures to authenticate users through

public-private key encryption protocol. Presently in this research, the conditions of traditional contracts have been manually modelled into that of a smart contract by following a procedural approach. In

future, automatic development of smart construction contracts will be explored through technologies such as Natural Language Processing and Machine Learning. The scope of data representation will also be extended from interim payments to other technically feasible areas of construction contracts. The construct of the smart contract code in this paper is similar to that of e-contracts, but deployed on a secure distributed framework and regulated by a customized consensus. However, it has further potential to function as a fully enforceable contract management system through integration with resources such as BIM, which will be explored in the future. The performance of such smart contracts will also be studied in more complex scenarios such as that with various levels of project organizational structure spread across a construction supply chain.

Abstract –

This paper proposes a cloud-based data management framework that integrates open data from the government and monitoring data from construction site sensors. The integrated data can be consumed by artificial intelligence for smart construction project management, e.g. schedule control, resource arrangement and workers' safety. The framework includes two major parts: one is the IoT (Internet of Things) sensors and edge computing devices for collecting data from a construction site; the other one is a cloud database with Autodesk Forge for managing 3D Building Information Modeling (BIM) model information and government open data. In addition, web-based management interface and information dashboard for desktop computers and App software for hand held devices are provided for users to easily manage, query, and visualize the integrated data. Because weather and environmental conditions often affect management of a construction site, the proposed framework is prototyped for a feasibility test to see how the integration of Taiwan government open weather/environmental data and construction site monitoring data can be implemented and helpful for construction site management.

1 Introduction

In recent years, through popular application of Building Information Modeling (BIM), a good foundation has been laid for construction management to integrate digital construction and sensor technology for achieving lean construction with better efficiency [1]. The potential applications include site design, material inventory control, transportation vehicles scheduling, construction machinery and equipment management, remote structural health monitoring and progress checking [2], especially for risk control of large scale construction projects [3]. To monitor real-time construction progress and avoid construction hazards, the use of various kinds of sensors to collect data for management analysis in the construction sites is getting popular and even become necessary [4]. Furthermore, Taiwan's labor law always concerns the construction workers' health and safety and has increasing restrictions for the workers to be exposed to extreme weather conditions and hazard environmental conditions, e.g. PM2.5 air pollution. In India, excessive PM10 concentration produced during construction was studied and it was found that the health condition of workers is related the air pollution Index. Workers at sites with less precautionary measures suffer more with respiratory illness than those at sites with more safety measures against air pollution [5]. Besides the labor law issues, the everyday weather and environmental conditions on the construction site can affect working productivity of workers and indirectly impact the construction schedule. Although project managers can always refer to the national weather report to get the measured and predicted data for the city or the district where the site is located, they may need more precise and higher resolution data on the site for better decision making on project scheduling or resources arrangement. With some monitoring systems implemented, when the system detects an abnormal situation based on the comparison between real-time data from the site sensors and historical data accumulated in the database, the project managers will receive an alert message through their hand held devices for them to quickly adjust the resources accordingly to avoid extra cost due to law violation or schedule delay. On the other hand, government open data may be very useful for construction site management. For example, for those sites in the seismic zone, early earthquake warning messages published by the government agency can help to reduce disasters due to strong earthquake. For those construction sites beside the ocean areas, the project managers may benefit from the information provided by an early-alert ocean wave system for optimal resources utilization and risk control [6].

To assist construction project managers for smart site management, this paper proposes a cloud-based data management framework to facilitate integration of

government open data and construction site monitoring data.

Based on the framework, a prototype BIM-based Smart Site Assistant (called BSSA) platform was implemented and tested for proof of concept. The prototype BSSA platform used Autodesk Forge as 3D BIM cloud database to manage digital construction site and integrated weather open data from Civil IoT Taiwan services (https://ci.taiwan.gov.tw/index_ne.aspx) as a testing and demonstration example for integrated application of government open data. The data collected by the various kinds of IoT sensors, such as vibration, PM10/2.5, and temperature sensors, installed in the construction site are gathered by edge computing control boxes through the DDS (Data Distribution Service) network protocol and stored into MariaDB database on a web-based server.[7] To ease the real-time management and access of needed data for the project manager, a web-based data management Graphical User Interface (GUI) and information dashboard are designed for desktop computers and an App software is designed for mobile hand-held devices. The rest of this paper will discuss the design of the framework and the implementation of the platform in more details.

2 The Framework

Figure 1 illustrates the system framework for the BSSA platform, which can be divided into three main parts, including data collection hardware devices in construction site, web-server for data management and applications for data visualization. First, different type of IoT sensors are needed at construction site for collecting site conditions, such as temperature, humidity, wind speed, air quality (PM10/PM2.5), ground water level, etc. These sensors data are collected and sent to edge computing devices (e.g. one per one floor) via Bluetooth, RS485 or RS232 interface. The edge computing devices communicate to each other using the DDS protocol to achieve low-latency, high-throughput data communications and one selected device is responsible for uploading collected data to the web server through network.

The second part is a web server for data management which uses Autodesk Forge for 3D BIM model data management (including basic project information) and MariaDB database to store the construction site sensing data and government open data from the Civil IoT Taiwan services. To compliment open data provided by the Civil IoT Taiwan services, which provide broad range but low resolution data, various kinds of sensors are needed to collect weather and environmental status data for the construction site.

The final part is data management GUI and APP software for users to effectively manage and access contents from the web server using desktop computers or hand-held devices.

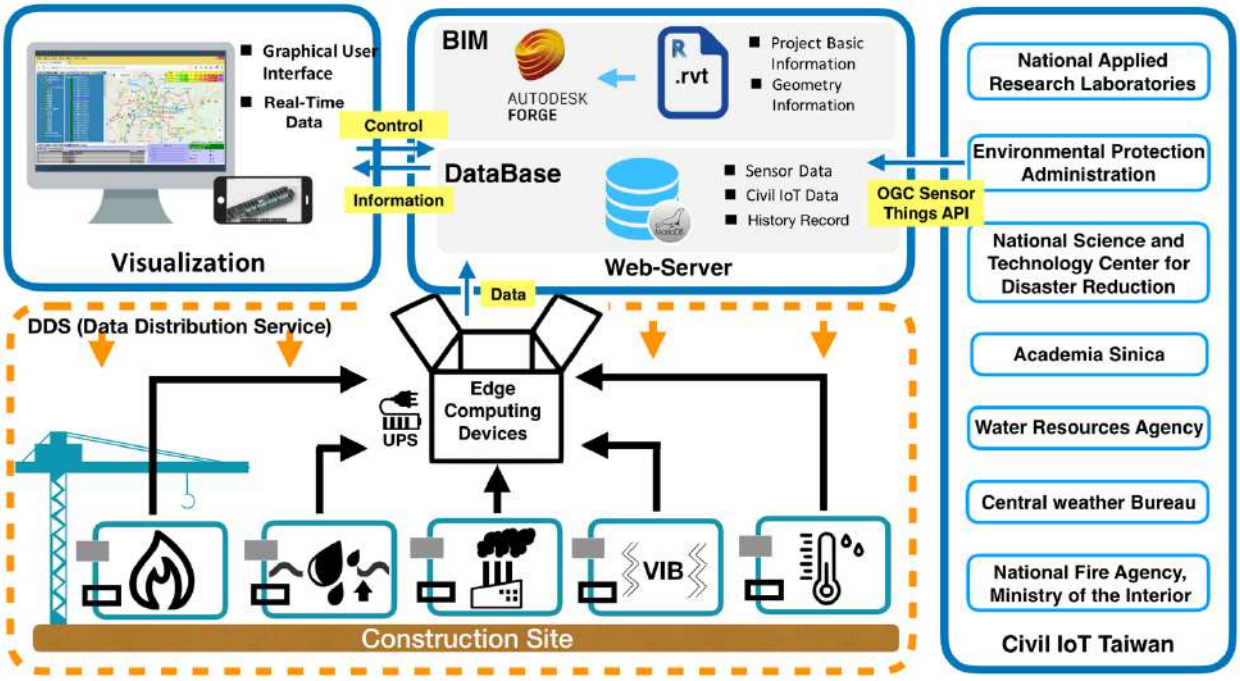

Figure 1. System Framework of the BIM-based Smart Site Assistant (BSSA) Platform

3 Prototype and Demonstration

With the rapid development and application of IoT and big data technologies, more and more government agencies have published their data as open data for public goods, especially environmental monitoring data, including temperature, humidity, air quality, precipitation, wind speed, river and ground water levels data and so on. In this work, the BSSA platform collects real-time environmental data from Civil IoT Taiwan services using OGC Sensor Things API (http://www.opengeospatial.org/ogc/markets-technologies/swe). However, the data in Civil IoT Taiwan database not only are multifarious but also come from various sources. Data filtering and integration are needed to increase their usability and reliability for construction management. Also, there are data collected through sensors installed on the construction site for a project manager to monitor the progress and various conditions of the construction, e.g. structural safety, air quality, etc. In the BSSA platform, a data management GUI is designed with the use of MariaDB, an open-source relational database management system, to help users to select and integrate data. Also, Autodesk Forge is employed for managing 3D BIM model data of the construction site. The BIM model is often built by Revit, one of the most popular building modelers, and uploaded by the user to the Forge cloud. The platform connects the model to the related environmental data and provides a viewer on the website for data visualization. In addition, mobile app software is designed for on-site project managers to easily retrieve and visualize data for decision making.

3.1 Data management GUI and information dashboard

Figure 2 illustrates the three-level data management scheme designed in the BSSA platform. The first level includes basic functions for users, such as historical data query, real time data and event alert and getting government open data. The second level includes operations for users to manipulate data in the database. The database in the third level integrates two types of data, open data (such as Civil IoT Taiwan) and local data (Edge Computing data). The central data management GUI includes six blocks, namely A, B, C, D, E, F (see Fig.3). Block A shows environmental data from the Civil IoT Taiwan database which orders contents by government administrative areas (i.e. cities, provinces, counties, etc.). There are construction sites under each area and users may connect to those sites to quickly access the surrounding environmental information. Block B provides links to all governmental sensors' data with a scroll down menu. Block C uses Google Map API to lay down different sensors' locations on map by transforming the coordinate system from WGS84 to TWD97 to help users understand better the sensor

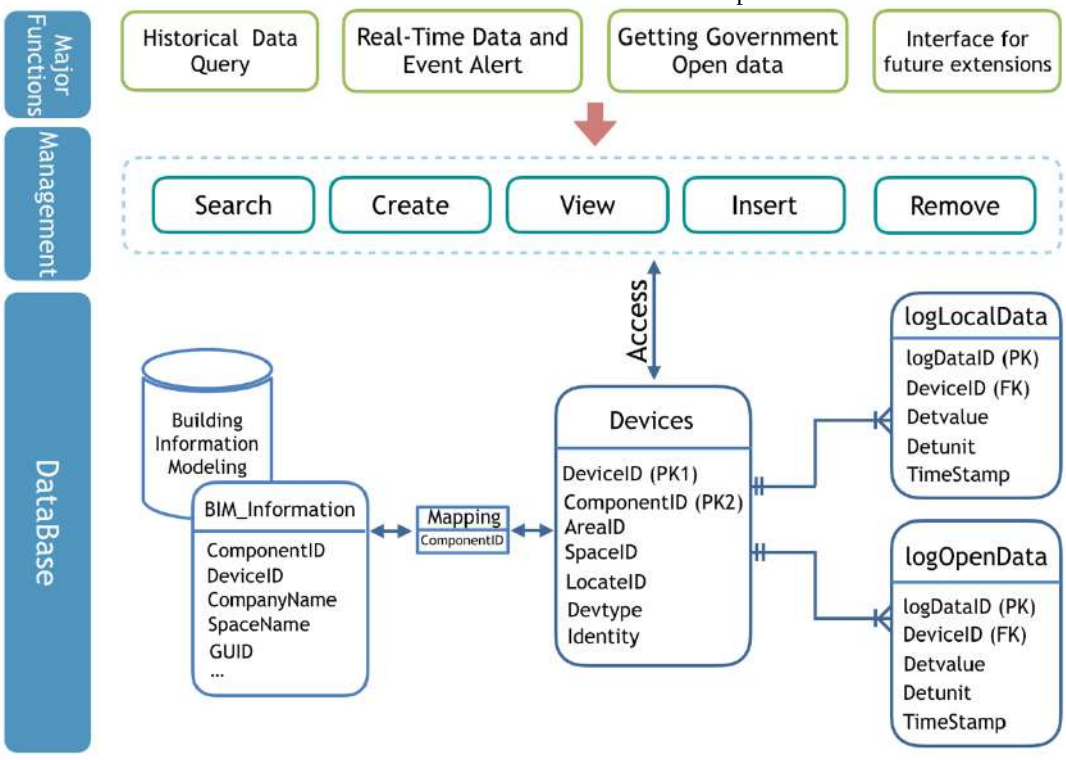

Figure 2. Data Management

locations and improve data readability. Block D records the logs of all system activities for system and data security. Block E shows the real-time data plots from the selected data source so that the user can monitor if the data remain within the normal range. This block provided the capability functions of prediction or historical data review. Block F reports the current overall status of the construction site based on all of the available data.

The dashboard interface for construction site status is shown in Fig.4, which has three blocks. Block "a" is an online building model viewer allowing users to query information about building objects and check the construction schedule. Also, the user can easily visualize the locations of the sensors in the model. Block "b" plots history data for the selected sensor, shows the location of the construction site on Google Earth, and the overall index of site conditions for construction tasks. Block "c" shows the navigation tools for viewing the model and its attributes, and users can use them to modify, explore and query more information from the model.

3.2 App software for information query

The design of an App software for the platform is for helping site managers to quickly find and visualize needed information. The App connects to the web server built by Forge and put the building model on the frontpage (see the block a in Fig.5(a)). Moreover, the block b on the frontpage is associated with environmental data. When any abnormal value of the monitoring data is detected, the user is alarmed (see the block b in Fig. 5(a)) and the level of impact by different environmental properties is visualized by colors. If the users need more detailed information, they can use the menu provided (see Fig.5(b)) to get the information. In addition, Fig. 6 shows the page displaying detailed information on some environmental aspects.

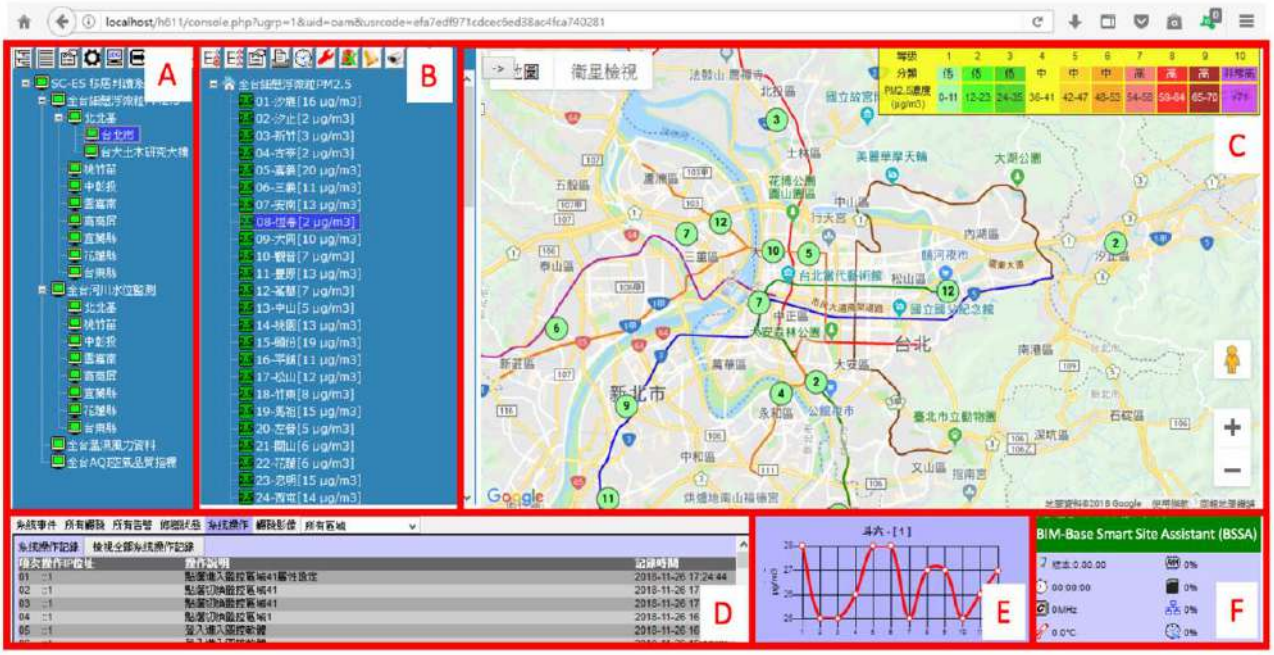

Figure 3. GUI for Central Control Management

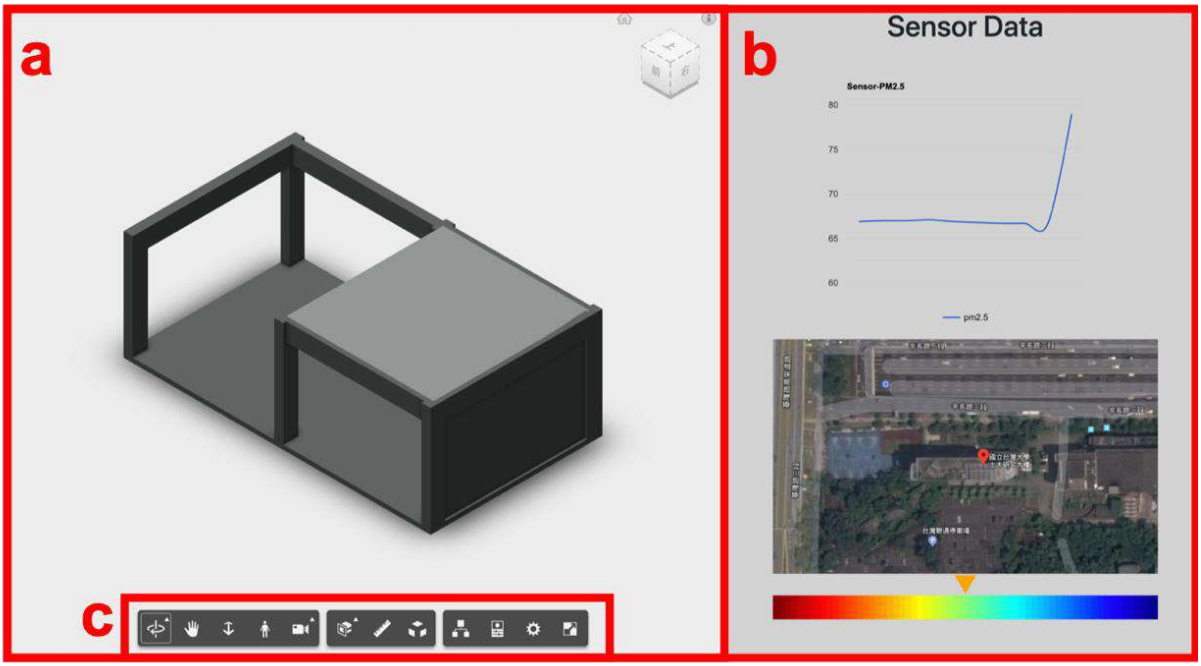

Figure 4. Construction Site Status Dashboard

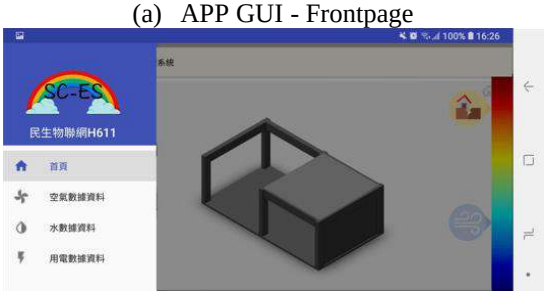
(a) APP GUI - Frontpage



(b) APP Menu Interface

Figure 5. App User Interfaces

Figure 6. Data Screen

3.3 Platform Demonstration

The demonstration of the platform can be summarized by 6 steps (see Fig. 7):

Step 1: From the GUI provided by the central control page, the user can select first the construction site from the map and its nearby sensor data from the catalogue of government open data (e.g.

those from Civil IoT Taiwan database). Then, the system will display the data retrieved on screen using a data synchronization engine.

The user may use the Google map interface to interactively examine the sensors and retrieve their monitoring data with colour indicators for easy identification of the conditions detected by the sensors.

Step 2: The user may zoom in and out the location of a construction site and examine the sensors around the site and their data.If the user selects the location icon of the construction site from the map, the platform displays the BIM model of the site on the screen.

Step 3: The user may select a specific data source (e.g. monitoring sensors) for detailed examination of its data. The source can be either from the Civil IoT Taiwan services or one of those sensors installed on the construction site. With the data from all related sources and sensors, the data-analysis engine of the platform provides analyzed data for the site manager to make decision on construction management tasks.

Step 4: When the platform detects abnormal data, it alerts the user to take proper actions.

4 Conclusion

This paper presents an effort on designing a cloud-based data management framework for integrating government open data and local monitoring sensor data for construction site management. The framework consists of two major parts: one for managing local sensing data with IoT sensors and edge computing devices; while the other one for managing 3D BIM model information and government open data with a cloud database and a web server. A BIM-based platform for facilitating smart site management has been prototyped based on the framework. Although the present effort is just a preliminary one and requires more work on the development and testing of the prototype platform, the preliminary results have shown promising feasibility of the proposed framework for assisting smart construction site management.

Abstract –

Thanks to the digital representations provided through Building Information Modeling (BIM), successful adoption of emerging digital technologies have been increasingly reported within the constriction and facility management research community. On the other hand, the number of research studies exploiting the principles of the Internet of Things (IoT) to enhance automation and control for the existing construction and facility management systems has been increasing within the last decade. By realizing the ample opportunities that can be seized through a combination of IoT and BIM, researchers have started to explore the potential benefits of BIM-centered IoT deployments. In this light, this paper aims to report the sate-of-the-art research trends for creating integration between BIM and IoT. To this end, relevant studies have been carefully reviewed to highlight the previously used sensing technologies, IoT communication protocols, BIM-centered middleware components and their ultimate application scenarios. Moreover, some of the key opportunities available through technological advancements in both IoT and BIM disciplines, along with the major open challenges threatening successful implementation of IoT-enabled BIM systems are highlighted in order to provide suggestions for future research directions.

Keywords –

Building Information Modeling (BIM), Internet of Things (IoT), Sensing technologies, BIM-centered IoT, Facility management, Construction 4.0

1 Introduction

Within the last few decades, successive waves of technological advancements have brought about the rise of the so-called 4th industrial revolution. The ultimate vision of this revolutionary movement is to blur the boundaries between physical and digital environments. The internet of things (IoT) plays a pivotal role in shaping this revolution. IoT can be viewed as networks of interconnected objects (e.g. sensors, actuators, machines, etc.) allowing real-time communications between those objects as well as communication with computer applications. Such a connectivity could significantly enhance automation and remote control of "things". Since sensors and actuators are increasingly improving in terms of power, cost, and size, more and more industries are encouraged to deploy IoT solutions [1]. The Architecture/Engineering/Construction and Facilities Management (AEC/FM) industry has been no exception to this emerging trend. Yet, according to a recent industry report published by World Economic Forum [2], this sector has been markedly slow to find its way into the mainstream of the 4th industrial revolution. This is, for the most part, due to legacy IT systems and highly fragmented nature of the construction industry.

Recently, the emergence of Building Information Modeling (BIM) has boosted hopes for expediting shifts towards a digital era for the construction industry. We have been witnessing a proliferation of research efforts for BIM during the last two decades. On the other hand, a brief look at the latest research trends reveals that there exists a growing interest among researchers to explore the potential values of the integration between IoT-driven solutions and BIM. As two emergent and fast developing technological breakthroughs, IoT and BIM offer countless opportunities for enhancing the current status of the AEC/FM industry. Evidently some of their key benefits cannot be easily achieved by approaching them separately. In this light, the research community has started paying an increasing attention to the integration of BIM and IoT. Consequently, the number of proposed BIM-centered system architectures built upon the principles of Industry 4.0, IoT, and Cyber-Physical Systems (CPS) has been rapidly growing.

This paper reviews those previous studies that have been conducted with the particular purpose of creating fusion between IoT and BIM in AEC/FM settings. By conducting this literature review, the authors pursue three main objectives: (i) identifying commonly used IoT enabler technologies that have been successfully combined with BIM-centered middleware and their

corresponding domain applications, (ii) Investigating key opportunities currently available to be exploited for increasing the benefits of IoT-enabled BIM systems, and (iii) highlighting the current and future challenges for designing effective orchestrations of BIM and IoT deployment for the construction industry.

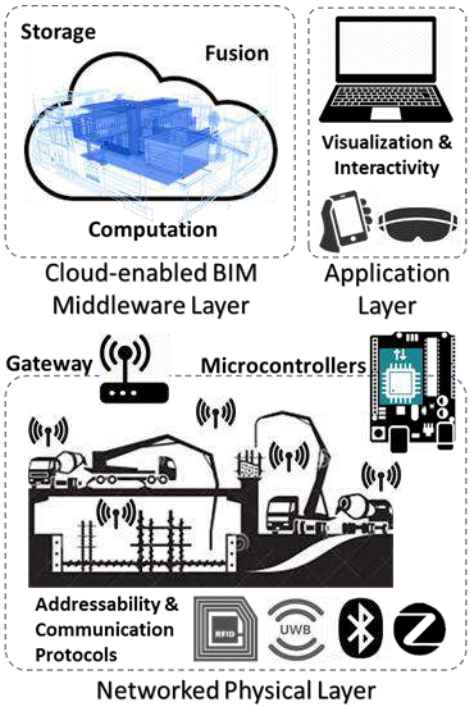

Figure 1. Conceptual framework of generic BIM-centered IoT architecture

2 Methodology

As the primary objective of this review article was set to put the current and future issues related to IoT-enabled BIM architectures into a broad perspective, the authors followed the principles of writing a narrative literature review [41]. The narrative overview presented here does not include the critique for each study reviewed. The following provides the reader with the delineation of how the present review has been conducted.

The main sources of information for this review have been selected by searching through two reputable electronic research databases namely as Science Direct, and, ASCE Library. The Google Scholar search engine was also used to ensure a reasonable breadth of potential articles. Accordingly, the three main high impact journals which together account as the primary source for the majority of the reviewed articles were: Automation in Construction, Advanced Engineering Informatics, and, Journal of Construction Engineering and Management. Moreover, in order to benefit from the knowledge in the electrical and electronics engineering domain and to bring a balanced perspective to the research issues regarding IoT development, IEEE Xplore database was also used.

The search keywords fall into two main groups each related to one of the main concepts of our primary interest. The terms within the first group which referred to the notion of BIM were: "Building Information Modeling", "BIM", and "BIM tools". The keywords within the second group indicating to IoT were: "Internet of Things", "IoT", "Cyber-Physical Systems", "Sensors", "Wireless Sensor Networks", "WSN", "Sensing devices", and "Remote sensing". Different combinations of keywords from both groups were used to find articles relevant to BIM-centered IoT architectures.

Finally, the main selection criteria applied to include/exclude searching results from the review was to make sure that the research efforts reported in the searched studies have been dedicated to the creation of a seamless integration between BIM platforms and sensing devices/networks. Respectively, the selection process was done by carefully and critically reading the methodology (or architecture description) sections of the papers found within the databases. The publication time spectrum of the final candidate studies to be included in our review spans between 2011 and January of 2019.

3 State-of-the-art Research Trends

In order to create a shared sense of what is intended by "BIM-centered IoT deployment" in this paper, we present a broad definition of it on the basis of various definitions of IoT provided in [3]: remote sensing and control of physical objects within a construction site or an existing facility through seamless communication of real-time data with BIM as the unifying framework. In that sense, for the search terms used for this review, in addition to "Internet of Things", other relevant terms such as "Cyber-Physical Systems" and "Wireless Sensor Networks" have been considered in combination with "BIM". Hence, frameworks such as those presented in [4] and [5] which bear close correspondence to the aforementioned definition have been included in our review, though no explicit indication has been made in them to the IoT concept. Moreover, the reader should bear in mind that among existing studies with the main theme of BIM-centered IoT exploration, this review mainly deals with the most recently published ones. A conceptual framework for the generic BIM-centered IoT deployment scenario is shown in Figure 1. As it can be seen, the framework is basically divided into three main

layers. The following is a summary of the state-of-the-art research trends for the architecture of our interest. Selected studies for this review are presented by taking into account the essential elements of the three layers depicted in Figure 1.

3.1 Networked Physical Layer

This layer consists of a network of physical entities which could be prefabricated building components [6], construction machinery [7], facility assets [8], [42], construction wearables [9], etc., as well as various sensor devices. Such connected entities are basically capable of communicating data with each other and to the edge of the network (to an IoT gateway for instance) in a real-time manner. In a broad sense, this layer is responsible for collecting information about physical objects and their surroundings and transferring the information to the BIM-centered middleware layer for further processing. This is done with the aid of one or more sensing technologies embedded within the network architecture. The choice for the appropriate sensing technology used in this layer depends on various factors such as the type of information that is of interest to be collected and transmitted, the rate of power consumption, implementation cost, required communication range, etc. Collected information can be about environmental conditions in construction workspaces [9], real-time location of construction workers [10], motion and orientation of building components [11], or any other useful data which could enrich the BIM model for future use. The information collected within the network is then transmitted over one or more communication medium (IoT protocols). A quick glimpse of previous proposals reveals that RFID-enabled short range communication has been the most frequent option for communicating IoT data to the BIM-centered layer. This is no surprise since RFID has been traditionally a key technology used for bringing physical objects into the digital realm through a short-range point-to-point wireless communication. Additionally, RFID tags attached to physical objects can act as distinct identifiers of those objects making them addressable within the network. Most recently, an extensive review of RFID-enabled BIM systems has been appeared in [12]. Hence, for this review we tried to include other studies that have exploited sensing technologies other than RFID and the interested reader is referred to the mentioned study for deeper insights about RFID-enabled BIM architectures. One of the emergent IoT-enablers which appears to be gaining in a rising popularity among researchers is Bluetooth Low Energy (BLE) technology, also known as Bluetooth Smart. The seminal work of Park et al. [10] is one of the pioneering examples of integrating a BIM-based system with BLE sensors used for fostering real-time location-awareness of construction workers. More recently, Teizer et al. [9], made the case for BIM-based visualizations of data about environmental conditions and workers' location in a real-time manner, with the aid of BLE beacons installed to their hard hats. Zigbee [13], is another emergent wireless communication standard famously known by its low-cost and low-power consumption rates. In [14], for the purpose of environmental monitoring of working conditions in confined spaces, researchers have developed a prototype of self-updating BIM system consuming sensor data coming from TelosB mote based sensor network which works on IEEE 802.15.4 standard (the basis for the Zigbeee specification). Another application of Zigbee-based sensor networks has been reported in [15]. In that study, the sensor network has been integrated with a multi-agent software system capable of interacting with BIM models on the basis of IFC schema to support facility management. The low data rate of indoor thermal comfort monitoring has convinced the researchers in [16] to choose Zigbee as the appropriate wireless technology for receiving and sending temperature and humidity readings to be imported into the BIM-based model of subway spaces. Despite the increasing number of studies exploiting recent sensing technologies, RFID still remains as the dominant technology used in combination with BIM systems. More discussion of opportunities available through advancements in WSNs and emergent protocols for network-based communications is given in the coming sections.

3.2 BIM-centered Middleware Layer

The main responsibility of this layer is to receive the information collected from the previous layer to be aggregated with BIM models. As depicted in Figure 1, this layer is expected to deliver three main functionalities namely as: storage, data fusion, and computation. For storage, sensor readings must be linked to a database which can be separated from or integrated with the BIM database. Since a typical IoT deployment most often encompasses multiple and heterogeneous sensing nodes, a communication medium will be needed for aggregating the multiple streams of sensor readings. To this end, an IoT gateway must be set up in order to acquire sensor datasets and prepare them to be processed and conveyed to the BIM model. As most of the reported deployments in previous studies are prototype systems, the most frequent medium used as an IoT gateway has been personal computing devices such as laptops or smartphones. In [12] for instance, with the help of an android application a smartphone was turned into an RFID-to-BIM gateway. Nevertheless, for real-world production implementations cheaper and less power-consuming computing devices such as Raspberry

pi microprocessors used in [17] will be the ideal choice for the IoT gateway. Parallel with data storage, developing intelligent data fusion algorithms will be of high importance for the realization of an effective integration of IoT and BIM data. An effective data fusion scheme allows for making sense of sensor readings streaming from multiple sources, and also dealing with almost inevitable imperfections in sensor data. Although provision of such fusions will ultimately result in producing more accurate and consistent sensing data to be aggregated in BIM models, it has not been adequately investigated within the previous studies. One of the few examples in this respect can be found in [18] where a knowledge-based approach consisting of pre-defined rules has been taken to create fusion between data coming from Bluetooth beacons and motion sensors with building's geometric information. Obviously, an intelligent information fusion requires some computational power which will be provided through the third main functionality of the middleware layer: computation or data processing. It serves for data integration, automated decision-making, and action-invoking on the basis of information received from the networked physical layer and a pre-established knowledge layer. Such computational power is also essential to a proper responding to the queries raised in the application layer.

3.3 Application Layer

This layer provides BIM-based visualizations of sensing data and an end-user access to the information contained in the BIM model that has been enriched with IoT data. The most significant feature of such data access is that the needed information is retrieved in a real-time manner. This layer makes it possible for end-users to seamlessly interact with the physical layer objects through a digital interface linked to IoT actuators/microcontrollers in the networked physical layer. Actuation could be done automatically from computation module in the middleware, asked from the user for confirmation at the application layer's interface, or triggered manually by the end-user at the application layer. Various digital devices such as personal computers, smart mobile devices, and wearable computers, can provide BIM-based visualizations and the interface between the end-user and the IoT-enabled BIM system.

Since, BIM models are typically responsible for IoT data visualizations, any computing device capable of running the BIM authoring software will be a potential medium for enabling BIM visualizations that have been augmented by real-time sensing data. For example, an Ultra-Mobile Personal Computer showing the 3D BIM-model and sensor-based visualization of construction objects has been used in [7]. In [4], results of indoor localization estimations over location sensing data were visualized in a BIM authoring tool available on any computing device. By integrating fire simulations and real-time feedback information streaming from IoT sensors about the fire scene conditions, a BIM-based fire visualization and warning system for rescue planning has been realized in [19]. Another similar example of IoT visualizations in BIM software can be found in [9].

There are several application areas that have been investigated in previous studies for BIM-centered IoT architectures. Safety management has been one of the most frequent application areas reported for both construction and facility management. Accordingly, a significant portion of previous relevant studies have attempted at combining BIM-based architectures with sensor-based safety monitoring systems. In [7] for example, researchers developed a tower crane navigation system which is capable of visualizing lifted objects in the context of 3D BIM models of the under-construction building and its surroundings. Other studies have been published with the main focus on fire related safety issues [17], [19], [4]. There have been also studies investigating construction workers' safety through real-time monitoring of construction working conditions [14], [9]. Most recently, interesting application scenarios have been proposed in the context of construction 4.0. For instance, with respect to intelligent decision making for construction activities (site planning, workflow logic, etc.), application of cyber-physical systems has been proposed for enabling real-time communications among BIM-based virtual models, physical construction entities, and pre-existing knowledge bases [20], [21]. Prefabricated construction is another interesting area that researchers have contributed to by integrating BIM with sensing technologies. In [22], by developing an IoT-enabled platform established upon a BIM-based infrastructure, RFID- and GPS-based information made it possible to improve real-time traceability and visibility of the construction progress, physical building information, and cost related data in a prefabricated construction settings. Similar attempts have been reported in [23], [6], [17]. Finally, when it comes to operating facilities, energy use management and indoor comfort monitoring have been the most recurrent domain applications [16], [24], [25].

4 Opportunities

One of the most promising possibilities of the IoT solutions combined with BIM systems is that it paves the road towards creating more realistic "digital twins" for the built environment. Generally speaking, a digital twin is responsible for imitating the dynamic behavior

of a given physical system. Although various technical definitions of digital twin already exist within the literature, we have adapted the one which is of our particular interest on the basis of the definition provided in [26]: a virtual representation of building components, construction processes and maintenance operations through the streams of real-time data throughout the facility lifecycle, enabling understanding, learning and reasoning about various aspects of that facility.

Through provision of digital representations of facilities' physical characteristics and functionalities, BIM models have paved the road for realization of such "digital twins". By drawing an analogy between BIM and Product Lifecycle Management in the manufacturing industry, Woodhead et al. [27] indicated that strong ties can be expected between BIM and Industry 4.0. Real-world examples of such ties have been most recently reported. In [11] for instance, researchers have been able to provide a digital twin of hoisting operations in underground construction through BIM representations standing for the virtual model of hoisting and various IoT sensing devices fulfilling real-time communications between the physical and cyber twins. Another example is a prototype of RFID-enabled BIM system presented in [8] which could be deemed as a digital twin of inspection and maintenance tasks for building assets. The evolution of BIM along with the advances in Artificial Intelligence and real-time analytics can unlock profound possibilities for the creation of digital twins with enhanced predictive capabilities for the built environment [27].

Finally, thanks to an unprecedented amount of data about building components, indoor environmental conditions, construction resources, assets, etc., that can be collected and integrated with BIM models for further processing, BIM-based immersive technologies can be more effectively deployed for AEC/FM applications. In other words, the more realistically digital twins are created for construction sites or operating facilities, the more enhanced and rich immersive experiences can be provided accordingly. Since many successful implementations of BIM-based immersive solutions such as Augmented and Virtual reality have been reported within the last two decades [28], the combination between BIM and IoT can significantly improve the effectiveness of such immersive experiences with the aid of real-time sensing data aggregated to BIM elements.

As an emerging technology, IoT can be viewed as a fast progressing filed of technology. As it was mentioned in section 3, application of RFID technology as a primary enabler of IoT has been proliferated within the existing body of knowledge. Nonetheless, owing to the continuous advancements in IoT, especially in wireless communication technologies, new opportunities are open for designing novel architectures of IoT-enabled BIM systems. Although the number of studies investigating relatively recent communication protocols such as BLE is increasing, the research community has been slow to adopt more recent advancements such as Zigbee and Lora. Hence, future research should pay more attention to this issue because such advancements most often offer new features and tackle some of the existing limitations. For the case of Zigbee for instance, the technology has already demonstrated an enormous potential for replacing traditionally used communication technologies for enabling indoor automation such as WiFi, by delivering similar functionalities at a fraction of cost and power consumption. Additionally, plenty of opportunities can be seized through developing hybrid architectures which exploit different IoT technologies within a single architecture. One prospective scenario in this regard can be explained as follows: while Zigbee will be an excellent choice for those indoor applications requiring low-rate data transitions (indoor comfort monitoring for example), it will not fulfil the requirements of the applications used in construction job-sites which generally require long range data communications. This is where adding a Lora-based module can properly address the limitation of Zigbee for long range communications. A review of Lora-based communications has been most recently reported in [29]. In summary, more experimental research should be conducted in the future to explore the potential benefits of integrating BIM systems with standalone or hybrid solutions based on emerging IoT-enabler technologies.

One of the major technological breakthroughs that has hugely contributed to the success of IoT is cloud computing. The integration of cloud computing and IoT promises new directions for both business and research [30]. Cloud computing also has made significant positive impacts on BIM. Therefore, it can be expected that the combination of cloud-enabled BIM with IoT could unlock ample opportunities for the construction industry. Such opportunities have been already realized by researchers in the construction sector for enabling more efficient procedures for storage, fusion and processing of IoT data. The cloud server used in [10] for example, has enabled a real-time communication of safety-related contextual information between a BIM-based hazard detection system and mobile devices of project participants. The generic concept of the IoT-cloud-BIM intelligent system has been thoroughly discussed in [31]. A cloud-based IoT platform has also been proposed in [23] for improving the leanness of prefabricated construction. Other examples in this regard can be found in [32], [17], and [33].

5 Challenges

IoT currently faces many challenges in general as an emerging and progressing technology. On the other hand, an effective adoption of BIM for AEC/FM has its own challenges as well. Hence, it can be expected that not only challenges facing IoT and BIM remain to be addressed individually, but also new challenges could rise when the integration of the two is considered.

Security is one of the most significant challenges for the IoT in general. IoT security can be broadly described as making sure that information about physical objects and properties collected from the networked layer is transmitted to the pre-assigned destinations. Encryption which has been the key approach to the Internet security can be also used for establishing secure communications between IoT nodes. However, currently available encryption methods are not adequately efficient to be used for addressing the IoT security [34]. In addition to security, privacy is another important issue in IoT. Generally speaking, IoT privacy deals with the ownership issues of data collected form the physical layer. In the context of IoT-enabled BIM solutions, privacy issues could constitute serious impediments to the proliferation of such systems. This is mainly due to the fact that the construction industry is fragmented in nature and different parties are typically engaged within it. From a business standpoint, aggregation of real-world data into BIM models could give rise to serious conflicts about data ownership rights between stakeholders since the construction sector has been traditionally reluctant to embrace the open data sharing culture. For instance, most of the constructor companies prefer not to share productivity-related data about their workers and machinery with other project participants (client, consultants, etc.), because it might help them for making financial claims. All in all, despite the fact such issues play a major role in shaping shifts towards digital construction and maintenance of facilities, the number of existing studies that put security and privacy issues at the center of attention for BIM and IoT integration are extremely low. Recent technological advancements in the internet security, such as Blockchain technology promises new opportunities for addressing such issues for IoT-enabled BIM systems. In this regard, Ye et al [35] have presented a theory named "Cup-of-Water" which suggests the application of Blockchain technology to securely and transparently preserve IoT data in BIM models during the whole life cycle of buildings.

In addition to challenges which are generally applicable to any IoT deployment, there exists other challenges which are specific to the BIM-centered IoT deployments. For instance, one of the main challenges of creating a seamless integration between BIM and IoT is to fill the gap between currently used schemas for BIM data representation such as IFC, and various IoT standards used for representing sensor data. To date, some attempts have been made to address this issue. Although IFC representations can greatly facilitate interoperability between various BIM platforms, mapping sensor data to IFC objects will be challenging if standardized IFC export guidelines and corresponding web parsers are not placed within the architecture in advance [36]. This issue has made the case for creating more semantically enhanced versions of IFC schema to provide the required readiness for integrating sensor readings with BIM models. In [8] for instance, the EXPRESS-based model of IFC schema has been edited manually to make allowance for interrelating BIM entities with RFID data. On the other hand, distributed and heterogeneous sources of IoT data streaming from the physical layer also urge the need for more semantically enriched IoT and BIM data representation schemas if an advanced information fusion is required. In this light, applications of formal data and knowledge representation methods have been proposed within the previous studies. In some studies such as those reported in [15], [20], and [37], researchers have attempted to exploit the formal representation capability of formal ontologies to address the sensor data integration with digital models of buildings. Most recently, results coming from real-world experimentations in [36] confirms that the open BIM paradigm holds the promise of improving the interoperability of IoT-enabled BIM deployments. Moreover, Semantic Web [38], Linked Sensor Data initiatives such as the SSN ontology [39], and Linked Building data initiatives such as ifcOWL [40] will open the door to more machine-understandable description of IoT data and more interoperable BIM-centered architectures.

6 Conclusion

This review article reported on the recent studies deploying BIM-centered IoT architectures in AEC/FM disciplines. The state-of-the-art research trends were highlighted in three main respects. First, previously used sensing technologies and network communication protocols were introduced. Next, key components of a BIM-centered middleware for an effective IoT-enabled implementation were discussed. Finally, those application areas that have reportedly benefitted from such fusion in the past, were also identified in this review.

The integration between BIM and IoT offers huge potentials for fundamentally altering the ways by which construction activities and maintenance of operating facilities are currently done. The primary promise of an IoT-enabled BIM solution is to bridge the real world construction sites and operating facilities to digitally

represented models. This could remarkably contribute to joining the mainstream of the paradigm shift toward digital construction era through the possibility of creating more realistic digital twins of construction job sites and operating facilities. Such digital twins can also improve the effectiveness of utilizing other digital technologies such as virtual and augmented reality for the built environment. In the light of technological advancements in IoT networking, wireless communications and the emergence of innovative breakthroughs such as cloud computing and the Blockchain technology, more and more opportunities will be available to be exploited for enhancing the usefulness of IoT-enabled BIM systems in practice.

As this review showed, there exists a significant gap between current research efforts done and unlocking the full potential of IoT-enabled BIM systems to move towards a more digitally-enabled construction and facility management paradigm. Since the integration between IoT and BIM is still in its early stages, much research is still required to be done in order to overcome the current and future challenges. This includes but is not limited to adding more intelligent information fusion algorithms, knowledge representation and inference capabilities, and developing open standards and platforms that secure information exchange and ubiquitous compatibility across various BIM environments. Moreover, the fragmented nature of the construction industry which involves participation of different role players urges for more profound investigations over security and privacy issues for IoT-enabled BIM deployments. This will encouragingly increase the willingness of industry practitioners to take steps towards such seamlessly connected solutions.

By grasping the available opportunities and overcoming the key challenges mentioned in this review, it can be expected that more and more leaders within the construction industry will be encouraged to fully embrace digital transformation and put steps towards this inevitable entirely new paradigm.

Abstract –

Preventing natural disasters from causing substantial social-economic damages relies heavily on the disaster resilience of the nation's critical infrastructure. According to the National Academy of Sciences, research on understanding and analyzing the disaster resilience of our infrastructure systems is a "national imperative". To address this need, this paper proposes an automatic keyphrase extraction methodology to extract relevant phrases on disaster resilience from documents in infrastructure domain. In developing the proposed methodology, a document collection including research papers and public reports are prepared. Noun phrases are first extracted from every sentence in the collection and form the candidates for keyphrases following a filtering procedure. Each candidate phrase is then represented as a global semantic vector and a local semantic vector. To select relevant phrases on disaster resilience, a semantic similarly measure is proposed to incorporate the semantics of candidate phrases in both the general and infrastructure domain. Ten physical resilience concepts from a pre-developed community resilience hierarchy is selected as the target concepts to evaluate the performance of the proposed methodology. When evaluated on the document collection, the proposed methodology achieved 66% of precision at top 20 extracted keyphrases on average.

Infrastructure disaster resilience; Automatic keyphrase extraction; Natural language processing

1 Introduction

Preventing natural disasters from causing substantial social-economic damages relies heavily on the disaster resilience of the nation's critical infrastructure. U.S. National Academies has defined resilience as "the ability to prepare and plan for, absorb, recover from, and more successfully adapt to adverse events" [1]. At present, United States is in dire need of resilient infrastructure systems as its physical infrastructure is aging and deteriorating. On this context, a report published by the National Academy of Sciences has defined the research on understanding and analyzing the disaster resilience of our infrastructure systems as a "national imperative" [1]. To facilitate infrastructure disaster resilience, one major prerequire is to understand disaster resilience in a more explicit and deep manner. Existing research typically provides conceptual or theoretical framework that identifies some key characteristics (e.g., robustness, redundancy) of disaster resilience without directly linking them to more detailed and specific concepts. There is, thus a need to analyze the vast amount of text documents (e.g., reports, papers, news articles) on disaster resilience to facilitate a better understanding on the definition, interpretation and classification of disaster resilience in the infrastructure domain.

To address this need, this paper proposes a methodology that automatically extracts keyphrases about disaster resilience from documents in the infrastructure domain. Extracted keyphrases can provide highly condensed and valuable summary of disaster resilience in the infrastructure domain. The proposed methodology and the extracted keyphrases could facilitate the information and knowledge management of disaster resilience, such as the preparation and development of disaster recovery/resilience guidance manuals, and the retrieval of disaster recovery/resilience best management practices. The remainder of the paper discusses about the background and knowledge gaps, presents our proposed methodology, and analyzes the experimental results.

2 Background and Knowledge Gaps

Automatic keyphrase extraction is the process of selecting important and topical phrases from the body of

a document [2]. Keyphrase extraction starts with identifying a list of candidate phrases using some heuristics rules, which rely on syntactic features like part of speech tags, and/or statistical features like the frequency of n-grams [3]. There are commonly two different approaches to determine which candidates are correct keyphrases: supervised and unsupervised approaches. Supervised approaches utilize supervised machine learning algorithms to learn how to extract keyphrases from pre-labeled training documents and formulate the keyphrase extraction task either as a text classification problem or a sequence labeling problem [3]. For example, John et al. [4] presented a multi-feature supervised automatic keyphrase extraction system which uses a combination of statistical, linguistic, syntactic, semantic, and topic-based features with a Random Forest classifier. Zhang et al. [5] proposed a deep recurrent neural network (RNN) model that jointly extracts and ranks keyphrases from tweets based on keywords and context information.

As labeled training documents can be hard to obtain, unsupervised approaches have also been widely adopted, which commonly identify keyphrases using graph-based ranking method or topic-based clustering method [3]. For example, Liu et al. [6] proposed the topical PageRank (TPR) model, which decomposes traditional PageRank into multiple topic-specific PageRanks and extracts keyphrases based on their importance scores to different topics. Mahata et al. [7] proposed the Key2Vec model which trains multi-word phrase embeddings as thematic representation of scientific articles and ranks extracted keyphrases using theme-weighted PageRank algorithm.

Despite the above-mentioned research efforts, two major knowledge gaps for automatic keyphrase extraction have been identified: (1) most of the research works focus on extracting keyphrases from scientific papers or social media posts and have not yet been evaluated on public reports. Public reports are documents developed by public agencies such as department of transportation, metropolitan planning organization, and emergency management department. Public reports provide us an opportunity to understand the view of disaster resilience from public agencies perspective; (2) most of the existing works rank the importance of candidate phrases based on statistical and document structure features, which has limited capability to incorporate the semantics of candidate phrases into the evaluation process.

3 Proposed Automatic Keyphrase Extraction Methodology

To address the above-mentioned knowledge gaps, the paper proposes an automatic keyphrase extraction methodology that extracts relevant phrases on disaster resilience concepts from documents in infrastructure domain. In preparing the document collection, public reports developed by important agency stakeholders during the infrastructure planning and design process were collected in addition to scientific papers. When identifying keyphrases for disaster resilience concepts, a semantic similarity measure is proposed to capture the semantics of candidate phrases in both the general and infrastructure domain. The proposed methodology includes six primary tasks: data collection, data preparation, reference hierarchy selection, candidate phrase extraction, and keyphrase ranking.

3.1 Data Collection

To create a document collection, the keyphrase "infrastructure disaster resilience" was used to search for scientific papers and public reports from search engines including Google and Google Scholar. The titles of the public reports and scientific papers collected are shown in Table 1 and 2. In total, the document collection contains 11 public reports developed by 8 agencies, and 8 scientific papers. For each paper or report, the original pdf file was first converted to a txt file. Only the textual contents in the main body were kept excluding the figures, table of contents, references, and appendix.

3.2 Data Preparation

To prepare for the implementation of keyphrase extraction, each document in the collection is divided into individual sentences based on sentence boundaries, such as period, question mark, and exclamation mark. Each sentence is further divided into individual tokens (e.g., words and punctuations), and every word is converted into its lowercase form. Lemmatization is then conducted to remove inflectional endings of a word, and return its base or dictionary form, which is known as the lemma. For example, after the lemmatization, the words "rebuilds", "rebuilt", and "rebuilding" would all be transformed into their lemma "rebuild".

3.3 Reference Hierarchy Selection

In order to identify keyphrases relevant to disaster resilience, a reference concept hierarchy is used to provide additional semantic information for the keyphrase ranking process. As there is no existing concept hierarchy available for the infrastructure disaster resilience, the community disaster resilience hierarchy (taxonomy) developed by Taeby and Zhang [8] was selected due to its similarity to the domain. As shown in Figure 1, the selected reference hierarchy includes 29 practices (R1 – R29) to enhance the disaster

resilience in residential communities.

3.4 Candidate Phrase Extraction

The Stanford CoreNLP toolkit [9] is used to extract all the noun phrases in each sentence from the collection. The following actions are then adopted to filter the extracted noun phrases:

- Remove the starting token of a noun phrase, if it (1) is a determiner (e.g., "a", "the", "this", and "that"); (2) is a number; or (3) belongs to a standard list of English stop word
- Remove all single-word noun phrases
- Keep only the unique phrases

After the filtering procedure, the resultant noun phrases form the list of candidate phrases. For example, for the sentence "these critical facilities include water and power lifeline, acute-care hospital, and organization that have the responsibility for emergency management at the local community level", the candidate phrases extracted are "critical facility", "water and power lifeline", "acute-care hospital", "emergency management", and "community level".

3.5 Keyphrase Ranking

To select phrases relevant to disaster resilience, a candidate phrase p_i is first represented as a global semantic vector $\widehat{V_i}$ and a local semantic vector V_i. A semantic vector is a real-valued vector of features that characterizes the meaning of a candidate phrase. A global semantic vector represents the contexts in which the candidate phrase appears in the general domain corpus. The global semantic vector is the weighted aggregation of the global word embeddings of its terms.

$$\widehat{V_i} = \{\cup_{j=1}^{m} w_j \hat{E}(t_j)\} \quad (1)$$

As per Equation (1), $\hat{E}(t_j)$ is the global word embedding for term t_j, w_j is the weight term of t_j, and m is the total number of terms in phrase p_i. For each term, the global word embedding is obtained from the pre-trained Fasttext embeddings on Wikipedia [10]. An entropy-based weight is adopted to accommodate terms with different contribution to the semantics of a candidate phrase. As per Equation (2) [11], $P(t_j|D_B)$ is the probability of the term t_j appears in the background sentences, and $P(t_j|D_T)$ is the probability of the term t_j appears in the thematic sentences. To differentiate thematic sentences from the background sentences, a set of keywords represent the concepts from the reference hierarchy was created. If the sentence contains any of the pre-defined keywords, it would be considered as a thematic sentence, otherwise a background sentence. When forming the global semantic vectors, common terms (words have similar probabilities to appear in both background and thematic sentences) would have lower weights and distinctive terms (words have very different probabilities to appear in background and thematic sentences) would have higher weights.

$$w_j = -P(t_j|D_B)\log\left(P(t_j|\,D_B)\right) - P(t_j|D_T)\log\left(P(t_j|\,D_T)\right) \quad (2)$$

A local semantic vector represents the contexts in which the candidate phrase appears in the domain-specific corpus. For a candidate phrase p_i, its local semantic vector V_i is defined in Equation (3), where $E(p_i)$ is the multi-word phrase embedding directly obtained using Fasttext embedding model [10] trained on the document collection. During the training process, a candidate phrase is treated as a single token and added to the vocabulary of the embedding model, a multi-word phrase embedding can thus be obtained directly without aggregating embeddings from term level.

$$V_i = E(p_i) \quad (3)$$

To select the keyphrases relevant to disaster resilience, a semantic similarity measure is proposed to incorporate the semantics of candidate phrases in both the general and infrastructure domain. For a candidate phrase pi and a concept c_k in the reference hierarchy, their semantic similarity $SS(p_i, c_k)$ is defined in Equation (4), where $\hat{S}(p_i, c_k)$ is the global similarity and $S(p_i, c_k)$ is the local similarity.

$$SS(p_i, c_k) = \hat{S}(p_i, c_k) + S(p_i, c_k) \quad (4)$$

The global similarity measures the semantic similarity between pi and c_k in general domain. As per

Equation (5), the global similarity $\hat{S}(p_i, c_k)$ is defined as the cosine similarity between $\hat{V}_i$ and $\hat{V}_k$, which are the global sematic vectors of p_i and c_k respectively.

$$\hat{S}(p_i, c_k) = \frac{\hat{V}_i * \hat{V}_k}{||\hat{V}_i|| * ||\hat{V}_k||} \quad (4)$$

The local similarity between pi and c_k measures their semantic similarity in the infrastructure domain. As per Equation (6), the local similarity $\hat{S}(p_i, c_k)$ is defined as the cosine similarity between V_i and V_k, which are the local sematic vectors of p_i and c_k, respectively.

$$S(p_i, c_k) = \frac{V_i * V_k}{||V_i|| * ||V_k||} \quad (5)$$

3.6 Evaluation

All the bottom-level sub-concepts (R1 - R10) under physical resilience were selected as the target concepts for evaluating the proposed keyphrase extraction methodology. For each target concept, the top 20 ranked keyphrases were extracted based on their semantic similarities. The authors then evaluated each extracted keyphrase and determined its relevance to the target concept based on the majority votes. The performance of the proposed methodology was then evaluated using precision at top 20, which is defined as the ratio of the number of relevant keyphrases over the top 20 ranked keyphrases.

Table 3. Performance of the proposed methodology

Disaster resilience concepts	Precision at top 20	Example keyphrases
• System reliability (R1)	85%	• system robustness, utility system
• System integrity (R2)	55%	• building integrity, structural integrity
• System vulnerability elimination (R3)	65%	• direct vulnerability reduction, vulnerability assessment
• System substitution and redundancy (R4)	50%	• power supply redundancy, structural redundancy
• Emergency transportation support (R5)	15%	• emergency transportation lifeline safety plan, public transportation emergency relief program
• Recovery resource availability (R6)	75%	• recover service, traditional disaster recovery funding
• System repair and replacement (R7)	100%	• rapid repair technology, housing repair
• Shelter availability (R8)	30%	• emergency shelter, special need shelter
• Rapid response (R9)	100%	• emergency response time, emergency response personnel
• Damage inspectability (R10)	85%	• damage evaluation, damage detection technology

4 Experimental Results and Analysis

For each target concept, the performance of the keyphrase extraction and two example keyphrases extracted are shown in Table 3. The average precision at top 20 for robustness (R1, R2, R3), redundancy (R4, R5), resourcefulness (R6, R7, R8) and rapidity (R9, R10) concepts are 68%, 33%, 68%, and 93% respectively. The proposed methodology extracted much fewer relevant phrases on redundancy concepts compared with on other concepts. This indicates that the redundancy concepts are less domain-specific and have a high level of ambiguity. For example, the concept "emergency transportation support" has the lowest precision at top 20 (15%) among the 10 target concepts evaluated. Many phrases related to transportation system are falsely extracted as keyphrases, such as "mass transportation system", and "key transportation infrastructure". On the other hand, concepts "system repair and replacement", and "rapid response" achieved 100% of precision at top 20 because of the less ambiguity they have in the infrastructure domain. Overall the proposed methodology achieved 66% of precision at top 20 extracted keyphrases on average.

5 CONCLUSION AND FUTURE WORK

This paper presents an automatic keyphrase extraction methodology to identify relevant phrases on disaster resilience from documents in infrastructure domain. In developing the proposed methodology, each candidate phrase is represented as a global semantic vector and a local semantic vector. A semantic similarity measure is proposed to incorporate the semantics of candidate phrases in both general and infrastructure domain. When evaluated on the document collection, the proposed methodology achieves 66% on average in terms of precision at top 20 extracted keyphrases.

In the future work, the authors will continue to improve the current work in four directions: (1) conduct surveys or focus-group meetings with experts on infrastructure disaster resilience to further validate the keyphrases extracted; (2) evaluate the proposed methodology on more disaster resilience concepts with larger document collection; (3) investigate how the extracted keyphrases are similar or different between scientific papers and public reports; (4) explore how the extracted keyphrases could facilitate the automatic construction of disaster resilience ontology or taxonomy.

Abstract –

In recent years, researchers have relied heavily on data (historical and real-time) and digital solutions to support informed decisions. Consequently, data analysis has become an integral part of the design and construction process. Researchers spend a tremendous amount of time cleaning, organizing, and understanding the data. Artificial Intelligence (AI) can be used to help overcome human limitations in processing and enriching large volumes of data from a variety of sources. AI can encompass millions of alternatives for various design and project delivery solutions and ultimately improve project planning, construction, and maintenance and operation process. AI can be a solution to the severely under-digitized Architecture, Engineering, and Construction (AEC) industry, however, there are two challenges with respect to creating intelligent agents in AEC; (1) finding appropriate ways of gathering information from the environment and transforming them into internal context, and (2) selecting an appropriate AI technique to succeed in decision-making based on the relevant knowledge about the environment. This study focuses primarily on the second challenge by looking at potential applications of AI in AEC. The AI techniques in AEC can generally be classified into two main areas: (1) decision making methods and algorithms, and (2) learning methods. Regarding the first area, search methods and optimization theories are used when there is enough information to tackle decision-making and the problem is solved by the selection of the best action (with regard to some constraints and criteria) from a set of alternatives. The learning methods, on the other hand, are further classified into knowledge-based, reasoning, and planning methods (to learn how to adapt to changing conditions), learning probabilistic methods (e.g. Bayesian learning), and machine learning (e.g. supervised learning, reinforcement learning).

Keywords –

Artificial Intelligence Techniques; Artificial Intelligence Applications; Architecture, Engineering, and Construction Industry

1 Introduction

Artificial Intelligence (AI) is no longer a science fiction. AI is used advantageously in different industries such as healthcare, agriculture, finance, and banking industries. AI is already embedded in our lives in a wide range of applications such as Siri, Google search, smartphone, and Amazon recommendations. People might even not realize that they are using AI in their daily life. AI uses computer processing techniques to complete tasks that need human intelligence for learning or problem solving to make human-like decisions [1]. As a result, AI performs tasks faster and with a higher level of accuracy [2]. AI is transforming all segments of numerous industries. For example, in the agriculture industry, AI can help farmers know when to plant, water, harvest, or to produce more food and less waste [3]. In the healthcare industry, AI can analyze complex medical data and also help in real-time decision-making [4]. In the banking and finance industry, AI can enhance financial cyber-security to a higher level and prevent potential fraud [5].

Architecture/Engineering/Construction (AEC) is moving toward increased automation to enhance productivity and safety. Like many other industries, the AEC industry is struggling to find analysts who can make informed decisions that require computationally intensive data processing fast enough or in real-time. AI can offer exceptional benefits to increase automation in the construction industry and can be integrated into different phases of a project during its lifecycle. It is important to note that AEC is behind other industries in advancing new technologies and implementing AI solutions [6]. Forward-thinking project managers consider AI applications to enhance productivity,

increase profits, and advance safety in their construction projects [7]. Data is the fuel of AI techniques which is produced and collected throughout the life cycle of construction projects. The collected data in each phase of a construction project, including feasibility, planning and design, construction, and operation and maintenance, can be used to feed AI techniques. Construction data are the documentation that every project collects in different forms such as requests for information, drawings, photos of the job site, change orders, contracts, list of stakeholders, communications among stakeholders, and safety issue logs [8].

AI can be used to help overcome human limitations in processing and enriching large volumes of data from a variety of sources. AI can encompass millions of alternatives for various design and project delivery solutions and ultimately improve project planning. The ultimate aim of this study is to make AI part of the AEC's digital journey. AI is basically any device (or system) that perceives its environment and takes actions that maximize its chance of successfully achieving its goals. After gathering information from the environment and transforming them into an internal context (perception), we should select an appropriate AI technique to succeed in decision-making based on the relevant knowledge about the environment (action). The information presented in this study will be used to understand potential applications of decision making and learning methods in the AI domain and thus to select the AI technique best suited to the problem at hand.

After this introduction, an overview of AI and related techniques is presented. This is followed by the applications of AI in AEC, particularly in order to support design and construction. The next section presents new opportunities and challenges for the use of AI in AEC. Finally, conclusions and recommendations are presented.

2 Overview of AI Techniques

Although it may not be scientifically accurate to classify AI techniques and algorithms into two main areas of decision making, i.e. methods/algorithms and learning methods, such classification enables researchers and practitioners, without a lot of AI and machine learning knowledge, to apply these techniques to their problems. The following sections will discuss each area separately. Search methods and optimization theories are used when we have enough information to tackle decision-making and the problem is solved by the selection of the best action (with regard to some constraints and criteria) from a set of alternatives. Examples include linear programming, genetic algorithms, and ant colony optimization.

Ant colony optimization algorithm is a simple mathematical procedure and probabilistic technique that simulate the shortest and most efficient route for solving computational problems through graphs in a way that is also used within an ant colony [9]. Artificial bee colony algorithm is also a nature-inspired optimization technique that mimics and simulates intelligent behavior of honey bees [10].

Genetic algorithm is inspired by the natural theory of evolution that can be used to solve large optimization problems such as a pre-processing technique to select the best function/attribute subsequent to trying iteration after iteration under a given set of requirements [11].

Linear programming techniques involve optimizing a quantity with a mathematical method to determine the best feasible solution with a set of constraints presented in the form of linear programming problems [12].

Teaching-learning based optimization is an efficient optimization method which is a population-based method. The population includes a cluster of learners and the quality of the instructors influence the outcome of the students based on their performances or grades [13].

Local search algorithms are a heuristic approach to solve a problem by using a number of solutions while applying local changes to find an optimal solution [14].

Game theory is the study of human being in a strategic setting that can be used to solve more difficult problems when there are at least two or more players collaborating or competing to accomplish a task. To have a game, the outcome of players might depend on how they play based on the rules and solution concepts [15].

Stochastic models have a probability-based approach and are used when the environment is not perfectly predictable and decisions are partly influenced by the user's feedback and the regulations, standards, and guidelines. The random variations used in stochastic models are observed and collected through historical data for a specified period of time by using time-series techniques [16].

Bayesian networks gain an understanding of a problem and anticipate the results of intervention when some data are missing. Bayesian networks are considered when using some data in combination with prior knowledge [17].

Meanwhile, hidden Markov models are similar to statistical Markov models with hidden or unobserved states. When decision making can be modeled as sequential decision problems in uncertain environments, decision-making algorithms such as Markov decision processes can be used [18].

The learning methods, on the other hand, are further classified into knowledge-based, reasoning, and planning methods (to learn how to adapt to changing

conditions), learning probabilistic methods (e.g. Bayesian learning), and machine learning (e.g. supervised learning, reinforcement learning, and unsupervised learning).

A knowledge-based system (KBS) is a form of AI which is based upon reasoning that uses a knowledge-base to support decision-making and solving problems more efficiently. KBS includes seizing the knowledge and problem-solving methodology with relation to real world problems with a particular domain of knowledge [19]. In another approach, case-based reasoning (CBR) substitutes cases for rules. Cases are solutions to existing problems that a case-based system would apply to new problems. [19] described the CBR as a cycle including the four REs: 1) RETRIEVE the most similar case(s); 2) REUSE the case(s) to attempt to solve the problem; 3) REVISE the proposed solution if necessary; 4) RETAIN the solution as part of a new case.

Machine learning is the study of mathematical and statistical models, algorithms, and applications of artificial intelligence that machines use to improve their performance by learning and improving from their experience. Machine learning and deep learning are subsets and core of AI (shown in Figure 1).

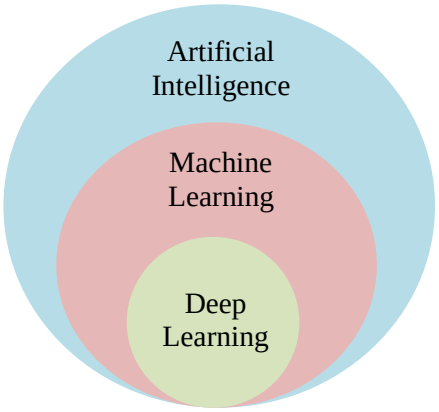

Figure 1. AI, Machine Learning, and Deep Learning

Machine learning technologies are helping computers to learn from data while thinking like a human and imitating the human brain. This became possible because of very powerful computers, availability of online data, large investment of businesses in AI, smarter algorithms, and revolution in programming. Deep learning covers a broader spectrum of machine learning methods using supervised, semi-supervised, and unsupervised techniques. In a supervised machine learning method, a machine learns from known quantities as an input that then maps an output as a future judgment. In an unsupervised technique, a machine learns from using data that is not labeled, classified, or categorized. The machine learns through the process without guidance.

3 AI Applications in AEC

In about 50% of the time, typical construction projects are behind schedule or over budget with many ongoing issues, many conflicts, numerous RFIs (Request for information), and frequent change orders [20]. Imagine having an intelligent assistant to provide help during building construction. AI has already started to change the conventional construction industry compared to the way that buildings used to be designed, constructed, and operated. AI applications can be used for many purposes, including those which have not yet been devised. Imagine the role of AI when machines provide assistance to a construction team by using algorithms. Alternatively, AI systems can collect and organize data related to projects for a project team to be used during all phases of a project like the job Watson did. Watson provides patient information to doctors in a new way to help them make better decisions related to their diagnosis.

AI can provide extra insights into data that a construction team cannot or that will take a longer time and might be processed with lower accuracy because of human errors. Construction robots can perform routine tasks that are performed by construction workers, such as a mason's job of bricklaying for a masonry project. Utilization of robots in the construction industry can be beneficial to accomplishing the job faster without the need for a break during the work or going for vacations which significantly increase productivity and efficiency. These robots enhance quality, precision, and safety while also reducing waste. Construction projects are unique in nature and can be complicated. Meanwhile, the construction industry struggles with skilled workers shortages, and the emergence of new technologies provides tremendous benefits to enhance productivity in construction and to bridge the gaps and helps the construction team with their tasks. AI works well with automation and does not get tired or make mistakes, unlike workers.

Most importantly, AI helps with projects' records. In the past, all of the construction team used paper records to save project data or used a blackboard to record information during a meeting, keep notes or create to-do lists. With all of this existing information, it was still hard to keep track of information properly and to stay on the same page with other co-workers. The use of the data being collected through mobile devices in combination with AI makes the information available, reliable, accessible, and consistent. It helps the project team to mine the information and see patterns in data that are not otherwise evident. The following examples

discuss various ways in which AI can help construction with automation through access to resources such as data.

3.1 Drones

Drones are one type of mobile robots that became a powerful innovation for the construction industry by being employed in surveying, inspection, aerial images and photography, and project monitoring and controlling. Each type of drone can be equipped with a variety of technologies and equipment, and more importantly, offers the opportunity to include AI. Drones can be controlled remotely or equipped with AI techniques to provide solutions for image detection and processing. Drones can be used for monitoring and maintaining purposes as they can provide views from a different vantage point and provide on-demand support to construction workers in their daily activities.

A drone can also be used as a first-responder at a job site for construction hazards as well as search and rescue operations including finding safety violations [21]. Project monitoring and controlling is another important area in which drones are transforming construction projects to the next level. Not only they can monitor projects, report progress, and spot problems, drones can also work together, exchange information, and collaborate in a real-time manner to complete their tasks. They can provide pictures with high resolutions to monitor projects in real-time. Drones can become the eyes of project engineers and project managers by providing vision in situations that are costly, require travel, and are challenging or hazardous. Finally, drones can determine different kinds of damage during any disaster.

3.2 Construction 3-D Printing

Construction 3-D printing includes the applications of different technologies that use 3-D printing to fabricate buildings or components of construction projects with different materials, such as cement, concrete, foam, and polymer. Construction 3-D printing has a variety of applications in the construction industry including residential, commercial, and industrial buildings, bridges, and infrastructure. 3-D printing of construction-scale projects offers design-driven construction process where the design determines the final product with a lower labor cost, shorter project duration, and making possible complex designs with the required functionality [22].

This technology has gained popularity in recent years within the construction industry. Adding AI to construction 3-D printing lets the printer create an object and then learns from the process to improve it. In addition, the use of 3-D printing was further promoted after NASA announced 3D-printed habitat competition for Mars.

3.3 Safety 4.0

With the trend of automation in construction, the internet of things (IoT), and cloud computing and cloud-based data exchange, it is necessary to take construction safety to the next level to be compatible with the new work environment. Safety 4.0 refers to conducting safety in a smart work environment or the way future safety will be practiced. With the merging of AI applications into the construction industry and shifts from conventional safety methods, safety management systems and inspections are used by project team members through using new technology, and field personnel becomes part of the decentralized safety program.

With real-time access to all of the safety information, there is no need to look for paper-based blueprints or going back to the office to look for a report. Safety 4.0 enhances communication among the project team members, specialty contractors, and stakeholders. Safety 4.0 enables team members to have access to real-time safety data. This can enhance the quality of data that can be used for AI techniques offering for the use of reporting accidents, forecasting potential incidents, or near misses. By having all the safety data, information, and report in hand, conducting regular safety meetings at the job site is made easier.

Smart wearable equipment or personal protective equipment (PPE) are developed in a way that is connected to the internet or other devices to provide real-time data while decreasing the exposure to construction safety hazards and sending automatic notifications [23]. Smart PPE can provide unlimited opportunities for field workers. For example, smart communication devices that can be connected to safety hard hats or face shields to facilitate communication in a noisy work environment can minimize hazard exposure. With all of these new technologies and AI applications, data can be transformed and adapted for safety to industry 4.0.

3.4 Autonomous Vehicles

Autonomous vehicles or self-driving cars can play an important role in construction projects. For example, some manufacturing companies have already developed heavy equipment for dozing and hauling for earthmoving projects that are able to provide 3-D pictures of the earth. As automation in construction becomes more practical, the use of autonomous vehicles that can be equipped with AI technology, robotic solutions, and sensors, enable construction equipment to operate without drivers and with better communication.

The equipment can be operated remotely and with all of the advancement in technology, it has the potential to increase productivity, efficiency, and safety and to be more cost-effective.

3.5 Generative Design

Generative design refers to a design process that employs AI techniques that generate several numbers of iterative designs according to the possibilities and constraints provided. Generative design can be used in AEC during the design process to empower the architects and designers particularly throughout the conceptual design process. Employing AI techniques by using algorithms to formulate project requirements generates design solutions and navigates them into the detailed design process. Recently, Autodesk [24] used the same approach as conceptual research and conducted the generative design approach to perform space planning. For space planning, several constraints such as building orientation, area, size of windows, daylight, and HVAC design criteria were considered in the developed algorithm.

Generative design augments architects and designers' capability and combines it with the cloud computations and machine learning to provide new solutions for clients. It enhances the ability of architects and designers to exceed current challenges during the design phase.

3.6 Risk Mitigation and Control

The use of AI applications for risk mitigation and control in construction projects is useful even with unstructured data. Cognitive analytics such as natural language processing (NLP), offers advanced algorithms to process unstructured data. Most of the generated data related to risk identifications are unstructured and it is beneficial to use cognitive analytics to leverage proactive risk identification in projects. With cognitive analytics, known and unknown risk identification can become more accurate.

3.7 Smart Sensor

In construction projects, smart sensors provide a unique role in facilitating IoT. Installing smart sensors at the job site creates continuous data collection that can be used for different purposes. For example, if there are any toxic substances or physical agents such as chemical substances or high-level noise above the permissible exposure limit in the environment, the sensors can sound an alarm and inform workers for evacuation. The sensors will be helpful for measuring air quality at the job site or in confined spaces. The real-time data collection and alarm can be shared with other people in the office such as the project manager, superintendent, or safety manager. The report can be developed automatically based on the data if AI techniques are used. Sensors can mitigate risks and issues and keep the job site safer.

To understand how the AI can be used in AEC, some of the AI applications during different phases of construction projects are summarized in Table 1.

4 Opportunities and Challenges for the Use of AI in Design and Construction

The rise of AI and machine learning in the construction industry has facilitated the construction process. It created and resulted in a more efficient and productive manner in managing the projects. This can be attributed to its application in any stage from design to pre-construction to construction to operation and maintenance. Recent advancement in technological solutions that integrates AI-powered algorithms has helped key players to tackle some of the challenges including cost and schedule overruns and safety concerns. However, in spite of the high return on investment and significant management interest in AI solutions, few construction companies and owners have the capability to employ them. One of the main challenges in implementing AI faced by these companies is the lack of critical mass data. AI is based on learning from past activities, decisions, and performances which requires a significant amount of data to train it. The other issue is the tremendous restrictions on data sharing and data ownership.

Therefore, the largest construction companies are potentially able to benefit more from AI applications in the near future. On the other side, some of the AI solutions that encourage the construction industry to adopt it are as follows: 1) project schedule optimizers which include millions of alternatives to improve project planning, 2) image recognition and classification to evaluate video data collected at the job site to determine the unsafe areas or behaviors, 3) analytical platforms to collect and assess the real-time data from various sensors installed at the job site to help project managers implement real-time solutions. Even though the construction industry is behind with technology adoption compared to other industries, now is the time to act and secure a place at the cutting-edge of implementing AI solutions and techniques into the sector.

5 Conclusions

The adoption of AI is slowly progressing in some areas of AEC, but there is still a long way to go. This study focused on identifying and leveraging synergies

between AI techniques and AEC with the aim of providing a better understanding of potential applications of AI and making AI part of AEC's digital journey. In order to provide a vision of some of the AI applications in AEC, an overview of some of the AI techniques is first explained and then application of AI specifically in AEC is summarized. This enables us to understand the potential applications of AI methods in the AEC domain. There are new ways to incorporate AI into the construction process to help the workforce become more efficient. The trend has already started and it will accelerate when using AI becomes more feasible.

Table 1. Summary of AI Applications in AEC

Construction Project Phases	Construction Activities	AI Applications	Notes
Feasibility Study			
	Collect historical information, process, and procedure	Pattern recognition	Apriori algorithm [26]
	Identify initial stakeholders	ANN	
	Identify feasible options Understand business case Develop project objectives	Neural Networks Fuzzy Cognitive Maps Genetic Algorithms Bayesian Models	Neural Networks, Fuzzy Cognitive Maps, Genetic Algorithms, Bayesian Models can be used as critical success factors identification [27]
Planning			
	Collect project requirements, constraints, and assumptions	Neural Networks Fuzzy Cognitive Maps Genetic Algorithms Bayesian Models	Neural Networks, Fuzzy Cognitive Maps, Genetic Algorithms, and Bayesian Models can be used as critical success factors identification [27]
	Determine standards and codes	Stochastic models	Cognitive computing and strategies can be used to develop stochastic models [16, 25]
	Identify risks	Cognitive analytics	Natural language processing (NLP) offers advanced algorithms to process unstructured data.
	Develop project management plan	ANN	Management by algorithm
	Define scope	ANN	
	Develop schedule	ANN	ANN can be used to optimize project duration. The mathematical model is developed based on the project network diagram, resource leveling, and time-cost trade-offs [30].
	Estimate cost and determine budget	ANN CBR	ANN and CBR can be used as a project cost optimizers to optimize the project's cost. The mathematical model is developed based on the project network diagram, resource leveling, and time-cost trade-offs [29, 30].
	Plan resource management Estimate activity resources	Generic Algorithms CBR ANN	GA can be used to search for an optimum solution for resource allocation and leveling integrated with time–cost trade-off model, resource model, and resource leveling model [29, 30].
	Perform qualitative and quantitative risk analysis and plan risk responses	CBR	Risk Mitigation

Design			
	Schematic design/rough sketches Refining the design	Generative Design	Kiviat diagram, better known as a spider diagram [24].
Construction			
	Construct the project according to the design	CBR	CBR can be used during the construction phase [28].
	Manage stakeholder engagement	CBR	CBR will be helpful for resource engagement and management [28].
	Safety	Image recognition and classification	Classify safety issues to the fatal four. Pictures and video data collected at the job site can help to identify unsafe worker behavior.
Maintenance & operation			
	Maintenance and operation of the project	ANN GA CBR	ANN, GA, and CBR can be used to assist the diagnosis and monitoring during the maintenance and operation phase [28, 30, 31].

Abstract -

Electrical resistivity is an important parameter to be monitored for the conditional assessment and health monitoring of aging and new concrete infrastructure. In this paper, we report the design and development of a frequency sweep based sensing technology for non-destructive electrical resistivity measurement of concrete. Firstly, a sensing system prototype was developed based on the Wenner probe arrangement for the electrical resistivity measurements. This system operates by integrating three major units namely current injection unit, sensing unit and microcontroller unit. Those units govern the overall operations of the sensing system. Secondly, the measurements from the developed unit were compared with the measurements of the commercially available device at set conditions. This experimentation evaluated the measurement performance and demonstrated the effectiveness of the developed sensor prototype. Finally, the influence of rebar and the effect of frequency on the electrical measurements were studied through laboratory experimentation on a concrete sample. Experimental results indicated that the electrical resistivity measurements taken at a closer proximity to the rebar had its influence than the measurements taken away from the rebar in the ideal set condition. Also, the increase in electrical resistivity to the increase in frequency was observed, and then the measurements show lesser variations to higher frequency inputs.

Concrete, electrical resistivity, frequency effects, frequency sweep, infrastructure, infrastructure health monitoring, non-destructive, rebar effects, sensor.

1 Introduction

Robotics play a significant role in the condition assessment of water utility assets for evaluating the integrity of pipelines [1]. Although robotic platforms are used for moving inside the pipelines, the key aspect to non-destructive measurements is the development of reliable sensors [2, 3, 4, 5]. In this context, this paper presents the design and development of a sensing system that can be used on the moving robotic platforms inside pipelines for infrastructure health monitoring applications.

The work reported in this paper is motivated by the concrete corrosion problem that wastewater utility faces globally [6]. The losses due to corrosion related problems are estimated to be in the order of millions of dollars worldwide [7]. Presently, the water utilities uses a predictive modelling approach to estimate the corrosion throughout the sewer network [8]. However, such models rely on the quality of sensor data [9, 10]. Surface moisture data is one of the parameter inputs used for improving the prediction of the model [11, 12]. Our previous investigations had studied the behaviour of concrete moisture conditions and the electrical resistivity measurements, where we employed direct current based electrical resistivity measurements [13] and through invasive approach [14]. Upon in-situ calibration, the electrical resistivity measurements can be used to determine the concrete moisture condition. However, reliable measurement of electrical resistivity is vital for the application motivated.

In this work, we aim to develop a alternating current based sensing system for accurate measurements of concrete electrical resistivity. In this regard, this paper proposes a frequency sweep based technology for non-destructive electrical resistivity measurement of concrete. The major contributions are:

- Development of a physical unit for measuring the concrete electrical resistivity, where the desired frequency can be set in the unit to perform measurements or a frequency sweep can be performed. Then, the measured readings can be stored in the system's data acquisition unit and visualized through the graphical user interface (GUI).

- Performance evaluation of the developed system was conducted by using a commercially available device's measurements as the benchmark readings. This evaluation demonstrates the effectiveness of the proposed system.

- Influence of rebar location and the effects of frequency levels on the electrical resistivity measurements were studied through the laboratory experimentation on a fabricated concrete sample.

For the readers, the rest of this paper is structured as follows: Section 2 describes the development of the sensing system. Section 3 presents the experimental results with analyses and finally, Section 4 concludes the paper by highlighting the key outcomes and future prospects.

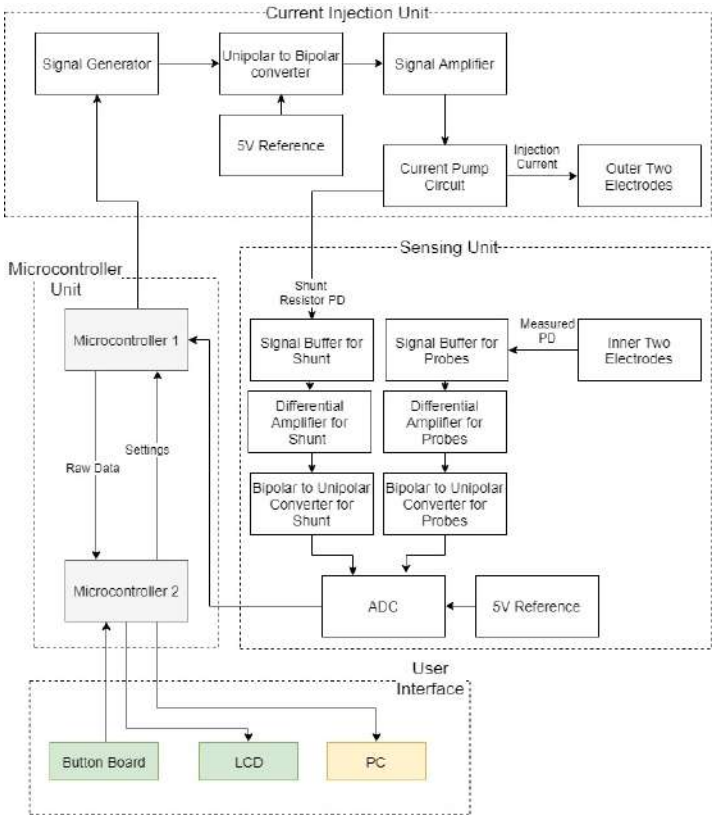

Figure 1. Hardware block diagram.

2 Development of the Sensing System

2.1 Sensing Principle

The Wenner probe method [15] is used to measure the surface resistivity of the material being tested. It uses four electrodes; outer two electrodes inject an alternating current to the surface while the inner two electrodes measure the potential difference. The principle is true for both DC current and AC Current, but there are some drawbacks when using the DC current. Applying a DC current on to the test material will cause macroscopic polarization, which will create an artificial DC potential on the surface. This will cause the measured potential difference to be inconsistent. This was eliminated by injecting a bipolar AC current in the form of a square wave or a sine wave. The alternating polarity of the injected current will prevent the material from generating an artificial DC potential.

The potential difference measured from the inner two probes and the known injected current can be used to compute the resistance of the material by using the Ohm's Law. The electrical resistivity of the material depends on the resistance and the probe spacing. Therefore, the calculated resistance and the distance between the probes can be used to compute the resistivity of the material based on the Equation (1).

$$ER = 2\pi a \frac{V}{I} \tag{1}$$

where ER is the measured electrical resistivity, a=38mm is the spacing between the electrodes, V is the measured potential difference and I is the applied current.

A major component of this design is the ability to vary the frequency of the injected current. The frequency of the injected current affects the penetration depth of the current. Lower frequencies will allow the current to penetrate deeper into the material than the higher frequencies. This characteristic behaviour can be used to determine the resistivity values at certain depths of the material being tested. The developed sensor will allow the user to perform a frequency sweep by setting the maximum and the minimum limits and the stepping frequency. During the frequency sweep, the resistivity is measured simultaneously at the set intervals.

2.2 Design of Sensing System

The three main components in designing the sensing system are the current injection unit, sensing unit and the micro-controller unit. The block diagram in Figure 1 shows the information flow through each of the major components of the system.

2.2.1 Current Injection Unit

The current injection unit produces a constant bipolar alternating current with a variable frequency. To generate this current, we used a Howland current pump circuit. The ideal Howland current pump circuit is essentially a voltage controlled current source, which can generate a constant current regardless of the load resistance. This is achieved by changing the voltage across the load accordingly to keep the current through the load constant. However, when the resistance of the load is too high, the voltage required to keep the current constant at the required amount will be higher than the input voltage to the circuit. In such situation, the current across the load will be lower than the expected value. This requires the current to be constantly monitored using a shunt resistor to prevent any errors in the resistivity measurements. The current output of the the Howland current pump circuit can be calculated using the Equation (2), where I is the injected current, V_{in} is the input voltage and R_s is the shunt resistance.

$$I = \frac{V_{in}}{R_s} = \frac{15}{60000} = 250\mu A \tag{2}$$

The output current, which will be injected into the test surface was kept very small in the range of micro-amperes due to several reasons. A lower current eliminates the heat generation on the surface from the injected current, which will cause the resistivity readings to alter. The power loss over transmitting wires is also minimized and any shock hazard from persons coming in contact with the current probes will also be eliminated by using a smaller current.

For producing the alternating current, we have used the analog devices AD9850 Signal Generator IC to generate the square wave. It is an integrated chip that uses advanced Direct Digital Synthesizer (DDS) technology coupled with a high speed 10-bit DAC to produce a sine wave. This sine wave is connected to a square wave using an internal comparator. The frequency of the signal can be digitally programmed for up to 125MHz with an accuracy of 0.3Hz. The signal generated from the AD9850 IC is unipolar with the signal alternating between 0V and 5V. The Wenner probe methodology requires a bipolar alternating current to produce the accurate results without generating any artificial potential differences. To achieve this, we have used a uni-polar to bipolar converter, which was designed using a differential op-amp configuration. After identifying the required gain and the offset of the differential amplifier, we came up with the transfer function in Equation (3) for the unipolar to bipolar converter, where V_{out} is the output voltage and V_{in} is the input voltage.

$$V_{out} = 2 \times V_{in} - 5V \tag{3}$$

The signal output from the uni-polar to bipolar converter has an amplitude of ±5V which is not sufficient for measuring resistivity using the Wenner probe method. The signal was amplified using a non-inverting op-amp configuration to an amplitude of ±15V. The op-amp used in the amplifier circuit had to have the rail-to-rail feature to allow the op-amp to output voltages equal to the supply voltage of ±15V.

2.2.2 Sensing Unit

The sensing unit measures the potential difference between the inner two probes of the Wenner array configuration. The potential difference generated in the inner two probes was first passed through a signal buffer circuit and then converted to a measurable value using a differential amplifier, which is then converted back to a uni-polar signal to be measured by the ADC. There is a high impedance difference between the ADC and the electrodes, which had to be taken into consideration when designing the sensing unit. It is also necessary to isolate the sensing unit with the current injection unit to prevent any errors in the measurements due to the common ground terminals. Those issues were addressed by using the signal buffer circuits. The buffer circuits used were voltage buffer amplifiers, which converts the high output impedance of the sensing electrode to a low impedance output to match the impedance of the ADC. The buffer amplifiers also prevented the sensing unit from loading the sensing electrodes and interfering with the current waves created in the test surface. In addition, they were used while measuring the voltage across the shunt resistors due to the same reasons. The circuit schematic in Figure 2 shows the buffer circuit used between the sensing electrodes and the ADC.

The ADC that we used in the sensing unit was the Microchip MCP3008 10-bit ADC. This ADC contains four pseudo differential channels, which are sufficient as this system requires only two differential inputs for the sensing electrodes and the shunt resistor. The voltage output from the buffer circuits was fed through a differential amplifier before being read by the ADC. Since this ADC accepts only a uni-polar input, the measured potential, which is a bipolar signal has to be converted back to a unipolar signal before being fed in to the ADC. The ADC will be powered using a regulated 5V supply and the the reference voltage needed by the ADC will be supplied using a voltage reference circuit consisting of a LM4040 reference voltage IC.

2.2.3 Microcontroller

The microcontroller is the central unit of the system, which manages all the other components. An Arduino Micro for the microcontroller was utilized as it supports SPI and I^2C communication protocol, which is required to communicate with the other components of the system.

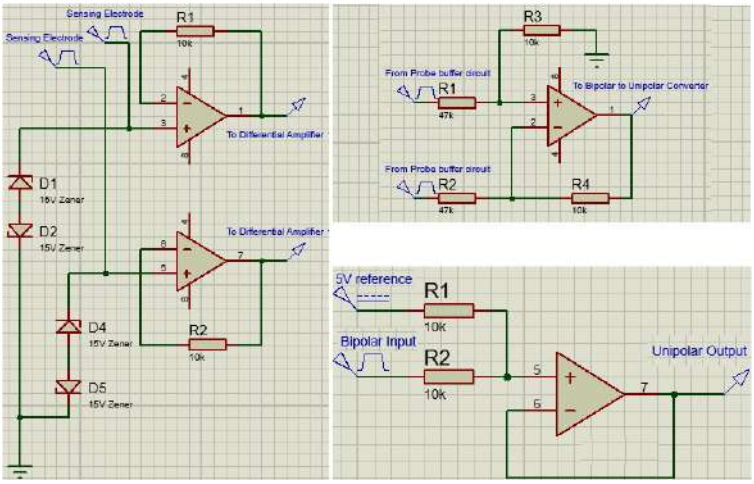

Figure 2. (Left) Signal buffer circuit schematic of the sensing electrodes. (Top Right) Differential amplifier circuit schematic of the sensing electrodes. (Bottom Right) Bipolar to unipolar converter.

The ADC needs to operate constantly without any interruptions during the measurement process. Therefore, it requires the Arduino connected with the ADC not to be interrupted during data logging. To carry out measurements and data logging at the same time, it is necessary to use a second Arduino to handle the data logging and the user interactions. This enables the results to be displayed in real-time while the device is in operation.

2.3 Operating System

The microcontroller programming of the system was carried out using the Arduino IDE and the GUI was designed and implemented using the Matlab software. The software was designed to produce useful information by processing the raw data, so that the user can interpret the measured readings easily to determine the health conditions of the structure under investigation. The control unit of this system consists of two microcontroller boards, which contains two different sets of programming instructions. The unit containing the first microcontroller board is referred to as the 'Sensor board' while the unit containing the second microcontroller is referred to as the 'UI board'

The sensor board was programmed to receive the system settings from the user including the information about the required frequency sweep and the data logging. The user information is then used to start the current injection unit, which injects a current though the outer two probes of the sensor. The potential difference measured by the inner two probes is then captured using the ADC in the sensor board. The UI board consists of the buttons, which are used to change the settings of the system and also, a LCD screen to display the settings and the real-time resistivity measurements. The raw data captured from the sensor board is passed on to the UI board for processing and to be presented to the user. The data received from the sensor board is the AC signal, which has been converted to a unipolar signal from the bipolar to unipolar converter. This signal is then converted back to a bipolar signal using software and sent though a set of filters and then, processed to plot a graph of resistivity against the frequency. The digital reading will be shown in the LCD of the UI board and plots for greater data visualization will be shown in a GUI on a computer connected to the sensor via USB. Figure 3 shows the overall software flow.

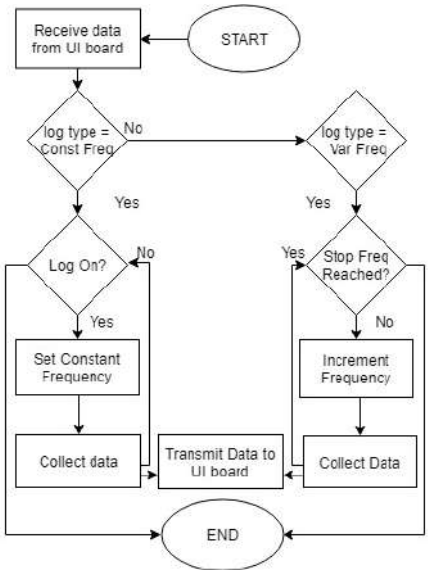

Figure 3. Overall software flow diagram.

2.4 Graphical User Interface for Visualization

The system can be connected to a computer via a USB that allows the results to be visualized graphically through the GUI, which was designed by using the Matlab software (R2016a version), and it interacts with the hardware through serial communication. The GUI allows real-time monitoring of the data and also the system can be completely controlled from the GUI rather than the hardware buttons. The resistivity values will be displayed in the system's GUI along with the frequency of the injected current. The system is programmed to plot the real-time measurements for better visualization of the resistivity variations during the frequency sweep. Further, the GUI offers an option to filter the data to remove any noise signals produced by the sensor. In addition, the GUI can also be used to easily save the logged data into a computer as a .csv or a .txt text file for comprehensive analysis. Figure 4 shows a screenshot of the GUI.

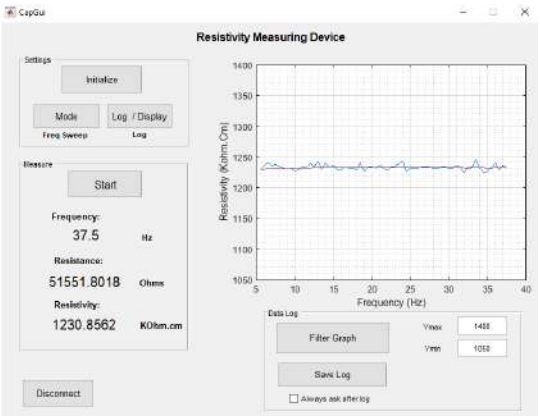

Figure 4. The GUI of the developed system.

2.5 Electrodes Arrangement and Enclosure Design

For the electrical resistivity measurement of concrete, the electrodes are required to be in contact with the test surface. A stainless steel 316-grade material bolts were chosen as electrodes mainly because of the reason that they highly resist in corrosive and high humidity environments, and has a good electrical conductivity. The electrodes were housed in a 3D printed enclosure containing a spring mechanism, which allows the electrodes to be pressed on the test surface firmly to allow maximum surface contact. Figure 5 shows the electrode arrangement with housing.

The main circuits including the micro-controller, signal generator, current pump circuit and all the other circuits were housed inside a plastic enclosure as shown in Figure 6, with cut-outs for the buttons, LCD display, power jack, USB port and the mini-DIN type connector that connects the circuits enclosure with the electrodes.

Figure 5. (Left) Assembled electrode arrangement. (Right) Electrode with spring mechanism.

Figure 6. Enclosure of the computing unit.

3 Experimental Results

3.1 Measurement Performance Evaluation

In this performance evaluation, we have utilized a commercially available electrical resistivity meter (Resipod, PCTE) [16] for the purpose of measurement comparison with the developed unit. The commercial device injects a current of 250μA at a frequency of 40Hz during measurements. To represent an identical test condition, we have set our developed system to produce a current of 250 μA at a frequency of 40Hz. A concrete sample having 10 cm thickness was fabricated and a rebar having 1cm diameter was embedded at 2cm distance from the top surface. Using both the devices, five sets of readings were taken on the concrete samples at each location and similar measurements were taken at varying horizontal distances to the rebar as shown in Figure 7.

Table 1 tabulates the electrical resistivity measurements

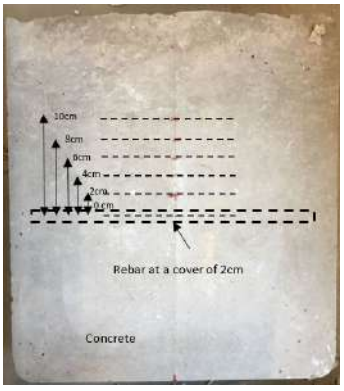

Figure 7. The concrete sample used for testing with embedded rebar and measurements were taken at 2cm spacing away from the rebar up to 10cm.

from the commercial device and the developed unit. It can be observed that the mean absolute error (MAE) for the measurements taken in different horizontal distances is less than 1 kΩcm, which indicates the effective measurement performance of the developed unit.

Table 1. Measurement Performance Evaluation

Horizontal distance to the rebar (cm)	Mean electrical resistivity from Resipod (kΩcm)	Mean electrical Resistivity from developed unit (kΩcm)	Mean absolute error (kΩcm)
0	3.27	3.20	0.07
2	8.83	9.63	0.80
4	10.9	10.07	0.83
6	13.2	12.5	0.7
8	16.23	16.17	0.06
10	17.9	17.83	0.07

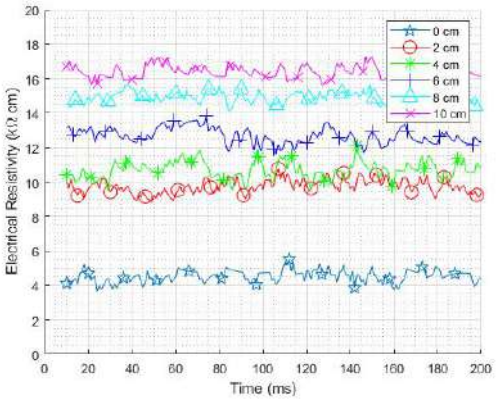

Figure 8. Resistivity vs Time graph, with the first measurement taken directly above the rebar (0cm) and last measurement at 10cm away from rebar.

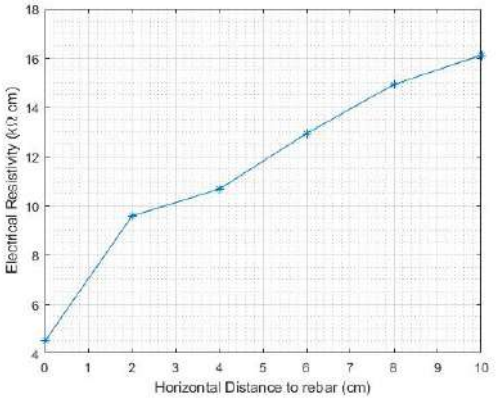

Figure 9. Resistivity vs Horizontal distance to rebar.

3.2 Influence of Rebar Location

In order to study the influence of rebar location on the electrical resistivity measurements, an experimentation was conducted on a concrete sample that has rebar at a known depth. In this experiment, the current of a constant frequency of 80Hz was injected to the surface of the concrete sample and the resistivity was calculated using the measured potential difference. A frequency of 80Hz was chosen as it is low enough to cause a variation in resistivity due to the rebar, which is located 2cm below the concrete surface. The sensor is prone to noise signals during measurements. Therefore, the resistivity readings were taken for a period of time so that an average can be obtained to minimize any error from the noise. The plot in Figure 8 shows the measurements taken on the concrete sample while moving 2cm horizontally from the rebar between each measurement.

A mean value for the resistivity was obtained by generating a line of best fit for the measurements during the 200ms interval. The constant frequency of 80Hz allowed the current to penetrate into the test material upto a certain depth and produce current flux lines. The rebar in the concrete affects the generated current flux lines, which will result in differences in the measured potential difference. The plot in Figure 9 shows the change in resistivity against the sensor distance to rebar, where we can observe that the resistivity increases as the sensor distance to rebar increases. This shows that rebar has an influence on electrical resistivity measurements taken at closer proximity.

3.3 Effect of Frequency on Measurements

The frequency of the injected AC current affects the penetration depth of the current flux generated from the outer two probes of the Wenner probe array. An experimentation was conducted, where the frequency sweep was carried out in the frequency range of 1Hz to 1.8KHz with the resolution of 2Hz. Measurements were taken on a concrete sample of 2cm rebar cover and the developed sensing unit was moved 2cm away between each set of measurements. The changes in resistivity measurements were plotted against the increase in frequency as shown in Figure 10 in order to analyze the effects due to the frequency sweep of the injected current.

It can be observed from the Figure 10 that there is an increase in resistivity as the frequency increases between 1Hz to approximately about 150Hz on the measurements taken with the sensor directly above the rebar (0cm), and similar trend was was observed with measurements taken at 2cm, 4cm, 6cm, 8cm and 10cm away from the rebar. This variation is due to the changes in the penetration depth as the frequency of the injected current changes and

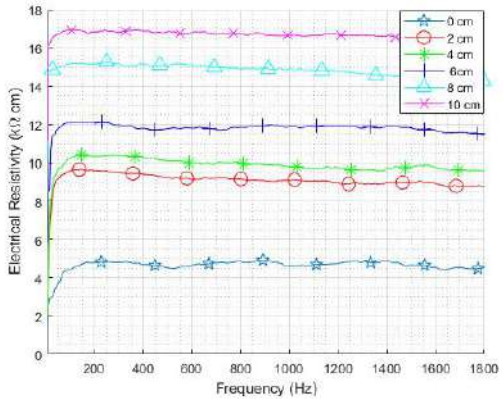

Figure 10. Resistivity variations for frequency changes on a concrete sample with 2cm rebar cover, with the first measurement taken directly above the rebar (0cm) and moving 2cm away from the rebar between each measurement until 10cm.

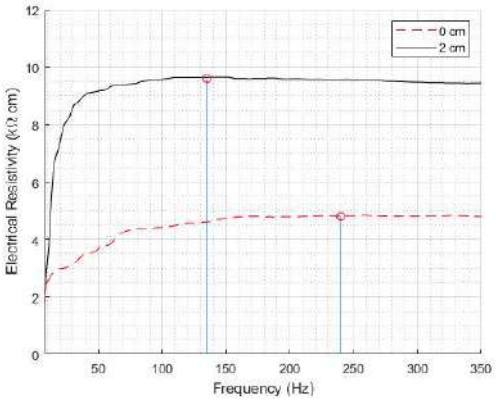

Figure 11. Resistivity versus Frequency graph for the concrete sample with 2cm rebar cover, with 0cm and 2cm plot, close up view that shows the point at which the resistivity converges to lesser variations.

the influence due to the presence of rebar in the region of interest of the sensing unit.

The current at lower frequencies has a larger wavelength, which allows for greater penetration. This enables more current flux lines to be created in the concrete, which increases the number of current flux lines interfering with the rebar. This causes the potential difference measured by the inner two probes of the developed unit to be smaller, which translates to a smaller resistivity measurement. Approximately, above 150KHz frequency, the resistivity readings shows less variations. When the frequency is greater than a certain value, the penetration power of the injected current is too low to penetrate deep enough into the rebar, which eliminates the influence on the resistivity due to the rebar.

The point at which the resistivity measurements starts to exhibit less variations is earlier when the sensor is 2cm away from the rebar than when it is directly above the rebar, as shown in Figure 10 and Figure 11. This is due to the variation of the distance between the sensor and the rebar. When the sensor was moved over 4cm away from the rebar, a less change of resistivity was observed, because of the reason that the rebar position is now away from the maximum penetration range.

4 Summary and Future Prospects

In this paper, we have presented the developments of a frequency sweep based sensing technology for non-destructive concrete electrical resistivity measurements. From the reported work, the key highlights include:

- Development of a sensor prototype for measuring the electrical resistivity of concrete and data acquisition.
- Measurement results indicated that the MAE between the developed unit and commercial device is less than 1 kΩcm, which demonstrates the effectiveness of the prototype.
- Effect of the rebar on the electrical resistivity measurement was studied. Experimentation results showed that the measurements taken at closer proximity to the rebar has lower values than the measurements taken at different distances away from the rebar.
- Effect of the frequency sweep on the electrical resistivity measurement was studied. Measurement results displayed that there is an increasing trend in the electrical resistivity measurements with the increase in frequency approximately upto 150Hz and then for higher frequencies, lesser variations in the electrical resistivity was observed.

In the future, the reported sensing system will be improved by integrating with wireless data transfer feature, and can be employed for real-world applications motivated in [17, 18].

Abstract –
Three-dimensional (3D) printing, as one of the additive manufacturing (AM) technologies, is transforming the design and manufacture of products and components across a variety of disciplines, however, architectural design and the construction industry have only recently begun to adopt these technologies for construction purposes. AM is considered one of the core technological advances in the paradigm shift to Industry 4.0 (the fourth industrial revolution). This term used to describe digitization and automation of the manufacturing environment and is widely recognized as a disruptive technology that could transform architectural design and the construction industry. The potential advantages of 3D printing in the construction sector are significant. They include not only improved environmental and financial resource efficiencies, but also, the capacity to produce complex customized designs for aesthetic and structural applications.

As the cost of building houses continues to rise, it is crucial to find innovative ways to build houses efficiently and cost effectively. The earliest records of 3D printing date back to the 1980's and many industries—from manufacturing to medicine—were early adopters of the technologies resulting in many significant technological advances in those sectors from organ printing to aircraft fabrication. Currently available 3D printing technologies can be adopted for building construction and this paper discusses the applications, advantages, limitations and future directions of 3D printing as a viable solution for affordable house construction with a focus on printing architectural freeform elements.

3D printing offers a new and innovative method of house construction. For this study, an analytical, as well as a numerical model were specifically designed for 3D printing. Previous studies conducted found that the construction of a 3D printed truss-like roof in a cement mixture with high-density polyethylene (HDPE), spanning the entire structure, was structurally feasible in the absence of steel reinforcements. These results led us to investigate the feasibility of 3D printing an entire house without the use of reinforcements. Investigations were also performed on comparing flat-roof and arch-roof structures and found that whilst maximum tensile stresses within flat-roof would cause the concrete truss structure to fail, the HDPE cement mix in an arch-roof structure had reduced the maximum tensile stresses to an acceptable range to withstand loadings. At the time of writing this paper, several 3D printing techniques could be adopted for the purposes of 3D printing an entire house, and the team believes that future adaptations of existing technologies and printing materials could eliminate the current limitations of 3D printing and become common practice in house construction.

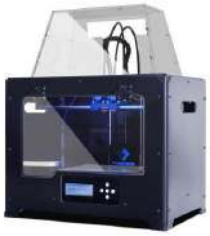
1 Introduction

There is a growing trend in architectural design and the construction industry to adopt Industry 4.0 and utilize additive manufacturing processes for building construction. Applying 3D printing in design and construction provides potential advantages as infinite forms and shapes, including large sized elements, can be created in-situ on congested or difficult to access construction sites.

The terms additive manufacturing and 3D printing both refer to the process of creating an object by sequentially adding build material in successive cross sections, or layer upon layer deposition. 3D printing also includes the hardware, machine control systems and software as well as the peripheral accessories which may

be required for producing objects during a building cycle [1]. The blueprint for the form is from a digitally constructed model created in 3D modelling software such as Fusion 360, Rhinoceros, Revit or a multitude of other 3D modelling software packages.

3D printing is the fabrication of objects through the deposition of a material using a 3D printing technology, or type of mechanism



with a print head and nozzle [1]. AM technologies include gantry systems, suspended platforms, and mobile rotating manipulators with an extension arm. The gantry system is the most commonly adopted technology by manufacturers of model size fused deposition

modelling (FDM) 3D printers such as MakerBot and FlashForge.

Whilst this system works effectively in laboratories, for in situ construction scale 3D printing, gantry systems have limitations akin to those of pre-fabricated houses in that they require transportation and installation of heavy infrastructure, which, in turn also can limit the size of the build envelope. Contour Crafting completed a proof of concept at full house scale 3D print in the United States in 2001.

The term "cable-suspended platform" is used for 3D printing technologies that consists of an end-effector that is manipulated by automated motors via multiple cables attached to a rigid frame. The flexibility within well-engineered frame design means that the cable-suspended platform frees up the size of the build envelope and can be constructed from light-weight materials that are assembled on site. Being lightweight and delivered in parts this system can be less expensive to transport to site but requires expertise for assembly.

Mobile rotating manipulators comprise of a rotating arm on a central base. Apis Cor in Russia was the first company to develop a mobile 3D printer for the construction industry and claims to have successfully printed a 37m² house on site in 24 hours at a cost of US$10,134. The Apis Cor has a reach of 8500mm from a central manipulator with 360° rotation and a maximum height of 3100mm. Due to its large build envelope and low cost of materials, the mobile rotating manipulator system in the form of the Potterbot Scara (Selective Compliance Assembly Robot Arm) XLS-2 clay printer was selected as the most appropriate 3D printing technology for conducting laboratory-based experiments for this study.

Previous studies have generally looked at 3D printing specific geometrical shapes such as wall segments, cubes and vertically extruded curves. Many recently completed 3D printed projects—such as Contour Crafting in the United States, Apis Cor in Russia, and Winsun in China—have provided evidence that the 3D printing of houses can be realised at various scales including 3D printing simple geometry houses at full scale. However, an under developed area in 3D printing in construction is the production of architectural freeform elements (AFE) including extreme slopes, angels and complex curves. This paper aims to create several AFEs and discusses the challenges of creating these models in a laboratory. The paper aims to identify different factors of attainable AFEs from a practical perspective. Many previous studies and built full sized projects focused on producing simple vertically extruded geometries but further investigation is required to find out what are the possible challenges and opportunities of creating AFEs at different scales and sizes.

Researchers in the field of aerospace and manufacturing have demonstrated that 3D printing can reduce costs, but limited investigations have been undertaken to support the assumption that savings will also apply in the construction industry [2]. However, it is still appropriate to hypothesize that utilizing 3D printing can reduce costs for aesthetic and structural applications in the construction industry. Another motive to apply 3D printing technology within the construction Industry is the potential for increased safety. The construction industry has been shown to have a higher rate of fatality, injury and illness than any other sector [3]. So whilst traditional construction may appear straightforward from two-dimensional (2D) drawings, building any kind of freeform or complex curvature structure requires formwork and much skilled labor. The proposed solution and a focus of this study is to minimize and simplify the level of human-interface and human-machine or robot interaction to enable 3D printing technologies to become safe, cost effective and accessible tools in the construction industry.

2 Research Method and Data

This study is a laboratory-based investigation. We designed nine architectural freeform models and scaled them to be fabricated as models in a laboratory. A total of 56 samples were created in the lab, and overall running time of printing was approximately 30 hours. A 3D Potterbot XLS-2 (Scara) clay printer (see Fig.1) was used for the experiments as it is able to print large models in continuous flow system of layer deposition.

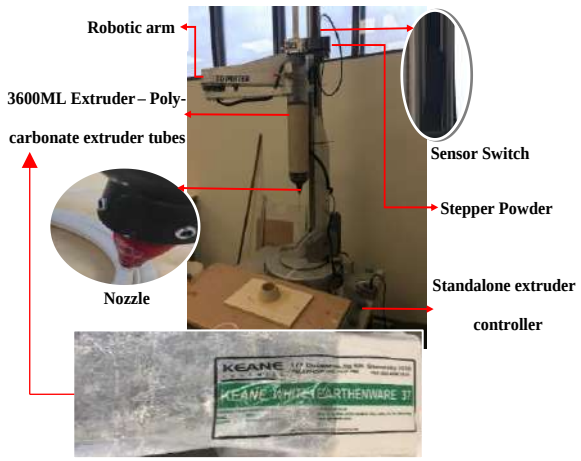


Figure 1. 3D potterbot SLX-2 (Scara) using clay for lab experiments.

The 3D potterbot SLX-2 (Scara) in its seventh series of development has evolved from the previous syringe extrusion method to a mechanical screw system. Earlier Potterbot technologies therefore required a clay and water mix which meant prints could not handle otherwise normal overhangs and did not have good success with achieving significant height.

The material used for this study is clay with no water added, which is suitable for a range of objects from very small to large, even hand applications. The study found that after the initial investment cost of the Potterbot equipment, this technology and material combination can be an efficient and inexpensive option for education and research testing.

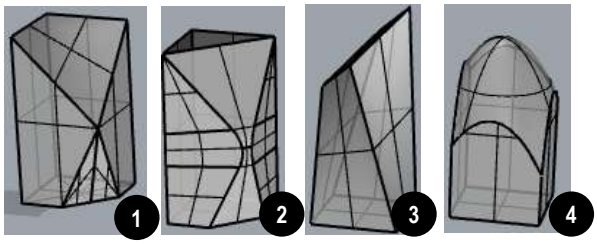

Figure 2. Selected AFE designed models of 4 to 7 for experimentations

Figure 3 shows four models, namely column (M4), column radian (M5), column slope (M6), and column dome (M7). Other models from M1 to M9 are shown in Figure 7. These models can be classified into two groups in terms of design: i) basic models ii) complex or curvature models (e.g. M4 to M7). The software used for these models are Fusion 360 and Simplify3D, which are recommended as compatible programs with the 3D printer Potterbot (XLS-2 Scara robot, 2018).

Models can be designed in any 3D modelling software and saved as STL files which are then imported into Simplify3D for layer slicing, making them them ready to print. The slicing process translates 3D models into instructions the printer understands by generating the G-code programming language, the required numerical code (NC) for motion control of the Potterbot. Any changes to scale or size of the object can be made in Simplify3D software before generating the G-code.

3 Experimentations and Failure Modes

Studies were conducted to verify the accuracy of the 3D printed output compared with the digitally produced model. The 30-degree column models were created on Fusion 360 modelling software (see Fig.1). The build envelope dimensions designed for the columns are 100mm x100mm x 120mm.

Table 1. A summary of software used evaluation.

Advantage	Limitations
Fusion 360	
(i) Cloud enabled collaboration platform can create a variety printable models including organic/complex models more naturally using both NURBS or T-Splines; (ii) Capacity to import models created on other software like Rhino or Revit and then edit specific sections; (iii) Capacity to export as STL file format which can be read directly by 3D slicing printing software like Cura and Simplify3D.	(i) Designing a building model has limitations because Fusion 360 is more suitable smaller objects (ii) It is relatively new software platform with kinks and issues but is constantly being updated and improved;
Simplify3D	
(i) Compatible with hundreds of different 3D printers; (ii) Can provide a pre-print simulation of model printing actions; (iii) Controls and communicates extruder information like speed and print time.	(i) Some aspects of 3D printer XLS-2 Scara robot motion are not possible to control / predict such as the start point of the extruder for a print; (ii) No free version of Simplify3D is available.

According to all the printed output dimension data, the 20-degree column physical model is the most accurate production of the designed model measuring 99mm x 97cm x120mm. This was more accurate than the 0-degree column output. The models with the most serious deformations are the 30-degree column and 45-degree column. Another factor for future analysis is the impact of increased human presence in proximity to the machine as the models with the most serious defamations correlated with an increase in the number of people present in the lab and in close proximity to the machine, at the time of print.

Name of the printable model.

Nozzle Diameter shown in Figure 3 (2).

Figure 4. A sample of G-code for model 8 (i.e. 30-degree column).

The 3D potterbot SLX-2 (Scara) robot can be fitted with with a variety of nozzle sizes ranging from 1mm to 25mm. The study models were printed using the 3.5mm diameter nozzle. The nozzle size in an important consideration before producing G-code (see figure 4) as various object designs are contingent on factors such as overall dimensions, level of detail required and angle of slope. Waste material is another consideration and clay loads can be loaded appropriate for the object size. The maximum build envelope height for XLS-2 Scara robot is 1828mm diameter and 1143mm Z height. It can be customized to print 2743mm diameter and 2590mm Z height.

Table 2. Selected causes of failure modes.

Models size/Scale	Failure
Appearance Designed Model 4	The start point of the extruder is hard to predict. The first layer printed outside the area of the intended base board. (see Fig.7 (1))
All 9 models	The size of the model is limited by extruder printing information such as the Nozzle Diameter in fig.5 and G-code in fig.6 for 30-degree column.
Squares, Rectangles and Arches	Due to the pressure in the extruder, the machinery cannot stop printing the clay resulting in wasted materials. (see Fig.7 (2) & (3)).
Appearance Designed Model 2 (100%)	The Shape structure changed as the size and scale of the models was modified. Same design, original size (left) collapsed, but the half size (right) printed successfully (see Fig.7 (5) & (6)).
Column models	The shape of the design is limited as the clay is soft and cannot stand by itself (see Fig.7 (9)).
All 9 models	The surface finish can be affected by the air bubbles, material may have flaws (see Fig.7 (11)).
All 9 models	Shrinkage and cracking occurred damaging the model. (see Fig.7 (12)).
Priming edge and the first layer of all models.	The start layers do not work well. The first layer is compressed, possibly caused by the height of the nozzle or the uneven moisture level of the board. The board is not flat due to the difference in water absorption (see Fig.7 (7)).
Square, Rectangle and Arches.	Due to mechanical errors the machine stopped working for three times during printing of simple shape models (Square, Rectangle and Arches).

Figure 7 shows all relevant images of the failure models. In order to observe the effect of slope in failures of the 3D printed models, the angle of the surface was changed from 0-degree to 60 and 80-degree for M8 and M9 respectively.

In the column-slope model (M6), the top section has

a collapse trend from 80% to 120%. The middle section of the sample with the scaled model of 120% (i.e. 20% larger sized printed) collapsed and cracked.

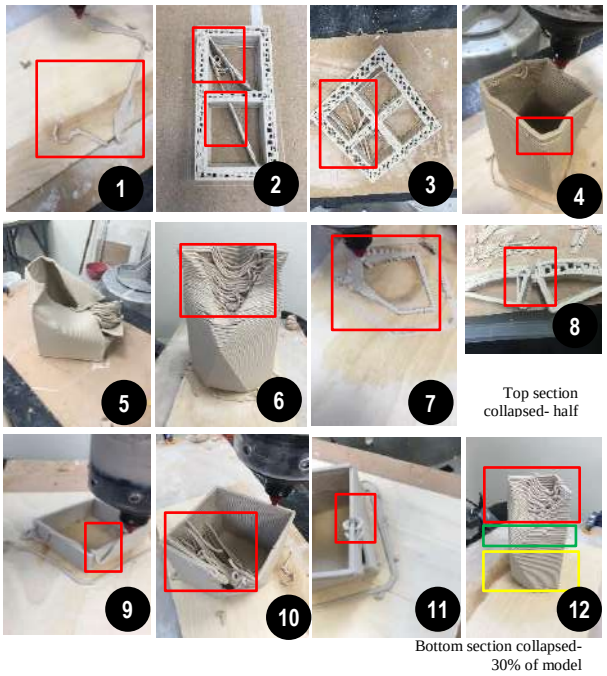

Figure 7. Selected 3D printed of failed models.

Table 3. The frequency of the issues during the 3DP process for 56 models.

The Issues during the 3D printing process	Frequency
Small Air bubbles.	44
Large Air bubbles and flaws (Fig.7 (11)).	41
One edge is wider, and the opposite is thinner due to one board moisture inconsistency (Fig.7 (7)).	8
The structure of rectangles and squares changed after scaling 130% of original size. (Rectangles and squares, Fig 7 (2)).	6
The top section collapsed for Column (M1) and Column Slope (M3) (see Fig.7 (6)).	6
Preparation time is much longer due machinery faults, generally issues getting the nozzles ready.	5
Total completion time is longer as G-code created for motion programming of machinery is inefficient.	4
The bottom section bent, and the clay path distorted for Column (M1) (see Fig.7(12)).	4
The paths distorted on top section for Column (M1) and Column Slope (M3) (see Fig.7(6)).	4
The model begins to collapse as the nozzle deposits clay a little further outside its intended path for Column (M3) (Fig.7 (4)).	3
The paths do not form a circle only a line for Column (M1) (see Fig.7(6)).	3
The center parts started printing for Column Radian (M2) (see Fig.7 (10)).	3
The machinery hardware stops working for a while	3
The path in the center at this layer cut off during the printing process for Column (M1) (see Fig.7 (6)).	2
The top paths distortion is more severe than before for Column (M1) (see Fig.7(12)).	2

The diameter of the cylinder is proposed as 10cm in models; however, the diameter in the 3D printed model with 0-degree is 96mm. Observation shows that the collapse starts at a layer with 20-degree slope in the cylinder (M8). Because the 60-degree cylinder shape is more like a triangle, which is the most robust shape in construction, the base diameter is smaller than the 45-degree cylinder and the same with the 20-degree cylinder's base diameter.

Table 4. Shrinkage Table after 7 daysfor 14 models in different slope.

Models code	Average shrinkage in each side
Cylinder 0 slope	2.56%
Cylinder 10 degree	3.16%
Cylinder 20 degree	6.39%
Cylinder 30 degree	5.10%
Cylinder 45 degree	9.70%
Cylinder 60 degree	12.51%
Column 0 degree	3.50%
Column 10 degree	4.35%
Column 20 degree	4.11%
Column 30 degree	2.96%
Column 45 degree	3.26%
Column 60 degree	2.68%
Column 70 degree	3.18%
Column 80 degree	5.56%

Note: Base on the laboratory personnel experience, the normal shrinkage rate should around 10%.

4 Results

Table 4 shows the descriptive analysis of the models. It shows that the mean time per layer for the models varies from 0.27 to 2.85 minutes.

An analysis of variance (ANOVA) test was employed to examine whether the differences of means are significant or not. Figure 5 shows the means for each model.

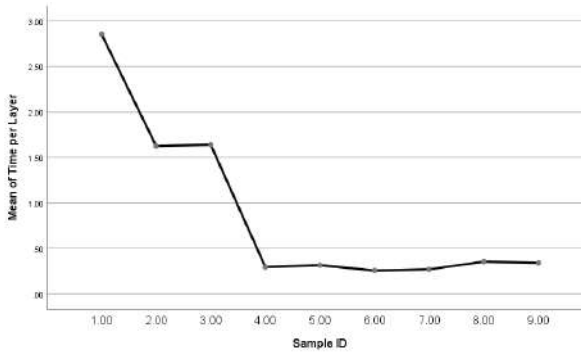

Figure 5. Mean for time per layer for all eight models.

The analysis shows that there was a statistically significant difference between models 1, 2 and 3 with all other models (e.g. from 1 to 8) except 2 and 3 as determined by one-way ANOVA ($F(8,47) = 20.782$, $p = 0.000$). The Tukey post hoc test was applied and showed that the time per layer to complete the first model was statistically significantly higher than all other models (2.85 ± 0.91 min, $p < 0.003$). The time was second highest for model 2 (1.63 ± 0.66 min, $p < 0.019$), and model 3 (1.64 ± 0.59 min, $p < 0.04$). There was no statistically significant difference between model samples of the model 2 and 3 ($p = 1.000$). There was no statistically significant difference between all models 4, 5, 4, 7, 8 and 9 with each other ($p = 1.000$).

Table 5. Descriptive analysis for time per layer.

M	N	Mean	Std. Deviation	95% Confidence Interval		Minimum	Maximum
				Lower	Upper		
1	12	2.86	0.91	2.28	3.43	1.61	4.27
2	12	1.63	0.67	1.20	2.05	0.66	2.63
3	6	1.64	0.59	1.02	2.26	0.91	2.58
4	3	0.30	0.04	0.20	0.39	0.26	0.34
5	3	0.32	0.05	0.20	0.43	0.27	0.36
6	3	0.26	0.04	0.15	0.36	0.22	0.30
7	3	0.27	0.05	0.15	0.39	0.22	0.32
8	6	0.35	0.04	0.31	0.40	0.30	0.42
9	8	0.34	0.02	0.33	0.36	0.32	0.36
T	56	1.28	1.14	0.98	1.59	0.22	4.27

Note to table: M refers to model, N refers to the number of layers per model, Mean refers to the time spent for each layer, T refers to Total.

5 Discussion

3D printing has been used in manufacturing for many years, but whilst its adoption into the construction industry has been slow, it is currently a growing area of development for building construction. Previous studies have generally investigated potential materials and their properties for 3D printing as well as adapting or designing 3d printing technologies for effective delivery on construction sites. However, investigations into combining complex geometries and construction by 3D printing have received less attention.

The potential advantages of 3D printing in construction are significant. They include not only not only increased efficiencies pertaining to financial and environmental resources but, also, the capacity for mass customization of designs to meet aesthetic, functional and structural purposes. Previous studies and realized 3D printed houses have shown the potential for minimization of construction waste from precise material deposition and eliminating the need for of formwork. Previous studies have also shown the potential for increased safety on construction sites. However, many factors need to be addressed before 3D printing can be fully utilized for complex shapes in construction. They include further research into material properties to a attain structurally stable material, not just for longevity but crucially, during printing. Challenges for 3D printing include material setting time, stability during printing, deformation, shrinkage and bonding between layers. Material behaviours require further investigation under a range of conditions to achieve a robust material that can take structural load during and after printing.[4].

This study examined the capability of 3D printing for producing complex geometries. Key factors such as shrinkage, time per layer or speed and material wastage were examined in the laboratory. We faced several challenges during the production of different models. The limitation during the laboratory experimentation was the lack of control of the machine by the user. These types of factors are very important on a real construction sites, when a worker needs to change specific dimensions, angles or position of the nozzle. To address this issue, we would recommend human-printing collaboration strategy, which helps human and 3D printers to work side by side to complete the construction of the item or structure.

Construction sites are not predictable and rarely flat and even surfaces or environments and so many adjustments are required to address issues such as slope of site, humidity and environmental factors like wind.

This study will be replicated with a variety of materials and model designs not with the intention of creating the ideal environment for 3D printing but by addressing the issues in their application on real construction sites.

Model designs can play an important role in creating feasible structural shapes to understand and predict how material properties change with curvature and slope of surfaces. However, other factors should be further investigated such as the volume of waste materials, total cost including the operation cost, optimization of nozzle path, and material properties such as brittleness of clay

and concrete. Another issue is increasing the level of automation of the entire process from design to construction.

In line with some of previous findings in different contexts [5,4,6,7], several limitations of the 3D printer were observed in our experiments. The PotterBot XLS-2 Scara was not able to generate digital data in terms of motion speed, volume of clay used and total length or volume of the printed layers. The process of 3D printing, from digital modelling in CAD programs to converting to machine instruction G-code in a CAM program, and operation of hardware requires vastly different skill-sets and knowledge than is common in current construction practices. CAD modelling software packages, with the exception of relatively costly Rhinoceros 3D Modelling package with plug-in RhinoCam, CAD platforms cannot directly communicate with 3D printers and intermediary Computer Aided Modelling (CAM) programs are required to convert vector based data to G-code to communicate with the machine, meaning that currently available software packages do not allow automation or real-time response between digital modelling and 3D printing. However, many advantages were also observed. 3D printing provides the possibility for continuous construction, not limited to working hours or visibility during sunlight with minimal supervision. Another further positive observation was the low level of noise produced during the 3D printing process which was negligible compared to that of construction sites. As predicted in numerous previous studies, the perceived and assessed safety level of using the PotterBot was of much lower risk level than for other common construction methods and has the potential to reduce injuries and fatalities in the construction industry.

6 Conclusions

This study aimed to examine the capability of 3D printing to produce complicated geometric and volumetric designs. Eight models were designed and 56 models were created in the laboratory by a 3D printer called PotterBot XLS-2 Scara robot. The entire production process was carefully observed and several factors including material setting time, stability during printing, possible unsupported material overhang, deformation, shrinkage and bonding between layers. for all 56 models were recorded. The results show that the first three models are significantly different than the last four models. In addition, the studies show that the waste material and motion path can be challenging for models with complicated designs. The key contribution of the paper is to compare several complicated models to measure how curvature and unique models can affect potential construction practices for creating complex curves and forms on construction sites without the need for formwork or reinforcements.

As discussed, future studies will continue to focus on adapting 3D printing processes, currently suitable for controlled lab environments, to real construction sites with a focus on automating and simplifying the process to enable the adoption of 3D printing into house construction.

Abstract –

Robots are expected to be widely used on future construction sites to assist human workers in the performance of repetitive physically-demanding tasks. Unlike typical manufacturing assembly lines, where parts are delivered to robots and workers in stationary workstations, construction robots and human workers must accumulate all necessary resources and repeatedly navigate to desired assembly locations on-site to perform useful work. The condition of such resources and the geometry of the environment are constantly changing and generally unstructured. As a result, the motion trajectories of any robot arms cannot be programmed beforehand. The robots must define the trajectory based on the encountered workspace geometry. Learning from Demonstration (LfD) methods have the potential to be used in teaching robots specific skills through human demonstration such that the robots can repeat the same process in different conditions. In this research, we explore the LfD method to teach robots to perform repetitive but geometrically adaptive construction tasks of installing suspended ceiling tiles within pre-assembled ceiling grids. The developed method translates the work context from the set of training videos demonstrated by humans to the target scene, then applies the reinforcement learning method to generate the policy for the robot to perform the subsequent ceiling tile installation. The first phase of the proposed method, i.e., the context translation model, is implemented and evaluated by characterizing whether robot-installed ceiling tiles are successfully moved to the grid area. The experiments demonstrate promising results that show the applicability of the LfD method in teaching robots to perform geometrically-adaptive construction tasks.

1 Introduction

Human-robot and co-robot collaborative teams are broadly envisioned to be deployed on future construction sites [1]. The construction industry accounts for 4.3% of GDP in the U.S. [2] and is predicted to reach over 1.4 trillion U.S. dollars in volume by 2021, and $15.5 trillion worldwide by 2030 [3]. Construction is the economic locomotive of the society, whose competitiveness is affected by speed and quality of the construction process. However, the construction industry is confronting major issues of the aging workforce and the lack of skilled labor [44]. The U.S. labor force growth is forecasted to be lower than 0.5% by 2030 due to demographic transition [4]. The average age of the construction worker in the U.S. is 43 years old, and the younger generation is reluctant to enter the construction industry [5] due to its dangerous and demanding working environment, which causes a significant decrease in the employment-population. As a result, applying co-robots to assist or relieve human workers from hazardous, dangerous, and repetitive construction tasks has emerged as a key prospect to help mitigate issues faced by the construction industry [6–9].

According to Manzo et al. [10], approximately 50% of the construction tasks can be automated and may potentially replace nearly 2.7 million construction workers with robots by 2057. The human workers will work alongside robots or supervise them on the future construction site. By applying robots on construction sites, the human workers will switch their duty to perform the planning and cognitive tasks as supervisors, and train the robots to perform the repetitive physical work.

Similar to the manufacturing assembly line setting, the construction process is performed by several repetitive basic tasks [11,12], as shown in Figure 1. Take suspended ceiling tile installation process as an example: workers have to measure the ceiling tile layout, maneuver and position the tile, place the tile, and inspect the alignment. However, unlike the manufacturing environment, the construction site is an unstructured and

dynamic environment [45]. The robots have to understand the environment, and then plan and execute the task accordingly. They need to navigate to the next assembling location as well, which makes it impossible for robots to perform the exact same task repeatedly [13].

Figure 1. The construction process involves repetitive tasks with different objects, such as ceiling tile installation, the tiles are maneuvered and placed repetitively at different locations.

On the other hand, construction projects are unique and unidentical. The loose tolerances and the relatively low quality control of the construction project causes each workpiece to be not strictly identical with each other and requires additional adjustments or improvisation on-site. Even though the workpieces such as tiles are designed to be the same size, the actual pieces may not be the same. Therefore, construction robots must learn how to plan and execute the construction process while overcoming the general uncertainty of the environment and the workpieces they handle.

2 Robot Learning from Demonstration

When training the human worker to perform a task, the human will learn the task by observing the demonstration from experts and practicing the action. The practical knowledge will be absorbed during the practice. Thus, similar to the human learning procedure, the Learning from Demonstration method (LfD) [14,15] can be utilized for co-robots to learn the collaborative task. One approach is imitation learning, where the agent attempts to clone the behavior of the expert [16]. Inverse reinforcement learning (IRL), on the other hand, estimates a reward function based on the expert's demonstration [17,18], then utilizes the learned reward function to obtain the policy. Existing demonstration methods include visual demonstration [19–23], force demonstration [24–26], visual and force demonstration [27,28], and trajectory demonstration [29–35].

First, the visual demonstration methods utilize several or limited video clips of expert's demonstration [36–38]. These methods usually apply to move, push or place simple and light objects, which is not suitable for the construction process, that require handling complex and heavy objects of various geometries. Second, the force demonstration methods are done by force sensors attached to robots and human experts. The robot will learn the contact force on the object and try to replicate the same action. These methods have only been demonstrated on simple tasks such as bolting or unscrewing bottle caps. They do not consider the environment and only try to repeat the action.

Third, the trajectory demonstration methods utilize demonstrating trajectory from expert to train the robot, such as driving simulation or path planning. One of the examples is the kinesthetic demonstration [25], where the robot is dragged by the human to finish the task while memorizing the trajectory. However, these methods require sufficient trajectory data from experts, which is difficult to obtain on construction sites. Finally, the visual and force demonstration methods combine the advantage of both methods to teach the robot to manipulate or grasp objects [28]. For construction tasks, in addition to visual observation, the workers have to feel the haptic or force feedback from the object and react accordingly, yet the existing visual and force demonstration methods only consider the pose of the human instead of the objects.

The objective of this research is to investigate the robot Learning from Demonstration method (LfD) [36] and evaluate the feasibility of applying LfD for teaching construction tasks to co-robots. The trained robots can collaborate with human workers while the human workers focus on the planning and cognitive tasks on the future construction site. The suspended ceiling tiles installation is used as the target construction process to describe the developed methods. The video of the human worker performing the tile installation is recorded in the laboratory and utilized to train the robot. The pose of the object, i.e., ceiling tile, and the target location, i.e., suspended grid, are extracted and tracked in the training video, then encoded as knowledge for the robot to learn. The success rate of the robot performance evaluates the learned skill of the robot.

3 Construction Task Learning

The method for learning the construction task is adapted from a context translation and imitation method by Liu et al. [36]. The practical knowledge of the skill is extracted from the training video as context and translated to the target scene. The robot can further learn the results of the translation through reinforcement learning method [39]. The detailed problem definition of the construction task and the context translation method are discussed in the following sections.

3.1 Problem Definition and Assumption

When teaching a robot to perform a specific task, the knowledge, or context, from the expert's demonstration must be defined in order to let the robot know what information needs to be tracked and absorbed, as well as how to determine the action to take for achieving the task. The context ω can be defined as the pose of the object and expert, the viewpoint of the camera, the condition of the environment, or the target location. In this research, we assume the camera is fixed in two different viewpoints, and the task is to perform in the same environment in order to reduce the complexity.

The demonstration of the task is defined as [36] (1):

$$\begin{bmatrix} D_1 \\ D_2 \\ \vdots \\ D_n \end{bmatrix} = \begin{bmatrix} O_0^1 & O_1^1 & \cdots & O_T^1 \\ O_0^2 & O_1^2 & \cdots & O_T^2 \\ \vdots & \ddots & & \vdots \\ O_0^n & O_1^n & \cdots & O_T^n \end{bmatrix} \quad (1)$$

where O_t is the observation at time t, which is generated from the Partially Observable Markov Decision Process (POMDP) [40]. The probability observation distribution $p(O_t|s_t, \omega_i)$, dynamics $p(s_{t+1}|s_t, a_t, \omega_i)$, and the policy of the expert $p(a_t|s_t, \omega_i)$ are utilized to define the POMDP, where s_t and s_{t+1} are the current and next state (e.g., unknown Markovian state), a_t is the action of the agent (e.g., maneuvering direction), and ω_i is the i-th context (e.g., pose of the ceiling tile, viewpoint). The context is unknown to the robot learner. Since the robot learner might try to track the mismatch context from the demonstration (e.g., follow the pose of the ceiling tile but consider as the pose of the expert), the context ω_i is assumed to be sampled independently and the robot learner has fixed context ω_l sampled from the same distribution [36].

Due to the undetermined feature of the context variables, the robot learner cannot know whether the context from the demonstration is the same as the context in their learning domain. This can be overcome by applying the context translation model [36] to translate the context from the source to the target, then defining the reward function based on the tracked context feature for reinforcement learning method, such as Trust Region Policy Optimization (TRPO) [41] or Deep Deterministic Policy Gradient (DDPG) [42], to learn the policy. The source and the target demonstrations are defined as follows (2)(3):

$$D_s = [O_0^s \quad O_1^s \quad \cdots \quad O_T^s] \quad (2)$$

$$D_t = [O_0^t \quad O_1^t \quad \cdots \quad O_T^t] \quad (3)$$

where D_s is the demonstrations from the unknown context of source video, and D_t is from the unknown context of target video. After training with sufficient examples, the context translation model is capable of translating the new demonstration D_n into the robot learner's context ω_l so that the robot can track and learn the feature.

3.2 Context Translation Model

The objective of the context translation model is to learn the translation function that can translate the source demonstration $D_s = [O_t^s]$, $t = 0,1,...T$ to the target context ω_t with the first observation O_0^t in the target demonstration D_t, that is, the first frame of the target demonstration video. The full translation function is defined as (4):

$$M(O_t^s, O_0^t) = (\hat{O}_t^t)_{trans} \quad (4)$$

where $(\hat{O}_t^t)_{trans}$ represents the translated observations in the robot learner's context.

The context translation model is constructed by several encoders, decoders, and autoencoders [43], which includes a source encoder $En_s(O_t^s)$, a target first observation encoder $En_t(O_0^t)$, and a target context decoder $De_t(z_{trans})$, as shown in Figure 2. On the left side is the framework of translating the source observations to the target observation through the translation function $T(z_s, z_t) = z_{trans}$, where z_s, z_t and z_{trans} represent the features of the encoded source, target, and translation. The loss function for training the translation is defined as L_2-norm (5):

$$L_{trans} = \left\| (\hat{O}_t^t)_{trans} - O_t^t \right\|_2^2 \quad (5)$$

Since the unknown context is translated from source to target, the features need to train on the target video in order to ensure the consistency of the feature representation between the encoder En_s and decoder De_t. The right side of Figure 2 is the framework of the autoencoder for training the En_s and De_t with a reconstruction loss, which is defined as (6):

$$L_{rec} = \left\| De_t(En_s(O_t^t)) - O_t^t \right\|_2^2 \quad (6)$$

The next step is to align the feature representation of the autoencoder with features z_{trans}. The loss function for the alignment is defined as (7):

$$L_{align} = \| z_{trans} - En_s(O_t^t) \|_2^2 \quad (7)$$

3.3 Network Architecture

The network of the encoder and decoder is illustrated in Table 1. In the encoder network, four convolutional layers with different filter size and stride followed by two linear layers with the size of 100 and 0.5 dropout are applied to the training video frame. In the decoder

network, one linear layer with 0.5 dropout followed by four deconvolutional layers with different filter size and stride are applied to the translated feature. All the convolutional and deconvolutional layers are followed by LeakyReLu activation function with 0.2 leak except the last deconvolutional layer in the decoder. The filter size of the linear layer in the decoder is dependent on the size of the input image. Batch normalization is applied to the network. The input image is cropped to size of 48 by 48 pixels for training and testing.

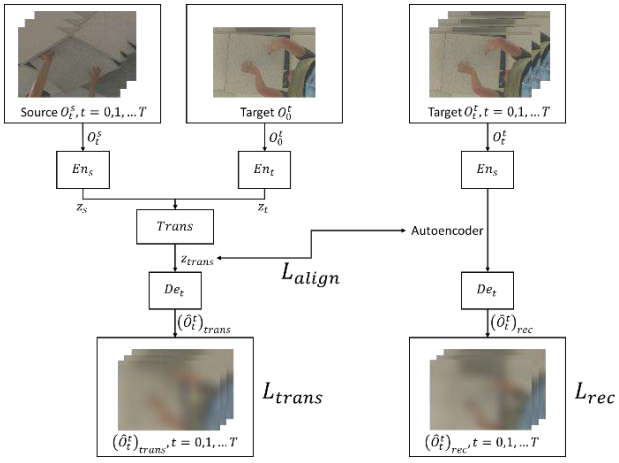

Figure 2. Architecture of the context translation model.

Table 1. Network architecture of the encoder and decoder.

Type	Layer	Filter size	Stride	Other
Encoder	Conv	32	1	LeakyReLu leak = 0.2
	Conv	16	2	
	Conv	16	1	
	Conv	8	2	
	Linear	100	n/a	Dropout = 0.5
	Linear	100	n/a	
Translation function	Linear	100	n/a	Dropout = 0.5
Decoder	Linear	*	n/a	Dropout = 0.5
	Deconv	16	½	LeakyReLu leak = 0.2
	Deconv	16	1	
	Deconv	32	½	
	Deconv	3	1	n/a

*Depends on the size of the input image

3.4 Reward Function for Robot Learning

After the source context is translated to the target observation, a reward function must be defined for the robot to learn the policy through reinforcement learning method. The reward function contains a feature tracking reward function (8):

$$\hat{R}_f(O_t^l) = -\left\| En_s(O_t^l) - \frac{1}{n}\sum_i^n T(z_s, z_t) \right\|_2^2 \quad (8)$$

and an image tracking reward function [36] (9):

$$\hat{R}_i(O_t^l) = -\left\| O_t^l - \frac{1}{n}\sum_i^n M(O_t^s, O_0^t) \right\|_2^2 \quad (9)$$

where $En_s(O_t^l)$ encodes the learner's observation O_t^l to z_l. Finally, the total reward function is defined as (10):

$$\hat{R}(O_t^l) = \hat{R}_f(O_t^l) + \omega \hat{R}_i(O_t^l) \quad (10)$$

where ω represents the weight.

4 Experiments

In order to evaluate the feasibility of applying the robot LfD method for construction tasks, the ceiling tile installation demonstration video was collected in the laboratory and utilized to train the context translation model. The performance of the model was evaluated by the success rate of the installation task.

4.1 Implementation and Training Details

The context translation model was implemented by modifying the original network using TensorFlow. A total of 55 videos were utilized to train the network, and 20 initial observations were used as the testing data, i.e., first frame of the video as the starting point for testing. In the demonstration video, the camera was set up at two fixed viewpoints for reducing the complexity, as shown in Figure 3. The network was trained by ADAM optimizer with learning rate 10^{-4} and the loss function described above.

Figure 3. Example of the ceiling tile installation demonstration video with two different camera viewpoints.

4.2 Results

We use the success rate to evaluate the performance of the context translation model on the ceiling tile installation. The success metric is defined as whether the final distance between the ceiling tile and the target grids is within a predefined threshold. After the source context is translated to the target scene, we identified the final location of the ceiling tile and the grid, then determined whether they were within the predefined threshold in order to calculate the success rate. Figure 4 is an example of the demonstration source video of ceiling tile installation. The human worker demonstrates how to install the ceiling tile.

Figure 5 shows examples of the target observations with two different viewpoints (iso view and bottom view). The target observation is the first frame of the demonstration video, which is utilized for translating the context from the source video. Figure 6 shows the results of the translated scene. The top row is the successful result, and the bottom row is the unsuccessful result. The red rectangle represents the ceiling tile, and the green rectangle represents the target grid. The distance between the ceiling tile and the grid is over the predefined threshold; thus it is determined as unsuccessful result. We compare the success rate of the translation with the different type of viewpoint, as shown in Table 2. The success rate of the bottom view is 25%, and the iso view is 43%. The overall success rate is 35%.

Figure 4. Example of a source video of ceiling tile installation.

Figure 5. Example of target observations, which is the first frame of the video.

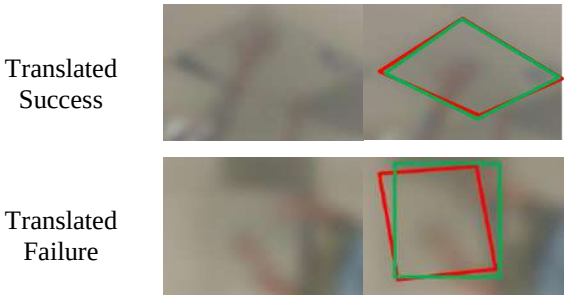

Figure 6. Results of the translated scene. Top - successful result; Bottom - unsuccessful result. Red rectangle represents the ceiling tile, and the green rectangle represents the target grid.

Table 2. Success rate of the translated result.

Viewpoint	Success	Failure	Success rate
Bottom view	2	6	25%
Iso view	5	7	42%
Overall	7	13	35%

In comparison with the Liu et al. [36], where they used the context translation model to teach the robot to ladle almonds into a frying pan and sweep the almonds into a dustpan, the success rate is 66% with 60 training videos of the almonds pouring and 75% with 100 training videos of the almonds sweeping. Thus, the performance can be improved by providing more demonstration videos. In addition, the bottom view has a lower success rate since most of the trajectories of ceiling tile installation are vertical types and the bottom view cannot provide sufficient information. This can be addressed by avoiding the vertical type viewpoint.

5 Conclusion and Future Work

In this research, we proposed and evaluated a Learning from Demonstration (LfD) method to train the construction robot to perform repetitive construction tasks, in which we utilized the ceiling tile installation as the target task. We adopted a visual LfD method, i.e., the context translation model, for our application. The context translation model only uses the visual demonstration as input to train the robot. The model is trained on a set of ceiling tile installation demonstration videos. The results showed that the model could translate the work context from the source video to the target observation with acceptable success rate when using the iso camera view, which can further apply the reinforcement learning method for robots to determine the control policy. In ongoing work, we are collecting more demonstration videos from new viewpoints. We are also implementing the reinforcement learning method for robots to learn and perform the policy.

Abstract –

Rebar inspection plays an essential role during construction phases to assure the safety of the construction. Usually, inspectors use 2D drawings and tape measures to inspect rebars. However, the effectiveness of the inspection is greatly hindered by indirect three-dimensional information in 2D drawings and visual obstruction of measuring by rebars, especially when the structural elements become more complicated. To address these issues, this paper proposes an Augmented Reality (AR) approach to assist rebar inspection, which includes a framework of inspecting rebars with AR models. An experiment on stirrup inspection is conducted to evaluate the benefits of the AR approach by comparing with the traditional method. The result of the experiment indicates that the AR approach takes shorter time for inspection but with less precision.

Keywords –

Augmented Reality; Rebar inspection; On-site inspection

1 Introduction

The inspection work is one of the most important parts during construction phases. This process assures the quality of construction. In most construction projects, rebars account for a great part of the construction inspection among all the inspected elements. The efficiency of rebar inspection works is influenced by two main factors. The first one is indirect 3D information retrieval from 2D drawings. 2D drawings are still commonly used in most construction projects but do not present 3D information clearly, often leading to information missing. The other one is the measuring tool used for length measurement. Mostly, inspectors use tape measures to check whether the rebar is in accordance with the 2D drawings. However, the tape measures need to be aligned to the specific rebar, which is probably obstructed by other rebars.

Augmented Reality (AR), a technique which allows the user to superimpose virtual information on the real environment, has showed its potential to be applied in the field of architecture, engineering and construction industry [1]. Webster et al. pointed out that AR could be used to provide an inspection guide for inspectors without the use of drawings [2]. Therefore, AR becomes a promising solution to address the aforementioned issues and an AR-based rebar inspection approach was developed in this research to improve the efficiency of rebar inspection. A case study was conducted to evaluate the feasibility of the approach.

2 Literature Review

Many attempts have been made with the purpose of inspection based on AR. Chung et al. [3] conducted an experiment on thickness inspection of manufactured parts, using the instruction and sequences in forms of manual, computer-aided and AR-aided methods. The experiment was taken at fixed location to ensure the superimposition of AR information. The results showed that different forms of information did not affect the accuracy apparently; however, the completion time of AR-aided method was faster than others. Moreover, the augmented information was unaffected by the part shape complexity, proving the benefits of conveying information to inspectors. Shin and Dunston [4] developed an AR prototype system for steel column inspection, including the deviation of position and plumbness. For tracking the deviation of position, the users had to manually move and rotate the virtual model to match the real one and the system would report the value of deviation. Compared to the use of total stations, the AR approach showed time-saving advantage but lost a little precision. However, the system was said to be lab-based and not yet developed for on-site inspection applications. In 2017, Zhou et al. [5] applied marker-based AR techniques for the inspection of tunneling construction. Markers were used as the coordination of the virtual segment models during the inspection of the segment displacement. Similarly, the AR-based method took less time than the conventional measuring method and met the precision requirements. However, the number of the attached markers would be a problem in

practice.

Learning from some design of AR inspection methods in previous research [4-5], this research proposes a marker-less AR-based approach that uses model-based superimposition of the virtual and real objects for rebar inspection.

3 AR-based Rebar Inspection Framework

3.1 The Framework

This research proposes an AR-based rebar inspection framework for solving current on-site rebar inspection issues. It consists of three main modules: motion tracking module, inspection module, and interaction module, as illustrated in Figure 1.

First, we need to have the Building Information Modeling (BIM) models of the on-site structural elements constructed during the design phase. Then, these BIM models are transformed into AR models which retain necessary geometry and non-geometric information for specific inspection items of rebars. Second, inspectors use devices like a mobile phone equipped with video camera to capture the on-site scene and target rebar. To fix the virtual coordinates of rebars while the camera is moving, the motion tracking module, which uses the feature descriptor technique from Google ARCore, increases the precision of position and rotation calculated by the Inertial Measurement Unit (IMU) in devices [6]. This process includes the transformation of global coordinates, camera coordinates, screen coordinates, virtual coordinates, and virtual camera coordinates, which are mainly derived from the pose estimation technique [7]. Besides, ARCore offers the function of detecting real horizontal planes from the photo images. This function is used for anchoring the virtual rebar objects on the real ground plane and minimizing the inaccuracy caused by the IMU.

After that, the user is able to retrieve information from the models, adjusts its position, switches layers of objects, and annotates problems through the interaction module. Last, the inspection module allows the user to transform the target rebar model into a simplified form used for inspection. The forms are based on the type of rebar and the items that are going to be inspected. This process prevents the inspector from the visual obstacle of the whole virtual model, which supports the inspector to focus on one item to be checked. Because of the length limitation of this paper, only the inspection module will be discussed in detail with the case of stirrups in the next section.

3.2 Inspection Module

For proper use of the AR models in the inspection work, the inspection module transforms the rebar model into different forms based on the types of the structural elements and rebars. In this research, we consider four main types of structural elements in the inspection module: columns, beams, slabs, and walls. Columns and beams have columnar rebar combination in their structure; in contrast, walls and slabs have planar rebar combination. This research concludes the BIM model parameters for general rebar inspection of these four elements, as illustrated in Figure 2. Columns and beams consist of main bars, stirrups and tie bars. The parameters of the main bar are size, length, hook length, and splice length. Stirrups and tie bars have the same parameters that are size, spacing, and total number. As for walls and slabs, the rows of rebars have two directions, and each row has its parameters which are size, spacing, and total number.

Considering the complexity and size of the rebar model, this research adopted only some of these parameters for prototyping, as showed in Figure 2. This

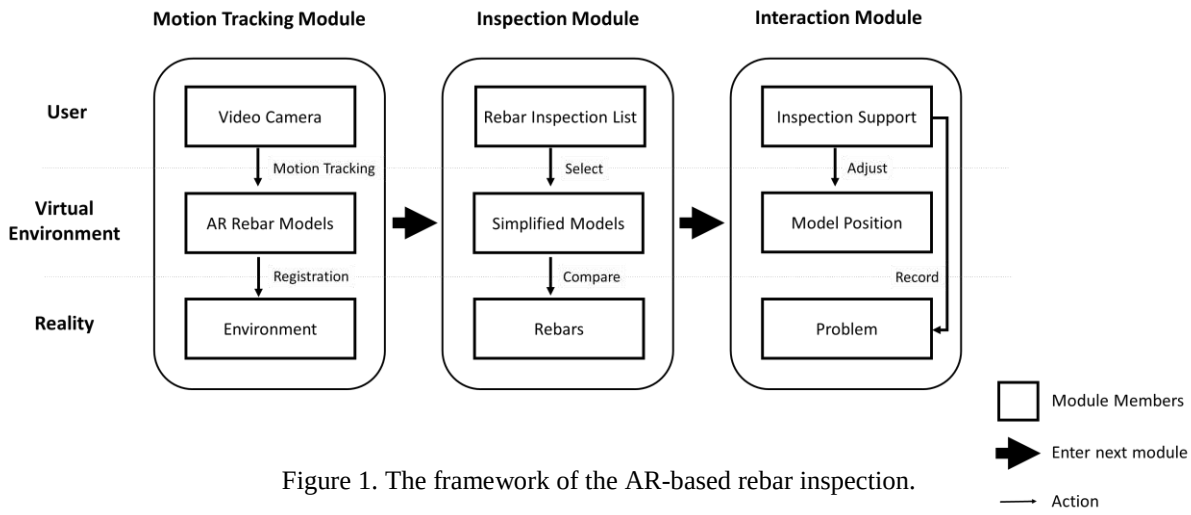

Figure 1. The framework of the AR-based rebar inspection.

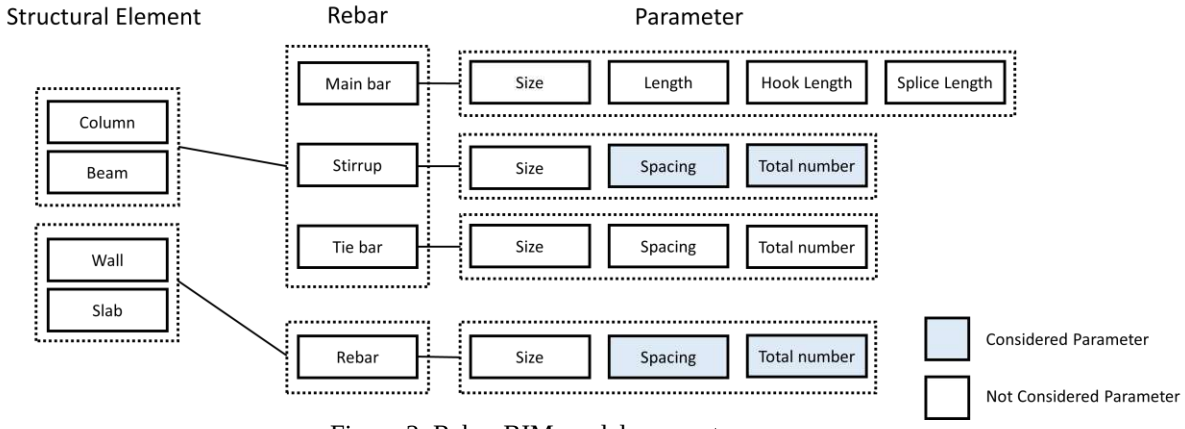

Figure 2. Rebar BIM model parameters.

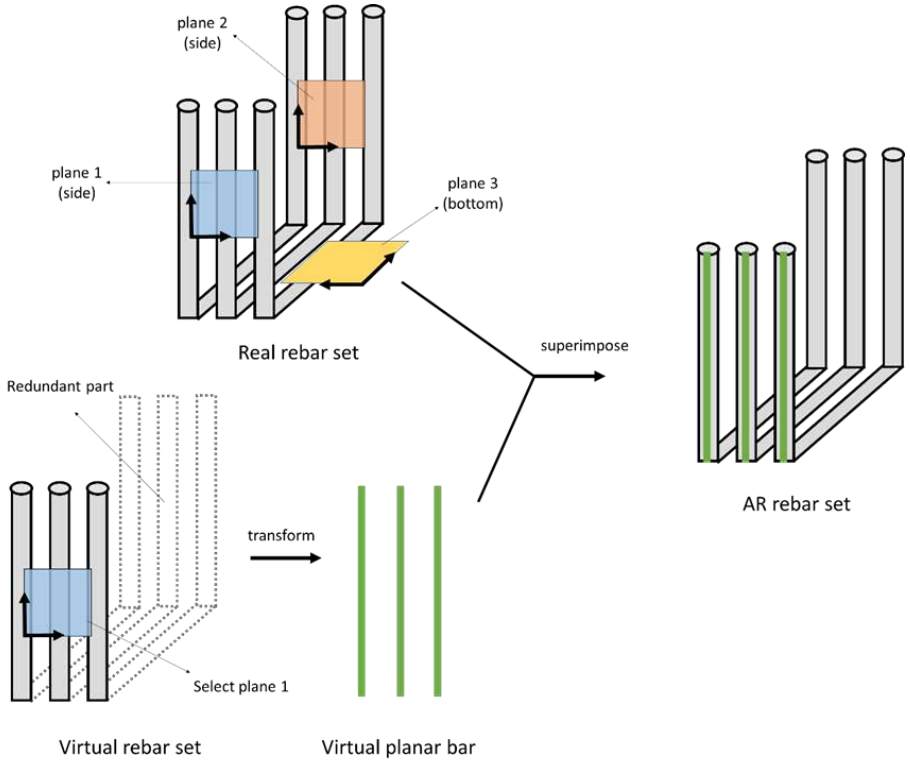

Figure 3. Spacing inspection for rebar sets.

form of AR model is called spacing check which is used for checking the spacing between the stirrups, rebars of walls and rebars of slabs. The size parameter was not used in the inspection on amount and spacing. Besides, this inspection can be implemented on each of the planes on rebar set as shown in Figure 3. Thus, this research transforms the original rebar into a planar bar on the plane facing the inspector. By doing this, the redundant part of the rebar model can be removed, remaining the planar bar representing the center line of the rebar.

When inspectors determine to check the spacing and amount of a specific rebar set, the first rebar in the rebar set will be used for duplication of the rest rebars in the form of planar bar objects. Each of the clones shifts a spacing distance along the same side plane of the rebar set. Through comparing the augmented planar bar with the real rebar, the inspector can check whether the real rebar is far from the correct position where the corresponding planar bar aligns or the rebar set has the wrong total number of rebars.

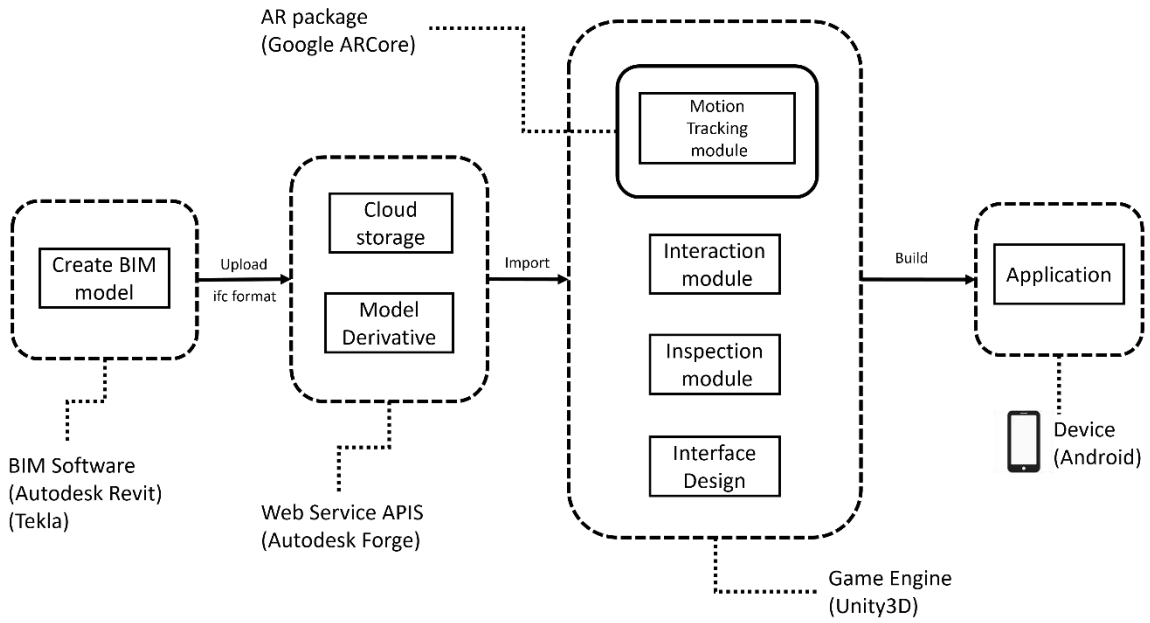

Figure 4. Application setup of the AR-based rebar inspection workflow.

4 Case Study

A case study was conducted to investigate the benefits of the proposed AR approach on stirrup inspection. The implementation of a prototype application system, the setup of experiments in the case study, and the results are discussed in this section.

4.1 Application Setup

To implement the AR rebar inspection framework, different software and packages have been adopted in this research. The process from input to output can be divided into four parts as illustrated in Figure 4. First, Autodesk Revit and Tekla are used as BIM model authoring software to create BIM models. Then, the models are exported to the format of Industry Foundation Classes (IFC) files because of the format's high interoperability. Second, the IFC files are uploaded to the cloud storage of Forge, which is a cloud-based developer tool from Autodesk Inc. Next, to import the model to the Unity 3D game engine, this research uses Forge AR/VR Toolkit to transform the BIM models into Unity 3D game objects that retain both the geometry and information from the original models. Third, this research uses C #, which is an object-oriented language based on the .NET framework, to program AR rebar inspection modules in Unity 3D. To build the AR environment, the Unity package from Google ARCore is adopted. Finally, the application is built on the device powered by the Android operating system.

4.2 Experiment Setup

To test the usability of the application prototype, this research adopted a precast beam as the target. The rebar model was created with Autodesk Revit according to its 2D drawings from the precast factory. In that process, the detail of the rebar model was simplified in order to decrease the data size. The finished model is showed in Figure 5.

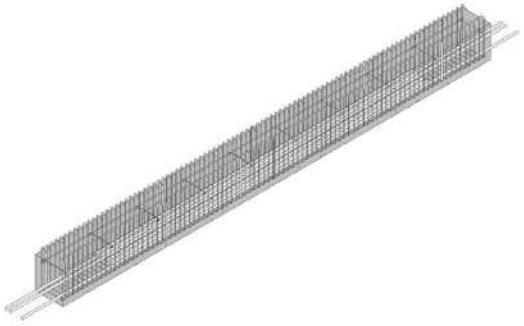

Figure 5. Test BIM model of a precast beam.

The total length of the precast beam is 9,190 mm, and the width by depth is 600 mm x 674 mm. The parts of the rebar tested with the inspection module are stirrups. The total number of the stirrups is 92, and its spacing is 100mm. The center-to-center distance can be expressed as (45 x 100 + 1 x 30 + 45 x 100). To match the model effectively, the origin point in the game engine is set to be in front of the beam section.

After the model was built, an experiment was conducted to evaluate the benefits of the AR approach. The subject was a civil engineer working in a precast factory and having good experiences in inspecting the rebars of precast structural elements. The task for the engineer was to inspect the total number and spacing of the stirrups using both the traditional manual method and the AR method with an Android phone. The inspection standards of both methods were judged by the inspector. The manual method for measuring stirrup spacing is to count the number within a section of one meter. Normally, inspectors sample two sections for inspection; on the contrary, the AR method inspects stirrups one by one. The picture of the stirrup is shown in Figure 6.

Figure 6. Stirrups of the precast beam.

4.3 Results and Discussions

The results of the experiment are shown in Figure 7, where t0 is the duration for the setup, t1 is the duration for the stirrup inspection, and sum is the total duration, which is the summation of t0 and t1.

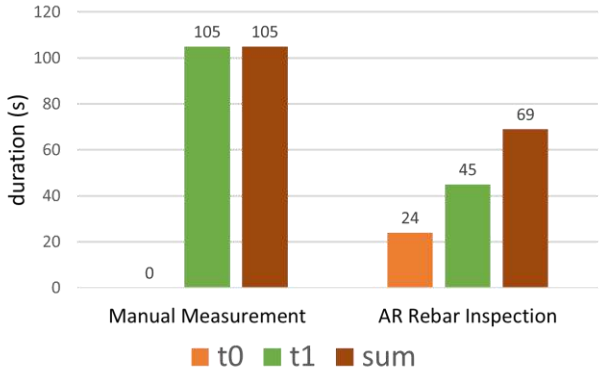

Figure 7. The duration of the manual measurement and AR rebar inspection in the experiment

At first, this research assumes that the setup time for manual measurement is zero because the tape measure and 2D drawings are handy for the inspectors. Thee setup duration for the AR approach is the time for matching the virtual model and the real rebar set. The snapshots of this process are shown in Figure 8. In this case, the inspector adjusts the model from each of the x, y, and z axis one by one to complete the matching task, which takes most of the time in this duration.

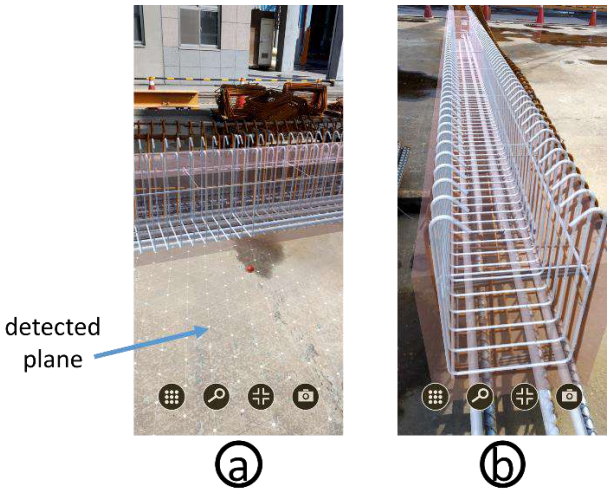

Figure 8. Snapshots of the AR-supported rebar inspection application in the setup duration. (a) Virtual rebar registration. (b) Position adjustment

As for t1, Figure 7 shows that the AR-supported spacing inspection for the stirrup takes much less time than the manual method. In the manual measurement method, the inspector counted the total number of stirrups, and then took two sections to inspect spacing, taking 65 seconds and 40 seconds, respectively. On the other hand, the AR method took almost half of the time to finish the inspection task because inspection on the number and spacing were carried out concurrently as showed in Figure 9. The correct amount of the stirrups can be easily checked. If the deviation between the real stirrups and the virtual planar bars becomes too big during the inspection, inspectors can easily infer that the total number of stirrups is not correct.

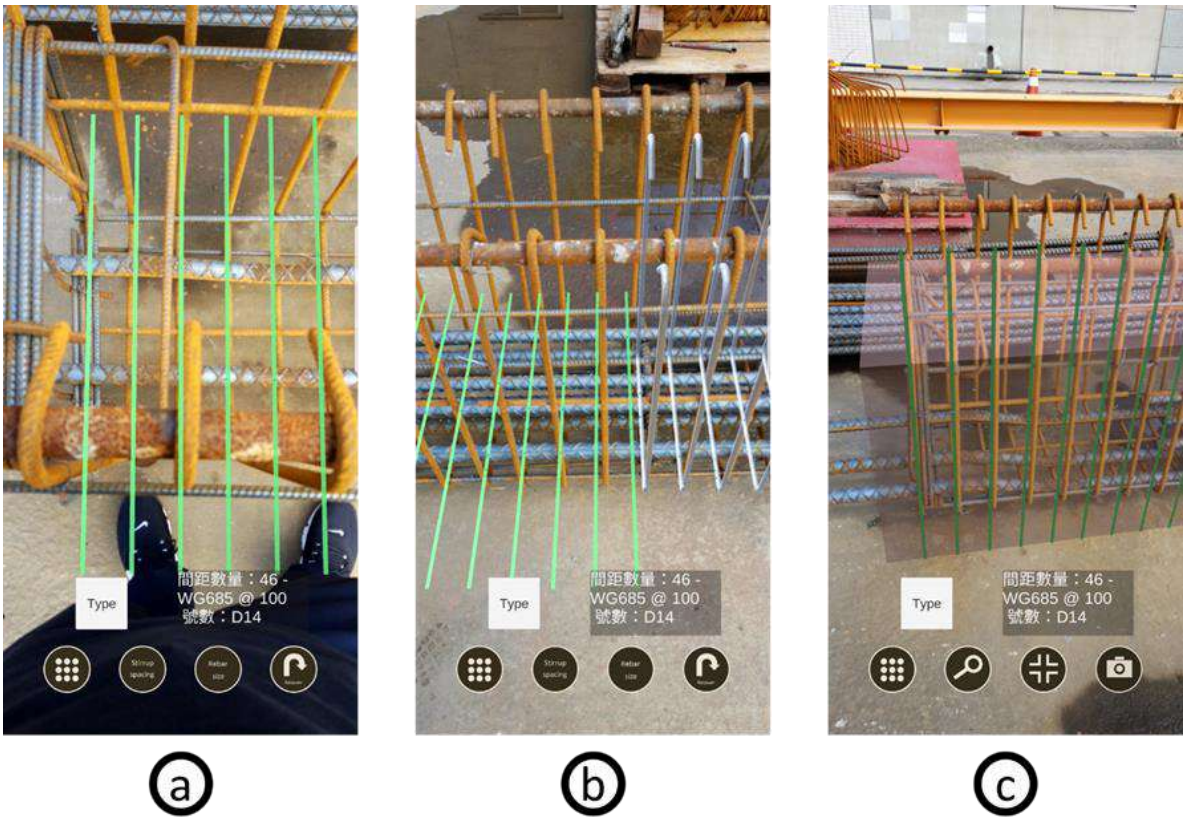

Figure 9. Snapshots of the AR-supported rebar inspection application in spacing inspection task. (a) On the left side of the stirrups, planar virtual bars are superimposed well on the bottom part of the stirrups. (b) In the middle of the stirrups, stirrups have a little deviation from the planar virtual bars. (c). The orientation of the planar virtual bars is changed to superimpose vertically on the front side of the stirrups

5 Conclusion

This research investigated an AR approach for assisting rebar inspection. The approach devised a framework that includes three main modules to facilitate the inspection task. A proof-of-concept experiment was conducted to validate the framework, especially the inspection module. The experimental results showed that the AR approach was 50% faster than the traditional approach in spacing inspection and with sufficient accuracy, proving the potential of using AR for rebar inspection.

However, it should be noted that some conditions have been controlled in the inspection test. For the tracking module, the quality of images captured from different environments may affect the accuracy of the tracking. In the experiment of stirrup inspection, the spacing is a constant, which cannot sufficiently prove the practicability of the inspection module in the AR approach. The user better faces right toward the side plane of the target stirrup so that the AR inspection would not be affected by viewing angles. Also, a proper distance from the target stirrup for the AR approach should be defined but needs further investigation.

There are still rooms for improvement on the proposed AR approach for rebar inspection. The experiment was conducted on a precast beam in a precast factory and the design of the inspection module has not considered all possible real circumstances in rebar inspection. For example, the structural elements in construction sites may be different from the tested one. Also, more inspection items like hooks can be considered in the future work.

Developing a Workflow for Cloud-based Inspection of Temporary Structures in Construction

C. Liu[a], S. Shirowzhan[a], and S. M. E. Sepasgozar[a]

[a]Faculty of Built Environment, the University of New South Wales, Sydney 2052, Australia
E-mail: liuchang1126@outlook.com, samad.sepasgozar@gmail.com

Abstract –

Temporary structures are used during construction and removed after construction. It is necessary to inspect these structures in terms of quality and stability in an automated manner. However, the storage and sharing of inspection data of temporary structures is a problem because most of them have not been included in Building Information Modelling. A cloud-based platform provides a possibility to improve the workflow of data collection and sharing the real-time information with different stakeholders. Hence, to address these issues, this paper aims to develop a workflow to monitor the temporary objects and share them through a cloud accessible to multiple users for safety management.

There is a need to measure the structure heights especially scaffolds during construction. However, traditional inspection methods like tape measurement and recording 2D images on site are tedious practices and sometimes not possible. This paper applied advanced 3D, 360 and action cameras for data collection. Two case studies have been selected. The accuracy of measurement and performance of the proposed workflow were evaluated. First, the initial results of this ongoing study show that implementing the proposed workflow is highly efficient. Second, the comparison of the results with the current practice demonstrates that the workflow can be used for estimating area and quality of certain objects in medium sized buildings. Third, the initial field experimentations reflect that the accuracy of this method depends on the complexity of sites. In conclusion, the developed workflow provides a new opportunity to site engineers to record objects and share information with head offices for further processes and updating information models off site.

Keywords –

3D building modelling; Photo modelling; cloud-based construction data analysis; virtual inspection; Temporary structure; Safety management

1 Introduction

According to "Safe work Australia" report from 2014 to 2015, construction is the third highest industry in serious incidents with 12,575 serious claims [1]. Thus, safety monitoring should be the first priority in construction. As a part of safety monitoring, checking quality of temporary structures is indispensable. For example, construction fencing should be fixed in order to not hurt people in windy and rainy days. However, Engineers usually ignore quality inspection of temporary structures because they will be removed after construction. This may result in serious incidents. For instance, scaffolding has collapsed on the playground of a primary school in Cardiff and frightened children due to lack of safety monitoring [2]. Hence, temporary structures should be checked constantly to ensure the safety in construction [3].

Although 3D-based safety monitoring and quality inspection is applied in construction, it cannot be used for temporary structure in most cases. This is because 3D information of temporary structures is always lack and not included in 3D Building Information Modelling (BIM). Moreover, data collection and transmission is an important task in safety monitoring of temporary structures. Conventional visualization collection methods for data collection are 2D image collection and taking periodical notes in situ. It is usually time-consuming to give data from one partner to another with these methods, and data loss can easily happen if no effective data recording and management method is provided. Thus, it is necessary to provide a feasible and cost saving 3D-based approach for information transferring and inspection of temporary structures.

Cloud computing provides a possibility of automated storing and sharing data of temporary structure conveniently and quickly. It is a type of technology using communication devices such as tablets, laptops and mobile photos to transfer information [4]. Receivers can know the updated information immediately via cloud computing. Related research has been operated. For instance, Matthews, et al. [5]

proposed a new process of progress management based on cloud-based BIM platform for real-time monitoring of a reinforced concrete structure. In this method, the contractor's site engineers can report the process daily using iPad. The project planners and other industry partners can see this real-time progress based on cloud-based BIM in office. Zou, et al. [6] developed a cloud-based information and communication system for safety management in infrastructure. They wrote a web page to connect a Google Drive for data storage shared to all partners. Although these research projects can improve communication and collaboration of different partners of construction projects, few of these visualization methods record temporary structures.

Virtual Reality (VR) provides better understanding of space to clients and contractors which can enhance collaboration such as revising design together [7]. For example, Paes, et al. [7] improved understanding of architectural components by designing an 3D immersive environment, and testers preferred to understand information in VR compared with 2D drawings. Hence, this paper will add VR technology to enhance information understanding for individuals who have no access to real construction sites.

Several digital cameras are applied in construction and civil engineering. 3D, 360 and action cameras are three types of digital cameras. 3D camera provides depth of image, which can create 3D scenes via structure light with stereo sensing or time-of-light sensing [8]. Traditional stereo cameras have two or more lenses to obtain 3D images. Time-of-light cameras project electromagnetic or other wave and record the time from projection to sensor received the reflected wave. 360 camera, also known as omnidirectional camera, is the camera having a field of view that covers approximately the entire sphere. It can be used in building engineering [9] and help to build surveillance system in construction site [10]. Action camera is designed for recording action process with low-cost, portable and high-resolution features.

This paper aims to present a workflow of recording temporary objects using advanced cameras and share the data in a cloud accessible to multiple users. It intends to utilize and evaluate visualisation technologies and investigate their applications in construction. It first introduces background of inspection of temporary structures. Second, the workflow with related methods is presented. Thereafter, challenges and opportunities of technologies are discussed from a practical sense.

2 Methodology

This paper presents a novel workflow for temporary structure inspection including data collection by advanced cameras and process and storage on cloud to make it available for multiple users.

Using advanced cameras, the developed workflow was employed to assist in real time communication for safety management. The whole workflow includes four main steps shown in Figure 1. First, collecting data with advanced cameras. Second, creating 3D models and 2D pano images. Third, inspecting the temporary structures including measuring dimension and adding markers. Finally, displaying scenes in a cloud-based platform with VR headset. Details are introduced as follows.

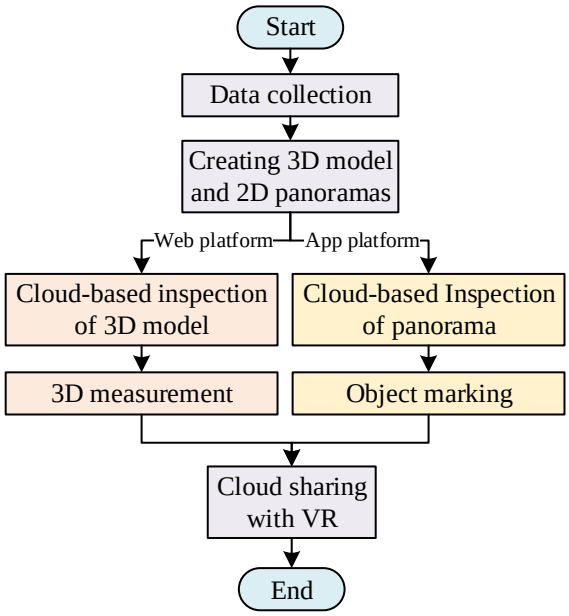

Figure 1. Developed workflow for the proposed experimentations.

2.1 Case Studies for Experimentation

The experimentation has been carried out in two places. The first place is Quadrangle Building construction site in the University of New South Wales (UNSW). Figure 2 (a) shows the plan view of the construction site from 3D model. The part in the red polygon is the construction site. Temporary objects in this scenario are mainly construction fences shown in Figure 2 (b).

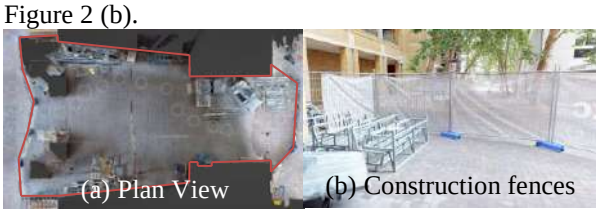

Figure 2. Quadrangle Building construction site.

The second place is a panel installation construction site with temporary objects such as unfinished panel installation shown in Figure 3 (b). The red rectangle in Figure 3 (a) is the location for data collection.

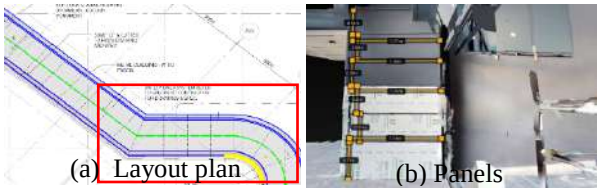

Figure 3. Panel construction site.

2.2 Data Acquisition Methods with Creating Models and Panorama

3D, 360 and GoPro cameras were used for image data collection. 2D camera is a traditional method for recording image data of temporary structures, which is considered as reference compared with other advanced cameras in this paper.

The first tool used for data collection is 3D camera. The structure light 3D camera in this paper can obtain panoramas with its self-contained App. It has an infrared light projector on the left side, an infrared light sensor on the right and an RGB camera in the middle. The projector and sensor create 3D models and the RGB camera creates the 2D panoramas. Thus, this paper uses it scan panoramas and collect 3D data of the site. A corresponding App of the camera is used for remote control. Data collection from 3D camera is shown in Figure 4.

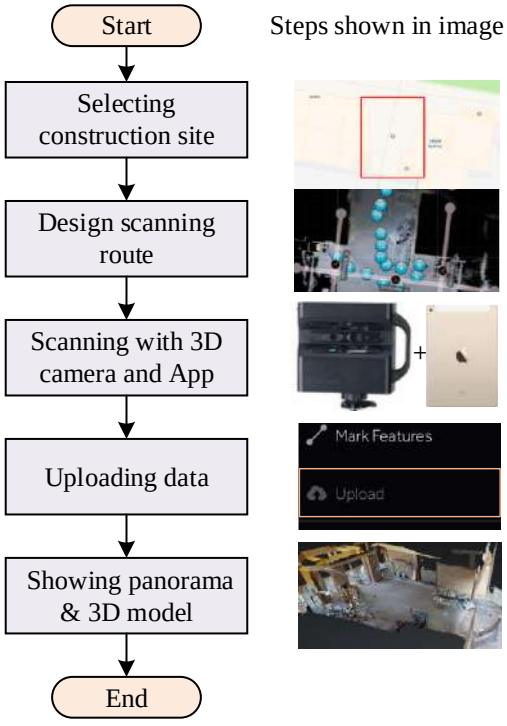

Figure 4. Steps of 3D camera data collection.

The second tool is a 360 camera shown in Figure 5. It is applied to record 2D panoramas of objects in construction site. It is small and portable with two fisheye lenses. The tripod under the lenses can help to fix the camera. Besides, a corresponding App in smart photo or tablet can aid to camera remote control. In order to compared with other cameras, the locations of 360 camera are the same as the locations of 3D camera. Thus, quality of pano images from 3D and 360 cameras can be compared, which helps site engineers to choose which device is more suitable for their construction projects. Data collection of 360 camera is quick and easy. Operators only need to tap the button for taking photos or recording videos on the device. If remote control is required, the corresponding App can be connected to the camera and operators can control the camera even a few meters away.

The third camera is a type of action camera, GoPro. GoPro has already been applied in civil engineering for displacement monitoring [11] and heritage reconstruction [12]. In this paper, GoPro is carried on with a headset by the authors to record the progress of the workflow from data collection to VR display. It is an advanced waterproof camera with wide angle lens shown in Figure 6. It is only around five hundred grams, so it is light enough to be carried on. Thus, it is widely used under the water, hiking and other sports. One of the most attractive functions is its anti-shake function, which is better than most traditional 2D cameras. This is the reason that this paper chooses GoPro to record videos other than ordinary 2D cameras.

Figure 5. 360 camera.

Figure 6. GoPro camera.

3D models will be created automatically by the 3D camera company after the collected data is uploaded by the operator. It could help to reduce modelling time. Besides, data of panoramas and 2D videos do not to be processed, so they can be shown directly in cloud-based platform. 3D models and panoramas can be seen in the website after automatically data process.

2.3 Inspection of structures

Two platforms for data from 3D and 360 cameras respectively are applied in this paper shown in Figure 1. One is an online website for inspection data from 3D camera. The other is an App for panoramas from 360 camera that can be used in tablet and smart phone. Section 2.3.1 introduces measurement based on 3D models operated on the website. Section 2.3.2 explains

how to inspect panorama in this App.

2.3.1 3D Model Measurement

Dimension measurement in construction is usually by tape measure or laser scanning. Tape measurement is easy but has limitations. For example, it cannot be used for measuring height of scaffoldings in tall buildings and it takes long time to measure of objects [13]. Besides, although laser scanning spends less time and has higher accuracy, the device is expensive and requires high professional operation to process the scanned data. Laser rangefinder is easy to measure and cheaper than laser scanner, but it is arduous and can only be worked in situ. It is also necessary to calibrate the laser rangefinder regularly, which takes workers time. Thus, this paper attempts to apply offsite 3D model measurement in construction. After obtaining 3D models from section 2.2, operators need to log on the website of the 3D camera company. Then, they can measure the distance from 3D models directly.

The measurement is compared with tape measure which is reference. The accuracy of the method is calculated by Relative Error and Root mean square deviation (RMSE) [14]. The equations are:

$$\text{Relative Error} = \frac{s_1 - s_2}{s_2} \quad (1)$$

$$\text{RMSE} = \sqrt{\frac{\sum_{t=1}^{T}(s_1 - s_2)^2}{T}} \quad (2)$$

T represents total times of measurement. s_1 means distance measured from 3D model. s_2 means distance from tape measurement. The results reflect the difference of measurement based on 3D model and tape. If the number is small, it means the difference is small. Thus, it could be judged that the method has a high accuracy.

2.3.2 Marking Objects

After taking photos by 360 camera, panoramas of temporary structures can be marked by every partner in the App. Thus, it is easy to communicate with each other using this App. Three main steps are included in adding markers. First, 360 photos should be imported into this App. Second, tapping the screen. The screen will show options including Talk+Draw, Markerup, Create Link, Comment and Insert Image. Users can choose what they need and even record their voice in this 360-view scene. After choosing an option, users can add their markers. Other users will see the changes and markers immediately if the data is revised by one user.

2.4 Panorama Shown in VR Headsets

The processed data from the two cloud-based platforms can both be shown in VR headset, which can provide visual experience to users. After logging in the platforms, the operator can choose certain accounts to access to data. Thus, engineers can share the space to multiple users and protect data that can only be seen by certain persons. It is convenient for site engineers recording temporary objects and checking construction conditions. It also provides an easy way for different offsite partners to realise and discuss danger and errors.

For the web platform for 3D camera data, VR experience can be achieved by clicking white circle button in the scene to move forward or backward. Users can see virtual scene as if they are in reality.

In order to show 3D spaces in VR headset, the user need to operate three steps after turning on the headset shown in Figure 7. The first step is logging in the website in VR headset. Next, selecting one of the scanned spaces and tapping VR button. Then, the left button in VR headset screen is the option that operators need to tap for this VR headset.

3 Results and Findings

3.1 Comparison of Results from Advanced Cameras and 2D Camera

The processed data results are listed in Table 1. 3D camera can create both 3D models, 2D images and 2D pano images. The quality of 2D images from 3D camera is the same as the quality of panoramas collected from 3D camera because the panoramas are merged from those 2D images. Besides, both 3D and 360 can create wider range 2D images than 2D camera. After comparing the data, the authors found that the quality of panoramas from 3D camera is the same as quality of images from 2D camera and is higher than panoramas from 360 camera, but data collection of 3D camera

spent more time than 360 camera.

Table 1. Results from different devices.

Device	Processed data	Measurement available	Marking available
3D camera	3D models, 2D images and panoramas	Yes	Yes
360 camera	Panoramas and videos	No	Yes
2D camera	2D images	No	Yes

Moreover, process recording videos from GoPro have deformation at edges shown in Figure 8. The left walls in Figure 8 (b) is not a straight line, while Figure 8 (a) can show straight line taken by the 3D camera. Besides, the recording area of GoPro is larger than 2D camera but smaller than 360 camera because it only has one fisheye lens and cannot show panoramas.

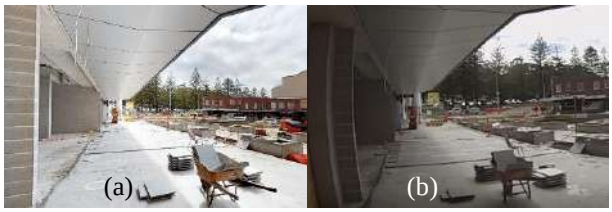

Figure 8. Images from 3D camera and GoPro; (a) 3D camera; (b) GoPro.

Based on results, it can be concluded that the accuracy of 3D models from 3D camera is enough for ordinary inspection of temporary structures. However, due to environment and device limitation, thin objects are hard to be scanned by 3D camera. That may be reason of accuracy of the first place is lower than that of the second. 360 camera is more convenient and portable than 3D camera.

As for video recording, 360 cameras can record the changes in all directions, which has the largest recording area, but the pixel of image in videos is not as high as 2D camera. The chosen 3D camera in this paper cannot record videos.

The authors in this paper created twenty-two models. The average data processing time of the models is less than one day. The time mainly depends on the area of the scanned place. The larger area needs more time.

As introduced in 2.2, after creating 3D models and 2D pano images from captured data, results can be shared in cloud-based platforms. In order to inspect 3D models, partners in a certain construction project should log in a web page designed by the 3D camera company to see the models directly. Besides, measured distance based on 3D models and panoramas collected by 3D camera can also be inspected on the webpage which is introduced in section 2.3.1. Th authors found that the change of the view from 3D model to 2D pano image can be operated easily by clicking different buttons.

Although panoramas from 3D camera can be seen from the aforementioned webpage, panoramas from 360 camera needs another platform to be observed. The platform is an App which can be downloaded both in smart phone and tablet. The App can show 2D images and panoramas but not 3D models. Since the App can show all construction site views from different directions, it is easy to help offsite engineers to inspect construction site situation. The authors in this paper imported the data from 360 camera and conventional 2D camera to the App to create over twenty spaces. The data was collected every week and showed that the construction process can be shown directly by the image recording. Partners can add markers easily based on the attempt by the authors which is introduced in section 2.3.2.

3.2 Inspection of Structures from Results

3.2.1 Comparison of 3D Model Measure and Tape Measure

The authors measured length and height of the fences based on 3D models of the first construction site and results are listed in Table 2. Table 3 lists results from wall panel construction site. Figure 3 (b) shows the measurement of panels based on 3D models. All the results measured based on 3D models are compared with the referenced tape measure results. The relative error and RMSE for analysing error are also listed. It needs to mention that relative error results keep three decimal and RMSE results keep one decimal in Table 2 and 3.

Table 2. Results from Quadrangle Building.

Width (cm)	Tape (cm)	Relative error	RMSE (cm)	Length (cm)	Tape (cm)	Relative error	RMSE (cm)
238	233	0.021		178	177	0.006	
231	233	0.009		181	177	0.023	
226	233	0.030	4.0	187	177	0.056	9.5
233	233	0.000		195	177	0.102	
232	233	0.004		180	177	0.017	

RMSE of width and length of fences shown in Table 2 are 4cm and 9.45cm respectively. The results showed that the accuracy of measurement from 3D models are enough if the requirement of accuracy is not very high. Thus, it could help engineers to decrease measurement time for height of floors even buildings.

Table 3. Results from wall panels.

Object	Place	Dimension (cm)	Tape (cm)	Relative error	RMSE (cm)
Width of Wall panel 1	Left side	59.0	58.0	0.017	0.9
		57.0	58.0	0.017	
		57.0	58.0	0.017	
		58.0	58.0	0.000	
		58.0	58.0	0.000	
		58.0	58.0	0.000	
		58.0	58.0	0.000	
		56.0	58.0	0.034	
	Right side	58.0	58.0	0.000	
		58.0	58.0	0.000	
		58.0	58.0	0.000	
		57.0	58.0	0.017	
		58.0	58.0	0.000	
		58.0	58.0	0.000	
		58.0	58.0	0.000	
		60.0	58.0	0.034	
		57.0	58.0	0.017	
Length of Wall panel 1	Right side	177.0	177.0	0.000	1.6
		177.0	177.0	0.000	
		176.0	177.0	0.006	
		174.0	177.0	0.017	
Length of Wall panel 2	Left side	75.0	77.5	0.032	1.5
		76.0	77.5	0.019	
	Right side	77.0	77.5	0.006	
		77.0	77.5	0.006	

The results in Table 3 show that relative error is low for the second construction site, and RMSE is even no more than two centimetres. Thus, It could be stated that the accuracy of measurement results from the second place are better than those from the first place. This may due to the shape of measured objects. As aforementioned, the 3D camera in this paper is hard to collect data of thin objects. Steel tubes and iron wires on the measured fences in the first place may not be captured by this 3D camera, so the loss of thin object data may influence the accuracy of measurement. The detected objects in the second place are panels whose data are easier to be captured, so their collected data are more accurately than data from Quadrangle Building.

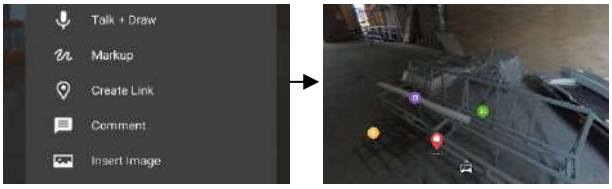
Although there are other methods for fast and accurate measurement of distance such as a laser rangefinder, these methods suffer from the following problems. First, lack of demonstration of real time data to other partners off site in a construction project is a main problem. Second, they will be time consuming and labour intensive if construction workers miss measurement of an area. Third, the difficulty of measurement between two points in case of existence of an obstacle cannot resolved now. Fourth, inability to store data results in the users have to record them manually. Visualising the measured distances by these methods in a digital environment is either impossible or inaccurate with time consuming operations.

Compared with the conventional measuring method, the major advantages of our proposed workflow are to overcome all these problems through automatically storing and sharing accurate 3D data in a cloud-based real time platform.

As for updating indoor 3D models specially for as-built BIM models, measuring floor height is time consuming and labour intensive. This becomes more difficult when the floor height is high such as the height of floors in shopping centres. Our method in automatic measurement of indoor buildings would be of high importance to deal with the problems of lacking time and budget for updating the as-built 3D models. It could also help to increase safety because construction workers do not need to stand in a high space to measurement dimension and height. The third benefit is that it can help to save labour because traditional methods may spend one hour while this method spends only ten minutes for data collection of the same place. However, the limitation is that the data obtained from 3D camera is hard to build 3D models of small or thin objects like thin tubes. The measurement of them cannot be operated.

3.2.2 Marking Objects from 360 Camera Data

Our method is easy to check the progress of construction. Engineers can see how much work has been done via cloud-based 360 views. In order to simulate communication of different partners in a construction project, several markers are added in the cloud-based App as shown in Figure 9. The markers will only show up when fingers tap them, so they do not block items in a construction site panorama. Based on the time of adding markers, the authors find that operating this function in the platform is quick and convenient. Voices, notes and markers can all be shown in one 360 view scene from different accounts that have access to the platform. Thus, different partners can share information quickly with others in this project. It can help to adjust the design during construction and warn dangerous area in time for optimizing construction management with providing effective communication for partners.



(a) Choosing one option (b) Adding markers

Figure 9. Markers in panorama.

3.3 Visualization

VR headset can access to data from both two cloud-based platforms, which helps to have a better understanding of construction environment. After processing all data, the authors invite testers to inspect VR scenes of the two places with VR headset. Based on the feedbacks from testers, VR scenes from both two places can help to understand information in construction site, which is better than 2D drawings. The quality of images in VR from both 3D and 360 cameras are high enough for inspection, while 3D camera images own higher pixels than 360 camera data. Engineers can inspect and discuss construction site situation in office shown in VR headset. Thus, they do not need to check the space in situ. What they need to do is only add markers, and then on-site construction workers can know the problems and dangers immediately shown in the cloud-based platform. One limitation is that some testers had headache or uncomfortableness of eyes if carrying on VR headset for a long time, so it is better to inspect not in a much long time.

Game engine is common for building 3D environment in VR. Operators can revise 3D models, add items and even add animation in game engine, which can provide a more vivid virtual environment than current cloud-based platform. This paper attempted to import 3D models into game engine to provide a virtual environment to multiple users in certain construction project. It can provide more options to revise models compared with cloud-based platforms, but it cannot share information in real time. In this paper, processed 3D models are imported in Blender, an open source game engine. Since the built 3D models can be downloaded in .obj format from cloud-based platform, Blender can read this format and show the models. However, after importing the data of the construction site, the model is shown without texture (see Figure 10 (a)). Figure 10 shows the comparison in different platforms. Based on it, it could be stated that 2D panorama has the highest pixel. Although Figure 10 (a) and (b) are from the same 3D model, Figure 10 (b) is clearer than Figure 10 (a). This may due to the .obj format has data loss besides texture loss.

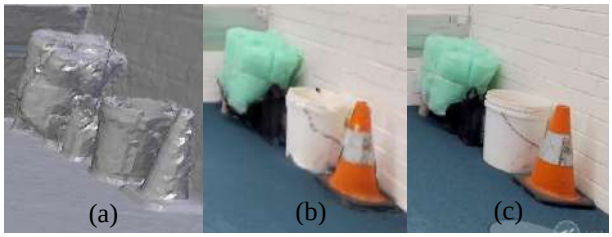


Figure 10. One scene in different platforms; (a) 3D model in Game engine; (b) the original 3D model in cloud-based platform; (c) Panorama.

4 Conclusion

This paper proposed a cloud-based recording and storing 3D data workflow of temporary structures for security purposes in construction. The novelty of the workflow is to provide a method of measuring and storing temporary structures data in a fast and safe way, because workers do not need to climb ladders or allocate a labour to observe and produce inspection reports in the construction site. The measurement results were evaluated based on computational error analysis methods relative error and RMSE. The results show that the accuracy of measurement is enough for inspection, so different partners can participate safety management off site in a cloud-based platform by inspecting information from construction site. Time latency would be eliminated, and efficiency of safety management can increase, because the time of transmitting data could decrease with the workflow.

Challenges and opportunities of temporary structure data sharing from advanced cameras for construction safety management have been identified with the several attempts in this paper. First, the cloud-based platforms in this paper can show 2D images, 2D pano images and 3D models. They provide more information than traditional safety management methods because traditional image methods only record ordinary 2D images. Based on the results of case studies, the accuracy of 3D model is enough for ordinary inspection. Thus, different partners can share information in real time. Second, in order to help engineers to measure dimensions off site, there is an attempt to inspect temporary structures based on 3D models and panoramas, which contains dimension measurement and marking addition. It needs to mention that the data that is hard to be obtained by tape measure such as height of a floor or the dimension of a wall can be measured in this workflow, so the workflow can save labour and time. Third, the workflow adds VR experience, which is few applied in safety management at the current stage. Based on the feedbacks from testers, VR can simulate the construction environment, so different partners can walk in VR environment by tapping the button to have a better standing of on-site situation and locations of construction objects in a construction project. It would be convenient to discuss and revise arrangement and method for construction. Although the workflow can realize cloud-based inspection without VR, the understanding would be as clear as the workflow with VR. Thus, VR is an important part in this workflow.

This study discussed significant potential benefits of the advanced cameras. However, the limitation of the study is that information of 3D models and panoramas are shared in two different cloud-based platforms. Besides, thin objects have not been shown in 3D models clearly because of the technological limitation of

devices. Future work should consider how to integrate information from all resources to be shown in only one platform. Selecting a type of advanced camera for inspection of thin objects is suggested Besides, adding animation and items in game engine for cloud-based publication could be a direction for future work. Moreover, there is another direction is that integrating 3D modelling with BIM to add temporary objects in BIM. It can help to provide more building information.

Towards Rule-Based Model Checking of Building Information Models

Abstract –

Designing a building, so that it adheres to all the relevant applicable constraints imposed by construction codes to cultural preferences to the owners' styles and aesthetics, can be a daunting task, requiring many laborious hours of review and modification. Given the increasing adoption of Building Information Modeling (BIM) in the design process, automated model checking is a pragmatic approach to expeditiously identifying errors that may otherwise cause issues later in the building phase. A variety of methods have been proposed, but they are opaque regarding the rules they consider, and they do not allow users to edit these rules. In this paper, we describe a simple, yet extendible, language for specifying building rules and a method for evaluating these rules in the context of a BIM instance, in order to assess the compliance of the building with these rules.

Keywords –

Building Information Modeling (BIM); Design Constraints; Rule Checking

1 Introduction

Building Information Modeling (BIM) has become a key part of the design and management process for Architecture, Engineering, and Construction (AEC). It supports the 3D visualization and design of buildings, while also making explicit the non-geometric properties of, and relationships between, objects. While this is extremely useful and valuable information for the domain experts, it can be an overwhelming amount of data for bigger buildings with complex models. Each additional object in the model implies multiple new relationships between this new object and existing objects, which increase exponentially as the final model takes form. The process of designing buildings can be a complex and error-prone task, given the attention that needs to be paid to each design consideration. Mistakes can be made if a designer is not aware of the ramifications of their design choices and, unless identified early, they can lead to inefficiencies and potentially excessive additional costs in the future [1].

Checking a BIM model against a set of design rules has been a major topic in BIM research for over a decade, and yet no broadly available solutions exist to support rules from a variety of sources, such as governing agencies, handbooks, and builders. While some model-checking software systems exist, they either require that their users possess a strong software-programming knowledge to configure them with rules of interest, or they are black boxes, not configurable at all. Since it is unlikely that all stakeholders will ever be able to agree on a single immutable set of rules, applicable to all buildings, these products are fundamentally limiting the wider adoption of automated model-checking of buildings. Other attempts at automated model checking have taken the Natural Language Processing (NLP) approach, aiming at automatically transforming rules from human-readable specifications into programmatic executable code. While these methods have many benefits in terms of ease of use, there is usually far too much leniency in the written language, which makes it impossible to process automatically and accurately; as a result, these methods are fundamentally limited in their capacity to capture the requirements around compliance checking.

Our methodology is grounded in the intuition that there can be no effective "one-size-fits-all" approach to the problem [2]. In fact, we suggest that model checking be organized around different levels, appropriate for the level of programming expertise of the stakeholder checking the model. Moreover, all levels of experience should be able to work on a single open platform and use the Application Programmable Interface (API) that they feel most comfortable with. This is because there is a trade-off between the complexity of the rules, the expressiveness of the language used to specify them, and the ease of use. While some rules may require intricate functions that can be difficult to formulate, a substantial portion of rules can be described using simple logic and standard geometric relations.

In this paper, we describe a simple, easy to use, logic-based language for describing rules. Our language

is expressive enough to cover a wide array of rules, and we argue that, in principle, it can be extended to broaden its coverage.

The rest of this paper is organized as follows. We first outline some of the previous approaches in the related work in Section 2. Our methodology is described in Section 3. Section 4 contains discussion points on our methodological assumptions and how the language and rules fit in the larger picture. Concluding remarks are in Section 5.

2 Related Work

Solibri. When researching compliance-checking tools, Solibri Model Checker (SMC) [3] is frequently as one of the few tools specifically built for the purpose of checking BIM models. SMC takes as input a building model in form of the BIM industry standard of Industry Foundation Classes (IFC) [4]. While the available rulesets, initially from the Norwegian Statsbygg handbook [5], can be modified by the end user (by combining rule sets and deleting rules), there is limited support for editing rules in the form of changing the parameters (but not the form) of the provided rules. Additionally, there are a few rule templates that can be manipulated, however, full customization of rules can only be done through the SMC API, which is not open.

There are a number of research papers that report how different checks might be implemented using the available rule templates [6], [7], and [8]; however, these are black-box approaches and it is impossible to comment on their accuracy, efficiency, generality and expressiveness.

Country-Specific Implementations. Model-checking tools have been implemented for the purpose of evaluating requirements of governing bodies, with differing levels of success. Singapore's CORENET ePlanCheck has been noted as the most successful implementation, since, at one point, it was mandatory as part of the government's building requirement legislation [9]. In Australia, DesignCheck [10] was built on the Express Data Manager (EDM) Model Server but, to the best of the authors' knowledge, it has since lost support. The General Services Administration (GSA) in the United States mandates that their project models be checked with rules implemented within SMC [9].

BIM API. While not specifically model-checking tools, BIM editors, such as Autodesk Revit [11] and Graphisoft ArchiCAD [12], provide APIs (the former public while ArchiCAD's requires permission) that allow access to the model's internal structure and object database and therefore, can, in principle, be used for model checking. This requires a high level of programming knowledge even for the simplest checks. To address this challenge, some tools have been developed to perform the same functionality in a visual environment. These include tools such as Autodesk Dynamo [13], which works on the Revit platform, and Rhino Grasshopper [14]. These two tools are both graph-based visual editors that have some scripting available - Dynamo's scripting being in Python rather than C# as the Revit API.

BIMServer [15], an opensource IFC model repository platform, has a model-checking plugin, however, it requires direct coding in JavaScript. The scripts are then linked to the model for execution. This also requires programmatic coding knowledge and a strong understanding of the IFC vocabulary and syntax.

Semantic Web Ontologies. More recently, there has been a conceptual shift in model-checking approaches, given the emergence of semantic-web technologies. Specifically, newer methods have worked with extendable IFC based ontologies of the BIM model to query for design flaws. While this technology can be useful in extending the data schema, the query languages require a steeper learning curve. The basics of this approach are outlined in [16].

Natural Language Processing (NLP). As we mentioned in the introduction, attempts have been made to parse natural-language rules from design handbooks and regulation texts. While such approaches could potentially simplify the rule-creation process, many of the natural-language rules lack the clarity and unambiguity required to be directly parsed without any human intervention or interpretation.

One of the more commonly cited approaches in this vein is that of Hjelseth who used a four-sentence component classification to parse natural language rules, namely Requirement, Applicability, Selection, Exception (RASE) [17] [18]. Another use of NLP has been to identify information from rules that is missing or may need to be added to models [19].

Rule-Checking Languages. The Building Environment Rule and Analysis Language (BERA) [20] was developed as a domain-specific programming language for model checking. The concept is built on providing model-checking capabilities without the need for precise knowledge of general-purpose programming languages [21]. However, the language derives heavily from Java which may be difficult for non-programmers and it is built on the Solibri IFC engine, and therefore is still quite opaque.

Visual Programming Languages (VPL). Some approaches have taken the Rule Languages one step

Natural Language Rule:	**ModelCheck Language:**
Dishwasher must be a minimum of 21" from a corner.	∀ a = IfcDishwasher ϵ ModelObjects ∀ b = IfcCorner ϵ ModelObjects (Distance(a, b)>=21INCH)) True=>Pass; False => Error

Figure 1. An example of a design rule in natural language converted to our rule language. Note that in IFC, there is not type *IfcDishwasher* or *IfcCorner* and the Distance function is not explicitly defined as a relation property. These three elements exemplify the three proposed extensions of our language namely Virtual Objects (*IfcCorner*), implicit geometric object relations (Distance), and expansion of the BIM object type hierarchy (*IfcDishwasher*).

farther by adding a visual component to them, in the same sense that Dynamo is a visual language for Revit's API. This is intended to allow for more complex rules to be created without adding the need to code programming. Check-mate [22] first introduced this as a very simple puzzle-based interface that allowed connecting pieces that together would form a structured rule, however, the expressiveness of this language is limited. The Visual Code Checking Language (VCCL) took a node-based approach, calling it a "white-box" approach with the available nodes to be extendable as the project matures [23], although, to the best of our knowledge, geometric properties and relations cannot be expressed, unless precalculated as properties.

3 Methods

Our methodology for rule checking follows the four-stage process outlined by [9]: (i) Rule interpretation, (ii) Model preparation, (iii) Rule execution, and (iv) Reporting. The following subsections outline our approach to each stage.

3.1 Rule Interpretation

In our work, we have opted to work with a custom, structured rule language approach. As many rules are inherently logic-based and BIM can be viewed as a database for building properties and relationships, our language derives much of its structure from mathematical logical reasoning and database languages, such as Structured Query Language (SQL). As Niemeijer et al. [22] suggested, it is easy to see the similarity between a statement "*For every x in Real Numbers…*" in mathematics with "*For every Window…*" in building regulations. As BIM is a collection of 3D objects, their properties and the relationships among them, we define a model as a set of objects and a set of relationships. Therefore, similar to SQL, our rule language expresses queries on two sets or tables (the FROM element) and determining the result (the SELECT element) of a logical expression (the WHERE element). The exact implementation does not use a specific database query language; we simply use SQL to illustrate our rule language. Figure 1 describes one example of a how a rule can be interpreted from natural language to our proposed rule language.

3.2 Model Preparation

Data in IFC is structured in a highly complex manner as an objects' mesh representation can take the form of extruded solid, Boundary Representation (BREP), or their combinations. This implies that, before the rules can be evaluated, the BIM data must first be transformed into structural objects that support efficient geometric calculations. Similar to [24], our method parses the model into an internal object structure that includes a global triangulated mesh, a local triangulated mesh, and a global bounding box that contains the direction and dimensions of the object in 3D space; a mesh being a series of vertices grouped into sets of three forming triangular boundary faces. Every object with type nested under *IfcElement* is extracted and placed in the set of objects that can be checked.

Once all the IFC objects have been read, our method constructs and adds to the model several different types of Virtual Objects (VOs) which, we define as objects that represent complex, multi-object relationships. By this definition, some VO types are already included in the IFC vocabulary, such as *IfcSpace* and *IfcSite* for example, nested under *IfcSpatialElement*. We extend this list of possible VOs to include *IfcCorner*, as shown in Figure 1, which is the connection between *IfcWall* objects. VOs have geometric bounds and therefore are represented internally much like *IfcElements*. The major difference between the two is that VOs are created based on *IfcElements* and thus depend on them, whereas *IfcElements* have no strict dependence relations.

Properties of objects and object relations are the

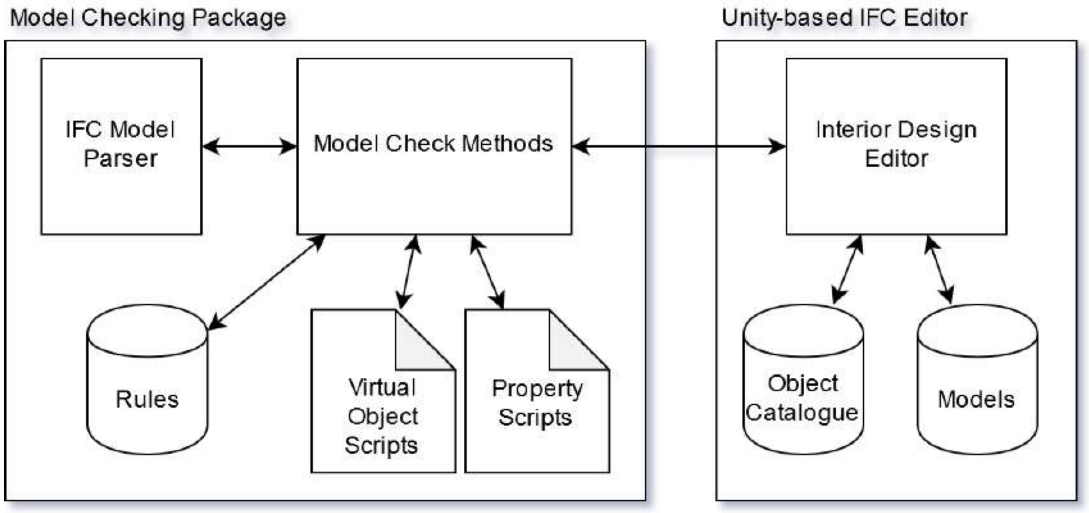

Figure 2. Current implementation of the IFC editor and model checking package.

underlying items being checked by the rules. However, these must be implicitly calculated from the model's geometric data. The geometric properties of objects, such as "Width" and "Height" for example, can be calculated directly on the object's mesh, while geometric-relation properties, such as "Distance" and "Overlap", must be derived from calculations between the two object meshes.

3.3 Rule Execution

All geometric properties and VOs are calculated on a need-to-know basis, thereby intertwining it with the model preparation. As an example, the distance between two objects of a certain type is not calculated unless it is necessary for a rule. Once calculated, it is cached, and can be reused as necessary, until the complete set of rules has been evaluated and the building model-checking is complete.

An interesting challenge is how to archive the computations performed, i.e., the VOs and the relations among objects, in support of the complete model-checking process. In principle, there are two choices: (a) they may be saved with the building model itself, or (b) they may be saved in a separate data structure but with references to the building model.

Should the VOs and properties be saved to the model, it would be necessary to develop a management process to remove the results of individual rule evaluations as the objects to which the rules apply are modified. For instance, if the "Distance" relation property was calculated but the dishwasher has been moved in the new model version, then the original "Distance" property should be removed and recalculated if required.

If the building model editor is capable of flagging the objects that have been modified since the last model check, the model check could recalculate the VOs and properties that depend on those modified objects. This would theoretically expediate the subsequent model checks.

The safer, more conservative, choice is to assume the building model has not been checked previously and that all VOs and properties must be newly calculated and, if existing, then overwritten by the new values. This is the current practice in our prototype, however, we are currently investigating the most efficient way to save and flag changes in our editor.

3.4 Reporting

Finally, all results need to be relayed back to the end user or application. This is returned in the form of an object set, along with the rules that have been evaluated relevant to those objects, and the result of the rule evaluation. While returning all results is important, the reports may also be narrowed down to only the failed rule instances. This allows the client application to parse the result information, graphically display the objects that failed the rule, and display the rule information including the error level of the rule.

4 Discussion

As validation for the proposed research, we have created a prototype model-checking .NET library, as seen in Figure 2.

The library is used by an in-house Unity-based IFC editor of building interiors that is currently capable of

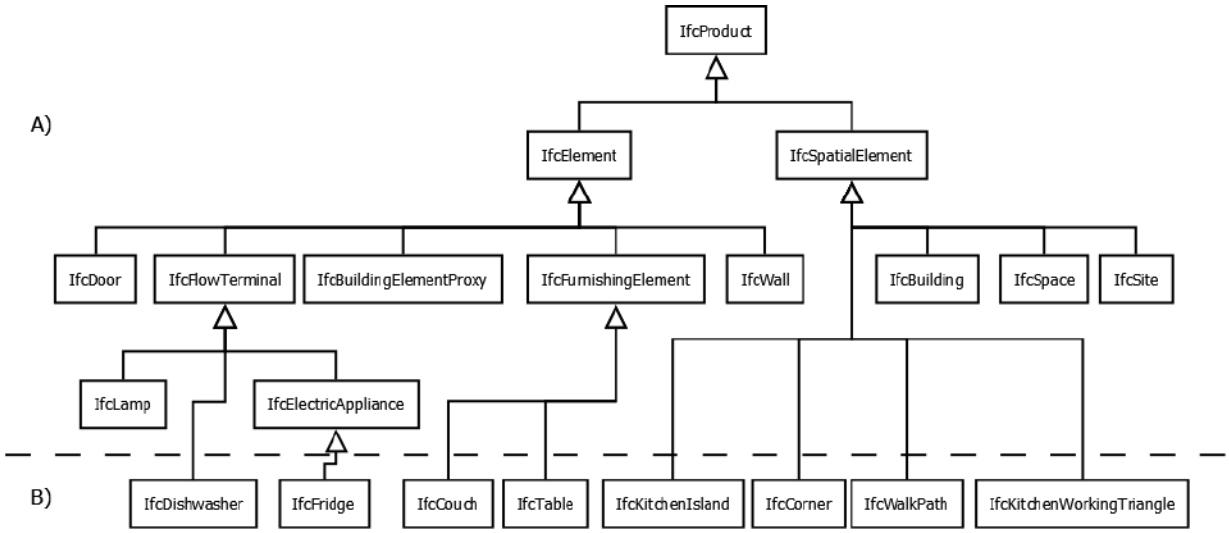

Figure 3. A) IFC object types above the dashed line represent a subset of the current IFC4 schema. B) IFC object types under the dashed line indicate sample extensions to the IFC hierarchy; those under *IfcSpatialElement* representing VOs that would be created implicitly from the existing model *IfcElements*.

reading an IFC file, displaying the model in 3D, and enabling a user to review an object catalogue and add *IfcSystemFurnitureElements* to the IFC model.

The underlying IFC model can be passed to the model-checking method, which is currently configured with an initial rule set, provided by our industrial partner. The rules in this initial set were specified in our language, and subsequently implemented into source code used by the model-checking module. The implementation process is currently manual, but we have developed a library of basic functionalities for computation of VOs and numerous geometric functions (i.e., for calculating object height and width, and distance between objects) and we are currently working on a model-driven method for automatically transforming rules into source code relying on this library.

After execution, the model-checking method returns the results for each of the rules. A rule result includes a pass/fail boolean as well as each instance of the set of objects that were checked against for the particular rule and the result of that instance.

For example, for the rule in Figure 1, an object set instance would be *dishwasher1* and *corner1*, which would have an instance result of pass/fail. The rule result is the collective result of the ANY/ALL/NONE of each object instance and their corresponding instance results. The IFC editor is therefore able to highlight the instances where an object fails a particular rule. The VO meshes are also accessible and can optionally be displayed in the IFC editor.

Since the majority of these rules deal with furnishings and appliances, there is an additional stage in the model preparation that is required but not yet implemented. In addition to restructuring the object representations into our mesh objects, we also believe the object type hierarchy within the IFC schema needs to be extended. Furniture and appliance items typically fall somewhere within either *IfcFurnishingElement*, *IfcFlowTerminal*, or *IfcBuildingElementProxy*, with each of these being the leaf or the second lowest level of the hierarchical tree. While it is possible to add a property to each object that states explicitly the object type (as in the current implementation), we believe more specific IFC types, such as *IfcCouch*, *IfcFridge*, etc. are required. Additionally, this hierarchy should be extendable such that new types defined later should be included. Figure 3 demonstrates a subset of the IFC4 [25] schema with examples of additional object types.

For the purpose of this study, we used the object name to determine automatically whether an object can be categorized, however, the onus is on a more intelligent BIM editor to infer the most specific type of the object, beyond *IfcElement*. It is also imperative that objects do not fall under multiple categories or are compositions of multiple other objects. For instance, difficulties can arise when a collection of objects, such as multiple chairs surrounding a table, are modeled as a single object. Therefore, good modeling practices should be adhered to the largest extent possible.

Other issues encountered included the direction of the objects not always being standardized in IFC, or at least by the BIM editors that export the models. Therefore, relationship properties such as behind and in

front of, which appear frequently in our rules, would occasionally return erroneous values. We see this as an error in the object design, since from an end user viewing the model, this error would not be visually apparent.

Finally, while we acknowledge there are many possible design rules and that they often come in the form of large, text-based documents, we believe that future iterations of these rule documents should be made in tandem with the rule language rules. This would both ensure that text-based rules can in fact be quantified and calculated and that automated rule check results are as the rule creator intended. The use of NLP may help expediate this process but our belief is the onus should be on the rule creator to interpret and test rules as they produce them.

5 Conclusion

In this paper, we have provided a brief introduction to our rule-specification language and a model-checking method able to evaluate rules in this language on IFC building models. Our work aims to connect many concepts put forward in previous model-checking approaches. Several building model-checking approaches exist, each with its own advantages and shortcomings. We therefore believe that providing an extensible framework to enable different rule sets to be expressed and evaluated against different BIM objects should each be supported. Each rule, regardless of method used for its specification (logical, mathematical expressions, or SQL operations on data), should be executable in the same process such that future applications can take advantage of model checking. For instance, we believe model checking can be a useful integration into generative design, which for runtime optimization would require rules sequences to be reprioritized. This will be created in latter iterations of the project and will be implemented as part of the grander scheme of a BIM service framework.

Smart Construction Monitoring for Disaster Prevention Based on Spatial Information and GNSS/USN/IoT

S. Yeon[a], C. Yeon[a]

[a]Semyung University, South Korea

Abstract –
The monitoring technique by combination of the measurement method with the fine precision of the sensor collecting the satellite-based information that can determine the displacement space, is available to a variety of diagnostic information. The measurement method by a GNSS with the sensors is being requested. The progress of natural disasters by various environmental factors and the surroundings is occasionally caused. Such attempts are carried out nationally by distributed torsional displacement of the terrain and facilities. The various sensors and instruments track to diagnose this spatial information. Such information contains the precise displacement of the main facilities and the first reference point in the Geospatial or more three-dimensional available map and location information using the installed sensors or the like bridges and tunnels produced by a USN/IoT change at any time. Each sensor installed on the facility is to collect and integrate the precise positioning and environmental factors. In other words, Combining of the various positioning analysis of mm-class for the facility of main area observed is to be required constantly in real time information of the USN/IoT environment sensors and to be able to utilize such information as a precisely fine positioning information for the precisely fine displacement of the semi-permanent main facilities. It's to be one of the efficient information management. In this study, for the installation of the receiving system, relatively easy access is available to the USN/IoT base line positioning for the target bridges. Transmitting hourly from the received data is also executed in real time using the wireless Wi-Fi/Bluetooth bridges and related facilities to automatically process a fine position displacement. The results obtained from a method can be analyzed by real-time monitoring for a large structure or facilities to disaster prevention.

Keywords –
GNSS, USN, IoT, Construction Disaster Monitoring, Spatial Information

1. Background

It is gradually increasing exposure to the risks to the deformation of the structure aging facilities and increasing natural disasters and unpredictable global warming is a quote that greatly increased the demand for diverse emergency management system to prepare for this in advance. Nationwide construction of bridges and dams, very high buildings, factories, etc. into aging of the various structures are those widely distributed it is happening largely a problem of the collapse and demolition level each year and requires a rational management technique to solve them. While such solutions are increased significantly in recent years various disasters dam, reservoir, pre-diagnosis and safe repair for several facilities and maintenance work on the embankment and has been actively conducted. Nationwide 50-year-old reservoir and the situation that primarily carry out maintenance and ground reinforcement for some areas judged dangerous by the structural diagnosis of the levee, or not monitoring for understanding the ongoing changes and the displacement statement of the situation to be done.

Using a variety of test and measurement equipment in order to check the ongoing security situation, the related building facilities in real-time of 24-hour data acquisition in less mm, combined with the USN/IoT environment factors to be sent through the wireless network. As a

result, the obtained data in real-time by diagnosing the conditions of the various irrigation risk reinforcement for the main structure of the facility is expected for repairs and disaster prevention measures and for support to be capable of preventing and prevention of various disasters and accidents in advance. It can be applied to new emergency management techniques demonstrated.

2. Research Contents and Methods

This study sets up a system to select a three-point displacement of the existing bridge. A GNSS goes into the access and acquisition to the target desired. In case of Bangwha Bridge (1000m) in han-river that station is opened in a few years ago, the real-time receiving from the wireless transmission of data is possible for repair of dams and bridges to the related facilities by the fine displacement measurement and analysis process. The obtained GPS data relays information and data transmitted wirelessly about a geospatial information infrastructure irrigation (dams, reservoirs, embankments) the fine-motion and displacement in the 24-hour real-time on those as well most of them will measure the displacement behavior of the corresponding repair facility during a certain period and do not always identified as dangerous situation. In this study, the corresponding facilities receive GNSS satellite signals that can observe the whole region in real time, and the displacement and behavior characteristics of the structure.

Measurement of the occurrence to sudden displacement as well as a fine long-term trends is both enable to the continuous measurement and the web-based service that you can check where you want it. Also, to minimize the measurement error due to weather conditions and poor GNSS environmental factors, you can take the reinforcement work, safety measures, etc. against the preventive measures due to the long-term trend analysis of measurement results and measuring the abrupt behavior of displacement. For example, the pre-set emergency and alert set up are possible.

But the GNSS method has a disadvantage in that it can only track the displacement of a precise base line over a long period of time. Therefore, the measuring method with an accelerometer is still preferred. Recently, with the development of smart sensor technology, a small mote is applicable and is able to be installed in a place where environmental factors such as changes of temperature, humidity, vibration, illuminance, fine dust, carbon monoxide, nitrogen and wind intensity etc. are desired. In other words, while tracking the fine positional displacement due to GNSS, it is possible to simultaneously monitor by the USN / IoT sensors collecting the changes of the related values at the same time and analyzing how the constructed facilities can be displaced and collapsed from external natural factors and disasters (Fig.2).

Figure 1. GNSS measurement at the bridge using VRS in Korea

Figure 2. GNSS results after processing

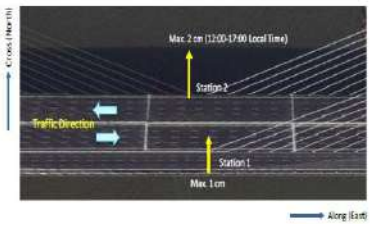

Figure 3. GNSS baseline confirm and 3D axis monitoring

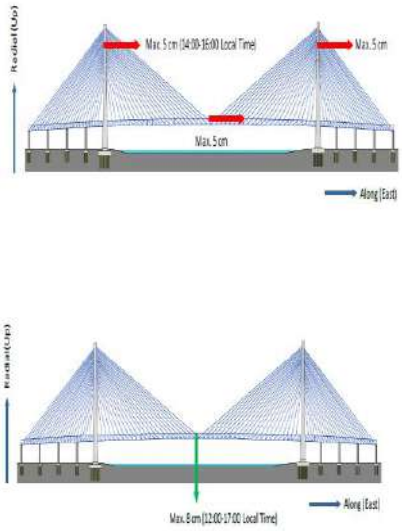

Figure 4. Test diagram at the bridge design sites

In case of bridges, there may be some variation depending on the measurement day and time. However, in case of the east and the west (X) and the north and the south (Y), traffic volume, traffic direction, wind strength, temperature and humidity, it can be seen that the repetitive displacements are continuing and the repetitive displacements occur in the vertical direction as well (Fig.4).

3. Construction Site Measurement

Type of slopes and the displacement of existing structures to install the GPS device and the receiver on the main point are suspected. The neighborhoods of the ground to install on a safe place for reference stations to the exact point by correcting the position information over the other party are received at various points (Stations) for continuously collecting the position information. The old structure continuously observed at least for three months in a year in order to make a fine displacement. The behavior of bridge structures are treated by tracking the displacement. Thus, in this study the relatively easy access to Cheongpung Bridge of Jecheon to install a GPS subject to the GNSS and the related data is transmitted using the wireless Wi-Fi in real time and the received data to the research laboratories hourly. The results from the corresponding Bridges to process fine positional displacement in real time are monitored and analyzed. The related GPS data is measured by calculating in a manner as to post-treatment such as by incomplete installation of the wireless Wi-Fi. Tracking the vibration changes in this case is tried on a valley river near Jecheon of selecting the iron bridge piers after two years of the demolition plan of Chuo-ku railroad track that run for decades over when there are no traffic of trains and the measurement of vibration by a sensor based on the IoT to diagnose conditions was performed for the test (Fig.6).

USN sensor and IoT sensor board are fabricated to collect the environmental factors such as temperature, humidity, roughness, carbon dioxide and nitrogen in the vibration displacement of railroad bridge over 50 years. The observation points for the real-time measurement are located with a wireless communication router. In addition, the environmental condition of the main facilities such as general roads and railways can be known so that they can be used in a fused manner. However, in the case of the expressway, a survey vehicle is applied for real time checking and the video imaging in the location information with various sensors.

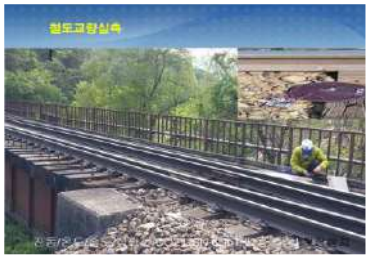

Figure 5. Measurement devices for inspection of road condition on the express way

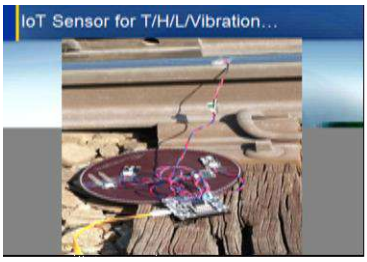

Figure 6. Measurement results from IoT on the railway bridge point

4. Results

Development and application of advanced technology that can monitor the precise displacement and the behavior of the terrain and structures with GPS and GNSS approach is one of a research fields that has a lot of attentions at nations, so its utilization is very extensive national government agencies and the academic practicality to receive much attention from research is a high technology research. Therefore, it provides the proposal studies to the Korea Research Foundation and of the disaster prevention research and support for national projects in this study. In addition, the practical application technology plan, precise safety diagnostics and prevention of observations are expected to be utilized in the corresponding areas that require a multidisciplinary.

As a result of attempting automatic matching of information that can be delivered in real time to environment sensor on the basis of digital information of object internet and remote sensing image, it is found that temperature, humidity, It is possible to integrate practical application technologies by collecting and analyzing the illuminance, carbon dioxide, nitrogen, moisture ratio, noise vibration, etc. simultaneously in real time using the wireless IoT / USN sensors.

In the near future, it is expected to be used in various fields requiring safety diagnosis and disaster prevention of medium to large-sized structures requiring precise displacement observation.

For the construction safety and disaster prevention, it is necessary to monitor the continuous state displacement by the smart sensor in addition to the periodical diagnosis of the construction structure. In recent years, the lifetime of the construction material may be changed due to the increase of environmental pollutants. It would be desirable to use a smart sensor appropriately. As we confirmed by applying in this study, it will be possible and necessary to collect desired data in real time by combining satellite sensors and various environmental sensors rather than past survey tools and methods.
