Small-scale cutting heads exist [8, 9], but are very limited in terms of rock strength. A robotic-miner equipped with a cutting head would possess very restricted capabilities, although the advantages of the system could be beneficial for certain scenarios.
Hence, partial-face cutting systems are considered in more detail in section 3.

2.2.3 Full-face cutting

The fellow of the partial-face cutting machine is the full-face cutting machine. As the name indicates, a full-face cutting machines' cutting head is constantly in contact with the rock face. The cutting head is a rotating part, equipped with pick or disc cutting tools and pushed against the rock face to excavate the material. [3, 10]
In reality, full-face cutting machines, e.g tunnel boring machines (TBM) [11, 12, 13], pipe-jacking machines (PJM) or boxhole boring machines (BBM) [14], are available in various designs from rather small to large diameters and mainly taken for boring tunnels, pipelines or shafts.

The cutting technology of full-face machines makes them capable of excavating very hard and abrasive rock. This requires, compared to the other methods, very high performance for the generation of the cutting and reaction forces. The demanded amount of power and traction lead to comparatively long and heavy machines, which make them much less flexible and mobile. [3, 7, 10]

Due to the existence of micro-tunneling machines or pipe-jacking machines with diameters below 1 m, it is worth checking the feasibility of the implementation in a mining robot (section 3).

2.2.4 Impact hammer

Impact hammers are rock excavation tools, especially used for breaking or scaling operations. A piston produces high frequent impulses and transmits it to the impact tool on the front end. [3]

The method is simple and an impact hammer can be mounted on different types of machines. Typical applications are breaking oversized boulders, quarrying or scaling operations. Impact hammers are mainly taken as an auxiliary tool to the main excavation machine. [3]
Excavation of soft rock or soil is not feasible. Further on, the reaction forces of an impact hammer are considerably high and the production rate is low. Hence, this technology is not further investigated.

2.2.5 Saw cutting

Rock cutting chainsaws are characteristically used in quarrying operations for extraction of dimensional blocks. The capabilities are limited to cutting of soft to medium hard rock. Rock cutting saws are not considered as a production tool for a robotic miner. [3]

2.2.6 Grinding

Characteristically for a grinding process are the high frequency and low amplitude of the process. Due to the fact, that grinding is not used for excavation and tools tend to wear off easily, it will not be analysed any further in this paper.

2.2.7 Auger drilling

Auger drilling combines both excavation and conveying in one method. Often used in coal seam operations, drill rigs with a rotating auger and a drill head on the front tool end require high thrust forces and torque. Continuous excavation of rock and tunneling are not viable with this certain method. [3, 15]

2.2.8 Dredging

Transshipping or excavation of very soft material can be managed by dredging. Excavation of greater amounts of hard rock and tunnels are not viable with a dredging technology.

2.2.9 Bucket wheel excavation

Bucket wheel excavators are employed for soft coal mining in open pit scenarios. The buckets dig into a layer of material and drop it onto a conveyor belt. [16] presents a mining robot with a bucket wheel excavation technology for lunar soil. This excavation method is not feasible for an underground, hard rock mining scenario. [17]

2.3 Alternative excavation systems

Alternative excavation systems cover non-conventional excavation methods apart from mechanical excavation and drilling and blasting.

2.3.1 High-pressure water cutting

Water jet cutting technology is a method for shattering and cutting material from very close distance. [18] The pressure of the water jet is increased by a high-pressure pump, pushed through a nozzle pointing towards the material to be cut. Often employed for precise cuts, high-pressure water jets have their reason for being utilized in

the mining industry. Various forms of water jets can be applied for individual operations. [18, 19]

[18] defines following appearances of high-pressure water jets:

- Continuous plain water jets
- Pulsating and modulated water jets
- Abrasive water jets

Cutting rock reasonably well requires a minimum water pressure around 100 MPa. A comparatively high specific energy leads to a prerequisite of large volumes of water and decreases the potential as a production tool in a robotic miner. A combination of high-pressure water jets with conventional mining methods seems to be more practical and will be discussed in section 2.4.1 and 2.4.2.

2.3.2 Hydrofracturing

Hydrofracturing, or hydraulic fracturing, is the employment of pressurized liquid (mostly mixed with additives) into a borehole to fracture rock formations. If the present pressure exceeds the rock's tensile strength, crack formations are induced. [20] Mainly used in oil and gas production, hydrofracturing is currently not used for rock excavation and is considered to be not important for detailed investigations.

2.3.3 Laser cutting

Laser cutting technology exhibits high specific energy levels and is typically used for precise cuts of blocks with rather small thickness. [21] Excavation of big volumes is not feasible, therefore not considered for further analyses.

2.3.4 Chemical excavation

Chemical excavation is a very restricted technology, only used in very special scenarios and therefore not discussed in detail. [22]

2.4 Combined excavation systems

Combined excavation systems combine the advantages of mechanical excavation systems with alternative, auxiliary methods.

2.4.1 High-pressure water assisted to drilling

As pointed out in section 2.2, mechanical excavation has some benefits over drilling and blasting. Though, the operating field of mechanical excavation is limited by geotechnical conditions. Many activities involve overcoming those limitations by improving the conventional technologies or developing new excavation systems.
A number of researches and studies [18, 19, 23, 24] investigate the improvement of the overall drilling time and efficiency of rotary-percussive drills.
Assisting water jets enter the cracks in the crushed zone and, due to the water wedge effect, increase the crushing effect.[24]

If the water pressure exceeds the critical stress of the rock, cracks will be induced and result is a reduction of the required drilling performance. In order to decrease drilling time and increase lifetime of the drill bit, high-pressure water jet assisted to drilling seem to be a practical solution. [24] In this specific case, only drilling will be used, if for the excavation method of the mining robot drilling and blasting is chosen. A trade-off between complexity respectively costs and efficiency has to be made.

2.4.2 High-pressure water assisted to cutting

Besides from drilling, cutting can also be assisted by high-pressure water jets. The purpose of assisting water jets are the reduction of the cutting force and decrease of the tool wear. [23]
The greatest disadvantage of currently used, mobile and flexible excavators (e.g. roadheaders) is the limitation of cutting rock with UCS above 150 MPa [7]. Joy Mining [25] has introduced a new disc cutting technology with assisted water jets, the Dynacut^{TM}. Aim of this research project is combining mechanical excavation technology for hard rock cutting with high-pressure water jets. Until now, no test results could be found. [7, 25]

The importance of assisting high-pressure water jets arises, when conventional cutting method reach their limits. Scope of the robotic miner is the excavation of hard rocks. An implementation of a common cutting drum with pick tools will not even be capable of excavating medium hard rock, and therefore, cutting technology with assisting high-pressure water jets will not be discussed further in this paper.

2.4.3 Microwaves assisted to cutting

The basic idea of using microwaves is the same as of using high-pressure water jets: Implementation as an auxiliary tool to a main excavation process for decreasing the rock quality. [26]
One method is the use of microwave irradiation to reduce the rock strength by inducing cracks. Cracks pre-weaken the rock and lower the cutting resistance. Researches show, that the net cutting force can be reduced by approximately 10 %. [26]

The operating fields of the mining robot are wet or submerged underground scenarios. Microwaves are

absorbed by water and as a consequence, the applicability of microwaves is not given.

2.4.4 Ultrasonic drilling

As mentioned in section 2.2.1, drilling is i.e. used for exploration, shaft drilling and extracting samples. Shortcoming of common rotary-percussive drills, while drilling hard and abrasive rock, is maintenance due to tool wear. Purpose of ultrasound drilling is the reduction of operating costs by increasing the penetration rate. A piezoelectric transducer converts the electric energy to mechanical vibration. This oscillation is superposed with the rotation of the drill and provides the penetration. [27]

Compared to conventional drilling, ultrasonic drilling is an elaborate technology and no applications in wet or completely submerged conditions have been found. A comparatively minimal increase of the penetration rate is not the most important point, hence, ultrasonic drilling is not investigated further in this paper.

3 Analysis

In this chapter, the most promising excavation methods, assessed in the previous section, are analyzed in more detail. The applicability of the production tool system is depending on some properties:

- Production rate
- Penetration rate (Advance rate)
- Specific energy
- Limitations

Following parameters are assumed for the calculations in this chapter:

- Input power: 40 kW
- Tunnel cross sectional area: 1 m^2

3.1 Drilling and blasting

The advantages of drilling and blasting already have been discussed in the previous section. The most important feature, for this study, is the capability of excavating larger amounts of very hard rock with one blast. Furthermore, a complete mechanization is state-of the art, however, a full automation of the loading process is a complex challenge to be mastered.

Drilling is the most time consuming step in drilling and blasting. To keep the blasting cycle to a minimum, the penetration rate of the drill to be used is crucial. The penetration rate reflects the drilled length per hour. In this case, a rotary-percussive drill is chosen with a bit diameter of 60 mm. The penetration rate is calculated after [28] (figure 3).

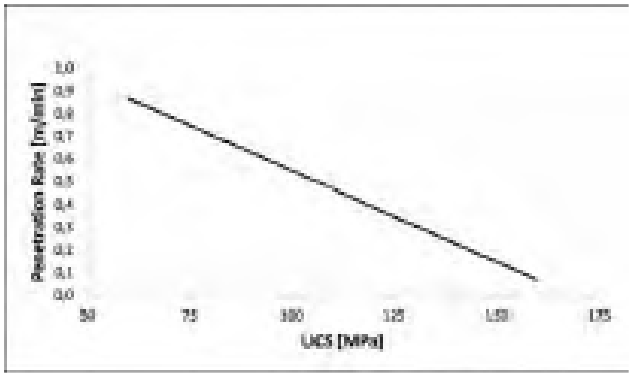

Figure 3. Rotary-percussive drilling - Penetration rate

The formula used for estimating the penetration rate results of a linear regression model of measurement data. The penetration rate is decreasing linearly with the rock strength. [28]
If a bore hole with 300 mm depth is assumed, the time for drilling varies between 20 seconds and 4.5 minutes. Depending on the employed explosives, excavating a tunnel with the assumed cross sectional area requires between 5 and 10 blast holes. Following from this, the total time for one blast (including loading the boreholes with explosives) is estimated between 1-2 hours. For simplicity, the time between drilling the individual holes, for crushing and for conveying is neglected. The precise analysis of the blasting cycle will be done in future investigations.

The specific energy is the amount of energy to excavate one unit volume of rock [3]. A drilling process exhibits, compared to other mechanical excavation systems, a high specific energy (calculated after [3]), see figure 4. However, this peculiarity is extensively decreased by the subsequent blasting operation.

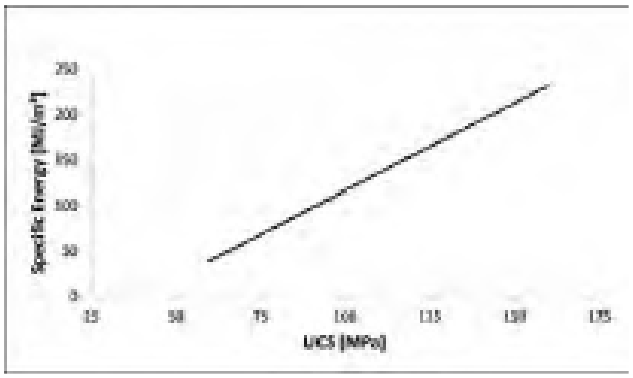

Figure 4. Rotary-percussive drilling - Specific energy

The specific energy of the drilling process is approximated by a linear regression model of [28]. This model provides satisfactory results according to the measurements.

3.2 Partial-face cutting

Partial-face cutting machines distinguish their self by their flexibility and mobility. Excavation of tunnels, cutting curves or limited selective mining are characteristic capabilities. Shortcomings are the severe restrictions by the rock properties. Standard partial-face cutting machines' cutting abilities fatigue at rocks with UCS around 150 MPa [3, 7]. In this paper, a cutting head with a considerably less lower amount of power is investigated, which will limit the mining robot's abilities to excavating soft rocks only. The instantaneous breaking rate, the rock volume excavated per hour, is calculated after [3] (figure 5) and is provided by a prediction model, which is based on full-scale linear cutting tests.

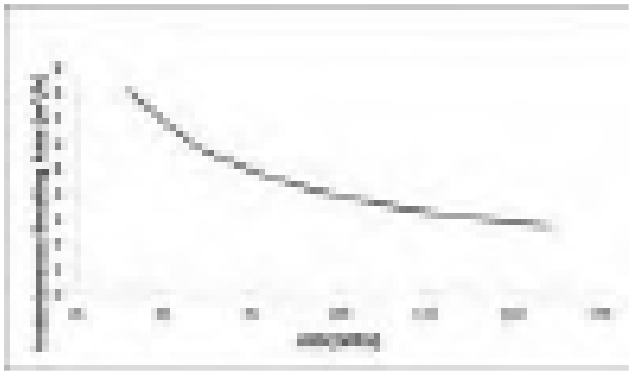

Figure 5. Partial face cutting - Instantaneous breaking rate

In practice, the mining machine would not be able to withstand the reaction forces, resulting from cutting, due to the little weight and traction. In this order of magnitude, the ability of cutting rock above 60 MPa is believed to be very unlikely.

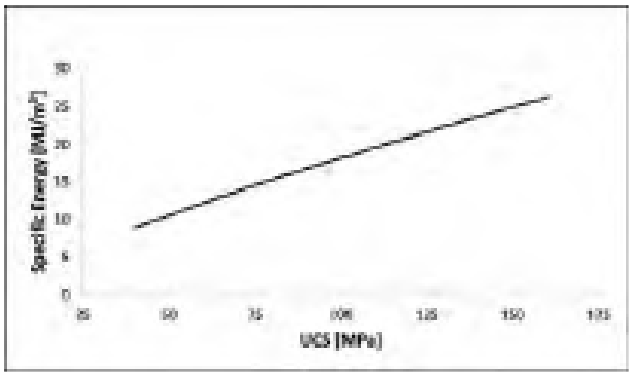

Figure 6. Partial face cutting - Specific energy

After [3], specific energies above 20 MJ/m^3 are not economical and lead to damage of the cutting tools. The estimated specific energy can be derived from the instantaneous breaking rate and the provided input power. [3]
However, for the chosen scope of application, the specific energy levels are bearable (figure 6).

The advance rate is the excavated length of the tunnel (with the determined cross sectional area) per hour. Again, for the advance rate, only the region below 60 MPa is important (figure 7). The estimation of the advance rate presupposes an ideal and continuous cutting operation and is calculated for the fictitious cross sectional area of 1 m^2.

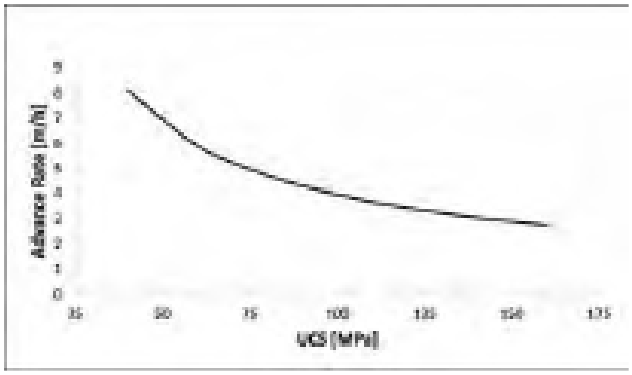

Figure 7. Partial face cutting - Advance rate

3.3 Full-face cutting

In practice, a number of reputable companies have developed small-scale full-face cutting machines. [11, 12, 13, 14] Exemplary machines are: Micro-tunneling machine (MTBM), pipejacking machine and boxhole boring machine.

Those machines already exist with diameters within the range of 1 m. Biggest advantage over the partial-face cutting machines is the ability of excavating hard rock. Despite the size, such machines are capable of excavating rock up to 180 MPa [11, 12, 13, 14].

The net production rate shows the volume of rock excavated per hour (figure 8), calculated after [3] and again based on full-scale laboratory cutting experiments.

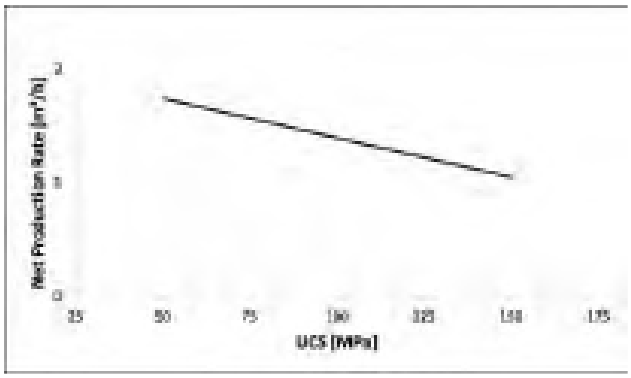

Figure 8. Full face cutting - Net production rate

Theoretically, an average net production rate of 1.5 m^3 per hour is feasible.

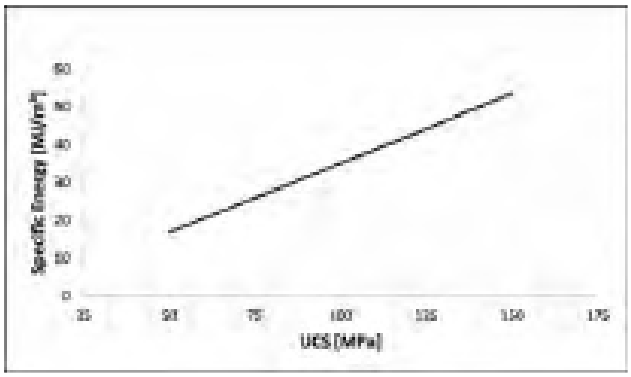

Figure 9. Full face cutting - Specific energy

Compared to the partial-face cutting machines, full-face cutting machines have relatively high specific energies, see figure 9 . Due to the higher power, full-face cutting machines are operating more efficiently in "high specific energy-regions". Specific energy levels are calculated by estimation formula of [3], obtained from full-scale cutting experiments.

The advance rate for the determined tunnel size is shown in figure 10. Ideal and continuous cutting operation is assumed and the fictitious cross sectional area of 1 m^2 is chosen for estimating the advance rate. In contrast to the partial-face cutting machines, the full-face cutting machines' advance generally slower, but does not slow down that much with increasing UCS.

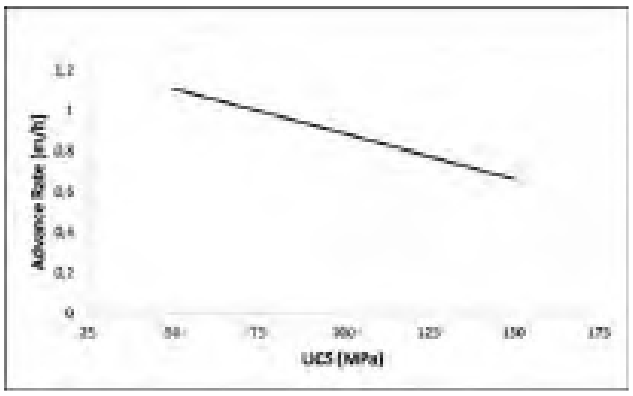

Figure 10. Full face cutting - Advance rate

Eventually, the cutting rate of full-face cutting machines is a crucial parameter to be investigated. The tendencially high cutting forces represent an omnipresent problem of mechanical excavators [3, 7]. [29] has introduced regression models for estimating disc cutting forces. In this certain case, the extraordinarily high cutting forces (calculated after [29]), seen in figure 11, can not be withstood by the robotic miner.

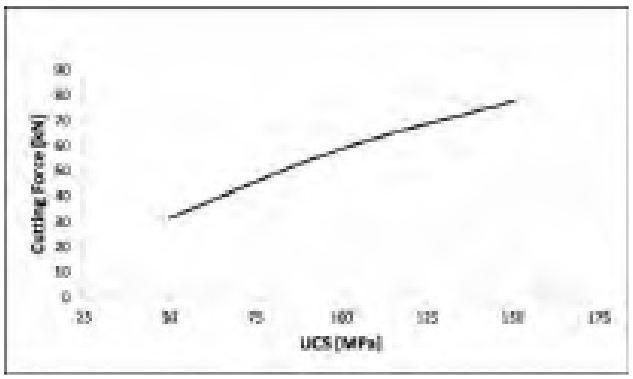

Figure 11. Full face cutting - Cutting force

4 Discussion

From the literature survey and analytical studies following conclusions can be made:

- Advantages of the partial-face cutting systems are the continuous material excavation, the high production rate, the flexibility and the possibility of selective mining. But they are limited by the rock's strength (UCS) and abrasivity (CAI). The excavation process requires very high cutting forces and frequent maintenance of the cutting tool. The cutting forces for excavation hard rock cannot be provided by the given power and weight. Partial-face cutting is only a viable option for small amounts of soft rock. For these special cases, a partial-face cutting robot seems to be a practical solution.
- The capabilities of full-face cutting machines (MTBMs or BBMs) theoretically exceed those of the partial-face cutting machines, but the cutting forces are generally even higher. Furthermore, the less flexibility and higher specific weight are additional limitations and counteract the applicability.
- Drilling and blasting is a very complex process. Multiple, individual tools and working steps increase the efforts of rock excavation and need to be adjusted precisely. Advantages are the comparatively low reaction forces acting on the robot and the excavation of hard rock. To excavate justifiable amounts of hard rock with the given boundary conditions, it is worth to focus on further investigations of drilling and blasting.

In the following chapter, a concept for the implementation of drilling and blasting process is introduced.

5 Conclusion

As explained previously, drilling and blasting requires a minimum of three individual steps:

1. Drilling: Drilling of the borehole
2. Loading: Charging of the boreholes with explosives
3. Hauling/Transporting: Transportation of the fragmented rock

The tool set which is required for excavation process only, consists of a drill, a tool for clearing the blastholes from the drilling debris and an arm for charging the blastholes with the explosives. In figure 12, the implementation of the main operations of the excavation process is visualized. The autonomous work of the mining robot demands a fully mechanized and automated production tool system,

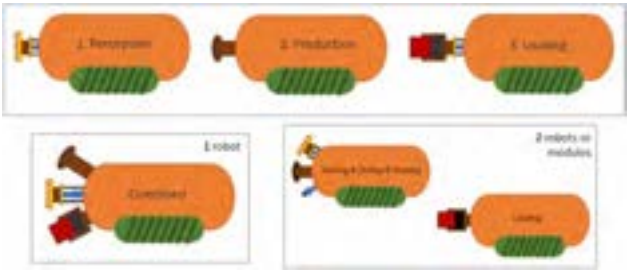

Figure 12. Implementation of drilling and blasting

including drilling, removing residues (debris or small rock grains), loading the blast holes and blasting.

Following the boundary conditions (limited size, weight and power) impede the development of an universally operating robot. Therefore, it is beneficial splitting up the tools into a reasonable number of robots. At least, one drilling and one blasting robot. Due to safety reasons and potential shortage of space inside the robot, the loading setup is completely isolated from the other equipment. In return, other instruments (e.g. perception and navigation instruments) can be installed in the drilling robot.

Aim is to develop a fully mechanized and automated robotic miner, which is capable of detecting the ore, excavating the material and transporting. For a better understanding of the complexity of the drilling and blasting method, a few important points need to be discussed: In addition to the excavation tools, a number of other instruments and equipment are necessary. Navigation and perception shall be executed completely autonomously and demand corresponding technology. If the robot has detected a potential ore vein, a decision of further proceeding has to be made. Samples of the material decide if it is worth mining. A sample can be extracted with the drill and then be assessed in terms of quality by chemical analysis. The fragmented rock is rarely evenly distributed in terms of grain size. Therefore, an on-board crusher is mandatory. After crushing the rock, the material has to be conveyed to a desired area. A feasible, mobile way of transporting material in an underground mining scenario is the slurrification of the excavated rock. Eventually, a couple of side tasks accompany the main excavation process. The mined tunnel possibly requires stabilization and mechanical parts typically tend to wear out. General utility and maintenance are tasks not to be underestimated.

The above mentioned tasks describe an entire mining ecosystem. To turn this ecosystem into a fully autonomously operating operation, it is not avoidable to define a robotic family with complete division of labor. A universal robot body creates the base for the individual robots. The tasks to be executed define the instruments

and tools implemented in every single robot. In this specific case at least six individual modules need to be built. A combination of specific modules can reduce the amount of robots. In figure 13 it is visualized, if every main task is done by an individual robotic vehicle.

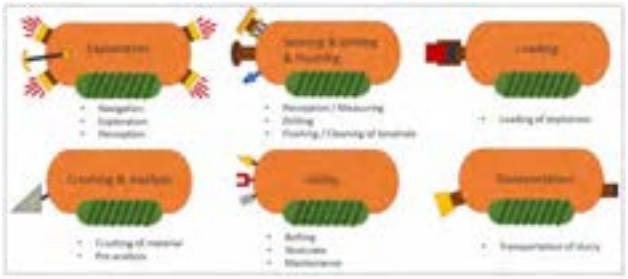

Figure 13. Robot family

The figure shows an exemplary robot family with the following tools implemented:

1. Exploration: Navigation, exploration and perception
2. Sensing, drilling and flushing: Perception / measuring, drilling and clearing of blastholes
3. Loading: Charging of the blastholes with explosives
4. Crushing and analysis: Crushing the fragmented material to evenly distributed size and analyse the excavated material
5. Utility: Stabilization of structures and maintenance
6. Transportation: Transportation of the crushed ore/slurry

Abstract –

Timber building industry is facing a major transformation with digitalization and automation being more broadly adopted. Prefabricated timber frame structures can be mass-produced on large robotic assembly lines, increasing the productivity and competitiveness of wood over standard inorganic materials such as steel or concrete. While standardization is likely to limit creativity, new digital tools, on the contrary, give the possibility to design and build complex and unique geometries. Recent research in bespoke digital prefabrication notably led to the development of Integrally Attached Timber Plate Structures (IATPS). This system consists in assembling wooden panels connected only with timber joints inspired by traditional Japanese carpentry. The elements are digitally prefabricated and inserted into one-another to form bespoke architectural structures. In order to propose a fully automated process for IATPS, from design to construction, this paper investigates a method for assembling the panels with a 6-axis robotic arm. Preliminary studies have shown that significant discrepancies can occur between virtual models and physical prototypes due to joint tolerances, hygrometric variations, and self-weight deformations. To address this challenge and to adapt the robot position to the actual location of the elements, a visual feedback loop was developed using fiducial markers. Several tests were performed with structural wood panels to assess the accuracy of the method for different configurations and adapt the geometry of the joints in consequence. Finally, the insertion of a panel with two through-tenon joints was achieved by taking pictures of the target with a camera mounted on the end-effector of the robot.

1 Introduction

The construction sector is recognized as one of the main players in the current ecological crisis, as the production of new construction materials is responsible for a significant share of CO_2 emissions and plays a major role in the generation of landfill waste. In order to reach the Sustainable Development Goals set by the United Nations for 2030 [1], it is necessary to reconsider the whole construction process and take material life cycles into account upstream in the design phase.

Engineered wood products have been identified as an alternative to commonly used concrete and steel components, which could lead to more sustainable construction systems by lowering the embodied carbon energy of the structure [2]. In addition, connections between timber panels can be integrated into the element geometry taking inspiration from traditional timber joinery techniques and benefiting from recent advances in digital fabrication to generate the toolpath [3]. This construction system, also referred to as Integrally-Attached Timber Plate Structures (IATPS), reduces the number of steel fasteners and improve the structural performance. Since additional connectors are not required, the amount of time allowed to the construction phase can also be reduced.

Previous research has both demonstrated the architectural and structural interest of IATPS, leading to the realization of large-scale projects such as the theater of Vidy [4], the BUGA wood pavilion [5], and the Annen head office [6]. Different workflows have been set up for each of those projects in order to integrate fabrication constraints in the design and automate the cutting of the different pieces using a CNC machine or a 6-axis robotic arm. For the BUGA wood pavilion, collaborative robots have also been used to glue the construction components. However, for each of the three projects, the assembly of the different modules remained a manual process.

First investigations about the robotic assembly of IATPS have highlighted two main challenges for automating the insertion of timber joints [7]. First, friction forces are growing with the number of connections and can hinder the insertion. Second, the robotic insertion has to be performed with enough precision to avoid the introduction of gaps, which would decrease the rigidity of the connections. This paper focuses on the development of a method combining different strategies to automate the insertion of the panels.

2 State of the art of robotic insertion

Pick and place operations are usual tasks, which can be handled by industrial robotic arms. If the initial and final positions of the objects relative to the robot are known, the trajectory can be easily computed and the precision of the insertion will only depend on the accuracy of the robot from point to point. However, for large and heavy construction elements, significant discrepancies can occur between virtual models and reality. Timber panels are typically subject to slight dimensional changes over time and are very sensitive to hygrometric variations. Even for standardized elements, fabrication tolerances are usually around 1 mm. Besides, wood-wood connections are not ideally rigid and gaps in the joints can add up through the structure causing large deviations and preventing the robot from assembling the pieces. Three strategies, which can be combined to ensure a precise insertion, have been identified in the literature and presented here.

2.1 Self-centering connections

A first method consists in adapting the design of the connections to enhance the tolerance and progressively guide the pieces to the final position. Usually the modification consists in chamfering one or both pieces or adding a separated guide.

Conic joints with a tolerance about 4 cm have for example been used in the FutureHome Project [8] in order to compensate for the swing of the automated crane, which was used to assemble the large modules. The slope of the cone was related to the friction forces between the different parts. In the extreme case of structures assembled by drones were precision is an even bigger challenge, specific joints have also been developed for masonry and timber elements [9]. Chamfering through-tenon joints is a commonly used technique in traditional woodworking. Such joints have notably been optimized for the insertion of the panels of the double-layered timber plate structure of the Vidy Theater [4].

A potential downside effect of self-centering connections is the diminution of the rigidity of the joint as the induced slopes are leading to smaller bending resistance.

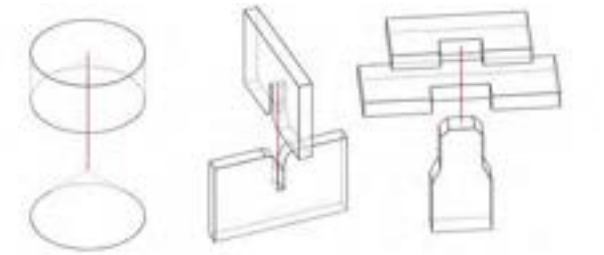

Figure 1. Three types of self-centering connections: conic joint (left), drone-compatible joint for interlocked timber beams (middle), and chamfered through-tenon joint (right).

2.2 Force sensitive end effectors

As manual insertion relies mostly on haptic feedback, another strategy is to use torque sensors to adapt the robot position according to the measured forces. A classic example consists in trying to insert a peg in a hole using integrated force sensors to align the robot position [10]. The need to manage material tolerances by developing robot sensitivity has also been illustrated in the DIANA project [11] where a robotic arm was interactively taught how to insert wooden rods to shape a ruled surface.

Impedance control has also been used for the insertion of gear-shaft mechanisms with a precision around 5 μm for applications in medical fields or aeronautics [12]. More complex feedback loops using behavior-based or machine learning approaches have also been used to develop optimal strategies for inserting pieces into one another [13].

However, the interpretation of the measured force is always dependent of the shape and weight of the piece to insert and the above-mentioned techniques are established for standards symmetrical elements. Developing an adaptive strategy for the case of timber joinery is challenging as elements come in different sizes and the number and type of connections can also vary.

2.3 Visual feedback

Different position tracking systems based on visual feedback loops have been already developed for on-site applications and could also be applied off-site.

A total station can be used to track selected points and deduce the robot position by triangulation while another possibility is to rely on cameras and image recognition. A comparative study has highlighted the performance of fiducial markers for reducing deviation with a clear advantage regarding the execution speed [14]. Fiducial markers have also been used to guide the In situ Fabricator developed at ETH Zurich [15].

Other applications of visual detection includes precisely laying mortar on a brick wall [13] and assembling large modular frames [16] using a combination of cameras and lasers to guide the insertion.

Photogrammetry and laser scanning technologies have also been combined with robotic arms to gather data on-site for indoor and outdoor localization [17][18][19]. However, image reconstruction, point cloud acquisition, and mesh post processing are all computationally intensive and data interpretation requires complex machine-learning algorithms in order to work with different geometries.

3 Methodology

3.1 Integrated design framework

Our approach consists in linking project design and technical constraints by means of computational geometry. Instead of locally solving the insertion problem, the goal is to inform the designer with fabrication and assembly constraints by developing a cross-platform workflow. Custom scripts are used to convey the geometric information between software.

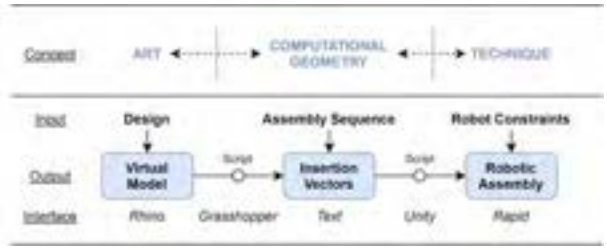

Figure 2. Integrated design framework linking design to robotics constraints.

The assembly is driven by three major inputs: design, assembly sequence, and robot constraints. In a traditional workflow each input is integrated one at a time in the construction process. Digitalization allows for more agility since parameters can be modified and information can flow back and forth.

It was decided to rely on existing specialized software for each part of the workflow instead of building a single custom program from scratch. *Rhinoceros 6* (Robert McNeel & Associates) was chosen as the design interface and the plugin *Grasshopper* as a tool to extract and manipulate data from the model. To simulate and execute the robot trajectory, the research benefitted from a collaboration with a specialized industrial partner, Imax Pro S.A. A custom application was developed, for the purpose of the research project, on the game engine *Unity* (Unity Technologies) to convert geometric data from text file to robot instructions.

Splitting the workflow between different software avoided making compromises between design possibilities and robotic performance. Meanwhile custom scripts ensured a smooth transition between the different interfaces allowing almost instantaneous feedback and testing of multiple design iterations.

3.2 Insertion vectors

Insertion vectors are an essential parameter for IATPS as the geometry of the joints is tightly connected to the assembly sequence. In fact, it is not possible to design the shape of the connectors without knowing the trajectory of the insertion beforehand. The integration of fabrication and assembly constraints follows an iterative process and is inherent to the design of IATPS.

A parametric script was thus coded inside the Grasshopper interface to deduce insertion vectors from a geometric input and a specific assembly sequence. Contact zones are identified by computing intersections between the panels while the type of joints that is generated depends on which faces are connected (e.g. through-tenon joints are created for a connection between the side of a panel and the face of its neighbor).

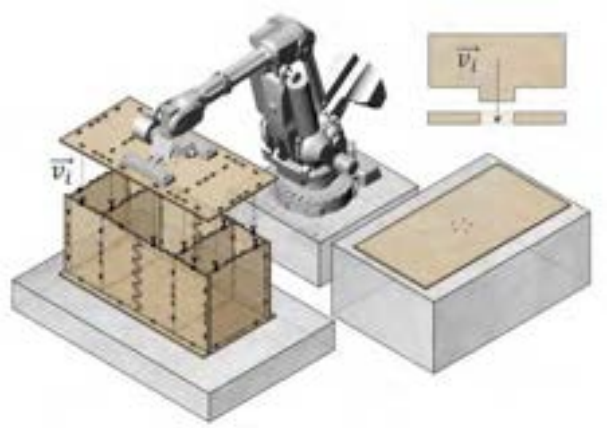

Figure 3. Insertion vectors are inducing the shape of the connections as well as the robot trajectory.

Once the 3D model is created, the contour of the panel can be extracted and the panels can be cut using a CNC. Then insertion vectors are used a second time to generate the robot trajectory, as further described in section 3.5.

3.3 Position detection using fiducial markers

Given the variety of possible configurations for IATPS, the use of fiducial markers was found to be the most efficient method to keep track of the position of the different timber panels. The open-source library OpenCV [20] provides a robust solution for estimating the position of fiducial markers (ArUco) from different sizes. A custom python executable was, therefore, developed to assess the performance of the detection before being integrated to the global workflow.

The algorithm consists in taking one picture from a targeted marker on a panel, computing its orientation and position coordinates and saving those results in a text file. This information is later accessed by the robot controller to update the trajectory.

The image is processed by applying perspective transformation and thresholding to get potential markers from the pixels. Analyzing the color of the 36 cells composing the ArUco provides the unique identification number of the marker. The position and the orientation are obtained by finding the tridimensional transformation from the coordinate system of the camera to the coordinate system of the marker. Rotations are obtained in Euler angles but converted to quaternions to ease the conversion to Unity software, which is using another axes convention.

Figure 4. Image processing of an ArUco Marker using OpenCV library to get the position and orientation of a timber panel.

A key feature of the developed application is that the position of the different targets constituting the robot trajectory are expressed relatively to different coordinate systems. The position of some targets is associated to the coordinate system of the starting location while the position of some other targets is expressed relatively to the position and orientation of an ArUco marker. Hence, updating the position of this marker will automatically update the absolute coordinates of all associated targets while others will remain unchanged.

A unique marker has to be assigned to each panel and positioned at the center of gravity of the panel. Although the point of reference can be set arbitrarily, making it coincide with the point from which the tool would lift the panel, seems the most logical. Potential bending of the panel is minimized by picking it from its center of gravity.

Before proceeding to the robotic assembly, the position of the stack of panels is precisely referenced. Hence applying the visual feedback loop to adjust the starting location of the panels was not considered as necessary and only the end point of each trajectory is updated using fiducial markers. Prior to each pick and place operation, pictures of a marker, placed on the panels on which the insertion will occur, are taken with a camera mounted on the robotic arm (technical specifications are given in 4.1).

3.4 Fail-safe process

One drawback of working in relative with a feedback loop is that detection errors can potentially lead to unexpected trajectories, different from the simulation. Indeed, under certain circumstances, such as in case of insufficient luminosity or when the marker is too far or in the periphery of the angle of view of the camera, the precision of the detection significantly decreases.

In order to prevent updating the position of the marker with inaccurate coordinates, it was decided to take three pictures of each marker at different angles and set two tolerance parameters. If the dispersion of the results or the deviation from the model is too high, new pictures are taken and the updated values are again compared.

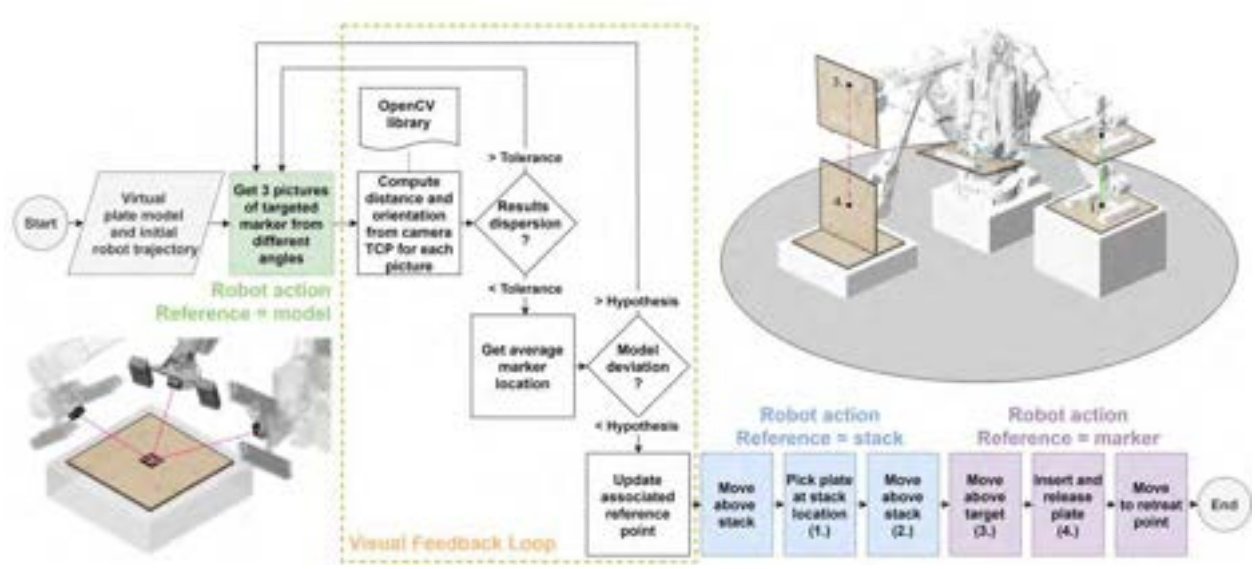

Figure 5. Robotic workflow: camera shooting with robot moving according to model (green), image processing (orange), picking phase with robot moving according to the stack of panels (blue), insertion phase with robot moving according to marker (purple).

3.5 Robotic Workflow

Putting together the initial information given by the insertion vectors with the visual feedback loop, a complete workflow was established to insert the timber panels with a robotic arm (Figure 5). No path planning algorithm was used for the robot trajectory. Instead a strategic approach was preferred.

After the first panel of the sequence is placed, the robot positions itself above the marker using the information of the model as reference. The visual feedback loop is executed and pictures are taken from different angles at a distance of about 50 cm. Then the position of the marker in the virtual model is updated through image processing.

The second step consists in picking the next panel at the stack location. As the position of the stack as well as the dimensions of the panels are known, the robot uses that information to move right above the stack and lift the panel from its center of gravity.

For the third step, the updated position of the fiducial marker is used as the new system of reference and a target is generated above the place of assembly. As a linear move is not always possible between those two position, a joint move is then preferred for this part of the trajectory. In order to constrain the interpolation additional targets can eventually be created in between.

For the last step, the insertion of the panel is finally performed (Figure 7). The robot reaches a target located a few centimeters away from the final position, in the opposite direction of the vector of insertion associated to the panel. Then it follows that vector until the panel is inserted. The panel is released by the vacuum gripper and the robot moves away along the normal to the panel surface before going back above the assembly. A structure is gradually assembled by repeating the process with the next panels.

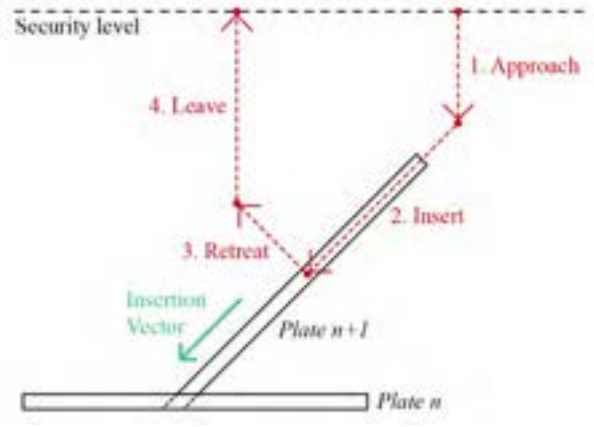

Figure 6. 2D representation of the assembly strategy based on the vector of insertion associated to the panel.

3.6 Intermediate robot language

Once established, the workflow was converted to robot instructions. Target positions and special actions such as taking a picture or activating the vacuum gripper were interpreted from a text file, which was manually typed or automatically generated by script (e.g. in the case of complex assemblies or when a high number of elements needs to be inserted). An intermediate programming language with a high level of abstraction was therefore developed in order to integrate custom commands.

Two examples of instructions are given in Figure 7. The number of parameters on each line depends on the first keyword: *Camera* will start the visual feedback loop and requires 4 additional parameters while *JointMove* requires up to 12 parameters including the coordinates of the targeted position to execute an unconstrained motion between the actual position of the robot and the specified point.

Other typical commands include *LinearMove,* which takes the same parameters as *JointMove*, *Vacuum* followed by *On/Off,* which is used to activate the suction of the gripper, and *Wait* followed by a number to pause the execution of the code during a certain amount of time.

Finally, each line of the code is parsed by our application in Unity for simulation, and converted to the specific programming language of the robot for execution. On a side note, the additional layer of abstraction added by this intermediate language proved to significantly enrich the user-experience by providing an explicit workflow.

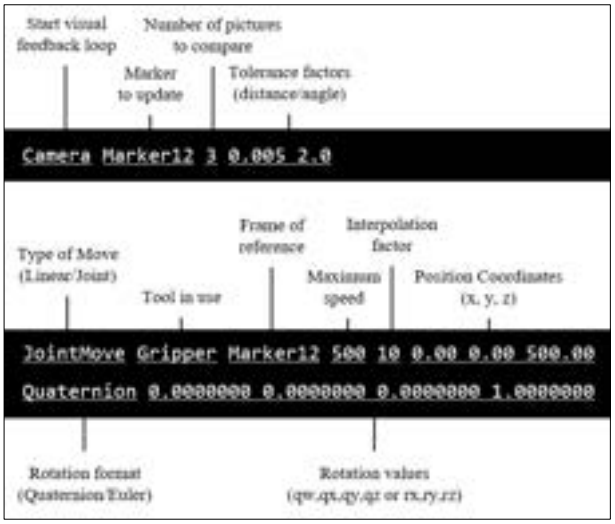

Figure 7. Samples of a text file interpreted by our custom application in Unity to send instructions to the robot controller: Activation of the visual feedback loop (top) and joint move above a marker (bottom).

4 Tests and results

4.1 Experimental set up

Experiments were led with a 6-axis robotic arm (ABB IRB 6400R) with a reach of 2.5 m. The end effector was equipped with two vacuum grippers, which can lift panels up to 80 kg. In addition, a standard webcam (Logitech C270) with a resolution of 1 megapixel was mounted on top of the robot effector and connected by USB cable in order to take pictures of the ArUco markers. Calibration was carried out by taking a series of 20 pictures of an ArUco board from different angles to get the intrinsic parameters of the camera such as the focal distances and the center of the camera. Fiducial markers were then printed as 10 cm square and precisely fixed to the center of the panels following guiding lines previously engraved with a CNC.

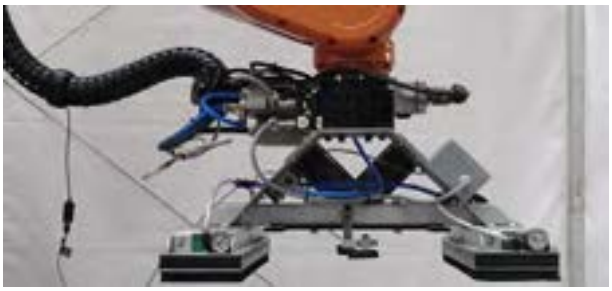

Figure 8. End-effector of the robot equipped with a vacuum gripper and camera for visual feedback.

4.2 Insertion without visual feedback loop

A first test was led without the visual feedback loop to evaluate the difficulty of inserting panels with a robotic arm. The objective was to automate the assembly of 3 non-orthogonal timber boxes composed of 13 panels of 45 mm thick cross laminated timber (CLT). The gap between the tenon and the mortise was set to 0.5 mm to reduce friction forces and reached up to 0.7 mm in some cases due to slight material deformations in addition to the tolerance of fabrication.

Figure 9. Assembly of 13 non-orthogonal timber panels without using the visual feedback loop.

The accumulation of small discrepancies due to the tolerance in the joints and the dimensional variation of the panels caused large deviations between the virtual model and the physical prototype. When inserting the last panel, a difference of about 1 cm was measured at the top of structure. This could be explained by the fact that only the first panel was anchored while the rigidity of the connections for the other panels was not enough to prevent them from slightly rotating. This led to the impossibility of assembling the pieces without a manual intervention. In conclusion, as inaccuracy increases with the number and the size of the elements in the structure, a visual feedback loop was found to be necessary.

4.3 Precision of the visual feedback loop

Prior to testing the insertion of panels, the accuracy of the visual feedback was evaluated. The position of the camera in relation to the end effector of the robotic arm was found by manually referencing the position of 4 markers (Figure 10) and matching the values obtained by taking a picture. It is assumed that both the calibration of the sharp tool and the manual referencing of the markers was achieved with a precision of about 0.5 mm.

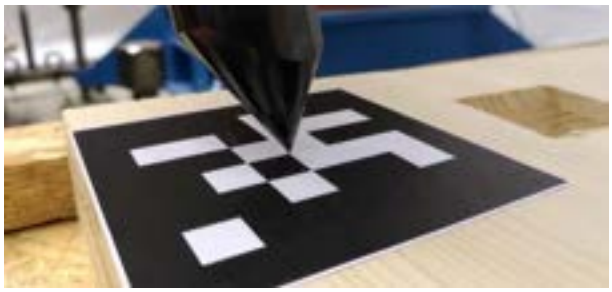

Figure 10. Finding relative camera position by comparing manually referenced coordinates with computed values from the visual feedback.

Once the position of the camera was properly set up, new pictures were taken with multiple camera orientations and distances and the acquired data was compared with the coordinates of the manually referenced markers. Three pictures were taken at each location to assess the consistency of the results.

Extreme values for distances of 30, 50 and 80 cm between the camera and the fiducial marker are reported in Figure 11. Both precision and accuracy were affected by the distance from which the picture was taken. However, below 30 cm, the dispersion of the results stayed below 1 mm, which stays in the range of precision of the manual measurements. Further than 50 cm, the accuracy of the visual detection was decreasing considerably reaching several millimeters at 80 cm. In addition, a loss of precision was also observed as the dispersion of the results which were obtained from the same camera position raised to 2 mm at 80 cm.

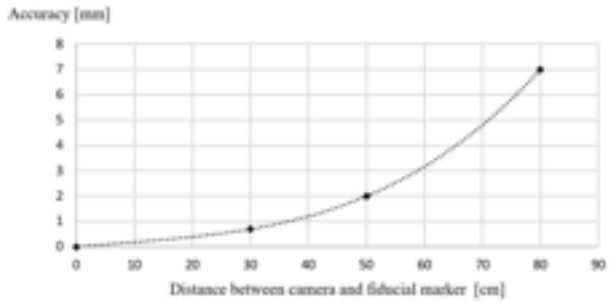

Figure 11. Maximum distance between target position and the results obtained with the visual feedback loop.

Additional tests were performed with different orientations of the robot end-effector and also produced slight deviations from the referenced point. Targets on the edge of the field of view of the camera were particularly misinterpreted by the algorithm and reported position errors up to 2 cm. On one hand, the calibration of the camera was found to be a key parameter to reach more accurate results but was, at the same time, limited by the precision of the manual measurements. On the other hand, the precision of the detection was also limited by the algorithm itself and the exactitude of the spatial transformation.

4.4 Insertion with visual feedback loop

Based on the previous results, a tolerance threshold was established. It was shown that all pictures taken at a distance below 50 cm, with the camera parallel to the marker, were interpreted with a maximum error of 3 mm. The design of the timber joints was therefore adapted in consequence to match that tolerance threshold as shown in Figure 12.

A test of insertion was conducted using two panels with 1 square meter each connected by two trough-tenon joints. Following the principles of auto-centering connections, a chamfer of 4 mm was applied to tenons and mortises. As the fabrication process excluded cutting the panel from below, the chamfer was doubled on top of the tenon instead of being equally distributed. Using the visual feedback loop, the two panels could finally be inserted into one another (Figure 13).

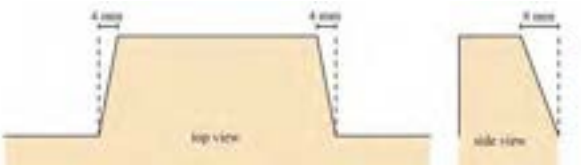

Figure 12. Chamfered tenon based on the measured precision of the visual feedback loop.

Figure 13. Insertion of a laminated veneer lumber (LVL) panel with the visual feedback loop.

5 Conclusion and outlook

A complete workflow was established to assemble prefabricated timber panels connected by wood-wood connections with a robotic arm. The study included the development of a strategy of insertion using different software and linking design and assembly constraints by the means of computational geometry. In addition, an explicit programming language was introduced to ease the interactions between designer and machine.

A particular focus was set on performing a precise insertion despite the large deviations that might occur between physical prototypes and virtual models. The visual detection of fiducial markers, which can easily be placed on top of timber plates, was found to be a cheap and effective solution for updating the position of the panels through a feedback loop.

The evaluation of the method performance showed satisfying results at distances up to 50 cm. For larger distances, the precision of the detection of the markers showed some limitations but could probably be enhanced by refining camera calibration. Eventually, increasing the camera resolution or the size of the ArUco markers could improve the quality of image processing and lead to better outcomes.

Finally, applying the visual feedback loop to the assembly of two timber plates demonstrated the potential of the concept and the feasibility of the proposed workflow in order to automate the assembly of Integrally Attached Timber Plate Structures. The method presented in this paper could have applications on-site. However, further research is still required to extend the workflow to the architectural scale such as solving issues related to friction when inserting multiple joints at the same time.

Abstract -

Boom cranes are among the most used cranes to lift heavy loads. Although fairly simple mechanically, from the control viewpoint this kind of crane is a nonlinear underactuated system which presents several challenges, especially when controlled in the presence of constraints. To solve this problem, we propose an approach based on the Explicit Reference Governor (ERG), which does not require any online optimization, thus making it computationally inexpensive. The proposed control scheme is able to steer the crane to a desired position ensuring the respect of limited joint ranges, maximum oscillation angle, and the avoidance of static obstacles.

Keywords -

Boom crane; Constrain control; Obstacle avoidance; Explicit reference governor; underactuated system.

1 Introduction

Cranes are one of the most commonly used devices to hoist heavy equipment and/or materials. Due to benefits such as high maneuverability and low costs, boom cranes are particularly common. Compared with gantry cranes and tower cranes, boom cranes are much more flexible and can be easily transported and deployed. Currently, this kind of cranes are operated manually. The piece is moved in proximity of its final position, then, a worker uses his hands to finish the positioning. Considering the potentials dangers and uncertain factors of manual operations, it is essential to design efficient control methods to improve the control performance of boom cranes and restrict the payload swing amplitudes.

Compared with gantry cranes, that are simpler and have been extensively studied in the literature, boom cranes have much more coupled and nonlinear dynamics [1]-[2]. In particular, boom cranes involve pitching and rotational movements, which generate complicated centrifugal forces, and consequently, make the equations of motion highly nonlinear. Furthermore, as all cranes, boom cranes are underactuated [3], having fewer independent actuators than the system degrees of freedom (DoFs). Accordingly, it is fairly challenging to control boom cranes effectively.

In the literature, some interesting and meaningful solution have been proposed for the control of boom cranes[4]. Open loop control schemes have been widely used because they are easy to implement. Input shaping is one of the most used open loop techniques based on a linear system. [5] discusses three types of input shapers including positive and modified specified negative amplitude, positive zero vibration, and positive zero-vibration-derivative input shapers, which can reduce the sway angle during rotation. [6] proposes a combination of input shaping and feedback control to counteract the effect of the wind. Open-loop trajectory planning methods [7]-[8] such as the S-curve trajectory and the straight transfer transformation model, are proposed and demonstrated to be effective for boom crane systems. The main drawback of open loop control schemes is that they are sensitive to external disturbances and to model mismatch.

Recently some research focused on the development of closed-loop control schemes for boom cranes. Closed-loop control methods allow for increased robustness and can usually lead to better control performance in the presence of perturbations. A Linear Quadratic Regulator (LQR) is used in [9] with a cameras system to move the crane to the desired position and reduce the payload swing angles. To reduce the payload oscillation of boom cranes, [10] proposes a delayed position feedback antiswing control strategy. In [11] the authors present a partial-state feedback control method with an integrator to achive accurate rotary positioning and swing suppression. A Model Predictive Control (MPC) for an industrial boom crane is shown in [12]. A second-order sliding mode control law is proposed in [13] for trajectory tracking and anti-sway control. In addition to model-based controllers, a series of intelligent algorithms, such as neural networks [14] and fuzzy logic control [15], are also introduced for boom cranes to improve the overall control performances.

Note that almost all existing control approaches focus on stabilization objectives, i.e., boom positioning and payload swing suppression. However, from the practical perspective, the payload swing's transient responses also need to be ensured, e.g., swing angles should be restricted within prescribed safety ranges to ensure stable transportation. Furthermore, it must also be guaranteed that the trajectories avoid obstacles (e.g. walls).

On the basis of this analysis it is possible to point out two open problems in the control of boom cranes:

- Existing closed-loop control laws focus on reducing residual oscillations only when the system reaches the desired position. Instead, a good control strategy should take into account of oscillations throughout the movement in order to reduce the energy stored by the system and avoid potentially dangerous situations;
- There are only few results for the trajectory planning (and for obstacle avoidance) for this kind of crane (see e.g. [16]). These solutions are almost always very complicated, based on the specific nonlinear trajectory planning process and focus on kinematics aspects, not taking into account the dynamics of the crane.

Recently a novel approach for the control of nonlinear systems subject to constraints called Explicit Reference Governor (ERG) has been introduced in [17]-[18]. The ERG is an add-on control unit to be used on a pre-stabilized system and is based on the general Reference Governor (RG) philosophy (see [19] for a survey on RG schemes) which ensures constraint satisfaction by manipulating the reference of a pre-stabilized system so that the transient response does not violate the constraints. An interesting feature of the ERG is that it can enforce both state and input constraints of nonlinear systems without having to solve an online optimization problem.

This paper *aims* at designing a novel control framework, the ERG, for boom crane subject to limited joint ranges and static obstacle avoidance constraints.

2 Dynamic Model and Problem Statement

The dynamic model of a 3-D boom crane (see Fig. 1), with fixed cable length, can be described by the following equations [7]:

Figure 1. Model of an underactuated boom crane system. [20]

$$
\begin{aligned}
&ml^2(1+\theta_1^2)\ddot{\theta}_1 + ml^2\theta_1\theta_2\ddot{\theta}_2 + mlL(-\theta_1 sin\theta_3 + cos\theta_3)\ddot{\theta}_3 \\

&+(J_x - J_z)\dot{\theta}_3 sin(2\theta_3)]\dot{\theta}_4 + mlL\theta_2\dot{\theta}_3^2 sin\theta_3 = u_4.
\end{aligned} \tag{4}
$$

The system parameters are reported in Tab. 1. The system can be compactly rewrite as

$$
M(q)\ddot{q} + C(q,\dot{q})\dot{q} + g(q) = \begin{bmatrix} 0_{2x2} \\ I_{2x2} \end{bmatrix} u, \tag{5}
$$

where q = $[\theta_1, \theta_2, \theta_3, \theta_4]^T \in \mathbb{R}^4$ represents the state vector, and u = $[u_3, u_4]^T \in \mathbb{R}^2$ represents the control input vector. The matrices M(q) $\in \mathbb{R}^{4x4}$, $C(q,\dot{q}) \in \mathbb{R}^{4x4}$, and g(q) $\in \mathbb{R}^4$ represent the inertia, centripetal-Coriolis, and gravity.

2.1 Control objective

The control objective is to move the boom to a desired position and dampen the load swing at the same time. This can be described mathematically as follows:

$$
\begin{aligned}
&\lim_{t\to\infty}\theta_1(t) = 0, \quad \lim_{t\to\infty}\theta_2(t) = 0, \\
&\lim_{t\to\infty}\theta_3(t) = \theta_{3d}, \quad \lim_{t\to\infty}\theta_4(t) = \theta_{4d},
\end{aligned} \tag{6}
$$

where θ_{3d} and θ_{4d} are the boom's desired angles.

Typically in this kind of applications we have three main types of constraints: constraints concerning the maximum

range of the joints, safety constraints related to the suspended load, and constraints modelling the collision avoidance with objects and structures (e.g. walls).

In this paper for the joint range constraints we will assume that the boom pitch angle (i.e., $\theta_3(t)$) is constrained within the range $(\frac{8\pi}{9}, \frac{-\pi}{18})$. Thus

$$\theta_3 \leq \frac{8\pi}{9}, \tag{7}$$

$$-\theta_3 \leq -\frac{\pi}{18}. \tag{8}$$

For what concerns safety constraints linked to the swinging load, a number of different constraints can be defined. A simple form of safety constraints is to impose that θ_i never violates a maximum swing angle. In this paper we will consider the constraint $|\theta_i| \leq \theta_{mi}$, with i =1,2, where $\theta_{mi} = \frac{\pi}{36}$. Thus

$$\theta_1 \leq \frac{\pi}{36}, \tag{9}$$

$$-\theta_1 \leq \frac{\pi}{36}, \tag{10}$$

$$\theta_2 \leq \frac{\pi}{36}, \tag{11}$$

$$-\theta_2 \leq \frac{\pi}{36}, \tag{12}$$

Collision avoidance constraints are constraints where we want to avoid that the load collides with some object/structure. We consider a wall construction scenario where the mason waits for a new brick to bring it to its final position (Fig. 2). In this paper we assume that we want to avoid the collision of the swinging load with three obstacles that are present during this activity: the mason, the brick already placed and the wall.

Since the cable length is fixed and since constraints (9)-(12) will be enforced, we embed the obstacles into boxes taking into account a safety margin equal to the maximum displacement between the rest condition of the load and the maximum swing compatible with constraints (9)-(12). A schematic view of these three boxes is shown in the Fig. 3.

Table 1. Parameters of the boom crane system

Parameters	Physical	Units
$\theta_1(t)$	Payload radial swing angle	rad
$\theta_2(t)$	Payload tangential swing angle	rad
$\theta_3(t)$	Boom pitch angle	rad
$\theta_4(t)$	Boom yaw angle	rad
M	Boom mass	kg
m	Payload mass	kg
M_1	Ballast mass	kg
L	Boom length	m
l	Rope length	m
L_1	Ballast length	m
J_x, J_y, J_z	Moments of inertia of the boom	$kg \cdot m^2$
I_b	Ballast inertia moment	$kg \cdot m^2$
$u_3(t), u_4(t)$	Control inputs	$N \cdot m$

Figure 2. Mason activity

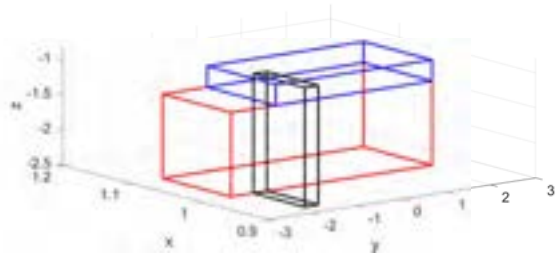

Figure 3. Obstacle constraints. Blue line: Bricks. Red line: Wall. Black line: Mason .

To write these three constraints in the operational space, the direct kinematics of the crane is used [16]:

$$x = Lsin(\theta_3)cos(\theta_4) + l\theta_1 cos(\theta_4) - l\theta_2 sin(\theta_4), \tag{13}$$

$$y = Lsin(\theta_3)sin(\theta_4) + l\theta_1 sin(\theta_4) + l\theta_2 cos(\theta_4), \tag{14}$$

$$z = Lcos(\theta_3) - l\theta_2 cos(\sqrt{\theta_1^2 + \theta_2^2}). \tag{15}$$

Thanks to (13)-(15) we can translate the constrains of each obstacles (e.g. mason, brick and wall) into the joint space. Since the boxes considering the constraints are robust for any swing satisfying (9)-(12), we can consider $\theta_1 = \theta_2 = 0$, and write the constraints only in terms of θ_3 and θ_4 as follows

$$W_i = \{h_i(\theta_3, \theta_4) \geq 0\}, \quad i = 1...3, \tag{16}$$

where h_i is a nonlinear function. These three nonlinear constraints mapped in the joint space are reported in Fig. 4. Note that in the joint space each of these constraints is easily embeddable as a union of linear constraints. This fact can be exploited for the control law following the same lines proposed in [21].

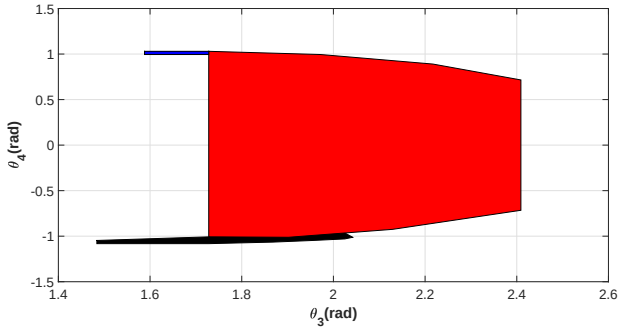

Figure 4. The constraints in the joint space. Blue: Bricks. Red: Wall. Black: Mason.

In conclusion, constraints (7)-(12) are linear constraints, while the constraints obtained by (16) are non linear constraints.

The main goal of this paper is to build a control law able to stabilize the system around each desired point of equilibrium ensuring good dynamic performances while, at the same time, ensuring the satisfaction of constraints (7)-(12), and (16).

3 Control Desing

The control architecture proposed in this paper consists of two cascade control loops as shown in Fig. 5. The first loop pre-stabilizes the system, whereas the second loop manipulates the reference of the pre-stabilized system to ensure constraint satisfaction and reference tracking. In this paper a Linear Quadratic Regulator is used in the inner loop to ensure stability and fast dynamics. For what concerns the constraints management, the external loop consists of an Explicit Reference Governor.

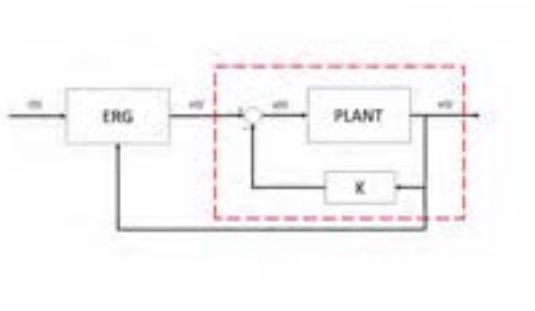

Figure 5. ERG based feedback control scheme.

3.1 LQR Synthesis

Let us define $x = [q \quad \dot{q}]^T$ as state of our system.
In order to design a control law for the system at hand we proceeded with the linearization of the nonlinear equations (5) around the point of equilibrium $x_v = [0, 0, \frac{\pi}{3}, 0, 0, 0, 0, 0]^T$, and considering as equilibrium input u_{eq}:

$$u_{eq} = \begin{bmatrix} -g(\frac{1}{2}ML + mL - \frac{1}{2}M_1L_1)sin(x_{v,3}), \\ 0 \end{bmatrix} \tag{17}$$

which represents the so-called "desired gravity compensation".
The resulting linearized system

$$\delta\dot{x}(t) = A\delta x(t) + B\delta u(t), \tag{18}$$

is then used to compute an LQR control law $\delta u(t) = -K\delta x$ for the linear system (18).

Using this gain matrix K the following control law is obtained

$$u = -K(x - x_v) + u_{eq}, \tag{19}$$

It is worth noticing that the matrix A in (18) depends on the value of the equilibrium angle θ_3. However, it has been numerically verified that, for the choices of weight used in this paper and in the operative ranges prescribed by the system constraints, the control law (19) is able to stabilize the system regardless of the initial condition.

3.2 ERG Synthesis

The idea behind the Explicit Reference Governor [22] is to generate the applied reference signal v (see Fig. 5) so that, if v was to be frozen at any time instant, the transient dynamics of the pre-stabilized system would not violate the constraints. This is achieved by manipulating the derivative of the applied reference in continuous time using the nonlinear control law.

$$\dot{v}(t) = \Delta(x(t), v(t))\rho(r(t), v(t)), \tag{20}$$

with

$$\Delta(x(t), v(t)) = k \min_i(\Gamma_i(v(t)) - V_i(q(t), v(t))), \tag{21}$$

where $k > 0$ in a tuning parameter, and i=1...n_c, with n_c is the number of the constraits. $\Delta(x(t), v(t))$ and $\rho(r(t), v(t))$ are the two fundamental components of the ERG scheme, called the Dynamic Safety Margin (DSM) and the Navigation Field (NF), respectively. The scheme is proven to ensure recursive feasibility and asymptotic convergence to a constant reference [22].
The definition of the DSM differs for the linear constraints and non linear constraints.
For the linear constraint, the first step is to write the (7)-(12) in the form $\beta_{x,i}x \leq d_i, i = 1...6$. For the i^{th} linear constraints (7)-(12), $\Gamma(v(t))$ is

$$\Gamma_i(v) = \frac{(\beta_{x,i}^T x_v + \beta_{v,i}^T v - d_i)^2}{\beta_{x,i}^T P_i^{-1} \beta_{x,i}}, \tag{22}$$

where accordingly to [17], the matrix $Pi > 0$ can be found by solving the offline LMI optimization problem:

$$\begin{aligned} &P_i = \min_P \, logdet(P) \\ &s.t. \\ &(A - BK)^T P + P^T (A - BK) < 0 \\ &P > \frac{\beta_{x,i}^T \beta_{x,i}}{||\beta_{x,i}||^2} \end{aligned} \tag{23}$$

For the nonlinear constraints (16), to be able to evaluate the DSM, we propose the following procedure.
These constraints are well embedded as a union of linear constraints. Fig.6 shows the embedding for the mason constraint. The same approach is used for the other two constraints. In this way, for each obstacle, we obtain a set of linear constraints that we can exploit in the design of the control law. Accordingly, we can rewrite each new set as the union of sets described by linear constraints in the form $\beta_{t,i,j} x \leq d_{i,j}, i = 1...n_{t,j}, \quad j = 1...3$, where $n_{t,j}$ is the number of tangent used for each of the embeddings.

Accordingly to [21] the DSM of the union of $n_{t,j}$ sets defined by linear constraints can be evaluated as

$$\Delta_{t,j}(q(t), v(t)) = \max_{l=1,\ldots,n_t} (\Delta_{t,l,j}(q(t), v(t)), \tag{24}$$

where

$$\Delta_{t,l,j}(q, v) = \Gamma_{t,l,j}(v) - V_{t,l,j}(q, v), \tag{25}$$

whit $1 = 1,...,n_{t,j}, \quad j = 1...3$, where $\Gamma_{t,l,j}$ and $V_{t,l,j}$ can be evaluated by solving the (22)-(23) for each tangent constraint.

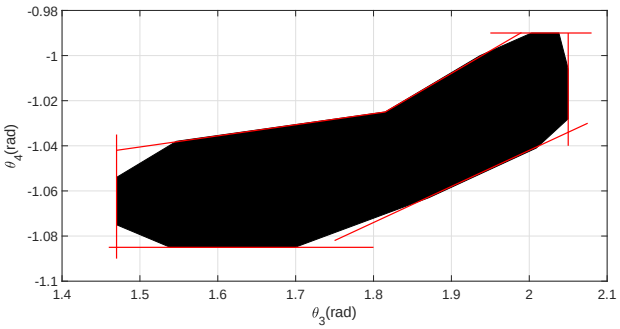

Figure 6. Embedding mason constraint

For what regards the NF, it can be designed by decoupling into an attraction and a repulsion term as [23]

$$\rho(r(t), v(t)) = \rho_a(r(t), v(t)) + \rho_r(r(t), v(t)), \tag{26}$$

where $\rho_a(r(t), v(t))$ is a vector field which points towards the desired position, and $\rho_r(r(t), v(t))$is a vector field which points away from the constraints. For the attraction term $\rho_a(r(t), v(t))$, the most intuitive choice is

$$\rho_a(r(t), v(t)) = \frac{r(t) - v(t)}{\max\{||r(t) - v(t)||, \eta\}}, \tag{27}$$

where $\eta > 0$ is a smoothing factor. Repulsion terms can be split into two terms as:

$$\rho_r(r(t), v(t)) = \rho_{r,1}(r(t), v(t)) + \rho_{r,2}(r(t), v(t)), \tag{28}$$

where

$$\rho_{r,1}(r(t), v(t)) = \sum_{i=1}^{6} \max\left\{\frac{\zeta - \beta_{x,i} x(t) - d_i}{\zeta - \delta}, 0\right\} \frac{\beta_{x,i}}{||\beta_{x,i}||}, \tag{29}$$

$$\rho_{r,2}(r(t), v(t)) = \sum_{j=1}^{3} \max\left\{\frac{\zeta - \beta_{l(t)_j^\star} x(t) - d_{l(t)_j^\star}}{\zeta - \delta}, 0\right\} \frac{\beta_{l(t)_j^\star}}{||\beta_{l(t)_j^\star}||}, \tag{30}$$

where $\zeta > \delta > 0$ and $(t)^\star$ is the index such that $\Delta_{t,j}(q(t), v(t)) = \Delta_{t,l(t)^\star,j}(q(t), v(t))$ in 24.

In this paper, we will use a discrete-time implementation of the ERG. Note that, one could use the Euler approximation of (20), such as

$$v(k+1) = v(k) + kT_s \Delta(q, v) \rho(r(k), v(k)), \tag{31}$$

where T_s is the sampling time of the system. However, as it is, this approximation might not ensure recursive feasibility if T_s is not sufficiently small with respect to the dynamics of the system. For this reason in this paper we will use the scheme introduced in ([18]), which verifies that the candidate reference $\hat{v}(k)$ ensures recursive feasibility one step ahead. To do so, it predicts the evolution of the close loop states $\hat{x}_{cl}(k+1)$, given this candidate reference $\hat{v}(k)$, and evaluates if the dynamic safety margin is positive when maintaining the candidate reference one step ahead, i.e., $\Delta(\hat{x}_{cl}(k+1), \hat{v}(k))$. If the candidate reference holds feasibility, it is applied as the reference at the current step, i.e. v(k) = $\hat{v}(k)$.

4 Simulation Results

To demonstrate the effectiveness of the proposed ERG strategy, in this section we simulate the boom crane shown in Fig. 1.The physical parameters are shown in Tab. 2

The parameters of the control architecture of Fig. 5, are as follows.
For the inner feedback loop:

$$K = \begin{bmatrix} -106.1665, 0, 89.6362, 0, -11.28, 0, 68.877, 0 \\ 0, -91.3357, 0, 31.6228, 0, -7.8488, 0, 52.3688 \end{bmatrix} \tag{32}$$

For the ERG loop, $k = 30$, $\eta = 10e^{-4}$, $\omega = 0.6$,$\zeta = 10$, $\delta = 0.09$.

To validate the proposed scheme experimentally, we consider the following case scenario. Starting from the initial position $x_0 = [0, 0, \frac{105\pi}{180}, \frac{\pi}{2}, 0, 0, 0, 0]^T$. Similar to what happens in reality, we decided to first apply the first desired reference $[\theta_{3,r1}, \theta_{4,r1}] = [\frac{59\pi}{180}, \frac{-48\pi}{180}]$ to move the crane over the mason. Later on, we apply the second desired reference $[\theta_{3,r2}, \theta_{4,r2}] = [\frac{88\pi}{180}, \frac{-58\pi}{180}]$ to move the payload in front of the mason.
Figg. 9- 10 show that the boom pitch and yaw angle follows the desired reference.
As one can see, in Fig. 7 the system follows the desired reference and the control law is able to avoid collisions with the wall. In Fig. 8 it is shown the same trajectory but in the space of end-effector.
Figg. 11-12 show that, during the desired trajectory, the payload swing angles do not violate the constraints (9)-(12).
It is worth noting that in this paper no constraints have been imposed on the actuation limits (see Figg. 13- 14)). However, as one can seen from Figg. 13- 14, they do not represent a problem as the inputs profile and values are reasonable and well within the typical limits of the crane actuators.

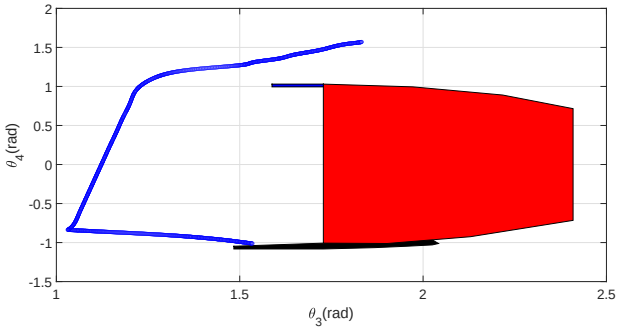

Figure 7. Trajectory in the joint space

Figg. 15- 16 show the comparison between the proposed control strategy and the control reported in [20]. As one can see, our controller is able to drive the crane to the desired position while the payload swings have a smaller amplitude.

5 Conclusion

This paper proposed a constrained control scheme based on the ERG framework for the control of boom cranes. The main contribution of this paper w.r.t. existing closed-loop control methods for boom cranes is that the proposed solution is able to guide the crane towards a desired reference, avoiding collisions with the wall and ensuring that the non-actuated variables (i.e.,θ_1 and θ_2) do not exceed a pre-defined maximum value. It is worth noting that no off-line trajectory has been calculated that it is the control law itself that decides how to move the reference to avoid the obstacle.

Abstract –

Transportation is one of the major contributors in global energy consumption and greenhouse gas emissions. Currently, there are approximately 1.32 billion on-road vehicles around the world, which is expected to be doubled by 2040. This increase has triggered deep concerns over the global issues of climate change and sustainable development. Current GPS navigation systems determine the best travel route in terms of time or distance. However, there are significant challenges to determine an optimal travel route considering sustainability. This paper aims to develop an automated system in order to evaluate different travel routes and suggest the most sustainable one. In this paper, a mathematical model is proposed to estimate the travel time and fuel consumption given different travel route options. Five operational and engine variables of acceleration rate, speed, road slope, engine load, and fuel consumption rate are incorporated in the quantitative analysis. Remote data acquisition was conducted using a GPS-aided inertial navigation system (GPS-INS) and an engine data logger for seven days. The results indicate that the fastest route selected by the current navigation system may not be the most sustainable option. It was also found in the field experiments that the most sustainable route could potentially save on average 5% fuel consumption compared to the fastest route.

Keywords –

Sustainability; Route Selection; Vehicle; Fuel Consumption; GPS-INS

1 Introduction

The transportation field has been widely regarded as one of the major sections of energy consumption, which has produced a significant amount of greenhouse gases (GHGs) worldwide, leading to negative impacts on the environment as well as the climate. There are more than 1.3 billion vehicles in operation throughout the world, which can consume approximately five trillion liters of petroleum annually [1]. The rate related to which petroleum is being consumed and the external costs that result from its use are incredibly unsustainable [2].

Family vehicles play an important role in the total use of global fossil fuels in the transportation field. There is still a rapid increase in the number of family vehicles in the current situation. It is predicted that the number of global on-road vehicles and cars will reach two billion by 2050 [3]. Therefore, it is of great importance to provide quantitative models with high accuracy to estimate the amount of fuel use and emissions caused by on-road vehicles.

There are several GPS navigation systems for vehicles such as Google Maps, which can show the best route in terms of time to users; however, this selected route may not be the best way in terms of sustainability. For this reason, how to measure the best route in terms of sustainability requires to be taken into critical consideration.

The main purpose of this study is to provide a comprehensive model to compare the sustainability of each travel path quantitatively. Furthermore, this research will confirm that the best route offered by current navigation systems may not be the most sustainable route, as well as to potentially develop an updated concept of GPS navigation systems. A comprehensive framework of methodology has been developed to model the fuel use of vehicles as well as evaluate the sustainability of route choice. Three experimental parameters including speed, acceleration, and road slope have been identified and investigated in this study. Two main instruments called GPS-based inertial navigation system (GPS-INS) device and on-board diagnostics (OBD) engine data logger have been employed to collect real-world data. At the end of this study, research limitations as well as recommendations for the future studies are provided.

2 Literature Review

This section focuses on the parameters which can affect the traffic modeling and the fuel use modeling of on-road vehicles.

The value of speed can be used to measure the service level of traffic. As is known, the on-road vehicles can keep the speed around a relatively high value without interruption, e.g. running on a freeway, which means that the traffic condition is on the highly satisfying level [4]. In addition, flow is a relatively macroscopic parameter in traffic modeling, which can help controlling the traffic condition under a macroscopic view. California Department of Transportation (Caltrans) Freeway Performance Measurement System (PeMS), a widely used traffic modeling, can offer 30 seconds or 5 minutes per-loop averages of lane occupancy, flow, speed, and delay for various links in the roadway network [5].

Ahn and Lee developed the operation efficiency parameter to consider idling and non-idling emission coefficients [6]. Besides, Barati and Shen chose both engine attributes (size and load) and operational parameters (operation efficiency, cycle time, and operator skill) as affecting parameters on fuel use [7]. Lewis and Hajji presented a model to estimate the total fuel use, unit cost, activity duration, and emissions of vehicles. Using multiple linear regression (MLR) method, the impact of different affecting parameters including distance and speed was modeled on the fuel use and cost [8].

3 Methodology

This section introduces a comprehensive framework which has been developed to model the fuel use of vehicles as well as evaluate the sustainability of available routes. This methodology can be applied to estimate the fuel consumption of vehicles at the operation level and to appraise the routes sustainability. It can help drivers to identify the best route in their daily trips in terms of sustainability rather than the time.

The fuel use model in this study can be developed in three steps. As the first step, instantaneous engine load value is estimated based on collected operational and environmental parameters. Then, the fuel use in each second can be predicted considering the engine attributes. The fuel use for each trip is eventually measured having instantaneous fuel consumption (IFC) and travel time.

As Figure 1 presents, five steps should be followed to develop the model. Instrumentation and data collection phases are to obtain real data from the field. Raw data should be synchronised and filtered to remove potential errors. The processed data must be finally analysed to estimate the fuel consumption and evaluate the available routes in terms of time and sustainability.

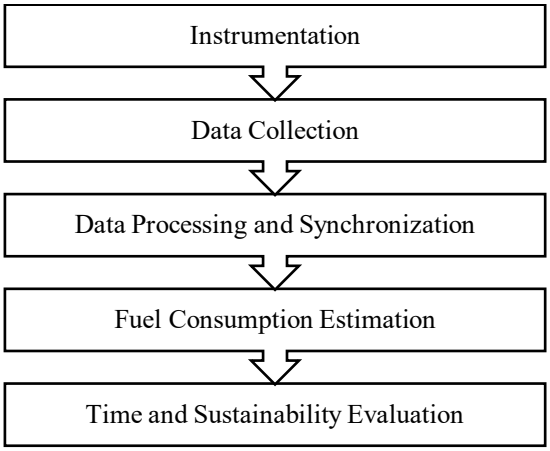

Figure 1. Research framework for selecting most sustainable route

3.1 Parameters Identification

The parameters related to engine size and engine load have been widely regarded as two essential attributes affecting fuel consumption and consequently emissions. The engine load can be defined as the ratio of the used power in different working conditions comparing to the maximum power as a percentage [9]. As for engine size, the greater capacity of the engine generally means more fuel use and emissions. The operational parameters which can influence engine load are acceleration and speed. In addition, the vehicle may use more power of engine at an upward slope than a levelled route. Therefore, the effect of road slope, as an environmental variable, cannot be ignored on engine load estimation. Further, gross vehicles' weight (GVW) is a major variable impacting the effect of other operational parameters on engine load.

The fuel use of a vehicle has a direct relationship with its engine load and size. Having the values of engine load and engine size, the instantaneous fuel use of vehicles can be estimated.

3.2 Instrumentation

There are two main instruments called GPS-INS device and OBD engine data logger employed to collect real-world data of identified parameters. The V-gate iCar Pro OBD2 Scanner is an OBD instrument used to collect field data of engine attributes in this research. It can satisfy almost all the required parameters except acceleration and road slope. JY-GPSIMU is a three-axis inertial navigation GPS-INS device, which can collect, measure, and record the accurate position, speed, acceleration by using an attitude and heading reference system (AHRS). This GPS-INS instrument is installed

inside the cabin of vehicle on a leveled surface, and it should be fixed on a surface with minimum vibration and without any lateral movement to increase the accuracy of data collection. In order to collect data of higher accuracy as well as keep better satellite signal connection, the antenna of GPS-INS is installed on the roof of the vehicle cabin and connected to the main unit via a wire. Finally, all the data collected by OBD engine data logger and GPS-INS device will be stored, synchronised, and analysed in a Toughpad.

3.3 Data Collection

In this research, the data collection has been completed in two preliminary testing and field experimentation parts. The preliminary tests in this study were completed by three selected family vehicles to check and evaluate the performance of instruments. Completion of the whole preliminary experiments took around six hours, and more than 20000 data points have been collected. The field experimentation was conducted by the same vehicles used in the preliminary experiments. The total field experimentation took about 20 hours with more than 80000 collected data points. In order to collect more reliable data during experimentation, several deliberate arrangements have been applied to make the location and time of each experiment different. Moreover, there were significant differences among different routes in each experiment. For example, some had longer distances and fewer traffic lights, some had shorter distances and more traffic lights, and some routes included part of highways.

Table 1 summarises four conducted experimentations. Table 2 demonstrates the samples of the operational parameters collected by instruments. Photos of instrumentation and experimentation, as well as an operation interface version of master computer software are shown in Figure 2a-d. There are five parameters identified to be used for measuring the experiments in this research. Three of them, i.e. acceleration, speed, and road slope, are collected by the GPS-INS device. The other two parameters, i.e. engine load and fuel use rate, are recorded by the OBD engine data logger.

Table 1. A summary of conducted experimentation

Experiment	Vehicle Model	Experiment Location	Experiment Time	Model Year	Engine Size (kW)	Empty/Total Weight (kg)	Number of Data Points
1	Honda Civic	Suburban	Evening Peak	2016	104	1255/1505	15832
2	Honda Civic	Suburban	Midnight	2016	104	1255/1505	17251
3	Toyota Corolla	City	Midnight	2010	81	1060/1210	17449
4	Honda Sylphy	City	Evening Peak	2012	86	1220/1445	20558

Table 2. Samples of field data collected by instruments

Time	Angle X (deg)	GPS V (km/h)	Acceleration (m/s^2)	Calculated Engine Load (%)	Fuel Use (L/100km)
12:54:32 AM	8.09	19.083	0.6508	60.4	8.4
12:54:33 AM	7.40	21.518	0.6764	59.9	7.9
12:54:34 AM	7.34	23.174	0.4600	54.7	6.2

4 Result Analysis

The aim of this section is to develop a model to estimate fuel consumption as well as the most sustainable route selection of on-road family vehicles by the analysis of operational parameters collected in the experimentation. As one of the essential sections of this research, this section presents the estimation of fuel use among different routes and the results of model validation.

4.1 Model Development

This section examines how to estimate the total fuel use of a trip. As mentioned in section 3.1, engine load can be described as a function of acceleration, speed, road slope, and vehicle load factor (LF). As for LF, it is the ratio of current vehicle weight to its GVW. The LF of the three selected vehicles, Honda Civic, Toyota Corolla, and Honda Sylphy, are 0.67, 0.4, and 0.6, respectively, and their engine size are 104kW, 81kW, and 86kW, respectively. The highest speed of these vehicles during the experiment are 64.35 km/h, 70.29 km/h, and 49.18 km/h, respectively. The acceleration fluctuation range of these vehicles in the experimentation are between -2.37 m/s^2 and 3.15 m/s^2 (-8.52 km/h.s to 11.3 km/h.s), -3.08 m/s^2 and 3.22 m/s^2 (-11.1 km/h.s to 11.6 km/h.s), -3.08 m/s^2 and 3.22 m/s^2 (-11.1 km/h.s to 11.6 km/h.s), respectively. The parameter of road slope in the selected routes varied from -17.9° to +16.7° (-19.9% to 18.5%).

4.1.1 Engine Load Estimation

Barati and Shen developed a model based on the real-world data to estimate of engine load by acceleration, slope, speed, and the LF. In addition, they also offered the relationship among these coefficients and LF (Equation (1)) [7]. Table 3 presents LF and three experimental coefficients of vehicle acceleration (C_{AC}), slope of road (C_{SL}), and vehicle speed (C_{SP}). Using linear interpolation technique, a relationship between C_{AC}, C_{SL}, C_{SL}, and LF can be developed (Equations (2-4)).

$$EL = (C_{AC} * AC) + (C_{SL} * SL) + (C_{SP} * SP) + C \quad (1)$$

where:

EL Engine load of vehicle (%)
AC Acceleration of vehicle (m/s^2)
SL Slope of road (degree)
SP Speed of vehicle (km/h)
C Engine load of vehicle in idle mode which is around 20%.

Table 3. The coefficients of parameters in the engine load estimation model

Model	Coefficients			
Load Factor	0	0.33	0.67	1
C_{AC}	15.65	16.36	24.8	27.37
C_{SL}	1.12	1.29	1.67	1.86
C_{SP}	0.41	0.52	0.57	0.64

$$C_{AC} = 12.163\ LF + 15.713 \quad , R^2 = 0.985 \quad (2)$$

$$C_{SL} = 0.749\ LF + 1.096 \quad , R^2 = 0.0.986 \quad (3)$$

$$C_{SP} = 0.221\ LF + 0.424 \quad , R^2 = 0.973 \quad (4)$$

4.1.2 IFC Estimation by Engine Load

According to the field data provided by Klein et al. there is an exponential relation between IFC and engine load (Equation (5)). In other words, a small increase in engine load may result in a significant growth of IFC [9]. Figure 3 shows all the results of IFC estimation and engine load of experimented vehicles in this study.

$$IFC = 0.126 * e^{0.036*EL} \quad (5)$$

where:

IFC Instantaneous fuel consumption (L/sec)
EL Engine load of vehicle (%)

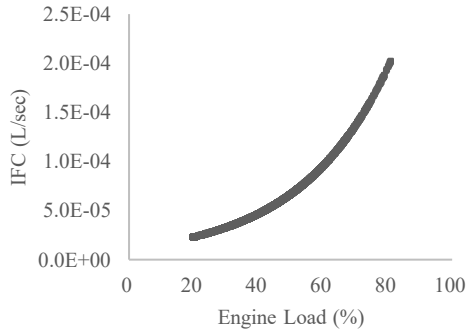

Figure 3. IFC results based on engine load

4.1.3 Total Fuel Consumption Estimation by IFC

The last step of fuel consumption estimation is the calculation of the total amount of fuel used in one trip. The total fuel consumption in a small unit of time can be regarded as the product of IFC and one unit of time. The amount of total fuel consumption in one route is the sum of IFC (Equation (6)).

$$TFC = \sum(IFC) \quad (6)$$

where:

TFC Total fuel consumption (L)
IFC Instantaneous fuel consumption (L/sec)

4.2 Time and Sustainability Evaluation

A vehicle navigation system equipped with GPS-INS can use a significant amount of real-time information for route planning. On the one hand, this GPS-INS system first searched the origin and destination of the trip and used positioning information and internal program algorithms to find several alternative routes. On the other hand, the real-time mega data will be used to simulate the running condition of each route and make an evaluation, which can finally select the best route in terms of time. The GPS-INS system can provide drivers with the best route in terms of time; however, this route might not be the best choice in terms of sustainability. Figure 4 makes a comparison of time and sustainability evaluation.

As an example, in experiment 3, route 1 took the least time but with the most fuel consumption, which means that this route is the most unsustainable one in all three routes. Although the route 3 took a relatively long time to arrive at the destination, it is the best route selection in terms of sustainability. In addition, in experiment 5, route 2 seems to spend almost the longest time; however, the

fuel consumption of this route is significantly lower than the other two paths. The experimental results also confirmed three rules, which can be regarded as the principle of sustainable traveling. First and foremost, it is more sustainable to travel during off-peak hours rather than peak hours in both urban and suburban areas. Secondly, it is more sustainable to travel in suburban areas rather than urban areas. Thirdly, it is more sustainable to select the route which has less road slope fluctuation as well as traffic signals.

In conclusion, according to the results of this experimentation, the best route in terms of time provided by the GPS-INS system is not the best route in terms of sustainability sometimes. For the concept of reaching a higher level of sustainability, it is essential to develop another algorithm in the GPS-INS system, which can make simulation and calculation to choose the best route in terms of sustainability.

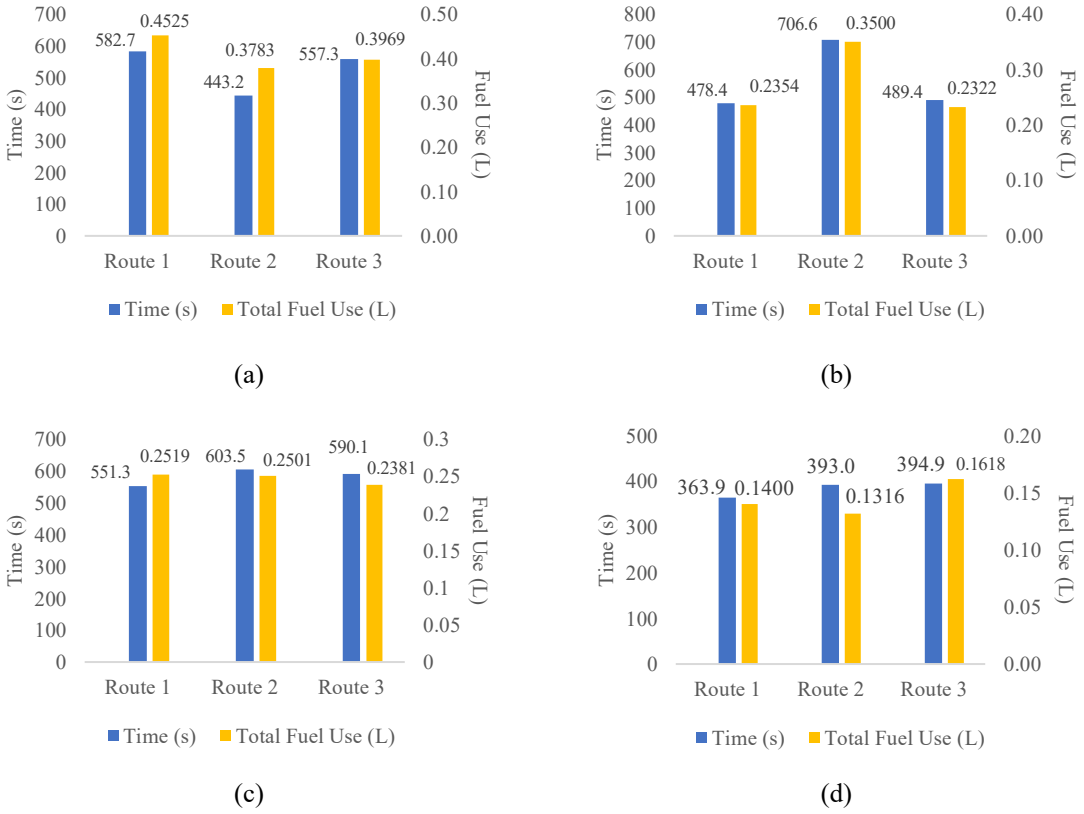

Figure 4. Time and sustainability evaluation of the four conducted experiments, (a) experiment 1, (b) experiment 2, (c) experiment 3, and (d) experiment 4.

5 Conclusion

The transportation field has been widely considered as one of the major sections of energy consumption, such as the use of fossil fuels by vehicle engines. The widespread use of fossil fuels has also produced a significant amount of air pollutants worldwide. It requires a quantified model to estimate family vehicle fuel consumption and select the best route. An assumption has been presented that the best route offered by current navigation systems, which cost the shortest time may not be the most sustainable route. This paper mainly concentrates on confirming the validity of this assumption as well as developing a comprehensive methodology to quantify the total fuel consumption in alternative routes.

The model used in this study can be divided into three steps: engine load estimation by operating parameters, instantaneous fuel consumption estimation by engine load, and total fuel consumption estimation by instantaneous fuel consumption. The concept of this modelling can be applied to all on-road family vehicles. The GPS system can be updated to provide the best route selection in terms of sustainability based on the model in this study.

The experimentation and the results of this research confirmed that the total fuel consumption of each alternative route can be calculated by the identified parameters. Due to the fact that the GPS navigation systems can make simulation and calculation with the support of GPS real-time mega data, it can make the modelling reach a more practical level and be widely applied. It is strongly recommended that the GPS navigation systems should perform the normal route selection as well as the best route selection in terms of sustainability based on the model concept in this study at the same time. Moreover, the GPS navigation systems can present both these two plans of route selection to the user interface for operators to determine. Furthermore, the GPS navigation systems can even simulate the travel of a short period of time in the future to provide better travel recommendations. For example, the evening peak will last for half an hour, and then the updated GPS navigation system can present the total fuel consumption of the current travel and the deferred travel after the simulation and calculation. The simulation may show that a 30 min deferral in a travel can save significant time and fuel. The core concept of this research is to make the traditional navigation systems combine with sustainability and make operators take sustainability into consideration in their daily life.

Abstract -

Automation of cranes can have a direct impact on the productivity of construction projects. In this paper, we focus on the control of one of the most used cranes, the boom crane. Tower cranes and overhead cranes have been widely studied in the literature, whereas the control of boom cranes has been investigated only by a few works. Typically, these works make use of simple models making use of a large number of simplifying assumptions (e.g. fixed length cable, assuming certain dynamics are uncoupled, etc.) A first result of this paper is to present a fairly complete nonlinear dynamic model of a boom crane taking into account all coupling dynamics and where the only simplifying assumption is that the cable is considered as rigid. The boom crane involves pitching and rotational movements, which generate complicated centrifugal forces, and consequently, equations of motion highly nonlinear. On the basis of this model, a control law has been developed able to perform position control of the crane while actively damping the oscillations of the load. The effectiveness of the approach has been tested in simulation with realistic physical parameters and tested in the presence of wind disturbances.

Keywords -

Boom cranes; Robotics; Motion control; Underactuated systems; Nonlinear control.

1 Introduction

A crane is a type of machine, generally equipped with a hoist rope, that is used to move materials. Cranes can be classified in overhead cranes [1]-[2], offshore cranes [3]–[4], and rotary cranes [5]-[6]. Currently, the automation of cranes is still in a relatively early phase. To improve the efficiency and safety of cranes some control approaches have be proposed using sliding-mode control [7]-[8], optimal control [9], adaptive control [10], prediction control [11], intelligent control [12].

In this paper we focus on the modeling and control of a very common type of rotary crane, know as 'boom crane'. Compared with other cranes, boom cranes have higher flexibility and lower energy consumption. Therefore, boom cranes have been widely used in the maintenance of buildings and to handle masonry in urban streets and construction sites. There the cranes have a boom that can rotate in two directions (e.g. pitch and yaw motions) and the load swing can be split into two dimensions. Consequently, the nonlinear dynamic models of boom cranes are more complex than those of other types of cranes.

In recent years, a number of studies have been carried out to solve the control problems of such complex systems. [13]-[14] proposed the use of S-curve trajectories as an open-loop control approaches to achieve anti-sway control for the payload. Moreover, input shaping has been widely applied to control boom cranes [15]. However, the open-loop control strategies are sensitive to external disturbances and to model mismatch. Motivated by these reasons, closed-loop control approaches have been proposed. In [16] the combination of command shaping and feedback control was proposed which can reduce payload oscillation. In [17], a state feedback control law based on linearized model is used to achieve the control objectives. In [18]-[19] the authors proposed a Proportional-Derivative (PD) controller with gravity compensation based on the nonlinear model of the boom crane. In [20] the authors present constrained control for boom cranes.

Most of the existing closed-loop control laws for boom cranes have two main drawbacks:

1. The dynamic of the hoisting mechanism is neglected (e.g. the length of the cable is considered as constant).
2. In the design of the control law, the possibility of measuring the oscillations of the payload (e.g. angular positions and speeds) is usually ignored.

In order to address these problems, we propose a control law that exploits all states of the system to control it. The proposed control scheme is based on a detailed mathematical model in which we takes into account all the degrees of freedom (DoFs) that characterize this type of system (i.e. the two rotations, the length of the rope, and

the payload swing angles). Realistic physical parameters of an existing boom crane are used in simulation tests to show the effectiveness of the proposed approach.

2 Dynamic Model

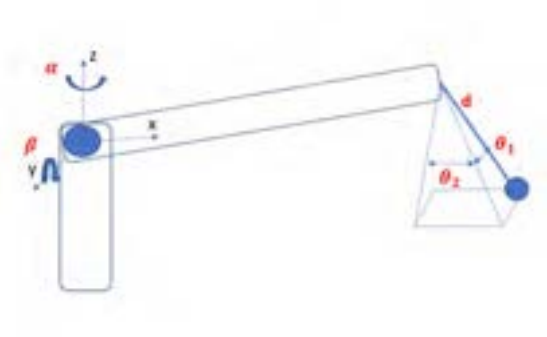

Figure 1. Model of a boom crane

The type of crane considered in this paper (see Fig.1) is represented by five generalized coordinates: α is the slew angle of the tower, β is the luff angle of the boom, d is the length of the rope, θ_1 is the tangential pendulation due to the motion of the tower, and θ_2 is the radial sway due to the motion of the boom.
The equations of the motion obtained using the Euler-Lagrange approach are

$$\begin{aligned}
&I_t\ddot{\alpha} + d^2\ddot{\alpha}m + \ddot{\alpha}l_B^2mC_\beta^2 + (\ddot{\alpha}l_B^2m_BC_\beta^2)/4 - d^2\ddot{\theta}_2mS_{\theta_3}\\

\end{aligned} \tag{3}$$

$$\begin{aligned}
&dmC_{\theta_2}(gS_{\theta_1} + 2\dot{d}\dot{\theta}_1C_{\theta_2} + d\ddot{\theta}_1C_{\theta_2} - \dot{\beta}^2l_BS_\beta S_{\theta_1}\\
&-2d\dot{\theta}_1\dot{\theta}_2S_{\theta_2} + \ddot{\alpha}l_BC_\beta C_{\theta_1} + d\ddot{\alpha}C_{\theta_1}S_{\theta_2} + 2\dot{d}\dot{\alpha}C_{\theta_1}S_{\theta_2}\\
&+\ddot{\beta}l_BC_\beta S_{\theta_1} - d\dot{\alpha}^2C_{\theta_1}C_{\theta_2}S_{\theta_1} + 2d\dot{\alpha}\dot{\theta}_2C_{\theta_1}C_{\theta_2}\\
&-2\dot{\alpha}\dot{\beta}l_BC_{\theta_1}S_\beta) = 0,
\end{aligned} \tag{4}$$

$$\begin{aligned}
&-dm(d\ddot{\alpha}S_{\theta_1} - 2\dot{d}\dot{\theta}_2 - d\ddot{\theta}_2 + 2\dot{d}\dot{\alpha}S_{\theta_1} - gC_{\theta_1}S_{\theta_2}\\
&-(d{\dot{\theta}_1}^2S_{2\theta_2})/2 + \dot{\alpha}^2l_BC_\beta C_{\theta_2} + \dot{\beta}^2l_BC_\beta C_{\theta_2}\\
&+\ddot{\beta}l_BC_{\theta_2}S_\beta + \dot{\beta}^2l_BC_{\theta_1}S_\beta S_{\theta_2} + d\dot{\alpha}^2C_{\theta_1}^2C_{\theta_2}S_{\theta_2}\\
&+2d\dot{\alpha}\dot{\theta}_1C_{\theta_1}C_{\theta_2}^2 - \ddot{\beta}l_BC_\beta C_{\theta_1}S_{\theta_2} + \ddot{\alpha}l_BC_\beta S_{\theta_1}S_{\theta_2}\\
&-2\dot{\alpha}\dot{\beta}l_BS_\beta S_{\theta_1}S_{\theta_2}) = 0.
\end{aligned} \tag{5}$$

where m, m_b denote the load mass, and the boom mass, respectively, l_b is the boom length, I_t is the inertia moment of the tower, and I_b is the inertia moment of the boom. Moreover, the following abbreviations are used:
$S_\alpha \triangleq sin(\alpha)$, $S_\beta \triangleq sin(\beta)$, $S_{\theta_1} \triangleq sin(\theta_1)$, $S_{\theta_2} \triangleq sin(\theta_2)$, $C_\alpha \triangleq cos(\alpha)$, $C_\beta \triangleq cos(\beta)$, $C_{\theta_1} \triangleq cos(\theta_1)$, $C_{\theta_2} \triangleq cos(\theta_2)$.

The system dynamics (1)-(5) can be rewritten in matrix form as

$$M(q)\ddot{q} + C(q,\dot{q})\dot{q} + G(q) = \begin{bmatrix} I_{3x3} \\ 0_{2x2} \end{bmatrix} u, \tag{6}$$

where $q = [\alpha, \beta, d, \theta_1, \theta_2]^T \in \mathbb{R}^5$ represents the state vector, and $u = [u_1, u_2, u_3]^T \in \mathbb{R}^3$ is the control input

vector. The matrices M(q) $\in \mathbb{R}^{5x5}$, $C(q,\dot{q}) \in \mathbb{R}^{5x5}$, and G(q) $\in \mathbb{R}^5$ represent the inertia matrix, centripetal-Coriolis forces, and gravity term, respectively.

As one can seen from (6), the boom crane is an under-actuated system, having fewer independent actuators than system degrees of freedom (DoFs). Thus, we can rewrite its model as

$$\begin{aligned} M_{11}(q)\ddot{q}_1 + M_{12}(q)\ddot{q}_2 \\ +C_{11}(q,\dot{q})\dot{q}_1 + C_{12}(q,\dot{q})\dot{q}_2 + G_1(q) = U, \end{aligned} \tag{7}$$

$$\begin{aligned} M_{21}(q)\ddot{q}_1 + M_{22}(q)\ddot{q}_2 + C_{21}(q,\dot{q})\dot{q}_1 \\ +C_{22}(q,\dot{q})\dot{q}_2 + G_2(q) = 0, \end{aligned} \tag{8}$$

where $q_1 = [\alpha \quad \beta \quad d]^T$ is the vector of actuated states and $q_2 = [\theta_1 \quad \theta_2]^T$ of non-actuated states and

$$M_{11}(q) = \begin{bmatrix} m_{11} & m_{12} & m_{13} \\ m_{21} & m_{22} & m_{23} \\ m_{31} & m_{32} & m_{33} \end{bmatrix}, M_{12}(q) = \begin{bmatrix} m_{14} & m_{15} \\ m_{24} & m_{25} \end{bmatrix},$$

$$M_{21}(q) = \begin{bmatrix} m_{41} & m_{42} & m_{43} \\ m_{51} & m_{52} & m_{53} \end{bmatrix}, M_{22}(q) = \begin{bmatrix} m_{44} & 0 \\ 0 & m_{55} \end{bmatrix},$$

$$C_{11}(q,\dot{q}) = \begin{bmatrix} c_{11} & c_{12} & c_{13} \\ c_{21} & c_{22} & c_{23} \\ c_{31} & c_{32} & c_{33} \end{bmatrix}, C_{12}(q,\dot{q}) = \begin{bmatrix} c_{14} & c_{15} \\ c_{24} & c_{25} \end{bmatrix},$$

$$C_{21}(q,\dot{q}) = \begin{bmatrix} c_{41} & c_{42} & c_{43} \\ c_{51} & c_{52} & c_{53} \end{bmatrix}, C_{22}(q,\dot{q}) = \begin{bmatrix} c_{44} & 0 \\ 0 & c_{55} \end{bmatrix},$$

$$G_1(q) = \begin{bmatrix} 0 \\ g_2 \\ g_3 \end{bmatrix}, G_2(q) = \begin{bmatrix} g_4 \\ g_5 \end{bmatrix}, U = \begin{bmatrix} u_1 \\ u_2 \\ u_3 \end{bmatrix}.$$

3 Control Design

The aim of the control is to move the crane to the desired position and to dampen the swing angles of the load. In our development we will consider the following reasonable assumptions.

Assumption 1 *The payload swing are such that* $|\theta_{1,2}| < \frac{\pi}{2}$.

Assumption 2 *The cable length is always greater than zero to avoid singularity in the model (6), i.e.* $d(t) > 0, \forall t \geq 0$.

As one can see, (8) can be rewritten as

$$\begin{aligned} \ddot{q}_2 = -M_{22}^{-1}(q)(M_{21}(q)\ddot{q}_1 + C_{21}(q,\dot{q})\dot{q}_1 \\ +C_{22}(q,\dot{q})\dot{q}_2 + G_2(q)). \end{aligned} \tag{9}$$

It is worth noticing that in (9) the $M_{22}(q)$ is a positive definite matrix due to Assumptions (1)-(2).

Substituting (9) into (7), one obtains

$$\bar{M}(q)\ddot{q}_1 + \bar{C}_1(q,\dot{q})\dot{q}_1 + \bar{C}_2(q,\dot{q})\dot{q}_2 + \bar{G}(q) = U, \tag{10}$$

where

$$\begin{aligned} \bar{M}(q) &= M_{11}(q) - M_{12}(q)M_{22}^{-1}(q)M_{21}(q), \\ \bar{C}_1(q,\dot{q}) &= C_{11}(q,\dot{q}) - M_{12}(q)M_{22}^{-1}(q)C_{12}(q,\dot{q}), \\ \bar{C}_2(q,\dot{q}) &= C_{12}(q,\dot{q}) - M_{12}(q)M_{22}^{-1}(q)C_{22}(q,\dot{q}), \\ \bar{G}(q) &= G_1(q) - M_{12}(q)M_{22}^{-1}(q)G_2(q). \end{aligned}$$

According to Assumptions (1)-(2), the matrix $\bar{M}$ is positive definite. Then, (10) can be rewritten as

$$\ddot{q}_1 = \bar{M}^{-1}(q)(U - \bar{C}_1(q,\dot{q})\dot{q}_1 - \bar{C}_2(q,\dot{q})\dot{q}_2 - \bar{G}(q)) \tag{11}$$

Substituting (11) into (9) yields

$$\begin{aligned} \ddot{q}_2 = -M_{22}^{-1}(q)(M_{21}(q)\bar{M}^{-1}(q)(-\bar{C}_1(q,\dot{q})\dot{q}_1 - \bar{C}_2(q,\dot{q})\dot{q}_2 \\ -\bar{G}(q) + U) + C_{21}(q,\dot{q})\dot{q}_1 + C_{22}(q,\dot{q})\dot{q}_2 + G_2(q)). \end{aligned} \tag{12}$$

Following the classical approach of a feedback linearization technique, (11) can be "linearized" by using the control law

$$U = \bar{M}(q)v + \bar{C}_1(q,\dot{q})\dot{q}_1 + \bar{C}_2(q,\dot{q})\dot{q}_2 + \bar{G}(q). \tag{13}$$

Thus, (11) becomes

$$\ddot{q}_1 = v, \tag{14}$$

where $v \in \mathbb{R}^3$ as additional control inputs.

To move the crane to the desired position, the additional control inputs (14) can be chosen as

$$v = \ddot{q}_{1d} - K_{ad}(\dot{q}_1 - \dot{q}_{1d}) - K_{ap}(q_1 + q_{1d}), \tag{15}$$

where $K_{ad} = diag(K_{ad1}, K_{ad2}, K_{ad3})$, $K_{ap} = diag(K_{ap1}, K_{ap2}, K_{ap3})$ are positive diagonal matrices. Substituting (15) into (14), we obtain

$$\ddot{\tilde{q}}_1 + K_{ad}\dot{\tilde{q}}_1 + K_{ap}\tilde{q}_1 = 0, \tag{16}$$

where $\tilde{q} = q_1 - q_{1d}$ is the tracking error vector of the actuated states. (16) is exponentially stable for every $K_{ad} > 0$ and $K_{ap} > 0$.

To stabilize the non-actuated states q_2, following what is proposed in [21], we define a second additional inputs as

$$v_u = -K_{ud}\dot{q}_2 - K_{up}q_2, \tag{17}$$

where $v_u \in \mathbb{R}^2$ are additional inputs which take into account the non-actuated states, $K_{ad} = diag(K_{ud1}, K_{ud2})$, $K_{ap} = diag(K_{up1}, K_{up2})$ are positive diagonal matrices.

Considering $q_{1d} = const$, the overall additional inputs are proposed by linearly combining (15) and (17)

$$v = -K_{ad}\dot{q}_1 - K_{ap}(q_1 - q_{1d}) - \alpha(K_{ud}\dot{q}_2 - K_{up}q_2), \tag{18}$$

where

$$\alpha = \begin{bmatrix} \alpha_1 & 0 \\ 0 & \alpha_2 \\ 0 & 0 \end{bmatrix} \tag{19}$$

is a weighting matrix.

Substituting the (18) into (13) the overall control law is obtained as

$$U = (\bar{C}_1(q,\dot{q}) - \bar{M}(q)K_{ad})\dot{q}_1 + (\bar{C}_2(q,\dot{q}) - \bar{M}(q)\alpha K_{ud})\dot{q}_2 - \bar{M}(q)K_{ap}(q_1 - q_{1d}) - \bar{M}(q)\alpha K_{up}q_2 + \bar{G}(q). \tag{20}$$

Replacing (20) into (12), we obtain

$$\ddot{q}_2 = -M_{22}^{-1}(q)(-M_{21}(q)(K_{ad}\dot{q}_1 + K_{ap}q_1 + \alpha(K_{ud}\dot{q}_2 + K_{up}q_2)) + C_{21}(q,\dot{q})\dot{q}_1 + C_{22}(q,\dot{q})\dot{q}_2 + G_2(q)). \tag{21}$$

Considering Assumption 1, in the rest of this Section we have to demonstrate that (21) converges to the equilibrium point expressed by: $q_2 = \dot{q}_2 = 0$ to achieve the control goal.

Setting $q_1 = q_{1d}$ in (21), one achieves

$$\ddot{q}_2 = -M_{22}^{-1}(q)(-M_{21}(q)(\alpha(K_{ud}\dot{q}_2 + K_{up}q_2)) + C_{22}(q,\dot{q})\dot{q}_2 + G_2(q)). \tag{22}$$

The stability analysis of (22) is analyzed by linearizing (22) around the equilibrium point $q_2 = \dot{q}_2 = 0$.
We can rewrite (22) as

$$z_1 = \theta_1, \quad z_2 = \dot{\theta}_1, \quad z_3 = \theta_2, \quad z_4 = \dot{\theta}_2.$$

Then, we obtain the following state-space forms:

$$\dot{z}_1 = z_2, \tag{23}$$

$$\dot{z}_2 = h_1(z), \tag{24}$$

$$\dot{z}_3 = z_4, \tag{25}$$

$$\dot{z}_4 = h_2(z), \tag{26}$$

with $z = [z_1 \quad z_2 \quad z_3 \quad z_4]^T$ as a state vector. Linearizing (23)-(26) around $z = 0$, we obtain

$$\dot{z} = Az, \tag{27}$$

where

$$A = \begin{bmatrix} 0 & 1 & 0 & 0 \\ \frac{\partial h_1}{\partial z_1} & \frac{\partial h_1}{\partial z_2} & \frac{\partial h_1}{\partial z_3} & \frac{\partial h_1}{\partial z_4} \\ 0 & 0 & 0 & 1 \\ \frac{\partial h_2}{\partial z_1} & \frac{\partial h_2}{\partial z_2} & \frac{\partial h_2}{\partial z_3} & \frac{\partial h_2}{\partial z_4} \end{bmatrix}_{z=0} = \begin{bmatrix} 0 & 1 & 0 & 0 \\ a_{11} & a_{12} & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & a_{21} & a_{22} \end{bmatrix}. \tag{28}$$

The non-zero elements in (28) are the flowwing:

$$a_{11} = -\frac{(g - a_1 K_{pu1} l_B cos\beta)}{d}, \tag{29}$$

$$a_{12} = \frac{a_1 K_{du1} l_B cos\beta}{d}, \tag{30}$$

$$a_{21} = -\frac{(g + a_2 K_{pu2} l_B sin\beta)}{d}, \tag{31}$$

$$a_{22} = -\frac{a_2 K_{du2} l_B sin\beta}{d}. \tag{32}$$

The linearized system (27) is stable around the equilibrium point $z = 0$, if the A matrix (28) is a Hurwiz matrix. Therefore, it is necessary to properly choose the control parameters that appear in (29)-(32). In this way, (27) is stable around equilibrium point z = 0, which leads to the local stability of (21). In the Section 4 the values for each of the control parameters are listed.

4 Simulation Results

In this section, three different simulation scenarios will be shown to demonstrate the proposed control scheme. In each of them the goal is to move the crane to a desired position and to reduce the swings of the payload as much as possible. In the second and third simulation, the effects of a gust of wind for the payload will be shown.

To get realistic values for the simulation tests, we consider a small boom crane: the NK 1000 Mini Crane from NEMAASKO [22]. Some parameters are taken directly from the datasheets. Others, like the boom dimensions were estimated by CAD simulations.
The crane system parameters are selected as follows:

$$I_t = 207.13kgm^2, \quad l_B = 6.2m, \quad m_B = 312.2kg,$$
$$I_B = 2068kgm^2, \quad g = 9.81ms^{-2}, \quad m = 50kg.$$

The control parameters for controller (18) are set as $K_{ad} = diag(100, 100, 150)$, $K_{ap} = diag(10, 20, 50)$, $K_{ud} = diag(120, 120)$, $K_{up} = diag(10, 10)$, $a_1 = -1$, $a_2 = sign(\beta)$.

Scenario 1. In this simulation scenario, we show the performance of the proposed control law described in the Section 3. The goal is to move the crane to a desired configuration while damping the payload swing angles as much as possible. In this first scenario no external disturbances to the crane will be considered. The simulation results are shown in Figg.2-6. We can see that the boom arrives at the desired positions in around 30 seconds, Additionally, the maximum payload swing amplitudes in the two directions are confined in $-2.5°$ and $1°$, respectively. In Fig.7 the input controls are shown. For the boom actuator following the [22], the limit of the working range of the crane is of 210kg for the payload mass with a boom length of 8.9m then the maximal torque should be around $u_{2max} = 18.2kNm$. The values of the other two inputs do not represent a problem as the inputs values are reasonable and well within the typical limits of the crane actuators.

Scenario 2. In this simulation scenario, we consider a gust of wind as external disturbance for the crane. The desired configuration for the crane is the same of the previous scenario. In this case the controller must be able to counteract the effect of wind during the whole movement of the crane. The perturbation seen by the system will be characterized by a duration and a time dependent amplitude. Concerning the first one, a study from a meteorological center of the Netherlands reported that wind gusts have periods of 2 to 7 seconds with average speeds comprised between 4 and 20 m/s [23]. The force applied on the payload can be seen as distributed force $F = \frac{1}{2}\rho V^2 A_w C_D$, where V is the wind average gust speeds, and A_w is the surface exposed to the wind. According to [24], $C_D = 1.05$ will be chosen. Assuming ISA conditions at sea level, $\rho = 1.225[kg/m^3]$.
In this Scenario, we consider a force that acts laterally to the load (e.g. increases the swing angle θ_1). In this scenario, only one gust of wind will occur when the simulation is at 20s. In our simulations, the wind speed will have a trapezoidal shape (e.g. increase linearly from zero, constant for a time window and finally linearly decrease to zero).
As one can see in Figg. 11-12, due to the wind gust, the swing angle θ_1 increases and consequently also the angle θ_2 oscillates. To counteract this effect, the controller modifies the tower angle α (Fig.8 and Fig.13) and the boom angle β (Fig.9 and Fig.13) to reduce the swing angles as fast as possible. The small effects on the length of the cable can be seen in Fig.13, where one can see that the force on the cable changes a little.

Scenario 3. In this Simulation scenario, the main effect of the wind is on the angle θ_2. In this case, the swing radial angle increases (see Fig.18) and consequentially the controller modifies the value of the luff angle (Fig.15) and the length of the cable (Fig.16) to reduce the oscillations as much as possible. There are no significant effects on the angle θ_1, therefore no changes are required for the slew angle α. As one can see in Fig.19, to quickly counteract the effect of the wind, the control input u_2 reaches its limit value and then decreases.

freedom (DoFs) that characterize this type of system (i.e. the two rotations, the length of the rope and the payload swing angles). Despite the complexity of the model, we design a nonlinear control law that exploits all the states of the model to guide the crane towards a desired reference

and ensuring that the non-actuated variables (i.e., θ_1 and θ_2) go to zero in a fast way. The simulation results with realistic physical parameters show the efficiency of the proposed control scheme even in the presence of wind disturbance.

Abstract -

Path planning, as a primary mission in crane lift planning, has a profound and direct impact on the safe and efficient execution of lift jobs on construction sites. Typically, the main objective of path planning is to find the shortest (or a relatively short) and collision-free path from the load supply point to the demand point in a finite 3D space with the presence of obstacles, while considering the mechanical constraints of the crane. Despite collision-free being a primary criterion in path planning, other critical safety issues have not been adequately addressed in existing methods. For example, blind lifts and reduced visibility of crane operators are prevalent in construction and have been recognized as major safety concerns in crane lifts. Furthermore, complex coordination of crane motions and frequent changes of moving direction potentially lead to human errors. To address this gap in the knowledge, this paper proposes a semi-automated planning approach by using Building Information Modeling (BIM) and an intelligent path finding algorithm. First, dimension and weight data of building components to be lifted are retrieved from the BIM model. Then, a modified RRT* algorithm is used to generate a short and collision-free path that satisfies the desired level of path smoothness, visibility, and motion coordination. Finally, paths for all lifts are stored and associated with corresponding elements in BIM for easy analysis and visualization. Preliminary results show that the proposed method can effectively reduce the occurrence of blind lifts while ensuring a practical path for execution. In the future, the proposed method is expected to enable a BIM-based risk analysis tool for the safety of crane operation and its impact on other adjacent construction activities.

1 Introduction

A crane is a piece of indispensable equipment on construction sites, undertaking both vertical and horizontal transportation [1]. However, it is also one of the main contributors to the construction fatality [2]. According to various accident analysis research, these fatal accidents related to cranes were primarily caused by inappropriate positioning of the lift load, which either violates the maximum reach or has spatial conflicts with workers, machinery, existing structures, and prohibited area [3]. Therefore, planning the load position during the lift, which is also known as path planning, is an essential procedure to avert safety hazards. In conventional practice, path planning is manual and based on experience, usually leading to a time-consuming process and error-prone outcomes [4].

In recent decades, researchers have made significant efforts to optimize and automate the path planning process. Multiple pieces of literature utilized the robotic path finding algorithms to generate the shortest and collision-free path abide by the load chart [5]. This method is able to shorten the planning time and eliminate multiple safety hazards, such as crane tipping-over and collisions between the load and static obstacles [6]. However, using robotic path finding algorithms is subjected to a number of strong assumptions, leading to incomplete considerations of safety hazards. For example, it is assumed that the operator has the ability to precisely execute the planned path. In reality, however, it is impractical for a human operator to carry out over-complicated maneuvers such as blind lifts [7] or complex coordination of swinging, luffing, and hoisting [8]. Meanwhile, most algorithms assume that the obstacles are static [9]. This assumption is inconsistent with the dynamic nature of construction sites and ignores the risk of spatial conflicts between the lift load and dynamic obstacles. Although in recent years, several novel frameworks enabled the path re-planning based on real-time monitoring of moving objects [10], these works sorely rely on the crane operators to alter the path on the spot and cannot coordinate with the affected objects and workspaces to avoid spatial conflicts.

To mitigate the spatial conflicts between the crane and other workspaces, one strategy is to visualize the crane workspace in the planning stage based on crane parameters [11]. It helps the construction stakeholders to understand the spatial relationships between the crane and dynamic/static obstacles and to identify potential safety hazards proactively. This strategy usually involves data visualization and analysis, on an effective information management platform. Building Information Modelling (BIM) has been exploited as a core data generator for risk management tools to demonstrate geometric information, analyze spatial conflicts, and communicate safety risks [12]. In such an approach, the parametric crane workspace is usually over-estimated and unable to explicitly reflect the location of the lift load [13]. There is a demand for a realistic path finding algorithm that guides and predicts the trajectory of lift loads. The algorithm-planned results for each building component need to be stored in BIM for further risk analysis.

Therefore, this paper proposes a novel approach that integrates a modified RRT* path finding algorithm and BIM to create a decision support tool for proactive path planning. Firstly, the original RRT* algorithm is improved to incorporate common practicality considerations. These practicality considerations determine the operational complexity for a crane operator and profoundly impact the crane lift safety, including avoiding frequent turning, minimizing blind lifts, and limiting the coordination of crane motions. Secondly, BIM is utilized to interoperate with the modified RRT* algorithm bi-directionally, which provides information to the algorithm and visualizes its output.

In the rest of this paper, Section 2 introduces the background information about the practicality considerations in path finding algorithms with respect to crane safety, as well as the potential application of BIM in this paper. Section 3 introduces the proposed methods, including the overall framework and the development of a prototype system. The proposed methods are validated and demonstrated in a case study in Section 4. Section 5 concludes the paper and indicates future directions.

2 Background

2.1 Path Finding Algorithm

Planning the lift path is a critical task in the lift planning process. In reality, an experienced human path planner not only avoids collisions between the lift load and obstacles but balances the operational complexity and path length [14]. A number of studies have been proposed to automate this task with path finding algorithms, including A* [15], Genetic Algorithm (GA) [16], Probability Roadmap [7], and Rapid Random-exploring Tree algorithm (RRT) [17]. These algorithms were designed to find a collision-free path within its kinematic ranges and comply with capacity limits. However, rather than applying these algorithms directly, these studies had to scrutinize the characteristics of crane lifting and modified the algorithms accordingly to generate a practical path with acceptable operational complexity. These unique considerations are referred to as practicality considerations in this study.

Three practicality considerations have been discussed in the related work, including the smoothness of a path, the blind lifts, and the motion coordination. First, a smooth path benefits construction safety since it requires gentle maneuvers and reduces the likelihood of human errors [18]. However, “smoothness” is a vague description and researchers have divergent opinions on what it embodies. For example, Ali et al. [5] defined a roughness index, which accumulated the angular displacements for each point on the paths. Together with the path length, the roughness index was integrated into the objective function for optimization. The description of operability using path roughness was later adopted by Zhang and Hammad in an RRT-based path planning method [18]. This interpretation of smoothness yields a continuous path and prevents abrupt changes in moving direction. Similar efforts can be found in [17], which employs a spline function to remove acute angles in the path. These efforts smoothen a path to prevent abrupt turnings, but it requires constant and complicated adjustment of moving directions. To address this issue, other researchers defined a smooth path as a path with fewer motion switches and consequentially fewer way-points. To remove redundant way-points, two strategies have been applied, which either adds operation switching cost to the objective function [19] or post-process a candidate path via the “straight-line strategy” [20]. These two strategies have both strengths and weaknesses. Using an operation switching cost can guide the path searching process to find a smooth path, but the definition of cost is subjective [20]. Also, the “straight-line strategy” is effective but it cannot compare the “smoothened” path with other alternatives generated during the planning process.

Motion coordination is another factor determining the operational complexity and thus researchers attempted to limit the number of coordinated motions in path planning. For example, Olearczyk et al. [21] avoided the coupling of crane rotation (i.e., swinging) and translation (i.e., luffing, hoisting, or both) to decrease the operational complexity. Chi et al. [7]assumed that crane operators can at most coordinate two motions simultaneously and applied this assumption to the generation of the roadmap using the probabilistic roadmap (PRM) algorithm. Cai et al. [16] adopted similar measures of prohibiting three simultaneous motions out of four degrees of freedom (i.e.,

swinging, luffing, hoisting and load rotation) and eliminated the complex motion coordination in post-processing. While these pieces of research followed an overwhelmingly stringent restriction on motion coordination, Hung et al. [22] allowed the combination of all crane motions and designed a user-defined parameter to limit the maximum number of coordinated motions.

In addition to being smooth and with a minimum level of motion coordination, a practical path should avoid blind lifts and ensures clear visibility to the load. Good visibility is essential for the crane operator to gain acute situational awareness, which helps to recognize and mitigate the severe safety risks [23]. In addition to safety concerns, blind lifts often compromise efficiency as the operator has to maneuver slowly with extra caution while communicating with the signal person [24]. To account for the extra time due to lifts in blind areas, researchers often estimate the total lift time using a mathematical model where poor visibility incurs a time penalty [25]. Abundant studies were devoted to enhancing the vision of crane operators [4]. However, there still lacks precaution against blind lifts in the planning stage [26]. Among the literature reviewed, only Chi et al. [7]examined the visibility of the path generated by a PRM algorithm. If the candidate path has any invisible segment, they execute PRM for an extra iteration until the path is fully visible. Although this method ensures the result to be visible, it did not modify the mechanism of PRM itself. Thus, the computational efficiency and success rate are subject to randomness due to the nature of PRM.

To accommodate these three practicality considerations, the RRT* algorithm is selected as the base for further modifications. RRT*, which is a variant of the classic RRT algorithm, is designed to efficiently search a high-dimensional space and converges towards the shortest collision-free path [27]. The optimality in the path length comes from two searching procedures, “Choose Parent” and “Rewire”. These two procedures dynamically reduce redundancy in the path set and remove unnecessary movements along every alternative path, which not only shorten the path length but smoothen the path. Additionally, the searching mechanism of the RRT* algorithm is highly adaptable, which allows modifications to consider visibility and motion coordination.

2.2 Building Information Modelling (BIM)

BIM is an emerging research focus in construction risk management [12]. In this task, BIM serves as two fundamental roles: the core data reservoir which provide baseline data to BIM-based risk management tools; and a visualization platform that enhances the identification, communication, and prevention of safety hazards [28]. Specific to the crane, BIM can both provide component information for automated lift planning [13], and visualize the paths and workspace of the crane to help stakeholders identify potential spatial conflicts [29]. For example, Ji and Leite [13] proposed an automatic rule-based checking system for reviewing a lift plan by using a 4D BIM model as the information source to reduce tedious manual input. Wang et al. [30] used BIM as an information source for a location optimization algorithm (i.e., firefly algorithm) and further visualized the algorithm-planned crane locations.

Despite some attempts, path planning, as a critical planning task, has not leveraged full benefit of BIM yet. Integrating BIM and the path finding algorithms is expected to not only eliminate tedious manual inputs, but explicitly predict the risks of cranes by analyzing the spatial relationship between an algorithm-planned path and existing structures in the pre-construction phase.

3 Methodology

3.1 Framework

This paper proposes a novel approach to improve the safety of lifting activities in the pre-construction phase via the integration of a practicality-and-safety-aware RRT* algorithm (PSRRT*), and BIM. Figure 1 presents the overall structure of the framework, which has three components: information retrieval, path generation, and path visualization. This framework starts with a query in the BIM model to retrieve information relevant to the building components to be lifted, the site area, existing structures, and the crane specifications. The retrieved information formulates the search space for PSRRT* who generates a path that satisfies the practicality considerations specified. The geometry of the path is then stored and visualized in the BIM model with invisible parts highlighted.

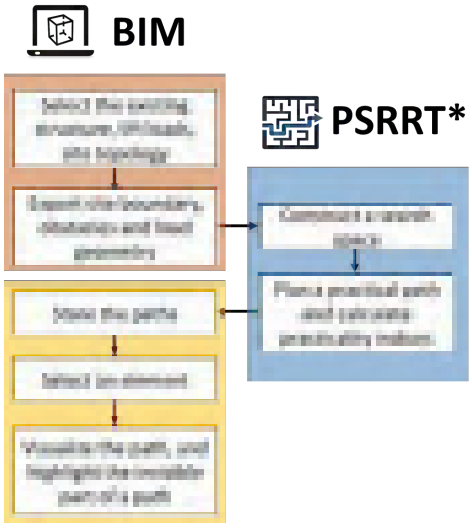

Figure 1. Research framework

3.2 Prototype Development

To validate the proposed framework, a prototype system was developed using Autodesk Revit, Dynamo Studio, and Python programming language. Python was employed to realize the PSRRT* algorithm while Revit and Dynamo were used to enable the data exchange between the BIM model and PSRRT*.

3.2.1 Information Retrieval

The first step in the prototype system involves the search for and retrieve of lift-related information from a Revit model using Dynamo. The information to be retrieved includes (1) the geometry and location of existing structures; (2) the ID, geometry, location, and weight of the lift load; and (3) the geometry of site topology. In addition to the building information, crane specifications are also required. In some cases, there exist detailed crane information models, which include the crane specifications such as the capacity, the boom length, and location of the crane and its cabin. However, more often, the crane information has a source other than the BIM model, such as a spreadsheet from crane manufacturers. Therefore, this step focuses on general cases and retrieves building information only.

Based on the retrieved information, the search space of PSRRT* can be constructed, with the location and dimension of obstacles and the space boundary. First, building structures existing prior to the lift are given axis-aligned minimum bounding boxes (AABB), which are further buffered with the length and height of the lift load. The buffered boxes are used to represent obstacles in the search space. To minimise computational complexity, existing structures with a top constraint lower than the base constraint of the lifted load in the BIM model are consolidated to be one single obstacle. Then, the search space boundary is determined by the site topology, which is presented by toposurface in Revit. Figure 2 shows the Dynamo code overview for retrieving necessary information from Revit models to construct the search space for PSRRT*. As a result, three .csv files are exported, which contain information on obstacles, the lift load, and the site boundary.

3.2.2 Path Generation

As an integral component in this framework, PSRRT* is devised to find a practical path given the search space, obstacles, and load supply and demand points. Although the algorithm can easily adapt to other types of cranes, in this study, PSRRT* is designed for cranes with three DoFs (i.e., swinging, luffing, and hoisting), such as the luffing tower crane or the truck mobile crane. As discussed in Section 2.1, a practical path is defined as a smooth and visible path with an acceptable level of motion coordination. As the original RRT* algorithm can produce a smooth path, PSRRT* mainly aims to improve the outcomes' practicality in visibility and motion coordination.

The flowchart in Figure 3 illustrates how PSRRT* explores the search space and makes adjustments to reflect the practicality considerations. The searching mechanism relies on a "tree" with the "root" at the initial point of the lift load. The tree is defined as vertices and edges that connect the parent vertices and its child vertices. Since one child vertex only has one parent vertex, a path connecting the initial point to the goal point is found when the tree grows to reach the goal. To expand the tree, PSRRT* randomly samples a node (q_{rand}) in the search space and attempts to connect q_{rand} to the nearest node ($q_{nearest}$) on the existing tree rooted in the initial node ($q_{initial}$). If the distance between $q_{nearest}$ and q_{rand} is longer than a given resolution for tree expansion (Δq), a new node q_{new} is created Δq away from $q_{nearest}$ in the direction towards q_{rand}.

If q_{new} is visible and collision-free, the nearby nodes (q_{near}) are found. For each q_{near}, if the edge between q_{new} and q_{near} is visible and collision-free, the cumulate distance from $q_{initial}$ to q_{new} via q_{near} and the distance between q_{near} to q_{goal} are calculated. These two distances are summed up as a total distance to reach q_{new}. The q_{near} with the smallest total distance is considered as the parent of q_{new}. This procedure is known as "Choose Parent". It is followed by the "Rewire", which measures the cumulative distance from $q_{initial}$ to q_{near} via q_{new} if the in-between edge is visible and collision-free, and changes the parent of q_{near} to q_{new}. This loop iterates until any tree

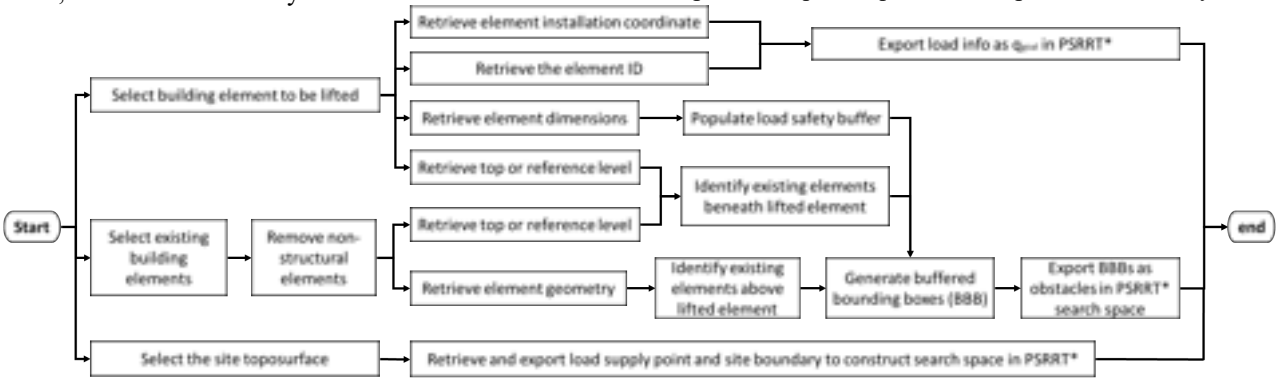

Figure 2. Flowchart for information retrieval from BIM model to PSRRT*

node can be connected to q_{goal} with a collision-free and visible edge.

In this process, the motion coordination is limited by redefining distance in the algorithm. Usually, distance is defined as the Euclidean distance, which neglects the complex coordination of motions in the configuration space (C-space). As a result, PSRRT* uses a weighted Manhattan distance to model the cost between any two configurations:

$$\text{Cost} = w_1 \Delta \alpha + w_2 \Delta \theta + w_3 \Delta \text{L}$$

Where α indicates the swing angle, θ indicates the luffing angle, L indicates the length of the hoist line, which connects the tip of the crane boom and the lift load; weights (i.e., w_1, w_2, w_3) are determined according to the operating speed of each crane motion.

On the other hand, blind lifts are avoided via visibility checks. The visibility check uses the AABB collision detection technique to examine the spatial relationship between the points along the vision line and the physical obstacles. The vision lines are straight lines in the Cartesian space, starting from the crane cabin. It is worth noting that a search space usually has two representations: a Cartesian space and a C-space, and these two representations are transformable. In this algorithm, tree expansion is conducted in the C-space since it is convenient to identify motion coordination, while the collision detections and visibility checks are implemented in the Cartesian space.

Once a valid path is found, PSRRT* executes a post-processing procedure, to further eliminate redundant motion coordination by restricting the first and last segments of the path to be vertical (i.e., only hoisting is allowed) to reflects the real practice. If they are collision-free, the algorithm returns a new path that is exported to Revit for visualization.

3.2.3 Path Visualization

Although the algorithm-planned path has already incorporated most practicality considerations, there still exist various safety concerns in path planning, depending on the site condition and the characteristics of lift loads. Therefore, it is necessary for construction stakeholders to review the algorithm-planned path in a context-rich manner. Figure 4 shows an overview of the dynamo code for path visualization. By selecting the building component to be reviewed, this component automatically reads the path from an excel and presents the path geometry with the invisible parts highlighted.

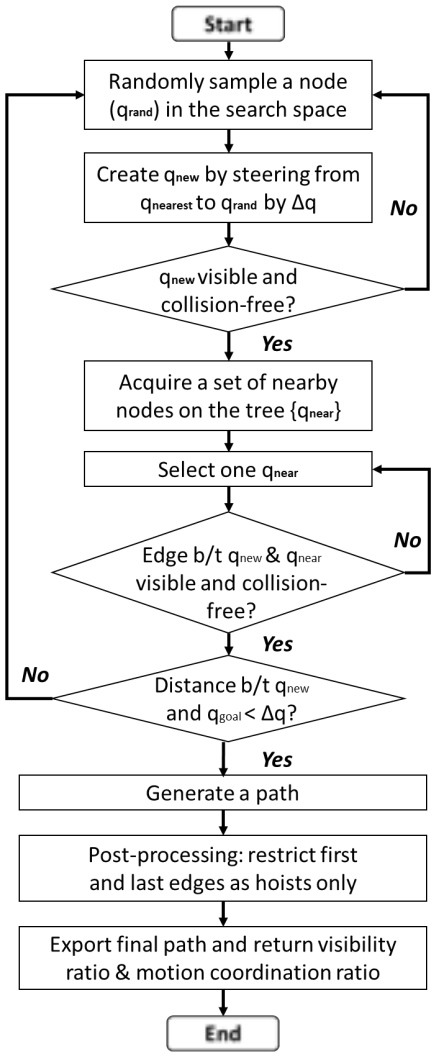

Figure 3. PSRRT* path generation mechanism

4 Case Study

The performance of the prototype system was assessed in a case study on a building project at Monash University, Melbourne, Australia. The building project consisted of a 5-story steel structure errected by three 28m-high luffing boom tower cranes with a 40m boom. The model of these tower cranes is FAVCO M390D and the deployment locations for each crane is indicated in Figure 5(a). According to the schedule, Tower Crane 3 (TC3) was required to lift three beams to level 1 in one working day, as shown in Figure 5(b). These lifting activities are selected as the test scenario in this case study. The building information was stored in a Revit model. Meanwhile, since there was no available Revit family for this particular crane model, the crane specifications and location of the supply area were stored in a .csv file.

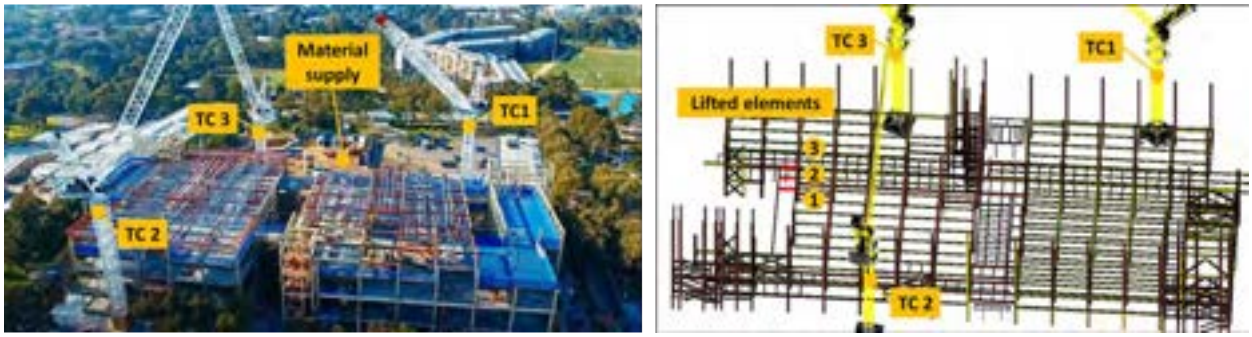

Figure 4. Overview of the project (left) and building elements to be lifted in the BIM model (right)

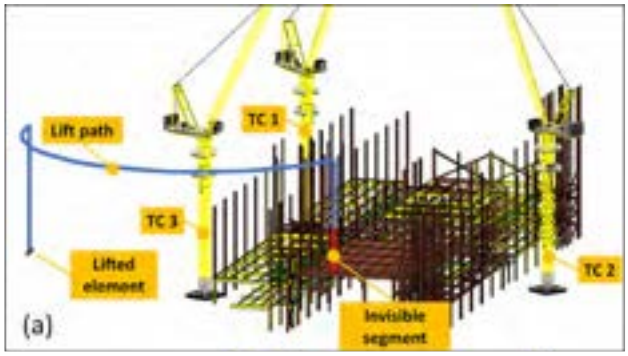
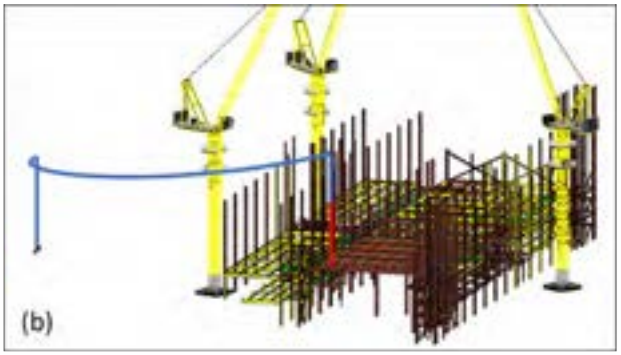
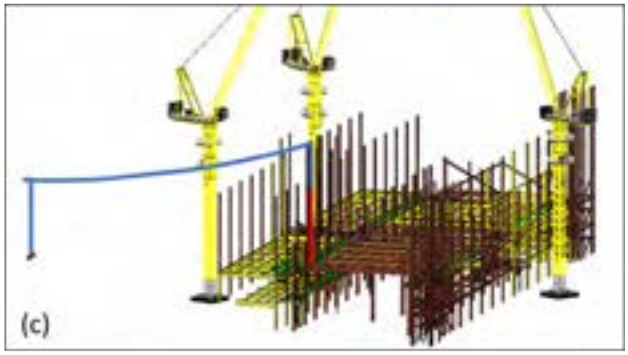
Firstly, the prototype system retrieved information from the Revit model. In this process, there were 1390 elements retrieved as structures existing prior to the lifts. These elements were exported as 503 obstacles in a 150m x 140m area. Based on this information, PSRRT* calculated the paths for the three lift tasks, as shown in Figure 6(a-c). All three paths have similar trajectories, where the load is vertically lifted from the material supply area, then moved to above the demand points through a combination of swinging and luffing, and finally lower the loads to the target elevation for installation. As illustrated in Figure 6(d), although the number of obstacles is high, the computing times of PSRRT* are relatively low. The average computing time is 0.0523s for the paths. For a project with 3000 elements to be installed, the proposed method is anticipated to finish the planning task within 3 minutes. This prediction requires further verification since RRT* is stochastic and its computing time is influenced by random sampling. Meanwhile, to quantitively evaluate the improvement of the proposed path finding algorithm in smoothness, visibility, and motion coordination, Figure 6(d) also tabulated the number of way-points, the ratio of the visible path to the entire path, and the ratio of the path with three coordinated motions to the entire path. It is observed that the average visibility ratio is 91.5%, and the invisible parts for each path are visible to the beam connector (i.e., the last segment). Furthermore, the coordination ratio for these three paths is zero, indicating an optimal complexity of operations.

Despite the encouraging outcome from the proposed approach, several limitations of the proposed methods are also identified. For example, the proposed method assumes the structures below the lift load as a rectangular







Lifted Element	1	2	3	Average
Computing time (second)	0.063	0.053	0.041	0.0523
Number of way-points	4	4	4	4
Path Length (meter)	142.398	131.425	123.364	132.396
Visibility ratio	93.5%	92.1%	88.6%	91.5%
Coordination ratio (3 motions)	0	0	0	0

Figure 5. Planned paths for the lifted elements (1) to (3) in (a) to (c), respectively, and results for computing time, path length, visibility ratio and coordination ratio for each path

obstacle to decrease computing complexity, which is only valid for building projects with a rectangular geometry. This limitation can be overcome by using advanced collision detection algorithms (e.g., OBB) or voxelizing the search space. Furthermore, the proposed approach requires a comprehensive BIM model, which is not always available. Essential information for path planning, including lift sequences and the crane specifications are usually stored in other software, causing difficulty in interoperability. Therefore, there is a demand to create and standardize customized parameters and family types to store the necessary information for lift planning. Thirdly, the proposed approach focuses on the BIM model and may ignores environmental obstacles (e.g., adjacent buildings). In congested environments, the BIM model is expected to fuse with reality capturing technologies, such as laser scanning, to acquire information on site conditions.

5 Conclusion and Future Research

This paper proposes an approach to automatically plan and visualize a safety and practical lifting path using a novel path finding algorithm and BIM. Two main contributions can be highlighted: (1) the modified RRT* algorithm successfully incorporates the practicality considerations to generate a feasible and realistic path. (2) the proposed approach exploited the BIM model to visualize the planning results to facilitate coordination between stakeholders.

Furthermore, this paper demonstrated the potential of the proposed approach as a 4D risk management system where engineers can proactively plan the activities and workspaces under the impact of crane lift activities. In the future, the proposed method is expected to automatically plan paths for the entire building project for lifting experts to review and adjust. By analyzing adjusted paths, the hazardous zone of crane swing-over is generated to support safety-related decisions, such as coordinating active workspace and crane operations.

Abstract – This paper proposes an autonomous crawler carrier system to improve productivity of earth and sand transportation work. In general, multiple crawler carriers on the transportation work repeatedly move on almost the same route between loading and unloading locations. There is a risk that the crawler carrier deviates from the transport path due to the driver's fatigue and reduced concentration since the transportation work is a monotonous and repetitive operation. The proposed system enables multiple crawler carriers to automatically move on the same route without collision using an artificial intelligence (AI) based control. There are four steps in the AI control flow. First, the driver performs the teaching operation while checking the route from the camera image. Then, teaching route data for an autonomous crawler carrier is created. Second, the AI on the personal computer selects several routes that can maintain safe crawler carrier positions for all routes of multiple carriers. Third, AI generates an efficient operation plan that minimizes the working cost and time from all positional relationships. Finally, when the operator presses the start switch on the control panel, AI controlled multiple crawler carriers move efficiently without collision. This smart control was introduced for the construction of earth and sand transportation in the Aso-Ohashi area, and efficient operation was confirmed.

Autonomous crawler carrier system; Artificial intelligence; Productivity improvement

1 Introduction

In recent years, information and communication technology (ICT) [1] has made great progress with the development of signal processing technology [2], computer technology [3], wireless communication technology [4], and so on. As a future society, "Society 5.0" has been proposed by the Cabinet Office, which is a Japanese administrative agency [5]. Although life has become more convenient in Japan with the progress of ICT, an aging society causes labor shortages and increasing energy consumption. Society 5.0 tries to incorporate robot technology [6], artificial intelligence (AI) technology [7, 8], etc. into society in order to solve such social issues. To realize Society 5.0 in Japan construction industry, a big project called "i-Construction" is underway to improve the productivity of the entire construction production system.

This i-Construction, which is managed by the Ministry of Land, Infrastructure, Transport and Tourism, includes the development of an unmanned system for construction machinery [9-11]. In the automatic control of this construction machine, the personal computer (PC) in the control device drives the crawler carrier instead of human operators. The application of the automatic control reduces the needs of skilled operators, solves the shortage of human resources, and can be expected to improve productivity.

In this paper, we noticed that the earth and sand transportation work is a monotonous repetitive work of reciprocating the route. This cyclical work causes physical and mental fatigue of the operator. Therefore, we are developing an automatic driving technology for crawler carriers to reduce accidents by operators during the transportation work using the AI technology [12].

The remainder of this paper is organized as follows. Section II introduces the details of automatic driving system in the earth and sand transportation field. In Section III, we explain the proposed autonomous crawler carrier system with AI based transportation control. Moreover, in Section IV, we verifies the effectiveness of our proposed scheme by the computer simulation. In addition, experimental results of Aso-Ohashi area are briefly explained in Section V. Finally, the conclusion and future works are presented in Section VI.

2 Automatic driving system in the soil and sand transportation field

2.1 System configuration

The automated driving system uses a network-compatible crawler carrier that enables human-less construction. Figure1 shows two crawler carriers which are used for transporting earth and sand. The specifications of this crawler carrier, which is manufactured by KATO WORKS, are as follows. It has a payload of 11,000 kg, a machine mass of 14.100 kg, a length of 6.05 m, a width of 2.84 m and a height of 2.91 m.

Figure 1. Two Crawler carriers for transporting earth and sand.

Figure 2 shows system configuration for the automated driving system. In this construction, the crawler carriers are controlled using the internet protocol (IP) network. The automatic driving system is composed of the following devices.

- Global Navigation Satellite System (GNSS) / IMU(Inertial Measurement Unit) device that measures the position information of the moved route, where this device includes GNSS reference station
- PC for automatic driving control (1 vehicle side, 1 remote control side)
- Vehicle camera to watch the surrounding conditions during remote control

IP addresses are assigned to these devices, and they can be controlled by packet transmissions using a wired local area network (LAN) system or a wireless LAN system. GNSS / IMU is a combined inertial measurement device for GNSS and IMU. In addition to the position information from the G

GNSS device, the position and direction of the vehicle can be combined with the IMU device to measure the position of the vehicle with high accuracy.

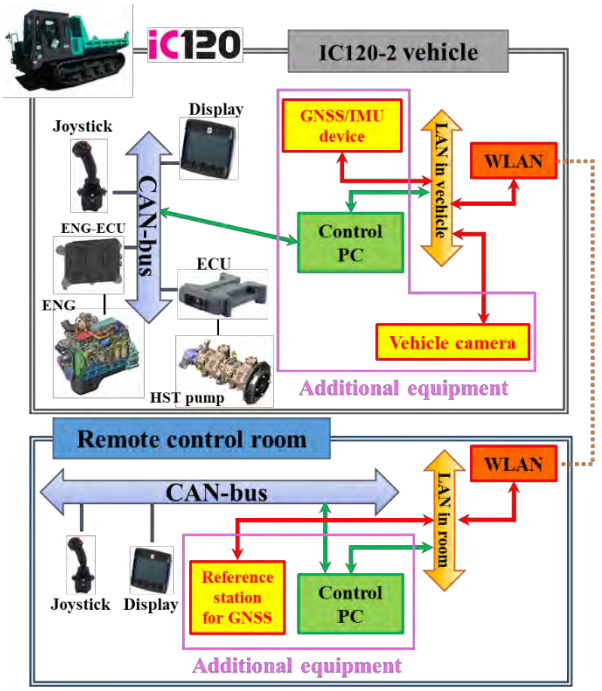

Figure 2. System configuration for the automated driving system where wireless communication is conducted between the remote control room and crawler carriers.

2.2 System control flow

Figure 3 shows a framework related to the important devices for teaching and automatic driving operations. In this figure, there are two modes, which are teaching mode and auto-driving mode. As shown in this figure, a remote and automatic operation panel including the PC is set in the remote control room which has monitors, PCs, and wireless communication devices. If the operator would like to control the crawler carrier, command signals are transmitted to the PC which is set in the crawler carrier via the WLAN packets. On the other hand, the crawler carrier's information is transmitted to the remote control room via the WLAN packets.

There are three flows: teaching operation, preparation of automatic driving, and automatic driving mode. These flows are explained as follows in detail.

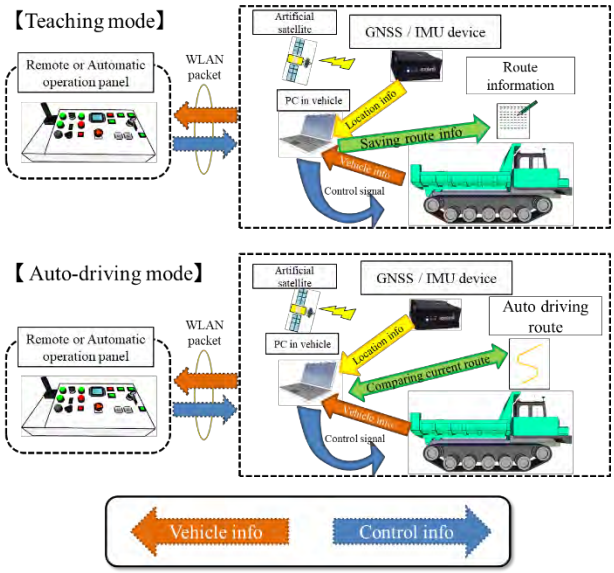

Figure 3. The framework related to the important devices for teaching and automatic driving operations.

2.2.1 Teaching operation

A start signal for the teaching operation is transmitted from the remote control room to the PC in the crawler carrier, and the operator moves it remotely. When the crawler carrier is running, the position and speed information from the GNSS / IMU device are stored in the in-vehicle PC as a teaching path. This information is used in the automatic driving mode.

2.2.2 Preparation of automatic driving

First, a control packet for switching the remote driving mode to the automatic driving mode is transmitted from the remote control room to the crawler carrier. Secondly, the control signal to start the automatic operation is transmitted. Third, the teaching data for the automatic driving is saved in the in-vehicle PC inside the crawler carrier. Thirdly, the teaching data for automatic driving is saved in the hard disk of the PC stored inside the crawler carrier.

2.2.3 Automatic driving mode

The in-vehicle PC automatically drives the crawler carrier while comparing the teaching data with the current position from the vehicle's GNSS / IMU device. In addition, the movement of the crawler carrier is automatically stopped when the teaching path and the current position greatly deviate from each other.

3 AI based automatic driving technique

3.1 Necessity of AI-based autonomous driving

In the automatic driving system described in the previous section, a stop operation by a worker in the remote control room is required in order to halt the crawler carrier during the automatic moving from the start point to the end point. Therefore, at least two operators are needed in the working field. One remotely controls the excavator and loads the crawler carrier with sand, and the other manages and watches the movement of the crawler carrier. If the number of autonomous crawler carriers increases, operation management by one worker becomes much difficult, and there is a possibility of collision among crawler carriers. In order to prevent collisions, a system that manages the operation of multiple crawler carriers on behalf of the worker is required. Therefore, in this paper, we propose an AI-based autonomous driving technique.

The developed AI-based automated driving technology does not require human operation management, and single worker can perform a series of operations from loading and unloading sediment. Figure 4 shows the configuration of the AI-controlled automatic driving system. As shown in this figure, the PC in the remote control room (PC-r) controls two remote and automatic operation panels via and two in-vehicle PCs (PC-v). The PC-r transmits the AI start signal to the PC-v via the operation panel. Moreover, the PC-r directly transmits the stop signal to the PC-v. On the other hand, the PC-v transmits the vehicle information to the PC-r via the operation panel, but it directly transmits the position information to the PC-r. There are two information flows among the control PC in the remote control room and two crawler carriers.

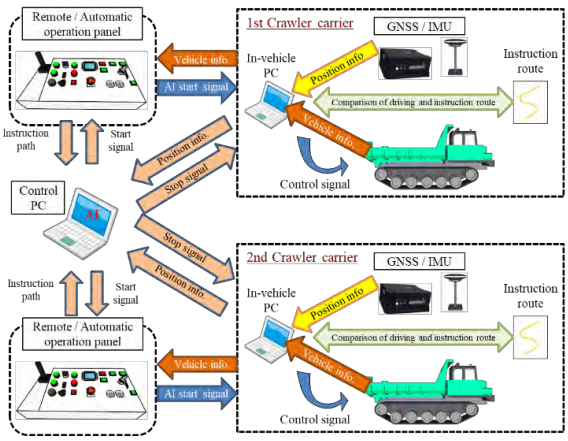

Figure 4. Configuration of the AI-controlled automatic driving system.

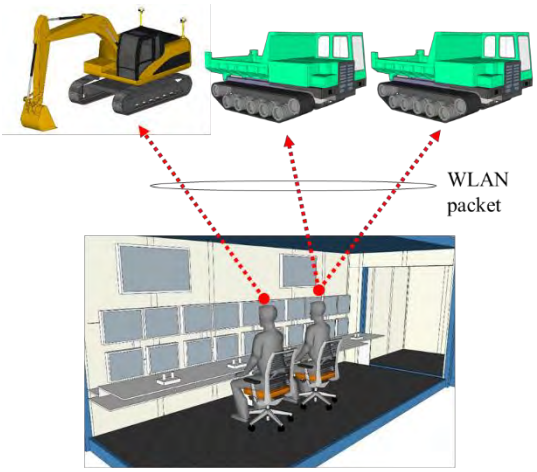
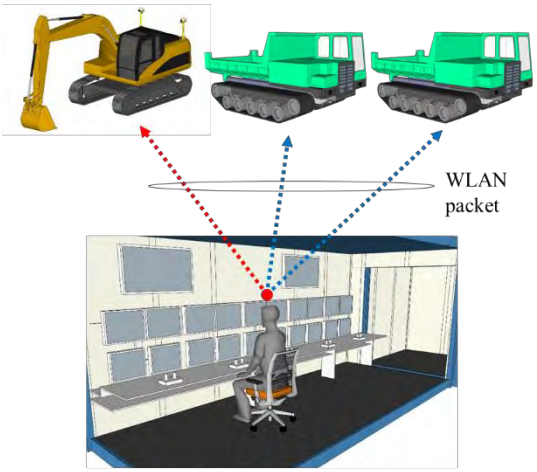


The number of construction machineries is three.
The number of operators is two.

(a) Before AI based remote control room



The number of construction machineries is three.
The number of operators is one.

(b) After AI based remote control room

Figure 5. Control of multiple vehicles by one operator.

Figure 5 shows the control of multiple vehicles by one operator. As shown in this figure, the number of operator is two, when the number of construction machineries is three before AI based remote control room. On the other hand, the number of operator is only one after the AI based remote control room. This means that our proposed system is one of the best solutions for the shortage of human resources in Japanese construction field.

3.2 AI control flow

Figure 6 shows our proposed AI control flow in which there are four steps: instruction, analysis, plan, and command. These steps are explained as follows.

- First, the operator remotely moves the crawler carrier, and the route information for teaching process is generated.
- Second, based on the obtained route data and crawler carrier size conditions, the AI on the PC-r finds safety positions between crawler carriers and positional relationships in possible. Then, several candidate routes that allow safe operation are selected.
- Third, the operation pattern that minimizes the cost and time is selected from the candidate routes in the previous step, considering the productivity of earth and sand transportation work. At this time, the start and end positions of the instruction route are also taken into consideration. For example, the unloading and loading operations are conducted in the start and end points. Optimal operation pattern of vehicles is calculated from the candidate routes and other conditions. The operation pattern satisfies spatial limitation to avoid interference between vehicles while minimizing expected time necessary to complete load and unload of sediment. In this phase, algorithms to solve multi agent path finding problem are used with original expansions to increase flexibility and efficiency [13].
- Finally, the PC-r remotely controls the two crawler carriers on the most efficient operation pattern. The GNSS position information from the each carrier is sent to the remote control room, and the start and stop of moving can be determined by the AI monitoring in constant. Moreover, the second and third processes are re-conducted in our proposed scheme if the variation of the environmental condition, for example a muddy road and an increase of loading time, changes the position relationship between two crawler carriers.

As a result, the number of operators for monitoring the crawler carriers can be reduced. When the number of vehicles is only one, the difference of driving efficiency between the automatic driving with and without the AI is none. However, in the case of more than two vehicles, the AI based automatic control considers the collision avoidance on the driving route. On the other hand, in the case of the automatic control without the AI, if a forward vehicle and a return vehicle meet on a narrow road, either one vehicle needs to return to the back wide road, which incident wastes operation time. Therefore, the AI control will enable efficient transportation in the construction field.

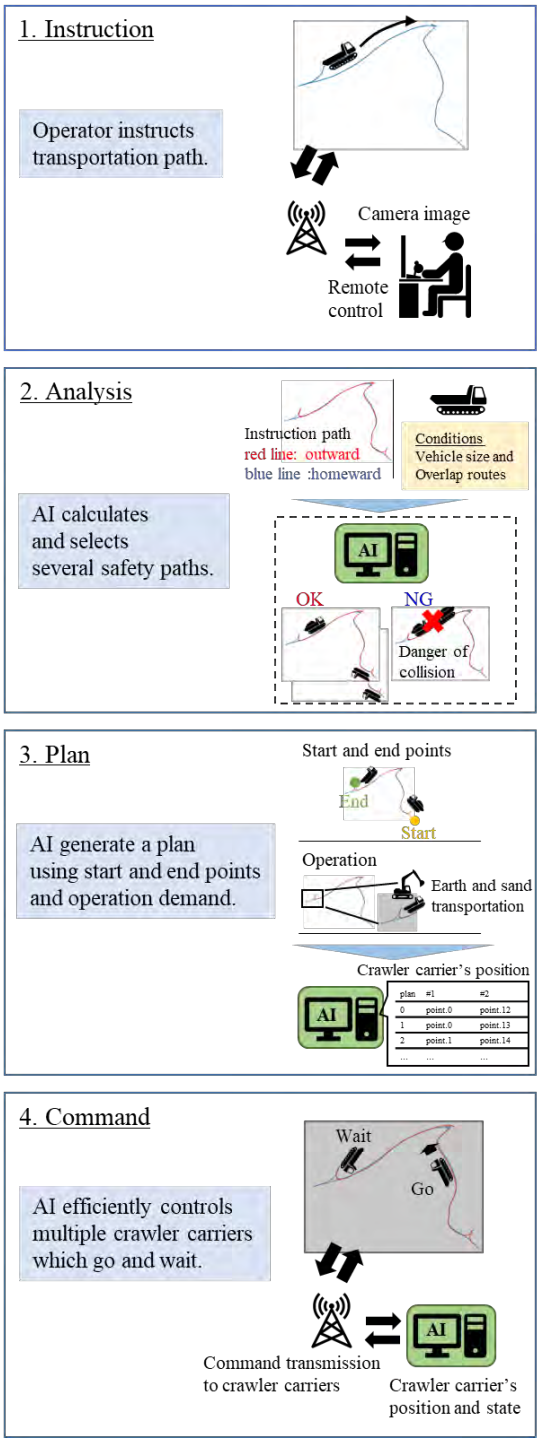


Figure 6. Configuration of the AI-controlled automatic driving system including instruction, analysis, plan, and command processes.

4 Computer simulation

4.1 Simulation parameters

Performances of our proposed AI-controlled automatic driving system are evaluated by the computer simulation. There are three fields in this simulation, where the first field is in the Aso-Ohashi area, the second and third fields are in Tsukuba area.

In this simulation, the sand loading time to the crawler carrier using the excavator was not considered. The maximum number of crawler carriers (maximum N_t) is two. In addition, the start point for moving the crawler carrier is the unloading point. There are two routes. One is an outbound route from the unloading point to the loading point. The other is a homeward route from the loading point to the unloading point. Overlap of forward and return routes is allowed. Even if there is no overlap between the forward and return paths, it is not possible to pass each other within 6 m. We set the waiting and separating points in the driving route. These points increase the driving efficiency and they are determined by the operator's empirical knowledge.

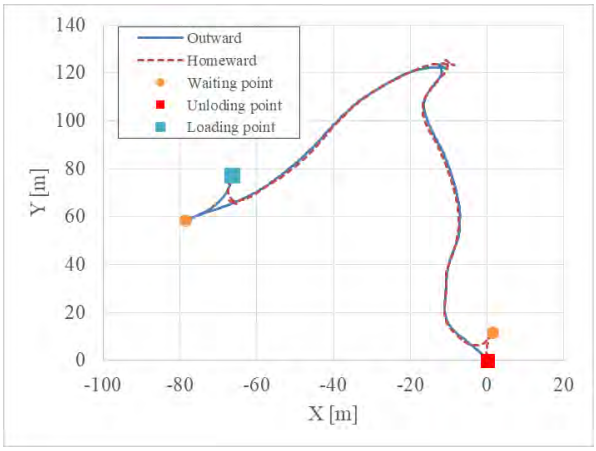

Figure 7. Driving route in the Aso-Ohashi operation area in which the number of waiting points is two.

Figure 7 shows driving route in the Aso-Ohashi operation area which size is 80m by 120m. There are two separating points. When one crawler carrier is in the loading point, the excavator loads its crawler carrier with earth and sand. The other crawler carrier waits until the loading work is completed at the waiting point which is near the loading point. Similarly, when one crawler carrier is unloaded, the other crawler carrier waits until the unloaded operation is completed at the waiting point which is near the unloading point.

Figure 8 shows driving route in the 1st Tsukuba area which is inside Technical research & Development institute on Kumagai Gumi. The area size is 40m by 30m. There are two waiting point.

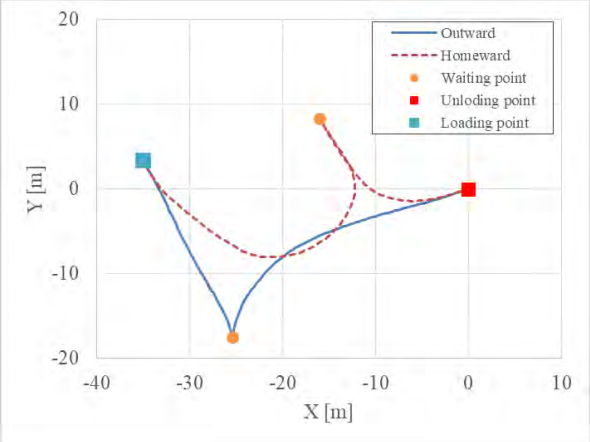

Figure 8. Driving route in the 1st Tsukuba area in which the number of waiting points is two.

Figure 9 shows driving route in the 2nd Tsukuba area which is inside Technical research & Development institute on Kumagai Gumi. The area size is 40m by 30m. There are two waiting points in order to increase work efficiency for more than two crawler carriers. Moreover, two separating points(SPs) are added to this filed. If there are no waiting points, either of crawler carriers frequently stops the movement on the outward and homeward path because the AI based control selects the extremely safe operation plan. Therefore, it is expected that two waiting points improve work efficiency in the case of $N_t = 2$.

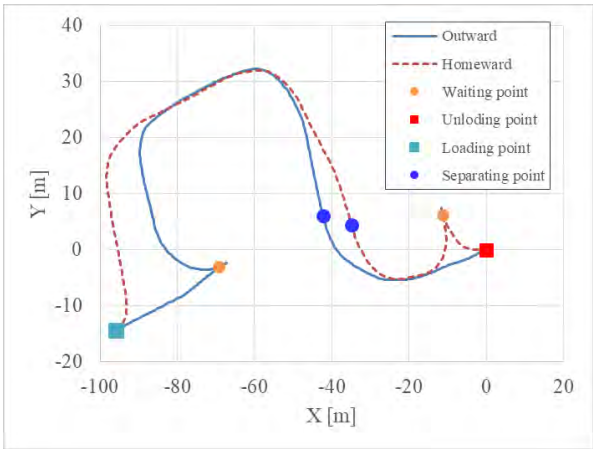

Figure 9. Driving route in the 2nd Tsukuba area in which there are two waiting points and two separating points in order to increase work efficiency for more than two crawler carriers.

4.2 Simulation results

Table 1 shows work efficiency in Aso-Ohashi and Tsukuba area in the simulation. As shown in this table, at first, work efficiencies for the case of $N_t = 1$ and $N_t = 2$ are 16.2 and 31.1 cycle/hour in the Aso-Ohashi area. In this area, work efficiency for the case of $N_t = 2$ is improved by 72% compared to the case of $N_t = 1$.

Secondly, work efficiencies for the case of $N_t = 1$ and $N_t = 2$ are 66.1 and 105 cycle/hour in the 1st Tsukuba area. In this area, work efficiency for the case of $N_t = 2$ is improved by 59% compared to the case of $N_t = 1$.

Thirdly, work efficiencies for the case of $N_t = 1$ and $N_t = 2$ are 24.5 and 42.2 cycle/hour in the 2nd Tsukuba area without two separating points. In this area, work efficiency for the case of $N_t = 2$ is improved by 72% compared to the case of $N_t = 1$. On the other hand, work efficiency for the case of $N_t = 2$ is 46.4 cycle/hour in the 2nd Tsukuba area with two separating points. Work efficiency for the case of $N_t = 2$ is improved by 89% compared to the case of $N_t = 1$.

By determining two separating points and planning the automatic driving routes, the unnecessary waiting time of the two crawler carriers due to the overlap of the outward and homeward routes is reduced. Efficiency ratio for the case of $N_t = 2$ with separating points is 17% higher than that for the case of $N_t = 2$ without waiting points. Therefore, if our proposed automated driving is applied in an area where the travel paths are complicated, it is important to provide some separating points when making the driving plan.

Table 1. Work efficiency in Aso-Ohashi and Tsukuba area in the simulation.

Area	Work efficiency [cycle/h]		Efficiency ratio
	1 vehicle	2 vehicles	
Aso-Ohashi	16.2	31.1	1.72
1st Tsukuba	66.1	105	1.59
2nd Tsukuba (w/o SP)	24.5	42.2	1.72
2nd Tsukuba (w/ SP)		46.4	1.89

5 Experimental results

In this section, experimental results of the construction in Aso-Ohashi area are briefly described.

Table 2 shows construction outline in this area. As shown in this table, verification period of this construction was in September 2018. The verification place was a collapse slope area at the top of the soil retaining embankment. One way distance was about 300m. Path width and maximum path gradient were about 5m and 20%. The path gradient was able to

decrease the moving speed of crawler carrier. The number of construction machines was three including one excavator and two crawler carriers.

Table 2. Construction outline in Aso-Ohashi area.

Construction name	Slope countermeasure work in Aso-Ohashi area	
Verification period	September 2018	
Verification place	Collapse slope area at the top of the earth retaining embankment	
Path condition	Distance (one way)	about 300m
	Width	about 5m
	Gradient (maximum)	20%
Num. of construction machines	Excavator	1
	Crawler carrier	2

Figure 10. External remote control room in Aso-Ohashi area in which the number of operators is only one.

Figure 10 shows an external remote control room in Aso-Ohashi area. There were two remote control panels including the PC-r. Multiple monitors were set on the table in order to check movements of crawler carriers and their surrounding area. The excavator loaded earth and sand to the crawler carrier which was controlled by the AI when the operator remotely moved the excavator.

Figure 11 shows the snapshot of the verification in Aso-Ohashi area, which is a partial area of -80 to -60 m on the X axis and 55 to 80 m on the Y axis in Fig. 7. The crawler carrier (green) had waited at the waiting point while the earth and sand loading operation for the other carrier (magenta) had been conducted. After its operation was finished, the crawler carrier (magenta) with earth and sand went to the unloading point and the crawler carrier (green) approached the loading point as shown in Fig. 11. If the waiting point was not set on this path, the incident may happen where one of the crawler carriers turned back the way which it came from.

Figure 11.Snapshot of the verification in Aso-Ohashi area where one crawler carrier (magenta) moves to the unloading point and the other (green) moves to the loading point near the excavator.

Table 3 shows work efficiency in Aso-Ohashi and Tsukuba area in the simulation and real environment. As shown in this table, the simulation result is same as Table. 1. Work efficiencies for the case of $N_t = 1$ and $N_t = 2$ are 7.47 and 13.1 cycle/hour in the real field. In this case, work efficiency for the case of $N_t = 2$ is improved by 75% compared to the case of $N_t = 1$.

The results of work efficiency for the real environment are low compared to the simulation results, because time durations of earth and sand loading and discarding are not assumed in the simulation environment. In addition, we consider that the influence of mud and gradient in the real field can decrease the speed of crawler carriers. Moreover, the maximum speed of the crawler carrier is adopted in the simulation. On the other hand, the difference of efficiency ratio between the real and simulation environments is almost the same value. The simulation analysis enables us to search the semi-optimal waiting points and separating points in the driving route. Therefore, its analysis is important before the verification of our proposed scheme in the real environment.

Table 3. Work efficiency in Aso-Ohashi area in the simulation and real environments.

Area	Work efficiency [cycle/h]		Efficiency ratio
	1 vehicle	2 vehicles	
Aso-Ohashi (simulation)	16.2	31.1	1.72
Aso-Ohashi (real)	7.47	13.1	1.75

6 Conclusions

This paper proposes an autonomous crawler carrier system with the AI based transportation control. In the proposed scheme, the AI based operation management eliminates the need for the safety confirmation between two crawler carriers. Moreover, it reduces the number of operation monitoring workers, which means that the proposed system is one of the best solutions for the shortage of construction workers in Japan.

The AI makes the movement plan for crawler carriers in the earth and sand transportation. This plan is produced by the major flow consisting of instruction, analysis, plan, and command processes. In the simulation results, when two crawler carriers in the Aso-Ohashi area are automatically controlled by the AI, work efficiency improves 72% compared to the case of one crawler carrier. In addition, when the same AI controls the automatic driving in the 1st Tsukuba area, work efficiency improves 59% compared to the case of one crawler carrier. Moreover, work efficiency improves 72% compared to the case of one crawler carrier in the 2nd Tsukuba area which is larger than the 1st area when there are no separating points. On the other hand, work efficiency improves 89% compared to the case of one crawler carrier in the 2nd Tsukuba area with setting two separating points.

Moreover, results of efficiency ratio for real and simulation environments are almost the same value. Therefore, we aggressively use the simulation analysis before the verification of the AI based auto driving system in the real construction field.

As a future study, it is possible to further improve work efficiency of the earth and sand transportation by efficiently arranging the waiting and separating points in the driving routes. Furthermore, determination of waiting and separating points using AI control will be conducted.

Abstract –

An optimization system of a lifting plan must have generality to manage different design conditions and real-time changes at a construction site. Furthermore, it must optimize the construction planning and scheduling. In a previous study, we trained a two-point locomotion model for crane hook movement using deep reinforcement learning to generate and optimize lifting plans automatically. However, we did not test the accuracy and generality of the model. In this study, we test (1) the accuracy and (2) the generality of the trained model using a new environment. To evaluate the accuracy of the optimal solution, we examined the locus of the movement of each frame between two points. To verify the generality of the trained model, we solved an optimization problem of the crane hook movement under different conditions of the crane's learning environment using the trained model. From the results, we found that the movement path was 3.6 times the shortest path and the crane hook initially moved vertical. Furthermore, the agent solved the optimization problem of the crane hook movement when the size of the crane changed. Therefore, the corresponding range increased with increasing size of the crane. However, the agent did not solve the problem when the slewing angle in the target position was larger than the slewing angle in training. Based on these results, we believe that the limited vertical movement range and rotation range of the crane reduces the accuracy and generality of the trained model.

1 Introduction

Improving efficiency in building construction is a principal research topic in the construction field, where the shortage of skilled workers is increasing. Therefore, optimization and automation of construction planning and scheduling is important to improve construction [1]. However, optimization of construction planning and scheduling is a complicated task. Therefore, it is generally prudent to optimize each task [2].

The following two aspects are considered necessary to optimize construction planning and scheduling: (1) solving complex combinatorial optimization problems and (2) providing general versatility to manage design and real-time situation changes during construction. Considering (1), problems such as those concerning work interference, route planning, placement planning, and quantity planning can be replaced with typical problems, and optimization research has been conducted [2]. In case of (2), solving problems can be difficult or impossible when changes not existing in the optimization simulation, such as work delay and obstacle interference, occur in the real space. Furthermore, adding all necessary factors in the optimization simulation to provide generality is challenging.

Therefore, we focused on using deep reinforcement learning (RL) to ensure generality. In a previous study, we developed a crane lifting plan using deep RL. Reasons for optimizing lifting tasks are as follows:

1. lifting task is a cooperative task involving several sub-tasks, and
2. lifting task is a complex optimization problem because it includes factors such as the lifting route, layout, model, quantity, and building order.

In Section 2, we review some related work on lifting planning and deep RL.

In Section 3, we first explain the trained model for two-point movement developed in the previous study, and then we present the methods to test the accuracy and generality of the trained model of the previous study.

In Section 4, we discuss the results of the verifications, and in Section 5, we propose a method for creating the environment.

2 Related Work

2.1 Previous Research on the Construction Planning Optimization Problem

In general, construction planning and scheduling can be considered as an optimization problem. Therefore, research is conducted from optimization perspectives in work interference, construction equipment arrangements, and route planning. The construction planning optimization problem considers factors, such as safety, environment, cost, time, and work cooperation.

Wo et al. indicated that a lifting plan requires a planning scheme that considers the numbers, layouts, models, and operating times of cranes. They established a mathematical model for the spatio-temporal planning of tower cranes that reduces the total cost compared to the initial solution, indicating that it provided the optimal solution for all construction projects [2].

2.2 Previous Research on Deep RL

We focused on RL to ensure the generality of the optimization and/or automation system. RL is a machine learning method; it is different from supervised learning because it acts by itself and collects environmental information regardless of the existence of accurate or ground truth data. Therefore, it responds to unknown events for which the correct answer is unknown.

RL is mainly used for autonomous control of machines and problems with no accumulated data. When creating an autonomous control system for a robot, it is difficult to establish rules for sensor systems, control values, etc. Therefore, the robot learns the surrounding situation through RL and controls itself [3]. In addition, RL is used to generate data when there is no accumulated training data, such as building vibration control, to derive optimal vibration control values [4].

There are several phenomena where the correct answers are unknown because data are not accumulated. Construction planning and scheduling are among them.

Moreover, we can perform complex information processing by combining deep learning and RL (called deep RL). This combination aids in generating an optimal solution. The solution is used to generate long-term strategies, such as artificial intelligence for gaming.

This study combines the aforementioned features to develop a crane lifting plan.

The crane lifting plan optimization problem (based on the features of deep RL) is classified as follows.

1. A path creation function for lifting a target object by controlling movements such as slewing, derricking, and lifting and lowering.
2. A function to provide a strategy for deciding the order of construction that is the most efficient.

By developing a model with these functions, we aim to automatically develop a lifting plan for an unknown condition in a simulation. We partially performed this task in a previous study and developed a trained model. This outline is presented in Section 3.

In addition, research is being conducted to investigate methods to generalize trained models developed using RL. According to Miyashita et al., a trained model for car collision prevention using deep RL prevented collisions with cars not learned during training [4].

When training a lifting task, a construction site with several factors, is difficult to reproduce. However, if the inference model can be provided with a general versatility as described earlier, the need to describe each element in the field can be minimized. In this study, the versatility is verified using a trained model [5] for moving a crane hook between two points, as developed in the previous study. Furthermore, we propose a method for creating a learning environment for general purposes based on the inference result.

3 Method

3.1 Research Aim

In this study, we perform a simulation to investigate the following.

- Accuracy of the trained model.
- Generality of the trained model.
- Creation of a learning environment to improve the accuracy and versatility of the trained model at the learning stage.

3.2 Outline of the Research Method

In this section, we present the development environment for deep RL and the structure of the study using deep RL.

We use Unity ML-Agents [6] for deep RL. Unity ML-Agents is a framework for building "environment" for RL on Unity and for "training" and "inference" agents. The proximal policy optimization algorithm [7] is used for the RL algorithm.

As shown in Figure 1, deep RL is categorized into

two processes: learning and inference. In the learning stage, an agent learns an action to maximize the cumulative reward in some environment (learning environment). A model (a formula/method of calculation) developed by this process is called a trained model. In inference, a trained model is applied to an unknown data to provide an answer. At the inference stage, we create an unknown environment for 4D construction simulation and scheduling with several changes.

In Section 3.3, we first explain the trained model developed in the previous study. In Section 3.4, we describe the methods to test the accuracy and generality of the trained model developed in the previous study.

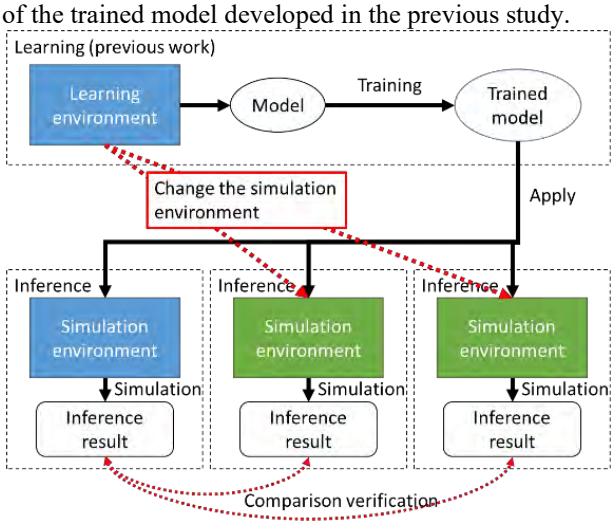

Figure 1. Verification of inference results with changed simulation environment

3.3 Training Environment

3.3.1 Simplification of Learning Content

The optimization problem of the crane lifting plan using deep RL based on the features of deep RL is categorized into the following problems.

- Optimizing hook route: lifting a target object by controlling movements such as slewing, derricking, and lifting and lowering.
- Optimizing assembly order: providing efficiency order to assemble building components.

By developing a model with these functions, we aim to automatically create a lifting plan for an unknown site in a simulation. To learn these functions, we divide the route creation function into moving between two points and collision prevention, as shown in Figure 2. This approach simplifies the environmental information and aims to converge learning.

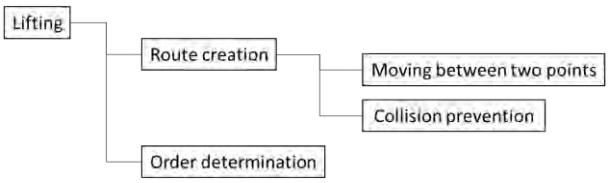

Figure 2. Simplification of learning content

3.3.2 Environment

This section presents an overview of RL, the environment, and inference results under the same conditions as during training.

RL is a machine learning algorithm that learns from the interaction between agents and the environment. Agents are learners and decision-makers. The environment is a non-agent factor on which the agent operates. As shown in Figure 3, the agent refers to the crane; the environment refers to the target, floor, coordinate space, reward, status, and other information. The agent (crane) operates on the environment and receives information such as coordinates, vector, and speed from the environment to determine new actions.

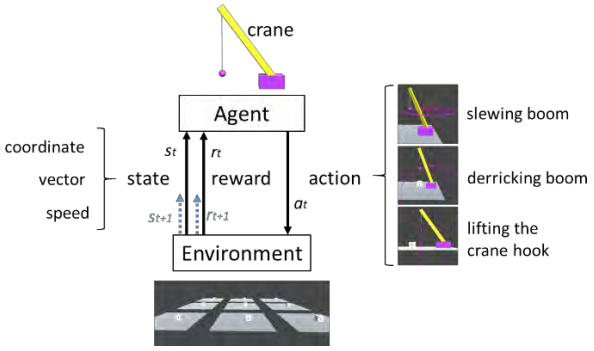

Figure 3. Interaction between agent and environment in reinforcement learning

Figure 4 (a) shows the start and end points when the crane moves between two points. Figure 4 (b) depicts the installation range of the target (box). The center coordinate of this box is the end point. During training, a target (end point) randomly appears in this range (on the horizontal plane). Figure 5 presents the inference result from the trained model for movement between the two points. The crane instantly moves between the two points, and when the end point is reached, the end-point position is initialized.

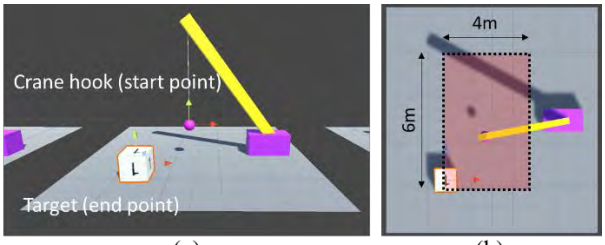

Figure 4. Start and end points (a); target (end point) installation range (b)

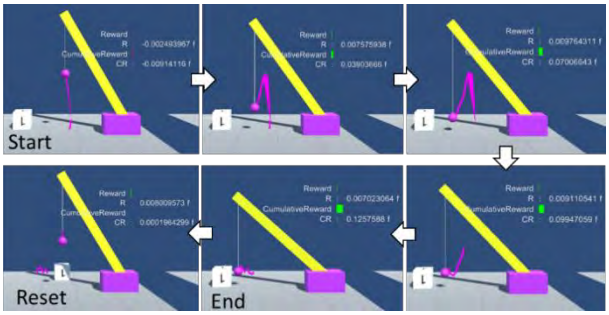

Figure 5. Trained model for moving between two points

3.3.3 Agent Action and Crane Models

In this section, we explain the operations of agents (crane) on environments in deep RL.

As shown in Figure 6, we developed a crane with three operations: slewing the boom, derricking the boom, and lifting and lowering the crane hook. The agent learns these control values by training, without limiting the rotation angle of the slewing and derricking. When lifting the crane hook, the vertical direction is restricted such that it does not exceed the boom tip. By simplifying the model in the initial stages of training, unnecessary information is deleted from the search, and the search converges easily, as shown in Figure 7.

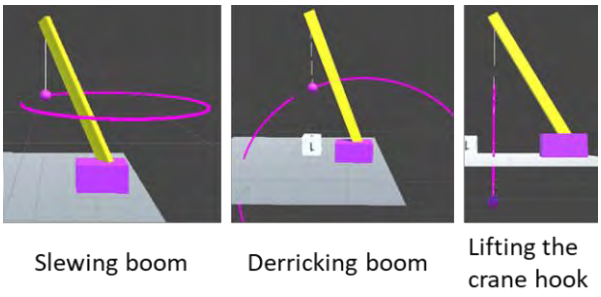

Figure 6. Movement of the crane

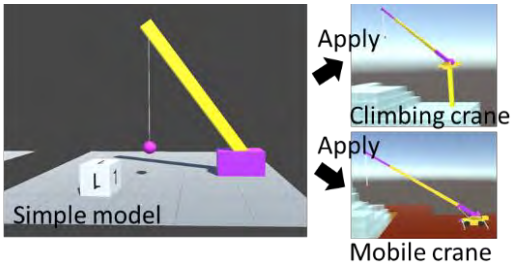

Figure 7. Simplified crane model

3.3.4 Training Method

Figure 8 shows the situation during training. The model training time was reduced by 87% by parallelizing and training nine models simultaneously. The number of iterations was 500,000.

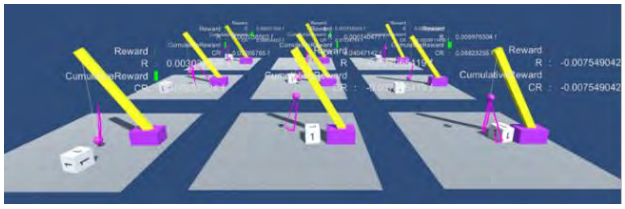

Figure 8. Parallel training of nine models

3.3.5 State and Reward

In this section, we detail a remarkable method to develop a route for a crane hook to move between two points. In deep RL, the environment rewards agents based on their behavior; agents learn behaviors that maximize their cumulative rewards. We created an environment to reward the agents as follows.

- Reward when the crane hook reaches the end point.
- Reward the movement of the crane hook towards the end point.

For a route search between two points in the horizontal direction, we can create a movement route between two points by only giving a reward when the crane hook reaches the end point. However, the optimization of the crane hook route is a path search in a three-dimensional space; hence, we created an environment to reward the operation of the crane hook approaching the end point. We used the inner product to reward the action of the crane hook approaching the end point. We multiply the inner product of the two vectors by the reward and assign it as the reward. As shown in Figure 9, the two vectors are crane hook to target direction vector and crane hook speed vector. If the angle between these two vectors is small (i.e., the inner product is close to 1), the reward is close to 1×reward.

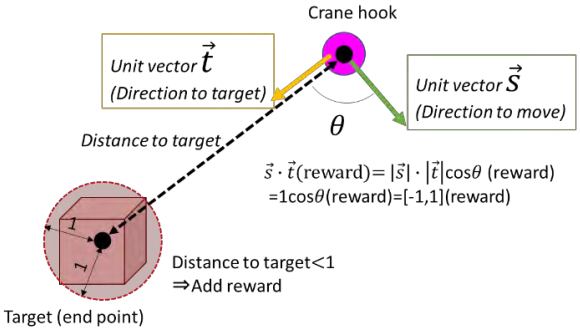

Figure 9. Simplification of rewards

3.4 Method of Verification

3.4.1 Verification of the Optimal Solution

This section presents a method investigate the accuracy of the optimal solution of the trained model.

We verify the accuracy of the optimization of the movement between two points by comparing "the length of the trajectory of the crane hook" and "the length of the shortest path between the two points."

To obtain the length of the crane hook trajectory and the shortest path between the two points, we record the coordinates of the crane hook and the start point for each frame, as listed in Table 1, and track the length and the shortest distance between the two points.

Furthermore, to visualize the crane hook's trajectory, we draw the trajectory of the crane hook, as shown in Figure 10.

3.4.2 Verification of the Generality of the Trained Model

This section presents methods to investigate the generality when altering the environment in which the trained model is adapted.

As discussed in Section 2.2, the models trained by deep RL can perform in situations different from the learning environment. However, its adaptability is unknown. Therefore, we make the following changes to the simulation environment during inference.

- Placement: Change the positional relationship between the crane and the end point. We set the end points inside and outside the "installation range of the end point during training." As shown in Figure 11, we examine the inference results while installing the end points in sequence on the horizontal plane. We do not change the position of the crane and the position of the start point.
- Type: We use a default crane for training and a large crane with a different boom length and vertical height (Figure 12).

From the inference results, we examine the generality of the inference model and propose a method to create a learning environment to improve generality.

4 Results and Discussion

4.1 Verification of the Accuracy of the Trained Model

In this section, we present the results of the accuracy verification of movement between two points using deep RL and propose a method for creating an environment to improve the accuracy of this movement.

Based on the coordinates of the start and end points, trajectory length, and the visualization of the crane hook trajectory, the following were observed.

- The movement path was 3.6 times the shortest path
- The trajectory length was almost constant, regardless of the change in the distance between the two points.
- Vertical movement was rapid, whereas horizontal movement was slow.

Figure 13 shows the transition of the locus length for each frame, i.e., the locus of movement between the two points for six iterations, with different lengths between the two points. In addition, as shown in Figures 13 and 14, the length of the trajectory is constant regardless of the distance between the two points. Figure 14 compares the shortest distance between the two points and the actual trajectory length. The length of the trajectory is approximately 3.6 times longer.

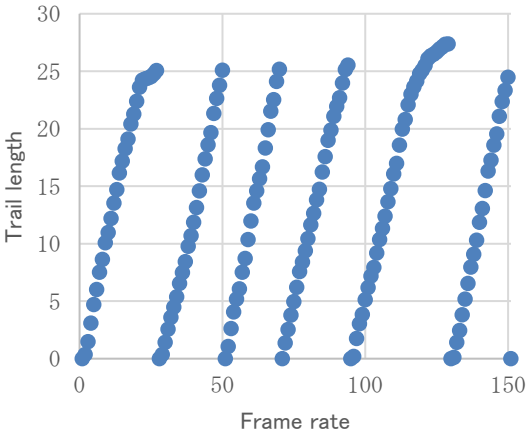

Figure 13. Change in the crane hook trail length for each frame

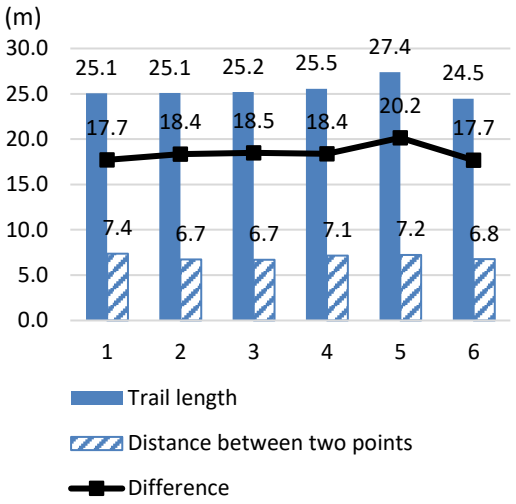

Figure 14. Comparison of shortest path length and crane hook movement path length

As shown in Figure 15, the crane hooks initially moves in the vertical direction and then in the x and z horizontal directions. This occurs because although the position of the end point is rearranged in the horizontal direction during training, it does not move in the vertical direction. Therefore, it is essential to lower the crane hook, and a reward can be obtained based on the movement toward the target direction. Therefore, when the end point is set on the plane, as shown in Figure 16 (a), the agent learns to move the crane hook and then move in the horizontal direction.

To prevent the agent from moving excessively by prioritizing the movement of the lowering of the crane hook, we propose to create an environment, as shown in Figure 16 (b). We randomly set the installation position of the end point in the vertical direction such that the crane hook lifts in the vertical direction above the start point.

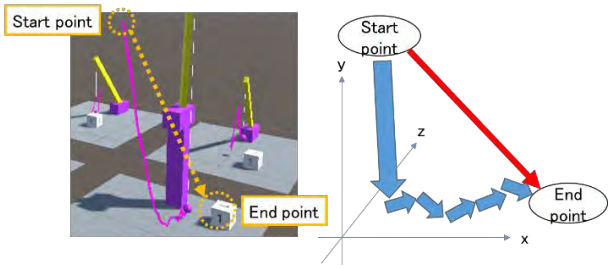

Figure 15. Trail of movement between the two points of the crane hook

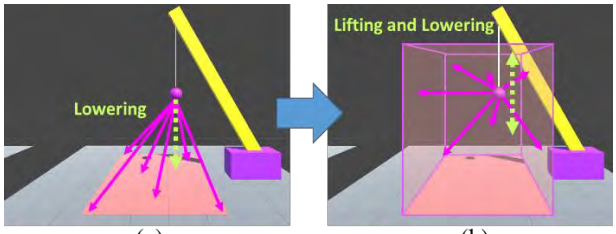

(a) (b)

Figure 16. Environment that causes wasted movement of lowering the crane hook (a); environment for preventing wasted movement (b)

4.2 Verification of the Generality of the Trained Model

In this section, we describe the inference results that were examined based on the method discussed in Section 3.4.2 and propose a method to create an environment that improves the generality from inference results.

For the simulation environment, in inference, we set the end points inside and outside the "installation range of the end point during training" and let the agent infer. Consequently, as shown in Figure 17, the inference result is classified into three cases: reaching the end point, reaching the end point and performing unnecessary movements, and not reaching the end point. Figures 18 (a) and 19 (a) show the inference results corresponding to the location of the end point. Figures 18 (b) and 19 (b) depict the list of images of each inference result with the end-point position changed. Figure 18 shows the inference results using the default size crane. The inference result of installing the end point on the front of the crane includes the result that the boom is not sufficiently long. Figure 19 illustrates the inference result from the movement between two points using the larger crane with different boom lengths and crane heights.

These results show that changing the crane size does not affect the agent performance. When the size of the crane is changed, the positional relationship with the end point changes vertically. However, we confirmed that the agent can perform the movement between two points even if the positional relationship between the crane and the end point is changed. In addition, the range of movement between two points is expanded according to the size of the crane.

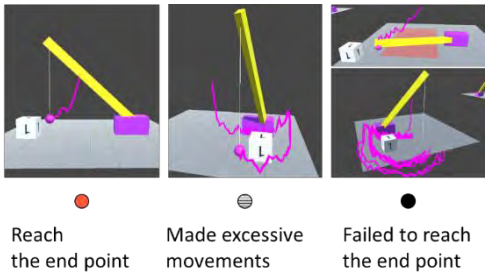

Figure 17. Three types of inference results

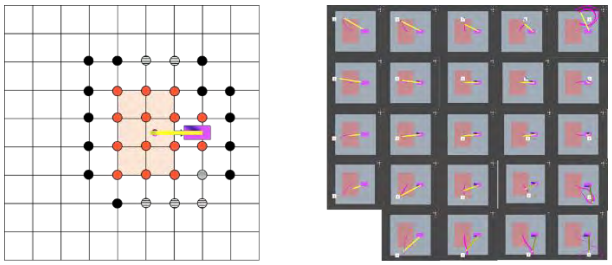
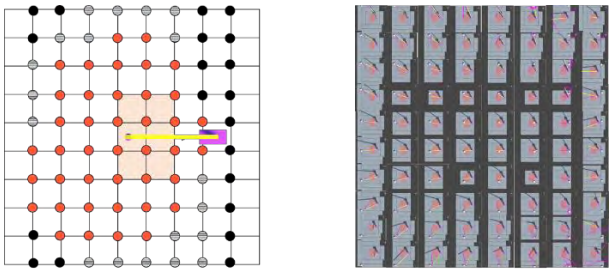


(a) (b)

Figure 18. Result of reaching the end point by the default size crane (a); simulation of movement between two points with the end point placed at each point (b)



(a) (b)

Figure 19. Result of reaching the end point by the big size crane (a); simulation of movement between two points with the end point placed at each point (b)

Based on Figures 18 (a) and 19 (a), we hypothesized that the range of end-point positions where the agent can perform a movement between two points is proportional to the size of the crane. Therefore, we expanded the mapping of the default size crane (Figure 18 (a)) and verified the similarity of the range of movement between two points by superimposing it on the mapping of the big crane (Figure 19 (a)), as shown in Figure 20 (a). Consequently, the range of movement between the two points was the same.

Furthermore, as shown in Figure 20 (b), the agent did not perform the movement between two points when the slewing angle of the crane increased. The slewing

angle remains within the range to reach the installation position of the end point during learning. This is probably because the slewing angle of the crane is narrow with respect to the installation range at the end point during training. Therefore, to obtain a trained model that moves in a wide range in the horizontal direction, we propose setting the end-point position such that the slewing angle becomes large, as shown in Figure 21. Additionally, when training with a small crane in a small range during training, the process can be adapted to a large crane by inference.

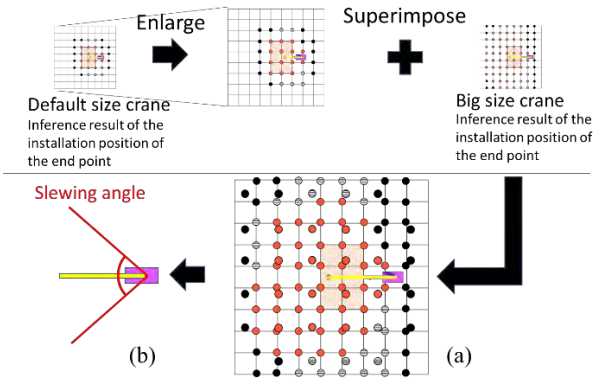


Figure 20. Similarity of the two ranges (a); limit of slewing angle for trained model (b)

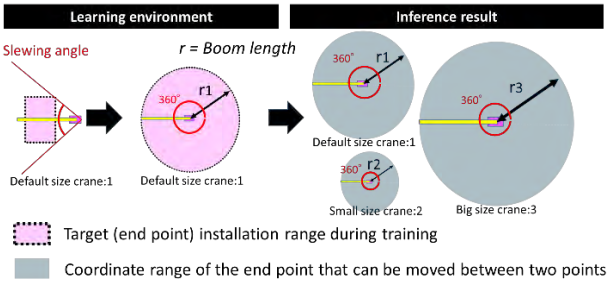

Figure 21. Environment that improves model slewing

5 Conclusion

In this study, we evaluated the accuracy of the trained model and the generality of an environment using a trained model that learned the route creation for a crane hook in a lifting task using deep RL.

We observed the following.

- The trained model's movement between two points did not traverse the shortest path. Although, it was not the optimum solution, it was inferred that the accuracy of movement between two points can be improved by creating an environment in which the crane hook is vertically lifted and lowered.
- Changing the crane size does not affect the model performance.
- The agent did not perform the movement between two points when the turning angle of the crane increased. To obtain a trained model that traverses a wide range in the horizontal direction, it is necessary to position the end points for large slewing angles.

Therefore, we conclude that the method for improving the accuracy and generality of the model for moving the crane hook between two points involves the creation of an environment that moves the crane hook vertically and horizontally (Figure 22).

Abstract –

Hydraulic excavators are used for various purposes, such as excavation, dismantling, and leveling. The accurate positioning of the excavator is particularly important in loading operations, such as positioning a bucket immediately above a target. The positioning of a bucket via the swinging operation can also be regarded as a kind of pointing operation. There are the dynamic characteristics of hydraulic excavators. However, a pointing motion model that considers dynamic characteristics, such as delay, has not been proposed. In this study, the swinging operation of a hydraulic excavator was simulated and experiments were performed to clarify the relation between the dynamic characteristics of hydraulic excavators and their work efficiency. The dynamic characteristics of the swinging operation of the hydraulic excavator were assumed as a first-order system with dead time. Based on this result, a new difficulty model considering dead time and the time constant was proposed, and it was compared with the original Fitts' model based on the coefficient of determination. It was confirmed that the proposed model represented difficulty more accurately compared to the original Fitts' model.

Hydraulic excavator; Pointing; User Interface

1 Introduction

Hydraulic excavators (Figure 1), which are a type of construction machinery, are used for various purposes, such as excavation, dismantling, and leveling, because of many degrees of mechanical freedom and a variety of attachments. In recent years, teleoperated hydraulic excavators have been used at multiple disaster sites. These excavators are highly versatile. However, there are design problems based on ergonomics, such as the lack of feedback information and low visibility, and these problems reduce the work efficiency of excavators [1].

The operation of a hydraulic excavator in general civil engineering works is broadly divided into three operations, i.e., swinging, running, and excavation. Operators control hydraulic excavators using joysticks that are located close to their hands. When the swinging operation is carried out, according to the International Organization for Standardization, the swinging direction and swinging speed of a hydraulic excavator are determined by moving the left lever to the right or left. The accurate positioning of the excavator is particularly important in loading operations, such as positioning a bucket immediately above a target. Conventionally, the pointing operation involves pointing and selecting a target using a mouse or touchpad on a graphical user interface. However, the positioning of a bucket via the swinging operation can also be regarded as a kind of pointing operation. Hayashi and Tamura [2] experimentally investigated the pointing operation using a bucket to verify the effectiveness of the vibration of a joystick in a teleoperated hydraulic excavator system.

In our previous study [3], we developed a difficulty model that extends Fitts' law for the relationship between the range of view and work efficiency. The field of view affects the work efficiency of a hydraulic excavator when it performs the swinging operation. There is a boom on the right side of the driver's seat of the hydraulic excavator, and the field of view on the right side is narrower than that on the left side. Particularly in the case

Figure 1. Hydraulic excavator components

of teleoperation, the field of view is limited by the display range of the monitor. In addition, the dynamic characteristics of hydraulic excavators, such as dead time and inertia, cannot be neglected. The purpose of this study was to investigate the relationship between the dynamic characteristics and work efficiency of a hydraulic excavator. However, as it is difficult to change the dynamic characteristics of an actual hydraulic excavator, the swinging operation of a hydraulic excavator was simulated and experiments were performed. The dynamic characteristics of the swinging operation were assumed as a first-order system with dead time, and the time until turning to the target angle was measured for different dead times and time constants. Additionally, a difficulty model for estimating task time was proposed. By using this model, we can evaluate and increase the rotate work efficiency of the excavator.

2 Previous Studies on Pointing Motion Models

Numerous studies have attempted to model the difficulty of pointing motion. One of the existing models is Fitts' law, which models the relationship between the index of difficulty, ID, and the pointing time, MT, of a pointing task. According to Fitts' law, MT increases as the distance from the starting position to a target increases and the target size decreases. MacKenzie [4] improved Fitts' model and expressed the ID as follows:

$$ID = \log_2\left(\frac{D}{W} + 1\right) \quad (1)$$

where D is the pointing distance and W is the pointing size. MT tends to increase linearly with ID. This relationship can be expressed using experimentally obtained constants a and b, as follows:

$$MT = a + bID \quad (2)$$

Fitts' law was originally proposed as a simple motor response model with one dimension. MacKenzie [5] extended this model to consider two-dimensional pointing operations. Subsequently, Murata and Hirose [6] extended it to consider three-dimensional pointing operations. Various studies have extended Fitts' law to consider factors other than distance and size. Jax et al. [7] proposed the following equation to predict pointing time when pointing motion was performed on a curved line, OI, assuming that an obstacle existed:

$$MT = a + bID + cOI \quad (3)$$

where a, b, and c are experimentally obtained constants. Accot and Zhai [8] proposed an index of difficulty for the steering operation required by a vehicle passing an elongated path, such that the vehicle does not extend beyond the path's width.

Figure 2. Swinging operation simulator

$$ID = \frac{D}{W} \quad (4)$$

MacKenzie and Buxton [9] proposed the following equation for extending Fitts' law to two dimensions. The equation incorporated the target width W and the target height H.

$$ID = \log_2\left(\frac{D}{\min(W,H)} + 1\right) \quad (5)$$

Bi et al. [10] conducted a pointing test using a smartphone-sized display and proposed a more accurate difficulty model for small displays. It is possible to evaluate the operability of pointing devices and environments using appropriately designed pointing difficulty models.

In our previous study [3], we attempted to model pointing motion considering the effect of the field of view. We created a simulation environment for swinging pointing operations and examined the relationship between the range of the field of view and pointing difficulty. Based on the results, the following equation, which incorporated the size, V, of the field of view, was proposed:

$$ID = \log_2\left(\frac{D}{W} \cdot \frac{D}{V} + 1\right) \quad (6)$$

To the best of our knowledge, a pointing motion model that considers dynamic characteristics, such as delay, has not been proposed. In this study, the swinging pointing operation with delay was simulated and the relationship between the delay parameter and pointing difficulty was investigated.

3 Approximation of Dynamic Characteristics of Hydraulic Excavator

A hydraulic excavator is operated using joysticks, and the angular velocity of the operated object changes according to the angle of the joysticks. The input from

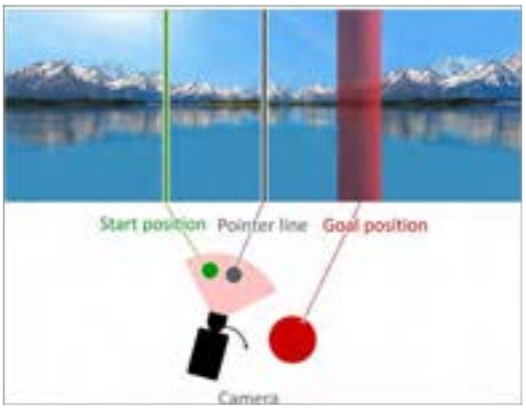

Figure 3. Display image of Simulator

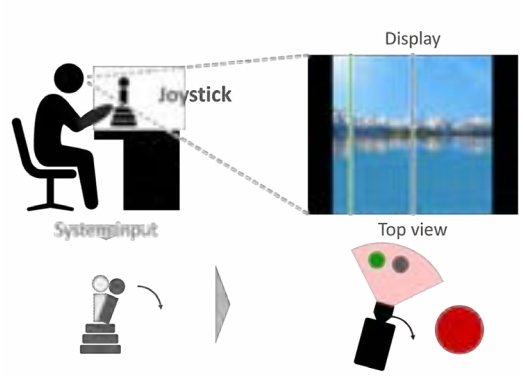

Figure 4. Task of simulation experiment

the joysticks causes attachments to move and swing through a hydraulic circuit and a hydraulic cylinder. Therefore, there is response delay. In this study, the dynamic characteristics, $G(s)$, of the swinging operation of the hydraulic excavator were assumed as a first-order system with dead time, as follows:

$$G(s) = \frac{K}{1+Ts} e^{-Ls} \quad (7)$$

where K is system gain, T is the time constant, and L is dead time. Dead time is the time elapsed from application of the input to the observation of the output, and the time constant is the constant about the rise time. We constructed a difficulty model that incorporated these parameters.

4 Experiments Using Swinging Pointing Simulator

4.1 Simulator Configuration

We created a system to simulate the swinging operation of hydraulic excavators to clarify the effect of dynamic characteristics. The system is shown in Figure

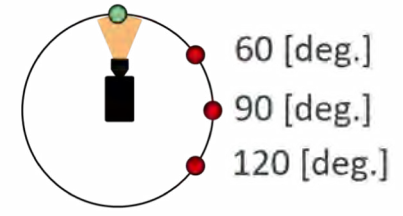

Figure 5. Target position

Table 1. Parameters of transfer function in simulation experiment

	Dead time (s)		Time constant (s)	
Condition	L_{acc}	L_{dec}	T_{acc}	T_{dec}
1	0	0	0	0
2	0.16	0.08	0.6	0.35
3	0.16	0.08	1.2	0.69
4	0.32	0.16	0.6	0.35
5	0.32	0.16	1.2	0.69
6	0.32	0.16	2.4	1.40
7	0.64	0.32	1.2	0.69
8	0.64	0.32	2.40	1.40

2; it consisted of a personal computer, a monitor, and an input joystick. The experimental system was created using Unity, which is a three-dimensional game engine. The start point, pointer line, and target area were displayed on the monitor, as shown in Figure 3. When the joystick was tilted, the camera in the Unity environment rotated according to the tilt direction and the angle of the joystick.

4.2 Experimental Protocol and Conditions

Experiments were performed with four participants (Sub. A to D). We recruited the participants from the students at Hiroshima University. Informed consent based on the Declaration of Helsinki was obtained from all participants prior to the experiments. The participants performed a swinging pointing task by viewing the image projected by the camera in the Unity environment (Figure 4). First, the camera pointed to the start point, which is indicated by the green line. The camera turned according to the operation of the joystick by the participants. The pointer line, which is indicated by the black line, existed at the center of the camera. The task was finished when the pointer was stopped in the target area, which is indicated in red. Prior to the task, the participants were informed that the target area exists in the right direction and that they must finish the task as quickly as possible. When one task was completed, it was displayed on the monitor that the task has been completed, and the next task was started after 1 (s).

The distance to the target, D, was defined as 60° ,

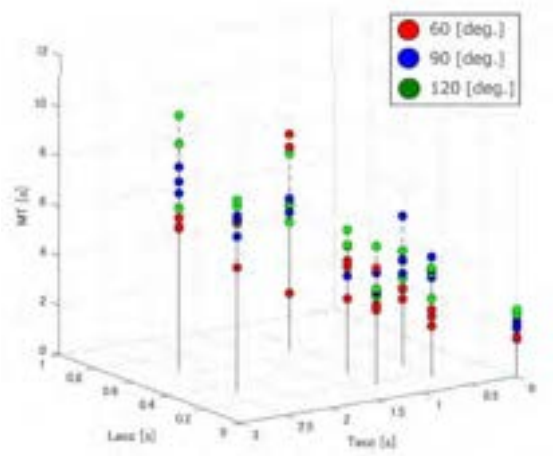

Figure 6. Experiment result (Sub. A)

90° , and 120° (Figure 5). The values of the time constant, T, and dead time L are shown in Table 1. In the swinging of the hydraulic excavator, these parameters are different for acceleration and deceleration. The time constant and dead time were T_{acc} and L_{acc} for acceleration and T_{dec} and L_{dec} for deceleration, respectively. The target size, W, was 0.5 (m) and the range of the field of view was constant.

There were 24 experimental conditions, which were obtained based on the combination of three conditions of the distance to the target, D, and eight conditions of the dynamic characteristics. The order of the conditions was random for each participant. Each participant performed the task three times under each condition, and pointing time was measured. Participants practiced three times when conditions changed. The average pointing time calculated using the three measurements was considered as the pointing time under a particular condition.

4.3 Results

The experimental results for Sub. A are shown in Figure 6. This figure shows the pointing time, MT (s), under the target distance conditions of 60° , 90° , and 120° for the dead time, L_{acc} (s), and time constant, T_{acc} (s). It can be seen that the pointing time tends to increase as the distance to the target, D, increases, as in the original Fitts' law. Furthermore, it was confirmed that the pointing time increased with the time constant and dead time.

5 Modeling of Swinging Pointing Operations

5.1 Proposed Model

A new difficulty model is proposed based on the above results. The difficulty model incorporates dead time and the time constant for Fitts' model considering that pointing time increases with dead time and the time constant and difficulty increases with pointing time. The equation for the model is as follows:

$$ID^{\mathrm{new}} = \log_2\left\{\frac{D}{W}(L_{\mathrm{acc}} + L_{\mathrm{dec}} + T_{\mathrm{acc}} + T_{\mathrm{dec}}) + 1\right\} \quad (8)$$

In this work, the coefficient of determination is used as an evaluation index, and the proposed model is compared with the original Fitts' model.

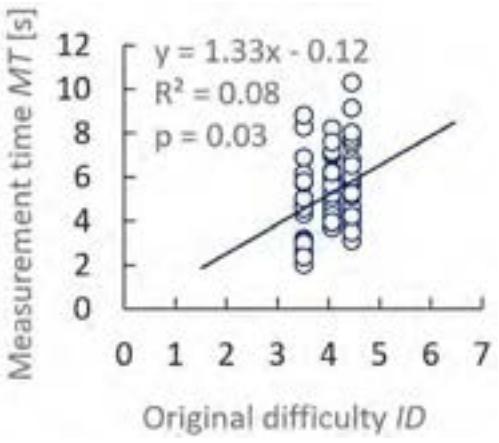

Figure 7. Correlation between index of difficulty ID and pointing time MT for original model

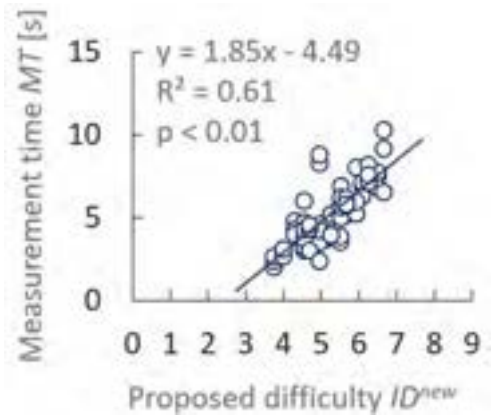

Figure 8. Correlation between index of difficulty ID^{new} and pointing time MT for proposed model

5.2 Evaluation of Proposed Model

Figures 7 and 8 show the relationship between the index of difficulty (horizontal axis) and pointing time (vertical axis) for Sub. A. The regression line and the coefficient of determination are shown. Figures 7 and 8 show are for the original and proposed models, respectively. The coefficient of determination for the

Table 2. Coefficient of determination (all subjects)

	Sub.A	Sub.B	Sub.C	Sub.D	Mean
for ID	0.076	0.078	0.073	0.063	0.073
for ID^{new}	0.61	0.45	0.34	0.35	0.44

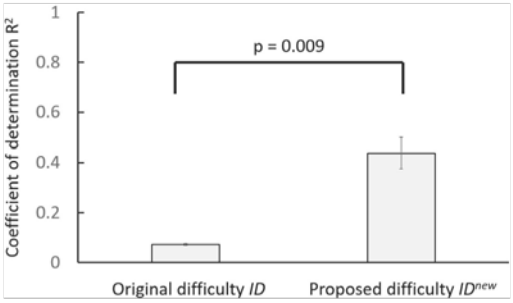

Figure 9. Comparison of coefficient of determination between original and proposed models

proposed model is R^2=0.61, which is higher than the coefficient of determination for the original model (R^2=0.08). Table 2 and Figure 9 show the coefficients of determination for all subjects and their mean values. The coefficient of determination for the proposed model is higher than that for the original model for all subjects. In addition, the average values of the coefficient of determination for the original and proposed models are compared using Student's t-test, and a statistically significant difference is observed (p=0.009).

6 Discussion and Conclusions

In this study, the swinging operation of a hydraulic excavator was simulated and experiments were performed to clarify the relation between the dynamic characteristics of hydraulic excavators and their work efficiency. The dynamic characteristics of the swinging operation were approximated as a first-order system with dead time, and the time until swinging to the target area was measured for different dead times and time constants. It was confirmed that pointing time increased with dead time and the time constant. Based on this result, a new difficulty model considering dead time and the time constant was proposed, and it was compared with the original Fitts' model based on the coefficient of determination. It was confirmed that the proposed model represented difficulty more accurately compared to the original Fitts' model. The original Fitts' model may not be applicable to the swinging operation of a hydraulic excavator because it does not consider response delay. The proposed model can be used to evaluate the performance of hydraulic excavators, and it is expected to improve their work efficiency. However, the size of the field of view is not considered in this study. It is necessary to develop and evaluate a model that considers the size of the field of view. In addition, the suitability of the proposed model must be confirmed in actual environments where hydraulic excavators are used.

Mechatronic Control System for Leveling of Bulldozer Blade

Alexey Bulgakov[a], Thomas Bock[b], Georgii Tokmakov[a]

[a]South-Russian State Polytechnic University (NPI), Russian Federation
[b]Technical University of Munich, Germany
E-mail: agi.bulgakov@mail.ru, thomas.bock@br@br2.arch.tum, tokmakov.tun@gmail.com

Abstract – Recently, it began the spread of bulldozers using information technology during controlling the machine to increase the efficiency of the entire execution of work, including avoiding the usually necessary final surface treatment. Blade control mechatronic system for leveling work of bulldozer blade enables the bulldozer to effectively perform a ground leveling work or a grading work with high accuracy in a minimum amount of time. The system compensates for pitching of a tractor portion of the bulldozer, and for variations in the amount of earth to be moved by a blade of the bulldozer.

The biggest feature of this mechatronic system is automation of digging and soil carrying work by optimally controlling a load applied to the work equipment even if there is digging depth to some extent up to the finishing surface, while the work application range of conventional bulldozers was limited mainly to finishing leveling work under light load. Seamless automatic execution without concern for damage to a finishing surface has been enabled by automatically switching from digging control to leveling control as the work progresses and approaches the finishing surface.

This will reduce operator fatigue during operation, and will also allow even an inexperienced operator to perform work equivalent to the work of a qualified operator.

1 Introduction

Industries such as mining and construction in which earthmoving plays a fundamental role are constantly under pressure to improve productivity (amount of work done), efficiency (cost of work done in terms of labor and machinery), and, safety (injury sustained by workers). Mechatronics and robotics offers the possibility of contributing to each metric but has been slow in being accepted. Until recently, it has been possible to make gains using traditional means— over the last four decades earthmovers have become progressively larger and their mechanisms more efficient. Also, automation of fieldworthy earthmovers is a difficult problem.

These machines must operate in unstructured, dynamic, outdoor environments, often in poor visibility conditions and inclement weather. However, after decades of increases in size and power, practical limits have been reached and now automation is being sought for further improvements. At about the same time, several enabling technologies relevant to earthmovers, particularly in the area of environmental perception, are becoming reliable and affordable. Computing technology has also reached the stage where fast, compact and rugged components can match the bandwidth of sensory data.

The cycle of operation for a mechatronics machine is: sense, plan, and execute. First, a machine must sense its own state and the world around it. Next it must use this information along with a description of a goal to be achieved to plan the next action to be taken. In some cases the mapping from sensing to action is direct, and, can take the form of a pre-determined control law. In other cases, deliberation, or the use of models (sensors, mechanisms, and, actions) is necessary. Finally, the action must be executed via the mechanism. Since, relatively few systems are fully autonomous, depending on human input or control to achieve some of their function, this article examines various aspects of the enabling technologies used by partially automated systems [1].

The cycle of operation for a fully autonomous machine is: sense, plan, and execute. First, an automated machine must sense its own state and the world around it. Next it must use this information along with a description of a goal to be achieved to plan the next action to be taken. In some cases the mapping from sensing to action is direct, and, can take the form of a pre-determined control law. In other cases, deliberation, or the use of models (sensors, mechanisms, and, actions) is necessary. Finally, the action must be executed via the mechanism [2].

Bulldozers equipped with modern navigation and information systems are mobile mechatronic objects, and they can be integrated into general process of intellectual construction [3]. The integration will provide optimal efficiency of the construction cycle and will ensure lean

production process [4,5].

Application of regulators based on classical control theory is difficult due to the frequent changes in workflow conditions. Thus, it is necessary to develop adapted control systems to eliminate the difficulties described. The system includes both the bulldozer's dynamics modeling and bulldozer's workflow control method to take into consideration the complex non-linear dependencies between workflow parameters and incomplete information on its working conditions changes.

Having reviewed adaptive and intellectual control methods [6, 7], we propose to create an adaptive control system for technological processes to increase efficiency of bulldozer's control in comparison with traditional control methods.

2 Bulldozer - mathematical description as mobile mechatronic object

When researching a dozer's working process usually a number of design schemes are considered – straight line, thread milling, wedge and exponential cutting. Meanwhile, a dozer moves along the surface that is formed by its blade. Therefore, when driving onto any surface roughness resulting from the dozer blade control or the change in its position due to any reason, causes position changes of the machine frame and along with the cutting edge that is any face deviation from a straight line in some extent is copied by the dozer.

Observations [8] show that quite often while designing a face its roughness is progressing, reaching a size at which the control over the workflow is lost. In this case, the operator has to align the face deliberately, trying to ensure its "tranquil" profile that allows doing excavation works smoothly, without frequent control system switching and reducing the dozer's operating speed that causes a slowdown and shows inferiorities of the blade control system. Obviously, if the control system operates in the antiphase towards deviations of the tractor frame with sufficient accuracy, the initial face roughness will not evolve and will be gradually cut. One of the most likely causes of the opposite phenomenon observed in practice, is the disparity between the velocity of the dozer V_p and actual conveying speed of the working body V_{ot} required in certain areas S_i of the digging operating cycle, where *i* – is the number of the speed change V_{ot}. Speed ratio depends on the dozer's geometrical dimensions (Figure 1) and its control system.

Mathematical model of the dozer's movement on a straight line tracking (frame alignment) is built using the Lagrange equations of the 2nd kind, under the assumption that the contribution to the dynamics of the drive gears and a track is small, compared with the contribution of the remaining parts of the dozer.

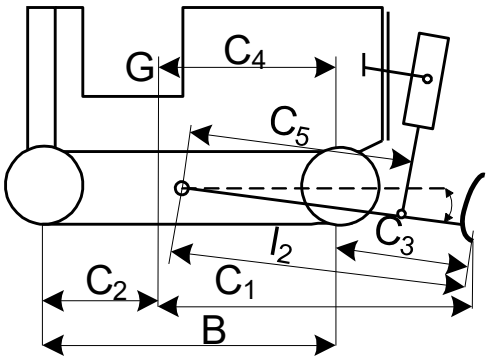

Figure 1. Dozer's geometrical dimensions

$$\begin{cases} \frac{d}{dt}\left(\frac{\partial T}{\partial \dot{x}}\right) - \frac{\partial T}{\partial x} = Q_x, \\ \frac{d}{dt}\left(\frac{\partial T}{\partial \dot{\varphi}}\right) - \frac{\partial T}{\partial \varphi} = Q_\varphi. \end{cases} \quad (1)$$

where kinetic energy:

$$T = \frac{1}{2}m_1\dot{x}^2 + \frac{1}{2}m_2\left(\dot{x}^2 + (l_2 l_{c2}\dot{\varphi})^2 + 2\dot{x}l_2 l_{c2}\dot{\varphi}\sin(\varphi)\right) + \frac{1}{2}J_{c2}\dot{\varphi}^2 + \frac{1}{2}\sigma hx\left(\dot{x}^2 + (l_2\dot{\varphi})^2 + 2\dot{x}l_2\dot{\varphi}\sin(\varphi)\right) + \frac{1}{2}\sigma hx i_{rz}^2\dot{\varphi}^2, \quad (2)$$

generalized forces acting on a dozer:

$$Q_x = -\sigma hgl_2\sin\varphi + F_т - F_s, \quad Q_\varphi = -(m_2 l_{c2} + \sigma xh)gl_2\cos\varphi + M. \quad (3)$$

m_1 – tractor mass; m_2 – blade frame mass; σ – soil surface density; $F_т$ machine pulling power; F_s ground cutting resistance; h – depth of the soil cutting; l_{c2} – center of the blade mass; i_{rz} - gyration radius of the dumping soil.

$$m_1\ddot{x} + m_2\ddot{x} + m_2 l_2 l_{c2}\ddot{\varphi}\sin\varphi + m_2 l_2\, l_{c2}\dot{\varphi}^2\cos\varphi + \sigma h\dot{x}^2 + \sigma hx\ddot{x} + \sigma h\dot{x}l_2\dot{\varphi}\sin\varphi + \sigma hxl_2\ddot{\varphi}\sin\varphi + \sigma hxl_2\dot{\varphi}^2\cos\varphi - \frac{1}{2}\sigma h\dot{x}^2 - \frac{1}{2}\sigma hi_{rz}^2\dot{\varphi}^2 - \frac{1}{2}\sigma h(\dot{x}^2 + l_2^2\dot{\varphi}^2 + 2\dot{x}l_2\dot{\varphi}\sin\varphi) = -\sigma hgl_2\sin\varphi + F_т - F_{сопр}. \quad (4)$$

$$m_2 l_2^2 l_{c2}^2\ddot{\varphi} + m_2\ddot{x}l_2 l_{c2}\sin\varphi + m_2\dot{x}l_2 l_{c2}\cos\varphi\dot{\varphi} + J_{c2}\ddot{\varphi} + \sigma h\dot{x}l_2^2\dot{\varphi} + \sigma hxl_2^2\ddot{\varphi} + \sigma h\dot{x}l_2\sin\varphi + \sigma hxl_2\cos\varphi\dot{\varphi} + \sigma h\dot{x}i_{rz}^2\dot{\varphi} + \sigma hxi_{rz}^2\ddot{\varphi} - m_2\dot{x}l_2 l_{c2}\dot{\varphi}\cos\varphi - \sigma hx\dot{x}l_2\dot{\varphi}\cos\varphi = -(m_2 l_{c2} + \sigma xh)gl_2\cos\varphi - (m_2 l_{c2} + \sigma xh)gl_2\cos\varphi + M. \quad (5)$$

The system (1) solution allows getting the differential equations (4) and (5) that describe the dozer's movement on a straight line track, and determining control actions through the parameters of the machine in areas S_i of the digging operating cycle as the coefficients a_i in the dependence $V_{ot} = a_i V_p$. Such a dependence is typical for dozers with a single-motor drive with a hard pump hydraulic drive connection to the motor shaft.

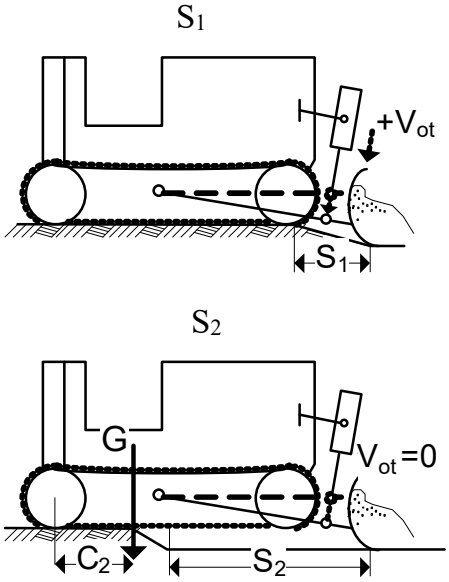

Figure 2. The movement of the tractor frame the beginning of digging.

At the beginning of digging (Figure 2), the frame of the tractor makes a strictly forward movement over a distance of S_1+S_2 without hesitation relatively its mass center. The blade cutting edge in the area S_1 dives into the soil to a depth equal to a predetermined cutting thickness h. Thus, the control action a_1 may be determined by the formula:

$$a_1 = \frac{30 i_{tr} m l_2}{\pi r_k F_z i_{pr} C_5 n}, \quad (6)$$

where i_{tr}, i_{pr} - tractor transmission and hydraulic pump ratios; n - number of hydraulic cylinders; m - fluid mass in the hydraulic cylinders;

In the area S_2 the movement is made with $a_2=0$ until the mass center of the tractor won't move to the buttonhole edge.

On further movement the dozer "dives" in the drawn buttonhole (Figure 3), so in the area S_3 it is necessary to lift the blade at a rate of V_{ot}, determined by the coefficient a_3:

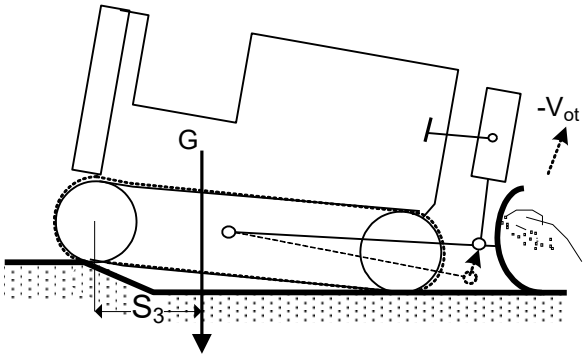

Figure 3. The movement the dozer "dives" in the drawn buttonhole

$$a_3 = \operatorname{tg}\beta \left[e^{\frac{a V_п t}{C_1 + V_п t}} \left(1 + \frac{a C_1}{C_1 + V_п t}\right) - 1 \right]. \quad (7)$$

The area S_3 ends after the dozer's back gear hits the edge of the face and reverse alignment of tractor frame starts. Length of the alignment area is $S_4 \approx S_1$. Obviously, during this period it is necessary to start dropping the blade. The a_4 determines the rate of dropping the blade in the given area:

$$a_4 = \frac{C_3 S_1}{(C_4 + S_3 + V_п t)^2}. \quad (8)$$

To implement control actions $a_i = f(S_i, t, h)$ the dozer must be equipped with a vertical blade control system.

3 Adaptive control principles for a mechatronic bulldozer blade control system

The article proposes the bulldozer workflow neural network model adaptive learning algorithm based on the recurrent least square method (exponential forgetfulness method) and on the algorithm of Forward Perturbation or dynamic back propagation.

The autoregressive model structure with external inputs (Figure 4) is a dynamic two-layer recurrent neural network. It is found from the autocorrelation signal functions that the autocorrelation coefficient is greater than 0.8 in the time interval 0.1 sec. for speed $\vartheta(t)$ of 0.5 sec. for digging depth $h(t)$ and 0.2 sec for the resistance force $P(t)$. Length of delay lines TDL taking into account the sampling frequency of 10 Hz are up to 1, 5 and 2 accordingly (Figure 4).

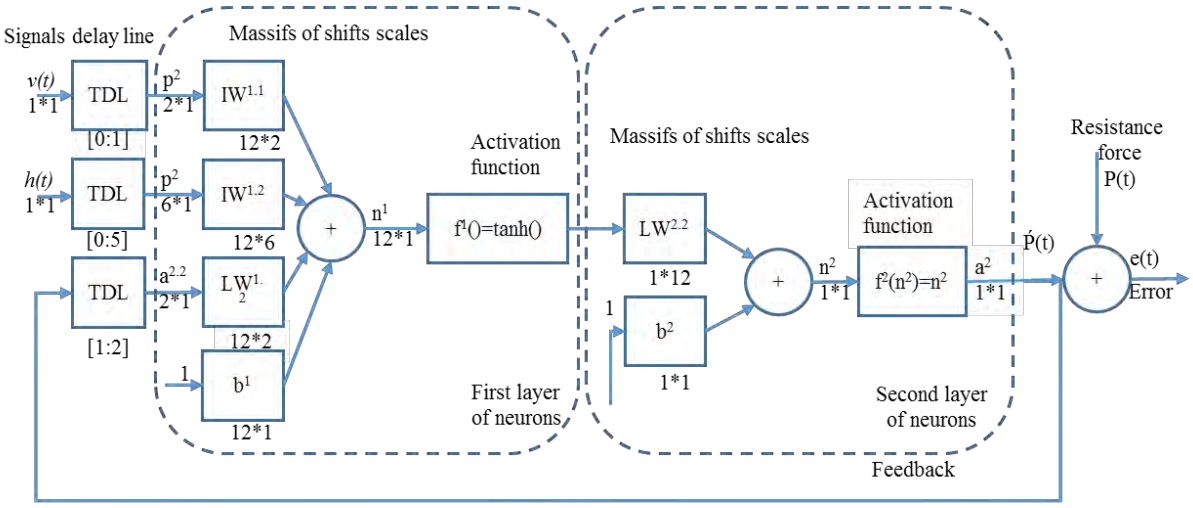

Figure 4. Autoregressive model structure

In the process of learning the neural network accumulates information on workflow dynamics, new tendencies of process development prevail on the earlier ones at that.

It is a method of random search with elements of adaptation, which is based on principles similar to the Darwin's evolution process of biological organisms. In this case, three types of operations are performed: crossing, mutation, selection. The fitness degree (how the population corresponds to the given task) is defined through the fitness function that can also include penalty functions for violation of additional restrictions on variable variables. There are various forms of crossing [8]. They make a selection of the fittest specimen, which constitute a parental pair and the crisscrossing of the chromosomal chains takes place, i.e. the descendant line code inherits fragments of codes of parental chromosomes. The mutation operator produces a local change in the line code of chromosomes with a given probability, which is one of the configurable parameters of the genetic algorithm [9, 10].

The selection operator allows creating a new population from a set of specimen, generated and modified descendants of specimen after mutation. The genetic algorithm is used to adjust the membership functions that are defined within the accuracy of a few changeable parameters, such as triangular, trapezoidal, radial functions. When simultaneously configuring several membership functions, the parameters of each of them are coded by their own segment of the chromosome, so that during the process of crossing the code sharing occurs only between chromosome segments of the same type. To configure a rule base to a specific chromosome fragment, some variant of the rule base is corresponded and in accordance with the accepted coding the choice of the genetic operators' type is performed.

Conclusions and Results

Adaptive neural network model of digging allows you to simulate and predict the dependence of the resistance strain of gauge bogie displacement depending on the dig depth and trolley speed in dynamics. The accuracy of the prediction $P(t)$ being estimated, the average relative error after learning the network is 4.5 %[11-13].

A neural network model of bulldozer workflow has been developed, allowing modeling the dependence of pulling power from the blade penetration.

Input model signal, used for training, simulation and verification is presented in Figure 5a. Adaptive learning for the model is stopped at time t = 9,5 sec. Receiving at this moment a neural network model parameter values, modeled digging resistance force and speed of the machine (Figure 5b, 5d) are accomplished, as well as the forecast for another 0.5 seconds is developed.

Figure 5c shows the output of neural network models-pulling power of the bulldozer. In modeling and prediction of the neural network output is close to the experimental data only in the time interval of 7-10 sec. This is due to a change in unmeasurable chip thickness, as well as the rapidly changing conditions of the mover clutch with the ground. Therefore, the parameters of the adaptive neural network model must be adjusted in real time. The accuracy of prediction of pulling power $N(t)$ has been estimated; the average relative error being 14.7 % on an interval from 7 to 10 s [14]. Identification Technique of bulldozer workflows and models obtained on its basis, are designed for use in the development of adaptive systems of automatic workflow management of bulldozer [15-16].

The development methodology of the adaptive control systems of bulldozer workflows is based on the application of neural network technology [17].

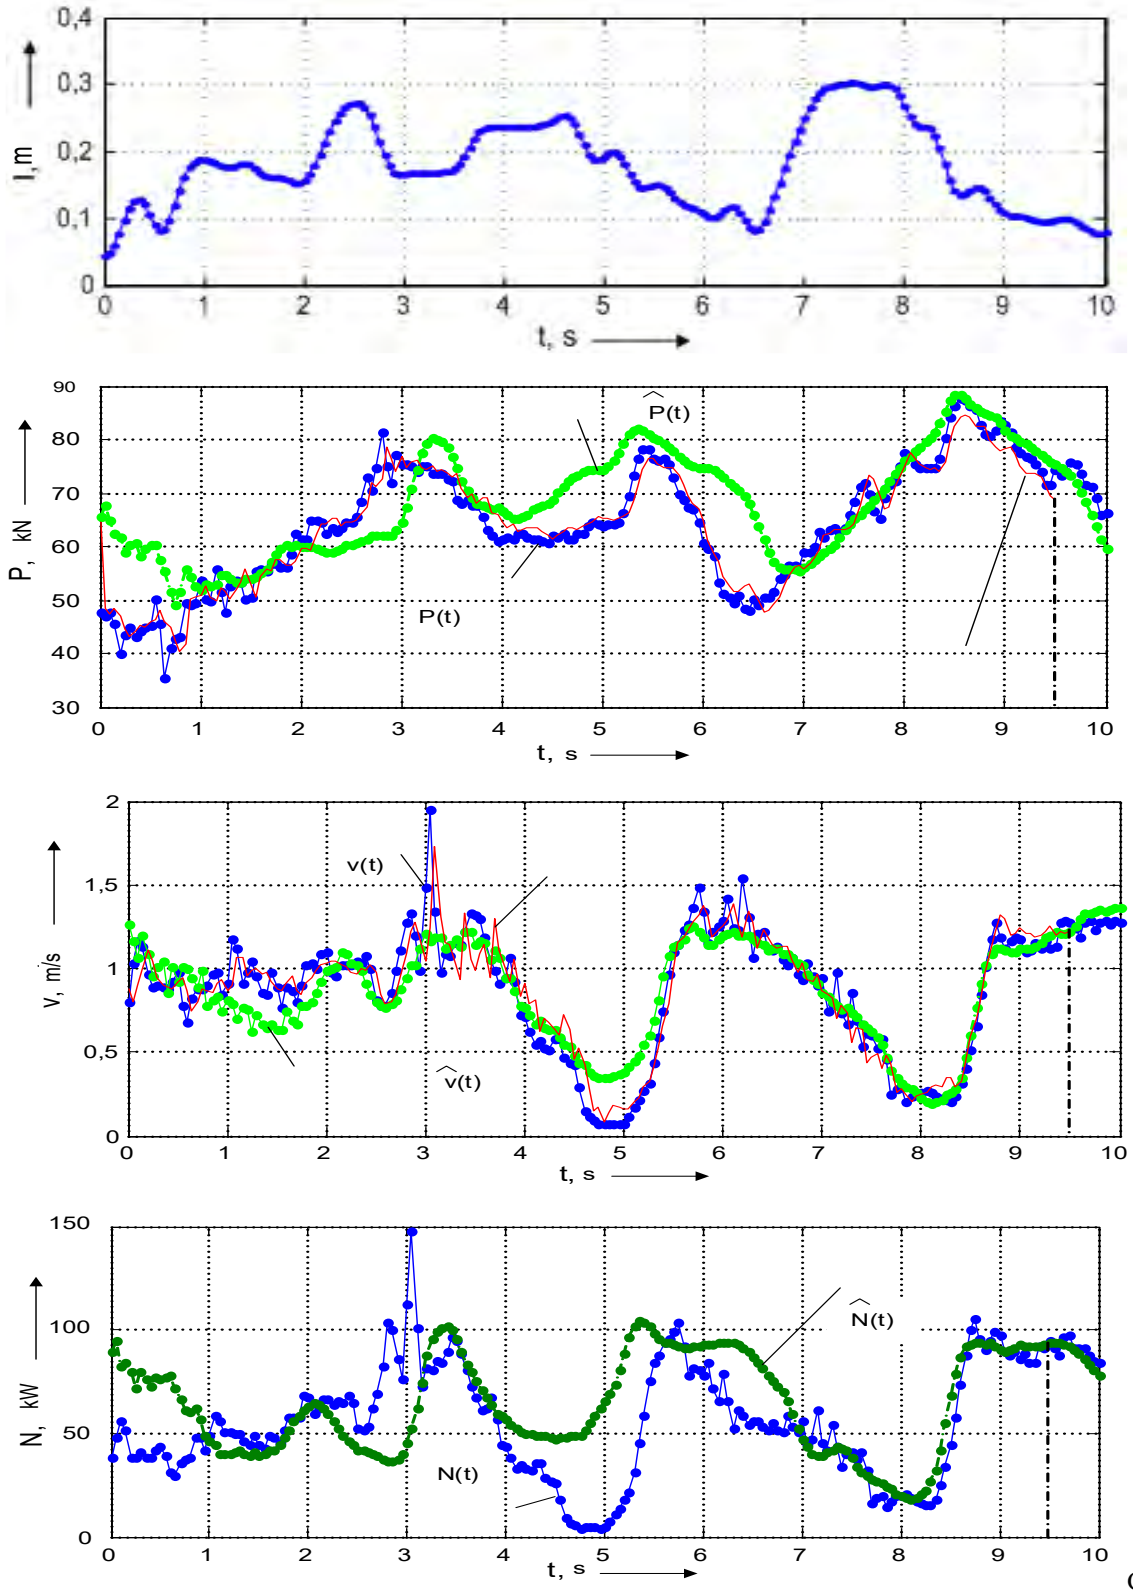

Figure 5. Comparison of Bulldozer operational parameters obtained with the Model and actual operational parameters: A) Deepening Dozer Blade; B) Digging Resistance Force; D) Bulldozer Current Velocity; C) Bulldozer Pulling Power.

For the formation of the control actions influencing the bulldozer, particularly electrical signals actuating control valves of hydraulic cylinders lifting and lowering the working organ, the structure and algorithms of adaptive neural network controller have been designed. Based on the obtained results of practical measurements and the simulation carried out on their basis, the team set the following goal as the practical testing of the machine in real working conditions.

Abstract –

Equipment selection for a construction project is a complex decision making task that impacts the project cost significantly. The literature highlights the increasing focus of recent studies on tower crane (TC) optimization, largely due to the shift from horizontal to vertical construction. Many studies tend to select a single TC model to be used throughout the site and assume the number of cranes to be used as a priori knowledge or is calculated using heuristics and schedule demands. Selection of a combination of TC models is relatively unexplored. Existing literature focuses on finding a single most optimum solution to a multimodal problem. Need to look for multiple optimums arises from the uncertainties of an integral but disjoint simulation process and the local and specific nature of un-modelled constraints. Thus to address this gap the study presents a selection approach, aiming to leverage the long reach of TC, formulated as a function of the rental cost and lifting requirements. The selection of the equipment is of prime focus in this research with implicit consideration for the positioning of the TC. A Bi-level optimization problem is formulated involving task allocation to different TC models and minimization of required crane count for each model. Genetic Algorithm (GA) has been employed to work with non-differentiable multimodal function and obtain the preferable TC combinations from the available model variations. The results derived from the proposed model included optimal yet dissimilar TC combination options, task allocation to the utilized TCs and feasible regions for crane placement. The major limitations were parameter setting for the adopted algorithm and the inability of the distance metric to robustly capture phenotypic differences.

Keywords–
Genetic Algorithm; Tower Crane selection; Bi-level optimization; Multimodal optimization.

1 Introduction

Site Layout Planning (SLP) involves optimum space utilization for the resources required to aid construction. The equipment and machinery form an integral part of these required resources. Construction activities involve tasks like shifting of materials, lifting and hoisting along with holding up of loads in place for processing. Cranes being better suited for such tasks have gained the interest of site practitioners. Crane selection is one of the many critical decisions that construction managers have to make. As highlighted by Shawney and Mund [1], time, cost and safety pertaining to construction operations are significantly hinged to the selection of a suitable crane. Deployment of tower cranes typically demands the biggest investment for construction equipment on a site. On an average, major equipments amount to nearly 36% of the total procurement cost [2].

Crane selection consists of two components i.e. type selection and model selection. The former pertains to the selection of the crane type from the range of options available like Tower Cranes, Derricks, Wheel or Crawler mounted Cranes etc. This is highly dependent on the nature of work, geotechnical conditions of a particular construction site and limitations of crane type. Crane model selection is the next step which involves choosing the best combination of cranes of certain type. This choice is governed by a multitude of criteria like rental and operation costs, safety etc. Another challenge faced by construction practitioners is related to positioning of this heavy lifting machinery. This study is an attempt of TC model selection addressing certain limitations of present literature.

2 Crane Selection and Location Optimization Research

Extensive research has been undertaken on the topic of crane type selection in the existing studies. Alkass et al.[3] proposed a methodology utilizing object oriented programming providing solutions to the crane selection

problem using Rule-based and Case-based reasoning with project specific user inputs. Another Fuzzy logic approach to the problem was proposed by Hanna and Lotfallah[4] to incorporate qualitative factors like soil conditions, access road requirements etc. Sawhney and Mund[1] used Artificial Neural Networks in Intellicranes selection tool to tackle the subjectivity involved in decision making regarding the aforementioned factors. These studies laid down the drivers of crane type selection decision using codified expert knowledge. Simulation was relied upon in [3] & [1] for ensuring that the geometric constraints and productivity demands were met at possible crane locations for the suggested solutions. However no guided search algorithm was used in these efforts.

Many TC location optimization models have been developed. Tam et al.[5] used genetic algorithm to minimize the hook travel time by varying the TC and supply point locations around fixed demand points for sites using a single TC. Abdelmegid et al.[6] contributed in improving the travel time minimization model by incorporating the vertical velocity of the hook. Wang et al.[7] further linked this model to BIM and simulation modules to detect schedule conformance and clash detection. However these studies either considered a single TC ([5] and [6]) or assumed a single TC model by largest lift weight and task distances and number of TCs decided by heuristically derived crane efficiency ([7]). Shapira et al.[8] quantified a safety index for any construction site with TC. Safety related to the wind, operator proficiency, shift length, positioning of the cranes with respect to surrounding facilities etc. was captured.

Selection and location of group of TCs has garnered only limited attention. While the primary hard constraint for TC model selection is to ensure the ability of the TC group to lift the prescribed material weights, divergent approaches have been used for location determination. Zhang et al.[9] optimized the safety and efficient operation by minimizing the number and extent of jib clashes and balancing workloads of cranes respectively. A major limitation included pre-determination of number and model of TC to be used. Irizarry and Karan [10] built on this work and displayed the selection of minimum number of TCs when a particular model was specified while claiming that the model being capable of finding the best combination with multiple models at disposal. Minimization of overlapping area of cranes among themselves and with facilities was used to reduce conflicts. Marzouk and Abubakr[11] used maximum site coverage for the same. Y. Ji and Leite[12] minimized the hook travel time and demonstrated the importance of doing so for the crane group as a whole rather than for each TC individually. However all these TC selection and location studies only find a singular most optimal solution to a multimodal problem. The potential value addition in looking for the local optimums is described below.

TC location finalization is subject to it being free from spatial clashes and the arrangement possessing the ability to adhere to the schedule. Simulations have been widely proposed to test for such requirements. As pointed out in [11], the processes of location optimization and simulation in most research efforts have been disjoint, i.e. visualization for clash detection is done in a separate module by using outputs of the optimization module. Thus, the study reported, that a wide range of feasible solutions must be tested in simulation runs to find the near optimum. In case of a discovery of any issue through simulation, the knowledge of a favorable yet dissimilar solution to the one under consideration would add great value. Models integrating the optimization and visualization processes can be a viable option to tackle the issue. However, the gains, as stated by Einbu[13], of greater reusability, concealment of data and operations and higher adaptability that modularization provides to the software manufacturers and the service providers cannot be ignored. Moreover, Sepasgozar and Forsythe[14] highlighted how the studies up till now have focused on project specific factors while the organization based factors have remained largely unattended. The difficulty of factoring the complexity of maintenance and local availability of after sales services demands greater alternatives for decision makers to compare and choose from.

Thus to counter the unforeseen hindrances in simulations and the inability to model an exhaustive list of constraints in an optimization problem a TC selection model capable of giving multiple and varied sub-optimal solutions from a multitude of feasible options can provide flexibility. This study borrows from the framework adopted in [10] of a rental cost based TC selection model while the subsequent location determining objective not focused upon. The model uses Genetic Algorithm (GA) to minimize the rental cost of the group of TCs with an attempt to find local optimums has also been demonstrated. The scope of this study is TC selection and the aim is to supplement the currently proposed TC location methodologies by providing varied alternative solutions.

3 Optimization Model Description

This section contains a detailed description of the underlying logic used in the model. For a crane to successfully perform a task, i.e. shift a weight w from supply point (S) to demand point (D), it must be able to lift the prescribed weight at both the locations. Every crane can be characterized by their jib length (R) and

the maximum lifting capacity (W_m). The lifting capacity of a crane varies along its jib, decreasing towards the tip, and is obtained from the load-radius curve provided by the manufacturer. Thus, for each weight $w \leq W_m$, a circular area of radius „r" (obtained from the curve) exists for a particular crane inside which it can lift that weight. To perform a task, the crane must lie within the intersection area of the buffer zones centered about S and D points. This intersected region is called the feasible task area. No intersection implies the task cannot be performed by the crane. The size of the area is related to the distance between S and D, the weight of the load, and crane capacity. Larger the feasible area, more easily the task can be handled. A tower crane can handle two or more tasks, if it is located within the feasible areas of all those tasks (Fig. 1(a)), which is essentially the intersection of feasible areas of those individual tasks. If no common overlap exists, then a single TC is inadequate to handle all of those tasks (Fig. 1(b)).

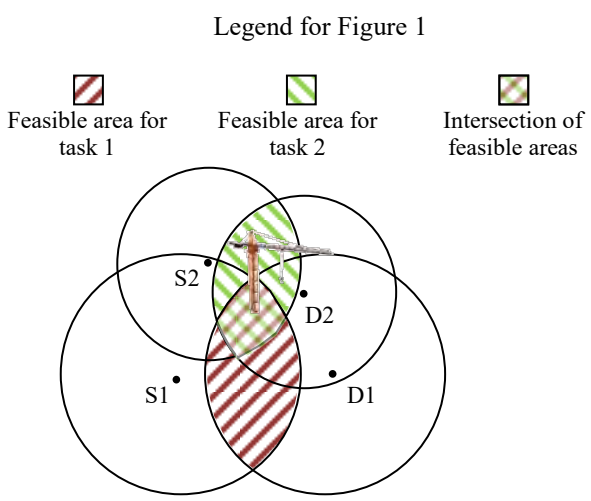

Figure 1(a). Single TC sufficient for two tasks if placed in the common feasible region

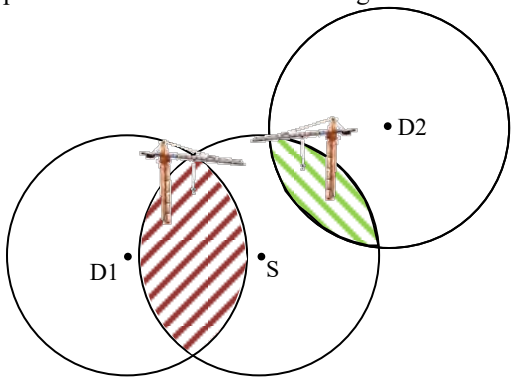

Figure 1(b). At least two TCs required for the tasks, one in each feasible region.

Assumptions of this study:-

1. Geometric Layout of all the S and D points is known along with the module weights for each S-D pair (task).
2. Only one TC is designated to perform any task.
3. For every task, there exists at least one crane in the database which is capable of performing it.

3.1 Bi-Level optimization

Two decisions are involved in finalizing the TC selection for a group of tasks - TC model that will be used to do certain tasks and the number of cranes of that model required to perform the allocated tasks. Thus for every task allocation, a minimization operation is required for each utilized TC model to find the respective number of cranes.

A bi-level optimization problem is a hierarchy of two optimization problems (upper-level or leader, and lower-level or follower). Although different objective is optimized at each level independent of each other, the decisions of each level have effects on one another [15]. The decision of the upper level (TC model allocation to tasks) determines the search space of the lower level (tasks for which minimum TC count is to be determined). The result of the follower contributes in the objective function evaluation of the leader.

3.1.1 Upper Level :- Crane Allocation to Tasks

Ability of a crane to perform amy task i depends on the distance between S and D points ($Dist_i$) and the module weight to be carried (W_i). Subject to them, the potential TC models for each task can be finalized. The constraint has been handled through a combination of two measures - appropriate structuring of population initialization and mutation operators and through exterior static penalty functions as summarized by Smith and Coit[16]. Initially, TC models capable of doing a task are filtered by comparing jib lengths and $Dist_i$ and if they are rendered incapable for that task due to reduced reach owing to load-radius curves, a penalty is added. In addition, the aggregate feasible region after considering all the allocated tasks for a single TC of any model must be greater than a typical threshold value.

Let m be the number of tasks to be undertaken and n be the different TC models available for selection, an identification label is attached to each model. Number of optimization variables is equal to m. The variable x_i assumes the label value of the crane model being used for i^{th} task. Thus, the variables are of categorical type. Ordinal encoding has been preferred over one hot encoding to keep the dimensionality of the problem low, which in turn obviated handling of the constraint- every task must be allocated one and only one crane model.

$$Minimize \quad \sum_{TC=1}^{n} N_{TC}(x) R_{TC} \qquad (1)$$

Subject to constraints

1. $x_i = y,\ y \in \{z \mid 2*(\text{reduced radius})_z \geq \text{Dist}_i\} \forall\ i,$
2. $(\text{aggregate feasible area})_y \geq (\text{Threshold area})_y,$

where denotations are as follows
i = i^{th} task, z = label given to the TC model, R_{TC}= rental cost of the TC model, $N_{TC}(x)$=minimum number of cranes of a model required according to the allocation x, obtained from lower level of optimization. Threshold area is set as the base area of crane.

A widely utilized fitness sharing method for multimodal optimization has been used. It is based on evolution of different species in separated niches of nature. The search space is divided into niches and search for local optimums in them occurs in parallel. Fitness of closely resembling chromosomes is decreased to maintain diversity in population. Thus convergence to single optimum is prevented since the presence of a high number of similar individuals is discouraged. In this study, similarity between two chromosomes has been measured using genotypic distance which is the number of string positions by which they differ. Greater the distance, lesser is the similarity. As outlined by Deb and Goldberg[17], setting the dissimilarity threshold (the minimum distance between two chromosomes above which they don"t affect each others" fitness) must be done carefully. Method proposed by them for calculating the parameter for binary string is as follows

$$\frac{2^l}{q} \leq \sum_{i=0}^{k} {}^{l}_{i}$$

where l stands for the string length, q for the number of optimal/suboptimal solutions and the lowest integer value of k for which the inequality holds gives the parameter value. The parameter is denoted as $_{share}$.

The LHS denotes the average volume of search space occupied by each niche and the RHS denotes the number of possible different strings if at most k bit differences are allowed. Same logic was applied to get the value of dissimilarity threshold although with modification to the expression since the categorical variables of proposed model are not necessarily binary but can take multiple values. The q is an input from the user to be decided arbitrarily when no prior information is known about the problem.

Following is a summary of how the fitness of individuals is altered according to the fitness sharing method as described by Deb[18]. The value of sharing function is defined for a pair of individuals with d as the distance between them.

$$Sh(d) = \begin{cases} 1 - (\frac{d}{\text{share}}), & d < \text{share} \\ 0, & otherwise \end{cases}$$

The summation of sharing function values for an individual paired with every other individual gives the scaling factor (m_i") for that particular individual.

$$m_i" = \sum_{j=1}^{N} \text{Sh}(d_{ij})$$

The fitness value is divided by the scaling factor to get the shared fitness value.

$$f_i' = \frac{f_i}{\text{mi'}}$$

Greater the population density in a certain search space area, greater is the scaling of fitness of those individuals. .

3.1.2 Lower Level :- Minimum Crane Count

Once the crane model has been allocated to each task, determination of the minimum number of cranes of each model required to perform them remains, i.e. finding the values of $N_{TC}(x)$ for evaluating function (1).

Let m_1 number of tasks from the total m be allocated to TC model with label 1. The variable encoding is similar to the upper level with the exception that all the cranes here are exactly identical. Earlier, two variables assuming different label values of TC models implied they had been allocated to different models of TC whereas at this level, two variables assuming different label values implies that they will be performed by two physically different cranes of the same model. Thus a maximum number of cranes of each model must be fixed to limit the search space. Let this number be n_1.

The objective function value is the number of cranes used which is equal to the number of unique label values taken by the variables. The task variables with the same label value are said to be grouped together. Feasibility of these grouped tasks to be performed by a single TC is tested. For every such infeasible task group, a constant penalty equal to n_1 is added. The objective function is minimized and its value, representing the number of cranes is fed into the upper level as N_{TC}.

Derivation of n_1 is empirical. Lower level optimization model is run for each TC model separately assuming all the tasks satisfying the constraint (1) and (2) of upper level are allocated to that TC model. A large n_1 translates to a huge search space for the algorithm which might result in inability to find the least sufficient crane count. Initially, n_1 is kept large and its value updated after every algorithm run, changed to the output of the previous run until there"s no difference in the value of n_1 and result. Hence n1 is the minimum number of cranes of model 1 required if it gets assigned all the tasks it can perform.

The presented case in this research targets selection of TC from a pool of options available to the construction practitioner to choose from. This underlying assumption of availability of multiple options of TC represents the market scenario and thus providing a single solution will make the decision making task stringent. Also, the fitness function is highly sensitive to the underlying decision variable values. Due to traditional optimization algorithms‟ reliance on derivative or slope information and their ability to reach a single optimum solution only, they are not suitable for this problem. Therefore a nature inspired algorithm capable of providing a set of optimal solutions is adopted in this study. Moreover , the ability of GAs to move from highly fit lower order schemata to higher order ones [19] is of particular interest as it translates to grouping of geometrically closer tasks in the phenotypic space. Fig.2 explains the flow process of the adopted algorithm. At every fitness evaluation step, lower optimization function is called for each TC model used.

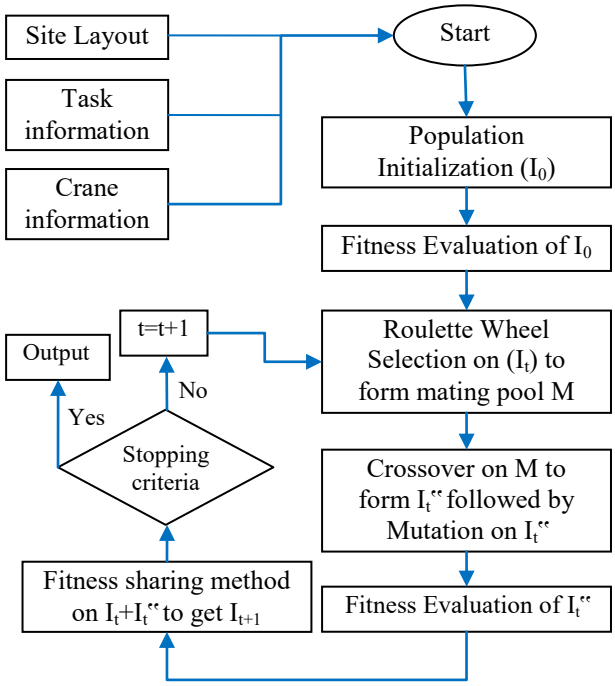

Figure 2. Flow process of the GA fitness sharing model

4 Case Study

A hypothetical site layout was used to test the proposed selection model. The boundaries of both temporary and permanent facilities in the layout are considered to be enclosing the areas not allowed for TC placement. These boundaries also include the minimum clearance from entities required for placing a TC. The inputs to the model include geometric information of temporary site facilities and the details for coordinates and module weights for each task, as highlighted in Table 2. Load charts and rents of available TC models are uploaded. As mentioned in Table 3, four models of varying jib lengths and lifting capacity were used. Table 1 summarizes the input parameters used for the upper level problem.

Table 1. Algorithm parameters

Parameter	Value
Population Size	100
Maximum Generation	150
Number of Variables	17
Crossover Rate	0.8
Mutation Rate	0.06
q (Number of peaks)	3
$_{\text{share}}$	12

Setting of GA parameters for the lower level problem like population size and n_1 as discussed before is empirical and requires fine tuning with multiple runs to ensure correct answers and also to keep run time in check.

The final population of chromosomes produced by the algorithm contained different optimal solutions with varying task allocation to different crane models and hence varying combination of crane requirements. The results display a combination of TCs of dissimilar jib lengths and lifting capacity can result in lower rental costs as against the common practice of a common TC model usage across the site. Table 4 gives the total rental cost for the solutions and the number of tasks performed by each utilized crane. The feasible areas for TC combinations for the obtained solutions along with the temporary and permanent facilities of the site have

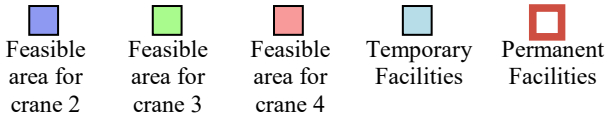
Table 2. Task information:-S&D coordinates, lift weight

ID	Supply (in m)		Demand (in m)		W_i (t)
	Abscissa	Ordinate	Abscissa	Ordinate	
1	46.25	116.25	41.25	141.71	2.25
2	46.25	116.25	25	100	2
3	15	30	25.25	60.71	2.25
17	91.84	90.62	25.25	127.71	1

Table 3. Tower Crane Model information

Label	1	2	3	4
Rent ($\times 10^3$/day)	15	20	27	35
Jib Length	25m	40m	50m	60m
Max. lift capacity(t)	3.5	8	9	12

Legend for Figure 3



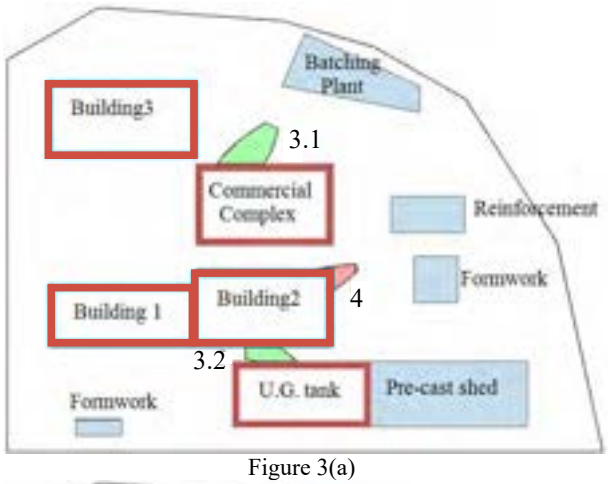


Figure 3(a)

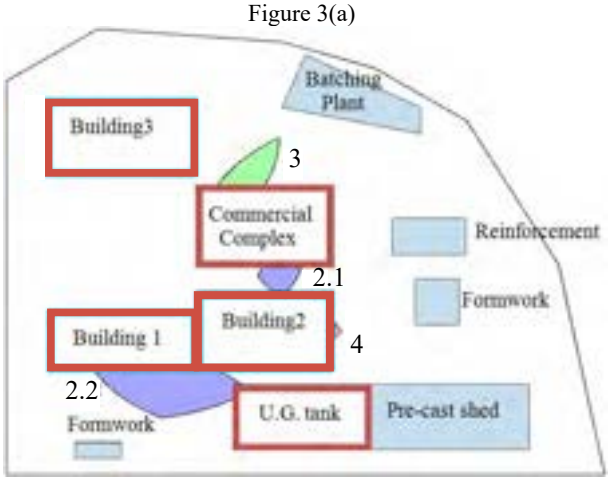

Figure 3(b)

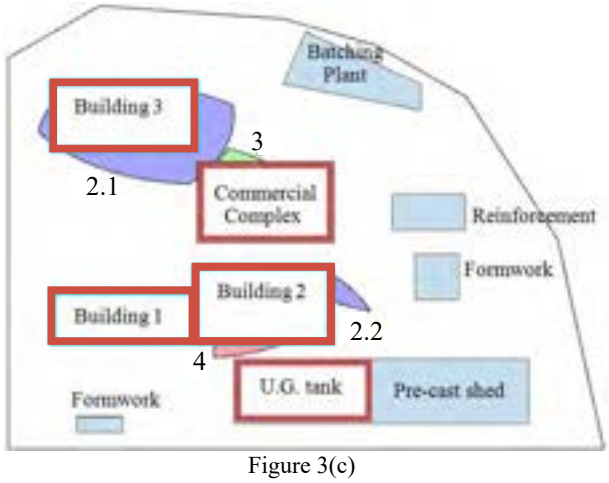

Figure 3(c)

been shown in Figure 3. Legend indicates what the shaded regions represent. One TC model of the indicated type is required to be placed in each of the shaded feasible region. The neighboring number to the shaded region points to the corresponding entry in Table 4 to get the number of tasks it handles. For example two TCs of model 3 are required in solution of Figure 3(a) with the crane placed in the region corresponding to 3.1 performs four tasks.

Table 4. Total rental cost and number of tasks performed by each crane

Solution	Rental cost per day	TC model 2		TC model 3		TC model 4
		2.1	2.2	3.1	3.2	
Fig. 3(a)	89000	-		4	5	8
Fig. 3(b)	102000	3	3	3		8
Fig. 3(c)	102000	3	5	3		6

The algorithm was successful in maintaining sub-optimal solutions through the generations. Also, the feasible regions produced by them showcase a certain degree of variety in terms of the potential TC locations. Such provision can endow the decision makers with flexibility while making decisions about TC model selection and location. Difficult to encode constraints like soil conditions or to account for intangibles like TC maintenance, availability of options can prove helpful. Moreover, the flexibility of multiple solutions can provide options if clashes are detected in simulations. It must be noted that for a certain ownership cost, more than one Task Distributions can be possible. The ones shown above have been chosen from the solution set based on more equitable task distribution among TCs.

5 Limitations and Future Scope

K-means clustering was used to separate the final population into 3 clusters, equal to the set value of q. Relatively low silhouette values suggest weak clustering in the population. The genotypic distance between the optimal solutions from different clusters was lesser than the value of $_{share}$ used which points towards a revision to a lower value. A smaller $_{share}$ implies sustenance of more number of solutions which demands higher population levels leading to impractical processing times. Moreover, the existence of individuals in a niche with fitness values lower than the local optimum indicates a highly rugged landscape which leads to survival of less fit but different individuals even within

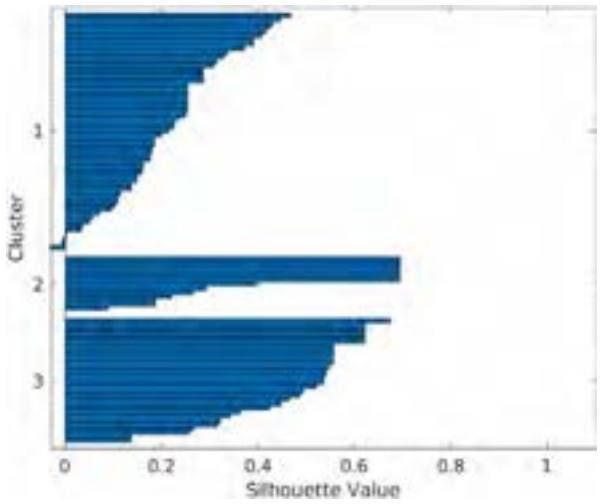

Figure 4. Silhouette plot for k-means clustering

a niche.

The root cause of this limitation of the study lies in the distance metric. As outlined in [17], phenotypic distance can perform better than genotypic distance in certain problems. The problem with this approach is the limited translation of genotypic distance to the physical space. Consider two instances of task distribution for 5 tasks using the scheme described above

X= [4 4 4 3 3]
Y= [4 4 4 2 2]
Z= [4 4 4 1 1]

The genotypic distance between X&Y and X&Z is equal to 2. But if a single TC of model 2 and 3 is sufficient in X and Y, it is plausible two TCs of model 1 are required in Z. Thus a measure to capture phenotypic information i.e. the feasible area for each task, for distance calculations between two individuals can result in better results. The presented approach in this study is part of an ongoing project and the developed code to select TC is yet to be validated on a real construction project. The code will be made available in public interest but only after validation. Till then any request in this regard can be made directly to the authors.

6 Conclusion

Fitness sharing method for Genetic Algorithms was used for multimodal optimization problem of TC selection. The proposed methodology in the study was particularly aimed at finding cost effective combinations of TC from the available models without restricting to finalization of a single model based on aggregate site demands or heuristics. The results produced alternative solutions for TC selections, which provided varied feasible solutions for the user to choose for location optimization and subsequent simulations. The process of planning site utilization involves intertwined tasks. This calls for addressing interdependencies between these tasks. Therefore as part of an ongoing project, the presented approach is sought to be integrated with site layout planning problem where positioning of temporary facilities would be dealt. These positions would be taken up as input for the demonstrated approach in this study and is expected to result in a much robust solution.

Abstract –

This research presents the design framework of the artificial intelligent algorithm for an automated building management system. The AI system uses wireless sensor data or IoT (Internet of Things) and user's feedback together. The wireless sensors collect data such as temperature (indoor and outdoor), humidity, light, user occupancy of the facility, and Volatile Organic Compounds (VOC) which is known as the source of the Sick Building Syndrome (SBS) or New Building Syndrome because VOC are often found in new buildings or old buildings with new interior improvement and they can be controlled and reduced by appropriate ventilation efforts. The collected data using wireless sensors are post-processed to be used in the neural network, which is trained in accordance with the collected data pattern. When the users of the facility have the control of the building's ventilation system and the AI system is fully trained using the user input, it will mimic the user's pattern and control the building system automatically just as the user wants. In this research, data were collected from 4 different buildings: university library, university cafeteria, a local coffee shop, and a residential house. Fuzzy logic controller is also developed for better performance of the HVAC. Indoor air quality, temperature (indoor and outdoor), HVAC fan speed and heater power are used for fuzzified output. As a result, the framework and simulation model for the energy efficient AI controller has been developed using fuzzy logic controller and the neural network-based energy usage prediction model.

Keywords – IOT; AI; Neural Network; Fuzzy Controller; Smart Building

1 Introduction

The energy efficiency has become an urgent issue for sustainability of our society under global warming and it is closely related to infrastructure design such as buildings and the usage patterns of residents. Energy efficient buildings have evolved over decades, and intelligent control systems have been adopted for efficient operations of the buildings. Next generation buildings will be smart buildings equipped with various sensors and autonomous control systems that interact with the users.

This research paper suggests an innovative and systematic approach in smart building management system for energy saving and sustainable development of society. Smart building means automated control of building systems such as lighting, heating and cooling, ventilation, security, etc. to provide the users productive and comfortable environment. Lighting, power meters, pumps, heating, and fire alarms are all connected and monitored as part of the building management system.

The authors of this paper have been working on developing wireless sensor network (WSN) to monitor indoor air quality and energy profiles, and this current paper aims at testing the WSN at real community facilities and developing a method for objectively evaluating the energy consumption patterns of the participating community organizations. This research suggests the preliminary investigation and study of feedback from the community participants regarding the deployment of the wireless sensor network and the integration of the feedback into the design of smart building management system. The smart buildings system will automatically control building functions such as lighting, heating, cooling, ventilation, security, etc. to provide occupants with more productivity and comfort.

2 Smart Building Technologies for Public Facility

2.1 Smart Facilities and the Community

In this project, the wireless sensors collected data from the buildings that are used in the community. Installed sensors are temperature, humidity, light, Volatile Organic Compounds (VOC) level, and movement sensors. The collected sensory data along with the user input will be fed to the Artificial Intelligent (AI) system, which learns the usage patterns and produces

similar outputs just like users control the air-conditioning and heating units. In addition to copying the usage pattern, the researchers will look for the way to improve energy efficiency by optimized control of building management system.

Artificial intelligent system using neural network and fuzzy logic algorithms is used to analyze the IoT data and controls the smart building systems. Volatile Organic Compounds (VOC) which is known as the source of the Sick Building Syndrome (SBC) is also monitored. The control of VOC can be done by controlling HVAC system. The authors have developed the pilot model of automated HVAC system as the proof-of-concept for the smart building system.

The authors of this research have been developing collaborative relations with several community partners for energy efficiency improvement in their public facilities. The testing facilities are (1) New Britain Police Station, (2) New Britain Public Library, (3) Hospital of Central Connecticut, and (4) YWCA at New Britain. The four different community partners have very unique characteristics in size, number of users, and the form of ownership as follows:

(1) New Britain Police Station. The HVAC system is 20 years old and the system is very energy inefficient.
(2) Public Library is management by the New Britain Foundation that is non-government, non-profit organization.
(3) The Hospital of Central Connecticut (New Britain General) is very large facility with the daily float population is 80,000~100,000. Residents like doctors and nurses stay most of time in the building while visitors like patients and helpers are float population. User pattern analysis and customer feedback will be very beneficial to the development of adaptive smart building.
(4) YWCA building in New Britain, CT has been renovated and expanded. The adaptive smart building system will be tested and compared on existing building and new expansion.

2.2 Energy Peak Demand Control

The authors of this papers have been with the local energy company in the state of Connecticut and New England area. The energy company can provide energy consumption of the buildings in real time monitoring the peak usage as well as low usage time. The peak power use is critical because more than maximum peak power usage may cause catastrophic power outage. The smart building helps alleviate the peak use and reduce the risk of the power loss. The researchers of this paper have designed artificial intelligent system for smart building management, and the community partners' energy usage data to be collected in this research will verify the effectiveness of the developed system.

3 Methods

Smart building systems are beneficial for both the owner and the users working within. These benefits range from energy savings to productivity gains to sustainability. They reduce energy consumption, increase the productivity of the users, improve building operations, support sustainability efforts and enhance decision-making across the organization for efficient use of optimal start/stop of HVAC system.

3.1 Artificial Intelligence in Building Management

Artificial Intelligent (AI), first introduced in the Dartmouth Conference in 1961, is a flexible rational system that perceives its input data and produces outputs that maximizes the goal. For example, if the energy cost saving while maintaining the user's comfort level is the goal, AI would provide the optimum heating/cooling operation scenarios.

3.2 Sensors and IoT

Smart sensors collect environmental information that can be processed to manage the facilities better for effective heating, cooling and electricity saving. Temperature, motion, vibration, light, and indoor air quality sensors such as VOC sensor are installed. They monitor occupancy and floating population to recognize the usage patterns, which are analyzed by artificial neural networks.

3.3 Interpretation of Sensor Data using Neural Network

The sensor data are collected, preprocessed and fed to the neural network to determine the usage patterns of the facility, which are recognized to produce the optimized operations of the smart buildings. Elevators, HVAC, lightings, security systems, and electrical usage of the buildings can be analyzed and optimized for the most energy efficient operation.

3.4 Fuzzy Logic Systems and Fuzzy Controller

User's inputs are verbal values or although it is in numerical scale, they are not exact number but they can be considered as fuzzy numbers or fuzzy membership functions which can have error tolerance. Fuzzy membership and membership functions is a simple and easy to use tool to convert verbal expressions in numerical values. For example, if user answers "very satisfied", "satisfied", "moderate", and "not satisfied" in the customer experience in new automated heating and cooling system, user's response can be converted into certain numerical representation in order to be used in

computer system.

4 The Development of Neuro-Fuzzy Controller for Smart Building

4.1 IOT Data Collection and Post Processing

The indoor sensors utilized in this research are (1) Temperature, (2) Humidity, and (3) Volatile Organic Compounds (VOC) that is considered as the main cause of the bad indoor air quality. Any materials that have chemical compounds such as new paints and new carpets can result in high VOC readings. VOC is also known as a cause of the Sick Building Syndrome (SBS). VOC can be monitored by IoT sensors and can be controlled automatically in the smart building systems.

In this research, data were collected in the Elihu Burritt Library and Devil's Den (Student Cafeteria) at Central Connecticut State University (CCSU). In addition to the indoor temperature and VOC, outside temperature and the number of people using the facility were monitored. The number of people in the facility was indirectly estimated by the wireless motion sensors. Persons sit still and not moving will not be detected. However, simple motion sensors provide an effective indirect way of measuring how the facility is used. The result of collected data are shown in the figures below.

The wireless sensors were tested and successfully utilized. The collected data are analyzed using neural network which is the machine learning algorithm for artificial intelligence systems. In order to complete the machine learning training and develop the robust smart HVAC system, the automated HVAC controller needs to be developed.

The researchers have tested the wireless sensors on the community facilities and the result is processed and fed to the feedforward neural network. The authors of the paper used simulated HVAC control data to develop the energy usage pattern analysis. The controlling system of HVAC is designed using fuzzy controller system.

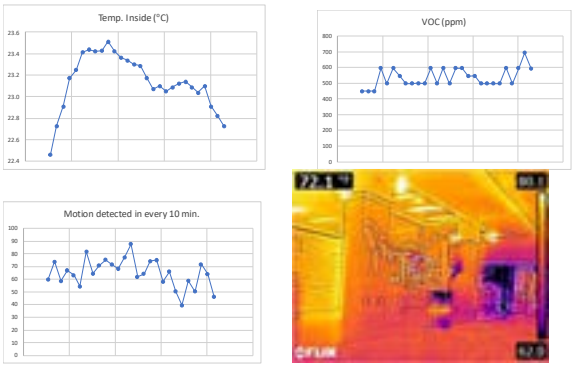

Figure 1. Wireless sensor data and infrared images at the library

The neural network model for the energy usage pattern utilizes the variables such as: Outdoor-Temperature, Number-of-occupancy, Time, Date, and Day. The variables such as Time, Date, and Day have been converted into 2-digit codes for the neural network pattern training purpose. The neural network for energy usage pattern recognition and energy usage prediction model has been developed and it is continuously being compared with the real energy consumption data. The more data are collected the better prediction model can be developed.

4.2 Fuzzy Controller

There are some research findings that compares traditional Proportional-Integral-Differential (PID) controller and fuzzy logic controller for heating and cooling system (Gouda et al. 2000, Attia et al. 2015). PID controller is considered reasonable and efficient alternative to the manual or simple on/off controllers of HVAC systems. However, recent studies showed that fuzzy logic controllers perform better than PID controllers when the users satisfaction level is considered. PID controller uses simple mathematical formulas of integration and differentiation of temperature changes over time, while fuzzy logic controller converts users' linguistic expressions into mathematical functions, and calculates the fuzzy if-then rules using fuzzy inferences.

Conventional PID controller can be shown as following equation,

$$u(t) = K_P e(t) + K_P K_I \int_{t=0}^{t} e(t)\,dt + K_P K_D \frac{de(t)}{dt} + u(0) \quad \text{eq. 1}$$

where K_P is the controller gain representing a proportionally constant between error and controller output, K_I is the reset constant relating the rate to the error in units of [%/(%-sec)], K_D is the rate constant in units of [(%-sec)/%], and u(0) is the controller output at t = 0 (Tsoukalas 1997).

Once the fuzzy variables are defined, the fuzzy logic controller is simply shown as,

$$u(k) - u(k\text{-}1) = \Delta u^*(k) \quad \text{eq.2}$$

where $u(k)$ and $u(k\text{-}1)$ are temperature readings at time k and $k\text{-}1$ and Δu is the extent of change of the control variable u at time $t = k$ that is change in action and the defuzzified output is $\Delta u^*(k)$.

In this research, authors developed the fuzzy membership functions and inference rules to control the heater and indoor air quality. Defined fuzzy membership functions are: (1) Current Temperature and Humidity (indoor and outdoor) and forecast temperature and humidity; (2) Time, Day, Date, and holiday information; (3) Number of people; and (4) VOC (Volatile Organic

Compounds). The simulation model shown in this research, only the temperatures and VOC are fuzzified. The fuzzy controller was developed only the heating and indoor air quality control. The fuzzy membership functions are defined such as VH for very high and L for low, etc.

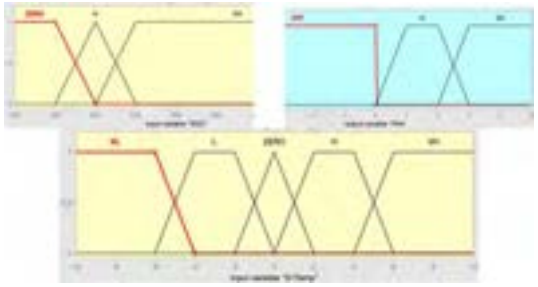
The outputs of the fuzzy controller are: HVAC fan speed and heater power. So, the fuzzy membership functions for HVAC fan speed are *VH, H, and OFF*, and fuzzy membership functions for heating power are *VH, H, and OFF*. The fuzzy controller inputs variables are crisp values such as: Temperature reading, temperature setting, and temperature differences (*D_Temp*) between temperature setting and temperature reading. Indoor air quality read by VOC sensor is also used as input variable. Figure 2 shows input, output variables and if-then rules.

The fuzzy controller for heating/cooling system has been created. Variables are the differences between the target VOC and current VOC level. If fuzzy variable *D_VOC* (differences of VOC level) can be defined as *Very_High, High, and Zero*. According to the fuzzy values of *D_VOC,* the HVAC control can be *High, Low, and Off*. In the same way, fuzzy variable *D_Temp* can be driven from the Temperature and Target-Temperature. The fuzzy controller delivers accurate control of the heating/cooling system for optimum temperature and VOC levels.

Fifteen sample fuzzy if-then rules were developed. Rules are very simple. If the temperature difference is high, turn the heater high, if the indoor air quality is low turn the fan high, and so on. Fuzzy if-then rules are defined as followings:

- R_1: If *D_Temp* is *VL* and *VOC* is *H* then *HEAT* is *VH* and *FAN* is *VH* *ELSE*
- R_2: If *D_Temp L* and *VOC* is *VH* then *HEAT* is *H* and *FAN* is *VH* *ELSE*
- …..

By using the Mamdani-min for fuzzy implication, defuzzification results are shown as Figure 2. As an example, when *D-Temp* is 5^{O}F and VOC is 600ppm, the controller settings will be 2.65 for heater and 3.65 for fan speed.



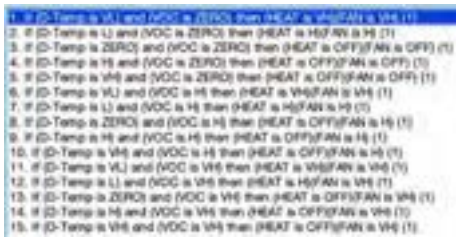


Figure 2. Input/Output Variables and Fuzzy If-then Rules

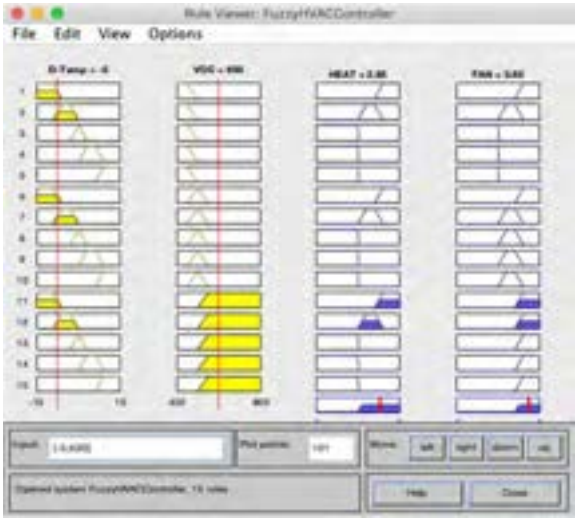

Figure 3. Fuzzy implication and defuzzification result for HVAC controller

5 Conclusions

The main advantage of the developed neural network prediction system and fuzzy logic controller is that it will deliver precise control of the heating/cooling system as well as energy consumption prediction models for different temperature and VOC target levels. The predictive system operates the HVAC pre-emptively saving energy cost and more efficient use of the heating/cooling system. Fuzzy logic controller makes precise control of HVAC improving comfort of the users.

In this research, fuzzy logic controller algorithm is developed only for the heater and indoor air quality control. Neural network prediction model was developed for HVAC usage prediction but the energy saving results and analysis are still under development.

Abstract –

Automation of construction machinery has the potential to improve efficiency and safety during the construction process. However, most construction machinery is directly teleoperated limiting the control to a single paradigm. Moreover, the abundance of non-linearities due to the design of pumps, valves and the interaction of different actuators complicates planning precise movements. Complicated motion planning optimization can be applied to program the movement in the desired manner which often requires a model representing the system dynamics. Whereas this approach is promising, modeling the system dynamics is a formidable task. In this work, we present a framework that uses a probabilistic approach to learn movements from expert demonstrations. In this way, efficient movements can be learned without explicitly estimating system dynamics. Here, efficiency is defined by the experiences of the human operator which makes the programming able to benefit from existing knowledge of operators. The performance of the proposed scheme is evaluated with a real demolition machine BROKK 170.

Keywords –

On-site robotics; construction robotics; robot motion programming; automation in construction

1 Introduction

Currently, remote-controlled hydraulically driven construction machinery is of great importance and mainly used on construction sites. However, local accuracy is often limited in remote-controlled systems due to the interface (for example 2D camera feedback). Moreover, it is challenging for the operator to generate optimized motions with a remote controller since the operator can only see the appropriateness of the motion only when it is already executed. As a result, manual work is still mostly preferred on construction sites. Sequentially, automating construction machinery has already drawn much attentions over the last years [1–5]. The common goal in automating construction machinery is to generate accurate motions in an automated way under various conditions (outdoor conditions, dirty and dynamic environments) to fulfill given tasks.

In particular, the automation of machinery can be regarded as controlling the end-effector in the desired manner. In automated machines, a precise movement is a key part, however, there are several difficulties in automating hydraulic construction machinery arising from the abundance of non-linearities due to the design of pumps, valves and fluid flow [6]. A common approach is the design of dynamics-based control, which typically uses a model for the system to be controlled to predict system states and develop a controller minimizing the discrepancy between the predicted and measured system states. Although this model-based control shows promising results in many researches [7, 8], modeling system dynamics can be often challenging due to its nonlinear characteristics. Moreover, force sensors required for force control are not standard components of construction machinery, since the system is designed to be directly controlled by human operators [9]. Hutter et al. [10] achieved joint torque control based on feedback from pressure sensors integrated into servo valve. However, it is common that pressure sensors are not installed in each valves but only in the main valve due to economic reasons [11].

On the other hand, with the advent of research advances in robotics, robotic systems with a large number of degrees of freedom were developed [12, 13]. Subsequently, Programming by Demonstration (PbD) has drawn the attention of many researchers [14–15], since it allows to program a robot just by showing the desired manner of performing tasks. In contrast to traditional motion planning methodologies, this approach offers an intuitive and less time consuming alternative for non-experts to teach a robot skill [16-18]. Popular approaches for encoding the demonstrations in a way that can be used for motion planning include Dynamic Movement Primitives (DMPs) and Gaussian Mixture Regression (GMR).

Our work concentrates on mitigating the aforementioned issues in automating construction machinery by utilizing the recent methodology from robotics. More precisely, we aim at replacing the time-consuming model-based motion programming of hydraulic construction machinery by an automatic programming process: Programming by Demonstration. In this paper, we present a framework that learns a direct

joint motion mapping from expert demonstrations. This learned mapping so-called policy allows to reproduce joint space motions under different environmental conditions while non-linearities in the hydraulic system are handled by utilizing experiences of the human expert in operating the system.

2 Previous work and challenges

In our previous work [19], we presented a teleoperated demolition machine BROKK 170 that has been retrofitted with controllers, so that one can also program its motion with high-level commands. Although the experiments from our previous work showed the feasibility that proven construction machinery can be adapted and accept advances from robotic to extend its capability, we identified that a Cartesian controller solely based on encoders is not sufficient to enable accurate arm control. As depicted in Figure 1, the machine was not able to follow the given trajectory without any error. The main error source is the unstable system pressure. The hydraulic machine BROKK 170 used in our work consists of one main pump supplying volumetric flow for the whole system. This flow is used in each control valves to move actuators and returned into the tank. During this circulation, flow losses are raised by partially closed or opened valves, bent pipes, expansions or contractions. A generic joint position level controller such as an Inverse Kinematics (IK) solver rapidly reaches its limits, since it typically takes the desired (x, y, z) values as input and outputs the corresponding joint configuration without considering the non-linearities in a hydraulic system.

We aim at overcoming the aforementioned issue by demonstrating basic movements to the machine. Using prior experience and trainings, expert human operators can create more controlled motion with the hydraulic system than IK-based motion controller. By capturing the operator's behavior to overcome the non-linearities of the system, we aim at improving the accuracy in planning of the motion.

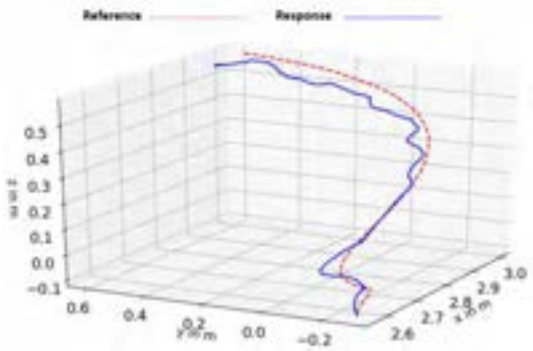

Figure 1. Tracking result using an IK solver based framework

3 Manipulator Control

The manipulator control can be formulated as finding proper joint space configurations $\boldsymbol{q} \in \mathbb{R}^N$ given an operational space description $\boldsymbol{x} \in \mathbb{R}^M$,where N is the number of degree-of-freedoms (DoF) of the machine and M is the operation dimension. As depicted in Figure 2, the operational space $\boldsymbol{x}$ and joint configuration $\boldsymbol{q}$ of the demolition machine can be described as:

$$\boldsymbol{x} = [x \quad y \quad z \quad \theta]^T \in \mathbb{R}^4 \tag{1}$$

$$\boldsymbol{q} = [q_1 \quad q_2 \quad q_3 \quad q_4 \quad q_5]^T \in \mathbb{R}^5 \tag{2}$$

The mapping problem can be formulated as:

$$\dot{\boldsymbol{x}} = \boldsymbol{J}(\boldsymbol{q})\dot{\boldsymbol{q}} \tag{3}$$

where $\boldsymbol{J} \in \mathbb{R}^{M \times N}$is the Jacobian matrix. To obtain the $\dot{\boldsymbol{q}}$ out of the relation in (10), we use the closed loop inverse kinematic (CLIK) approach introduced in [20]. However, as described in the previous section 2, this analytical method does not consider non-linearities in a hydraulic system causing a discrepancy between the estimated and real motion. To address this problem, we employ a probabilistic approach based on Gaussian Process Regression (GPR) first to learn policies from expert demonstrations and program the manipulator by reproducing the learned policies under different environmental conditions.

3.1 Closed-loop inverse kinematic controller

For manipulators with N > M, the inverted Jacobian matrix can be obtained as follow:

$$\boldsymbol{J}^+ = \boldsymbol{J}^T(\boldsymbol{J}\boldsymbol{J}^T)^{-1} \tag{4}$$

The pseudo-inverse has the property to provide the best possible solution according to the equation $\boldsymbol{J}\dot{\boldsymbol{q}} = \dot{\boldsymbol{x}}$. If $\dot{\boldsymbol{x}}$ is not in the range of $\boldsymbol{J}$, an exact value of $\dot{\boldsymbol{q}}$ is not available. However, the provided $\dot{\boldsymbol{q}}$ still minimizes the magnitude difference of $\boldsymbol{J}\dot{\boldsymbol{q}} = \dot{\boldsymbol{x}}$ [21]. By using this property and closed-loop behavior in CLIK, the convergence to the desired $\dot{\boldsymbol{x}}$ can be ensured. The equation from (3) can be formulated as follows:

$$\dot{\boldsymbol{q}} = \boldsymbol{J}^+(\dot{\boldsymbol{x}} + \boldsymbol{K}\boldsymbol{e}) \tag{5}$$

where $\boldsymbol{K} \in \mathbb{R}^{M \times M}$ is a positive definite gain matrix and $\boldsymbol{e} \in \mathbb{R}^{M \times 1}$ is the remained difference between the desired and actual motion. The CLIK controller is further extended with damped-least squares for achieving robustness in the vicinity of singularities [21] and with weighted least norms for joint limits [22].

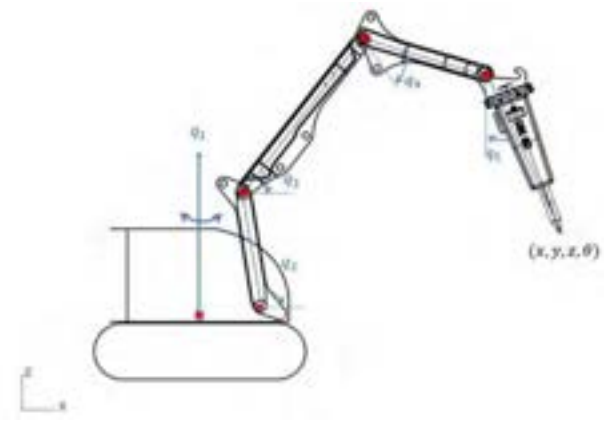

Figure 2. Joint geometric representation of the 5 degree of freedom BROKK 170. The joint space coordinates are noted in blue, whereas the operational space coordinates are in black. The joint positions are noted in red.

3.2 Gaussian Process Models

GPR is a non-parametric method for regression that models a joint distribution of the observed data without directly modeling a regression function[23]. By assuming the existence of m demonstration, each demonstration can be described as $D = \{\xi_i, y_i\}_{i=1}^{n}$. Here, ξ denotes the environmental information, such as the temporal value, y refers to the observations such as the trajectories in the joint space that ξ should be mapped to and n denotes the length of the demonstration.

In GPR, the distribution of observations can be modeled as follows:

$$\begin{bmatrix} y \\ y^* \end{bmatrix} \sim \mathcal{N}\left(0, \begin{bmatrix} K(X,X) & K(X,X^*) \\ K(X^*,X) & K(X^*,X^*) \end{bmatrix}\right) \quad (6)$$

where K is the kernel matrix defined as follows:

$$\begin{aligned} K(X,X) &\in \mathbb{R}^{M\times M}, & K_{i,j} &= k(\xi_i,\xi_j) \\ K(X^*,X) &\in \mathbb{R}^{1\times M}, & K_{1,j} &= k(\xi^*,\xi_j) \\ K(X,X^*) &\in \mathbb{R}^{M\times 1}, & K_{i,1} &= k(\xi_i,\xi^*) \\ K(X^*,X^*) &\in \mathbb{R}, & K &= k(\xi^*,\xi^*) \end{aligned} \quad (7)$$

A key parameter in GPR is the kernel function denoted as $k(\cdot,\cdot)$ in (2). It encodes the structure of functions in the space of distributions. In this work, the squared exponential kernel function is employed:

$$k(x_1,x_2) = \sigma_f^2 \, exp\left(-\frac{1}{2l^2}(x_1-x_2)^T(x_1-x_2)\right) \quad (8)$$

The goal of GPR is to predict the joint motion y^* conditioned on the new environmental information $\boldsymbol{\xi}^*$ and the observed information from the demonstrations. It is assumed that noises σ_n from process and measurement are identically distributed within demonstrations. In this case, the joint distribution of y^* can be described as:

$$y^*|y, D \sim \mathcal{N}\,(\mu^*, \Sigma^*) \quad (9)$$

where

$$\mu^* = K(X^*,X)(K(X,X) + \sigma_n^2 I)^{-1} y \quad (10)$$

$$\Sigma^* = K(X^*,X^*) + \sigma_n^2 I - K(X^*,X)(K(X,X) + \sigma_n^2 I)^{-1} K(X,X^*) \quad (11)$$

The performance of GPR depends on so-called hyper parameters [σ_n, σ_n, l] which can be defined by maximizing the marginal log likelihood [23]. We use GPflow to model GPR and also to estimate the parameters [24].

Using these equations, the proposed controller generates joint trajectories based on expert human demonstrations which indicate the operator maneuvers we would like to apply to the manipulator.

3.3 Programming by Demonstration Framework

During demonstrations of different lengths, the sensor information is collected and stored as training input-output pairs. The mapping from the input to the output is called a policy and is modeled from equations (6) - (11), so that the model can predict a new output based under different input conditions based on the learned policy. In our work, multiple demonstrations of different lengths are used to model the policy. Accordingly, the time alignments of the demonstrated trajectories are normalized using Dynamic Time Warping (DTW) method [25].

Suppose we have m demonstrations with BROKK 170, then the demonstrations are normalized to the length T. The data set D for the GP will be of length $n = mT$. Thus, the data set can be formulated as $D = \{\xi_i, y_i \} \mid i = 0, \ldots, mT$.

In our training phase, policies are created with respect to the initial joint states q and the temporal value. In our experiments, we use simple timestamp t as the temporal value. More precisely, joint angle values are collected and stored during an expert demonstration, where the expert controls each joint to move the end-effector tip straight forward. Policies are created with respect to these collected values so that new trajectories in the joint space can be generated for the new initial joint angle values and the timestamps.

In the reproduction phase, a new initial starting point is defined with joint angle values. Together with the timestamps, the initial joint angle values are used as input for the trained Gaussian process models.

In the evaluation phase, the predicted trajectories are directly tracked with a fixed maximum joint speed. The

resulting end-effector trajectory is obtained by computing the forward kinematics relationship and compared with the end-effector trajectory generated by the CLIK solver.

4 Experiment

We demonstrate our framework on a hydraulic demolition machine BROKK 170. Originally, the BROKK 170 demolition machine is designed to be controlled with a remote controller in a strict master-slave relationship limiting the control to a single paradigm. To control the machine with computation algorithms and integrate computational capabilities in the machine control, we follow the approach introduced in [19].

Our host PC interacts with the main control unit (MCU) of the machine through a bus controller MCP2515 and an embedded controller Mega2560. The communication takes place via the Controller Area Network (CAN) bus system. The bus protocol containing information about bus messages is obtained from the manufacturer. The script is developed in C++ on the host PC and then compiled and deployed to the embedded controller via Arduino IDE.

In this work, the kinematics of the machine and the shape of each axes are assumed to be known, so that the joint angles are enough to describe the full configuration of the machine, in particular the end-effector pose. Like most other construction machines, BROKK 170 used in this work is not equipped with any sensors. We use wire-type encoders (BCG05, SICK) to measure the joint angle values q_2, q_3, q_4, q_5 and a rotary encoder (A3M60, SICK) to measure q_1. The joint angle values are separately measured and sent to the host PC via Wi-Fi-Modules ESP8266 at a rate of 20 Hz. UDP packets are used for data exchange between the Arduino IDE and the proposed controller developed in Python.

The experiment consists on moving the manipulator straight forward from the initial point which requires structured joints movement. Moreover, the non-linearities of the hydraulic system complicate the task, so that trajectories generated by a conventional IK solver result in poor quality, as depicted in Figure 4. Throughout the experiments, the base q_1 is not used, since the trajectories for the given task lie within the xz-plane. The second axis q_2 is also not utilized in our experiment, since it cannot be simultaneously moved with other axes in the current setup.

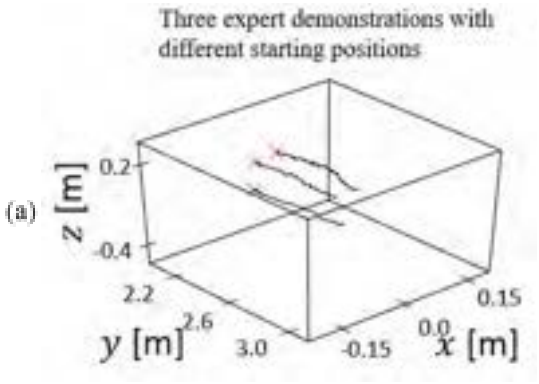
Figure 3. The task considered in this work: By moving the joints q_3, q_4 and q_5 with joysticks the operator tries to end-effector tip straight forward.

For the given task, the environment conditions are the initial joint positions and the timestamp, $\boldsymbol{\xi} = \{(q_{3\_o}, q_{4\_o}, q_{5\_o}, t_i) | i = 0, \dots, T\}$. The joint trajectories are used as observations, $y = \{(q_{3\_i}, q_{4\_i}, q_{5\_i}) | i = 0, \dots, T\}$. Three demonstrations are performed under various initial positions, as shown in Figure 4. Since the execution time for demonstrations slightly differs The demonstrations are of different lengths. We order these demonstrations according to their length:

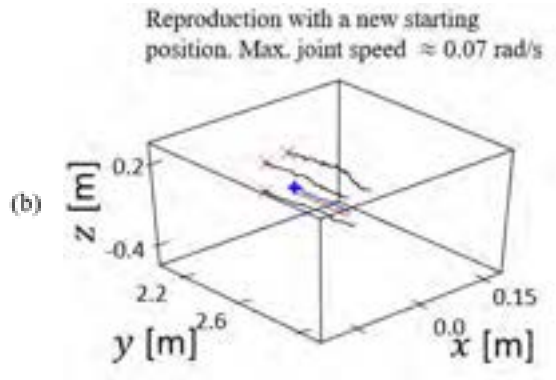
$$D_{m-1} < D_m < D_{m+1} \tag{7}$$

Using the median length sequence $\overline{D} = D_{[2]}$ as a reference demonstration, the rest of the demonstrations are aligned in the time domain using DTW. The result of the DTW is illustrated in Figure 5. The thick trajectories represent the reference trajectories estimated as described above. It can be clearly seen that the temporal variations in the demonstrations are synchronized after the DTW process.

We perform trajectory planning with a new initial joint values $[q_{3\_o}, q_{4\_o}, q_{5\_o}] = [-0.547, 1.107, 1.016]$. The reproduction of the expert's demonstrations with respect to the new condition is visualized in Figure 6. It is worth noting that the step size for each joint trajectory is empirically estimated. The resulting end-effector trajectory is visualized in Figure 5. Since the effect from the non-linearities in the hydraulic system increases with the joint angle speed, we evaluate the developed system with two different joint angle speed: $\dot{q}_{max} = 0.11\ rad/s$ and $\dot{q}_{max} = 0.07\ rad/s$.



.



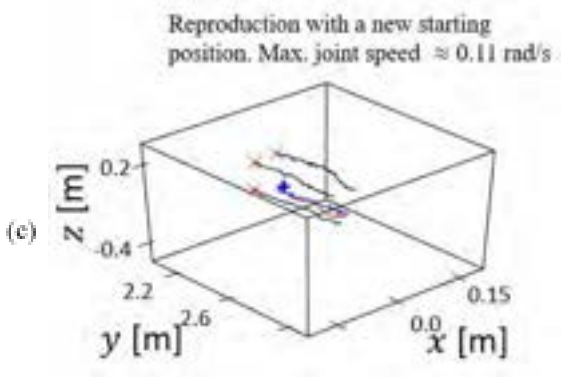


Figure 4. Three demonstrations for the given task in 3D Cartesian space (a). During the demonstrations different initial joints angles are considered. The resulting end-effector tip positions are visualized with 'x' signs. The demonstrations are reproduced for the new initial joints angles (blue '+' signs). The corresponding end-effector tip trajectories are visualized in (b) and (c) by computing the forward kinematic relationship (blue). The red trajectories are generated using the CLIK solver.

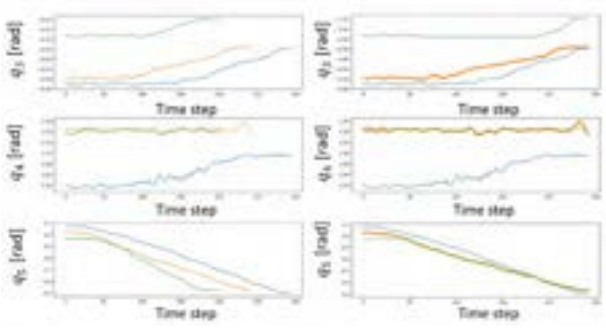

Figure 5. Results of collected trajectories in the joint space before (left) and after (right) the DTW process. The thick lines in the right plots represent the reference trajectories.

To quantify the correctness, first, the end-effector position is computed using the forward kinematic solution with the reproduced joint trajectories. Then, the desired end-effector trajectory (i.e. from the given initial position straight forward) is uniformly resampled with the total number of data points on the computed end-effector trajectory. Finally, the RMS error between the computed and planned end-effector trajectories in the operational space is computed.

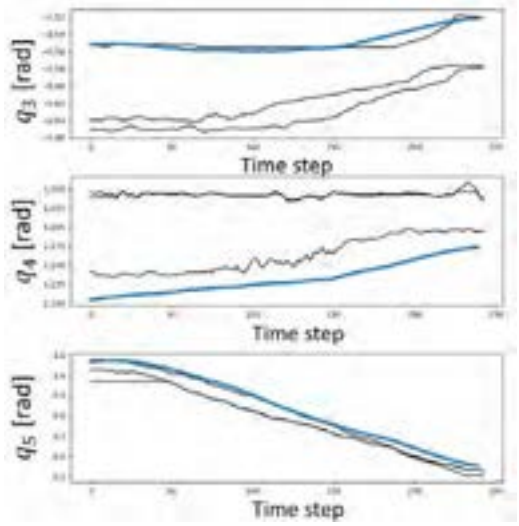

Figure 6. The black trajectories show the collected values from the demonstrations. The blue trajectories show the reproduction attempt by considering the new condition $[q_{3\_o},\ q_{4\_o},\ q_{5\_o}] = [-0.547,\ 1.107,\ 1.016]$. It can be clearly seen that the joint 5 q_5 is mainly used in the demonstration and this policy is preserved in the reproduced trajectories.

The same task is executed using the CLIK solver and the results are compared with the tracking results from the developed GPR based system. For the given task, the RMS errors of the CLIK solver are 0.027 m at the maximum joint angle speed of 0.07 rad/s and 0.039 m at

the maximum speed of 0.11 rad/s, respectively. Whereas the reproduced trajectories result in 0.016 m and 0.025 m, respectively.

Table 1. RMS error comparison in tracking task

	Max. Speed	RMSE
CLIK	0.07 rad/s	0.027 m
GPR	0.07 rad/s	0.016 m
CLIK	0.11 rad/s	0.039 m
GPR	0.11 rad/s	0.025 m

The end-effector tip trajectories generated by both the CLIK solver and the proposed system are visualized in Figure 7. We see that the trajectory from the CLIK solver deviates from the desired trajectory, whereas the deviation is smaller by the trajectory that is generated from expert demonstrations.

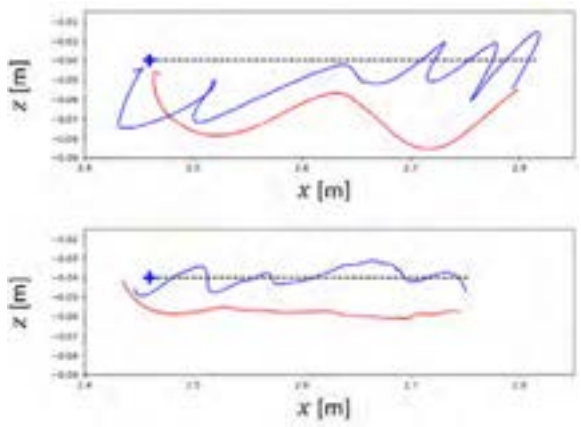

Figure 7. Results with both the reproduction from expert demonstration (blue) and from the CLIK solver (red). The desired trajectory is visualized with dashed line.

5 Discussion

In the experiments, the dimension of environmental conditions was set to four. Because of the low dimensionality, the policy of controlling a nonlinear hydraulic system could be modeled and reused to generate an appropriate end-effector trajectory using a relatively small number of expert demonstrations.

The proposed approach presents advantages by directly providing reference trajectories in the joint space. Compared to the inverse kinematic approach which typically generates joint motion without considering the non-linearities in a hydraulic system. As a result, the discrepancy in Figure 7 occurred which is increased according to the increased joint angle speed. During the demonstrations the expert corrects the joint motions according to the effect generated by the non-linearities in the hydraulic system. More precisely, the expert takes into account that he cannot perfectly move multiple axes at the same time and adapt the axes motion according to the resulting non-linear motion. By reproducing trajectories in the joint space considering this policy we slightly improve the tracking result. The captured policy that the joint 5 q_5 should be mainly utilized for the given task is valid for the faster joint angle speed, thus improving the tracking result as shown in Table 1.

However, as the GPR models the joint distribution of the observed data, the learned policy is only valid in the range of given demonstrations. Although the expert can demonstrate to cover the great area of workspace to reduce the uncertainty in the prediction caused by unforeseen environmental conditions. An efficient approach which can apply the existing demonstrations for the unforeseen conditions should be studied.

6 Conclusion

This study presented a framework for generating trajectories based on expert demonstrations. This work showed an alternative to programming a teleoperated construction machinery without a dynamical model. The experiment showed the preliminary performance of the proposed scheme. The expert demonstrations were normalized in the time domain using DTW and the mapping between the environmental conditions and the joint trajectories was modeled using GPR. By learning the mapping between the exact joint trajectories and the initial joint positions, the policy from a human expert could be learned so that a specific joint can be mainly utilized to perform the given task. The proposed scheme was implemented in a teleoperated deconstruction machinery, and the performance of the developed system was tested through preliminary experiments showing improved results compared to the inverse kinematic approach. Experimental results indicate the feasibility of construction machinery automation using generalizing the human demonstrations.

Future work will consider the use of Reinforcement Learning to equip the machine with self-improvement abilities. As shown in Figure 4, it was even for an experienced operator a challenging task to move the tip of the end-effector straight forward, since the operator can only see the appropriateness of its joystick manipulation after the machine has moved. We also aim at extending our framework to dynamic environmental conditions, since in this work only static conditions such as the initial joint angle values are considered.

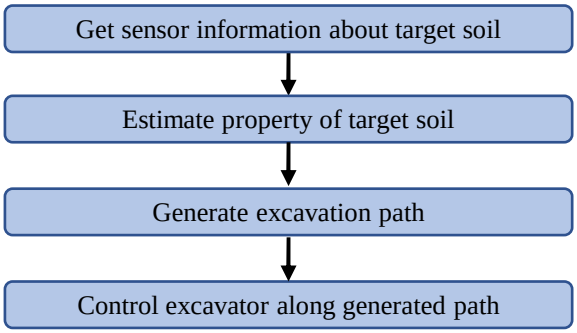

Figure 1. Overall process of autonomous excavation

does not consider the interaction between the excavator tools and the soil. Therefore, it is unclear whether this method will even work in an actual excavation process.

Yamamoto et al. developed a prototype of an autonomous hydraulic excavator using 3-D information of the construction model and successfully demonstrated the autonomous operation of hydraulic excavators[2]. However, while this method does not require any orders from human operators during the excavation process, the users must manually specify the excavation path in advance according to the target soil ' s properties. Therefore, the efficiency of the excavation process might degrade in a situation where the soil properties are unknown.

To address the above-mentioned problems, this study aims to establish an excavation path generation method that guarantees high efficiency based on the soil type. For this purpose, the excavator must automatically generate an excavation path itself according to the property of the target soil. Therefore, we focus on the bulking factor of soil, which is a soil property frequently used in construction sites, as an indicator of soil type. By considering the bulking factor of the target soil, we realize an efficient excavation for different soil types.

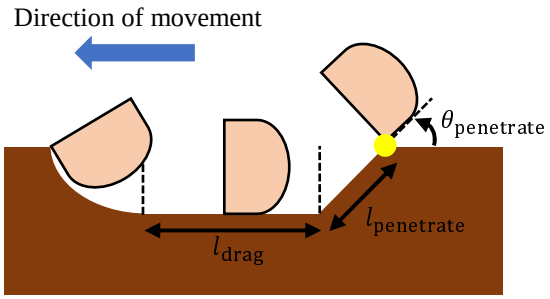

Figure 3. Modeled excavation path

we find a set of appropriate parameters $[\theta_{\text{boom}}, \theta_{\text{arm}}, \theta_{\text{bucket}}]$ for the entire excavation process.

2.3 Excavation Model

In this study, the excavation process is modeled using three parameters: $[\theta_{\text{penetrate}}, l_{\text{penetrate}}, and l_{\text{drag}}]$. In this modeling, we refer to the excavation motion performed by experienced operators as a reference. In general, the excavation motion can be classified into three phases: penetrate, drag, and scoop [5]. In the penetration phase, the operators pierce the surface of the target soil using the bucket edge and move the bucket until it reaches the bottom line. Then, the bucket is dragged horizontally along the bottom line. Finally, to collect the accumulated soil into the bucket, the scooping motion is executed. To model this excavation motion, the three above-mentioned parameters have been used; the excavation path represented by them is illustrated in Fig. 3. Here, $\theta_{\text{penetrate}}$ indicates the angle between the soil surface and the penetrating line, $l_{\text{penetrate}}$ indicates the length of the penetrating line, and l_{drag} indicates the length of the dragging line. In the scooping phase, only the bucket part is rotated by 90°, with the tip of the arm part fixed in position. Once these parameters are determined, the position of the bucket tip and the rotation of the bucket over the whole excavation process can be determined. By using this position and rotation of the bucket, the parameters $[\theta_{\text{boom}}, \theta_{\text{arm}}, and \theta_{\text{bucket}}]$, explained in section 2.2, can be calculated using inverse kinematics.

2.4 Bulking Factor of Soil

As discussed in Section 2.3, three parameters have been used to specify the excavation model. The values of these parameters need to be defined. In this respect, the soil property is accounted for so that the generated path can guarantee its efficiency for different soil types. For this purpose, this study considers the bulking factor of soil, which is a soil property based on the phenomenon observed in the excavation process [6]. In general, the exca-

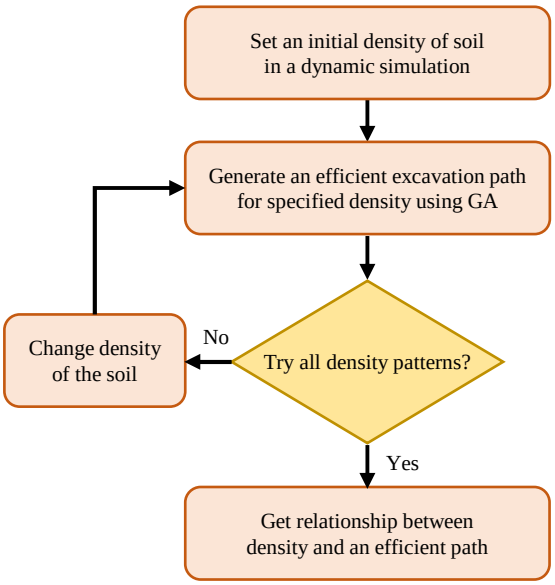

Figure 4. Excavation path generation process

vated soil particles do not fit together as they did before excavation, which increases the void space among these particles. Thus, the soil volume increases after excavation, and the bulking factor of soil is used to quantify this volume increase. Qualitatively, soil with a large bulking factor means the soil is hard. Conversely, soil with a small bulking factor means the soil is soft. Assuming k to be a bulking factor of soil, it can be defined as follows:

$$k = \frac{V_{\text{after}}}{V_{\text{before}}}, \tag{1}$$

where V_{after} and V_{before} denote the volumes after and before excavation, respectively. In related works, there are other properties of soil such as soil density used in [7]. However, this study focuses on the bulking factor of soil because of its simplicity of measurement. Compared to the other properties of soil, the bulking factor can be easily calculated, by simply measuring the volumes before and after excavation with an RGB-D sensor.

2.5 Path Generation with Dynamic Simulator

In this section, the excavation path generation method using a dynamic simulator has been explained. As discussed in Section 2.4, the proposed method generates an efficient excavation path based on the soil properties, to guarantee efficient excavation for any soil type. To enable this, the proposed method learns the relation between the soil property and an efficient excavation path using a dynamic simulator before executing the actual excavation. The use of a dynamic simulator allows us to replicate the interaction between the excavator and soil during the excavation process. In addition, the properties of the target soil can be changed by specifying the simulator parameters.

The process of excavation path generation using a dynamic simulator is shown in Fig. 4. To understand the relation between soil property and an efficient excavation path, efficient excavation paths for different soil properties were determined in advance. Specifically, an efficient excavation path is generated while changing the initial density of soil in the simulation. In terms of the method for finding an efficient excavation path for each condition, a genetic algorithm (GA) is used, where the excavation model parameters $[\theta_{\text{penetrate}}, l_{\text{penetrate}}, and l_{\text{drag}}]$ are regarded as the genes of each individual. Based on this setting, the fitness of each individual is defined as follows:

$$f = \frac{V_d}{E}, \tag{2}$$

where f denotes the fitness of each individual, V_d denotes the volume of soil accumulated in the bucket during one excavation motion, and E denotes the total energy consumed by the excavator joints during the excavation motion. According to this formalization, an efficient excavation path is ideally assigned high fitness. Thus, an efficient excavation path can be obtained as the final output of GA. This operation is repeated until an efficient excavation path for all density patterns is obtained. Furthermore, the relation between the density and efficient excavation path is obtained, which will be used for path selection during the actual excavation process.

2.6 Path Selection via Bulking Factor

In this section, the path selection method based on the bulking factor has been explained. As discussed in Section 2.5, the proposed method has already analyzed the relation between the soil density and an efficient excavation path through a dynamic simulator. These findings are used in the process of path selection. However, it is not easy to measure the density of the target soil directly. Therefore, the bulking factor of soil is used to estimate the soil density because measuring the bulking factor is not difficult. In terms of the density estimation method, empirical knowledge is used. According to the model described in [8], higher the soil density, larger is the bulking factor. In this way, the soil density is estimated via the bulking factor calculated using the measurement data. After we obtain information about the density of the target soil, we select an efficient excavation path using the knowledge gained via the dynamic simulator.

Table 1. Conditions of the genetic algorithm

Parameters	Value
Number of generations	10
Number of individuals	15
Probability of crossover	0.8

Table 3. Three conditions of soil

Conditions	Density [%]
Soft soil	20
Medium soil	50
Hard soil	80

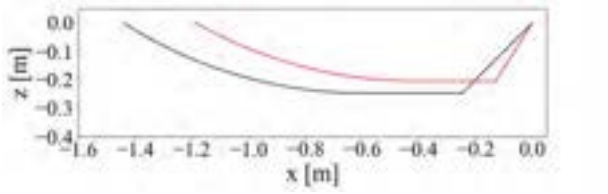
(b) Medium soil



(c) Hard soil

Figure 5. Calculation results for each condition

$[\theta_{\text{penetrate}}, l_{\text{penetrate}}, and l_{\text{drag}}]$ were set to $[\pi/6, 0.35, 0.35]$, respectively.

3.2 Experimental Result

Figure 5 shows the calculation results for each condition. In Fig. 5, (a) shows the result for soft soil, (b) shows the result for medium soil and (c) shows the result for hard soil. In each graph, the red line shows the trajectory of bucket tip in case of using the proposed method, while the black line shows the trajectory of bucket tip in case of not using the proposed method. Here, the origin [x, z] = [0, 0] is defined as a position where an excavator starts penetrating. As shown in Fig. 5, the proposed method changed the excavation path according to the soil condition. Figures 6 and 7 show the results of the simulation experiment. Figure 6 shows the efficiency of soft and medium soil and Figure 7 shows the efficiency of hard soil. In each graph, the left light-blue bar shows the excavation efficiency in case of not using the proposed method, while the right dark-blue bar shows the excavation efficiency generated by the proposed method. As shown in Figs. 6 and 7, the

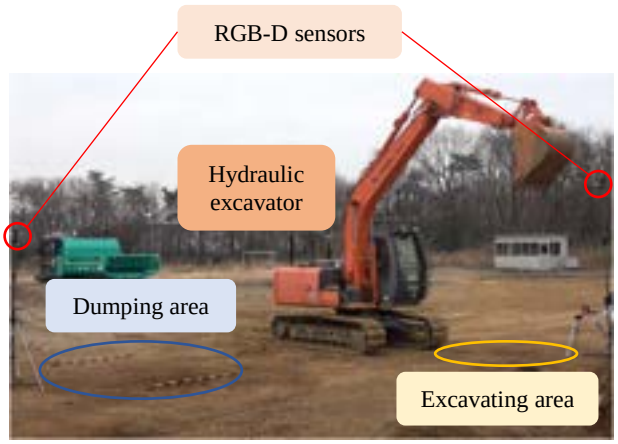


Figure 8. Field experiment setting

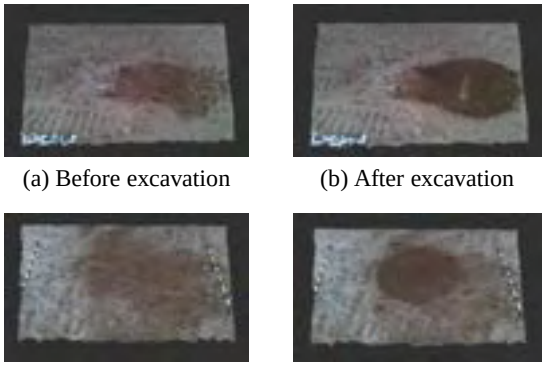


(a) Before excavation (b) After excavation

(c) Before dumping (d) After dumping

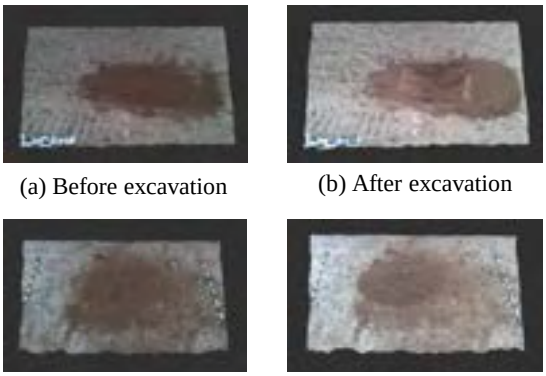
Figure 9. 3-D point cloud data (First trial)

of soil was calculated by considering the differences between the soil volume before and after dumping. Based on the above volume changes, the soil volumes before and after excavation were calculated, and its bulking factor was calculated based on these data.

In this experiment, the bulking factor was calculated under two conditions. For the first trial, compacted soil was excavated. For the second trial, the soil we filled back after the first trial was excavated. Thus, the soil for the second trial was loosened than that in the first trial. This enabled us to confirm the possibility of calculating the bulking factor of soil, which has a different density.

4.2 Experimental Result

The 3-D point cloud data obtained in this experiment are shown in Figs. 9 and 10. Figures 9 and 10 show the data of the first and second trials, respectively. In both these figures, (a) shows the area before excavation, (b) shows the area after excavation, (c) shows the area before dumping, and (d) shows the area after dumping. Table 4 lists the soil



(a) Before excavation (b) After excavation

(c) Before dumping (d) After dumping

Figure 10. 3-D point cloud data (Second trial)

Table 4. Bulking factor k of soil

	$V_{\text{before}}[m^3]$	$V_{\text{after}}[m^3]$	k
First	0.4552	0.6619	1.4540
Second	0.5081	0.5926	1.1663

volume before excavation, V_{before}; that after excavation, V_{after}; and the bulking factor of soil, k, calculated using 3-D point cloud data. As discussed in Table 4, the value of the bulking factor of soil in the first trial is larger than that in the second trial. This indicates the difference in density between the first and second trials. Therefore, the bulking factor of soil can be calculated based on the 3-D measurement data.

5 Conclusion

This paper proposes an excavation path generation method for an autonomous excavator. The proposed method considers the bulking factor of soil as a soil property during the excavation process, which enables the generation of an efficient excavation path for different soil types. A GA was used to determine an efficient excavation path for a specific soil. Additionally, a simulation and a field experiment were conducted to validate the proposed method. For future work, it is necessary to complete the implementation of the entire system on an actual hydraulic excavator and perform full-scale field experiments to validate the proposed method.

Abstract –

In this research, a sway suppression algorithm was developed for a crane operator support system. To evaluate the effect of sway suppression, a crane experiment testbed was manufactured. The crane testbed is designed by the crane dynamic model, and the swing motion, boom motion and load hoisting are driven by the electric motors. The validity of the dynamic model for a crane was verified by the testbed experiment. The algorithm for sway suppression is consisted of the open loop control based on the phase plane theory, and was implemented in the testbed. The effect of sway suppression was verified by the testbed, and the effectiveness of algorithm was confirmed.

Crane; Sway Suppression; Phase Plane; Model

1 Introduction

In recent years, the number of skilled operator has decreased and many demands for safety work in construction site has increased. Therefore, the automation and improving safety function of construction machinery has become an important subject. Especially, there are many danger in rotary crane operation because of many reasons such as its fall down, load's sway, and so on.

There are many researches about sway suppression control of the translation crane[1][2][3]. Because the translation crane moves two axis independently, the load's sway in two dimensional plane can be suppressed easily.

But considering about the rotary crane, since it controls the load by swing and boom motion, it is difficult to move like the translation crane and the centrifugal force works to the load, so the load's sway is difficult to suppress.

For sway suppression for the rotary crane, there are some researches[4][5][6]. However, implementing feedback system or complex control system in real machine has many problems in ensuring safety.

To solve these problems, we had proposed a simple algorithm based on open loop control for crane sway suppression only using swing motion, and also developed a crane experiment testbed to evaluate the effect of the algorithm. This crane testbed has three electric motors for swing motion, boom motion and load hoisting, and we confirmed the effect of the algorithm by using the crane testbed.

2 Sway suppression algorithm

2.1 Principal of the algorithm

There are many researches of translation crane with using open loop control based on a phase plane which describes state of vibration[7][8]. The concept of the phase plane is shown in Figure 1, where l is the wire length, g gravitational acceleration, and θ deflection angle.

The equation of motion is described as Equation (1). From solving Equation (1), the deflection angle and angular velocity are described as Equation (2) and (3), where A is a constant.

$$\theta'' = -\frac{g}{l}\theta = -\omega^2\theta \quad (1)$$

$$\theta = A\cos(\omega t) \quad (2)$$

$$\theta'/\omega = -A\cos(\omega t) \quad (3)$$

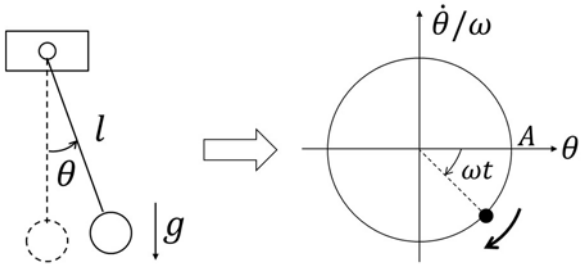

Figure 1. Concept of the phase plane

Based on Equation (2) and (3), the phase plane is described using the deflection angle as the horizontal axis, and the angular velocity, which normalized by natural

frequency ω, as the vertical axis.

The motion of pendulum is translated as rotation motion in the phase plane, and the time required for one round is pendulum period T ($=2\pi/\omega$).

As shown in Figure 2, considering when the acceleration a is applied to the crane, the equation of motion changes to Equation (4). Transforming this equation into Equation (5), it can be seen the rotary motion on the phase plane is switched into the rotation which its center is $-a/g$.

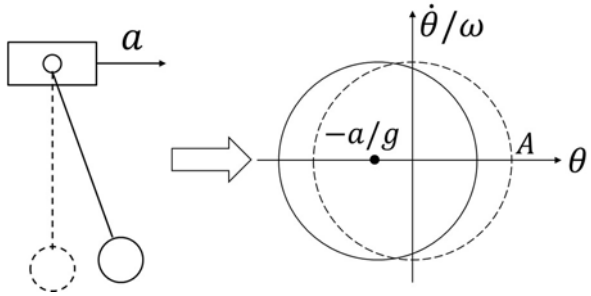

Figure 2. Effect of acceleration in the phase plane

$$\theta'' = -\frac{g}{l}\theta - \frac{1}{l}a \quad (4)$$

$$\left(\theta + \frac{a}{g}\right)'' = -\frac{g}{l}\left(\theta + \frac{a}{g}\right) \quad (5)$$

Hence, by giving the required acceleration at appropriate timing, the rotation motion can be directed to the origin. Shown in Figure 3, make the acceleration zero when the motion is reached to the origin, the vibration can be converged.

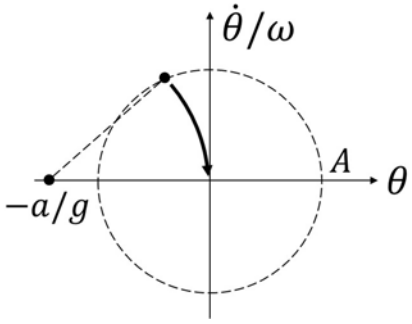

Figure 3. Convergence of the vibration

Based on the above theory, the acceleration pattern shown in Figure 4 is proposed as the sway suppression algorithm. According to this pattern, the acceleration a is first applied to the stopped crane for a time Δt. Next, the acceleration is set to zero for a time $T/2$-Δt, where the crane moves as uniform motion. Finally, setting the acceleration to a for a time Δt, the crane can accelerate without swaying. And then, after transporting the crane for arbitrary time, the crane can be stopped without swaying by applying the deceleration pattern, which the sign of the acceleration pattern is reversed.

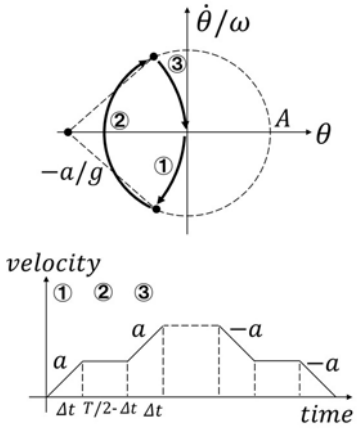

Figure 4. Sway suppression algorithm pattern

2.2 Pendulum model in crane's 3D motion

In order to apply the sway suppression pattern, which described in previous section, the dynamic model of the crane is expressed in this section. Figure 5 shows the model of the crane. By taking the coordinate system as shown in Figure 5, the position of boom tip (x, y, z) is expressed by Equation (4)~(6), where l is the wire length, g gravitational acceleration, B boom length, p swing angle, q boom angle, and ψ, φ sway angle.

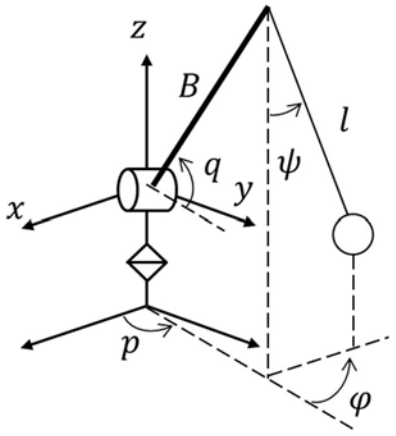

Figure 5. Crane dynamic model

$$x = B\cos q\cos p \quad (6)$$

$$y = B\cos q\sin p \quad (7)$$

$$z = B\sin q \quad (8)$$

Hence, the acceleration at the boom tip is described as Equation (9)~(11).

$$x'' = -Bq''\sin q\cos p - Bp''\cos q\sin p - B(q'^2 + p'^2)\cos q\cos p + 2Bq'p'\sin q\sin p \quad (9)$$

$$y'' = -Bq''\sin q\sin p + Bp''\cos q\cos p - B(q'^2 + p'^2)\cos q\sin p - 2Bq'p'\sin q\cos p \quad (10)$$

$$z'' = Bq''\cos q - Bq'^2\sin q \quad (11)$$

Then the position of load's centroid (x_p,y_p,z_p) can be described as Equation (12)~(14), where the origin of load's coordinate system is the boom tip.

$$x_p = lsin\psi cos\varphi \quad (12)$$

$$y_p = lsin\psi sin\varphi \quad (13)$$

$$z_p = -lcos\psi \quad (14)$$

According to Equation (12)~(14), the equations of rotary motion about ψ, φ are described as Equation (15), (16), where x'', y'', z'' is the acceleration at the boom tip described in Equation (9)~(11).

$$\psi'' = -\frac{1}{l}(2l'\psi' - l\varphi'^2 sin\psi cos\psi + gsin\psi + cos\psi cos\phi x'' + cos\psi sin\phi y'' + sin\psi z'') \quad (15)$$

$$\varphi'' = -\frac{1}{lsin\psi}(2l'\varphi' sin\psi + 2l\varphi'\psi' cos\psi - sin\varphi x'' + cos\varphi y'') \quad (16)$$

3 Simulation with crane testbed

3.1 Configuration of crane testbed

In the previous chapters, the sway suppression algorithm and the crane dynamic model were described.

In order to confirm these above, a crane experiment testbed has been made as shown in Figure 6.

Table 1 shows the specifications. The crane testbed has three electric motors for swing, boom and hoisting, and these motors has the encoder for measuring a motor angle and angular velocity. For holding the posture, the boom and hoisting motors are connected to the winches driven by the worm wheels.

Table 1. Specification of a crane experiment testbed

	Specification
Boom	length 1.0 m (parallel link)
Load	400.0 g (30.0*50.0*80.0mm)
Swing Motor	Max angular velocity 135.0 deg/s
Boom Motor	Max angular velocity 6.8 deg/s
Hoist Motor	Max angular velocity 32.6 deg/s
Camera	DFK Z30GP031 (30 fps)

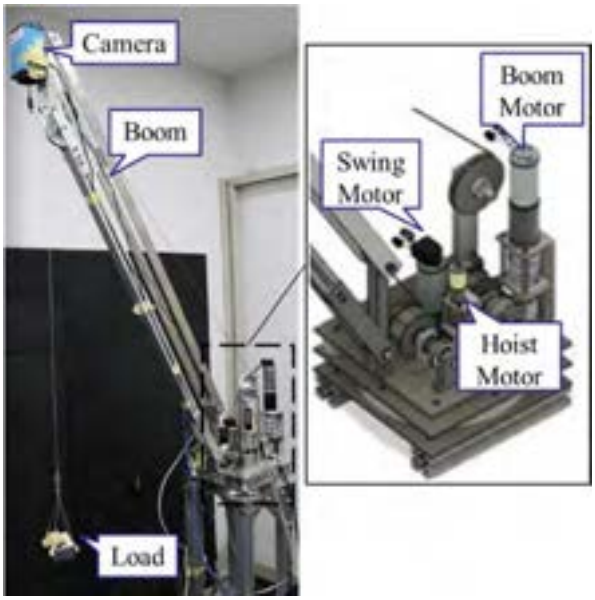

Figure 6. Crane experiment testbed

Here, a camera is mounted on the boom tip to measure the centroid of the load. The boom is composed of the parallel link so that the camera faces perpendicular downward regardless of the boom angle. Figure 7 shows the relationship of the coordinate of system between crane and camera. The xy coordinates of the camera (x_{cam}, y_{cam}) are expressed as a state, which they are rotated by $-\pi/2$ [rad] about z axis of the coordinate of crane and further by swing angle p.

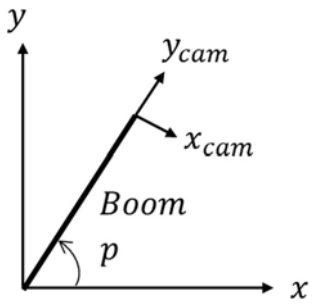

Figure 7. Camera coordinates

3.2 Configuration of control system

The control system configuration of the crane testbed is shown in Figure 8. This system has the crane testbed, a motor driver, an image processing PC for camera, a rapid controller which includes the crane dynamic model, and host PC for the rapid controller. These components are coupled and make one simulation system. The dynamic model in the rapid controller has been modelled as mathematical equations and implemented in MATLAB & SIMULINK models. The crane testbed is

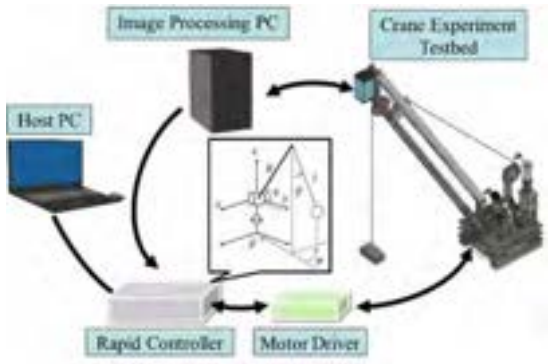

Figure 8. System Configuration

driven by the control signal, which outputted from the host PC via the rapid controller and the motor driver. In addition, the image acquired by the camera is sent to the image processing PC, and the *xy* coordinates of the load's centroid are calculated.

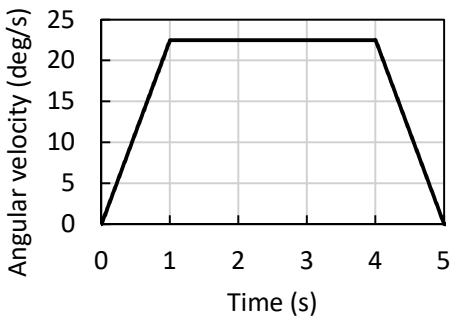
The *xy* coordinates are sent to the rapid controller for recording. The frame rate of the camera is 30 fps, and it is possible to calculate and output the coordinates of each frame in real time.

3.3 Verification of sway suppression

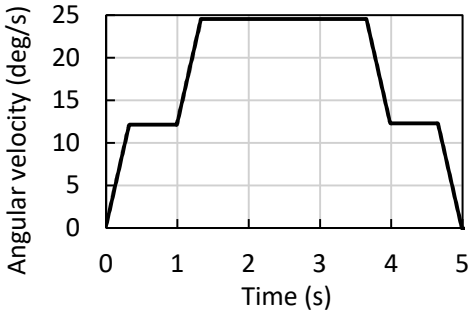
The sway suppression algorithm is verified in the crane testbed by applying the algorithm to the swing motor. The simulation conditions are shown in Table 2.

Table 2. Simulation conditions

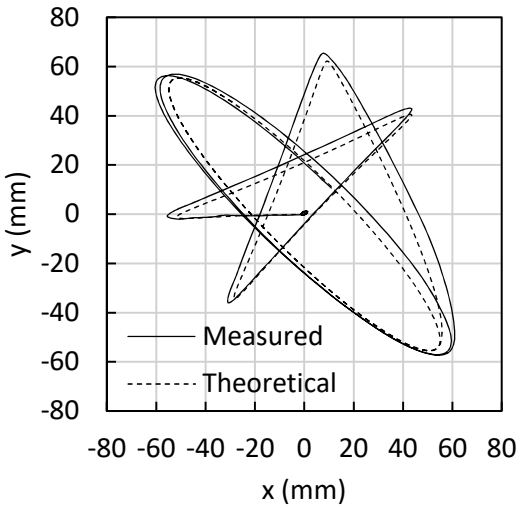
	Specification
Wire	1 m fixed
Boom Angle	60 deg fixed
Swing Angle	90 deg swing
Transport time	5 s



(a) Velocity Pattern

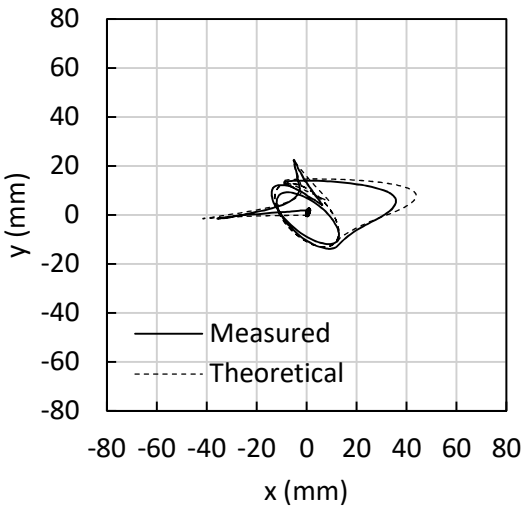


(a) Velocity Pattern



(b) Locus of load's centroid

Figure 9. Experiment results



(b) Locus of load's centroid

Figure 10. Experiment results

First, it is confirmed whether the behaviour of the load of the crane testbed follows the crane dynamic model. The results of the experiment are shown in Figure 9. The velocity pattern described in Figure 9 (a) is inputted to the swing motor, and then the locus of the load's centroid is observed, as shown in Figure 9 (b), by the camera on the boom tip.

Since this input pattern is not match the sway suppression algorithm pattern, it can be seen from the locus that the amplitude of the residual vibration ±60mm in the *x* direction and ±60mm in the *y* direction.

By comparing the locus calculated by the equation of motion with the measured locus of the load, the crane dynamic model is considered to be sufficient, though there are slight error in the locus. This error is considered to be occurred since there are many parameters not included in the equation of motion such as the vibration, expansion and contraction of the wire.

Next, the results of the experiment are shown in Figure 10 with inputting the sway suppression algorithm. The input pattern described in Figure 10(a) is inputted to the swing motor of the crane testbed, and then the locus of the load's centroid is observed, as shown in Figure 10(b).

Comparing with the result in Figure 9 (b), the amplitude of the residual vibration in Figure 10(b) is suppressed well, where the amplitudes are ±13mm in the *x* direction and ±13mm in the *y* direction. This residual vibration is mainly caused by the centrifugal force.

According to this experiment, the algorithm is also effective when it is applied only to the swing axis, if the posture change of crane is small during the acceleration and deceleration period.

Future work will aim the development of the sway suppression algorithm which includes the compensation of the centrifugal force, using this simulation system.

4 Conclusion

In this research, an algorithm for the crane sway suppression was proposed, which based on the phase plane theory, and confirmed its effectiveness by applying to a crane experiment testbed, which composed of the electrical motors and the link mechanism. And also, the validity of the crane dynamic model was verified.

According to the experimental results, it is confirmed that applying the algorithm only to the swing axis is effective, when the posture change of crane is small during the acceleration and deceleration period.

In future work, the new sway suppression algorithm needs to be proposed, which includes the compensation of the centrifugal force by the swing motion, and verified by applying to the crane testbed.

Abstract –

The energy consumption of a backhoe during digging operation is the sum of the energy due to earth pressure and backhoe motion. The authors' previous studies have revealed the earth pressure model on the arc trajectory, but not on the horizontal trajectory, which is often used in normal digging operation. Moreover, in order to optimize energy efficiency, a comparative experiment of energy consumption was carried out for the multiple excavation trajectories involving horizontal direction. However, since the theoretical model of earth pressure has not been completed, the experimental data obtained from the testbed is used as a reaction force. If it can be confirmed that the reaction force of the horizontal trajectory can be calculated with a theoretical value, the energy efficiency can be calculated from the excavation trajectory without experiment. In this study, the earth pressure model for the horizontal trajectory was confirmed, and the method for the evaluation of energy efficiency was verified using the theoretical values.

Keywords –

Backhoe; Digging force; Coulomb's earth pressure

1 Introduction

In recent years, autonomous construction machines have been developed due to the decrease in the working population and the deterioration of infrastructure. The automatic construction system for construction machinery is complicated by three-dimensional measurement, operation planning, electronic hydraulic control, etc. [1]. In the case of a construction machine that excavates sediment like a backhoe, automatic control is difficult because the reaction force affects the operation and the energy consumption of the machine. We have formulated the reaction force during digging operation based on Coulomb's earth pressure theory by observing the behavior of sediment in the bucket when the backhoe scoops sediment on the arc trajectories [2]. The energy consumption of a backhoe during digging operation is the sum of the energy due to earth pressure and backhoe motion, and the excavation efficiency was evaluated [3]. However, although the earth pressure model for the arc trajectory has been clarified, but not on the horizontal trajectory which is often used in normal digging operation. The earth pressure model for horizontal trajectories depends on the amount of sediment deposited on the upper side of the bucket. Therefore, it is necessary to consider the amount of sediment. In addition, in order to optimize energy efficiency, a comparative experiment of energy consumption was carried out for the multiple excavation trajectories involving horizontal direction [3]. However, since the theoretical model of earth pressure has not been completed, the experimental data obtained from the testbed is used as a reaction force. If it can be confirmed that the reaction force of the horizontal trajectory can be calculated with a theoretical value, the energy efficiency can be calculated from the excavation trajectory without experiment. In this study, we verified the earth pressure model for the horizontal trajectory and applied it to the calculation of the excavation energy. Using the sum of the energy due to earth pressure and backhoe motion, we evaluated the energy efficiency without any experiment.

2 Overview of experiment system

Figure 1 shows an excavation testbed used in this study. The mechanism consists of three axes: an X axis that moves horizontally, a Y axis that moves vertically, and an R axis that rotates the bucket. The backhoe excavation motion can be simulated by giving displacement and velocity to each axis. The sediment container installed at the bottom of the equipment is the same size as the drive range, and the wall on one side of the container is made of polycarbonate. This makes it

possible to observe sediment behavior during digging. The bucket made of stainless steel is designed on the 1/14 scale of the actual machine, and a removable side plate is attached. Only the side plates are made of polycarbonate, and the behavior of the sediment in the bucket can be observed in the same way. Table 1 shows the parameters of the sediment used in this experiment.

The dynamic friction angle between the sand and the bucket and the angle of repose were determined to be 23 degree and 32 degree from the results of the basic experiment.

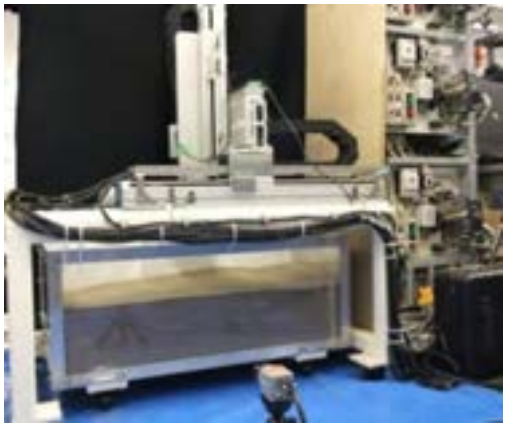

Figure 1. Overview of excavation testbed

Table 1. Parameters of sand

	Max.	Middle	Min.
density of sand [g/cm^3]	1.731	-	1.433
internal frictional angle [deg]	38.3	36.0	33.6

3 Modeling Reaction Force

3.1 Behavior during digging

Figure 2 shows the excavation trajectory using an excavation testbed. The trajectory is arc penetrating and horizontally sweep. At the end, scoop with the arc trajectory.

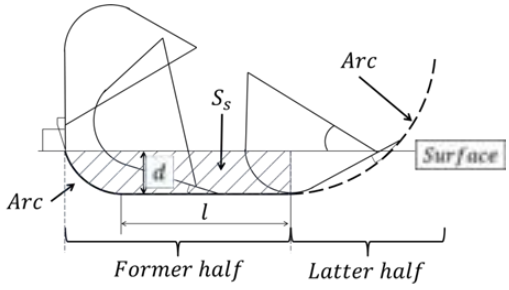

Figure 2 Digging trajectory for modeling

The behavior of the sediment in the bucket was observed from the video that reproduced a series of excavation motions of the backhoe. From the result, it was found that it is necessary to divide the process as follows for formulation (Figure 3).

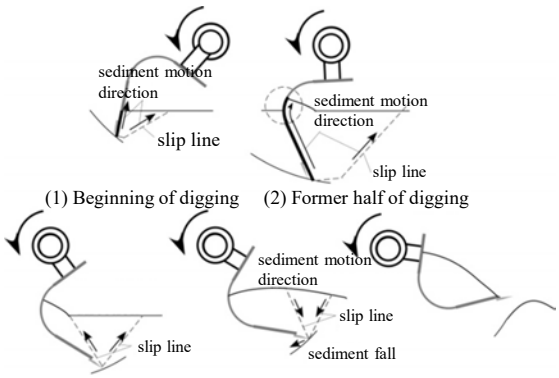

Figure 3. Divided digging phases based on sediment behaviour

1. Beginning of digging
2. Former half of digging
3. Latter half of digging
4. Soil fall phase
5. Lifting of sediment

The reaction force was formulated in each phase, and its validity was verified by comparison with the experiment result.

3.2 Reaction Force Model

It is known that the reaction force can be calculated with high accuracy by using a model of multiple triangles based on the Coulomb's passive earth pressure [4]. Based on this, the theoretical value of the reaction force was calculated using Coulomb's passive earth pressure.

First, assuming the slip on the bucket surface, the passive earth pressure is calculated. Next, the passive earth pressure assuming slippage in the sediment is calculated until the trajectory of the bucket teeth reaches the angle of repose. The phenomenon that actually occurs in this section is the one where the value of the passive earth pressure is small. In addition, the amount of sediment deposited on the upper side of the bucket is required to determine the passive earth pressure. The calculation of passive earth pressure is greatly affected by the accumulated sediment. From the observation results and the reaction force measurement results, it was assumed that sediment did not accumulate during the intrusion and 0.7 times the swept volume by the bucket accumulated after reaching the horizontal

trajectory. Furthermore, the shape of the deposited sediment was calculated from the slip line shape in the sediment. This assumption makes it possible to calculate the increase in the reaction force when sweeping horizontally. When the trajectory of the tooth tip exceeds the angle of repose, sand collapses in the space below the tooth, and the sediment above the tooth begins to flow downward. At this time, active earth pressure is generated. And the reaction force becomes even smaller than the active earth pressure. When the tip of the tooth comes to the ground, the horizontal component of the reaction force disappears and the vertical component becomes the weight of sand in the bucket. However, since the amount of sediment in the bucket is unknown, it is set to zero in this model.

4 Excavation reaction force measurement experiment and simulation

4.1 Reaction force measurement

In order to evaluate the validity of the reaction force model during digging, the measurements were carried out using an excavation testbed. The reaction force of the trajectory shown in Figure 2 was measured and a video was recorded. An analysis was performed based on the behavior of the sediment at this time. A 6-axis force sensor attached to the bucket root was used to measure the excavation reaction force. At this time, the weight of the bucket etc. is corrected. Figure 4 shows the horizontal and vertical components F_h and F_v in absolute coordinates of the measured reaction force, and the coordinate system of F_{hr} and F_{vr} based on the bucket bottom. These transformations are calculated using the rotation matrix.

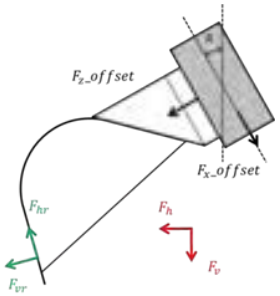

Figure 4. Coordinate system of reaction force

4.2 Comparison of excavation reaction force

For verification of the reaction force model, the difference between the theoretical value and the measurement result was compared. Figure 5 shows the horizontal component of the measurement result and theoretical value of the excavation reaction force, and Figure 6 shows the vertical component.

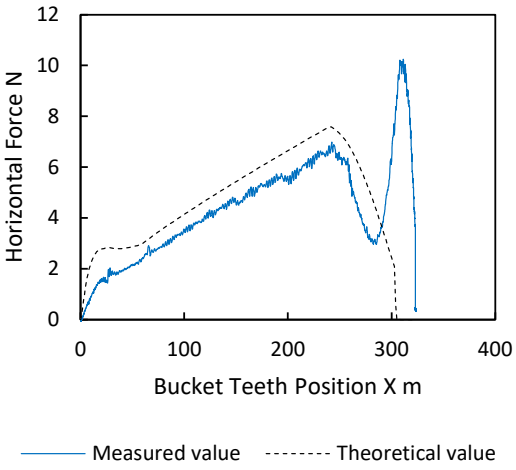

Figure 5 Reaction force comparison of horizontal direction

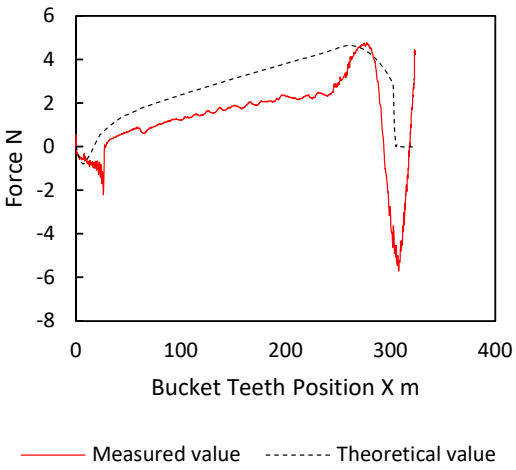

Figure 6 Reaction force comparison of vertical direction

From this result, it can be seen that the passive earth pressures until the tip of the tooth reaches 240 mm are approximately the same. The reaction force increase after 200 mm occurs in the phase of lifting the sediment. This is caused by contact between the sediment and the outside of the bucket. Since the trajectory does not contact the earth and sediment with the outside of the bucket, it is considered that the sediment that fell from the surroundings come into contact with the bucket. Ideally, there is no sediment on the trajectory, so the model does not consider this effect. Active earth pressure occurs at the tip of the tooth between 280 mm and 290 mm. The value of active earth pressure is very

small and is mostly controlled by the weight of sediment in the bucket. Approximately 300 mm, the tip pf the tooth reach the ground. The vertical component of the reaction force is adjusted by the weight of the passive earth pressure inside the slip line. However, it can be seen that the theoretical value is larger than the measurement result because the weight inside the slip line is large.

5 Backhoe energy consumption

5.1 Backhoe modeling

The backhoe attachment consists of three axes: boom, arm, and bucket, and is driven by a hydraulic system. Since each joint rotates as the hydraulic cylinder expands and contracts, it can be treated as a 3-link manipulator. Figure 7 shows the model when the boom drive is used as the origin. However, L_3 is the distance from the bucket joint to the point of action of the reaction force. In this research, the trajectory is generated so that the bucket attitude is uniquely determined for the excavation trajectory. By determining the angle of the third joint of the bucket, the remaining joint angles are derived by inverse kinematics.

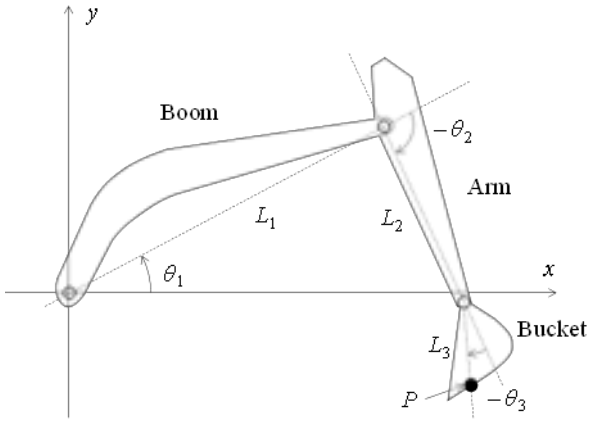

Figure 7. Kinematic model of backhoe

5.2 Energy consumption calculation

The work performed by each joint is represented by the product of joint displacement and torque. Energy is output when the rotation direction of the joint and the direction of receiving torque are different, but in the same direction, energy is received from the outside. However, in reality, torque is generated to keep the joint at the target angle. For this reason, the joint outputs the torque to oppose even if it receives a torque so as to receive energy. It is output as energy and consumes the energy that it should have received. This is called negative energy [5]. Therefore, in order to obtain the work, it is necessary to integrate the absolute value of the product of joint displacement and torque.

Since, the work required for the link to operate is represented by the sum of earth pressure and backhoe motion, the work required in the link model is expressed by Equation (1).

$$|\Delta\theta^T\tau_{ext}| = \sum_{k=1}^{3}|\Delta\theta_k||\tau_{ext\,k}| + |\Delta\theta_k||\tau_{mech\,k}| \qquad (1)$$

Negative energy is generated depending on the posture of the link, the direction of travel, and the direction of external force. Therefore, the excavation starting point where negative energy is not generated as much as possible can maximize energy efficiency.

5.3 Excavation simulation

The factors that affect the reaction force are the attitude of the bucket and the excavation depth. Therefore, in order to reduce the reaction force during excavation and increase energy efficiency, it is known that the excavation depth should be as small as possible and the bucket during digging should be tilted. In the past research [3], excavation trajectories with these characteristics were generated, but since the theoretical model of reaction force was not completed, the experimental data obtained from the testbed was used as reaction force. In this research, the excavation efficiency was evaluated from the simulation results using the earth pressure model with horizontal trajectory described in Chapter 4.2.

The excavation trajectory applied for the simulation is shown in Figure 2, and the trajectory conditions are shown in Table 2. In order to excavate a certain amount of sediment, the volume to be excavated before lifting must be greater than the bucket volume. For this reason, the ratio of the excavation volume S_s and the bucket volume S_b was used as the trajectory parameter. Two patterns of excavation trajectories were created by combining excavation depth and excavation volume.

This is the same trajectory as when the experimental data was used as a reaction force in the past research [3]. Therefore, the experimental results are shown in Table 3 for comparison with the simulation. This is the result of a partial revision of past research. According to the experimental result, the energy consumption of Test case 1 and Test case 2 is almost the same. This result is the energy consumption generated by the testbed when the excavation trajectory is applied, and is not the result converted to the actual scale shown in Chapter 5.2.

Simulations were performed for each trajectory to confirm the effectiveness of the method that consumes less energy. The simulation was carried out with the

value converted to the actual backhoe scale. The simulation results are shown in Table 4. Test case 1 is a "long and shallow" orbit, and test case 2 is a "deep and short" excavation trajectory.

Table 2. Trajectory conditions

Test case	S_s / S_b	l mm	d mm	Scooping velocity mm/s
1	2	208	23.5	20
2	1	47.5	33.5	20

Table 3. Experimental results of scooping [3]

Test case	Scooped soil [g]	Works [J]	Energy efficiency [g/J]
1	486	2.97	164
2	450	2.99	151

Table 4. Simulation results

Test case	Work ratio	Works ratio by earth pressure	Work ratio with gravity
1	1	1	1
2	0.486	1.099	0.408

From the simulation results, it is found that the backhoe consumes less energy under the condition 2 where the excavation depth is deep and the horizontal distance is short. The energy consumption at the tooth tip position during excavation is shown in Figure 8. The integral of this value becomes the energy consumption during excavation. It can be seen that Test1 consumes less energy at the same position than Test2, but the total energy is larger. This is because the excavated distance is long. It is considered that the influence of negative energy became large due to the long excavation distance. The energy consumption due to earth pressure has almost the same result. The experimental results in Table 3 show the energy consumption only by earth pressure, but both trajectories have the same energy consumption, and the simulation results and the experimental results show the same tendency. From this result, it can be said that it is possible to compare the energy efficiency with theoretical values.

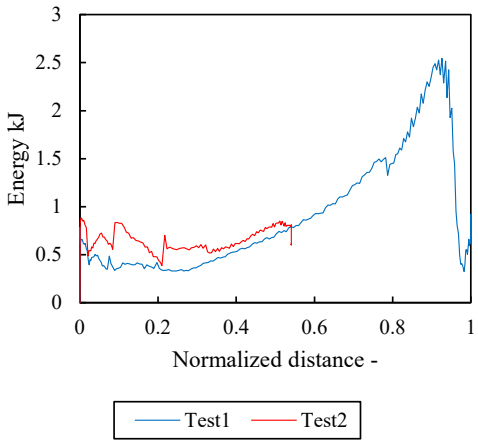

Figure 8. Energy consumption simulation result

The energy consumption due to the earth pressure is shown in Figure 9. As for the energy consumption due to the earth pressure, the maximum value of Test case 2, which is deep in the excavation trajectory, is large. It was also confirmed that the negative energy generation condition changes depending on the excavation start position, and the energy consumption changes. However, the energy consumption is about the same. The energy consumption due to the mechanism of the backhoe is shown in Figure 10. The energy due to the backhoe mechanism is more than twice as large in Test case 1 as in Test case 2. Under the condition that the distance to sweep horizontally is long, it is found that the energy consumption increases due to the negative energy.

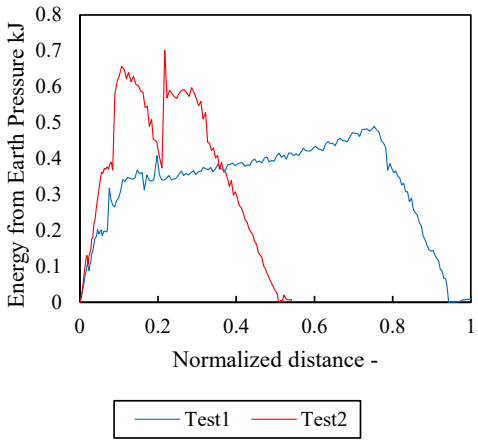

Figure 9. Energy consumption from earth pressure

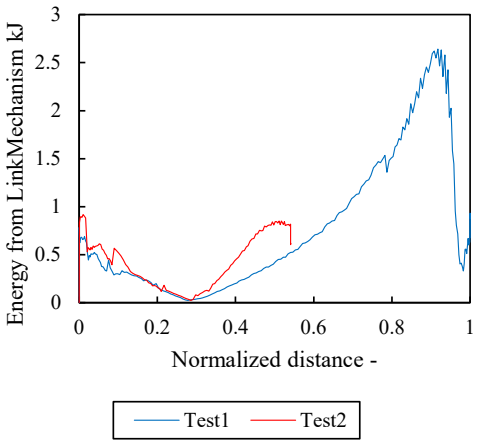

Figure 10. Energy consumption from link mechanism

6 Conclusion

From the analysis results of the reaction force using the testbed, the excavation reaction force in the horizontal trajectory, which is often used in digging operation, was formulated. It was confirmed that the theoretical values of the formulated model and the experimental results were almost the same. The energy efficiency in two patterns of excavation trajectories was evaluated using the newly derived earth pressure model. Regarding the energy consumption due to earth pressure, the results of simulation and experiment showed the same tendency. From this result, it was shown that the energy efficiency of the excavation trajectory can be evaluated by using the theoretical value. In the evaluation results of the excavation efficiency based on the theoretical value, the energy efficiency of the short excavation trajectory was good because of the energy consumption by the mechanism.

Abstract –

In the construction industry, continuous monitoring of actions performed by construction machinery is a critical task in order to achieve improved productivity and efficiency. However, measuring and recording each individual construction machinery's actions is both time consuming and expensive if conducted manually by humans. Therefore, automatic action recognition of construction machinery is highly desirable. Inspired by the success of Deep Learning approaches for human action recognition, there has been an increased number of studies dealing with action recognition of construction machinery using Deep Learning. However, those approaches require large amounts of training data, which is difficult to obtain since construction machinery are usually located in the field. Therefore, this paper proposes a method for action recognition of construction machinery using only training data generated from a simulator, which is much easier to obtain than actual training data. In order to bridge the feature domain gap between simulator-generated data and actual field data, a video filter was used. Experiments using a model of an excavator, one of the most commonly used construction machinery, showed the potential of our proposed method.

Action recognition; Deep learning; Video filter;

1 Introduction

In the construction industry, expenses related to heavy equipment, such as construction machinery, occupy large portions of the overall budget. Improving productivity and efficiency at construction sites is an important issue, and therefore, particular care has been attributed to the monitoring of such construction machinery. By obtaining and maintaining the time and costs required to complete a task, a more efficient construction plan can be made [1]. Traditionally, monitoring, consisting of recognizing and recording the actions performed by construction machinery, was conducted manually by the site manager's observations at the construction site [3]. This involved high costs and time. Therefore, automatic action recognition of construction machinery is highly desirable.

Figure 1. Simulator environment used in our proposed method (Vortex Studio [2])

Previous works dealing with the action recognition of construction machinery either employed added sensors onboard the machinery, such as GPS [4], or employed sensors positioned on the construction sites, such as cameras [5]. Approaches using cameras, which consist in placing several cameras in the construction site and recording the machinery at work, are especially appealing since they do not require modifications on the

construction machinery. Furthermore, inspired by the success of Deep Learning methods for Computer Vision-based approaches to human action recognition [6][7], several works have also managed remarkable results for the action recognition of construction machinery using Computer Vision and Deep Learning [8][9].

However, one of the major practical drawback of Deep Learning approaches is that a large amount of training data is required. Obtaining large amounts of training data is a tedious task. This was alleviated in some part for human action recognition thanks to the advent of the Internet and open-access data but it is not the case regarding specific targets such as construction machinery, which comes in a plethora of shapes and forms. High costs, in logistics, in manpower and in time, can be reasonably expected in order to obtain the training data appropriate for action recognition of construction machinery.

On the other hand, generating such training data using a simulator, illustrated in Figure 1, is comparatively easier: only a human operator to control the virtual construction machinery and a computer to run the simulator is needed. Therefore, the objective of the present paper is to conduct action recognition of construction machinery using Deep Learning based on training data obtained from a simulator.

Since the simulator differs too much from real construction sites to allow directly learning the features required for action recognition, a video filter is introduced in order to force a common ground between the data generated in the simulator and the data collected in actual construction sites.

2 Action Recognition of Construction Machinery based on Simulated Training Data

2.1 Concept

Training a model using training data generated from a simulator is not effective for action recognition of construction machinery at actual construction sites. This is because the training data would not be appropriate for the task at hand. This would be akin to train a model to distinguish pictures of dogs and cats and then testing it on pictures of cows. More generally, the features that could be extracted by the model from the feature space defined by the training data generated from the simulator do not match the features contained in the data collected at actual construction sites. Simply put, the construction machinery in the simulator does not *look like* real construction machinery.

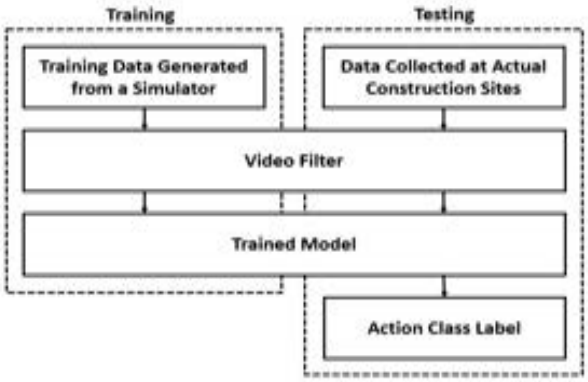

Figure 2. Overview of proposed method.

In such situation, a couple of options can be considered. Increasing the amount of training data, in a Big Data fashion, or a Data Augmentation approach could be considered. This would allow to expand the area of the feature space covered by the training data and hopefully encompass the desired portion of the feature space. However, in our case, this would have little hope to succeed since no matter the amount of additional training data generated from the simulator, the training data would still differ from the data collected at actual construction sites. Another option would be to attempt to bias the training data towards data collected at actual construction sites. To do so, domain adaption methods, i.e., using unlabeled data collected at actual construction sites in the training, or improvements to the simulator to match more closely actual construction sites can be considered. However, the former usually involves strong priors and expensive field data collection and the latter involves tedious software development.

The concept of the proposed method in this paper is a different approach: since the learning is hindered by a mismatch between the training data and the data collected at actual construction sites, the idea is to transform both of them into a third feature domain, which would be neither the feature domain of the simulator-generated training data nor of the data collected at actual construction sites. The introduction of a third feature domain would allow to bypass the previously mentioned issues related to trying to skew one domain towards another since the destination domain would be set independently of the available data.

An overview of the proposed method is shown in Figure 2. First, training data for action recognition of construction machinery is generated using a simulator. Then, both the training data generated from a simulator and the are transformed using a video filter. After this, the model for action recognition is trained on the transformed simulator training data and finally tested on the transformed data collected at construction sites.

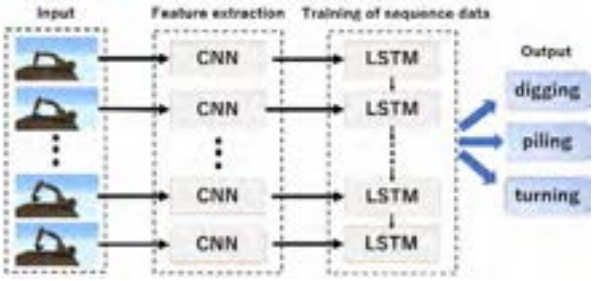

Figure 3. Learning model used in our proposed method consisting of a CNN coupled with LSTM.

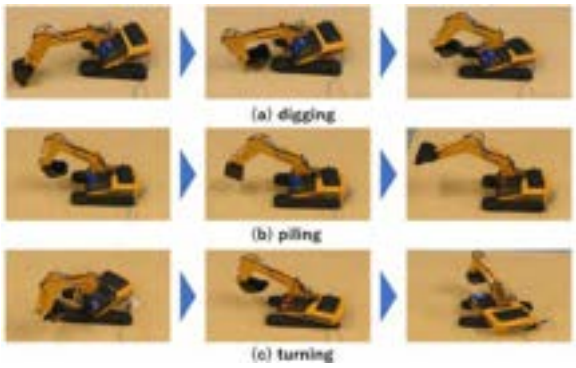

Figure 4. Examples of excavator action classes: (a) Digging; (b) Piling; (c) Turning

2.2 Training Data Generating using a Simulator

The most ideal training data for construction machinery action recognition is the data collected at actual construction sites, i.e., labeled data of the construction machinery working at the actual construction site. However, it is practically difficult to collect and label a large amount of data at the actual construction site. Therefore, in this study, Vortex Studio [2], which is a real-time simulator for mechanical system operation, is used to generate training data. A model of an excavator, one of the most commonly used construction machinery, is considered as shown in Figure 1.

In this study, RGB video data is used as input data, i.e., video of the construction machinery working. However, it is known that RGB data is easily affected by the background and camera viewpoint. Therefore, a background was created with only soil around the excavator. Moreover, the training data was generated from multiple camera viewpoints.

Concretely, to generate the training data, the camera viewpoint was first fixed while the excavator was moving in Vortex Studio and the excavator operation was conducted by human using a controller. The process was repeated several times with different camera viewpoints and different actions to generate training data.

2.3 Transformation to third Feature Domain using a Filter

In this study, the training data, generated from a simulator, differs from the data collected at actual construction sites. There is therefore a domain gap between the data used to train the model and the data used to test the model: the model trained in one domain cannot accurately conduct inference on the other domain. The concept of the proposed method is to match those two data on an independent third domain, where both would be similar.

The most obvious disparity between the data generated from a simulator and the data collected at construction sites is their appearance: they simply do not look alike and are easily differentiable. The differences mainly lie in color and texture: the simulator environment noticeably lacks the color modulations and textured appearance of surfaces compared to the real world. In order to erase those differences and basically make both the data generated from a simulator and the data collected at construction sites similar, an edge video filter is used. This edge filter is applied to both the training data generated from a simulator and the data collected at construction sites.

2.4 Action Recognition Learning Model

For action recognition, Deep Learning approaches such as using Convolutional Neural Network (CNN) and Long Short Term Memory (LSTM) [10] or a method using 3D CNN [11] has been recently used, and these methods using deep learning have higher accuracy of action recognition than other methods.

In this study, CNN and LSTM are used as network framework. CNN is a network which middle layer is composed of convolutional layer and pooling layer and extracts a feature map containing spatial information. LSTM is a network suitable for time sequence data and capable of learning long-term dependency. Therefore, by using CNN and LSTM, it becomes possible to recognize the motion of the construction machinery that considers spatial information and temporal information at the same time.

The proposed network architecture is shown in Figure 3. First, from each training data video sample, recorded at 30 fps, each frame of RGB data is extracted. Next, the extracted RGB data is resized to a size of 298×298×3. Resized RGB data is inputted to the CNN and features are extracted. The CNN network used in this study uses a trained model called Inception V3 [12] pre-trained on over 1 million images. After that, the result of feature extraction from Inception V3 is inputted into LSTM. LSTM consists of three layers and classifies action labels in the softmax layer.

3 Experiments

In experiments, an excavator was selected as target for action recognition since it is one of the most commonly used construction machinery. Furthermore, action recognition was narrowed down to 3 action classes: digging, piling, and turning.

Training data was generated from four viewpoints using Vortex Studio simulator according to the procedure in Section 2.2. As a result, about 60 videos segments at 1920×1080 resolution and 30fps were generated for each action class. The average video duration is 7s, with the shortest being 4s and the longest being 13s.

The CNN and LSTM network in this study for action recognition was trained for 150 epochs using a batch size of 32 with the Adam optimizer.

Two test datasets were considered. The first test dataset was generated from the simulator with the same procedure as for the training data for the purpose of providing a baseline in ideal learning conditions. We generated about 20 video segments for each action class. The second test dataset corresponds to actual data collected at construction sites, i.e., real world test data. However, since we were unfortunately not able to gain access to actual construction sites, we opted instead to use a remotely controlled scale model excavator. At that time, we created a background environment similar to the simulation environment, then filmed the excavator work from four different angles and generated about 20 video segments for each action class.

Regarding the edge video filter, the sketch filter of the open source video editing software Shotcut [13] was used.

The following experiments were conducted:

• (A1) CNN+LSTM trained on simulator-generated training data and tested on simulator-generated test data.

• (B1) The proposed method trained on simulator-generated training data and tested on simulator-generated test data.

• (A2) CNN+LSTM trained on simulator-generated training data and tested on real world test data.

• (B2) The proposed method trained on simulator-generated training data and tested on real world test data.

The performance was evaluated by calculating the classification accuracy defined as the ratio of the number of correctly classified samples n_{correct} over the total number of samples in the test dataset N_{samples}.

$$\text{accuracy} = \frac{n_{\text{correct}}}{N_{\text{samples}}} * 100 \quad (1)$$

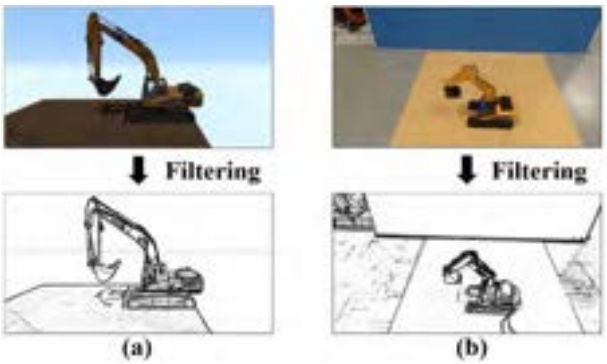

Figure 5. Effects of applying a video filter: both the data generated from a simulator (a) and real world data (b) have their differences suppressed.

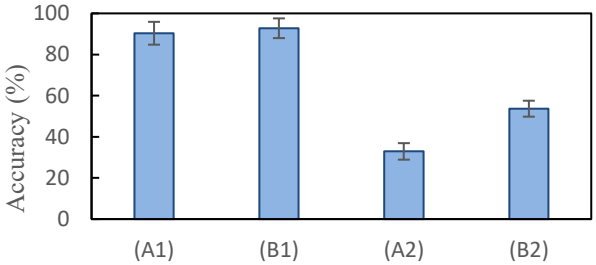

Figure 6. Average testing performance over 3 training runs of (A1) CNN+LSTM on simulator testing data, (B1) proposed method on simulator testing data, (A2) CNN+LSTM on real world test data and (B2) proposed method on real world test data. 3 action classes were considered. Error bars correspond to one standard deviation.

4 Results and Discussions

Figure 5 shows the simulator-generated data and the real world data along with the output after applying the filter. It can be noticed that most apparent features enabling differentiation have been successfully suppressed and that both data look very similar.

Results regarding action recognition performance are reported on Figure 6.

In experiments (A1) and (B1), when the training data and the test data are both generated from the simulator, it can be seen that both the proposed method and CNN+LSTM have high performance, exceeding 90%. This indicates that learning was successful. The proposed method achieved a slightly better performance at 92.3% accuracy. This is due to the fact that in our proposed method, the model learns on the training data on which the video filter was applied: this is simpler than learning directly from RGB.

In experiments (A2) and (B2), both CNN+LSTM and the proposed method were trained on the simulator-generated training data but testing was conducted with real world test data. It can be first noticed that both suffer

drop in performance. CNN+LSTM's accuracy dropped from 90.3% to 32.8%. Since 3 action classes were considered in our experiments, this is equivalent to random classification and it can be concluded that learning an appropriate model has failed. This illustrates the previously mentioned need for training data matching test data for successful learning of classification features in Section 2.1. On the other hand, the proposed method obtained an average performance of 53.7%. While there is still a performance drop, the proposed method managed to significantly perform better than a random classifier. This indicates that the introduction of a video filter allowed a performance gain of over 20%. This likely points out that the filter was successful in matching the simulator training data and real world data onto a similar domain.

5 Conclusion

A method to conduct action recognition of construction machinery from simulator-generated training data using a video filter was proposed. The differences between simulator data and real world data which prevented learning a successful model were suppressed by the use of a filter and allowed an accuracy increase of over 20%, effectively allowing the model to learn features for classification and not fail into a random classifier.

Experiments reported in this paper are still preliminary and served to demonstrate the potential of shifting the learning problem into a third domain. In the future, we plan investigate the effects of training data size and search for more suited filters for action recognition in order to improve performance. Incorporating the filter into the learning process, to learn a filter optimized for action recognition in parallel to the action recognition itself, is also considered.

Real-time Aarly Warning of Clogging Risk in Slurry Shield Tunneling: A Self-updating Machine Learning Approach

Qiang Wang[a], Xiongyao Xie [a], and Yu Huang [a]

[a]Department of geotechnical engineering, Tongji University
E-mail: wangqiang_tju@qq.com, xiexiongyao@tongji.edu.cn, yhuang@tongji.edu.cn

Abstract –

Clogging is one of the main risks when slurry shield tunneling in the mixed ground condition containing clayey soils. Severe consequences, such as instability in the excavation face and high cutter wear, may occur if the shield machine operators don't take specific measures to eliminate clogging. Therefore, early warning of clogging during one ring excavation becomes essential for the safety of tunneling. The currently available methods to judge the clogging risks focus mainly on field engineer experience, which seems arbitrary sometimes. In this paper, an automatic self-updating machine learning approach is proposed to realize the real-time early warning of clogging. More specifically, the random forest is employed with several minutes (e.g. 2 min at the beginning of one ring excavation) of tunneling parameters as input. When one ring has been finished, it will become a new training sample to update the model via randomized parameter optimization. With the case study of Nanning metro line 1, it's found that the self-updating mechanism is beneficial for better judgment of clogging, and 4 minutes tunneling parameters (24 samples) are suitable for early warning. The model can achieve an accuracy of 95% in the mixed ground condition. Meanwhile, in comparison with the other machine learning approaches is also discussed. With the training data set updating mechanism, the RF model can use less tunneling data to realized the clogging prediction. According to the feature importance result, the variation of cutterhead torque is essential for clogging prediction.

Keywords –

Shield tunneling; Clogging; Early warning; Random forest; Self-updating

1 Introduction

Shield tunneling in clayey soils is frequently obstructed by clogging problems, both for earth pressure balanced (EPB) tunnel boring machine (TBM) and slurry pressure balanced (SPB) tunnel boring machine [1,2]. The clogging problem will trigger risks during tunneling construction, such as slower tunneling efficiency[3], instability of tunnel face[4], higher wear of cutterhead[5], etc. As a typical kind of clayey soil, mudstone has a high potential to result in a clogging problem[4]. Several projects in China have been encountered with clogging problems in mudstone rich area, for example, Wuhan Sanyang cross-river road tunnel[6], the metro tunnel line 1&2 in Nanning city[7], Nanchang metro line 1[8], Nanjing Yangze river tunnel[9]. The filed experience indicates that it's difficult to maintain the normal tunneling state in mudstone rich area, especially for the mixed ground containing mudstone.

Clogging is induced by the stickiness of the excavated clayey soil, which can be influenced both by the clay mineralogy and the slurry flow behavior [2,10]. There are several laboratory tests have been presented for evaluating the clogging potential of one certain kind of soil and slurry flow behavior [2,10–12], which brings out some directly or indirectly methodologies for clogging judgment. These clogging elevation methods rely on the soil properties and most of them focused on either sand or clayey soils, which has a limitation in mixed ground conditions[2,13]. Moreover, there is still a lack of early warning methods for clogging during the tunneling process.

The criteria to evaluate clogging potential mainly focused on the soil properties but pay little attention to the slurry or foam properties well as shield driver operations in shield tunneling process[14]. When SPB shield tunneling in the mixed ground containing mudstone, it is difficult to determine whether clogging occurs only rely on the geological conditions. Therefore it is crucial to develop an early warning approach for clogging both based on the geological conditions and tunneling parameters. The data-driven approach, such as the random forest (RF) method, seems appropriate in the tunneling process. The clogging state can be regarded as an abnormal tunneling situation, thus it can be considered as a binary classification problem. RF algorithm for the development of descriptive and predictive data-mining models has become widely accepted in engineering

applications, promising powerful new tools for practicing engineers [15].

Kohestani et al.[16] presented an RF-based model for prediction of seismic liquefaction potential of soil based on the cone penetration test data, and the proposed RF models provide more accurate results than the artificial neural network (ANN) and the support vector machine (SVM) models. Zhou et al.[17] employed eleven algorithms to predict the rockburst classification and found the RF achieved the best result. The above-mentioned applications of the RF-based classification model are all static models. They employed well-trained RF models for all test data sets, which is not suitable for the shield tunneling process. As a real-time early warning model for clogging, the proposed model should be trained via as few rings as possible and is supposed to realize self-updating as new rings have been finished. As a result, a training data set updating mechnism will be designed in this paper to realize the real-time early warning of clogging risk in SPB shield tunneling.

The remainder of the paper is organized as follows: In section 2, we introduce the real-time early warning model based on RF. In section 3, the case study in Nanning metro will be presented. The impact of training data set updating mechanism will be discussed in section 4 before presenting the conclusions.

2 Real-time early warning of clogging risks based on RF

Figure 1 shows the process for real-time early warning of clogging risks with training data updating during shield tunneling construction. Suppose there are L rings in total for a tunnel section, and the shield machine is going to tunneling at the ring #i ($i \quad L$). Firstly, we select N minutes tunneling data at the beginning of each i-1 rings as the early warning input feature ($N = 0.5,1,2,3\ldots$) and take the i-1 rings clogging state as output, which will be composed as the training data set. Secondly, the ith clogging prediction model is trained with the above training data set, whose hyper-parameters are determined by the 5-fold cross-validation and randomized search[18]. Then, the proposed prediction model is used to predict the clogging state of ring #i via the N minutes tunneling data at the beginning of the ith ring. Finally, when the ring #i has been finished, we will determine the real clogging state for the ith ring based on the above mentioned three criteria. Moreover, the training data set will be updated by adding the input feature and clogging state of ring #i. This process will continue until the tunneling section has been finished.

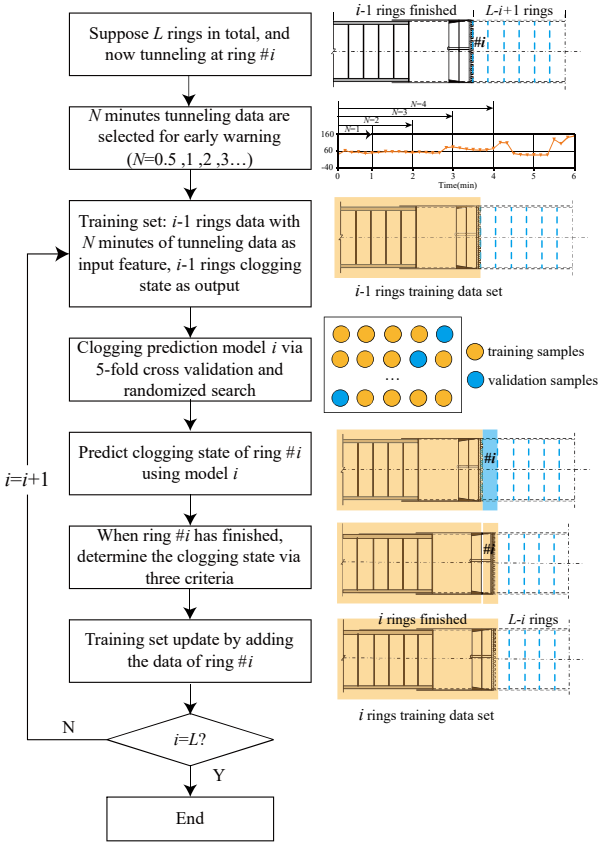

Figure 1. Flow chart for real-time early warning of clogging with training data updating

Random forest (RF) is an ensemble learning method for classification that operates by constructing a large number of decision trees at training time and outputting the class that is the mode of the classes of the individual trees[19]. As illustrated in Figure 2, samples and features are randomly selected from the data set using the bootstrap aggregating method. Therefore, many sub-samples are created by choosing random features with replacement. Then each decision tree will be trained on the sub-sample and the final class (clogging or normal) will be determined by averaging the probabilistic prediction of all the trees. Several hyper-parameters in the RF will be determined by cross-validation, such as the number of trees in the forest ($n\_estimators$), the maximum depth of the tree ($\max\_depth$), etc. To improve the training efficiency during shield tunneling construction, the randomized search strategy is employed instead of the traditional grid search method. This strategy implements a randomized search over the hyper-parameters, where each setting is sampled from a distribution over possible hyper-parameter values.

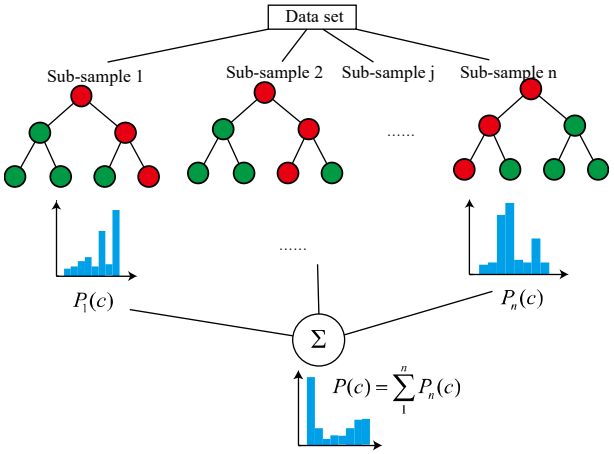

Figure 2. Schematic diagram of random forest classifier

3 Case study in Nanning metro

3.1 Project Overview

Nanning metro line 1 is the first metro line with twin tunnels in Guangxi province. The section of left line in Nanning Metro Line 1 between Bai Cang Ling Station and Railway Station (BR section) is 1209 m (806 rings in total with segment width of 1.5 m), which is encountered with the mixed ground condition of mudstone and round gravel and is thus selected as a case study. As a massive of sensitive adjacent buildings along the tunnel section, shown in Figure 3 (a), the BR section was excavated with a Herrenknecht SPB shield machine with a diameter of 6.28 m.

The tunnel in the BR section is surrounded by complex geological and hydrological conditions. The tunnel passing through geological profiles (illustrated in Figure 3 (b)) are mainly round gravel, mudstone, and sand, which are shown in different colors in Figure 3 (b). The mixed ground containing mudstone locates around ring # 120 to ring # 220, and ring # 283 to ring # 470. A total of 36 boreholes have been drilled to obtain the geotechnical characteristics of the soils found along the BR section (refer to Table 1). The distance between the ground to the tunnel crown ranges from 14 m to 22 m, while the distance between the underground water table to the tunnel crown is about 1.5m to 9m. The round gravel is saturated in the BR section, which mainly consists of gravel with a small number of pebbles (Figure 4 (a)). The average content of particles with a grain size of 2-20mm is 52.8%, and the average content of particles with a grain size greater than 20mm is 25.3%. The inter-particle filling is mainly medium and coarse sand. The round gravel has a very strong permeability coefficient of 90 m/d. In contrast, the mudstone (Figure 4 (b)) has a small permeability coefficient of 0.01 m/d, as listed in Table 1. Figure 4 (c) illustrates the grain size distribution of mudstone samples obtained in the BR section. It can be found that the grain size of mudstone is almost smaller than 0.1 mm and there are about 64% of particles with a grain size smaller than 0.005 mm.

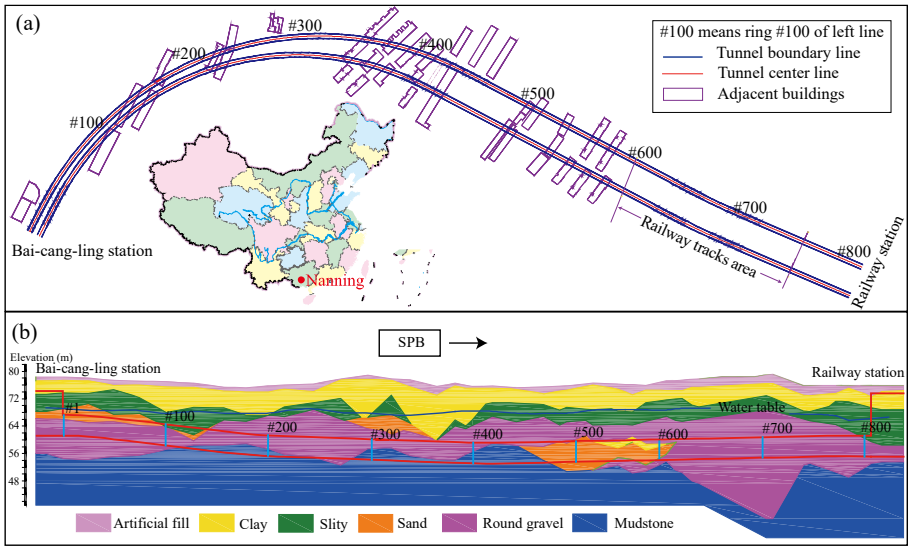

Figure 3. Schematic illustration of BR section of Nanning metro line 1, (a) plan view and parts of adjacent buildings, and (b) cross-section view. # 100 means ring # 100 in the left line

Table 1. Geotechnical characteristics of round gravel and mudstone in the BR section

Soil			c		K
	g/cm^3		kPa	°	m/d
Round gravel	2.05	0.27	0.0	35.0	90
Mudstone	2.15	0.20	90.0	21.0	0.01

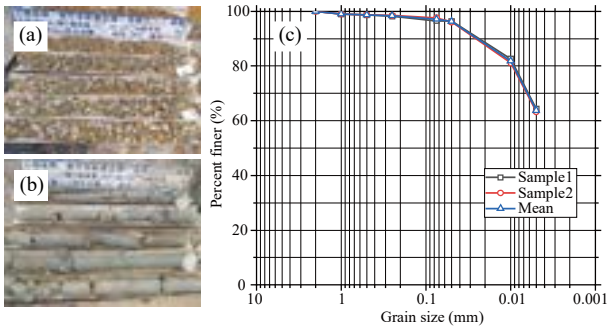

Figure 4. Borehole results of (a) round gravel and (b) mudstone, and (c) grain size distribution curve of mudstone in the BR section

According to the classification diagram raised by F. S. Hollmann and Thewes[1], the mudstone in the BR section is in the form of lumps, this may cause massive clogging because large lumps of this clay could form blockages in critical flow paths of an SPB shield machine. What's worse, to keep tunnel face stability of the water-rich round gravel, the marsh funnel viscosity of the slurry used in the SPB ranges from 24s to 32s, which has made the excavated material more easily clog at the opening of the submerged wall between the excavation chamber and the working chamber, as demonstrated in Figure 5.

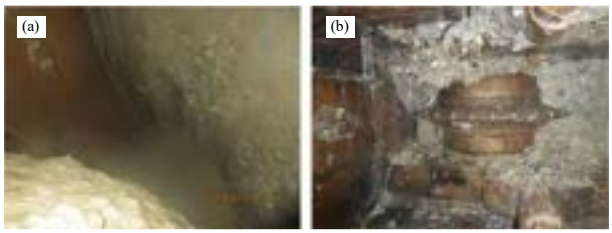

Figure 5. (a) clogging situation observed by opening the excavation chamber and (b) high wear of cutters

3.2 Data Description

The tunneling parameters in the BR section are recorded via the programmable logic controller (PLC) every 10 seconds. There is a total of 666 complete ring data that will be analyzed in this study. Four kinds of tunneling parameters are selected for clogging prediction, which are the difference (ΔSP) between slurry pressure in the excavation chamber (SPE) and slurry pressure in the working chamber (SPW), the cutterhead torque (TOR), total thrust (THR), penetration rate (PR). The SPE and SPW are measured by pressure sensors locating at the spring line of both chambers. To elevate the influence of mudstone, a mixed ratio λ [4] is defined as Eq. (2).

$$\Delta SP = SPW \quad SPE \tag{1}$$

$$\lambda = H_m / D \tag{2}$$

where H_m is the mudstone thickness in the tunnel excavation face and is determined by the geological report. D is the SPB cutterhead diameter.

Here we pay more attention to the instantaneous values of ΔSP, so we define a slurry pressure fluctuation index (SPFI) θ, as illustrated in Figure 6(a) and in E.q.(3). In normal conditions, the values of ΔSP are in the range of 0 to 20 kPa (Figure 6(d)). However, when clogging occurs, the values of ΔSP may range from -50 kPa to -150 kPa (Figure 6(b)). We plot 10 minutes of instantaneous values of ΔSP and their SPFIs in Figure 6 considering different ground conditions.

$$S_{positive} = \frac{1}{2}\left(\Delta SP dt + |\Delta SP| dt \right)$$

$$S_{negative} = \frac{1}{2}\left(\Delta SP dt - |\Delta SP| dt \right) \tag{3}$$

$$\theta = \frac{abs(S_{negative})}{S_{positive} + abs(S_{negative})}$$

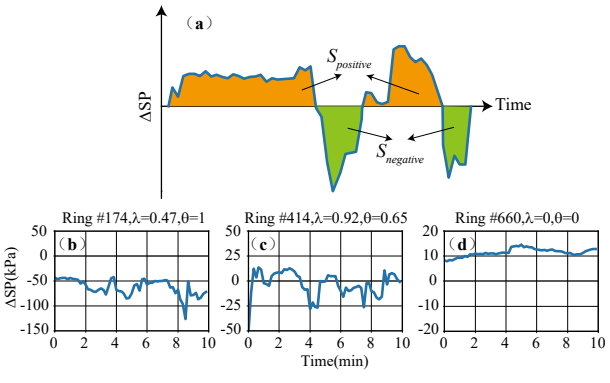

Figure 6. Definition of slurry pressure fluctuation index and typical examples in different ground conditions (10 minutes data), (a)schematic diagram of θ, (b) ring #174, $\theta = 1$ in half mudstone and half round gravel condition, (c) ring

#414, $\theta = 0.65$ in mudstone condition, and (d) ring #660, $\theta = 0$ in round gravel condition.

According to field observation, we plot the clogging rings distribution, as well as the SPFI θ and mixed ratio λ, as shown in Figure 7. It can be found that there are dramatic fluctuations of SPE in most clogging rings as the values of θ are all near one when clogging occurs. Also, the distribution of the mixed ratio is not always consistent with the clogging state, which may be caused by the uncertainty of the mudstone distribution in the geological survey as well as the mudstone that stuck to the cutterhead.

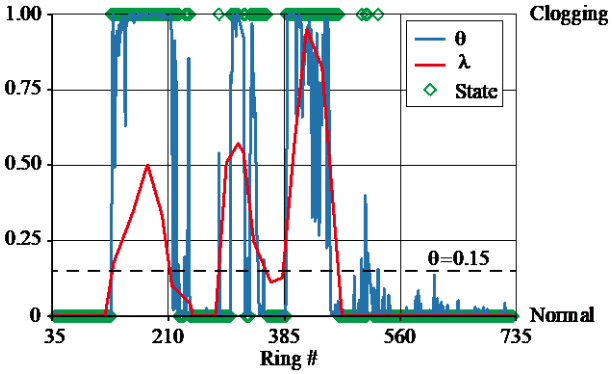

Figure 7. Distribution of mixed ratio, SPFI, and clogging state in the BR section

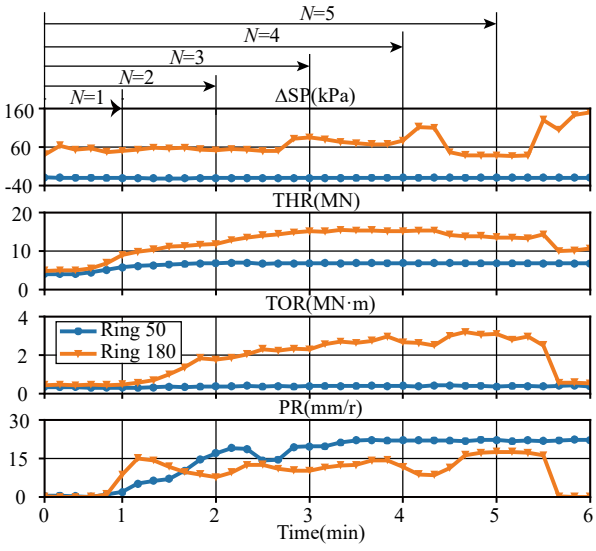

Figure 8. Demonstration of six minutes of tunneling data of clogging ring (ring #180) and normal ring (ring #50) at the beginning of each ring

Figure 8 demonstrates an example of the six minutes tunneling data that will be used as the input feature for clogging prediction.We employ 17 kinds of features as the input, including the statistical indexes (mean values, standard deviations, maximum values, and range values) of the ΔSP, THR, TOR, PR, as well as the SPFI (θ). We will explore the influence of parameter length N because the smaller of N value, the better for real-time early warning.

3.3 Clogging Prediction Results in the BR Section

We define the confusion matrix for clogging prediction in Table 2, where the P=Positive, that means the clogging state; the N=Negative, that means the normal state; TP=True Positive, that means the actual state of one ring is clogging and the predicted state is also clogging; FP=False Positive, that means the actual state of one ring is normal but the predicted state is clogging; TN=True Negative, that means the actual state of one ring is clogging but the predicted state is normal; FN=False Negative, that means the actual state of one ring is normal and the predicted state is also normal. We conduct the error rate, precision, recall, and F1 to evaluate the prediction model performance, as shown in E.q. (4). The high precision relates to a low false positive (FP) rate, and high recall relates to a low false negative (FN) rate. High scores for both show that the classifier is returning accurate results (high precision), as well as returning a majority of all positive (clogging) results (high recall).

$$
\begin{aligned}
error\ rate &= \frac{FP+FN}{TP+TN+FP+FN}\times 100\% \\
precision &= \frac{TP}{TP+FP}\times 100\% \\
reacall &= \frac{TP}{TP+FN}\times 100\% \\
F1 &= \frac{2\times precision\times reacall}{precision+reacall}
\end{aligned}
\tag{4}
$$

Table 2. Confusion matrix for clogging prediction

		Actual class	
		P: Clogging	N: Normal
Predicted class	P: Clogging	TP	FP
	N: Normal	FN	TN

As mentioned before, there are 666 rings for analysis in the BR section, and 229 rings are regarded as clogging state (Figure 7). We choose the first 90 rings as the initial training data set and then examine the different tunneling data length ($N = 0.5, 1, 2, 3, 4, 5, 6, 8$). The hyper-parameters ($n\_estimators$ and max_depth)

distribution for the RF model is the random number between 0 to 1000. To compare different model performances, we also employ the *K*-nearest neighbor (KNN) model[20], the support vector classification (SVC) model[21], and the multi-layer perceptron (MLP) model[22]. The hyper-parameters (*n_neighbors*) distribution for the KNN model is the random number between 0 to 10. The RBF function is adopted as the kernel function in the SVC model, which has a logarithmically spaced *C* values range from 1 to 1000 with a vector length of 20, a logarithmically spaced *gamma* values range from 0.001 to 1000 with a vector length of 7. The MLP model has one hidden layer with different neurons from 5 to 25 with an increase of 25. The learning rate of the MLP model is set as a logarithmically spaced values range from 1 to 1000 with a vector length of 4.

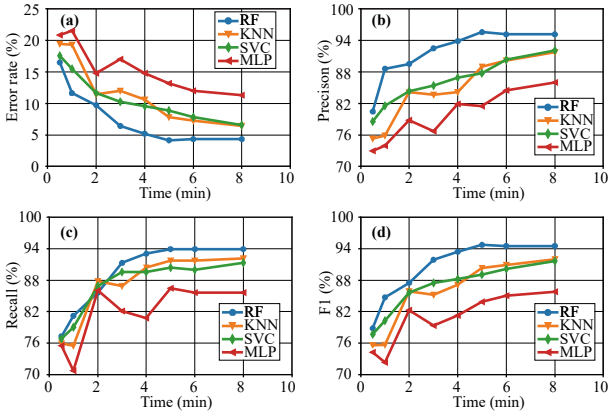

Figure 9. Clogging prediction model performances with different tunneling data length, (a) error rate, (b) precision, (c) recall, and (d) F1

After the simulation of 666 rings in the BR section, Figure 9 illustrates the metrics of the four clogging prediction models with different tunneling data length. The model performance becomes better as the tunneling data length increases, and the RF model performs best among these four models considering all the metrics. The KNN model performance is similar to the SVC model while the MLP model performs worst with a very high error rate. From Figure 9 (a), it can be found that when we use four minutes of tunneling data to predict the clogging state, the RF model error rate is 5%, which seems well enough for tunneling construction. What's more, the four minutes tunneling data makes the RF model yield a high precision (Figure 9 (b)), recall (Figure 9 (c)) and F1 score (Figure 9 (d)), which are about 94%. With the increase of tunneling data length, the RF model performance increases slightly. Therefore, we believe the data length of four minutes at the beginning of one ring tunneling period is a good choice for clogging state prediction.

3.4 Discussion on Model Performance

3.4.1 Model Performance without Training Data Updating

Table 3 lists the metrics of the RF clogging prediction model considering different training strategies. One strategy uses the updating training data set and the other one just employs the initial training data set without updating. We can see that the model with updating the training data set achieves a better prediction accuracy than the model with the static training data set. We can realize the early warning of clogging with the four minutes of tunneling data with an error rate of 5.2% in the proposed model. However, we need five to eight minutes of tunneling data to realize the same goal when the training data remains unchanged. One possible reason for this difference is that the RF model learns more patterns about clogging when the training data set is updated as shield machine advances.

Table 3. Metrics comparison of RF clogging prediction model considering different training strategies

Tunneling data length (minutes)	Error rate (%)		Precision (%)		Recall (%)		F1 (%)	
	Updating	No updating	Updating	No updating	Updating	No updating	Updating	No updating
0.5	16.5	20.7	80.5	80.2	77.3	62.8	78.9	70.4
1	11.6	18.6	88.6	77.5	81.2	75.2	84.7	76.3
2	9.7	24.5	89.5	64.3	85.6	84.5	87.5	73.0
3	6.4	12.5	82.5	80.1	91.3	91.2	86.7	85.3
4	5.2	9.7	93.8	84.6	93.4	92.7	93.6	88.5
5	4.2	5.4	95.6	94.1	93.9	92.8	94.7	93.4
6	4.3	5.5	95.1	95.2	93.9	92.6	94.5	93.9
8	4.3	5.2	95.1	94.2	94.0	92.8	94.6	93.5

3.4.2 Influence of Input Features on Clogging Prediction

In section 3.2, we employ 17 kinds of features as the clogging prediction model input. For better guidance for shield tunneling construction, here we carry out feature importance to investigate which kind of features has a crucial impact on clogging prediction. The permutation feature importance technology [23] is adopted with four minutes of tunneling data in the RF model. Figure 10 shows the feature importance result with the metric of error rate in different states. Firstly, we consider the whole tunnel section, and there are two kinds of input feature that has feature importance larger than 10%, which are the mean and maximum values of the TOR. Also, the maximum and range values of the PR should be considered. Then, if we just consider the normal state rings, the influence of PR seems quite important as the feature importances of maximum values, range values, and standard deviations of PR are larger than 10%. Finally, when we consider the clogging rings, it can be found that the feature importances of the mean and maximum values of the TOR are larger than 15%, which means the variation of TOR should be taken as the priority to make the judgment of clogging.

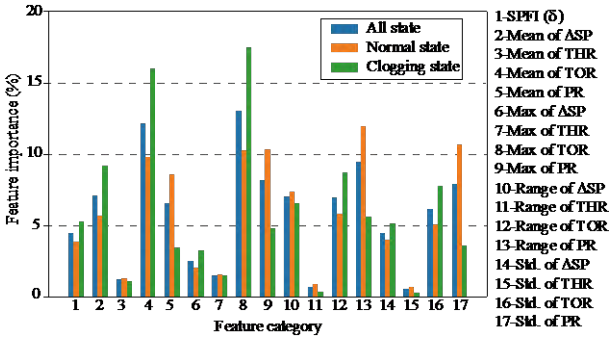

Figure 10. Feature importance of the RF model considering different states

4 Conclusion

This paper proposed a real-time early warning strategy of clogging risks based on RF. The clogging early warning model performance was evaluated. Results of conducted analyses show that:

(1) The RF model can realize the real-time early warning of clogging with four minutes of tunneling data at the beginning of one ring, which achieves an error rate of 5%. Compared with the KNN model, the SVC model, and the MLP model, the RF model gives the best performances.

(2) The statistical indexes of TOR are essential for clogging judgment while the PR is crucial for normal state identification based on the importance of the explanatory features. Without updating the training data set, the RF model needs more tunneling data to make a good prediction of clogging.

Although we have realized some achievements in the analysis and prediction of the clogging risks based on the tunneling parameters, we still pay more attention to the control measures to mitigate the clogging problem. For example, more appropriate slurry properties design for mixed ground containing mudstone is vital, which can keep the tunnel face stability and convey the excavated material more smoothly. Besides, it's significant to carry out the intelligent models that can have good control of tunneling parameters in high clogging risk areas instead of the trial-error process based on field experience.

Abstract -

This research investigates the development and validation of state-of-the-art high-fidelity models of soil cutting operations. The accurate and efficient modeling of complex tool-soil interactions is an open problem in the literature. Modeling options that provide more flexibility in trading off accuracy and computational efficiency than current state-of-the-art continuum or discrete element methods are sought. In this work, two modern numerical methods, the material point method (MPM) and a hybrid approach, are presented with the goal to simulate excavation maneuvers efficiently and with high accuracy. MPM, as an accurate, continuum-based and meshfree method, uses a constitutive model (here, nonlocal granular fluidity model) for computing internal forces to update particle velocities and positions. The hybrid approach, a combination of particle and grid-based methods, avoids explicit integration scheme difficulties and unnecessary computations in the static regime. Visual and quantitative data, including forces on the excavation tool, are collected experimentally to evaluate these two simulation methods with respect to geometry of the soil deformation as well as interaction forces, both as a function of time.

1 Introduction

On Earth, construction, mining, and agricultural vehicles are extensively in contact with soil as a granular material. In space, exploration rovers are as well, as will robots for in situ resource utilization. However, granular flows and their interactions with rigid bodies are still poorly understood. In fact, their modeling is complex since they can experience various solid-like, fluid-like and gas-like deformations in time. Besides experiments, simulations can hugely contribute to this end. Nevertheless, the accurate and efficient modeling of complex tool-soil interactions is still an open research problem. In terms of accuracy, one current direction of this research is the discrete element method (DEM), which simulates contact mechanics for millions of individual particles [1]. This state-of-the-art approach demonstrates promise in modeling but it is so computationally intensive as to be infeasible for real-time applications, and for large physical domains can be untenably expensive even in offline industrial applications [2]. On the other end of the complexity spectrum, several researchers highlight the insufficient predictive power of classical terramechanics models [3, 4], and their limitations to specific flow geometries [5], though they are computationally efficient.

In order to maintain a desired accuracy while enhancing computational efficiency, one possible direction is using methods from continuum mechanics. In continuum methods, there are two main aspects to make them appropriate for a specific modeling problem. One aspect is the constitutive model; it should be specific to the material being used to capture most of the static and/or flow regimes. For granular materials, they should generally cover elastic (solid-like), viscoplastic (fluid-like), and free (gas-like) behaviors. For the two extremes, elastic and free models have been developed based on soil mechanics (e.g. Drucker-Prager) and kinetic theory of gases, respectively. However, the middle regime of (visco) plastic deformation is more challenging. Plastic models can suffer from rate-independency [6] and in some cases, they may have issues with modeling strain hardening [7]. Whereas, viscoplastic models eliminate some numerical difficulties associated with plastic models, such as hardening [8]. In viscoplastic models, although local models [9] lack robustness in their ability to predict all flow phenomena, nonlocal models are accepted as highly predictive in different flow regimes [10]. The other aspect in continuum modeling is the numerical solver. Among the several continuum-based numerical solvers, finite difference (FD) for viscoplastic deformation, and finite element (FE) for elastic deformation, are the most common methods [11]. Both can yield good results in certain cases. However, the FD method has difficulties with extensional disconnection and static regime, while the FE method has issues when mesh dis-

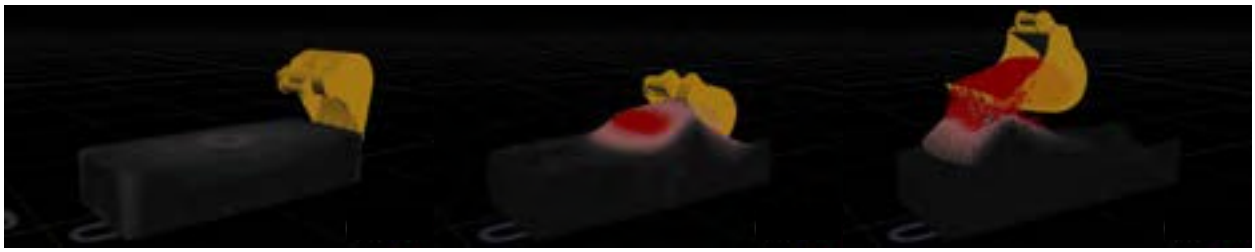

Figure 1. Industrial excavator modeling. Soil colors represent velocity magnitude.

tortion becomes large. Alternatively, the material point method (MPM) is a modern approach that combines the advantages of both FD and FE methods [12].

On the other hand, some novel techniques can be applied to terramechanics models to simultaneously maintain their efficiency and refine their accuracy and flexibility (i.e. extending to complex geometries). In fact, some intensive computations can be ignored in the physical domains that are in the static regime [13]. For the domains in the quasi-static regime which have less deformation, terramechanics models seem to be good candidates. With that, a classical terramechanics model is introduced by McKyes [14] as a method of trial wedges for 2-dimensional soil cutting (known as McKyes model). It is later generalized for 3-dimensional applications such as bucket of excavators and backhoes by Holz et al. [15]. In that, soil cutting forces are formulated based on the fundamental equation of earth-moving (FEE) [16]. Also, Skonieczny [17] replaces the generic surcharge force term in McKyes model with an explicit model of how cutting forces change due to accumulating soil. Thus, this model (McKyes) with all of its modifications can be employed for calculating forces on the cutting tool when the flow is quasi-static. Moreover, more flexible and advanced approaches can be applied to the domains in the intermediate regime specifically with (visco) plastic deformations. Particle-based methods are good candidates due to the nature of the granular flows. However, they often come with prohibitive computational cost, as in traditional DEM. An efficient granular material simulation method, based on Position Based Dynamics (PBD) Muller et al. [18], was introduced by Holz [19] as a faster variation of the traditional DEM. This method showed promising results and was experimentally verified in [20] for a wheel-on-soil configuration. Therefore, this parallel position based approach can be utilized to model the (visco) plastic granular flows when required, and even be used in combination with the modified McKyes model.

With the two aforementioned areas in mind, in this paper, two modern numerical methods are proposed for modeling of soil cutting. First, for the sake of accuracy, while being reasonably efficient, an efficient MPM (Moving Least Squares MPM) solver is utilized with an accurate constitutive model (nonlocal granular fluidity) developed specifically for 3D MPM in a thermodynamically consistent manner and written in C++. Second, a real-time capable and relatively accurate hybrid simulation approach, combining particle and grid-based methods, is presented. This approach was previously introduced by Holz et al. [15] and is here extended with a dynamic soil failure angle calculation for soil cutting operations. Furthermore, the numerical results are compared and evaluated by the experimental data collected by innovative robotic equipment, designed for this type of operation.

2 Methodology

2.1 Numerical Methods

MPM with Nonlocal Granular Fluidity. As discussed, MPM is similar to the FE method but also takes the advantage of FD method by keeping an undeformed Cartesian background grid appropriate for large-deformation problems as well. In addition to the grid, MPM consists of particles that carry information (mass and momentum) during the simulation. The particles can freely deform and, at the end of each time step, transfer the information to the grid nodes and vice versa. The procedure of MPM with the nonlocal model is shown in algorithm 1.

The momentum equation ($\phi\rho\dot{v} = \phi\rho G + \mathrm{div}T$) as the governing equation in the weak form

$$\frac{1}{\Delta t}\int_\Omega \phi\rho\Delta v q\, dV = \int_\Omega \phi\rho G q\, dV - \int_\Omega T\nabla q\, dV \qquad (1)$$

is solved on grid nodes. Where v is velocity, T is Cauchy

until *Simulation ends*;

stress tensor, G is gravity acceleration, ϕ is volume fraction, q is test function, ρ is density, and V is volume. The angular momentum and energy conservations are satisfied due to the symmetric stress tensor and the implementation of hyperelasticity framework, respectively. To discretize the spatial terms, the Moving Least Squares (MLS) shape function [21] is used. It can speed up MPM by eliminating the need for explicitly calculating the weighting function derivative. Furthermore, it is consistent with the APIC (affine particle-in-cell [22]) particle-grid transfer scheme in the sense that MLS-MPM uses the $\frac{\partial v}{\partial x}$ quantity from APIC, required in the deformation gradient update, to enhance efficiency.

One novel advance in this research is the accurate calculation of internal forces via the unsteady form of Nonlocal Granular Fluidity (NGF) model [23] with hyperelasticity. In fact, this is a thermodynamically consistent version of the nonlocal theory for three-dimensional MPM [24, 25]. Hyperelasticity requires keeping track of the deformation gradient, which is multiplicatively decomposed into elastic and plastic parts. The total deformation gradient is updated via $\dot{F} = \frac{\partial v}{\partial x} F$, and the elastic deformation gradient is calculated via $F^e = F(F^p)^{-1}$. The nonlocal constitutive model is hence utilized to calculate F^p. By assuming that the viscosity ($1/g$ where g is granular fluidity) is time-dependent, the unsteady PDE of the model

$$t_0 \frac{\partial g}{\partial t} = A^2 d^2 \nabla^2 g - (\mu_s - \mu) g - b \sqrt{\frac{\rho_s d^2}{p}} \mu g^2 \quad (2)$$

should be solved for granular fluidity g. Where t_0 is a constant time-scale, A is a dimensionless material parameter called nonlocal amplitude, and d, p, and ρ_s are grain diameter, mean normal stress and grain density, respectively. Also, b is a local rheology parameter, the friction coefficient μ, and static friction coefficient μ_s cause flow to happen. Then the equivalent plastic shear strain rate can be obtained via $\dot{\gamma^p} = g\mu$.

Since in MPM granular materials can be separated, the open-state particles should also be modeled. While kinetic theory of gases is capable of this modeling, in most cases it is accurate enough to handle granular gas via pure kinematics (stress-free). To detect this regime, pressure (mean normal stress) should be tracked for every individual particle. Figure 2 shows four possible states that can occur for a particle in the next time step.

The algorithm used to calculate the internal forces with the nonlocal model is inspired from [25] for the implementation of the hyperelasticity framework. It is well adapted for use in MPM with the techniques used to handle stress-free particles, and to solve the unsteady nonlocal equation explicitly (and uncoupled with the momentum equation). In this, the particle nonlocal Laplacian term is obtained via a second-order FD scheme on the centre grid node in the kernel support of the particle, via equation (3) and the particle internal force can be obtained given the calculated Cauchy stress tensor.

$$\nabla^2 g_{i,j,k} = \frac{1}{\Delta x^2}(g_{i+1,j,k} + g_{i,j+1,k} + g_{i,j,k+1} - 6g_{i,j,k} + g_{i-1,j,k} + g_{i,j-1,k} + g_{i,j,k-1}). \quad (3)$$

The MPM code used is from Hu et al. [21] with an unsteady nonlocal model extension developed by authors of this paper, and written in C++. Also, two issues addressed as corner and penetration issues in [21] are fixed here. From a high performance computing (HPC) viewpoint, multithreading (via Intel TBB) and vectorization (via explicit SIMD) are utilized in the code, in addition to some algorithmic improvements. These techniques make the current MPM 2x faster than a traditional MPM [21].

Hybrid Approach. The hybrid approach presented in this work extends on the hybrid, particle- and grid-based simulation method introduced by Holz et al. [15], which is included in the dynamics simulation toolkit Vortex Studio, created by CM Labs Simulations Inc. In this simulation model, the static soil state is efficiently represented by a grid (a height field in this case). Soil portions in the grid that transition into a dynamic, moving state are replaced by particles. These so-called soil particles are simulated using the Parallel Particles solver (P^2) which ensures efficiency and unconditional stability [19]. The organization of soil in particles and grid is illustrated on the left side of Figure 3.

The motivation behind the described approach is to provide a computationally efficient and stable, yet accurate model, which, by modifying select discretization parameters such as particle count or simulation frequency, can achieve real-time or faster than real-time performance. By using only a limited number of particles at a time,

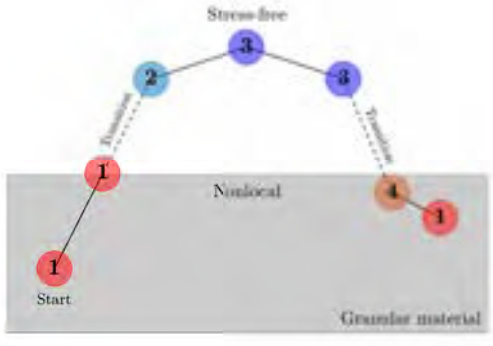

Figure 2. Possible states for a particle: under compression (red) and stress-free (blue). Gray area represents granular material.

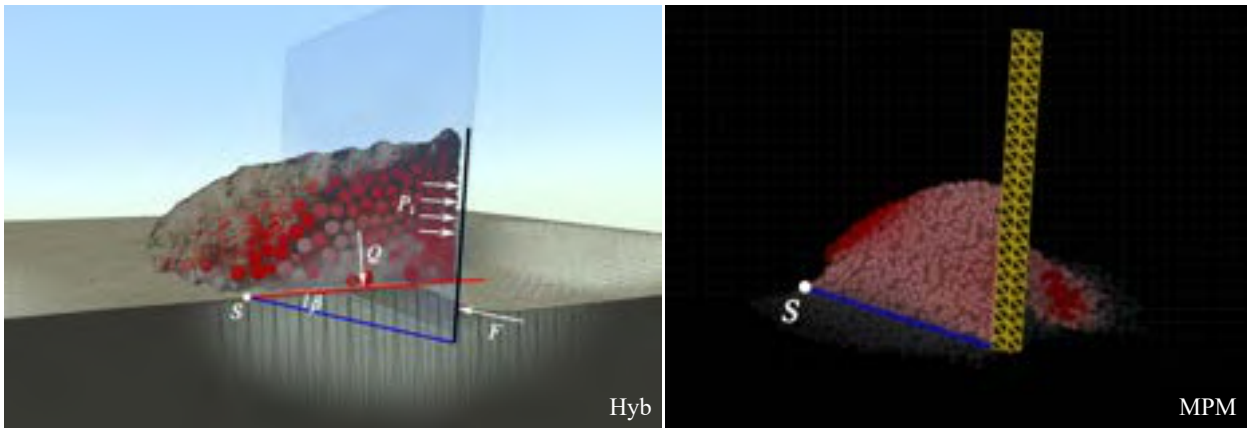

Figure 3. Left: Separation of simulated soil in particles and grid in the Hybrid method and force sources. Particle/blade contact forces, P_i, surcharge force, Q, applied to soil wedge, and McKyes cutting force, F, are indicated. Point S and angle β denote the soil failure point and the soil failure angle, respectively.
Right: Soil deformation pattern in MPM method shows soil failure point S and linear soil failure surface.

cies, i.e., fewer steps per second, can be used without significantly reducing the solution accuracy or causing instabilities. This measure is a great tool for speeding up the proposed method up to real-time running times, as will be shown in Section 3.2.

In the aforementioned setting, soil reaction forces applied to the cutting blade are produced by two sources, the soil mass represented by particles, and the soil mass represented by the grid. Soil particles, which model the surcharge in front of the blade, directly exert contact forces to the contacting blade surface. And the soil grid applies force via a semi-empirical terramechanics model developed by McKyes [14]. This separation of forces is depicted in Figure 3. With increasing surcharge, i.e., increasing amount of soil particles, the soil reaction forces also increase. This is modeled by injecting a surcharge force into the McKyes model as described by Holz et al. [15] and explained in the following sections.

In the McKyes model, soil surface and blade are both assumed to be linear. A non-cohesive soil in front of a moving blade can then be assumed to fail along a straight line. This results in a triangular soil wedge formed by the surface of the terrain, the failure line and the blade. The forces acting on the soil wedge are depicted in Figure 4. In this configuration, the cutting force F per tool width required to induce soil failure and deform the soil can be computed as

$$F = \gamma g d^2 N_\gamma + c d N_c + Q N_Q + c_a d N_a \tag{4}$$

where

$$N_\gamma = \frac{(\cot\rho+\cot\beta)\sin(\alpha+\phi+\beta)}{2\sin(\delta+\rho+\phi+\beta)}, \quad N_Q = \frac{\sin(\phi+\beta)}{\sin(\delta+\rho+\phi+\beta)}, \tag{5a}$$

$$N_c = \frac{\cos\phi}{\sin\beta\sin(\delta+\rho+\phi+\beta)}, \quad N_a = \frac{-\cos(\rho+\phi+\beta)}{\sin\rho\sin(\delta+\rho+\phi+\beta)} \tag{5b}$$

with gravity g, soil slope inclination angle α, tool/soil angle ρ, tool penetration depth d, soil failure angle β, soil internal friction angle ϕ, soil cohesion c, specific weight of the soil γ, tool/soil friction angle δ, tool/soil adhesion c_a and surcharge force per tool width Q.

In the original hybrid model [15], it was assumed that soil failure occurred in the passive Rankine state, leading to a constant soil failure angle β. However, it has been shown that the soil failure angle does not remain constant during a cutting operation and therefore must be dynamically updated [17]. We assume that for non-cohesive soils the point of failure (which is the intersection between soil surface and failure line) roughly occurs at the far end of the accumulating pile of soil that is being pushed by the blade. We verified this assumption in the context of our experiments based on visual inspection of soil failure patterns occurring in the experiments themselves, as well as by inspecting the particle flow in simulations obtained by MPM (cf. right side of Fig. 3). We make use of this assumption by walking across the particle skeleton in front of the blade and in the general blade's forward direction until no more particles can be visited. The position of the

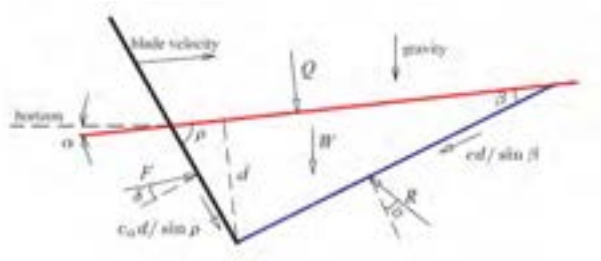

Figure 4. Forces acting on the soil wedge.

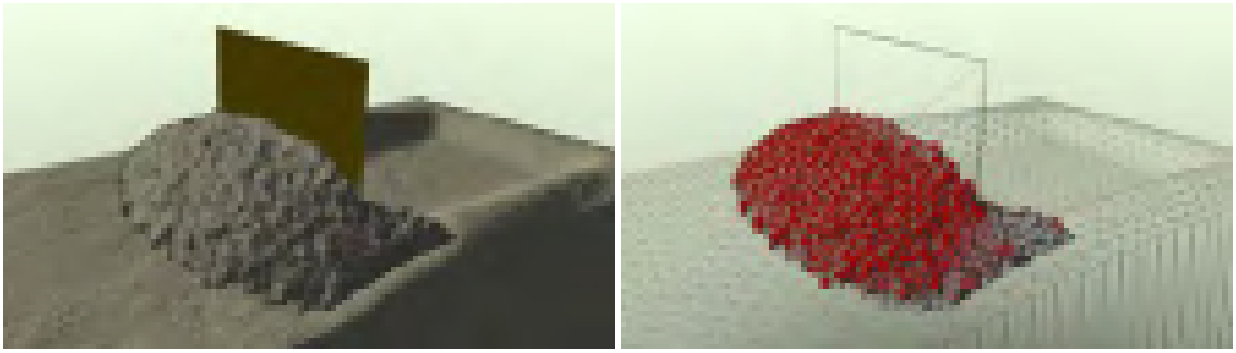

Figure 5. Hybrid method using real-time, screen-space visualization from [26] (left), and display of particles and grid (right), for experiment with 5-cm depth.

last visited particle indicates the location of the soil failure point and is used to compute the soil failure angle used in the McKyes model.

Once the soil failure point is found, the length of the soil wedge ahead of the blade can be determined. All particles sitting on top of this soil wedge contribute to the surcharge force Q from Equation 4, which is measured by summing up all contact forces of the particles colliding with the soil grid and sitting on top of the soil wedge. We experienced that introducing the full surcharge force into the McKyes model leads to too high a soil reaction force computed by the model. Consequently, we suggest a convenient force tuning parameter, denoted as *surcharge contribution factor* $s_q \in [0, 1]$, with which the surcharge force submitted to the McKyes model can be weighted, leading to the following modified version of Equation 4.

$$F = \gamma g d^2 N_\gamma + c d N_c + s_q Q N_Q + c_a d N_a \qquad (6)$$

As will be shown in Section 3, the s_q-factor can be used to calibrate the hybrid method in order to match the simulated soil reaction forces to the forces that are observed in experiments.

2.2 Experimental Method

In this research, an excavation experiment (identical to the simulations) was set up to validate the numerical methods. It consists of a sandbox positioned under a 3-degree-of-freedom motorized unit to which an excavation accessory is attached. For this experiment and for the numerical simulation presented here, the excavation accessory is a flat plate (blade) as depicted in Figure 6 (top). The rake angle of the blade can be set manually and it remains constant during the run. The excavator can be moved horizontally and vertically independently. The motors are controlled such that the impulses from the soil flow do not affect the trajectory of the excavator. The excavator is installed on a force-torque sensor Delta IP60 (ATI Industrial Automation Inc.) that measures the forces and torques on the blade along each direction. The blade trajectory is composed of three segments: first, a downward ramped motion at the start to dive into the soil with a specific depth, then a long-duration horizontal motion, and finally an upward ramp in the end to resemble the motion of an industrial excavator. Two tests were done based on this trajectory but at different (2-cm and 5-cm) depths.

The soil in the experiment is a NASA Glenn Research Center lunar soil simulant (GRC-1). The relative density used is 44.6 +/- 7.2%. This is calculated based on the cone index gradient of 5.30 +/- 0.6 kPa/mm using the correlation in [27]. Thus, the corresponding internal friction angle can be obtained as 35 deg. The grain diameter and density are 0.3 mm and 2583 kg/m^3. Using the triaxial test performed by Oraveca et al. [27] the estimated Young's and shear moduli are 150 and 60 kPa, respectively. Also, the measured external friction angle between the blade and soil is ~30 deg. The setup of the experiment is shown in Figure 6.

3 Results

3.1 Experimental Verification

The tool-soil interactions in the simulations here are evaluated by the forces measured in the experiments (torque comparison is left). Figure 7 compares all the forces from the experiment, MPM and Hybrid method. The quantitative force values are in good agreement with the experimental forces in the three (forward, vertical and lateral) directions. A quantitative assessment of the simulation accuracy in terms of mean percentage error (MPE) is provided in Table 1. Due to the fast technique used to calculate the nonlocal Laplacian term in MPM, the MPM results seem to be slightly more oscillatory than the experimental results. However, in addition to the overall trend, MPM is able to capture drops and rises in force at various time steps of the two experiments. This can highlight the unsteady form of the MPM solver as well as the nonlocal constitutive model. Also, as a real-time method,

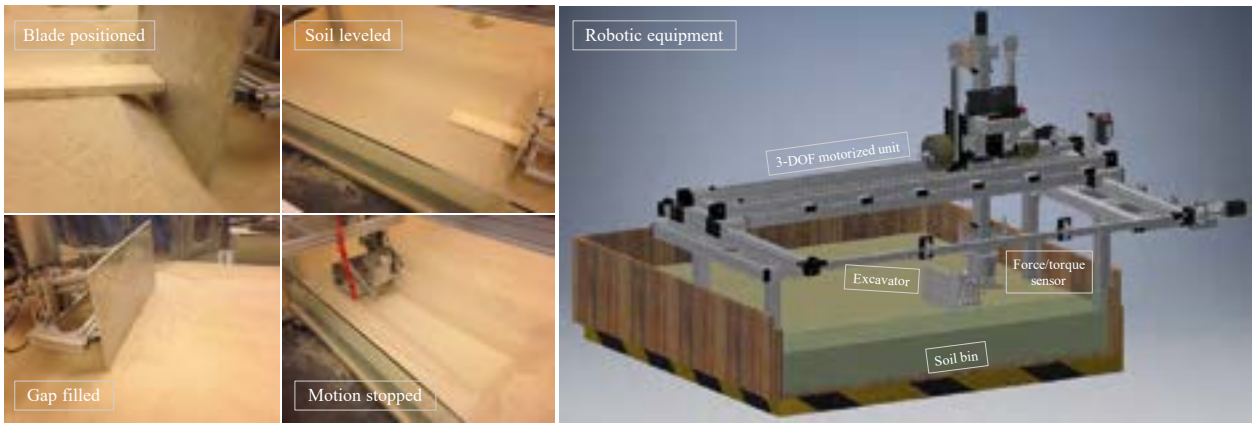

Figure 6. Robotic equipment and experiment setup.

Hybrid has the ability to predict forces as deformations increase. In fact, this time-dependent prediction is made possible by the introduction of the dynamic soil failure angle in the McKyes model, and modeling of the accumulating soil surcharge by particles. Note, that the surcharge contribution factor $s_q = 0.1$ was found to produce the best match between the Hybrid method and the experimental results. All other simulation parameters are set based on the physical properties of the soil used in the experiment.

A qualitative and visual comparison of the simulations and the experiment is shown in Figure 8. This illustration shows the soil geometry at the end of the second trajectory segment in the 5-cm experiment for both MPM and Hybrid method. Also, a real-time soil visualization for the 5-cm experiment simulated with the hybrid method is provided in Figure 5. In general, the soil behavior in MPM and Hybrid are predicted similar to the one in the experiment. The particle velocities visualized in colors clearly depict the static (gray) and dynamic (red) parts; while static parts in Hybrid are visualized as grid consistent with its methodology. The MPM velocity field is more compatible with the experiment. It can be due to either the nature of MPM as a continuum-based method or the higher number of particles used. However, even with a lower number of particles and with real-time running times, the Hybrid velocity field is still in good agreement with the experiment, as can also be seen in Figure 5.

3.2 Run-Time Measurements

We measured the computational time spent in both MPM and Hybrid method with 20 seconds of simulated time in the 5-cm depth excavating experiment. The measurements were performed on an Intel(R) Core(TM) i7-6700 CPU @ 3.40GHz with 4 physical cores for MPM, and on an Intel(R) Core(TM) i7-8700 CPU @ 3.20GHz with 6 physical cores for the Hybrid method. The results are provided in Table 1.

Run-time as well as accuracy of both methods can be influenced by modifying the simulation discretization parameters, e.g. particle count and simulation frequency. In order to demonstrate this fact, the mean percentage error (MPE) of the forward cutting force in the simulation relative to the experiment was calculated for different discretization settings.

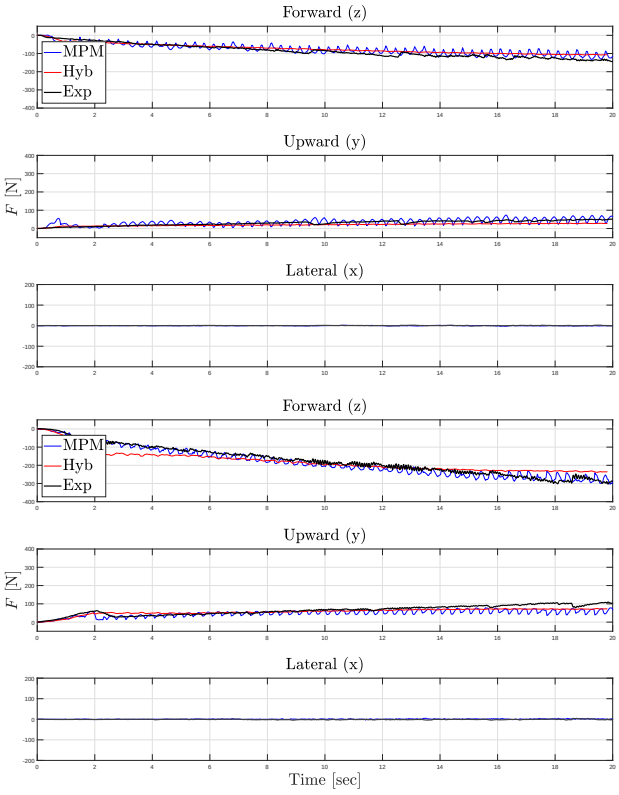

Figure 7. Interaction forces from MPM, Hybrid, and experiment for 2-cm (top) and 5-cm (bottom) depths.

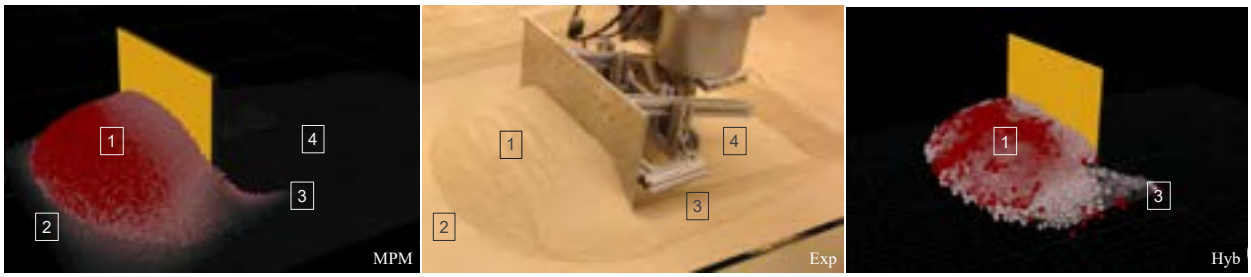

Figure 8. Geometries of soil deformations in MPM, Hybrid, and experiment for 5-cm depth. Four visual criteria are emphasized for comparison.

As can be seen in the results, MPM runs slower than real-time on the target hardware but can be substantially sped up by reducing the number of particles per cell (ppc) and/or increasing the grid spacing (Δx), both of which results in a lower particle count. Using a lower simulation frequency, i.e., a larger time step (Δt), would also lead to a simulation speed-up, but since in MPM equations are solved explicitly, the stability condition could become violated as a consequence. An implicit MPM solver could rectify this issue and would be future work.

The Hybrid method can run at real-time or faster than real-time by reducing particle radius and simulation frequency. Due to its implicit nature, the hybrid method remains stable regardless of the chosen simulation frequency. However, as can be seen in the results, the MPE increases significantly for simulation runs with lower simulation frequencies. This situation can be remedied by also choosing larger particle radii at which point the error reduces. This effect is likely due to excessive particle collisions or tunneling artifacts caused by particles being too small compared to the distances they travel between steps at low simulation frequencies. Thus, by choosing appropriate discretization settings, the error in the Hybrid method can be reduced to a level that rivals with the precision achieved in the MPM simulations with faster run-time settings.

4 Conclusion

Two efficient simulation methods for soil cutting operations have been presented and compared with experimental results. Both methods show good agreement with the experiments, with the MPM method yielding more accurate results than the Hybrid method. While the MPM method runs consistently slower than real-time, the Hybrid method can produce results at real-time and even faster than real-time without significant loss in accuracy. This ability makes the Hybrid method well-suited for use in virtual prototyping contexts such as the development of a real-time excavation automation control system. Accurate and efficient simulation methods are specifically useful in the training of machine-learning algorithms since faster simulation allows accelerating the training procedure. For an example application in which a precursor of the presented Hybrid method has been used for design of an excavator automation system the reader is referred to [28].

Abstract –

This paper proposes an IoT-enabled network of low-cost sensors that are co-located for construction site monitoring. The network performance enhancement is achieved via its system dependability in terms of improved availability, integrity, reliability, maintainability, security and safety in real-time monitoring of environment parameters. The sensor motes of various sensing modules form a reliable wireless in-situ cluster for gathering on-site information of air temperature, soil moisture, air pressure, humidity, particulate matters (PM), emissions and weather variables. They are useful for the site management, improving safety and effective operation of construction equipment. The components for the development include inexpensive microcontrollers ESP32 embedded with wireless gateway function and energy-efficient motes featuring cost-effective sensors. Here, the adoption of the dependability concept for collocated sensor motes aims to introduce a level of redundancy to allow for improving fault-tolerance and reliability. Extensive field tests have been conducted in different environments. Experimental results as well as statistical analysis are provided to verify the merits of the proposed approach.

Site monitoring; Volatile environment; Wireless sensor motes; Dependability; Reliability

1 Introduction

The Internet of Things (IoT) has been applied into various pieces of equipment which are called smart devices, incorporating digital intelligence. However, most of the IoT devices operate indoors with optimized temperatures, relative humidity (RH), dust filter or in well-controlled conditions, that may incur extra budget and resources. The rapid innovation of electronic platforms offers to mitigate these constraints from the availability of commercially low-cost devices. Nevertheless, the quality and performance of these inexpensive components need to be verified and standardized in practical conditions where unpredictable variations or imperfect conditions are unavoidable. The low-cost wireless sensor networks (WSN) adopted for environment-monitoring is an example for addressing this concern. The promising use of IoT-enabled systems operating in the harsh environment has recently attracted researchers in many areas including construction automation. A low-cost sensing system named AIRQino [1] was designed and developed to be as the auxiliary observatory point combining with high-quality reference stations in the Arctic. Cost-effective WSN are also being implemented for military, agriculture, transportation, on land and in marine environment [2], in which instruments may be easily prone to damage. In the construction sector, the IoT-based low-cost WSN technology is still in its infancy [3]. On a construction site, most of the studies focus on critical themes of safety, construction progress monitoring, BIM-related technology, project management, machine and resource management [4], which often consider normal operations with less concern to difficult conditions on a jobsite that may be subject to uncertainty and unpredictability.

Volatility in a jobsite is referred to as varying, unpredictable conditions, such as with varying weather, which may involve drastic changes in construction activities, and cause serious impacts. For example, earthworks usually take place under difficult conditions that have been widely referred to as 3D's, namely Dull, Dirty and Dangerous. In addition being vulnerable to a volatile environment, a construction process may also encounter abnormal disadvantages known as 3H's, i.e. Harsh, Hostile and Hazardous, such as in military or some mining and earthmoving missions [5]. Harsh conditions may degrade the quality of collected data and performance of controllers and the whole system. For reliable and resilient performance in construction processes against environmental variations, disturbances, imperfect conditions or ambient changes, the wireless sensing system should improve system dependability to allow for increased robust, safe and fault tolerant monitoring performance in real time.

The dependability of an IoT system is recently considered and explained as the ability of system proving justifiably trusted services [6]. A dependable system has typical characteristics such as availability, integrity, reliability, maintainability, security and safety. In cost-saving wireless sensing systems, reliability and availability are most critical in order to guarantee the continuous communication, data completeness and power consistency [7]. To increase reliability and availability of the system, and hence, resilience of construction or any industrial process, the downtime from the permanent failure of core controllers should be avoided [8]. In this regard, fault tolerance schemes have been developed in both hardware and software to improve dependability of a management system for solar energy consumption in a smart building [9].

This paper presents the design and development of low-cost wireless sensor systems that are collocated and controlled by our proposed dependable scheme. The availability of power supply is discussed by the combination of Dynamic Energy Conservation (DEC) scheme and the low-power network (ESP-NOW) from low-cost platform ESP32 in Section 2. The developed prototype is validated in laboratory before conducting field tests. Onsite collected data are analyzed by using statistic tools, whereby stochastic regression will be used to impute missing data during online operation. Sections 3 and 4 present the field test results for monitoring construction sites in different environments. Finally, a conclusion for the paper is drawn in Section 5.

2 Development of low-cost wireless sensor system

2.1 Hardware system

Figure 1 shows the proposed diagram of the dependable sensing system, developed for the low-cost WSN, which comprises two subsystems. The first subsystem is called *sensor mote* which constitutes four identical sensing modules of which one is operating while the others are in a stand-by status. Each IoT device operates as an autonomous sensor module (ASM) that consists of components such as micro-control unit (MCU), environmental sensors (soil moisture, soil temperature, RH, pressure, particulate matter - PM2.5 and PM10), two battery cells – Panasonic Lithium-Ion 18650 (3.7V-3400mAh/cell), one mini solar PV panel, real-time reading module, boost-buck converter and battery charging modules, all at a low cost, as shown in Table 1.

The second subsystem is called *gateway mote* or *router mote*. This device is assigned as the role of an intermediate transceiving point between sensor motes and the server when there is no cloud network in a construction site. The gateway mote is assembled by two redundant ESP-32s connecting each other by the serial communication protocol. One MCU communicates regularly with sensor motes in the local network (ESP-NOW) and the other connects to the cloud with Wi-Fi standard 802.11b/g/n. Data packets are sent to the Thingspeak server (https://thingspeak.com) by the hyper transfer text protocol (HTTP).

The printed circuit board (PCB) and main components are protected in a waterproof box (IP68 standard) from the intrusive water and dust at construction sites. Although each sensor module is designed separately, four modules are collocated on the same spots, ensuring redundancy of the sensor mote. Figure 2 shows the prototype with electronic components in a sensor module.

Table 1. Main components of the sensor mote

Components	Features
Sensor SDS011	PM2.5 and PM10
BME280	Air RH, air pressure and temperature
Soil Moisture	Corrosion resistance
Kit ESP32-dev	IoT Microcontroller
TP4506	Charging battery
HT016	DC-to-DC converter
Solar panel	Harvesting solar energy
Battery	Supply voltage (2 cells)

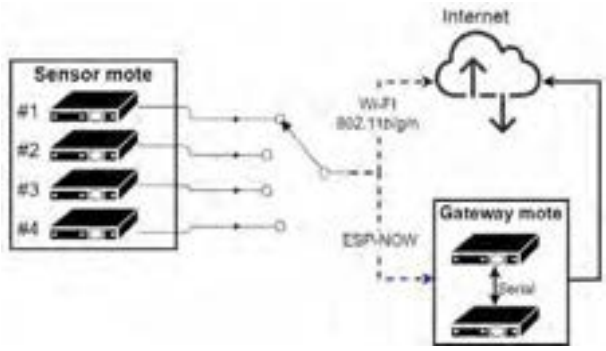

Figure 1. Diagram of the dependable IoT system

2.2 The microcontroller ESP32 and ESP-NOW communication protocol

The MCU ESP32, manufactured by Espressif System company, is a low-power System on Chip (SoC) with wireless communication features in both Wi-Fi and Bluetooth Low Energy (BLE) protocols. This low-cost platform provides multiple peripherals and various communication types (e.g. PWM, I2C, SPI, RS232, etc.). Thanks to the energy-saving architecture with different power modes and 2-core processing capacity at frequency up to 240MHz, the ESP32 MCU is suitable for cost-saving and real-time solutions [10]. The Wi-Fi protocol in ESP32 offers two IoT functions: *Station (ST)*

and *Access point (AP)*, from which the controller can be a member of an available network (e.g. cloud network) or can set up its own local network as a gateway respectively.

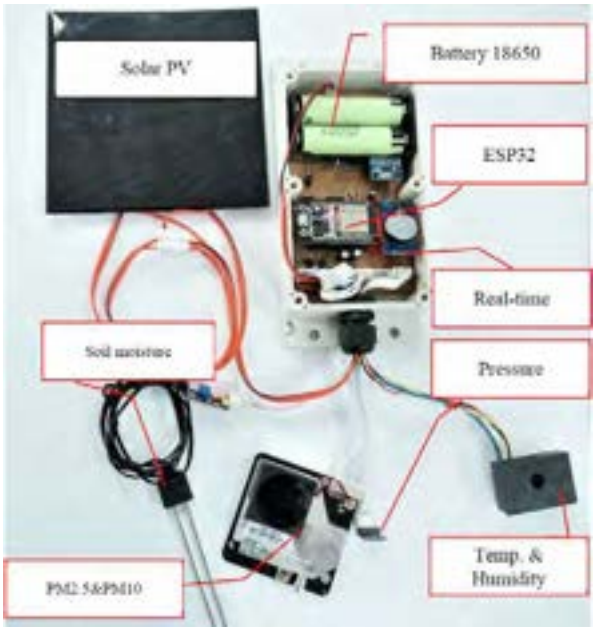

Figure 2. Low-cost sensor mote

Figure 3. Vendor-specific Action Frame and Vendor-specific Content [10]

For the machine-to-machine protocol, the Esprissef wireless ESP-NOW is used, featuring low-power 2.4GHz-radio communication that can connect up to 20 devices without handshake. As shown in the diagram of Figure 3, the data frame of this protocol is encapsulated by a vendor-specific action frame transmitted at the default bit rate of 1 Mbps. Moreover, data transceived by ESP-NOW are secured by the cryptography method (CCMP) defined in IEEE 802.11-2012. This method reduces the risk of interference from other devices or networks to assure the dependable feature of the proposed system in terms of network security.

The body of Vendor-specific Content allows the maximum data packet up to 250 bytes which are more than the requirement in this study because the total sensing data are 112 bytes in the proposed system. In order to validate the efficiency of ESP-NOW protocol, the experiment was conducted in the laboratory with the Virtual Bench NI VB-8012 All-in-one instrument, which could capture signals up to 100 MHz to measure and compare the energy consumption and duration for different wireless communication protocols (ESP-NOW vs. Wi-Fi standard).

In the first experiment with ESP-NOW, the current draining for transceiving a 112-byte packet is 324 mA in 1.6 ms, i.e. a small capacity $C_{ESP\text{-}NOW} = 0.144\times10^{-3}$ mAh. In comparison with sending directly the same packet by Wi-Fi protocol in the second experiment, the expensed capacity is 173 mA in 1285 ms, equivalent to $C_{Wi\text{-}Fi} = 61.751\times10^{-3}$ mAh. To this end, ESP-NOW communication is selected as the local network connecting with gateway motes due to its energy efficiency in radio communication. Besides, the real discharge current were measured without connecting to network ($I_{measure}$ = 162 mA) and during the deep-sleep mode ($I_{deep\text{-}sleep}$ = 10 mA) of the module for the later evaluation of power cost in each working cycle of WSN.

2.3 Dynamic Energy Conservation (DEC) scheme

We apply the Dynamic Energy Conservation (DEC) scheme based on the saving-energy features of ESP32 platform, which varies the duration of the active-sleep cycle dynamically. Here, the active-sleep cycle of the when sensor module includes (1) the active period counted from the "wake-up" and data collection time; (2) period for connecting the local network and transmitting data successfully; (3) the stand-by (sleep) period from triggering the deep-sleep mode until the next wake-up time.

In environmental monitoring application, the ambient parameters are measured as discrete variables with slow variation (e.g. temperature) to reduce constraints of power resource. Here, the regulation sampling frequency depends on the construction activities in dayshifts or nightshifts to flexibly increase the availability of the system. Next, we will consider the various active-sleep cycles from DEC to optimize the power consumption of this system.

The average discharge current in one cycle is:

$$I_{cycle} = \frac{\sum_{i=1}^{3} m_i I_i}{\sum_{i=1}^{3} m_i}, \quad (1)$$

where m_i and I_i (i=1,2,3) is the period and discharge current according to the mode i^{th} as listed in Table 3. In this study, the time to initiate sensors and wireless connection is at least 30 seconds prior to data measurement and transmission, we choose time for active mode m_1 = 30s, whereas the ESP-NOW transmission period for a data packet is very small (m_2 = 1.6 ms) that could be neglected. Hence, the dynamic operation cycles

will be determined by the sleeping time (m_3). We designed a switching mechanism for alternating the battery usage. One battery is charged by solar energy and the other is responsible for supplying power for the whole module.

Table 3. The active-sleep cycle of the sensor module with discharge current measured in each mode

Mode	Action	Period	Discharge current
Active	Measure data	Flexible	162 mA
Active	Communication	1.6 ms	324 mA
Deep-sleep	Stand-by	Flexible	10 mA

Due to the back-up design, this mechanism remains the power supply over the whole working duration, whereas it reduces the aging problem of the battery by intermittent charge and discharge. Therefore, the energy-discharged calculation will be considered for one battery cell. The expected working time of a battery cell in the sensor module is determined by the average discharge current in one cycle (1) and the battery time calculated as

$$T_{bat} = \frac{C_{bat}}{I_{cycle} . n_{cycles}}, \qquad (2)$$

where T_{bat} (in hours) is the average service-time of the battery being fully charged; I_{cycle} is the average discharge current in one cycle; n_{cycles} is the number of cycles per hour according to sleeping time, and C_{bat} is the capacitance discharge current. In our application, C_{bat} = 3000 mA from fully-charged to cut-off point (from 4.2V to 3.0V respectively) with Lithium-Ion NCR18650B battery [11].

From the estimated time listed in Table 4, the larger sleeping period the longer the battery service time. However, the over-extending idle time will reduce the temporal resolution of data, which may cause unreliable analysis results and decisions. This requires further improvement from dependable algorithms [12].

Table 4. The estimated battery service-time with fixed value of active mode (m_1+m_2 ≈ 30s; T_{total} = m_1+m_2+m_3)

Sleeping period	Cycle time (T_{total} - ms)	n_{cycles}	I_{cycle} (mA)	T_{bat} (hour)
30	60	60	91.5	0.6
60	90	40	64.3	1.2
120	150	24	42.6	3.1
300	330	10.9	24.8	11.5
600	660	5.5	17.7	31.6
900	930	3.9	15.3	51.6

3. Field test and results: on-campus construction site

3.1 Field testing and data validation

The first field test was conducted at a construction site in at coordinates 10.0323^{0}N, 105.7682^{0}E. Due to the safety policy from the contractor, the on-site testing period was conducted in a short period from 26th to 29th October 2019 and the sampling interval is 15 min/cycle.

The proposed IoT-enabled dependable scheme illustrated in Figure 1 was implemented with four modules (MD1-MD4), and installed at the site as shown in Figure 4. It will control the communication switch to connect gateways or the server to each sensor module consecutively. Hence, data samples increase four times compared to the single wireless sensor as conventional WSN. As a result, the spatial and temporal distributions of environmental parameters on the construction site have been significantly improved.

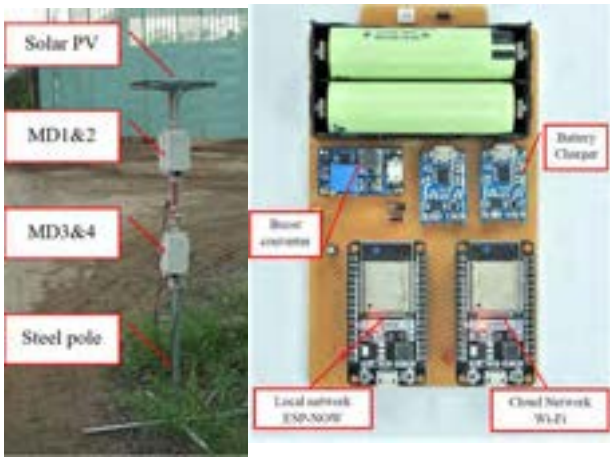

Figure 4. On-site sensor mote (left) and the gateways mote PCB board (right).

The temporal distributions of temperature, RH, PM2.5 and PM10 are illustrated in Figure 5. The profiles of all data show similar trends between collocated modules with small variations. Although some points are affected by noises, they could be removed by filtering out.

To investigate the correlation and linear relationship between the data collected from the low-cost sensor modules, Pearson's correlation coefficient is used

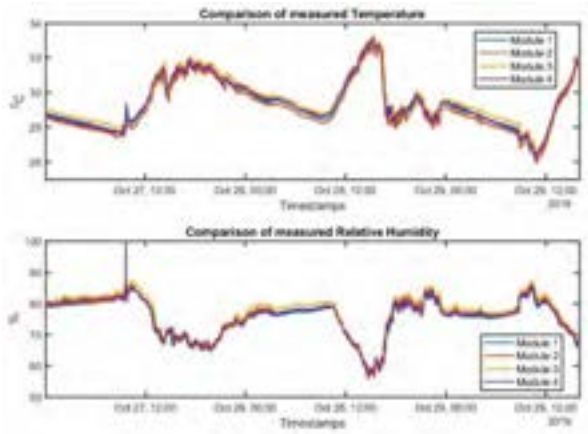
$$r = \frac{\sum_{i=1}^{n}(x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^{n}(x_i - \bar{x})^2}\ \sqrt{\sum_{i=1}^{n}(y_i - \bar{y})^2}}, \qquad (3)$$

where r is the Pearson's correlation coefficient; x and y are the measured values of two sensors; $\bar{x}$ and $\bar{y}$ are means of two datasets and n is the total samples. To evaluate on the deviation between measurements collected from the sensor modules, we use the Mean

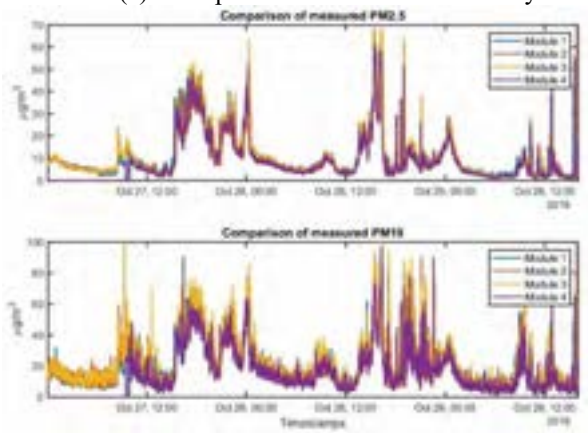
Absolute Error (MAE) and Root Mean Square Error (RMSE) calculated as [13],

$$MAE = \frac{1}{n}\sum_{i=1}^{n}|x_i - y_i|\,, \quad (4)$$

$$RMSE = \sqrt{\frac{\sum_{i=1}^{n}(x_i - y_i)^2}{n}}\,. \quad (5)$$



(a) Temperature and relative humidity



(b) Particulate matters (PM2.5 and PM10)

Figure 5. Profiles of environmental variables measured from the low-cost sensor mote

The correlations from the collocated sensors are depicted for temperature in Figure 6 typically for three modules MD1, MD2 and MD3. The results show that sensors are highly linearly-correlated with Pearson's coefficient r >0.9. From this analysis, we could also identify a sensor module which might have some issues during measuring data. Such a problem may be caused by inappropriate calibrations, misreading of the MCU, being located close to a noise source, or weather volatility.

Table 5 shows deviations in terms of MAE and RMSE of the inexpensive sensors collocated in the same spot. Therein, the highest MAE and RMSE can be observed for PM records, which remain an important component in monitoring of construction sites, particularly subject to a difficult environment. The dissimilarity could stem from calibrated issues that would require some benchmarking with authority stations for comparison and verification.

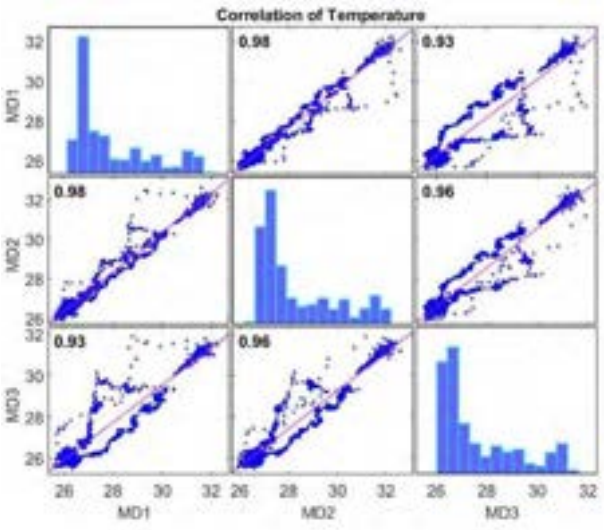


Figure 6. Correlations of temperature by three modules

Table 5. Calculated RMSE and MAE of the sensors

Types of sensors	Ranges of RMSE	Ranges of MAE
Temperature (°C)	0.48 – 0.72	0.37 – 0.69
RH (%)	1.72 – 3.20	1.23 – 2.1
PM2.5 (µg/m^3)	8.37 – 11.2	5.22 – 7.22
PM10 (µg/m^3)	12.57 – 15.34	8.38 - 9.14
Soil moisture (%)	6.13 – 6.55	4.60 – 8.83
Pressure (mbar)	0.51 – 0.99	0.36 – 1.12

3.2 Imputation for missing data

Missing data remain an issue that may cause misinterpretation or bias upon using low-cost WSN. Unlike other studies where missing values are imputed in the offline processing phases, here we propose the stochastic regression scheme that can be integrated in the embedded program to predict the lost data by considering the correlation of the previous data collected from all co-located sensors. The gateway motes could estimate online after receiving data from the sensor motes. The benefit from a co-located sensing system is that the data from well-operated modules can be used as the references without concerning the temporal and spatial distribution of other sensor motes as in [14].

Let P_{k+1}^{j} be the imputed value from module j^{th} (j = 1, 2, 3 or 4) missing information at the index (k+1). During the operation, if device j^{th} sends no data to the gateway, the gateway will poll d previous values received from all four sensors (assuming all previous d values are valid). Given known values of redundant data (P_{k+1}^{i}), the imputation is given by

$$P_{k+1}^{j} = \sum_{k-d}^{k} (w_{ij}.P_{k+1}^{i}) + rand(std^{j}), \quad (6)$$

where the weights w_{ij} are calculated by

$$w_{ij} = \frac{r_{ij}}{\sum r_{ij}}, \quad (7)$$

in which r_{ij} are the correlation coefficients of module i^{th} and module j^{th} ($i \neq j$, e.g. if j = 3 then i = 1, 2, 4), obtained in the range of indices from ($k-d$) to k. A random number, *rand*(.), in dependence of the standard deviation of sensor j^{th} (std^{j}), is added to ensure the estimated data being close to the actual measured data but not overfitting.

To validate the imputation method, we assume 1000 datapoints of temperature and RH in module MD3 are missed during the service time, while the others (modules 1, 2 and 4) still operate well with full transceiving of data packets. The selected polling threshold is d = 20 (i.e. 20 previous samples of the missing point are used to identify coefficients and weights). Figure 7 shows the imputation results for missing values of temperature and RH. The estimated and the actual data relatively fit with small residuals. The RMSE of those data are 0.684 (Celsius degree) for temperature and 2.84 for RH. Therefore, the proposed technique is promising in improving reliability of the monitoring system for the construction site.

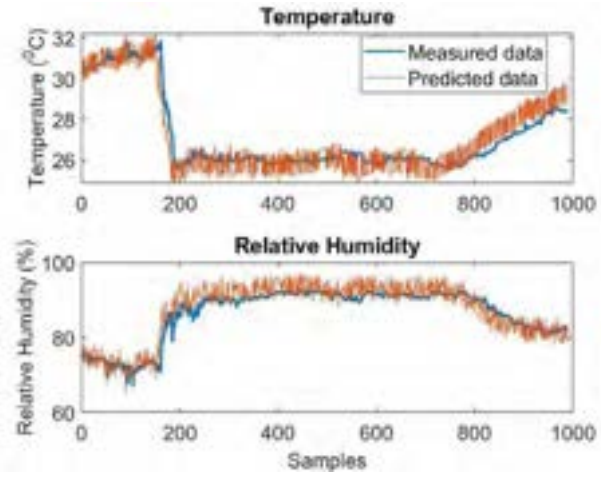

Figure 7. Estimated missing data of temperature and RH sensors from imputation.

4. Field test and results: residential construction site

The proposed dependable scheme is now adopted for monitoring the emissions of a construction site at coordinates 33°49′11″S, 151°4′38″E. The low-cost sensor motes are fixed on the electrical poles at the height of 3 meters above the ground to assure a proper coverage without damage risk from construction activities.

There were 15 devices denoted as T1 to T15 installed over the whole area of approximately 1 km^2. The construction site was monitored by co-located sensor motes T1 to T8, while the surrounding residential zones were monitored by T9 to T15, as depicted in Figure 8.

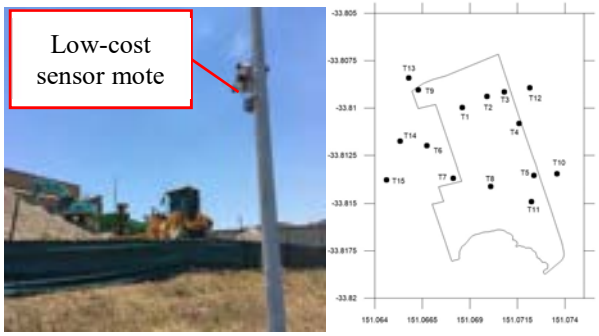

Figure 8. Low-cost sensing devices installed over the monitoring area

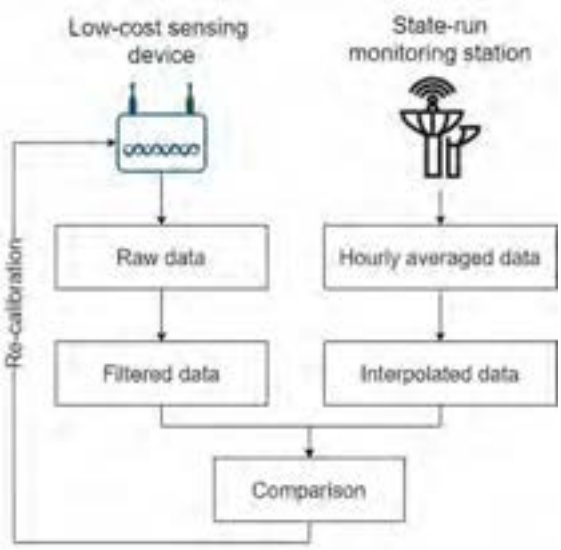

Figure 9. The iterative process of data processing of low-cost IoT-enabled monitoring system

Figure 9 presents the process of data interpolation and for long-term monitoring operations. Therein, two streams are considered: (1) data from a nearby state-run monitoring station, extracted for referencing; (2) data

measured by the developed system on the construction site. Both data are processed prior to comparison, and the differences will be analyzed and fed back to the devices for re-calibrating to reduce any issues in association (e.g. time drift, gain and bias, etc.).

4.1 Processing measured data

The raw data are collected from the devices wirelessly through the Thingspeak server. The surveying period covered 65 days (from 15th November 2019 to 19th January 2020), with 6161 samples/device for each sensor (temperature, RH, PM2.5, PM10 and battery voltage). For the scope of this paper, only data of fine particle concentrations (PM2.5) are used for evaluating the performance of the wireless sensing system. The low-cost sensors collected data continuously 24 hours per day with a sampling period of 15 minutes to ensure stable operation, network connection, and battery lifetime. The raw data were affected by multiple noises causing imperfect recording of monitored parameters, for which anomalous values were treated by a moving average filter. Figure 10 presents the graphs before and after processing. It can be observed of the contribution from construction emissions to the rise of PM2.5 level when resuming the onsite work after the New Year break, while the high concentration of the fine particle dust reflected the impact of bushfires at the time.

4.2 Interpolating reference data

For validation of information gathered by low-cost devices, the measured data are compared with the data recorded by state monitoring stations, managed by the Department of Planning, Industry and Environments (DPIE) of the NSW Government [15]. Here, the closest state-run monitoring station is about 7 km to the site. In order to match with the time scale of the measured data, the DPIE records are resampled, with a cubic interpolation method, from 1920 to 6161 samples over the studied period.

Figure 11 shows the comparison between the two datasets after processing, which display a good fit with a high correlation as presented in Figure 12 despite some small phase shifts between two temporal profiles. This could be due to the spatial difference between the two locations with a systemic delay in DPIE reporting as well as the effects from other meteorological parameters.

The collected data from all 15 low-cost sensor motes are visualized in 3D for the spatial distribution by Surfer® v.11 and MATLAB® v.2020a software for further evaluation the influence of construction activities to the air pollution over the surrounding residential area, as depicted in Figure 13, with data being obtained on Jan 8th 2020. Therein, it can be observed of some higher concentration of PM2.5 (over 90 µg/m^3) at the construction site, whereas the lower levels were in the residential area albeit still above the national threshold of 25 µg/m^3 [16]. The reason was attributed to the prolonged impact of bushfires in the state [17].

5. Conclusion

This paper has presented the development of effective wireless sensing networks for reliable monitoring of construction sites using IoT-enabled dependable co-located low-cost sensor motes. The availability and resilience of the proposed system is assured by the saving-energy modes of hardware architecture, DEC framework and the redundancy of stand-by co-located sensing modules. Extensive field tests have been conducted on construction sites at different environments to validate and verify the advantages of the system implementation and its meritorious attributes. The proposed monitoring systems, coupled with various data processing techniques and the developed imputation algorithm, have resulted in significant improvement of the monitoring performance in terms of accuracy and dependability. Our future work will focus on the incorporation of learning schemes in order to cope with site monitoring in challenging conditions of abrupt changes in a volatile environment for accurate assessment of micro-climate conditions.

Abstract –

Cybersecurity threats related to new technologies get little attention until an incident occurs, and vulnerabilities are highlighted. In the case of construction projects, any cyber breach, either malicious or incidental, has the potential to cause significant damage. This varies from unauthorized access of sensitive project information to hijacking construction equipment to cause structural damage to the site or harm to personnel. Given the potential implications of threats in cyber-physical systems, and the potential for physical damage to products and personnel, serious consideration from a research perspective is needed. The risk of such attacks occurring is exacerbated in regions such as the UAE, where new technologies, such as 3D printing, are trending.

With that in mind, the objective of this study is twofold. First, to raise awareness about the cybersecurity implications of the new technologies adopted by the AEC industry. Second, to understand the core cybersecurity aspect of threat modeling concerning cyber-physical systems applied to construction projects. Several threat modeling methods such as STRIDE, OCTAVE, PASTA, and VAST have been developed. However, they are not easy to adopt by construction professionals who generally have limited knowledge of the cybersecurity domain. To address that, this study aims to develop a preliminary threat modeling approach that is relevant to the construction industry and can be quickly adopted to investigate the current technology being implemented. To demonstrate the practical feasibility of the proposed threat model, we consider an industrial-grade robotic arm system to 3D print construction elements offsite. This threat model will provide insights into a range of different threats that these systems are vulnerable to, allowing us to secure these systems against such threats, and raising awareness about the cybersecurity implications of implementing such technologies in the AEC industry.

1 Introduction

The notion of having a digital model and a machine able to build it with a high degree of accuracy, with little human intervention, and in a timely fashion is very attractive and appealing. In the construction sector, that notion has been materialized with the development of 3D printing technology along with the use of contour crafting in which successive layers of cementitious material are placed to generate building elements. Although there are still many challenges to overcome (e.g., scalability, mobility, materials), there are already construction projects that have benefited from the use of 3D printing [1]. Some recent examples include the Apis Cor's two-story building in Dubai, UAE [2], Winsun China's villa [3], concrete bridges in Spain [4] and China [5], portions of the DFAB HOUSE [6] and the Concrete Choreography project [7] in Switzerland, single-family houses in Denmark [8] and France [9], and military barracks in the US [10].

A lot of efforts have been made in the research community regarding the technical aspects of 3D printing in the construction sector; however, the aspect of cybersecurity has been disregarded. The use of 3D printing in construction opens the door to new risks and vulnerabilities. Researchers are starting to consider the cybersecurity challenges and vulnerabilities caused by the digital transformation taking place in the construction industry [11, 12] and quantifying the cyber vulnerability of construction participants [13]. The ability to maliciously access to remote devices has already been documented. For example, [14] found that the radio signals typically used for crane controllers are not encrypted and can be easily intercepted and spoofed using off-the-shelf equipment and basic knowledge of electronics and radio engineering.

Similarly, regarding cybersecurity implications of 3D printing in other industries, [15] investigated how sabotage attacks could compromise the quality of 3D printed parts. Their study showed an attack against a desktop 3D printer used to manufacture propellers for an unmanned aerial vehicle (UAV). The sabotaged part experienced structural decay and caused the UAV to crash during flight.

As with other cyber-physical and connected systems, the connectivity requirements of 3D printing systems (e.g., controllers and manipulators, network connectivity, and peripherals, such as pumps or mixers), raises the potential for cyber-attacks. Considering the sensitive nature of construction projects, the introduction of the 3D concrete printing system as a cyber-physical system (CPS) that can be accessed by third parties with malicious intents poses several problems that need to be addressed.

The rest of the paper is organized as follows. In Section 2, we provide an overview of threat modeling, including existing methods and an evaluation of appropriate methods applicable to the construction industry. Section 3 discusses our efforts in the development of a threat modeling method (TMM), along with a high-level description of the overall procedure. In Section 4, we show the application of the TMM using a generic 3D Concrete Printing (3DcP) System. Also, we explain the specifics of each stage in the proposed TMM. Section 5 contains a discussion of the application and an identification of where the TMM succeeds and where it does not. Finally, we summarize key findings and suggest areas for future work in Section 6.

2 Threat Modeling

Threat modeling can be defined as the process of identifying potential threats, vulnerabilities, attackers, and targeted assets, with the goal to define countermeasures and plan risk mitigation strategies. The objective is to get a clear picture of the attack map, that is, how, where, why, and by whom an attack might occur. It consists of analyzing the security of an application or system by systematically cataloging and inspecting vulnerabilities present in a variety of contexts in the system under consideration [16]. The threat modeling process, as viewed by [17], can loosely be seen to consist of three high-level stages: (1) system characterization, (2) asset and access point identification, and (3) threat enumeration. Based on these principles, threat modeling requires a fundamental understanding of the underlying architecture, its design and implementation in order to prepare a thorough review and security analysis that can then be used to provide countermeasures that would prevent, or mitigate, the effects of any threats to the system. We proceed to identify two primary threat targets, Information Technology (IT) and Operational Technology (OT). The former relates to threats concerning the network infrastructure governing the system under consideration, while the latter relates to matters of physical security concerning the hardware operating in the system and potential damages to surrounding areas and people.

As with [18], in which a new threat modeling method was developed to fit a unique case, there is a need in the construction industry to investigate and consider the risks of cyberattacks due to the integration of new technology. With this in mind, we develop a threat modeling method that suits the small-scale but heavily interconnected nature of a 3D printing system used in construction.

2.1 Threat Modeling Methods (TMMs)

We place a heavy emphasis on understanding the nuances of existing TMMs, and what makes these methods suitable for specific systems. Our review of [19], [20], and [21] provided an understanding of a broad range of methodologies, from commonly used systems such as STRIDE and PASTA to uncommon ones such as CORAS and TRIKE. A summary of all the TMMs considered is shown in Table 1. This information will allow us to gauge the strengths and weaknesses of a range of TMMs along with which of their characteristics might come into use based on a variety of situations. There are a variety of characteristics to consider, from the range of threats, the existence of a built-in empirical component, to the availability of documentation.

2.2 Shortlisting Candidates

Considering the range of TMMs evaluated (Table 1), the following criteria were used to narrow down the selection of the TMMs to be used.

1. Threat Range (Low, Medium, High): Refers to the variety of threats captured.
2. Empiricism (Yes, No): Whether the TMM has an empirical component to gauge threats.
3. Consistency (Yes, No): Whether repeated use of the TMM yields the same results.
4. Risk-Mitigation (Yes, No): Whether the TMM contains some in-built component for mitigating the threats captured.
5. Suitability (Yes, No): Whether the TMM has not been explicitly developed for some specific system.
6. Documentation (Low, Medium, High): The amount of documentation available.

These characteristics are chosen based on our perspective on what would a generic situation be in which our TMM is used, with regards to the participants involved, the resources available, and the system under consideration. We chose the characteristics to capture a

broad range of threats, output an empirical result to gauge the magnitude of the risk of each threat, produce the same results consistently, contain in-built prioritization of risk mitigation and management that can be applied to a generic context while having proper documentation to aid during the threat modeling process.

Table 1. Summary of TMMs and characteristics used for selection in this study

Method	Threat Range	Empiricism	Consistency	Risk - Mitigation	Suitability	Documentation
OCTAVE	Medium	Yes	Yes	Yes	No	Medium
Trike	High	Yes	No	Yes	Yes	Low
PASTA	Medium	Yes	Yes	Yes	No	High
STRIDE	High	No	No	Yes	Yes	High
CORAS	Medium	Yes	Yes	Yes	No	Low
VAST	Medium	No	Yes	Yes	No	High
LINDDUN	High	No	No	Yes	Yes	Medium
hTMM	High	No	Yes	Yes (4)	Yes	N/A (3)
QuantitativeTMM	High	Yes	Yes	Yes (4)	Yes	N/A (3)
CAPEC (1)	Medium	No	N/A	No	No	N/A
ATT&CK (1)	Medium	No	N/A	Yes	No	N/A
IIDIL / ATC	High	No	Yes	Yes	Yes	Low
Security Cards + PnG (2)	Medium	No	Yes (SC) – No (PnG)	No	No	High (SC) – Low (PnG)

(1) CAPEC and ATT&CK are considered threat libraries and do not necessarily provide information as to modeling threats in a system
(2) Security Cards + PnG are essentially a gamification of the threat modeling process and should be used for training and brainstorming purposes only
(3) hTMM and QuantitativeTMM use STRIDE, and therefore we use the STRIDE documentation as a baseline for these TMMs; however, the methods themselves are not as mature as STRIDE
(4) Risk Mitigation based on STRIDE

Based on the selection characteristics previously described, Table 1 yields a few clear winners, with STRIDE and its derivatives meeting most of our criteria at their highest standards. Therefore, we have chosen the QuantitativeTMM as the basis for the modeling method for threat modeling in the rest of the paper.

3 Framework of proposed TMM – QuantitativeTMM

The framework of the QuantitativeTMM (QTMM) described in this section is a combination of the QTMM proposed in [22] along with parts of [23]. The high-level steps are shown in Figure 1 and described as follows.

Step 1: Define use case / problem statement
We begin by delineating our system; this includes an explanation of the system goals, the system components, information flows within our system, as well as users of our system [24].

Step 2: Define Data Flow Diagram (DFD)
Data Flow Diagrams are a method of breaking down the system into single components in the form of *Entities, Data Flows, Data Stores,* and *Processes. Trust Boundaries* are another component used to delineate the border between trusted and untrusted components in the DFD. The DFD acts as a graphical representation of these components in order to present the user with a high-level overview of the interactions between separate components in the system [23]. For a given use case or problem statement, the user creates a DFD with the required granularity. A finer granularity will produce a more refined overview that, at later stages, will yield a higher number of threats related to specific component interactions.

Step 3: Map STRIDE Elements into DFD
Once the DFD is created, we use the STRIDE classification of threats to 'map' individual components of the DFD to the respective threat classes. Table 2, adapted from [24], delineates the threat classes associated with each component. Once this is done, the user may begin to internalize the form of threats that may appear.

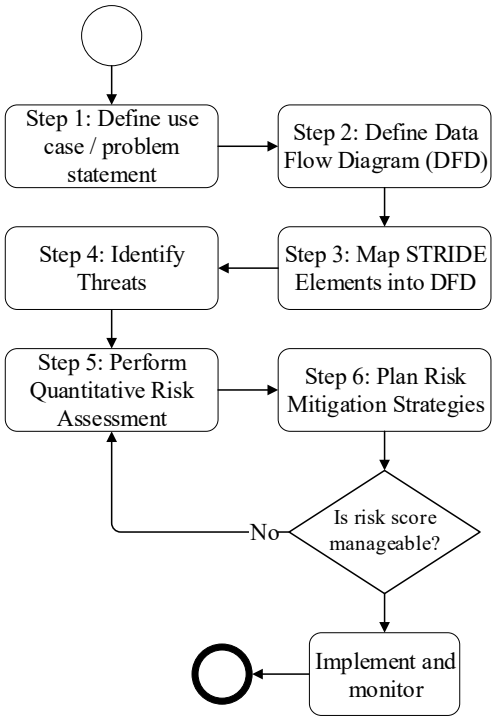

Figure 1. Main steps of the QTMM

Table 2. DFD Component Vulnerabilities as per STRIDE Threat Classes

Component	S	T	R	I	D	E
Data Flow		✓		✓	✓	
Data Store		✓		✓	✓	
Entity	✓		✓			
Process	✓	✓	✓	✓	✓	✓

A brief description of the different threat classes as per the STRIDE threat classification is summarized in Table 3. The purpose of this step is to identify the threat classes that are most prevalent to each component and prioritize the threat identification procedure for those classes.

Step 4: Identify Threats
Iterate over each component in the DFD and begin considering potential threats starting from generic attacks to more process-specific ones. If necessary, once threats are enumerated and cataloged, create short misuse case scenarios [25] for each attack. Due to space limitations, we forgo creating misuse case scenarios in this study.

Step 5: Perform Quantitative Risk Assessment
For each component in the DFD, and the relevant STRIDE threat classes, we generate attack trees using the information collected from the previous step. These component-based attack trees are then scored using a combination of the Common Vulnerability Scoring System (CVSS) and a risk propagation technique in order to gauge the final risk value of the threats [22].

Table 3. Threats classes per STRIDE

Threat	Description
Spoofing	An attacker attempts to mislead users or systems by falsifying either a process or an identity.
Tampering	An attacker modifies the system to cause harm.
Repudiation	An attacker rejects a transaction in the system.
Information Disclosure	An attacker obtains access to sensitive data concerning the system.
Denial of Service	An attacker makes the system unavailable to users.
Elevation of Privilege	An attacker manages to obtain administrator privileges.

Step 6: Plan Risk Mitigation Strategies
Considering the attack trees and their relevant scores, as well as the earlier generated misuse-case scenarios, the user can continue to ideate on potential actions to mitigate these threats. After mitigation strategies have been developed, a user may re-evaluate the previously defined attack trees to update the risk score for a threat class. Steps 5 and 6 are repeated until the user is satisfied with the level of threat mitigation. Once an acceptable risk score is obtained, the mitigations are implemented, and the system is monitored and updated as needed.

4 Example: TMM for 3DcP application

To illustrate the implementation of the proposed framework, we use a generic Robotic 3D Concrete Printing System as an example.

4.1 Define use case / problem statement

The system under consideration was chosen based on the review of existing literature and information obtained from industry experts to ensure a realistic case. The specification in question is based on ABB's IRB 6620 6-axis robot arm, with additional interfaces provided by the IRC5 industrial robot controller [26].

A schematic representation of the different elements for the 3DcP system used in this example is shown in Figure 2. The different elements identified in Figure 2 are described below.

1. **System Command:** The System Command refers to whichever device is used to relay instructions to the robot controller. This can be an Arduino microcontroller.

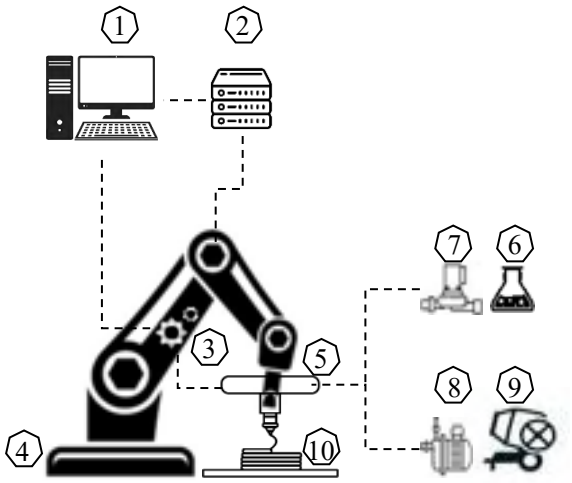

Figure 2. Schematic of the 3DcP system

2. **Robot Controller:** The Robot Controller is responsible for converting and relaying high-level commands passed through the system command onto the robotic arm itself. The IRC5 is an industrial standard for robot controllers.
3. **Printing Controller:** Based on the dimensions of what is being printed, the printing controller has several axes of movements that it can operate in to facilitate printing over a large surface area.
4. **Robotic Arm:** The Robotic arm is responsible for receiving instructions from the system command and passing on instructions to the precise part of the printing controller.
5. **Printhead:** The printhead is responsible for extruding the concrete mixture.
6. **Accelerating Agent:** A deposit containing the accelerating agent used in speeding up the concrete formation chemical reaction.
7. **Pump for Accelerating Agent:** Responsible for pumping the accelerating agent into the mixture, controls factors such as speed and throughput.
8. **Pump for Premix:** Responsible for pumping the premix into the printhead, controls factors such as speed and throughput.
9. **Premix Mixer:** A deposit containing the concrete premix used in the concrete printing process.
10. **3D Printed Object:** The designated 3D printed object as specified by the user.

4.2 Define the Data Flow Diagram (DFD)

Using the Legend defined in Microsoft's STRIDE Application article [24], we have defined the Data Flow Diagram, as shown in Figure 3, for our use case of the generic 3DcP application in Figure 2. Each of the data flows represent the flow of instructions in some digital format necessary in the 3DcP process.

A. 3D Specification Loaded into the System Command
B. Printed Item Specifications
C. Pump Control Information
D. Robotic Arm Printing Instructions
E. Robotic Arm Movement Instructions
F. Printhead Positioning Instructions
G. Printhead Extrusion Information

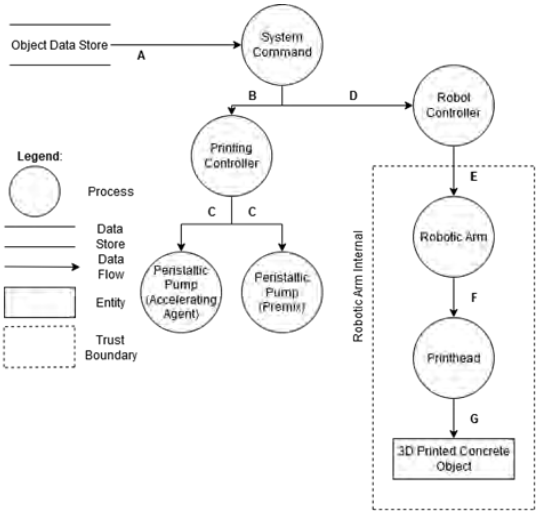

Figure 3. Data Flow Diagram

The trust boundary is a subjective measure of different levels of security that are present within the same system. The trust boundary in this example has been defined at the robotic arm and printhead, assuming that those elements would be less susceptible to direct access.

4.3 Map STRIDE to Elements into DFD

There are multiple 'process' components in the DFD. These components are, by nature, susceptible to all threat classes introduced by the STRIDE threat classification. Considering the data flows between these components, we realize that the information moved across the system is related to one another and, at times, are subsets of the preceding data flow. Threats that target one such data flow can potentially be replicated on another as per the goals of the attacker. However, the risk evaluation is dependent on the component in question. If we were to consider the "Robot Controller" component, it is unlikely that *Spoofing* or *Elevation of Privilege* threats are prevalent; *Tampering* threats, however, pose a serious concern.

4.4 Identify Threats

Consider the "Robot Controller" component. As a 'process,' it is susceptible to any of the STRIDE classes of attacks, but as mentioned previously, certain threats classes pose a greater risk than others. If we were to

deliberate on the potential threats that fall under the threat class of 'Tampering,' we would see threats like those delineated in Figure 4. As previously mentioned, these generic threats could take place in another DFD component, considering the nature of the data flow. To understand these threats in greater detail, the user may choose to generate misuse-case scenarios that dive into the context-aware specifics of these threats while providing a basis upon which risk-mitigation strategies are developed. The ideation performed at this step is fundamental to the remainder of the threat modeling process as it deepens the users' understanding of the system while providing a foundation upon which the Quantitative Risk Assessment may be carried out.

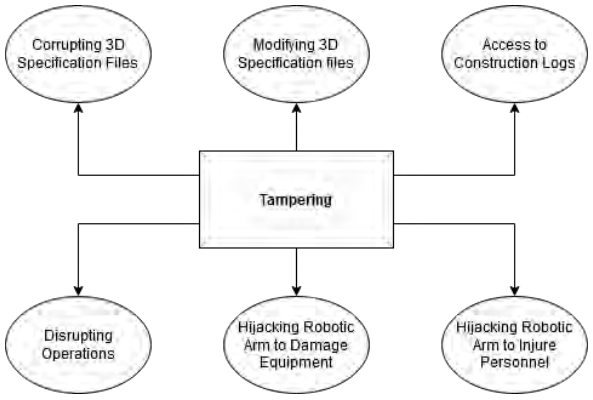

Figure 4. Potential Tampering Threats

4.5 Perform Quantitative Risk Assessment

An understanding of the variety of threats associated with the 'Tampering' threat class for the Robotic Controller aids us in developing the attack trees for this scenario. Using [22] as a guideline, we create Component Attack Trees (CAT) for a STRIDE threat class. This system uses four nodes, the *root node* (red), *intermediary node* (black), *leaf node* (gold), *class node* (white), and *mitigation node* (blue). The *class node* is designed to help systematically divide up threats. Each of the leaf and mitigation nodes are assigned a value reflecting the probability of success. This value is propagated upwards to the root node to determine the odds of success. To read the CAT, a user would begin at a leaf node and follow the path until the root node, at which point the attack has 'succeeded' [22].

Figure 5a is the high-level attack tree we generate for the Tampering threat class, and Figure 5b the risk propagation using CVSS. Unless otherwise specified, all leaf nodes are related by an 'OR'. Once we have created the attack tree, we use the CVSS to attribute a risk score to the leaf (gold) nodes. We then propagated these risks upwards as per the operations listed in [22] and summarized here.

"OR" operation between two nodes (x,y): P(x)+P(y)-P(x)P(y)
"AND" operation between two nodes (x,y): P(x)P(y)
"MITIGATION" of node (x), with mitigation P(m): P(x) = P(x)*(1-P(m))

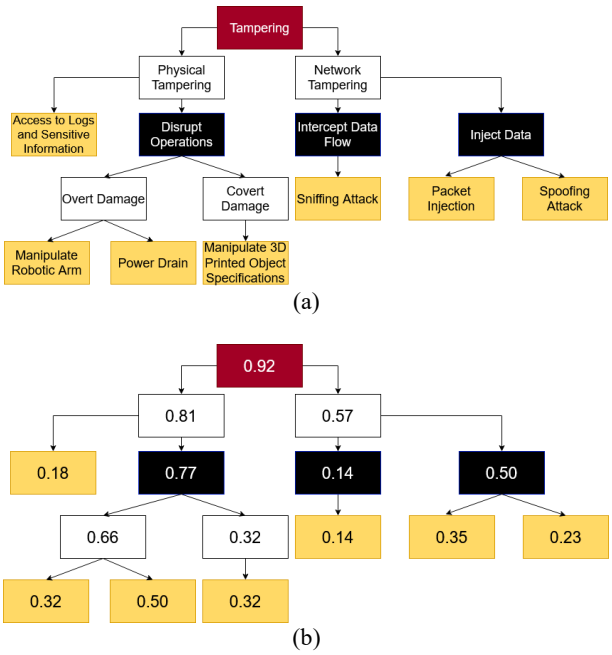

Figure 5. (a) Attack tree and (b) risk propagation and assessment for the Tampering Threat Class

Using the CVSS score [27] for the leaf nodes of this attack tree and the operations above to calculate the remaining risk scores for the various nodes, the overall risk score for the tampering threat class can be determined. This is showcased in Figure 5b. To illustrate the calculation of the score, consider the "Overt Damage" class, the 'manipulate robotic arm' threat has a lower risk value than 'power drain' because it is harder to accomplish while disconnecting the system from a power source is much easier to accomplish. However, they both present a threat, and together their risk score is calculated as follows:

$$0.50 + 0.32 - (0.5 * 0.32) = 0.66$$

Following the same approach, the overall risk score for the Tampering Threat Class is calculated to be 0.93 (9.3/10 in the CVSS scale), which is classified as a critical threat.

4.6 Plan Risk Mitigation Strategies

As a process, risk mitigation begins with the generation of the attack trees. Once a user has identified the different attack vectors, their understanding of the system will allow them to intuit strategies to counteract

threats at the lowest levels. The more detailed the DFDs and, consequently, the attack trees, the more nuanced simplified components will be available for a user to ideate mitigation strategies. Usage of attack libraries such as CAPEC and ATT&CK may help this brainstorming process. Figure 5 displays a scenario where there are no mitigation strategies. The user may update the attack tree with mitigation nodes (Figure 6) that would reduce the risk score of the corresponding leaf node (the "*" in Figure 6b indicates the pre-mitigation risk score). For illustration purposes, a subjective mitigation score was assigned to the mitigation (blue) nodes. Once the mitigations are considered, the overall risk score of the threat class can be recalculated. In this example, the mitigation nodes considered reduce the overall risk from 0.93 to 0.83, or a reduction of the risk of the tampering threat class from a critical risk threat, to a high-risk threat. This feedback loop can continue until the user is satisfied with the risk level, as well as the quality of the risk mitigation strategies in place.

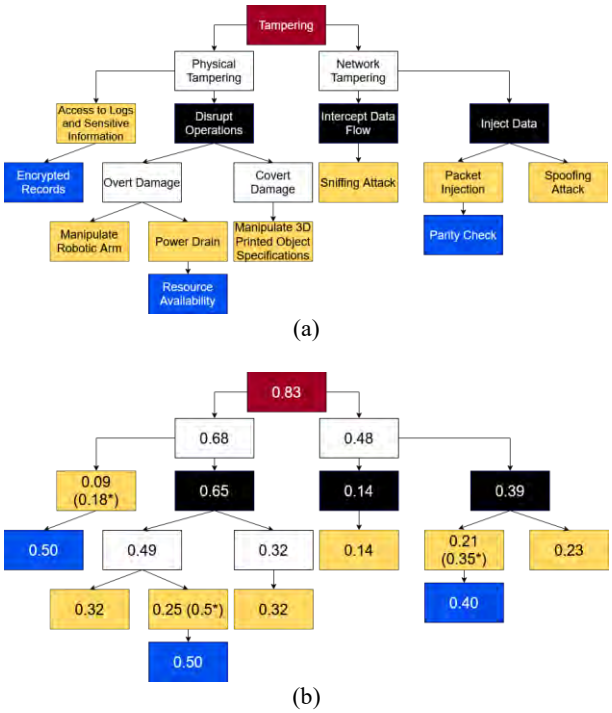

Figure 6. (a) Attack tree and (b) risk propagation and assessment for the Tampering Threat Class with countermeasures (mitigation nodes)

5 Discussion

The nature of this paper hinges on providing an example of applying a TMM in the field of 3D printing in construction. Section 4 shows an example that can be used as a guide for users when tackling similar systems.

Although the length of this paper imposes limitations on the extent of details shown in the example, enough information is provided to allow the reader to get a general idea of the different steps required in the threat modeling analysis. The DFD and attack trees are simplistic in nature to convey the idea of the threat modeling process as opposed to providing a thorough threat model of this system specification.

The threat class we chose for this application was the STRIDE threat class of 'Tampering' applied onto the DFD's 'Robot Controller' process component. Considering the nature of the data flows in our system, many of the attack trees generated are likely to contain the same threats in relation to those components that are either inside the trust boundary or outside of it. However, the threats delineated in these attack trees would be scored differently, and ultimately the same threat could have different risk levels based on the component in question. We consider the Robot Controller component, a rather central piece in the 3DcP process, and one that is highly susceptible to Tampering threats.

For our example, we modeled both physical and network threats as two separate classes. While there is a degree of overlap between the two, we realized it would be more beneficial from a practical standpoint to illustrate a wider scope of threats. The threats related to network tampering are a generic class of threats that involve exploiting known vulnerabilities in any network system. On the other hand, the physical tampering threats are process-aware and are attacks that are carried out respective to the system in question.

The methodology presented is effective in detailing and visualizing the extent of the threats posed to a system with minimal effort, that is, once the attack trees have been generated and the CVSS scores for the lead nodes calculated, the risk propagation is straightforward. The most significant obstacle to a TMM is in its ability to capture a substantial proportion of potential threats. To succeed in this endeavor, a great deal of emphasis must be placed into developing the DFD; this aspect of the TMM is core to all subsequent steps.

6 Conclusion and Future Work

As 3D printing technologies emerge and their use in construction projects become more common, it is of utmost importance to develop methods and frameworks to identify vulnerabilities and address them before full implementation or integration with other systems is done.

This endeavor is heavily based on understanding the nuances of a threat modeling method in relation to cyber-physical systems and developing a threat modeling method with a specific application in mind, in this case, the use of 3D printers in construction. A large part of this involves an understanding of both the existing threat modeling methods as well as contemporary 3D printing

technology in construction that would allow the creation of an applicable threat modeling method.

Our ongoing work includes improving the current threat modeling method to better suit a more extensive scope of 3D printing specifications and configurations that involve supplementary machinery that would complicate the threat landscape. Such improvements will be complemented with research into specific attacks allowing us to gauge their viability. Attacks that involve physical externalities can be conducted over a simulated environment, whereas more traditional IT-related attacks can be attempted directly with the appropriate equipment on hand.

Once a thorough modeling methodology to scope threats is in place, our focus will shift into techniques for securing the systems investigated. This process is two-pronged, considering both proactive and reactive measures. Proactive measures will aim to patch security flaws in the system that can be easily avoided. Reactive measures will seek to provide guidance to 'worst-case' scenarios.

The culmination of this research will be a holistic guide to identifying and securing 3D printing specifications in construction against any manner of threats for both OT and IT scenarios.

Abstract **–** The separation of exterior tiles from buildings diminishes the visual appeal of cities and can injure pedestrians when they are struck by falling tiles. Therefore, tiles should be inspected periodically. However, completion of the inspection process has hurdles, including high cost and the need for qualified human inspectors. This study describes a non-destructive inspection method for detecting voids that match those seen in tile separation in a concrete specimen using electromagnetic waves, specifically microwaves. The method can be performed using devices that are simpler, smaller, and easier to use than those required by conventional methods. In addition, this method can be used to measure the adhesion strength of tiles.

Keywords **– Non-contact inspection; Electromagnetic wave; Adhesion strength; Multi-layered scanning.**

1 Introduction

The separation of exterior tiles from buildings reduces the visual attractiveness of cities and falling tiles can injure pedestrians below, especially during earthquakes. Therefore, tiles should be checked periodically. However, high cost and the need for a qualified human inspector hinders the completion of inspections. In this study, voids that match those seen in tile separation were detected in a tiled concrete specimen using non-destructive inspection (NDI) with electromagnetic waves (EMWs), specifically microwaves. Several methods based on NDI techniques using EMWs have been developed and reported. These methods include ground-penetrating radar [1], microwave tomography [2], microwave non-destructive testing, and other evaluation methods [3] [4] that use a network analyser in the time/frequency domain to calculate the position of foreign bodies in the object; such methods are very complex and costly.

Our proposed method uses EMW reflection intensity data for analysis, and the measuring device required is simpler, smaller, and easier to use than that required for the above-mentioned methods. Our method can also use the reflection data to estimate the adhesion strength of the tiles. An antenna that transmits and receives microwaves was used to obtain the reflection intensity from the concrete specimen, and the distribution of reflection intensity was determined using a multi-layered scanning (MLS) method. This reflection intensity was compared with normal concrete data (trend data) to predict the integral of the difference, which indicates the size of the void [5] [6]. In our experiments, first, a tiled concrete specimen with voids was evaluated by MLS to calculate the strength distribution. Second, tensile strength testing of the tiled concrete was performed, and the strength to failure was measured. Third, the correlation between the tensile strength and the reflection intensity by MLS was examined to evaluate the possibility for practical use.

2 Microwave NDI

2.1 Inspection apparatus

The inspection apparatus for detecting voids consists of a linear actuator and a flaw detection device. The flaw

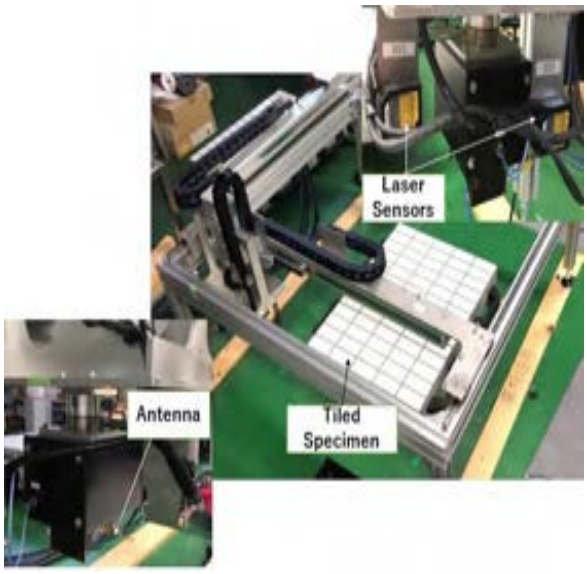

Figure 1. Inspection apparatus.

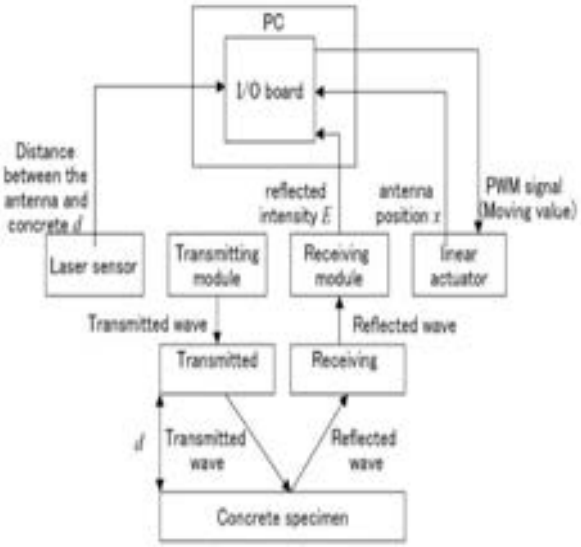

Figure 2. Measurement system.

detection device consists of a lifter, an antenna, and a laser sensor, as shown in Figure 1. An overview of the signal processing system is shown in Figure 2. The linear actuator is used to move the flaw detection device over the concrete surface, and the device scans the surface to detect voids.

2.2 Tiled concrete specimen

Figure 3 shows the tiled concrete specimen, which comprises tiles, adhesive mortar, and concrete. Figure 4(a) shows the dimensions of the tiled concrete and the positions and widths of the voids, Figure 4(b) shows the design of the tiled concrete specimen from the side, and Figure 4(c) shows the positions of the voids as seen from the side. The experiments demonstrate the effectiveness of the proposed void detection method by applying NDI using EMWs to an actual tiled concrete specimen. In addition, the system used the void sizes to indicate the tile adhesion strength.

2.3 MLS method

This section describes the MLS method [5-6], which is used to acquire the reflected intensity and to estimate and remove interference and noise caused by EMWs.

The detection void algorithm is shown in Figure 5. First, the total reflection intensity, E_r, is measured by MLS. In abnormal areas, the received intensity is the effective value of the sum of the direct wave, surface wave, and air gap reflected wave. Next, the trend reflection intensity, E_t, is measured by MLS. This shows the reception intensity of normal (void less) areas, which is the effective value of the sum of the direct wave and

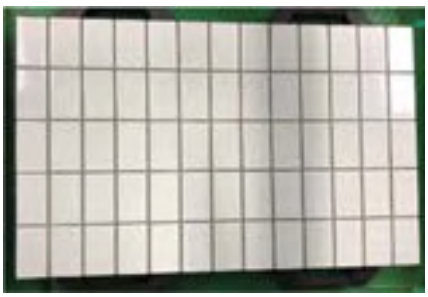

Figure 3. Tiled concrete specimen.

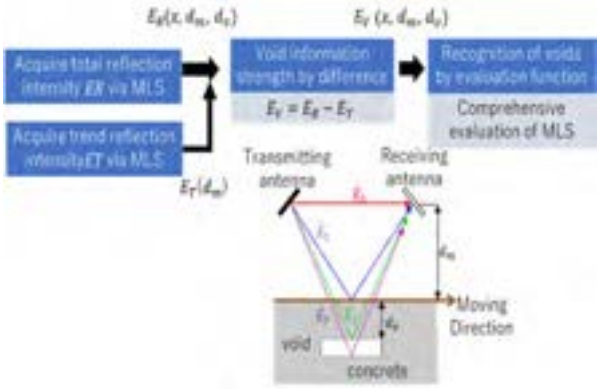

Figure 5. Algorithm for void detection.

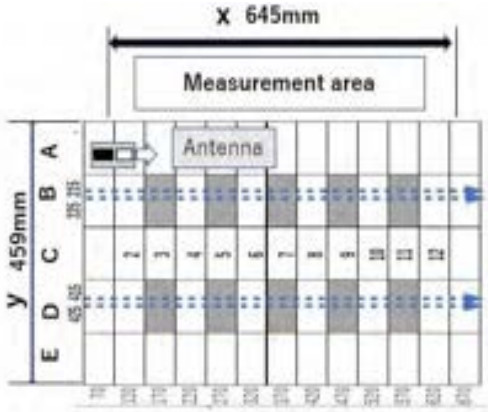

Figure 6. Overview of tiled specimen scanning.

the surface wave. Then, void reflection intensity E_v is obtained by taking the difference between the total reflection intensity and the trend intensity strength. The last step recognizes voids by a comprehensive evaluation of MLS.

2.3.1 Detecting voids

This section shows how an evaluation function $P(x)$ can quantitatively detect voids from the measured reflected intensity. $P(x)$ can detect voids from $\hat{E}_v(x,d)$ which is the void information is obtained by taking the difference between$E_t(d)$and$E_t(x,d)$. This compensation makes the scanning more robust against the noise caused by small variations in d. Hence, this procedure should be useful for scanning a real tiled wall. And is defined as

$$P(x) = \frac{1}{N}\sum_i^n |\hat{E}_v(x,d_i)| \quad (1)$$

where N is the number of data points along the d-axis at each value of x. Because $\hat{E}_v(x,d)$ is obtained from the difference between reflected intensities, it can be negative. By removing the variation of d, scanning collects only the reflected intensity from the voids and the concrete, allowing the voids to be detected and distinguished more easily.

(d) $y = 425$ mm (Line D 415).

Figure. 7. Distribution of $P(x)$ at various tile locations.

2.3.2 MLS measurement results

Experiments were conducted using real tiled concrete to demonstrate the effectiveness of the proposed method for inspecting actual tiled walls. The concrete specimen shown in Figure 3 comprises the tile, its adhesive mortar, and concrete. MLS was performed at $y = 215, 225, 415, \text{and } 425$ mm, with a measurement area as shown in Figure 6. Intensity $E_R(x, d)$ was obtained by scanning along the x-axis in each scanning area several times at intervals of $60 \text{ mm} < d < 90 \text{ mm}$. through changing y-axis, we can set up the Anita in position of Line. The evaluation function $P(x)$ using this result is shown in Figure 7. The vertical axis shows the variation of the integrated reflection intensity, which varies according to whether voids are present. The average integrated reflection intensity was taken at a distance ± 10 mm from joints. The horizontal axis is the tile position. Red tiles have voids ranging from 30% to 100% of the tile size. Other tiles are normal tiles without voids. In most scanning lines, the integrated reflection intensity is high at large voids and low at small voids.

Figure 8. Manual Pull-off adhesion tester.

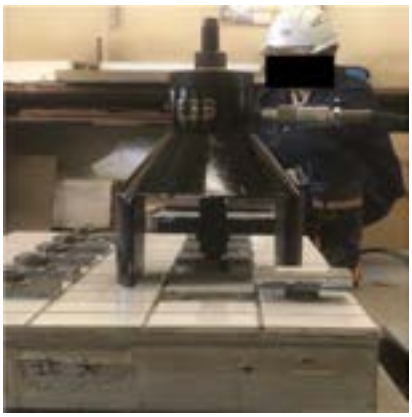

Figure 9. Tile removal operation. Nuts are installed on the tiles to be removed.

3 Tile pulling test

3.1 Inspection Apparatus

Measurement of the adhesion strength was demonstrated using a pull-off adhesion tester (LPT-3000, Ox Jack Co., Ltd.). Before using the adhesion tester, a hammering test was performed to determine whether a void was present. Figure 8 shows the tester, which

Table 1. Adhesion test results

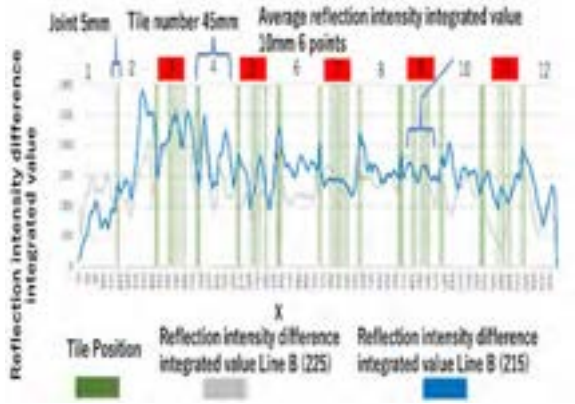
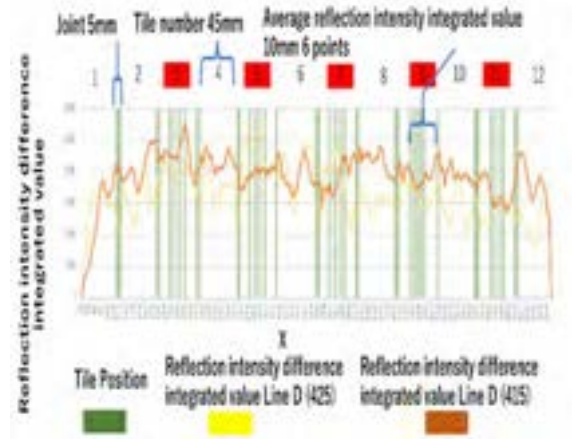
consists of an analogue load cell, a pump handle, and an attachment. When the pump handle is turned clockwise, the attachment rises and pulls the tile until it separates from the concrete, as shown in Figure 9. At the moment of tile removal, the strength is measured by the load cell and recorded. The recorded load data are shown in Table 1, columns 3 and 4.

3.2 Results of adhesive strength measurements and MLS analysis

Figure 10(a) and (b) show the values of exact value of P(x) of all lines at locations of each tile for which adhesion strength was tested. The six points of P(x) was taken over a total distance of 20 mm and ± 10 mm from joints to avoid effects from the joints themselves [6]. The points were distributed on Lines B 215, B 225, D 415, and D 425. Data recorded from the tile pulling tests and MLS analysis are shown in Table 1. Column 1 shows the location of each tile for which adhesion strength was tested and MLS was performed. Column 2 is the void size, which varied from 30% to 100% of the tile size in 20% increments. Column 3 shows the recorded pull strength data in kilonewtons, which is the power required to remove the tile and is directly analogous to load cell results. In column 4, the power is converted to newtons per square millimetre. MLS results are shown in column 5. Based on the adhesive strength and MLS data from Figure 10(a) and (b), Table 1, the scatter plot in Figure 11 was created. This plot shows the adhesive strength of all lines on the horizontal axis and integrated reflection intensity on the vertical axis. The intersection of the two values is shown by colours indicating the tile and scanning position.



(a) $y = 225$ mm (Line B 225) and$y = 215$ mm (Line B 215).



(b) $y = 425$ mm (Line D 425) and$y = 415$ mm (Line D 215).

Figure 10. Distribution of tensile bond strength.

3.3 Analysis of adhesive strength measurements and MLS results

The results of adhesive strength measurements plotted against MLS values in Figure 11 indicate that there is a negative correlation between adhesive strength and the value of the tensile strength. Also, there appears to be a linear relationship between the two variables. Testing of the significance of the correlation coefficient confirmed a strong negative correlation, meaning that a decreased tensile bond strength is correlated with increased integrated reflection intensity, with $R = -0.622$ at $p < 0.001$. Furthermore, regression analysis provided the result $R^2 = 0.382$ at $p < 0.001$.

3.4 Discussion

The results show that this method can estimate the adhesion strength, but with a large error. The regression analysis R-squared result is significantly low. This low value might be caused by the experimental procedure, or it might indicate that there was a problem in how voids were implanted under the tile to make the specimen. As

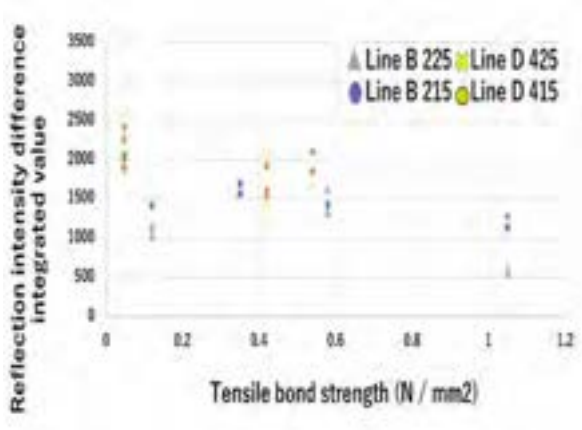


Figure 11. Reflection intensity integrated value versus tensile bond strength

seen in Figure 10(a), in Line D 425, tile No. 3 has a void size bigger than that of No. 5. Therefore, it should have a higher intensity value. However, the integrated value for reflection intensity difference is lower. In Line B, tile Nos. 7 and 8 have the same issue. These issues might have occurred because the tiled concrete specimen was not cured. Environmental effects on sheet strength due to the time that elapsed between performing MLS and measuring the tensile strength needs to be taken into consideration. To improve the accuracy of the estimation, more data are needed by analysing tiles of different sizes. In addition, the experimental procedure would be improved if the MLS scanning data and the adhesive strength were obtained at the same time. Furthermore, a more accurate adhesive strength measurement device should be used.

4 Concluding Remarks

This paper describes ability of the MLS method in determining tile adhesive strength. This method will increase the accuracy of the safety tests required for wall tiles used in building exterior finishes. In particular, the MLS method does not require an expert to implement it. Therefore, it has the potential to reduce the cost and time required for tile safety examinations.

Abstract -

The new Hachinohe indoor skating rink required an extremely flat concrete slab. ±2mm precision concrete surface was expected across 6,350 m^2 concrete slab. It is impossible to construct such a large super flat slab with a conventional construction method to maintain the height of the concrete surface at intervals of few meters using human hands and eyes. Therefore, we have developed a construction method using high precision height measurement which maintains the height of the concrete surface in the levelling and the finishing processes with high density and precision.

In the levelling process, a 18m long truss screed was used. Such a long truss screed is easily deformed and the deformation of the truss screed during the process directly leads to the deterioration of surface accuracy. Therefore, we developed a mechanism to measure and correct the deformation of the truss screed with high accuracy.

In the finishing process we precisely scanned the levelled concrete surface with a 3D laser scanner. An unevenness distribution map was calculated from the scanned point-cloud data and projected onto the concrete surface using a projector to remove the concrete on the convex part.

Finally, all the finished concrete surface was measured with a 3D laser scanner and confirmed that it had extremely high flatness.

1 Introduction

The Hachinohe Nagene indoor speed skating oval rink, equipped with 400m double tracks, is the third indoor speed skating facility that is in conformity with international standards in Japan. The construction of this skating rink involved various efforts to build a high-quality, indoor skating rink meeting international standards, one of which is the construction of the concrete slab beneath the ice.

The cross-sectional structure of the skating rink is shown in Figure 1. Refrigerate pipes were installed in the ice-making concrete slab, and the ice layer will be formed over the slab via cooling. The surface precision of the ice-making concrete slab affects the thickness of the ice layer, thereby affecting the hardness of the ice layer. Building a high-quality skating rink with an even level of ice layer requires ice-making concrete slab with high surface precision; in this construction, the goal surface precision was set within ±2mm.

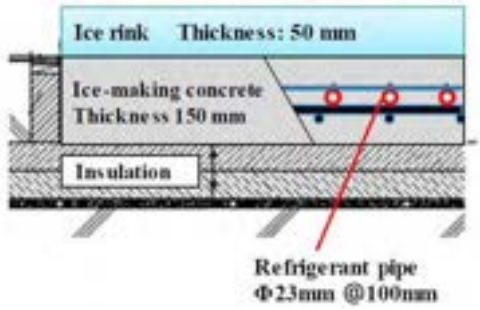

Figure 1. The cross-sectional structure of the rink

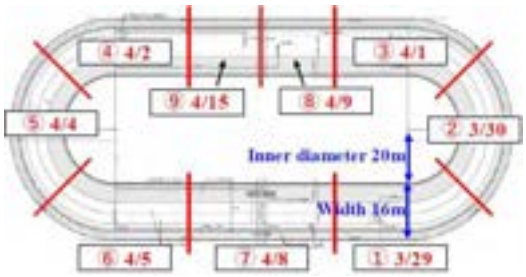

Figure 2. Construction sections of the ice-making concrete slab

The ice-making concrete slab is comprised of a straight section with a width and length of 16m and 110m, respectively, and a curved part with inner and outer diameters of 20m and 30m, respectively. The total area of the skating rink is about 6,350 m^2.

The conventional construction method of concrete

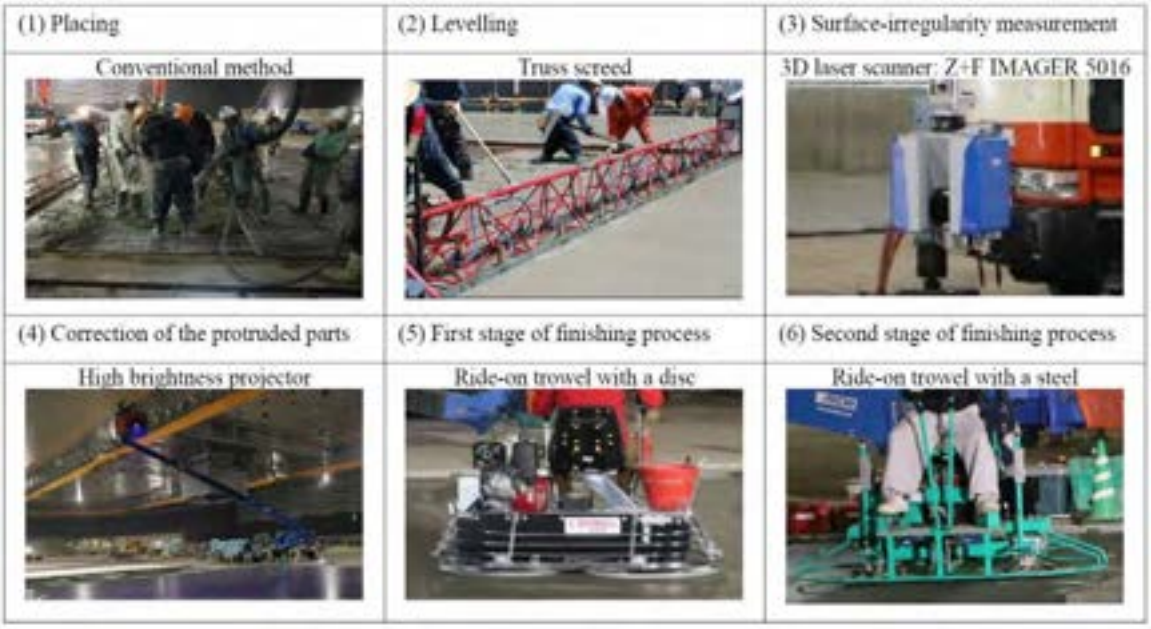

Figure 3. Construction processes of concrete slab

slab involves human hands and eyes to maintain the height of the concrete surface at intervals of few meters, thereby rendering the ±2mm precision across this large area practically inconceivable. Therefore, we assumed a mechanized construction method that maintains the surface height in the levelling and finishing processes with high density and precision. As shown in Figure2, the 400m circumference was divided into nine sections, and each section was constructed within one day. Figure 3 shows the construction flow and the machines used in the ice-making concrete slab. After the hardening of the concrete, 3D Laser Scanner was used to evaluate the flatness [1],[2].

2 Construction of Super Flat Concrete Slab

We have developed a construction method using high precision height measurement which maintains the height of the concrete surface in the levelling and the finishing processes with high density and precision.

2.1 Levelling Process

A truss screed, which was composed of an iron truss frame and a blade, was used to level the concrete. Units, each with a width of 3.5m, can be linked to make the maximum width of 20m. The portion that meets the concrete is an L-shaped blade with multiple oscillators driven by compressed air. Both ends of the truss screed are placed on rails installed outside the cast concrete area., and the concrete surface is levelled by moving the truss screed along these rails while providing vibration. Truss screed is deformed because of the loosening of the joints which is caused by vibration and of the force from the placed concrete. Because the shape of the truss screed directly affects the surface precision of the ice-making concrete slab, we attempted to improve the surface precision during the levelling process using a high-precision level monitoring system for managing the levelling. The method of level monitoring is described below.

At each joint, we measured the top height of the blade and adjusted it by tightening the joint every 2 m in the driving direction. As shown in Figure 4, we installed rotating laser receivers at five locations on the truss screed and used a level monitoring system which displayed the heights with 0.1mm resolution on a tablet PC in real-time. Using a rotating laser level, we can detect relative changes in height with high accuracy and in real time, but we cannot measure absolute height accurately. On the other hand, using a digital level, we cannot measure the height change in real time, but can measure the absolute height accurately. Therefore, we decided to measure the absolute height at each location using a digital level and monitor the changes from the measured values with a monitoring system using a rotation laser level. By using this system and adjusting the height of the blade to within ±1mm from the standard level, a precise levelling process could be performed.

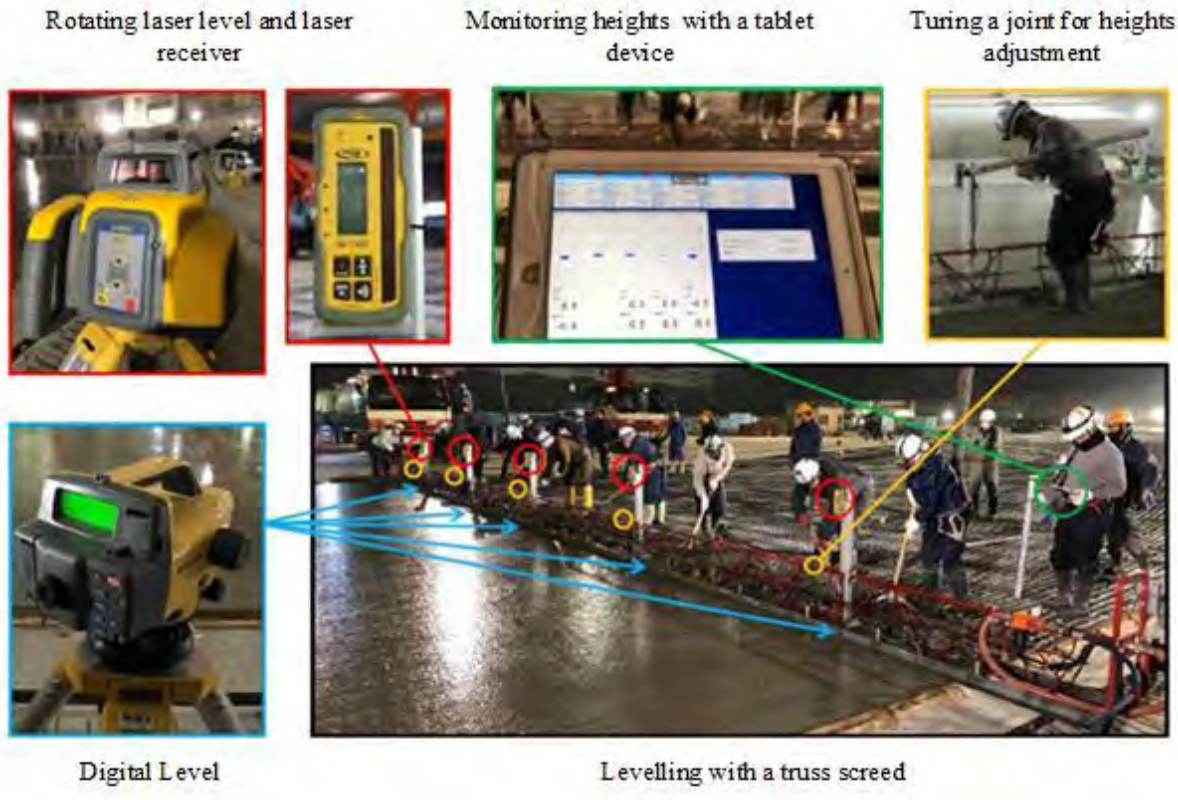

Figure 4. Monitoring for the levelling blade using a display system for level change

2.2 Measurement of Surface Irregularities immediately after Levelling

We used a 3D laser scanner to measure the surface irregularities immediately after levelling. Figure 5 is a picture of the situation of this measurement. The concrete surface, immediately after levelling, has a gloss that bends the laser light, so a small incident angle to the measured surface is preferred. Therefore, the scanner was attached at a boom of a crawler crane and scanned the concrete surface from a height of approximately 9 m. Each measurement was performed over a 16 m × 12.5 m area, 1/4 of the total placement area for a day, and it took 43 seconds for an irregularity measurement with a maximum 10mm pitch. Using this measurement method, the boom oscillation in the crawler crane and the boom drop were suspected to affect the measurement of surface irregularities. Therefore, we obtained the data on the boom oscillation and the boom drop in advance and verified that they would not affect the measurement results if the time of scanning was 43 seconds.

Figure 6 shows an example of point-cloud data for the concrete surface obtained by the 3D laser scanner. The point-cloud data are obtained in the coordinate system of the 3D laser scanner. Hence, if the coordinate axis in the height direction is not vertical, we cannot accurately evaluate the irregularities on the concrete surface against the design height. Thus, we evaluated the surface irregularities using the following method.

1) We placed four 700mm × 700mm reference plates around the target concrete surface.
2) The surface of each reference plate was levelled with a high-precision inclinometer, and the heights of the four reference plates were adjusted to be the same.
3) From point-cloud data obtained by the 3D laser scanner, we extracted the clouds corresponding to the reference plates and from that clouds, computed one virtual reference plane.
4) As shown in Figure 7, the reference surface is horizontal and its height (H) is known, so it was used to calculate the irregularity (h) compared to the design height based on the distance of each point cloud (d) from the virtual reference plane.

Figure 5. 3D scanning a concrete just after levelling process

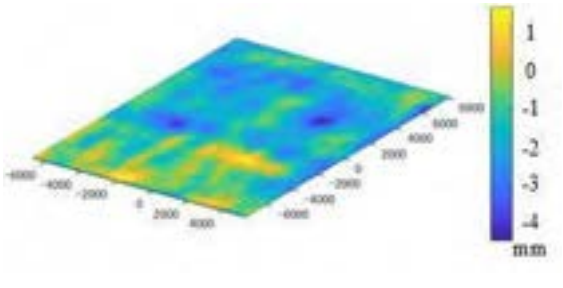

Figure 6. Example of a point-cloud data

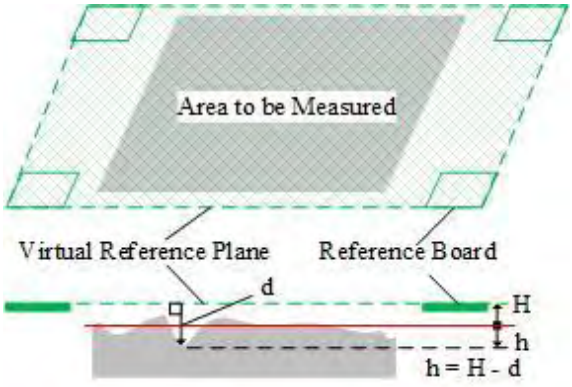

Figure 7. Calculate irregularity of surface

2.3 Correction of Irregular Portions

To further improve the surface precision of the concrete, which was levelled by the truss screed, we conducted a process of scraping the protruded concrete. When the craftsman with the plasterer's boots can stand on the concrete without deforming the concrete surface, the correction process can be started. From the previous setting test, we found that this condition was met when the penetration-resistance value exceeded 0.5 N/mm^2, thus, we began the correction process when the penetration-resistance value became 0.5 N/mm^2.

In the point cloud data of surface unevenness acquired after leveling, the part where the surface height is higher than the design height (= +0 mm) was set as a correction target. Moreover, we generated a 2D image (image for correction) of the point-cloud data with the target and other areas indicated by red and blue colors, respectively. Figure 8 shows an example of such a correction image. The scraping depth on the concrete was set 2 mm from the surface. Furthermore, to allow the operators to accurately view the operation areas, we directly projected and visualized the correction image on the concrete surface. For the projection, a large projector was installed on an elevating work platform approximately 10 m above the ground. Figure 9 shows a picture of the correction process. The concrete surface became rough after the scraping. Hence, a disc was installed on a trowel and the surface of corrected portions were smoothed.

Figure 10 shows an example of the comparison between the surface irregularities measured immediately after levelling and after the finishing process. The standard deviation of the surface irregularities decreased

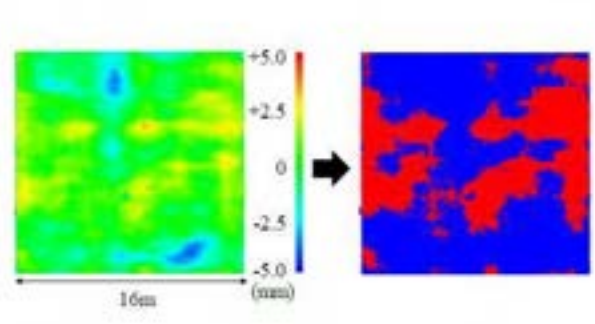

Figure 8. Example of a correction image

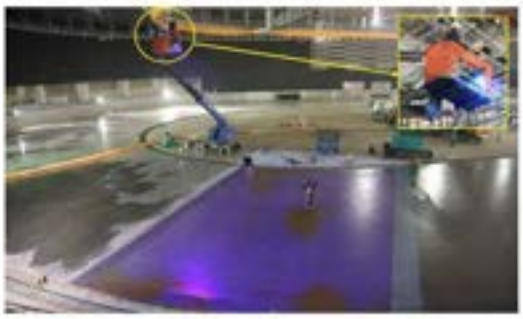

Figure 9. Projection of the correction image

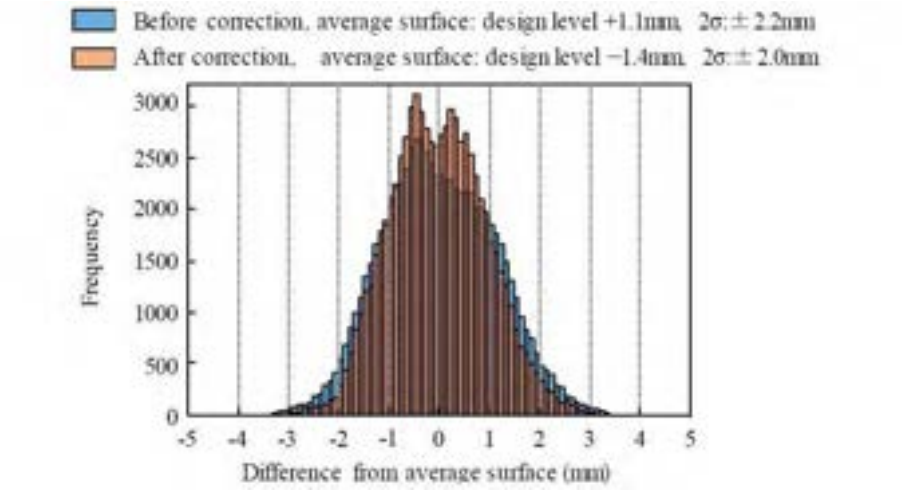

Figure 10. Comparison of the surface irregularities after the levelling and after the correction process

from 1.1 to 1.0 mm, and the frequency of the mean value ±1 mm increased by 14.4%, indicating an improvement of the surface precision. Here the median value is not the design height but the average height of the concrete surface. The average height of the concrete surface shifted from +1.1 to −1.4 mm, because of the rise in bleeding water and the compaction on the surface from the finishing process.

3 Flatness of the Completed Ice-Rink

3.1 Measurement using 3D Laser Scanner

In general, the 3DLS is not able to be set strictly horizontal and the level of the scanner is unknown. The scanner coordinate system is based on different height and attitude from a base coordinate system. To measure the height of the concrete slab, we must match the height and attitude between the scanner coordinate system and the base coordinate system. Around the scanning area, we put three reference boards and measure each height of the boards. We translate the scanned point-cloud in order to match each height of levelled boards in the point-cloud to the measured height of them in the real world. The detailed procedure is shown below.

1) Putting 3 boards, which size is 700mm x 700mm, around the scanning area. Adjusting lengths of the three support legs to level the boards.
2) Using a digital level, measuring Z_{DL1}, Z_{DL2} and Z_{DL3} which are the board surface heights.
3) Using 3DLS, scanning the area which includes the 3 reference boards.
4) From the scanned point-cloud, detecting Z_{ave1}, Z_{ave2} and Z_{ave3} which are heights of center of the 3 reference boards.
5) Deriving a rigid body translation T from an equation below.

$$\begin{pmatrix} x_1 & x_2 & x_3 \\ y_1 & y_2 & y_3 \\ z_{DL1} & z_{DL2} & z_{DL3} \end{pmatrix} = T \begin{pmatrix} x_1 & x_2 & x_3 \\ y_1 & y_2 & y_3 \\ z_{ave1} & z_{ave2} & z_{ave3} \end{pmatrix} \quad (1)$$

x_i, y_i, i = 1, 2, 3 are x-y positions of each center of the

Figure 11. Conventional measurement method

Figure 12. Proposed measurement method

reference boards in the scanner coordinate system.

6) Translating the scanned point-cloud with the rigid body translation T and getting a point-cloud in which, each height of board equals the height measured using a digital level.

3.2 Confirming Measurement Method

In order to confirm our proposed method, we measured a part of the rink (14m x 15m) using the proposed measurement method and a conventional measurement method. And we compared the data which was acquired with the two methods.

3.2.1 Conventional measurement method

We used a digital level for conventional measurement method. At first, we draw measured points on the floor in a grid of 0.5m. We divided the measurement area (14m x 15m) into 3 parts. 6 people, 3 pairs, measured each part. In the pair, one set a staff and the other collimated it and recorded the measured height (Figure 11). It took more than 4 hours to measure 899 points.

3.2.2 Proposed measurement method

3 people worked in the proposed measurement method. We set 4 reference boards and measured the height of each board. Since the circle with a radius of about 1.0 m just below the scanner cannot be scanned, we scanned the target area at two different points. It took less than 10 minutes and measured about 10,000 points height in grid of less than 10mm.

3.2.3 Comparing the two measured data

Figure 13 shows the measurement result using conventional method and proposed method. Visualization processing was performed so that irregularities with 100 mm grid spacing were displayed for comparison. According to this figure, the height distributions in each calculation result are almost the same in two dimensions. The height distribution is shown as a histogram in figure 14. Both have same standard deviations of 1mm. Although the number of samples is different, the height distribution tendencies are the same. Therefore, the measurement results of the proposed method are highly reliable.

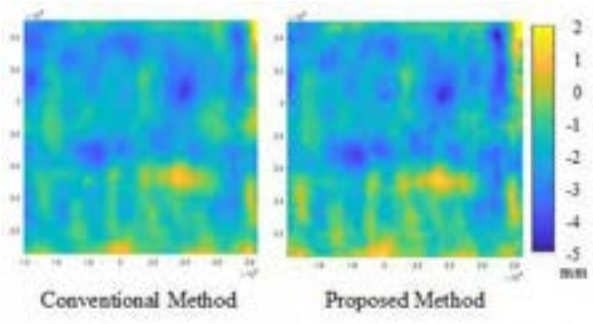

Figure 13. Comparison of two methods

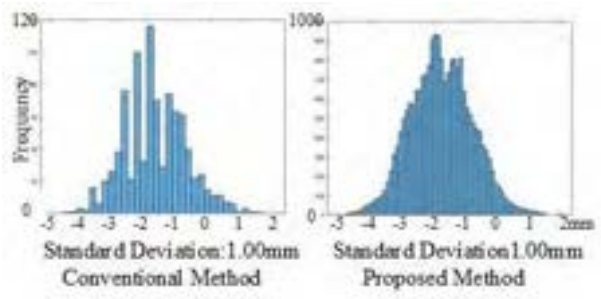

Figure 14. Comparison of two methods

3.3 Measurement Result of the Ice-Rink

Figure 15 shows that the ice-making concrete slab divided into 84 sections and the 3D laser scanner set at the centre of each section. Figures 16 and 17 show the measurement results. The standard deviation of the height is 1.22 mm, and 90.3% of the whole area is within ±2-mm precision. The curved portions in sections tend to be low. The reason is considered that the operation of the truss screed is difficult compared to the straight part of the rink owing to the difference in speed between the inner and outer portions.

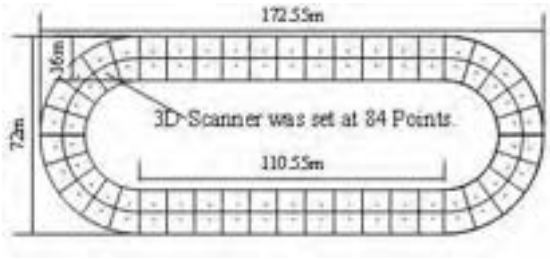

Figure 15. Scanned area was divided into 84 parts.

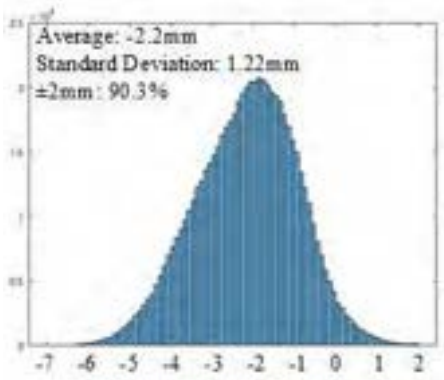

Figure 16. Height Deviation of the ice-rink

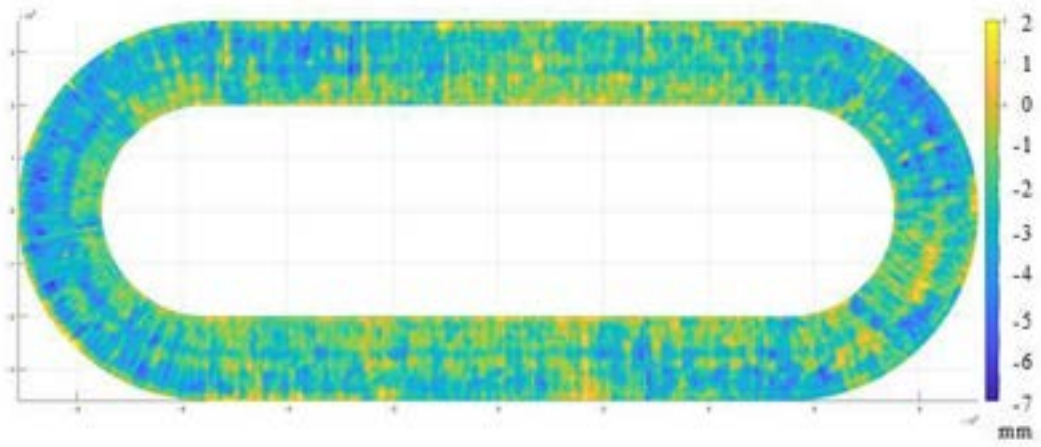

Figure 17. Height Map of the ice-rink

4 Conclusion

For the construction of super flat concrete slabs using a truss screed, we developed a method for obtaining the real-time level of the truss screed and achieved high precision levelling. After levelling, we measured the surface irregularities using the 3D laser scanner and applied the results to correct the protruding portions visualized with a large projector, thereby improving the surface precision of the concrete. Using the above methods, we achieved ±2mm precision for 90.3% of the entire area of approximately 6,350 m^2.

Abstract –

For several years, the compaction quality of embankments has been controlled by the dry bulk density and water content. However, the quality assessment is time consuming and merely a point measurement. We are developing a method that measures the mechanical properties of soil by observing the soil - wheel interaction behavior. In this study, we have proposed a method for estimating the subgrade reaction modulus of the soil by towing a wheel on the ground surface. This paper describes the theoretical basic concept of this method and discusses its validity with the results obtained from a laboratory model experiment.

Keywords –

Soil compaction; Quality control; Subgrade reaction modulus

1 Introduction

For several years, the quality control of soil compaction has been assessed by measuring soil density and water content. However, the measurement is time consuming and is only a point measurement. Recently, a new technique called "intelligent compaction [1]" has become widespread; this is because the quality is controlled by the number of roller passes required to achieve the desired compaction. Intelligent compaction using a GNSS-mounted roller enables real-time continuous measurements. In contrast, the number of roller passes is only considered to be an index without a physical meaning.

In this study, we have proposed a soil testing method that allows us to continuously evaluate the rigidity of soil (subgrade reaction modulus) by towing a wheel on the surface of the ground. Figure. 1 depicts an illustrative example of the possible future applications of this technique. One possible application is a mobile measurement in which a wheel-type testing tool is equipped in a construction vehicle. The other application is also a mobile measurement using a wheeled roller. The

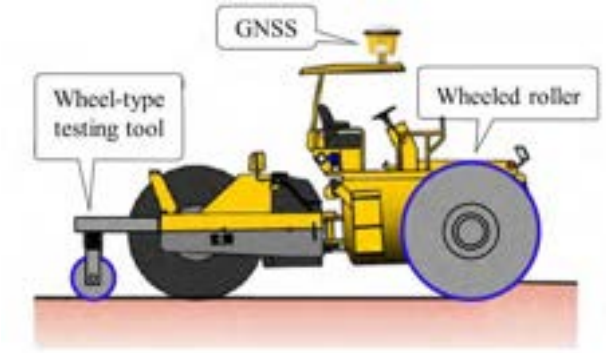

Figure 1. Possible future applications of the wheel testing tool

proposed method has the following two advantages:

- Direct measurements for assessing the mechanical properties of soil: As mentioned above, the existing methods for examining the quality control of soil compaction assess the physical properties of soil (e.g., soil density and water content) or calibrated index. This is based on the premise that as far as the compacted soil satisfies the desired control value, the quality also satisfies the requirements for mechanically stabilizing the soil structure. The proposed method directly provides the subgrade reaction modulus, which is an important mechanical parameter that is commonly used in pavement designs, foundation designs, and for predicting the behaviors of other soil-structures. We consider that the proposed method allows direct assessment to determine whether the compaction quality meets the requirements of the design.
- Continuous real-time measurements: As for in-situ soil investigation techniques for assessing the stiffness/rigidity of soil surface, the plate load test, California Bearing Ratio (CBR) test, and Falling Weight Deflectometer (FWD) are commonly used in practice [2]. The existing methods evaluate the point measurement of soil rigidity whereas the proposed method evaluates the continuous spatial distribution of soil rigidity.

At present, we have not implemented mobile

measurement using a vehicle-mounted device under actual situations; therefore, we cannot evaluate the practicality of the proposed method. As a feasibility study, this paper describes the theoretical basic concept of the method for estimating the subgrade reaction modulus and discusses its validity with the results obtained from a laboratory model experiment.

2 Method for estimating subgrade reaction modulus

The mechanism of wheel-soil interaction is complicated, as depicted in Figure. 2. When a rigid wheel travels on soft soil, a rut occurs on the soil surface. In addition to the soil compression that generates the rut, plastic soil flows of a soil bed occur at the front, rear, and sides of the wheel. Considering that the rate of energy input to the wheel is consumed by the soil-wheel interaction, we obtain the following energy conservation equation:

$$\dot{E}_t + \dot{E}_d = \dot{D}_c + \dot{D}_p + \dot{D}_e + \dot{D}_l \tag{1}$$

where $\dot{E}_t$ and $\dot{E}_d$ are the external rate of work performed by the drawbar pull and driving force, respectively; $\dot{D}_c$ and $\dot{D}_p$ are the rate of internal energy dissipation due to soil compression and plastic soil flows, respectively; $\dot{D}_e$ is the rate of potential energy variation of the wheel; $\dot{D}_l$ is the rate of mechanical energy transformation loss due to friction inside the wheel.

In this study, we have postulated a condition in which a rigid wheel is towed on a soil surface without a driving torque. In this situation, the wheel slip does not occur. In addition, plastic soil flows do not occur when the wheel sinkage is small. This suggests that the rate of internal energy dissipation due to plastic soil flows can be ignored. Furthermore, assuming a condition in which the mechanical energy transformation loss and variations in the wheel elevation are also negligible, Eq. (1) can be rewritten as

$$\dot{E}_t = \dot{D}_c \tag{2}$$

Eq. (2) suggests that the input energy rate is consumed by the soil compaction for generating the rut. Denoting the towing speed and drawbar pull as V and F, respectively, the input energy rate can be written as

$$\dot{E}_t = FV \tag{3}$$

In contrast, assuming that the load–settlement relationship of the surface soil can be approximated as $p = k_w z$, where k_w is the subgrade reaction modulus and z is the wheel sinkage, then the rate of internal energy dissipation due to soil compression can be expressed as

$$\dot{D}_c = \frac{1}{2} k_w z^2 BV \tag{4}$$

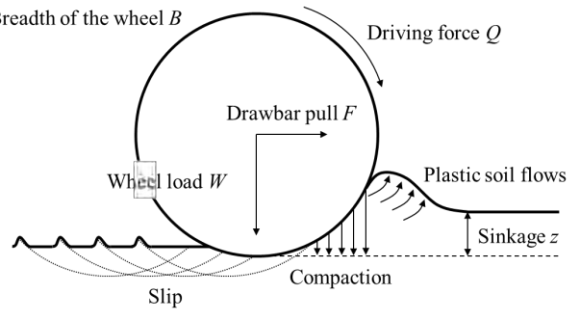

Figure 2. Soil-wheel interaction

where B is the breadth of the wheel.

By substituting Eq. (3) and Eq. (4) into Eq. (2), the subgrade reaction modulus can be obtained as follows:

$$k_w = \frac{2F}{z^2 B} \tag{5}$$

Eq. (5) suggests that it is possible to continuously estimate the variation in k_w as the wheel rotates by measuring F and z. Note that although the wheel load (W) is not explicitly included in Eq. (5), it will certainly influence both F and z.

Although we ignored $\dot{D}_e$ in Eq. (2), it could be taken into account by considering the following equation:

$$\dot{D}_e = W\Delta h \tag{6}$$

where Δh is the increment in the wheel elevation.

$\dot{D}_l$ can also be experimentally obtained by measuring the drawbar pull (F_0) of the wheel traveling on a horizontal rigid surface (this situation does not cause any energy dissipation except $\dot{D}_l$).

$$\dot{D}_l = F_0 V \tag{7}$$

3 Verification by laboratory model experiment

3.1 Experimental setup

In this study, a laboratory model experiment was performed to validate the theoretical concept of our proposed method. Figure. 3 depicts the experimental setup used in this study. An aluminum wheel with a diameter of 200 mm and breadth of 100 mm was used. As mentioned above, we used a wheel that spins freely in this experiment. A sheet that was made of rough sandpaper was attached onto the wheel surface to avoid slipping. The wheel could move freely in the vertical direction, and the wheel load (W) was adjusted using counterweights. The wheel was towed using a feed screw that was further controlled by an electric motor. A load cell was installed between the wheel and support jig to

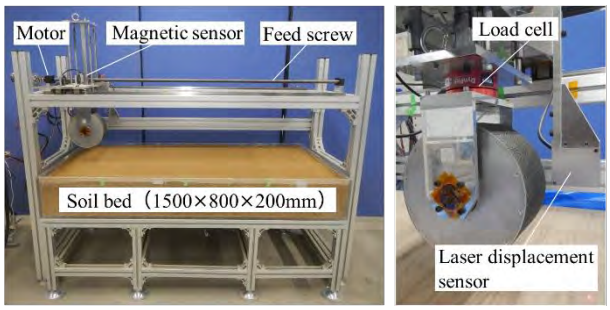

Figure 3. Experiment setup

measure the drawbar pull, F. The wheel elevation (h) was detected using a magnetic scale sensor attached to a support shaft that vertically moves in response to the soil surface topography and/or wheel sinkage. The wheel sinkage (z) was determined as the difference in the soil surface elevations at an arbitrary point between the wheel passes, and these were measured using a non-contact laser displacement sensor that was attached in front of the wheel and magnetic scale sensor as mentioned above.

In this experiment, the towing speed (V) was permanently set as 10 mm/s, and the wheel load (W) was changed to 68.6, 98.0, 127.4, and 156.8 N. Two types of decomposed granite soil were used for the model ground, namely, soil A: fine-grained sand with an average water content of 12.1%, and soil B: gravel-grained sand with an average water content of 14.9%. The soil bed was 1500 mm in length, 800 mm in width, and 200 mm in depth. The model ground was prepared to have three zones with different degrees of compaction: D_c = 65%, 70%, and 75% in the direction of travel, further indicating the varying rigidity of the soil surface with respect to the travel distance in one pass.

3.2 Small-diameter plate load test

In this study, the subgrade reaction modulus was independently measured using a small-diameter plate load test equipment (Figure. 4) to verify the estimate of k_w obtained by measuring the wheel-terrain interaction. A rigid circular plate with a diameter of 50 mm (same size as that of the CBR test), was set on the soil surface, and the plate was vertically pushed into the soil at a constant rate of 0.1 mm/s. The load-settlement behaviors (p-z relationship) were observed at various points on the model ground.

Figure. 5 depicts examples of the p-z relationship obtained from the test for the model ground of soil A. From the figure, it could be observed that the p-z relationship has an inflection point after a certain settlement. The inflection is usually regarded as a point at which the material fails. In this study, the subgrade reaction modulus, hereinafter referred to as k_p, is determined as the initial slope that appears prior to the inflection point.

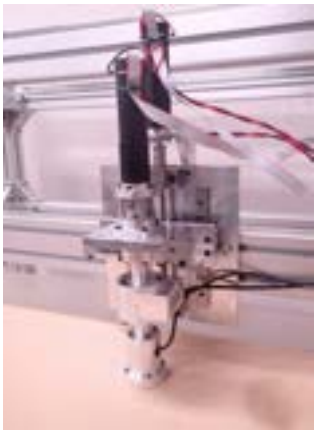

Figure 4. Small-diameter plate load test equipment

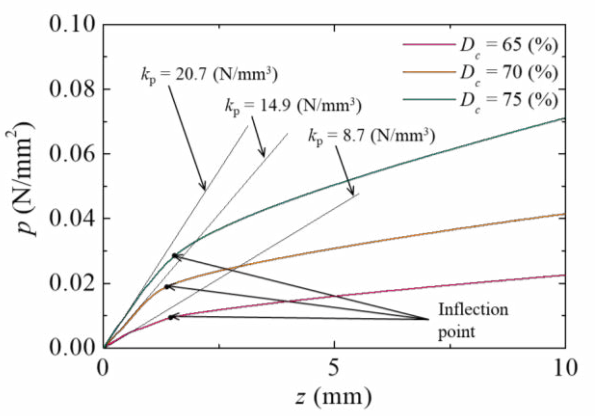

Figure 5. Typical examples of p-z relationship

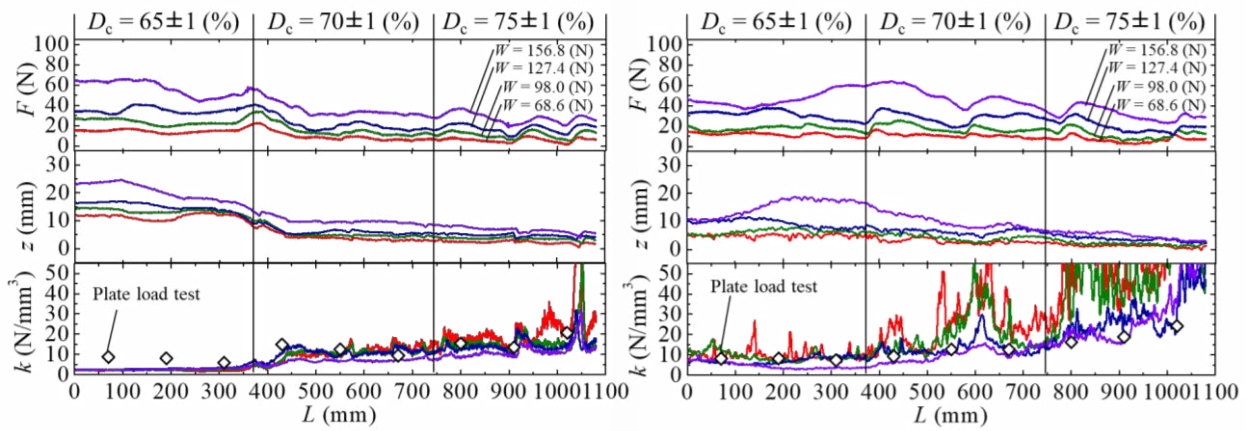
3.3 Results and discussion

Figure. 6 depicts typical examples of the drawbar pull (F), sinkage (z), and the estimated subgrade reaction modulus (k_w) obtained from the laboratory model experiment. k_p obtained from the plate-load tests were also plotted as ◇ in this figure. It can be observed from the figures that both F and z increase with an increase in W for each soil. With some exceptions, it also appears that both F and z tend to decrease with an increase in D_c. In Figure. 6 (a), k_w obtained for each W is consistent regardless of W in the zone when D_c = 65%, where the degree of compaction is relatively small. This provides evidence to support the hypothesis that k_w does not explicitly depend on W in Eq. (5). However, when the degree of compaction increases (in the zone when D_c = 65% and 75%), the differences in k_w due to W becomes remarkable. In particular, when W is small, as in W = 68.6 and 98.0 N, the estimates of k_w show random fluctuations further resulting in huge gaps between k_w and k_p. From Eq. (5), it can be noted that k_w is inversely proportional



(a) Soil A: fine-grained sand (b) Soil B: gravel-grained sand

Figure 6. Experiment results and estimated subgrade reaction modulus

to z^2, and thus, k_w drastically increases when z decreases by one order of magnitude. The gaps can be attributed to the fact that the wheel with a smaller wheel load travels on a zone with a higher degree of compaction, thus resulting in a considerably small sinkage.

Figure. 7 depicts the comparison between k_w and k_p. The plots of k_w are the extracted data corresponding to the points at which k_p was measured using the plate load test equipment. It can be noted that k_w has an approximately positive correlation with k_p, and many of them are consistent with each other. However, it could be seen that k_w tends to underestimate k_p when subgrade reaction modulus is relatively small. In addition, k_w tends to overestimate k_p when W is relatively small. Possible reasons for this inconsistency are as follows. The underestimation occurred when the soil rigidity was small, further implying that the plastic soil flows occurred owing to the excessive sinkage under the soft soil. In this study, we ignored the internal energy dissipation due to the plastic soil flows, and the energy conservation equation was simplified as in Eq. (2). This assumption may yield an underestimation. Conversely, the reason for the overestimation may be due to the small sinkage that was used to calculate k_w, as mentioned earlier. Although Eq. (5) may be simple to estimate, a positive correlation between k_w and k_p could be observed. Even though there is still room for improvement and experimental verification, we conclude that the feasibility of the proposed method was confirmed from the laboratory model experiment.

4 Conclusion

In this study, we have proposed a method for estimating the subgrade reaction modulus of soils from wheel-terrain interaction measurements. The experimental results demonstrated the potential of the proposed method for estimation of subgrade reaction

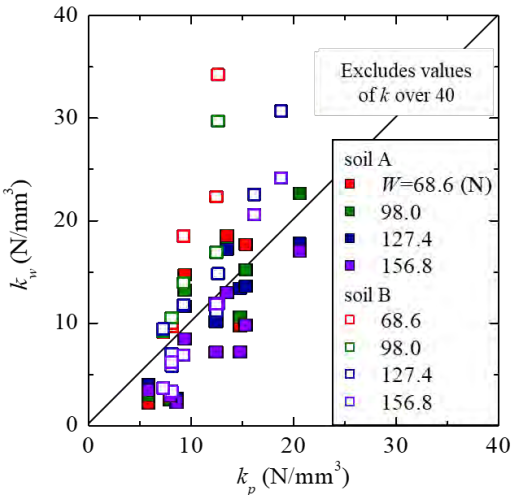


Figure 7. Comparison between k_w and k_p

modulus. However, it was revealed that the estimation equation had some limitations. We plan to proceed with the study for its practical use by improving the estimation equation.

Abstract –

We conducted a measurement accuracy and laborsaving in the spraying slope frame work by appli-cation of ICT earth works using UAV was verified by using field of actual work.

In the UAV survey, it was possible to apply the Ministry of Land, Infrastructure, Transport and Tour-ism (MLIT) standards to the UAV survey by facing front of a slope.

The measurement accuracy of the cross-sectional measurement of the frame was ensured by setting the frame cross-section at 5 mm/pixel and 90% wrapping, and In the area measurement, a difference of -1% to +2% could be calculated.

The introduction of UAV is expected to significantly reduce the time required to work in the field on steep slopes.

The measurement of a 1500m2 of a field was completed with about 50% less labor than the con-ventional method.

1 Introduction

The Ministry of Land, Infrastructure, Transport and Tourism (MLIT) says it will promote "i-Construction" with the aim of improving productivity and making construction sites more attractive.

The Ministry of Land, Infrastructure, Transport and Tourism (MLIT) has established various standards for ICT construction in order to promote "i-Construction".

At present, the guidelines for ICT earthworks and ICT paving have been established, and in March 2020, the glue surface construction was added.

In this report, we report on the measurement of the construction status of the slope surface by aerial photogrammetry using an unmanned aerial vehicle (UAV), which was carried out in 2019.

The results of the survey were used to confirm the accuracy of the measurements and to verify labor-saving measures.

2 Contents of the survey

The test was conducted at the Echigo-Kawaguchi Service Area on the Kanetsu Expressway, as shown in Figure 1.

Figure 1. Map of Kanetsu Expressway Area

The glue surface here had collapsed due to heavy rainfall in July 2017,to restore the disaster, we planned and commissioned the reinforcement using sprayed method frames and Tests were conducted as part of this work (test area was about 50 meters high and 30 meters wide).

Figure 2. Test Area (50m×30m)

The verification items were selected from the "Earthwork Construction Management Guidelines" of the East Nippon Expressway Co. It has been done.

The four items selected were (1) measurement of length, (2) measurement of cross section width and height, (3) measurement of extension, and (4) measurement of the area.

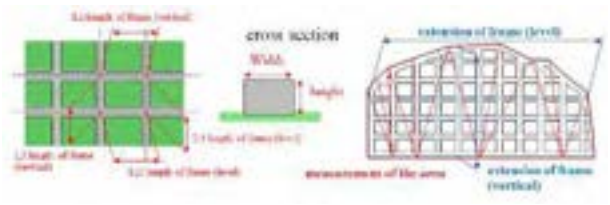

Figure 3. Verification items of sprayed frames

2.1 Measurement method

For the measurement of the profile of the spraying slope frame by UAV survey, the point cloud data obtained by field surveying with the 3D reconstruction data created by the method described in the previous section, the position of the workpiece was confirmed by tape surveying, and the shape dimensions and the extension was measured.

However, considering the differences in slope, complicated undulations and structural details, the issues to be addressed in the application of the slope work were discussed and some of the specifications were modified as shown in Table 1.

Table 1. Summary of Improvement Measures

item	ICT earth works standards (MLIT) : March 2018	Try and compare
photo shoot	downward direction	⇒facing front of a slope
measurement performance	pixel size 10mm/pix	pixel size ⇒5mm/pix
LAP rate	next to 80% lap course 60% lap	⇒next to 90% lap ⇒course 90% lap
reference point	outside of shooting area (outer edge)	⇒inside of shooting area

3 Inspection

3.1 Comparison with actual measurements (frame shape)

This presents the results of the comparison of measurements from 3D data and tape surveying of the frame profiles, i.e. (1) length of frame, (2) width and height of frame, (3) extension of frame area.

3.1.1 Length of the frame and section of the frame

The difference between the frame length and the reference value, which is the actual measurement, was less than ±1 cm. As for the cross-sectional width (W), an error of a few millimeters from the reference value was observed, but it was found that the NEXCO standard is not applied to the cross-sectional area. values. A maximum height (H) error of -55 mm was confirmed. When the comparison was carried out with the modified plan (5mm/pixel, 90% lap), the maximum margin of error was 9 mm. They converged.

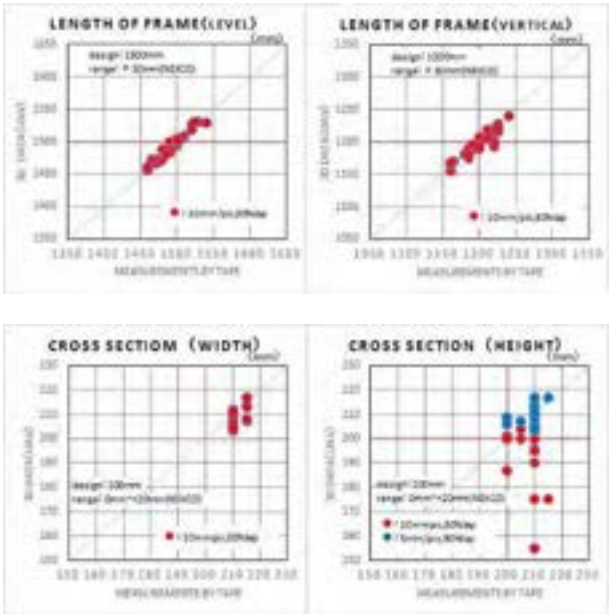

Figure 4. measurement of length, width and height

3.1.2 Length of the entire framework

The results of the comparison of the length of the entire framework with the actual measurement showed that the extension of the frame was a few centimeters (less than ±1%) in both vertical and horizontal directions.

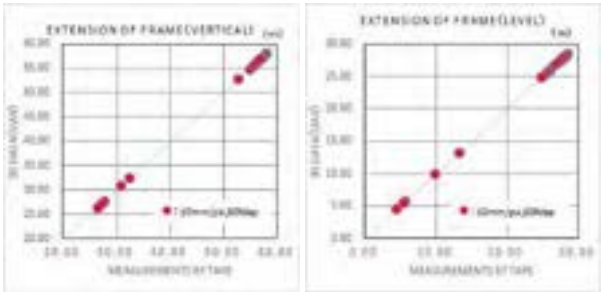

Figure 5. measurement of extension

3.2 Comparison and verification of actual measurement results (area)

The area was verified by comparing the results of the UAV survey with the development of the tape survey (triclinic method).

The difference between UAV survey and actual measurement is less than -1% in the calculation of area by actual measurement and co-located measurement as shown in Table 2. The total area of each frame increased by a little less than 2% compared to the actual measurement, indicating that the total unevenness was measured.

Table 2. Area Comparison

	Tape Surveying	3D data(UAV)	3D data(UAV) (in detail)
AREA	1522.67m²	1510.52m²	1548.16m²
difference		-12.15m² (-0.8%)	+25.49m² (+1.7%)
development view			

3.3 Verification of efficiency through the use of ICT

Surveying by UAV of the workpiece (per 1500m2) requires more off-site work than actual measurement (tape surveying). The reduction is about a quarter. However, the total reduction effect is about half due to the increase in internal work such as analysis work. As shown in Table. 3, the work was performed on a steep slope, and the use of the UAV made the work site safer. In addition, we have improved in the following areas.

Figure 6. Status of surveying works

Table 3. Improving Efficiency through ICT (UAV)

per 1500m2

reference point	2 workers × 0.5 days	3D modeling	1 worker × 1.0 days
TS survey	2 workers × 0.5 days	development view	1 worker × 0.5 days
UAV survey	2 workers × 1.0 days	Frame measurement	1 worker × 1.5 days
		Cross-section	1 worker × 1.5 days
fieldwork total	4.0	deskwork total	4.5

※Not including the time the PC calculates.

UAV survey	total:	8.5	4.0	4.5
Tape survey	total:	17.0	16.0	1.0

50% OFF

Area measurement	6 workers × 1.0 days	development view	1 worker × 0.5 days
Frame measurement	6 workers × 1.0 days	compilation	1 worker × 0.5 days
Cross-sectional	2 workers × 2.0 days		
total	16.0	deskwork total	1.0

4 Summary

The UAV surveying method for measuring the workmanship of the sprayed-on slope is the same as the UAV method. It is considered possible to apply the "as-is" rule to the case. As for the cross-section of the frame, 5mm/pixel, 90% wrapping is considered to be sufficient. However, the restriction of flight zones by trees and other factors needs to be considered. The area is affected by the subdivision of the triclinic method, but can be calculated with a difference of about -1 to +2%. In addition, safety has been improved and workloads have been reduced by about 50% compared to the conventional measurement method.

Single Camera Worker Detection, Tracking and Action Recognition in Construction Site

Abstract –

In Japan, the construction industry strongly be needed productivity improvement and increasing the number of new hires due to improvement of working environment. Site manager needs to grasp whether the daily progress is as planned and updates the schedule appropriately for improve site's productivity and safety. In image-based data acquisition approach in japan, there is a problem that learning is insufficient with only global public data, since construction worker in Japan has originality in image feature compare with other countries. In this study, we make original dataset for additional learning firstly. Then we proposed domain-specific algorithms specific to the Japan construction site, including a worker detection and tracking algorithm and a worker action recognition algorithm. As a result, our worker detection showed 87.9% accuracy in same-site evaluation and 77.5% accuracy in cross-site evaluation. Our worker action recognition showed 60.2% mean accuracy. Finally, the method of translation into activity element based on the output value of worker detection was indicated.

Construction Process; Worker Detection and Tracking; Action Recognition

1 Introduction

In construction management study area, many researchers try to improve productivity and safety by acquiring various data from construction work in construction site. Tarak et al [1] reviewed various paper and classified these research technologies into 3 types; Enhanced IT technologies, Geospatial technologies, and Imaging technologies. Amin et al [2] also reviewed various papers focusing on BIM and Computer Vision (CV) and describe the development.

In Japan, decreasing the number of construction workers is pointed out based on annual statistical data changes [3]. Therefore, the construction industry strongly be needed productivity improvement and increasing the number of new hires due to improvement of working environment. In construction management in Japan, site manager who belongs to general contractor company is assigned to the construction site to manage the progress of construction. Site manager needs to grasp whether the daily progress is as planned and updates the schedule appropriately. In the case of typical Japanese construction sites, site manager saves the construction time by subdividing the work space so that multiple contractors can perform their work on the same day. In order to appropriately update the schedule, it is necessary to understand the daily construction process. In data capturing, site manager wants to reduce management effort by reducing the number of capturing devices. It is better to use a camera that can sense the area with one unit than wearable sensors that be required the same number of workers.

In image-based approach in japan, there is a problem that learning is insufficient with only global public data, since construction worker in Japan has originality in image feature compare with other countries. From the safety awareness of Japanese construction workers, it is common in the construction industry to wear long-sleeve workwear that has both resistance and protectiveness. It also has color-variation. Due to the protective properties of workwear, safety vests in vivid color common on construction sites around the world are not usually worn on construction sites in Japan. The rules for wearing hard hat and safety belts have been generalized, and there are various product variations for tool bags attached to safety belts. In order to build image-based data acquisition technology for images with these unique characteristics of Japan, it is necessary to build a unique Japanese dataset.

In this study, we make original dataset for additional learning firstly. Then we proposed domain-specific algorithms specific to the Japan construction site, including a worker detection and tracking algorithm and a worker action recognition algorithm. Additionally, the method of translation into activity element which has effect to grasp whether the daily progress is as planned and updates the schedule appropriately based on the output value from the algorithms.

2 Literature review

2.1 Dataset in construction site

In study about image-based data acquisition technologies, there are many example of dataset for each case study. Jun et al [4] made 11 actions' movie clips for action recognition. Kaijian and Mani [5] described comparison of efficiency on various annotation task condition for out sourcing. Mohammad et al [6] made dataset of Excavator, Loader, and Truck for comparison of accuracy using various CV technologies. Recently, Mingzhu et al [7] made dataset of construction equipment and workers. Each of them, the images included dataset made from each country's construction site. These are not Japan. Still, Japanese construction site datasets need to be uniquely constructed.

2.2 Object Detection and Tracking

Object detection. There has been tremendous advancement in object detection in the last decades. Before the era of the deep learning, methods with hand-crafted feature descriptors for detecting specific types of objects were dominating in the literature. For example, various feature descriptors such as HoG (Histogram of Gradient) [10], SIFT (Scale-Invariant Feature Transform) [11] and DPM (Deformable Part Model) [12] have been proposed, which were customized for detecting pedestrians. While these methods made significant improvement in object detection, manual engineering of these feature descriptors requires significant efforts from the researchers for each individual type of object, making it difficult to generalize to other object types.

With deep learning technique becomes favorable in recent years, many modern data-driven object detectors have been proposed which can learn universal feature descriptor for many object types jointly from the data, removing the need of feature engineering. Among different approaches, region proposal-based object detectors [13, 14, 15, 16, 17, 18] are most popular. These approaches first define a set of anchors with different scales and size and covering the entire image, and then a box regression and classification network is applied to classify object class and meanwhile refine the box position and size. In this work, we choose one popular universal object detector, Faster-RCNN [15], and adapt it to specifically work on the construction workers in the Japan construction site, in order to achieve the best possible performance.

Multi-Object Tracking. Beyond classifying the object class and detecting the object location in the image, multi-object tracking aims to associate the detected objects in video and output movement of objects. To that end, recent multi-object tracking methods often employ a tracking-by-detection pipeline. Specifically, given detected objects in all frames, the tracker assigns the identity to each object where the same object receives the same identity. For example, SORT [19] proposed to use the motion information and used the Kalman filter with constant velocity as the motion model in the tracking-by-detection pipeline. To leverage the appearance cue in addition to the motion cue, deep learning-based methods such as Deep-SORT [20] and MOTS [21] incorporated an object re-identification branch to learn the object appearance feature for discriminative feature learning. While these data-driven methods with deep learning technique often achieves better performance than Kalman filter-based methods when the appearance information is sufficient, data-driven methods lack the ability to run in the real-time speed. In this work, we employ the Kalman-filter based tracking methods due to their favorable speed and the lack of appearance differences in construction workers who often wear similar uniforms and helmets.

2.3 Action recognition

Different from learning the location, orientation and trajectory of the object, action recognition aims to learn the internal logic of the object motions and its interaction with the environment. With the development of deep convolution networks in the computer vision area, a large number of CNN based methods have significantly improve the performance of traditional action recognition methods [25, 26]. We broadly categorize video action recognition methods into two genres: 2D and 3D CNN approaches. Methods of the first type make use of the recent advances in 2D single image CNNs by applying a CNN to each individual video frame and aggregating the prediction along the time axis [27]. In order to further consider the temporal dynamics of a motion rather than treat them individually, two-stream method [28, 29] are proposed to model appearance and dynamics separately and allow their interaction by early or late fusion. Among these methods, Simonyan et al. [30] first proposed the two-stream ConvNet architecture by introducing the temporal stream which takes optical flow frames as input. Wang et al. [31] proposed Temporal Segment Networks – a sparse temporal sampling strategy for the two-stream structure and fused the two streams by a weighted average. Other methods have taken different approaches to help better incorporate temporal information into single-frame feature extraction backbones such as CRF and LSTM [32, 33].

The other genre seeks to learn spatiotemporal features from videos directly with 3D CNN [34, 35, 36, 37]. Among them, C3D [34] is the first to leverage 3D

kernel on video data to learn spatiotemporal features, making it able to capture long range temporal information. Following C3D, Joao Carreira et al. [35] proposed i3D, in which they inflated the ImageNet pre-trained 2D kernel into 3D and take advantage of optical flow information with a two-stream architecture. They also proposed a new large-scale action recognition dataset named Kinetics and achieved competitive performance in other benchmark datasets. STCNet [36] inserted its STC block into 3D ResNet to capture the channel-wise correlation of both spatial and temporal features. Slowfast [37] proposed a slow-path to capture spatial semantics and a fast path the capture motion at fine temporal resolution.

Other than CNN, there is also method that model action recognition as a graph-based problem and use graph neural network to solve this problem [38]. In this work, we leverage two-stream 3D-ConvNet as our backbone [35] due to its stability and its strong feature extraction ability in complex scenario. We adapt the method to work in the Japan construction site scenario which contains high occlusion and complex actions and achieve the best possible performance.

2.4 Data usage

Output data from various data acquisition technologies reshape and use for each purpose. For example, Eirini and Ioannis [8] got the time when the worker stopping at workspace as production time from 4D trajectory data. Ye et al [9] showed time-space heatmap from workers' location data from BLE beacon for grasp usability of workspace. The former lack the method to grasp works on moving time, and the latter has difficulty to understand the meaning of location.

3 Method

3.1 Dataset creation

Dataset creation will be done by process below.

1. Selection of sites
2. Negotiation about permission
3. Capture movies and pickup movies
4. Annotate worker location and parameter

In annotation, we define three data; bounding box for worker detection, workers' ID for worker tracking, and tag of action categories for worker action recognition, into each frame. Action categories should be defined on common words for easily understand by annotator who not familiar with construction work and image of inside of construction site. In this study, we defined action as 6 actions; Walk, Crouch, Stand-up, Carry, Place, and Pick-up. Table 1 shows work definition for annotator and Figure 1 shows additional category definition about stable action Standing and Crouching which were needed because "other" tag was too large amount.

Table 1. Work definition for annotator

[Human Bounding Boxes]
●Description: A minimum enclosing box for a person
●Start: When all parts above shoulder (include face/head) is visible or when more than half of the person's body is visible
●End: When the above conditions no longer hold
●Notes:
○Must cover all the visible parts of the person, occluded parts do not need to be covered in the bounding box
○If the person is interacting with an object, all the contact points between the person and the object must be included in the bounding box, but it is not necessary to cover the whole object
○The bounding box should be as tight as possible. Small misalignment due to Imperfect interpolation is allowed, but it should be reasonable and calibrated at least every 10 frames.
[Actions]
Notes for all actions:
·There are 6 actions. All of them are single human actions. Walk, Crouch, Stand-up are atomic actions that do not have any object interactions. Pick-up, Place, Carry are interactive actions that depend on object interactions.
·One person can belong to one of the above 6 actions or none of them at a time.
·The 6 actions are not complete. A person can be doing "other" action, which does not need to be labeled.
·Only need to label when visually satisfies the definitions. For example, a man might start crouching when he is 90% occluded. We don't need to label this action. Another example, a man might pick-up something while the contact points between his hands and the object are totally occluded, we don't need to label this action.
[Action Definitions:]
●Walk
○Description: A person walking without carrying any object.
○Start: When the person starts moving and his first foot leaves the ground
○End: When the person stops walking.
○Note: Walking must be obvious and at least two steps. If a person is just changing the position by a little bit or moving just one step, that is not walking
●Crouch
○Description: A person starts to bend, sit, squat, crouch, knee down, etc. from a non-crouching status.
○Start: When the person's knees, waist, or back starts to bend
○End: When the person's knees, waist, or back stops moving or is fully bent
○Note: The actions must be obvious, for example a person looking down and bending only a little bit doesn't belong to crouch.
●Pick-up
○Description: A person makes contact, lifts, and starts to support an object against gravity.
○Start: When the person starts to lift the object up and begins supporting its gravity.
○End: When the person finishes lifting the object and reaches a stable gesture.
●Carry
○Description: A person starts walking/moving with a wide, long, large, or heavy object.
○Start: When the person starts walking/moving with the object
○End: When the person stops moving, or stops supporting the object's gravity
○Note: The object should be wide, long, large, or heavy. Carrying a small bag or backpack doesn't belong to carry.
●Place
○Description: A person lose contact, putting down, and stops supporting an object against gravity.
○Start: When the person starts lowering the object or starts to put it down
○End: When the person lose contact with the object, no longer supports its gravity, or body stops moving.
●Stand-up
○Description: A person stands up from a crouching or other non-standing status.
○Start: When the person's knees, waist, or back starts to recover from bent status
○End: When the person's knees, waist, or back is fully recovered from bent status

Figure 1. Additional category definition

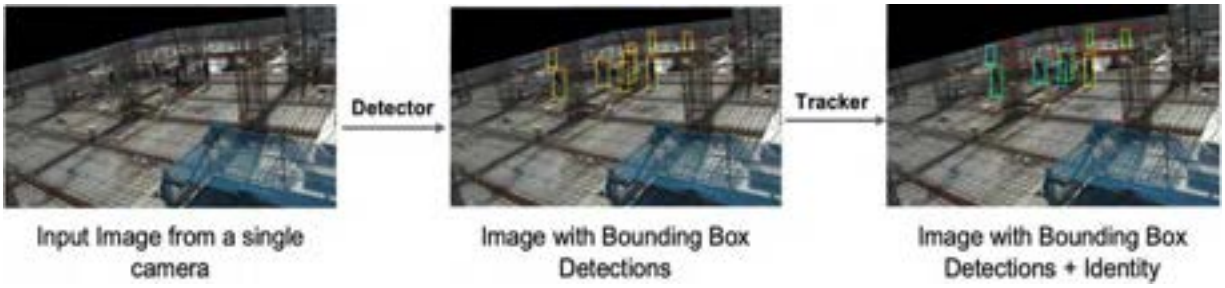

Figure 2. Illustration of our worker detection and tracking pipeline

3.2 Worker detection and tracking

We show the pipeline of our worker detection and tracking algorithm in Figure 2 Given a single image from video, we first run our worker detector to obtain a list of bounding boxes representing detected workers. Every worker bounding box has the same yellow color as we have not assigned an identity to each worker yet. Then, the outputs of the worker detector will be fed to the worker tracker, where we assign the identity to each worker based on temporal information. In the tracking outputs, each box is painted with a different color in the image as we know their identities now.

As we have mentioned in the related work, we use FasterRCNN [15] network as our worker detector, which was originally designed for universal object detection. To adapt the network for our task, which is to differentiate foreground workers and background, we change the dimension and parameters in the last few layers of the FasterRCNN so that the network only outputs for two classes instead of near 100 classes defined in COCO [22]. Also, to output more accurate worker detection, we change the size and aspect ratio of the default anchors so that the anchors are more aligned with the size and aspect ratio of our workers. To achieve the best possibly performance, we first train the original network on ImageNet [23] and COCO to learn universal features, and then we fine-tune the network on our own datasets with construction workers. We will show in the experiments that our pre-training help improve the performance and generalization to new videos compared to directly train on our dataset from scratch.

Besides customizing our worker detector, we also track the detected workers over time. Specifically, we use Kalman filter-based tracking method SORT [19] as our worker tracker. In this way, we remove the need of training for tracking algorithm and can also achieve real time worker safety monitoring. Beyond tracking in the images, we also develop a 2.5D tracking method by using homography transformation technique. As a result, we can visualize the resulting worker motion trajectory in the top down view so that it is helpful to site manager for better understanding the worker's activities. The final output worker trajectories from our tracker will be used as inputs to our action recognition system to obtain detailed action category information for each worker.

3.3 Worker action recognition

Following detection and tracking of the objects in the video, we further conduct action recognition with a two-stream 3D-ConvNet architecture. Our architecture follows i3D with an RGB appearance stream and an optical flow dynamics stream. As stated in the previous section, our tracker will aggregate bounding boxes in continuous frames of the same person as video clips, these videos are treated as input of our RGB stream. We use an off-the-shelf optical flow extraction algorithm from OpenCV toolbox. In order to ignore the background shift caused by bounding box shift, we calculate the flow directly from the video, and clip the patch from the generated flow videos.

We use 3D Inception-v1 as our backbone for feature extraction as used in i3D [35]. The image stream takes RGB frames as input, and flow stream takes optical flow frames as input. Each video clip is stacked by 60 continuous frames. After backbone network extracts appearance and dynamic feature maps, we leverage the late fusion strategy by averaging the two feature maps. Finally, a classification head is used to get the final the prediction. Horizontal flip and random translation of bounding box is used as data augmentation, and the same augmentation is conducted on all frames of a video sample.

3.4 Data usage

Site manager needs to grasp whether the daily prog-

Table 2. Method to get activity element

What	Work name	Search from worklist by When and Where
How	Process of action	Use output from worker action recognition

ress is as planned and updates the schedule appropriately. Daily progress can be grasped from some elements; when the work has done, who done the work, where is the worker done the work, what is the work, how the worker has progressed the work, as shown in Table 2.

4 Result and Discussion

4.1 Dataset creation

Selection of sites. We selected 6 sites in Japan managed by Shimizu Corporation which were under construction of main structures. Example image of 6 sites are shown in Figure 3.

Negotiation about permission. By promising that the image of worker not to link the workers' personal data (i.e. name), the legal department of Shimizu Corp and CMU permitted this study. Then we got permission about capturing movie from onsite manager and the owner of the building which the site construct. Then we displayed notification of movie capturing and its purpose for the workers in the site.

Capture movies and pickup movies. We set 2 cameras (Sony-FDRX3000, JVC-GZRY980) onto outer scaffolding frame using metal clip on little look-down direction. After capturing, we checked all movies and selected or cut into 52 movies on 17 scenes. As shown in Figure 3, site 1 was concrete placing work on sunny day, site2 was placing rebar of floor work in sunny day, site3 was formwork carrying in sunny day, site4 and site5 were formwork related work in cloudy day, site6 was formwork and scaffolding work in rainy day. Table 3 shows total length of movies. Total frame count was about 270k, and total length was about 2.5h.

Annotate worker location and parameter. Annotation was done by over 10 annotators hired by outsourcing company and spent over 2 months. The total count of data is shown in Figure 4. Since site1 and site4 had over 10 workers in each frame, total data count was be huge. Figure 4 colored by size category of height of bounding box (i.e. count of pixel), by this, we can understand the workers image size almost in Easy (>=40pixel) category. Action category ratio is shown in Figure 5. It can be seen "other" category occupied more then half of all and can be seen basic 6 categories has mis-balanced.

In the future data set creation, it will be necessary to set the video length according to the number of workers included in the video, and to define the action category as avoiding a mismatch in the number of tags.

4.2 Worker detection evaluation

We evaluate our worker detector on our dataset collected from the Shimizu Corp. construction site. We use the standard metric of average precision (AP) defined with an IoU (intersection of union) threshold of 0.5 for worker detection evaluation. Also, we use three difficulty levels for evaluation (easy, moderate and hard) where each difficulty level has a different threshold on the number of pixels (40, 25, 1 respectively) in the ground truth worker's bounding box height. For example, for the easy case, we filter out ground truth workers that have height less than 40 pixels and only evaluate the rest of workers which are relatively closer to the camera and easy to be detected. We compare our customized worker detector trained on our Shimizu data with generic detectors such as Faster RCNN [15] and Mask RCNN [24] pre-trained on the COCO dataset.

We use two types of data split during evaluation: (1) same site evaluation; (2) cross-site evaluation. For each construction video in the same site evaluation, we use first 70% frames for training, middle 15% for validation and the last 15% for testing. We summarize our results for same site evaluation in Table 4. We can see that, without any customization, the generic object detectors do not perform well on our construction dataset, and have lower performance than our customized detector, e.g., 33.5 AP of the Mask RCNN v.s. 66.8 AP of our detector in the easy case. Also, when we pretrain our customized detector on the COCO dataset before fine-tuning on our construction data, the final performance can be even higher, e.g., 87.9 AP v.s. 66.8 AP in the easy case. This proves that pretraining on the COCO dataset with many generic objects does help improve final detection performance on our construction dataset.

In addition to same site evaluation, we also perform the cross-site evaluation, i.e., evaluation across different construction site videos. This means that we select one site (e.g., 5 videos from the site 2) as the testing data, while using the rest of other data from other sites for training and validation. In this way, the detection is more difficult than in the same-site evaluation as the data in the testing set is not seen during training. We summarize the results in Table 5. We can see that our customized detector still achieves reasonable performance when evaluating on the construction sites that are not seen during training. This can be useful to construction manager as our customized detector can be potentially applied to other new site videos collected in the future. Also, same as the same site evaluation, our customized detector works better than the generic object detector Faster RCNN in the cross-site evaluation (e.g., 77.5 AP of our customized detector v.s. 50.7 AP of the generic detector in the easy case).

Table 4. Quantitative performance of worker detection in same-site evaluation

Method / AP	Easy (>=40)	Moderate (>=25)	Hard (>=1)
Mask RCNN (COCO)	31.7	31.3	31.3
Faster RCNN (COCO)	33.5	32.1	31.9
Our Detector (Shimizu)	66.8	66.5	66.4
Our Detector (COCO+Shimizu)	**87.9**	**87.4**	**86.2**

Table 5. Quantitative performance of worker detection in cross-site evaluation

Method / AP	Easy (>=40)	Moderate (>=25)	Hard (>=1)
Faster RCNN (COCO)	50.7	48.7	48.3
Our Detector (COCO+Shimizu)	**77.5**	**72.8**	**72.7**

4.3 Worker action recognition

Similar to detection and tracking task, we evaluate our action recognition model on our dataset collected from the Shimizu Corp. construction site. Specifically, we first pre-train the model on Kinetics and fine-tune on our dataset. The dataset is randomly split into 80% training set and 20% validation set. We evaluate the performance of each class by their recall rate, and the overall performance is measured by mean class accuracy. In order to get more information about surrounding environment, we expand the bounding box from detector by 10%. The learning rate for our model is set to 0.0005 with a weight decay 0.0001. Batch size is set to 4. We show some qualitative results of our model in figure 6. Note that the real data is in video format, and we show a representative frame of each video clip.

We summarize our quantitative results in Table 6. We can see that our method performs better than generic ST-GCN [38] and i3D [35]. Note that ST-GCN was trained on an early labelling strategy where standing and crouching are not specifically labeled, making the dataset simpler. As we can see, even with a simpler task, generic ST-GCN performs worse than our method. And generic i3D only performs marginally better on walk and carry class. We can see that for Other class, out method performs the worst, this is because we are using recall as our metric. A high recall of un-defined class is usually the result of many false positive samples in other classes. Also, we notice that the performance on Place class is very low. This is because of the internal imbalance of our dataset in number and

difficulty of each class. In real-world construction site, “Place” happens far less frequent than other classes of actions like walk or standing. Moreover, it usually lasts very short, sometimes less than 1 second. These results in the high relative difficulty of class “Place”.

Figure 6. Qualitative performance of our worker action recognition model

Table 6. Quantitative performance of worker action recognition

Method	Mean Class Accuracy	Walk	Crouch	Stand-Up	Pick-Up	Carry	Place	Standing	Crouching	Other
ST-GCN	33.1	34.7	49.2	49.5	14.7	8.1	**18.7**	-	-	**57.2**
i3D	54.0	**80.7**	37.2	85.9	38.2	**79.6**	5.6	73.8	30.3	55.0
Our Method	**60.2**	75.5	**84.1**	**90.5**	**59.0**	61.1	6.1	**82.2**	**34.3**	50.0

Table 7. Ablation study on our worker action recognition model

Method	Mean Class Accuracy	Walk	Crouch	Stand-Up	Pick-Up	Carry	Place	Standing	Crouching	Other
RGB	51.6	44.0	82.0	86.0	56.0	77.0	0.0	71.0	16.0	28.0
Flow	56.2	68.0	82.0	83.0	49.0	40.0	**18.0**	77.0	**39.0**	48.0
RGB + Flow	**60.2**	**75.5**	**84.1**	**90.5**	**59.0**	**61.1**	6.1	**82.2**	34.3	**50.0**

We also conduct ablation study as shown in Table 7. The first two rows are using only RGB stream or optical flow stream without late fusion. We see that using only one stream will result in a performance drop in mean class accuracy and most classes. This experiment also proves that RGB is better at extracting appearance feature like “Pick-up” and “Carry” which involves interaction with other objects that might not be visible in optical flow. On the other hand, optical flow steam helps the model by providing better dynamic feature, and thus improves classes like “Walk” and “Place”.

4.4 Data usage

The data acquisition technology was implemented except for the "How" element. A result of data acquisition using our method is shown in Figure 7. The rectangle frame was output from detector and the “id001” was output from tracker. The line in bounding box indicated a vertical line calculated from 2D coordination of bounding box output from worker detector and camera parameter. The XYZ and height of worker were calculated by regarding the center of the frame as the midpoint of the worker's height. It also can be seen the work name was successfully searched from list by datetime and XYZ coordination. The activity elements were acquired as planned.

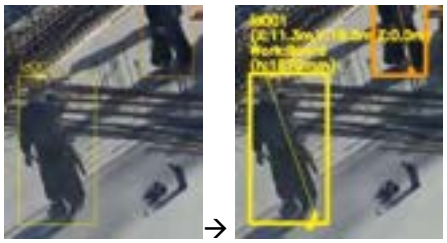

Figure 7. Translation to activity element

5 Conclusion

We first built a dataset for a Japanese construction site. Then, the domain specific algorithms of worker detection, tracking, and worker action recognition were customized. As a result, our worker detection showed 87.9% accuracy in same-site evaluation and 77.5% accuracy in cross-site evaluation. Our worker action recognition showed 60.2% mean accuracy. Finally, the method of translation into activity element based on the output value of worker detection was indicated. Whether these accuracies are actually sufficient needs to be verified in the future.

As a limitation, this method cannot deal with occlusion because it uses a single camera. It is possible to deal with this by installing multiple units on site so that occlusion is reduced.

As future work, it is essential to improve accuracy by increasing the data set, and it will be necessary to build technology to ensure data consistency when multiple cameras are installed.

Abstract –

Recently, as technologies combine, AR (Augmen ted Reality)/VR(Virtual Reality)/MR(Mixed Reality) and advanced sensing equipment are being developed. The possibilities of their application to construction fields is likewise increasing. Research into applying these techniques to facility maintenance, manager training, and safety/evacuation training is being actively conducted. In the case of the existing facility maintenance process, it is difficult to identify the exact management matters and departments that have problems during facility inspection or history management. In the case of complex equipment, it is necessary to respond to equipment maintenance needs through real-time support technology with on-site workers due to the difficulty of promptly dispatching related advanced equipment experts. In addition, digitization of the maintenance manual is required for time, cost and losses to be minimized due to equipment downtime; to improve understanding, thus proper utilization, of non-specialist facilities maintenance and work safety through realistic work guidance based on 3D content. Therefore, in this study, we propose MR-based remotely controlled technology, real-time worker decision-making and work performance support technology for process improvement, preventing quality problems in the field manager-centered equipment inspection maintenance.

Augmented Reality; Mixed Reality; BIM; Working Guidance

1 Introduction

1.1 Research Background and Purpose

Research into application of AR/VR/MR technologies in various ways are also being actively conducted in the construction field. In particular, studies are being conducted to apply such technology in semiconductor and battery factories, where demand continues to increase due to the rapidly accelerating technological development and the fourth industrial revolution.

Plant construction projects are large and involve complex maintenance activities. Therefore, they have a higher project cost than other construction projects and require efficiency in maintenance.

In the construction of battery and semiconductor plants, a huge amount of data is produced at various stages of operation due to complicated internal design, pipe installation, electricity, and other facilities; with many studies being conducted to efficiently maintain them.

As major research for enhancing the work efficiency of plant workers, research on information management systems using QR codes, barcodes, radio frequency identification (RFID), and cloud system technologies is actively being conducted.

However, these technologies make it difficult to provide visually intuitive information to workers, which increases the incidence of human errors. These problems extend the working time at the plant site and cause task revisions.

This study develops a suitable MR-based 3D digital working guidance system through analysis of the maintenance work process at the plant site based on the opinions of practitioners and presents a worker-oriented maintenance work process.

At the existing plant site, workers have performed inefficient operation management tasks due to lack of intuitive work information visualization systems and lack of interoperability due to the dualization of construction sites and offices. In addition, the worker had difficulties in communication with the manager due to the complex plant design. In order to solve this problem, this study draws a plant field maintenance plan for effective equipment location and installation by using a Mixed Reality-based smart device for general equipment maintenance work of the plant.

1.2 The Scope and Methods of Research

This study proposes a 3D digital working guidance system for workers using AR-based smart devices at the plant site. At the plant site, workers have performed maintenance work based on past information and manuals. Currently, due to extensive and complex plant field work, difficulties arise in actual work. The typical maintenance tasks of unskilled worker include difficulties in figuring out the route due to the wide range of plant sites, and human error occurs when replacing equipment. Therefore, in the case of maintenance work, it needs an information exchange system that can intuitively communicate the exact plant site situation between the worker and the manager. Therefore, this study intended to solve such problem through an AR-based smart device.

The method and process of this research is:
(1) Preceding Research Analysis
- Existing review of literature
- Analysis of management characteristic of plant maintenance and process
(2) Requirement Analysis and Function Derivation
- Figuring out smart device applicability in the plant field
- Requirement analysis to solve problems
(3) Establishing MR-based 3D digital working guidance for optimal plant maintenance
- Process Analysis of Plant maintenance
- Analysis of maintenance Work at Plant Site
- MR-Based Equipment Assembly Management Process
(4) MR-based 3D digital Technology at Plant Site.

2 Research Trend

2.1 Literature Review

From the mid-2000s, much research has been carried out in order to derive improvements to general interests in the construction industry such as shortening the construction period, cost reduction, flawless construction, accident-free planning, predictability improvement, waste factor elimination, productivity improvement, and maintenance cost reduction through the use of various IT technologies.

The table below shows some of the existing research pertaining to the subject of smart, IT-based construction. This research focused on the exchange and maintenance of construction information for smooth installation of facility equipment among participants in the project in relation to the plant maintenance process. The process is illustrated in Figure 1.

Table 1. Existing research

Area of management	Research subjects
Construction	Ontology-based BIM modeling; AR-based system framework
Site condition	4D tools for greater efficiency in site management
	Use of smart phone to improve management process; visualization of project information using real-time data sharing and management, wireless communication; and augmented reality
Safety	New 4D safety management and monitoring system ‘C-RTICS2’ for more efficient construction and communication among work partners
	Behavior-based preventive safety system, visualized management with VCS (Virtual Construction Simulation System)
	Note
Construction	Marker-based AR: Research on identification of objects, selection of marker type, marker detection, and marker-less AR technology
Site condition	Wearable device for real-time work coordination
	Wearable device; Cloud system for massive data management
Safety	Set apart in terms of device and visualization method, while similar in technology for communication between office and construction site
	Partly applicable to safety management in terms of carrying out preventive safety management in visualized form

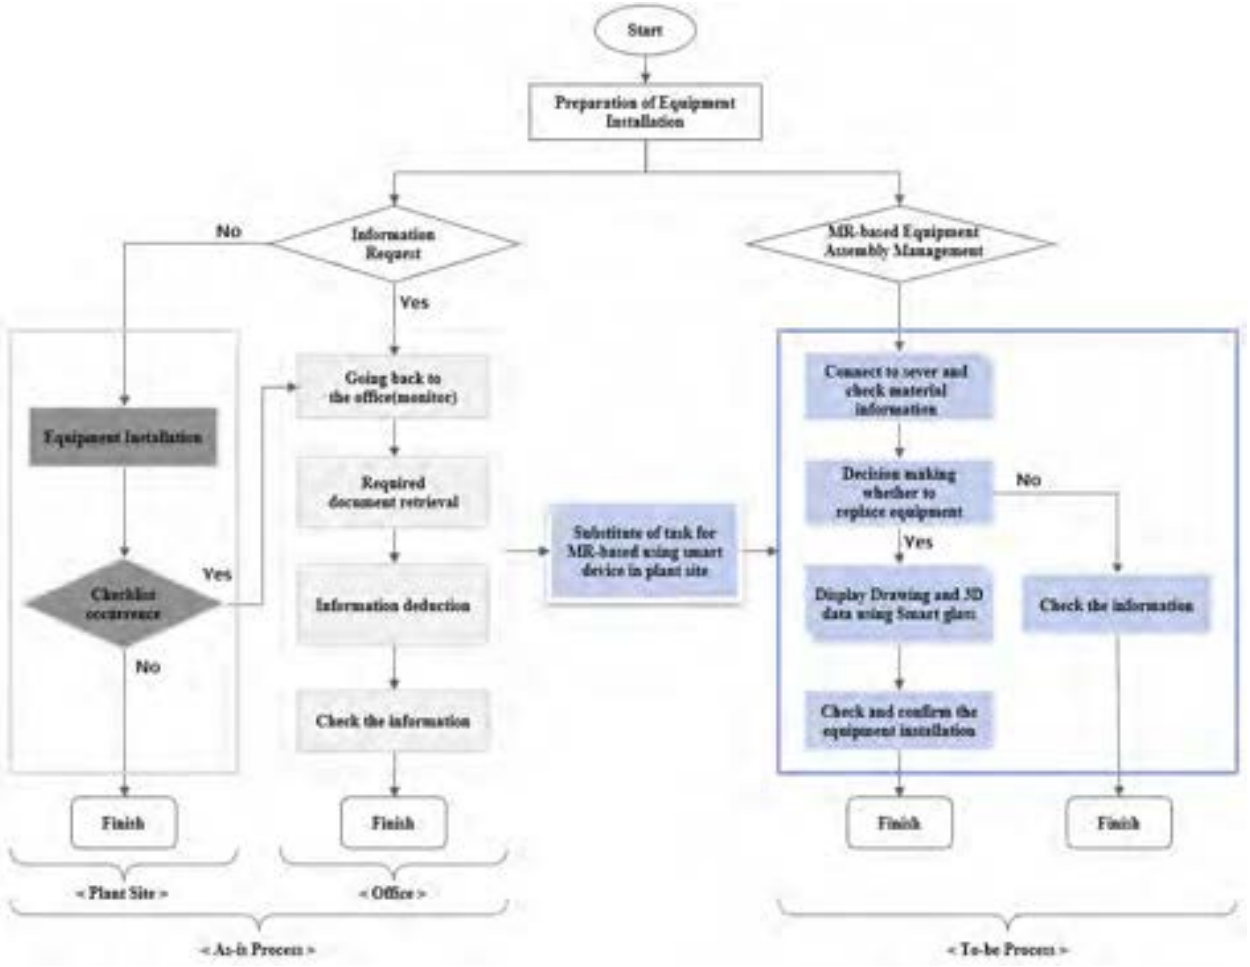

Figure 1. Improved Plant Site Management Process

2.2 Plant Maintenance Management

The equipment replacement procedure at the existing plant site differs depending on the method of obtaining equipment replacement work information. When the worker no longer needs to obtain work information, the worker goes to the site to proceed and finish the work. However, in the event of an unusual occurrence in the middle of the work or when the manager orders the work in the middle, the worker needs a means to receive information. In this case, if the information is complicated, face-to-face communication between workers and managers is needed, or a visualization information sharing system for work orders is required.

In the improved process based on the Mixed Reality, it is possible to intuitively figure out information through 3D digital working guidance during the process of equipment replacement work, and even unskilled worker can more easily understand the work to reduce the occurrence of human error.

3 Analysis of plant workers' needs

According to Moon (2015)[1], as a result of conducting site surveys and interviews with major construction company in Korea, "S", the Construction Assistance App, Data confirmation and check App, Guideline App, and especially Communication support App and Progress Management App at the plant site were found to be required. These territories are tabularized below. This shows that the MR-based smart device system for workers is required to share information at the plant site.

Table 2. Applicable work territories

Direction	Contents
1	Construction Assistance App.
2	Data confirmation and check App.
3	Data input App.
4	Guideline App.
5	Communication support App.

6	Progress management App.

During the materials management and product installation process at the plant site, workers need drawings and related information data. At this time, the information provided exists in various forms and is visualized in various ways and delivered to the worker. When one data is converted, new conversion information is generated by deriving from other data in real time. Various applications of smart devices must be provided to support this.

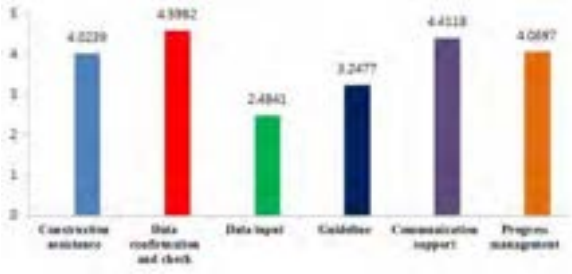

Figure 2. Overall result

4 MR-based 3D Digital Working Guidance

4.1 Worker Equipment Replacement Process Analysis in Plant Site

Through an interview with the Battery Plant Equipment Management Team at the battery plant site in Korea, a detailed work process of the worker was derived from the Mixed Reality-based to-be process.

Workers are assigned to equipment management tasks, identify the location of the target equipment, and move to the site. In addition, the state of the equipment is determined through visual inspection and it is determined whether the equipment is replaced. If it is necessary to replace the equipment, he/she selects a replacement and records the reason. Subsequently, a procedure for applying for replacement equipment is carried out, and another colleague carries the replacement equipment and delivers it to the work site. In the field, the operation of existing equipment will be stopped, and the equipment disassembled. The disassembled equipment is returned according to the return procedure, and new equipment is installed by determining the presence of abnormalities. When the installation of new equipment is completed, the test operation will be performed, and the test operation will be made for diagnosing the normal operation.

Figure 3. Worker Equipment Replacement Process

4.2 Usage of AR Data in the plant site

The data types that can be used in the detailed equipment management process based on the mixed reality derived above are classified into four types: 1) modeling data, 2) attribute information data, 3) AR data, and 4) job reporting data.

Modeling data and attribute information data can be extracted from BIM data. BIM data was converted to 3D model-based neutral file format (fbx, ojb) and then mapped to be usable in the AR environment. Also, the modeling data can be used to check the optimal path for operator's navigator and equipment transportation at the plant site, and to check interference between members. The attribute information data can identify the performance of the installed equipment or the cost information, replacement cycle, and the like.

AR data in the form of 3D model can be used to guide the on-the-spot movement route based on a digital map, work sequence guide, and to understand the current state of the equipment. The worker can always record the work contents in the work report data to check the past records of the activities in the field and to understand the operation information of how it is currently operating.

Table 3. Applicable work territories

	① Modeling Data
Image	Type	3D Model
Utilization	1. Use as a digital map on site 2. Equipment type can be checked 3. Check the optimal path for equipment transportation 4. Interference check between members
	② Attribute Information Data
Image	
Type	Object Specification
Utilization	1. Identify the performance of equipment 2. Identify the replacement cycle of equipment 3. Equipment unit price information
	③ AR Data
Image	Type	3D Model
Utilization	1. Identify the current position of the operator(Based on Device's GPS data) 2. Guidance on the on-site route 3. Guide to the sequence 4. Guidance on current status of equipment
	④ Task Reporting Data
Image	
Type	Work Sheet
Utilization	1. Confirmation of historical information 2. Records of workers' work activities 3. Checking factory operation information

4.3 AR Data-based workspace and equipment replacement procedure

The four types of data classified above can be divided to data available for each step in the worker equipment replacement process analyzed above. Each worker equipment maintenance procedure is divided into three groups as shown in Figure 4. : 'Decision to replace equipment', 'Procedure for returning existing equipment, and 'New equipment replacement procedure', and AR data has high utilization in 'Decision of equipment replacement' and 'New equipment replacement procedure' respectively.

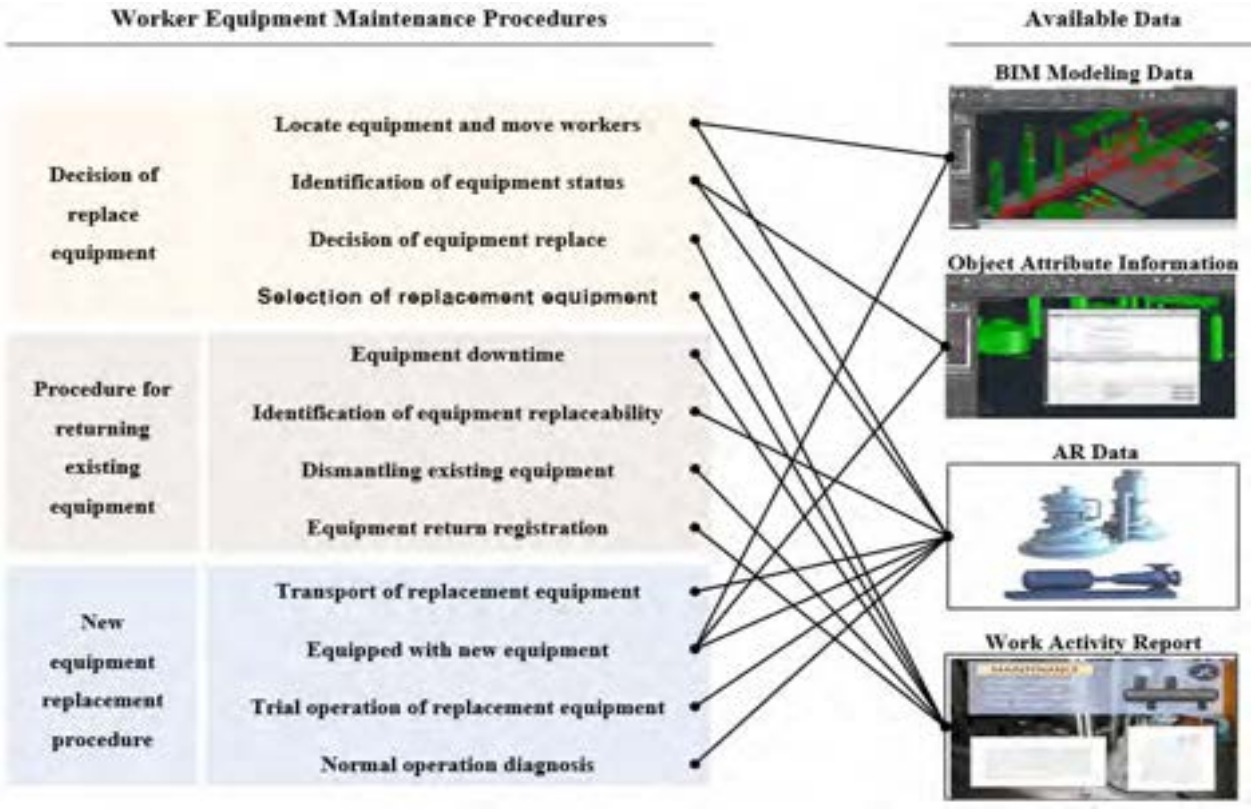

Figure 4. Matching of available data and equipment replacement procedure

When the work activity report is visualized as an AR image, the utilization of AR data is also increased in the 'Procedure for returning existing equipment' stage, and the AR visualization data is used in the overall worker equipment replacement process.

Therefore, BIM Modeling Data and Object Attribute Information can be used as data to implement AR Data. AR Data and Work Activity Report Data implemented based on this can be visualized in AR and used in 3D digital working guidance, as the example in Figure 5. illustrates.

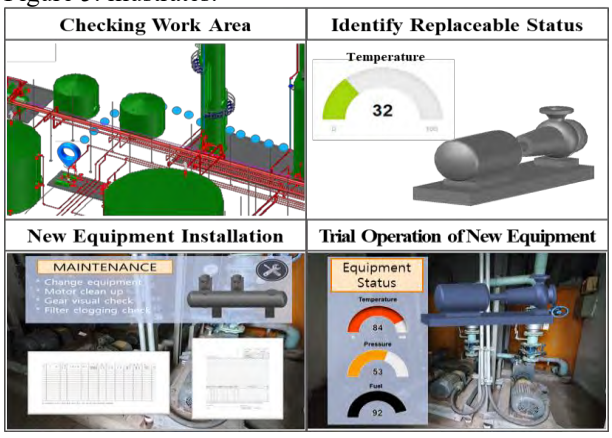

Figure 5. Main application methods of MR-based 3D digital working guidance

5 3D Digital Working Guidance in Plant Site

A 3D digital working guidance test-bed system was implemented in accordance with the Worker Equipment Replacement Process Analysis previously analyzed, and the MR-based work environment was tested based on the equipment replacement work generally performed by workers.

The test-bed environment (Figure 6.) was tested in the following six steps. 1) Work selection, 2) Checking work area and moving workers, 3) Worker Navigator, 4) Check work objects and work contents, 5) Check equipment status, 6) Dismantling existing equipment. The role of each stage is as follows:

1. Work selection: Confirms the work assigned to the worker with AR and selects the work to be performed.
2. Checking work area and moving workers: Figure outs the position of the selected work and the current position of the worker.
3. Worker Navigator: Guides the way for the worker to move from the field to the work location.
4. Checking work objects and work contents: Figures out the contents of the work to be performed by the current worker.

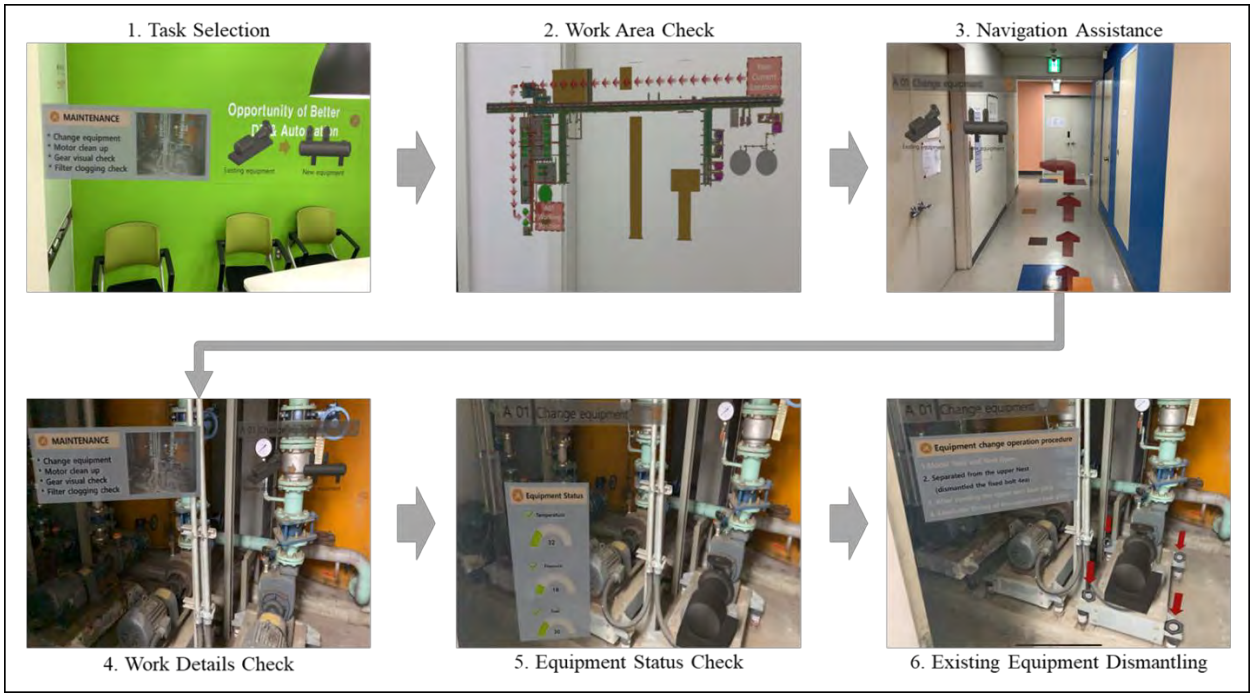

Figure 6. MR-based 3D Digital Working Guidance Test - Worker Perspectives

5. Checking equipment status: Figures out the status of currently installed equipment before the operator performs the equipment replacement work.

6. Dismantling existing equipment: Intuitively guides the operator to the dismantling order of the existing equipment.

In this study, the above 6 steps were experimentally implemented to test the 3D digital working guidance environment for the unskilled or alternative workers to accurately understand the work. If such a system is applied in the field, it is judged that human error can be reduced.

6 Conclusions

This study analyzed the process of the existing plant work, identified problems in the plant site through worker interviews, and analyzed the Worker Equipment Replacement Process. Based on this, detailed work process was derived based on the Mixed Reality-based to-be process, and the applicable data was classified into 4 types (BIM Modeling Data, Object Attribute Information, AR Data, Work Activity Report).

In addition, the purpose of using the data was identified by matching the operator's equipment maintenance procedures with data classified in four types. Among them, four main methods of using MR-based 3D digital working guidance include 'Checking work area and moving workers', 'Identify replaceable status', 'New equipment installation and check', and 'Trial operation of replacement equipment'. Working Guidance environment was built and tested according to Worker Equipment Replacement Process.

This study visualized AR information for workers using MR-based work information data. For visualization information, four types of data were set according to business procedures. Based on this, equipment maintenance workers can increase understanding of their services through AR visualization information. Furthermore, if CPS (Cyber Physical Systems) in which a virtual model and a physical model are connected is introduced, information exchange between managers and workers will be facilitated in real time. In future studies, this study will be used as basic data to conduct digital interface & physical object linkage research on a small number of objects.

Abstract –

Application of technologies as laser scanning, remote sensors, drones or mobile applications are playing a major role in changing the management procedures of maintenance and operation activities in the roads. Without scarifying the quality of the data, tasks can be performed in less time while maintaining the same level of accuracy of the outcomes and results.

Keywords –

Laser scanning; remote sensors and traffic data collection sensors; UAV (Unmanned Aerial Vehicles or drones) inspection; mobile application; assets management.

1 Introduction

The Ministry of Energy and Infrastructure (MoEI) is the arm of the Federal Government in the United Arab Emirates to plan, design, execute, operate and maintain the Federal roads Network in the five Northern Emirates (800Km center line, 1600Km carriageway and 3700Km lane of highways), *(figure 1)*

Figure 1. Federal Roads Configuration

Operation and maintenance of the roads is a cycle of various interconnected fields and specialties, being all of them interconnected and affecting each other.

By nature, that interconnection happens around numerous variables, and as a road network having hundreds or thousands of kilometers big amount of inputs for those variables are required, thus generating a big database.

UAE MoEIhas detected the need of a comprehensive system to manage and operate the maintenance activities with the highest efficiency. Developing an own assets management customized system to obtain, collect and process the related data of roads elements, intending to enlarge their life span and keep the level of service of some parameters within the suitable range.

The level of service for those established parameters are related to the sustainability aspects from which the MoEI is responsible for. [1]

These systems use the historical information contained in the database as a self-learning tool to enhance any analysis. Therefore, a good quality database will provide as well a good quality results through the modification and enhancement of the algorithms behind the calculations ensuring that self-learning process will also be improved.

The technologies that recently the MoEI has implemented within the assets management system are mentioned below as well as the reason of why were they chosen. [2]

1.1 Laser scanning (LiDAR)

The inventory of the elements within the right of way of the federal road is a requirement to perform the proper maintenance (it is impossible to asses a right maintenance either predictive or corrective if the elements to be maintained are unknown for the road owner). This knowledge is not only referred to “know” that the element exists; it is necessary to have some basic information which will allow the decision maker to choose the most appropriate method for intervention in order to preserve the assets, taking into consideration the reduction in time and effort reduction, and most importantly, ensure safety for the road users as well as the rest of the sustainability parameters. [3]

In the case of MoEI these pictures have been obtained since 2012 using a high-performance vehicle in which the pictures are taken and assembled every 2 meters composing frames of 10 meters length. The data collection can be achieved by using different cameras arrangement combined with a series of devices, which will relate the pictures with geographic positions (GPS, distanciometers and correlation of that information with the typical used road milestones used in the country,

which in MoEI's case are the light-pole number (sequential numbers placed in each light-poles). [4]

Within those 10-meter images, those elements constituting the road assets will be assigned to the system through their corresponding position and type through a file where their information can be stored after collecting it to create the full roads environment (dimensions, properties, condition, camber, slope, radius of curvature, etc.).

Implementation of *LiDAR* (*Light Detection and Ranging*) will combine all the previously mentioned parameters by generating a cloud of points then creating a 3D environment. This cloud of points creates a 3D attributes for each point, therefore we can obtain the geometric characteristics, relating them to 360 degrees pictures and describe the elements contained in the network, one by one.

LiDAR used to collect this information is a TRIMBLE MX9 equipment with capacity of 1 million points per second acquired with an average vehicle speed of 80Km/h and a mesh density of 1,000 points per square meter, *(figure 2).*

Figure 2. LiDAR vehicle used for data collection

Data acquisition from this device will provide the following described information .

As mentioned previously, within the information related to the inventory is very important to have the type, location and properties of the elements contained within the road network, *(figure 3).*

Figure 3. Data Inventory tables correlated with the Cloud of points and images

The typical data collection for the road network using the conventional methods took around 4 weeks of continuous work, and is compelled to be done during the daytime (considering as well the position of the sun to ensure the quality of the images). The data collection for the same length using LiDAR took only 14 days (saving therefore approximately 50% of the time required before).

The use of the cloud of points, allow to obtain cross sections of different segments of the road as well as distances between two or more points, areas and volumes. The benefit of that will be described after.

1.1.1 3D model creation

Both technologies mentioned previously, have been able to inventory more than 30,000 elements. And the creation of the continuous 3D model for the roads network can be integrated with other applications, systems and models in a near future as the usage in BIM *(Building Information Models)* or modeling base mesh for future growths or expansion of the roads, *(figure 4).* [5]

Figure 4. Bridge 3D model from LiDAR data collection

1.2 Remote sensors

Within the Bridge Management System (BMS), the main objective of these system is to store information of the bridge that can identify it as a singular and unique unit and to relate to that unit the condition of the structure, assessed by an assestment condition index developed by the MoEI and the University of Sharjah [6], [7], [8]

That index, indicates the condition of the structure according with a scale, depends on any defect affecting durability, structural behavior or operation of the bridge *(figure 5).*

Figure 5. Bridge Assessment Condition Index within the Bridge Management System

These defects in each structure can be detected through *principal inspections* that are performed in a period of 3 years by specialized engineers. This period can however vary, depending on the severity of the structure's condition. shortened if the needs of the bridge advise to do that. These conditions can be determined by:

- Unpredicted events (as for example, a flood or high tide stream, or any other extraordinary climate event)

- Hit by a vehicle or any other external element which can compromise the safety of the structure
- To follow special conditions of defects found (for example follow up the evolution of any mechanic or chemical phenomenon)

Sensors will be assigned to some found defects minimizing the need of site inspections, especially when their behavior can affect the assessment condition index of the bridge.

Below, the descriptions of the technologies used in the bridge assessment condition are described, divided into 2 main categories: Mechanical and Chemical sensors.

The main advantage of the mentioned sensors is the continuous data collection without the need of physical inspections to measure the values for some important parameters. The values measured on site, will represent the evolution of the parameter in a specific time. Using sensors for data registry, will provide not only that date during sequential shorts periods of time, but also the historical information of that parameter. The connection between the sensors is achieved by using an interface at the MoEI.

1.2.1 Mechanical sensors

Some bridges have special mechanical conditions to be monitored. These conditions can appear because of the combination of the loads, materials properties, excess of stress or/and strain, or similar, *(figure 6).*

In some bridges of the network, there are some required mechanical aspects to be followed as described below.

- Crack monitoring in beams
- Bi-directional tilting in piers
- Stress and strain in beams and piers
- Temperature in the elements

The defects found in a bridge might disturb some of the mechanical responses of the structure. The measurement of the defect response will help not only to know the behavior of the element of the bridge where that defect is located, but as well, to understand why that happened, and to predict what will happen to similar elements under similar circumstances.

The monitored parameters can be measured not only individually during the analyzed period of time but as well, all can be co-related to find existing interconnections. The analysis of that behavior along the time can help as well to predict and perform some preventive actions and maintenance. [9]

Figure 6. Mechanical remote sensors for bridge data collection

2.2.2 Chemical sensors

In the particular case of the highways located in the northern emirates of UAE, the majority representing 97% of the bridges are made of concrete (as well pre-casted in situ or prestressed, or casted in situ), *(figure 7).*

Figure 7. Chemical remote sensors for bridge data collection

Some of those locations are adequate to develop corrosion (because of the presence of chlorides or carbonation), creating the worst scenario for the structure's durability. Affection can be accelerated by high temperatures and humidity, presence of salt in the soil in some locations and chlorides due to sea tides in others. [9], [10]

The main parameters reported by the sensors, installed within the concrete of elements of bridges in service are:

- pH evolution
- Temperature
- Humidity
- Chlorides content

The way to prevent and control this situation is to monitor the progress of the parameters creating and propagating corrosion and create the preventive measurements according to each bridge affected.

2.2.3 Traffic sensors

The third category for sensors installed in the network, are the Traffic Sensors, collection traffic data. These sensors are registering the number of vehicles, speed, type and some of them weight.

nother significant aspects are traffic characterization and users' driving behavior. As roads operator, knowing these aspects are crucial in order to help to prevent and attend accidents, moreover, try to predict them in the best possible way. This information also helps to understands the effect of traffic on bridges and pavements, thus do the proper design as new and rehabilitated assets. Moreover, these analysis helps other stakeholders in their fields such as Ministry of interior in procedures related to traffic and security, Ministry of Justice to improve or create laws

related to traffic and Ministry of Health to prevent the resources dedicated to traffic accidents.

The traffic sensors are divided in two types, the Radars, which are utilized to measure the following group of parameters per lane and per direction in each road (22 out of 27), *(figure 8)*:

- Number of vehicles
- Type of the vehicles based on the length
- Speed

The remaining five (radars combined with piezo electric) in addition to the above parameters do register, *(figure 9)*:

- Gross weight of the vehicle
- Number of axles
- Weight per axle

Creation of enquiries about the traffic database will happen in special dashboards, which will provide in fast time the possibility to combine the information of different lanes and directions in a determined period of time, [11]. The enquiries parameters that can be calculated are:

- Average daily traffic
- Accumulated traffic
- Speed
- Intensity
- Occupancy
- Peak times (morning, mid-day and evening, time)
- Classification by length
- Classification by number of axels (using Federal Highway Administration criteria) (include here reference)
- Distribution on weight per axle per type
- Real time traffic conditions

Figure 8. Electromagnetic loops for traffic data collection

Figure 9. Radar traffic data collection

1.3 Unmanned Aerial Vehicles (Drones) inspection

Within the Bridge Management System MoEI included the bridge inspection by using UAV(drones), *(figure 10)*.

The inspection helps to enhance the inspection time by:

- Inspection components which are difficult to reach by conventional resources
- Creation of 3D cloud of points
- Creation of 3D model

Drones to do the inspection are equipped by different devices such as camera, LiDAR and GPS.

Figure 10. Drone for LiDAR data collection

The inspection outcome is a report showing the pictures and defect detected. These reports include the location, evidence and the quantity of the damage registered. Once the defect is reported, it can be transferred to the BMS carrying along the possibility to modify the assessment condition index.

The data collected offer as well the possibility of creating a 3D model of the bridge using photogrammetry tools combined with the cloud of points.

1.4 Mobile application

One of the most important aspects in MoEI Roads Department is to keep active tasks related to the daily maintenance. The daily found incidents can't be predicted and need to be attended as fast as possible, therefore the MoEI has implemented a Performnace Based Maintenance Contract based on KPI, (basically related to time response and quality). *(figure 11)*.

Since this type of contracts are controlled by penalties applied to the main contractor if the deficiencies or incidents are not attended on time, it is necessary to improve the registration, control and monitoring of all the road elements. [12]

An inspectors' fleet checking continuously the roads, can register any defect allocated in the road through a mobile application, relating that report automatically to the location of the mobile device live.

Fig 11. Mobile application for incidents management

The report will be uploaded in the database of the Assets Management System. In this way, MoEI as well is aware of the events pending to be finished and the available time before penalizing them, at the same time, allowing the contractor to register the closure of the report.

After, the inspectors are able to check and verify if the event was effectively closed and the quality level of service is achieved.

The mobile application shows the information contained in each report created by the road inspectors. And assuming that the reports can't have an "open" status for a longer period of 30 consecutive days without closing it by applying the corresponding maintenance, the reports for the last 30 days can be viewed in a list and in a map.

This mobile application as well allows to do the inspection of any other inventoried element in the road, including the bridges. The inspections will determine the assessment condition index of the elements that are in the same spot the inspector is.

2 Interrelation of all these technologies applied and benefit for the asset management in the Roads Department

All the previous described technologies can seem interesting from a technical point of view, individually.

However, a very important aspect is, how these technologies are interconnected amongst them and what benefit provide to the asset management of MoEI and how this benefit is can be noticed.

These properties and capabilities which are the base for the interrelation between them and the assets management, constitute significant aspects that will feed the specialized fields in the assets management tasks.

2.1 LiDAR (inventory and 3D model)

The inventory with LiDAR will feed the database of the mobile application and the inventory database for the main system for the Roads Department. The Road elements will be reflected in both and all the information as well as the assessment condition index can be modified and corrected by the user.

Moreover, the 3D models created during the process can merge with those 3D representations created by the *drones.*

3D models open possibilities to do a better analysis for specific road elements. For instance, if a structural/durability issue needs to be studied in a bridge, it will be easy to define the grid of this bridge and its elements, isolating it from the general cloud of points and exporting it to an 3D structural analysis software, *(figure 12).*

Figure 12. Cloud of points for post use in other applications

The importation of the cloud of points as a mesh to a conceptual design software for roads, used in widening or modification projects can provide with an initial high accuracy database for that project, without the need to collect more information with other methodologies, *(fig 13).*

Fig 13. 3D model from LiDAR data. Creation of cross sections for post analysis in structural analysis

A very important use of this tool will be to define the contour conditions for an *Autonomous Driving Car* simulation (of different road parameters and their current condition to calibrate the possibility of autonomous vehicles to circulate within the network).

As well, this model will be very useful for the creation of High Definition Maps, which will be used by this type of technology which constitutes one of the main pillars on the development of the transportation sector in the coming 20 years in UAE, *(figure 14),* [13]

Figure 14. Autonomous vehicles simulation

2.2 Mechanical and chemical sensors

They provide a real valuable information related to problems (mechanical or chemical) which can influence the response of the bridge in different ways.

The inputs these sensors can have in order to modify the condition assessment index of the bridge are evident (is not the same case to have a "dead" shearing crack in a beam that notice that it is progressing, *(figure 15).*

Figure 15. Bridge sensor's platform (location of sensors)

However, monitoring the same crack, and correlating this information with the traffic passing over the element can show if there is any need to restrict the traffic or make any urgent amendments to the element before the limits are reached (vehicles are calculated by the technologies mentioned in this paper as well).

Furthermore, the proper correlation between the crack and the registered stresses and strains can give an idea of the materials condition and characteristics, *(figure 16).*

Figure 16. Correlation between parameters in remote bridge sensors

Chemical sensors can provide information about the presence of carbonation and therefore some corroded steel bars which are not well appeared in some of the inspections performed, *(figure 17).*

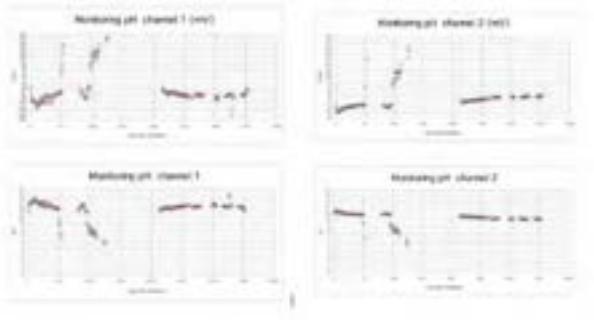

Figure 17. Chemical parameters correlated from bridge sensors

These actions will enhance the rehabilitation project and will make it to be adjusted to the real conditions that need to be corrected, *(figure 18)*

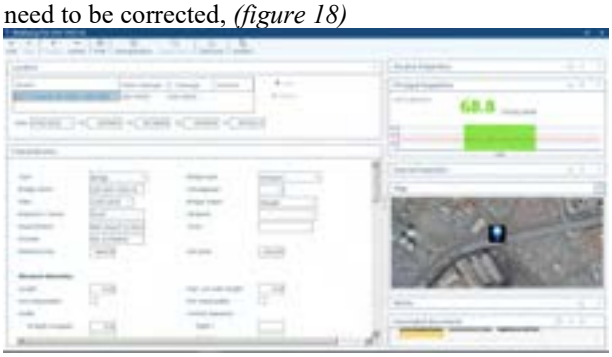

Figure 18. Modification of the Bridge Assessment Condition Index using the information from the remote sensors information

The proper rehabilitation project will be designed according with the traffic supported by the element and (as mentioned in this paper). The best solution will be the one therefore providing the best life cycle solution.

The possibility of having a 3D mesh from LiDAR representing the bridge and the possibility of overlapping pictures with the defects and parameters determining their behavior, allow to model and predict different scenarios as well as create maintenance programs for clusters of similar bridges.

The strategic knowledge of live traffic behavior makes possible to analyze some parameters as the growth factor, which will influence directly, not only the geometry of the roads and the elements within them to be built and maintain, but as well the development of urban or industrial areas, *(figure 19).*

Figure 19. Road live traffic conditions map

Instant conditions of the traffic are basic to operate the traffic management procedures in the correct way for the road user's safety, using those parameters as well as information of any anomaly in the road that can be attended by the maintenance contractor (accelerating the response time in those events, which can be register in the mobile application), *(figure 20)*.

Figure 20. Traffic incidents detection from traffic live monitoring

Knowing the traffic flow and conditions can help to apply restrictions and ban times for some vehicles in a more precise way, *(figure 21)*.

Figure 21. Traffic data integration. Parameters analysis

Integration of the traffic database allow to check the efficiency of some operational aspects, as better level of service usually implies a better the operation of the highway.

A good and accurate traffic data will provide better models (in 3D integrating the models created by LiDAR) to predict and model the traffic according to the corresponding economic, social and environmental conditions (see point 2.4).

2.3 Unmanned Aerial Vehicles (Drones) inspection

The inspections performed with drones will help to the creation of 3D models that can be merged into the cloud of points obtained by LiDAR along with photogrammetry technologies with inputs from the images taken during the inspection, (*figure 22)*.

Figure 22. Defects detection from Drone bridge inspection

Damages acquisition by drone can be as well overlapped on the 3D mesh of the bridge and analyze their influence into the context of the element or the bridge.

Information obtained in this inspection can be used as well in traffic modeling programs for example in the case of intersections and junctions. In some of our highways these points constitute "hot spots" and need to be simulated under special conditions. Counting with a 3D model of the bridge will make the microsimulation easier and more realistic, *(figure 23)*.

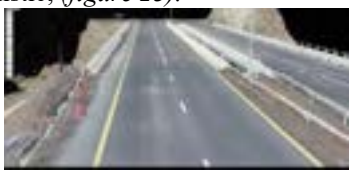

Figure 23. 3D model for traffic simulation implementation

2.4 Mobile application

The mobile application as smart tool allows to manage information of assets in the spot, live, *(figure 24)*.

This is an important aspect, considering the synchronization performed between both data bases which representing the reality of the road elements.

Figure 24. Mobile application for road maintenance incidences

Any new incidence registered by the mobile application will be automatically synchronized with the general database, which allows to manage the assets condition and the traffic management and maintenance actions.

If any incident is urgent an alarm is launched then immediate actions and monitoring with the traffic devices can be performed, *(figure 25)*.

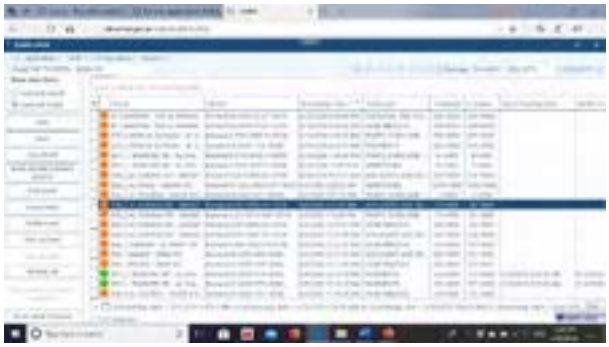

Figure 25. Data base synchronized with the mobile application

Then the MoEI is able to predict the consequences on traffic and road safety meanwhile having any repair or rehabilitation. Discussion with the corresponding police department can be started and all the possibilities to implement the best road safety action according with the urgency of the incidence and the traffic conditions can be done.

A fast update of this inventory data base using the mobile application, will allow as well, to do faster calculations involved in the asset management, maintenance plan and valuation of the assets.

3 Conclusions

The intense work at MoEI during the past 8 years, arose in the creation of a Roads Assets Management that has been continuously developing and improving.

Nowadays, the integration of the tools the MoEI already implemented to do a proper roads management leads to the implementation and integration of the following recent technologies:

- Data collected with LiDAR to create 3d models and cloud of points during the inventory of the road elements
- Remote sensors in bridges to monitor their mechanical and chemical conditions
- Traffic data collection with remote sensors to calculate the traffic parameters
- Drones to perform LiDAR and inspection in bridges to enhance the inspection result in less time and create 3D models for the bridge
- Mobile application to report and register the incidences in the roads live

Continuous feedback of the received information to different specialists in the Ministry allow to increase the service level to the road users and reduce the time response in different situations. All the technologies as mentioned before are interrelated and the outcome can benefit different aspects of the road management.

Abstract –

The growth in the size and the level of complexity of construction equipment imposes tremendous hazards in construction sites. Any breakdown or failure of such systems may not only cause the delay in construction but also lead to the loss of life and properties. To address these issues, this paper proposes an intelligent monitoring system based on multi-sensor technology, which consists of multiple sensor clusters, signal transmission and data acquisition systems, condition evaluation, identification and alerting systems, assisted by Wifi or Zigbee wireless transmission technology to obtain the real-time state data from various parts of construction equipment. The center computer can manage and analyze the relevant parameters to reveal the safety reserve of the tower crane, scaffolds, self-climbing platform and other construction equipment in a visual image. In addition, the alerting alerts can be sent directly to security officers and operators to respond to and avoid accidents. Lastly, the intelligent multi-sensor monitoring system is simulated tested in 6013 flat crane, which is shown the workflow of whole technology and demonstrates this technology is fast, accurate and valid for the safety management of construction.

Keywords –

Construction equipment; High-rise buildings; Intelligent safety monitoring system; Multi-sensor technology.

1 Introduction

Because of the high casualty rate, site safety is one of the most concerned issues in the construction industry. Statistics data from Ministry of Construction suggests that, in china, there have been 637 safety accidents and 736 deaths in the first ten months of 2018, with 6.52% and 4.69% increased, respectively, compared to 2017.

Although the construction technology is constantly updated and upgraded, the management of construction site safety still primarily relies on the manual approaches, such as the daily patrol and regular inspections by the safety officers. With the gradual introduction of Industry 4.0 technology[1] into the construction industry, some construction robots and large-scale integrated construction platforms have emerged[2], which enhance the size and the level of complexity of construction equipment. Traditional safety monitoring methods may not be applicable to such complex construction environments and many unexpected causes of risks may render faults or failure, even with the tight security control measures[3]. For instance, the long-term environmental exposition, the inappropriate use and maintenance, the installation tolerances and their growth may all give rise to the unpredictable risks, which may eventually cause the bucking or collapse of scaffolds and the toppling of the tower cranes.

This safety matter is especially challenging in the construction industry and requires intelligent methods to monitor the stiffness, strength and stability of these complex construction equipment and temporary structures, such as scaffolds, in order to eliminate potential hazards. Literature review suggests that a wide range of studies have looked at the intelligent monitoring system or technology used for construction sites. Moon[4] studied an automated data acquisition system and appliance based on the Ubiquitous Sensor Network (USN) technology to collect structural responses. Zhu and Roh[5-6] introduced a method based on multi-sensors, visualization technology and computer vision technology for updating 3D equipment movements in order to prevent the collision between equipment, workers and other objects on the construction site. Son[7] proposes an efficient, automated 3D structural component recognition and modeling method that employs color and 3D data acquired from a stereo vision system for use in

construction progress monitoring.

To address these issues, this paper proposes an intelligent monitoring system based on multi-sensor technology, consisting of multiple sensor clusters, signal transmission and data management systems, condition evaluation, identification and alerting systems. Assisted by Wifi or Zigbee wireless transmission technology[8], the structural parameters of key parts of construction equipment are received by the central server, which are used to monitor the working status of equipment structure in the real time. For instance, taking the data from the wind speed meter to measure wind velocity, inclination and displacement sensors to monitor deformation and movements, strain sensors to capture the stress/strain conditions and accelerometers to understand the dynamic properties, the data processing center can collect and analyze the relevant parameters to reveal the safety reserve of the tower crane, scaffolds, self-climbing platform and other construction equipment.

Safety monitoring of construction equipment technology is an intelligent and automated technology that the original data collected by multiple sensor clusters are automatically processed and converted to structural parameters in accordance with a predetermined programme and the damage degree of the equipment is shown by visualization. This paper mainly introduces the working principle and integration mechanism of systems, with the key focus on how to integrate, transmit and process data in each system.

2 Safety monitoring system

The intelligent monitoring system can automatically transform the original data collected by multiple sensors and feed to the evaluation modules[9] revealing and monitoring the structural health state of construction equipment in real time seen in Figure 1. The process entails the following steps: 1) data collection and acquisition by utilizing different types of sensors or multiple sensor clusters; 2) data analysis and modelling; 3) damage identification and health evaluation. The final step can be revealed by visual representation together with some alerting systems[10].

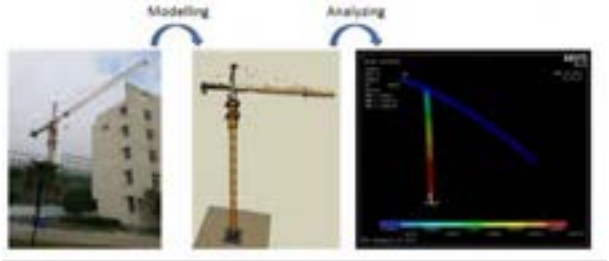

Figure 1. Data-driven modelling of tower cranes

The above process can be presented in the workflow as shown in Figure 2, which can be generally divided into four subsystems, namely multiple sensor clusters, signal transmission and data management subsystems, condition evaluation and identification an alerting subsystem. The data from various sensors, often in differing formats and output signals, are integrated so that the data, resources and process states can be shared across the system. Pre-alerting of impeding faults or failure of those construction equipment structures can be alerted. The key of this type of system is the stability and timeliness of wireless transmission[11] and the optimization of data processing[12]. The massive data will be accumulated in the data center and the big data analysis technology can be employed so that the minimal size of them should be stored and feed into the structural modelling.

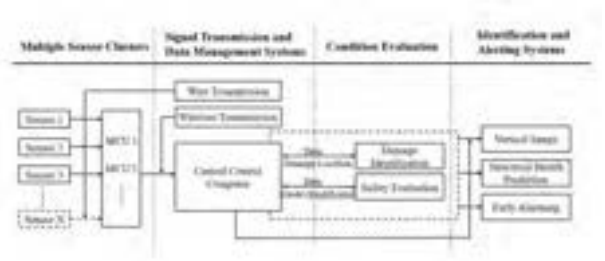

Figure 2. Workflow of safety monitoring system

2.1 Multiple sensor clusters

Multiple sensor clusters are the first tier in the intelligent monitoring system[13]. The common sensors used include the wind speed sensor to measure wind velocity, inclination and displacement sensor to record the movements, strain sensor to acquire the strain condition and accelerators to capture the dynamic properties. The locations of sensors are properly designed and selected, so are the acquisition frequencies.

In order to reduce the amount of data for transmission and storage, the initial processing of the original data is required so that the unimportant or redundant data are filtered out in the first instance. Kalman filter is usually used to preprocess the original data, which is an algorithm to extract the real value of the dynamic system in a series of measure data with noise. And then, feature selection of the initial preprocessed array is carried out to manifest the principal and precise characteristics in one set period. Common feature extraction methods are principal component analysis (PCA), linear singular analysis (LDA)[14], independent component analysis (ICA)[15], neural network, etc. The method of feature selection is properly selected on the basis of structural characteristics and monitoring requirements. In general, the application of feature selection is beneficial to reduce the amount of calculation and improve the accuracy of

structural analysis in the process of condition evaluation.

In the collection process, it is assumed that cycle of the sensor data collection is 2s and the cycle of central computer operation is 30s. So, within 30 seconds, the sensor-1 will gain 15 pieces of data: $[X]_1 = [X_1, X_2, X_3, \dots, X_{15}]$. Before feature selection, simple preprocessing should be carried out on the original data to delete the data with large errors. In the end, the eigenvalue X_1 will be calculated by single-chip microcomputer (MCU) and transmitted to the central control computer.

2.2 Signal transmission and data management systems

Signal and data transmission can be regarded as the logistics support for the whole system[16]. Only with stable transmission technology can the whole system be sampled synchronously and the structural data of each part at the same time point can be obtained. Otherwise, if data in different cycles arrive at the central computer and be processed simultaneously, it will yield data chaos[17].

In this present system, there are two transmission modes, wired transmission and wireless transmission. Wired transmission is used to transmit data from sensors to microcomputers, which is the front-end data transmission of the whole system. Due to the space limitation of wired transmission, the locations of both sensors and microcomputers need to be considered and a single-chip microcomputer (MCU) can process data up to 8 sensors at the same time. Wireless transmission, such as Wifi or Zigbee wireless transmission technology, transfers the data preprocessed from MCU to the central computer for the further data analysis. In the construction environment, due to the signal reception blocking of the concrete or metal, the wireless transmission signal is usually weak. In order to establish a wireless network for real-time data acquisition, the system uses ZigBee technology to receive data by using radio frequency (RF) signal transmission, which can connect up to 65,000 sensor nodes and transmit data at 250 kbps[18].

Data collection from multiple sensors is usually synchronized. In the real applications, such synchronization can be compromised due the delay in the data transmission (see Figure 3). To address this problem, step by step filtering (SSF) fusion algorithm is adopted. Compared with centralized fusion algorithm (CFA), SSF (see Figure 4) has fewer requirements for calculation efforts and the number of central processors and network bandwidth, but stronger system survivability[19-20].

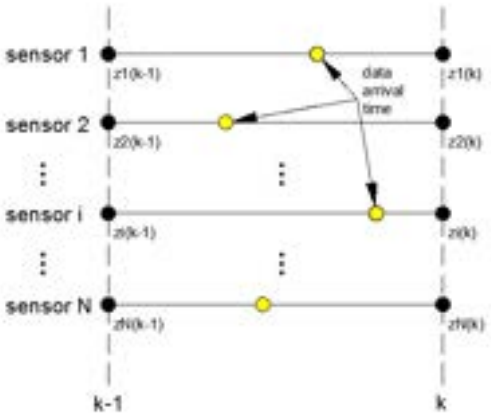

Figure 3. Simultaneous sampling with transmission delay[17]

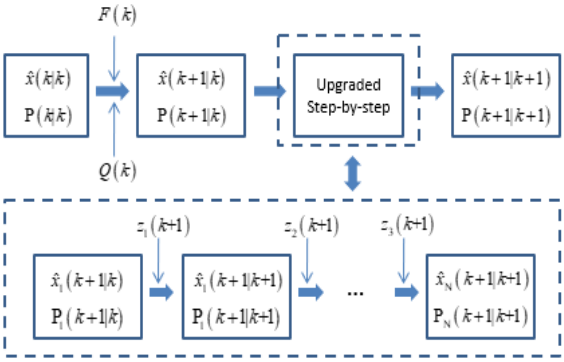

Figure 4. SSF Fusion Algorithms[20]

Table 1. Definition of mathematical expression

No.	Mathematical Expressions	Definition
1	k	A certain moment
2	$k+1$	The moment of one cycle after k moment
3	$x(k)$	State function
4	$x(k+1)$	State function in k+1 moment. $x(k+1) = F(x)x(k) + v(k)$
5	$\hat{x}(k\|k)$	The global estimated value
6	$\hat{x}(k+1\|k+1)$	The global information-based estimated value
7	$P(k\|k)$	The corresponding estimated error covariance
8	$P(k+1\|k+1)$	The corresponding error covariance
9	$z_1^k(i)$	The set of measurement sequences of the i-th (i =1,2, ⋯ ,N) sensor at

		1,2, ⋯ ,k moments. $Z_1^k(i) = [z_i(1)^T, z_i(1)^T, \dots, z_i(k)^T]$
10	Z_1^k	The set of measurement sequences of all N sensor at time 1,2,⋯,k moments.$Z_1^k = [Z_1^k(1), Z_2^k(2), \dots, Z_2^k(k)\ ]$
11	$F(k)$	Distribution function of X,X is random variable and k is any real. $F(k) = P\ (x < k)$
12	$Q(k)$	Covariance function. $Q(k) = E[v(k)v(k)^T]$
13	$v(k)$	White noise sequence of zero mean gauss process

In the actual monitoring process, due to the instability of data transmission, it is difficult to ensure that all sensor data can reach the computing platform synchronously. To solve this problem, the database store method is adopted. If a value X_n fails to reach the computing platform synchronously, the X_{n-1} of the previous array is retrieved. And if the value fails to reach the computing platform for three processing cycles, the warning system would started to report the error.

The subsystem involves both hardware and software. The hardware includes transmission cables, optical cables, RF transmitters, RF receivers, digital-to-analog conversion cards (A/D), etc. The software is used to store and manage the digital signals, using a common software platform such as C++.

In a real-time monitoring system, even in the case of data pre-processing, there are thousands of data collected every day, which requires a robust data management system and program. The data management system is not only responsible for managing the preprocessed data, but also managing all information in each subsystem, including materials, geometric information, and structural analysis results of devices. Should any accident strike, this type of data can be traced for the forensic analysis purpose.

2.3 Condition Evaluation

In this subsystem, the structural software is used to model the system based on the collected real-time data so that the health condition of the equipment can be assessed.

To this end, the first step is to transform the preprocessed data from multi-sensors clusters into physical data [Vm], such as strain or movements, and then check with the specified threshold value [Vd] to identify the any damages. If there's a big difference between the value [Vm] and value [Vd], the structure must be secure and there is no point to expand extra unnecessary computations. Once any damage is identified, a reliability analysis can be conducted to evaluate the severity of damage, based on which due alerting is released for the management purpose.

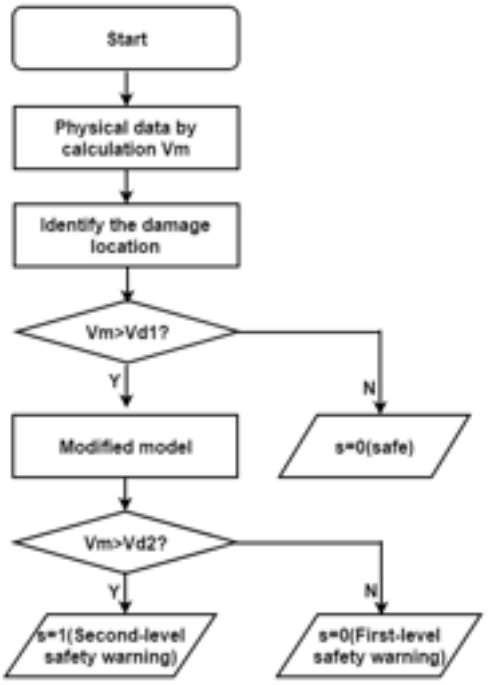

Figure 5. Workflow of condition evaluation

1. Safety assessment

Safety assessment consists of serviceability limit state assessment and ultimate limit states assessment. The evaluation indicators of serviceability limit state are the deformation of structure, cracking growth acceleration, etc. And the ultimate limit states can be assessed by structural analysis software. The simplest method of evaluation is to analyze the development trends shown by the measured stress, deflection, acceleration and other indicators.

2. Damage identification

At present, an increasing number of damage identification methods have been applied in engineering projects, such as structural modal parameter identification based on wavelet transform[21], damage sensitivity analysis based on structural modal parameters[22], structural damage detection based on neural network, structural damage detection based on improved genetic algorithm[23], etc. These methods mainly perform modal analysis of structural dynamic response, and then calculate the damage indicators with different damage identification methods.

2.4 Identification and alerting systems

Through data processing and mining, the system will eventually be able to obtain real-time visualized structural health monitoring images, structural health predictions and early warnings.

1. Visual monitoring image

The final structural health state can be showed by a visual image. Construction workers and manager can quickly and accurately monitor the structural health status of the equipment remotely, and then find problems in time and take measures.

2. Structural health predictions

Through sufficient data mining, state estimation and prediction of the structural state of the construction equipment can be performed. A large amount of data collected and the simulated force model can be used to detect the weak places of the equipment structure for focal monitoring. the weak points can be predicted by well-rounded algorithm, including linear regression method, nonlinear model method, unsupervised supervised learning method and other methods, so as to prevent risks in advance.

3. Early warming

The identified damages with its location and size are systemized for formulating the alerting information, which can be circulated via mobile electronically devices or other type overall alerting system. Due measures can be taken to respond to such alerting information.

3 Case Study

The intelligent monitoring system is employed for the real-time supervision of the construction equipment and temporary structures used in the construction site. Four subsystems are instrumented to collect, transmit and process the data. A visualization program is to reveal the data and work status of the monitored systems.

The system is mounted into a tower crane, which is presented below to show the entire process of coordinated work and data processing of each subsystem. In the simulated test, 6013-flat-head tower crane is selected as the experimental tower crane with 800KN*m load moment, 46 meters maximum free height, 60 meters maximum radius of revolution and lifting 6 tons materials at most

According to the specifications for tower crane design, there are five key performance indicators for the overall structure safety operation, namely, temperature $[T]$, the bending strength $[\sigma_1]$ and deflection $[v_1]$ of crane jib, the vibrational frequency $[f]$,the deformation of crane column$[v_2]$. For each indicator, one or more sensors are placed to obtain the corresponding structural parameters directly or indirectly. By data fusion, calculation and estimation, the large amount of original data are processed to the structural parameters to realize the visual monitoring of the loading state of the tower crane.

It is worth noting that the working stress of crane tower is constantly changing due to the moving load during the lifting operation. Under different loading scenarios, the maximum stress points change, and, therefore, the sensors need to be placed in some crucial places. According to the "Tower crane design specification (GBT 13752-2017)", the layout of the sensors should follow the following principles:

a) The places with significant stress changes or large stress, which can be calculated by the finite element analysis;

b) Important component of the structure, such as structural cross-middle rod parts and suspension rod parts, etc;

c) Representative and regular places, such as fatigue-prone and corrosion-prone positions, etc.

3.1 Multiple sensor clusters

In this simulated case, five types of sensors are mounted in selected locations, i.e. temperature sensors, wind speed sensors, accelerometers, displacement and strain sensors. Ten sensors were placed in the simulated experiment (shown in Figure 6)and the original data obtained were named as $[A_1]$, $[A_2]$, $[B]$, $[C]$, $[D_1]$, $[D_2]$, $[D_3]$, $[E_1]$, $[E_2]$, $[E_3]$, $[F_1]$, $[F_2]$, $[F_3]$, $[F_4]$, as shown in Table. Among them, the displacement sensor consists of a transmitter and a receiver. It can simultaneously collect the displacement in X, Y, Z directions, and the data are all collected by the receiver.

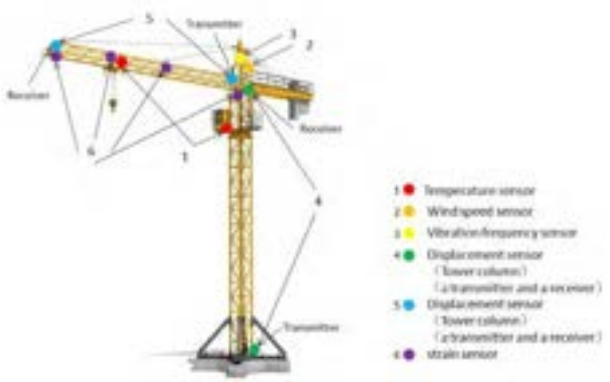

Figure 6. Diagram of the location of multiple sensor clusters

Table 2. Types of sensors and corresponding dataset

No	Sensors	Data Set	Note
1	Temperature sensor	$[A_1]$, $[A_2]$	Environment temperature $[A_1]$ and engine

			temperatur e $[A_2]$
2	Wind speed sensor	$[B]$	Wind velocity
3	Accelerom eters	$[C]$	
4	Displacem ent sensor （Tower column）	$[D_1]$-X Direction $[D_2]$-Y Direction $[D_3]$-Z Direction	A transmitter and a receiver
5	Displacem ent sensor （Tower jib）	$[E_1]$-X Direction $[E_2]$-Y Direction $[E_3]$-Z Direction	A transmitter and a receiver
6	Strain sensor	$[F_1], [F_2], [F_3], [F_4]$	Key position

3.2 Signal transmission and data management systems

Through wired transmission, the original data will be transmitted to MCU for initial processing, and then the mathematical sets$[A_1]$, $[A_2]$, $[B]$, ⋯, $[F_4]$ acquired by multiple sensor clusters will gain the corresponding values A_{1i}, A_{2i} , B_i ⋯, F_{4i}.Since the wired transmission is limited by space, an MCU connected up to 8 sensors is to process data at the same time. In installing MCU, the quantity and locations of MCU shall be determined by the relationship between the sensor clusters and MCU.

In this case, three single-chip microcomputers are placed in the tower crane (Figure 7). The first one is on the top of tower column, which is used to collect the engine temperature $[A_2]$, the displacement of tower column $[D_1]$, $[D_2]$, $[D_3]$, the stain of tower column $[F_1]$; the second one is at the junction of tower column and jib, which is used to collect wind velocity $[B]$, vibration frequency $[C]$ and stain of tower jib $[F_2]$; the third one is at the end of tower jib, which is used to collect the environment temperature $[A_2]$, the displacement $[E_1]$, $[E_2]$, $[E_3]$ and the stain of tower jib $[F_3]$, $[F_4]$.

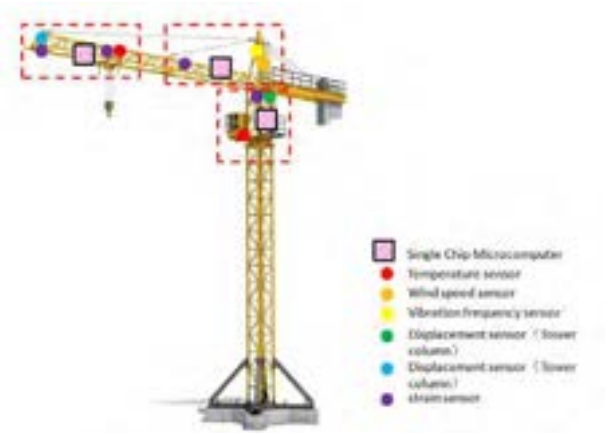

Figure 7. Diagram of the location of MCU

The preprocessed data (A_{1i}, A_{2i} , B_i ⋯, F_{4i}.) are transmitted wirelessly to the central control computer, using the robust and fast wireless transmission technology, Zigbee. The central control computers not only are responsible for data processing, but also for date management and storage. Date management subsystem is responsible for storing the pre-processed data, the modelled structural parameters, and the structural images at certain intervals, which is used for continuous system inspection and identification and analyzing the cause of failure if the tower crane collapses.

3.3 Risk assessment

The obtained values are analyzed by using MATLAB software to determine the presence, the location and size estimation of damages. Furthermore, the safety evaluation can be conducted and reported.

3.4 Identification and alerting systems

ANSYS software is used to simulate the component response of tower crane based on the collected data. The displacement of x-component, y-component and z-component, the rotation of x-component, y-component and z-component, elastic strain and plastic strain can be calculated for the entire structure (Fig. 8).

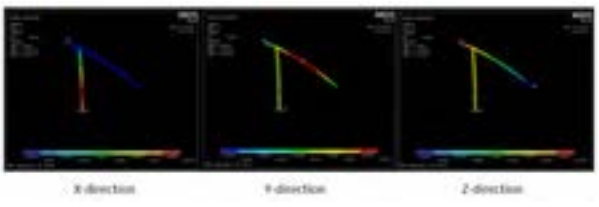

Figure 8. Diagram of modelled deformation

4 Conclusion

The safety monitoring system can intelligently monitor the working status of construction equipment in real time, establish visual model for the strength and deflection of the entire structure, and inform the safety state of construction site in the visualized way. By means of data collection of sensors and step-by-step processing of computers, security officers can obtain real-time structural state of construction equipment or temporary structures to avoid accidents, especially in severe environment. Such system possesses the following features:

1. **Fully automation.** Except installation and regular system inspections, the system can archive data collection, multi-software interactive data processing, and identification of the location and size of damage, visual representation and producing alerting messages to the related personnel.
2. **High timeliness**. The sensor collects data in the real time, and the data is processed by program in automatic way, so the final structural state can be obtained in a nearly synchronized manner.
3. **Visualization.** The displacement and stress of the structure can be visualized.
4. **Other applications**. A large number of environmental and structural parameters collected in the data management subsystem can provide detailed experimental data for equipment structural design, from which the correlation relationship between the environmental action and vibration frequency can be established.

The safety monitor system can replace the traditional methods of maintaining construction equipment, such as tower crane, which provides improved accuracy and enhanced safety level.

Abstract –

In this study, we propose autonomous UAV flight using the total station to estimate self-localization at a dam in a non-global navigation satellite system (GNSS) environment and suggest a flight path planning method for the UAV's flight position. As a result of the UAV's stable autonomous flight, a certain distance from the dam body's surface can be maintained by flying accurately along the planned path, allowing for uniform quality and high-resolution images to be captured. Moreover, geotags can be added to the image by measuring the flight position of the captured images; this is achieved via the total station, which can track the UAV even in a non-GNSS environment. Resultantly, the accuracy of the three-dimensional reconstruction model using photogrammetry technology can be improved.

We further implement a field study to demonstrate the utility of the proposed approach. Moreover, we propose aging detection using AI analysis.

Autonomous UAV flight; Non-GNSS; Total station navigation system; Flight path planning; Dam

1 Introduction

An unmanned aerial vehicle (UAV) can fly autonomously via self-localization and flight attitude stabilization technologies, including global navigation satellite systems (GNSSs) and various sensors; e.g., gyroscopes, an accelerometer, a barometric sensor, and inertial measurement unit (IMU). Therefore, UAVs have recently seen increasing use in various inspections [1,2,3,4] owing to their high functionality and practicality. Conversely, autonomous UAV flight in outdoor environments, where GNSSs are unavailable, is a challenge.

In Japan, many social infrastructures are aging and inspections are necessary for maintenance. As shown in Figure 1, it is necessary to efficiently capture the dam body's surface image for an inspection or survey, via a digital camera mounted on the UAV. However, GNSSs cannot normally be used because the radio waves from global positioning system (GPS) satellites do not reach mountainous areas; i.e., a dam's location cannot be determined, or a multipath caused by interference and phase shift of the radio waves occurs around a dam body.

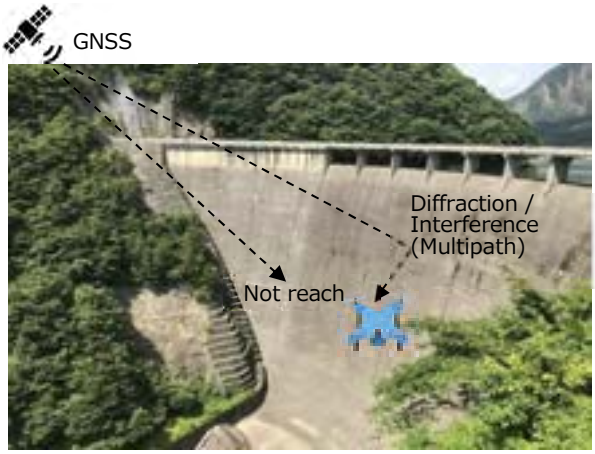

Figure 1. Depiction of the GNSS environment at the dam. The GNSS is likely to be unavailable or unreliable due to sky occlusion in mountainous areas and multipath around the large structures.

Therefore, the UAV needs to be manually controlled by a pilot, which increases the UAV operator workload and makes it difficult to: 1) Obtain high-resolution images with uniform quality for inspection and management, or 2) prevent human errors, such as lapses in capturing the image. Hence, the realization of autonomous UAV flight in a non-GNSS environment is required.

The remainder of this paper is organized as follows. Section 2 introduces the related works. Section 3 presents the proposed system applied to autonomous UAV flight at the dam in a non-GNSS environment. Section 4

validates the proposed system in a field study. Section 5 proposes the flight opportunity. Finally, the conclusions and future work are discussed in Section 6.

2 Related Works

There are three important technologies for obtaining clear and high-resolution images of uniform quality to inspect and manage the dam's body via a digital camera mounted on a UAV: the flight path planning method, self-localization for autonomous UAV navigation, and photogrammetry technology. An overview of each method is presented below, with an application of this research.

2.1 Flight Path Planning Method

A flight path is planned by successively creating way points (WPs) and arranging and connecting them continuously. The WPs contain the latitude, longitude, and altitude of the UAV and action information, such as the change in nose and flight speed direction at that time. There are three approaches for setting WPs: manual creation, simulation-based, and pilot flight trajectory.

2.1.1 Manual Creation Method

This method requires the pilots to manually and sequentially set all the WPs using the general autopilot software function.

However, it is difficult to accurately set the WPs near the reservoir on the upstream side of the dam body or in the complicated shape of the dam body and its surroundings as the terrain information available to pilots and software is only approximate.

2.1.2 Simulation-Based Method

If there is a three-dimensional point cloud data of the dam, it is possible and useful to accurately set the WPs to maintain a certain distance from the dam body surface via coordinate calculation.

However, many dams do not have three-dimensional point cloud data as they are time-consuming and costly. Therefore, an inexpensive, highly accurate flight path planning method for dams that do not have three-dimensional point cloud data is required.

2.1.3 Using Pilot Flight Trajectory Method

Some commercial autopilot software attached to general consumer UAVs, such as DJI, possess a function for recording the flight trajectory of the pilot [5], allowing for flight path planning. In addition, there is a method that collects and analyzes many pilot's flight paths and analytically plans a path from them [6].

There are many artificial errors in the flight trajectory via manual UAV operation as the position of the UAV does not work in a non-GNSS environment. In addition, the GNSS flight trajectory coordinate is noisy and inaccurate. Therefore, this low-precision GNSS flight trajectory coordinate is not suitable for inspecting flight paths. However, it is a useful method if the flight trajectory can be accurately measured, even in a non-GNSS environment.

2.2 Self-localization Technology for UAV Autonomous Navigation

For the UAV to automatically navigate along the flight path, it needs to estimate its flight position. The general basic structure of the UAV is shown in Figure 2. The autonomous navigation of a UAV can be classified according to the difference in the self-localization estimation method shown in Figure 2. An overview of each method is presented below.

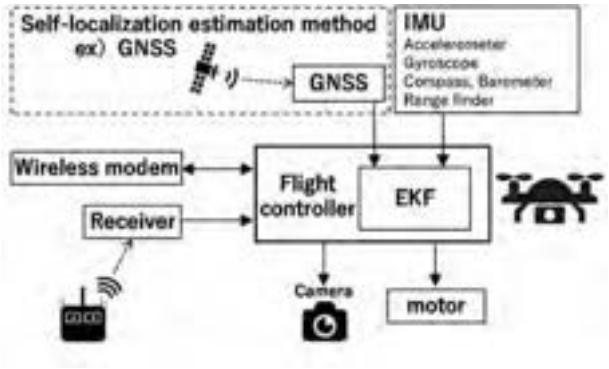

Figure 2. The general basic UAV structure

2.2.1 GNSS Navigation

GNSS positioning information is used as a self-localization estimation method and can be received by a small and inexpensive sensor mounted on the UAV. Therefore, this is the most popular method of autonomous UAV navigation using widespread communication technology.

However, as GNSSs cannot normally be received at a dam, this navigation system cannot be adopted. Even if GNSSs can be received normally, the positioning error is in the order of several meters or more, which is not suitable for inspection flights that require high accuracy.

2.2.2 SLAM Navigation

Simultaneous localization and mapping (SLAM) technology consists of front-end processing that focuses on sensor signal processing and back-end processing that focuses on optimizing the pose graph and performs simultaneous self-localization estimation of a moving body and constructs a three-dimensional spatial map. In addition, SLAM is approximately classified into visual SLAM and light detection and ranging (LiDAR) SLAM,

according to the front-end processing. As feature points, visual SLAM uses the color and light/dark information of each pixel of the camera or image sensor image, and LiDAR SLAM uses the point cloud coordinates measured by the laser sensor (distance sensor). In both SLAMs, the three-dimensional spatial map is recognized by matching the feature points, the movement is estimated sequentially, and the self-localization is estimated via accumulation.

Although this is a self-localization technique that does not depend on GNSS, some problems do exist:

- The position estimation errors accumulate and are not cleared; hence, the estimated position does not return to a true value.
- The self-position is lost if the feature point extraction fails.
- A high calculation cost for processing and optimization is required.
- The flight safety and image efficiency are reduced because the UAV flies close to the target object so as not to lose the feature points.

2.2.3 Total Station Navigation (TS Navigation)

The total station is a surveying instrument comprising a light wave rangefinder, which measures distance, and a theodolite, which measures angles. In this method, a prism is attached to the UAV; the prism's position is measured as the flight location via the total station. The UAV recognizes the self-location by feeding back the measurement result to the UAV. Originally, as a method of enabling autonomous flight even in a non-GNSS environment, this technology was predominantly developed for indoor flight using a consumer UAV [7].

We also attempted to apply it to autonomous UAV flight for dam body surface inspection. However, the flight control of the consumer UAV is a black box, and the fail-safe function cannot be completely canceled. Thus, the UAV did not fly autonomously owing to limited flight control and altitude.

It is a useful technique if flight control is possible as the position information accuracy is higher than that of other methods.

2.2.4 Cooperative Navigation

Two UAVs fly at the same time and communicate with each other. The first UAV flies where GNSS can be received normally, and the second UAV flies in a non-GNSS environment. The second UAV receives the position information estimated via the first UAV's optical tracking in real-time and can recognize the self-location by processing this information with low latency [8,9].

Advanced and complicated control technology for two UAVs is also required. Moreover, large-scale structures, such as dams, cannot be shot over the course of one flight as the flight time is limited by the battery. Thus, it is very difficult to maintain two UAVs simultaneously, and several operational issues exist.

2.2.5 Marker Recognition Navigation

The AR markers, or QR codes, placed on the flight route are successively read via the camera mounted on the UAV, and flight control can be enabled via recognition of the respective information on the marker; e.g., flight position, flight direction, travel, and distance.

Thus, this method enables autonomous flight, even in a non-GNSS environment; it is easy to prepare for indoor use, by placing a paper with a marker printed on the wall, but is difficult to install, manage, and maintain for outdoor use in large-scale infrastructure, such as a dam.

2.3 Photogrammetry technology

In recent years, the development of a scale-invariant feature transformation (SIFT) algorithm has automated the extraction and matching of image feature points and camera lens calibration. Therefore, it has become possible to easily reconstruct the three-dimensional model via SfM (structure from motion) and MVS (multi-view stereo).

As GNSSs cannot normally be received at the dam, it is not possible to add geotags to images captured using the digital camera mounted on the UAV. Therefore, three-dimensional reconstruction relies only on the feature points of the image. However, a problem is presented as the shape of the dam is distorted and approximate, even if the three-dimensional reconstruction model is corrected via GCPs (ground control points), as GCPs exist only in a limited flat space, such as the dam's top.

3 Proposed System Overview

This paper proposes a self-localization technique by using the total station applied to an autonomous UAV flight at a dam in a non-GNSS environment. In addition, UAV tracking by the total station is enabled to plan a highly accurate flight path for inspection and to add geotags to images. Therefore, it is possible to properly inspect and manage the entire dam body by analyzing the clear high-resolution images of uniform quality captured using a digital camera mounted on a UAV.

3.1 TS Navigation System Configuration

Figure 3 shows the proposed UAV autonomous navigation system at the dam using the total station. First, the coordinates of the installation position, the direction of the lens, and the vertical angle are set to the total station. Next, a prism is attached to the UAV, allowing flight position measurement by automatically tracking

the total station; the measurement result is sent to the UAV. Finally, the flight position is automatically adjusted while the error between the estimated position and the WPs is checked.

The equipment used in this system is shown in Table 1. The image of the prism attached to the UAV is shown in Figure 4.

Figure 3. Image of the proposed UAV navigation system using the total station.

Table 1. System specification

UAV	
Product name	QC730 produced by ENROUTE
Size [mm]	D1100×W1100×H310
Flight controller	Pix hawk
Sensor	Accelerometer (3 axes), Gyroscope (3 axes), Compass, Barometer, Light ware LW20

3.2 Flight Path Planning with Pilot Flight Trajectory

It is necessary to plan the flight path to confirm the resolution required by the AI analysis and to accurately set the WPs that are a certain distance away from the dam body surface, considering the performance of the digital camera.

In this study, if three-dimensional point cloud data of the dam exist, the flight path for inspection, which maintains a certain distance from the surface of the dam body, is planned by coordinate calculation. Conversely, if there is no three-dimensional point cloud data of the dam, the flight trajectory of the pilot's manual operation is used to plan an inexpensive, efficient, and highly accurate flight path. The UAV tracked at the total station uses the position information to control its attitude, even by manual operation in a non-GNSS environment, resulting in a stable flight path. This stable flight enables accurate flight path planning by using the self-position estimated by the UAV as the WPs while measuring the distance to the dam body surface with the range finder sensor mounted on the UAV.

3.3 Improved Accuracy of Photogrammetry Technology

In this study, geotags can be added to the image by measuring the flight position at which the image is taken and using the total station, which even tracks the UAV in a non-GNSS environment. Therefore, it is possible to accurately reconstruct a three-dimensional model using the captured image's geotags, as shown in Figure 5.

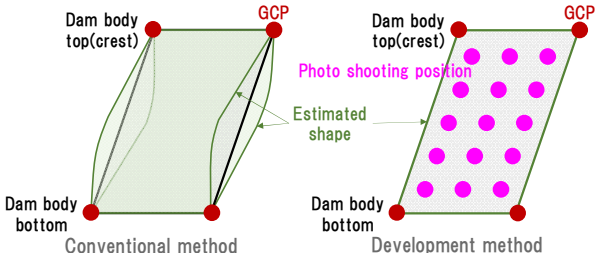

Figure 5. Improving the accuracy of the three-dimensional modeling

4 Field Study

In this paper, we implement a field study to demonstrate the utility of this proposed system for two types of concrete dams in Japan, as shown in Table 2. In a field study, uniform quality and high-resolution images of 2.0 mm/pixel are required for the dam body's inspection by AI analysis.

Table 2. Dam structure specifications

Classification ID	Dam-1	Dam-2
Dam type	Gravity	Arch
Dam height[m]	156.0	94.5
Dam top length[m]	375.0	215.0
Three-dimensional point cloud data	No-exist	Exist

4.1 Flight Path Planning

The flight path has to be planned approximately 18.0 m from the dam body's surface as per the AI analysis request. Since the horizontal flight exerts a lower battery load and involves more flight time than those of vertical flight, the flight path has to be essentially horizontal.

The flight path is planned by the pilot flight trajectory because there is no three-dimensional point cloud data at Dam-1 as shown in Table 2. Figure 6 shows the UAV flying and tracking by the total station at Dam-1. This flying UAV is manually operated while being tracked by the total station. Figure 7 shows an example of the WP results and the planned flight path using the manual flight trajectory of the UAV, via tracking using the total station; thus verifying that an accurate flight path can be created.

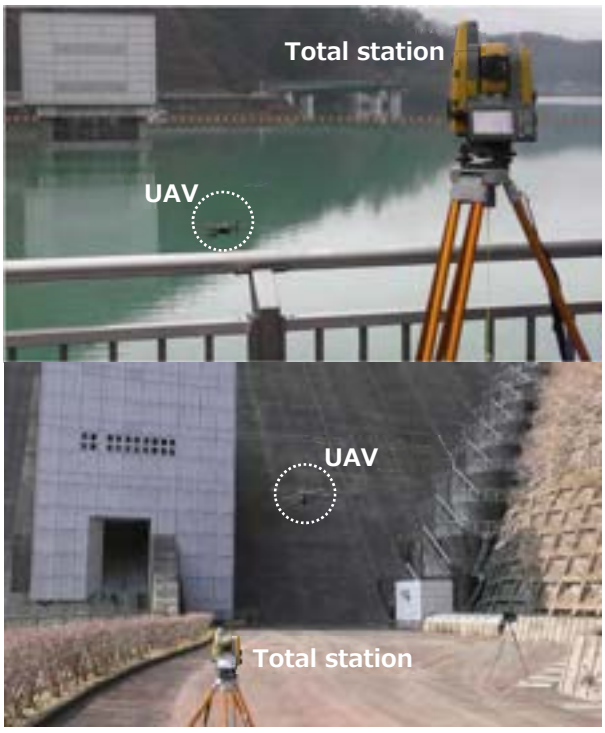

Figure 6. The flying UAV and tracking by the total station (Dam-1). The above image shows the tracking from above and the image below shows tracking from below.

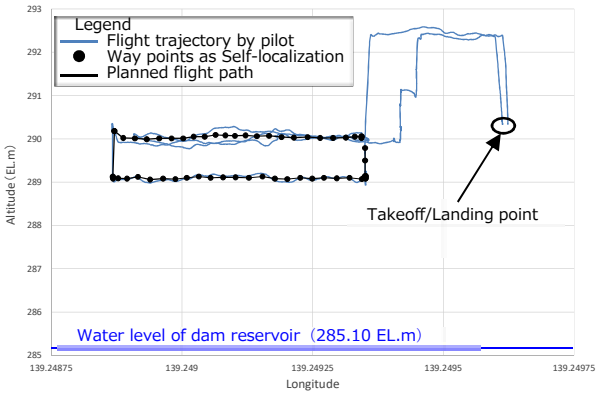

Figure 7. The WP results and the planned flight path using the manual flight trajectory (upstream side of the dam body at Dam-1). The blue line shows the manual flight trajectory of the UAV by tracking using the total station. The black marker indicates the self-estimated position as a WP and the black line shows the planned flight path for inspection.

4.2 Autonomous Flight Accuracy

Figure 9 shows a comparison of the WPs and flight trajectory for autonomous UAV flight. It can be verified that autonomous UAV flight is conducted with high accuracy, even if the vertical direction of the levee gradually thickens from top to bottom and has a complicated shape with horizontally curved lines.

In addition, the difference in distance between 228 WPs and autonomous flight coordinates is summarized in Figure 8. The maximum deviation distance was 0.90 m, the minimum was 0.03 m, and the median was 0.29 m; 90 % of the distance was covered within a deviation of 0.50 m. This flight accuracy is impossible with manual operation.

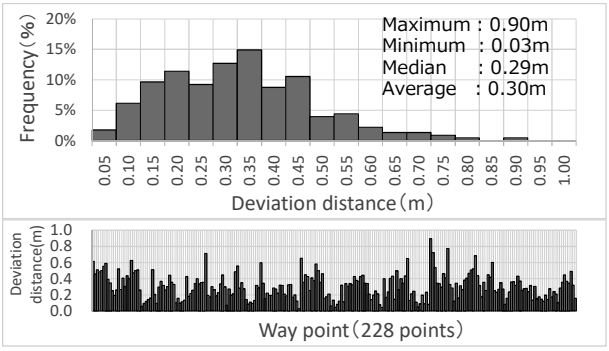

Figure 8. The distance difference frequency distribution between 228 waypoints and autonomous flight coordinates (Dam-2).

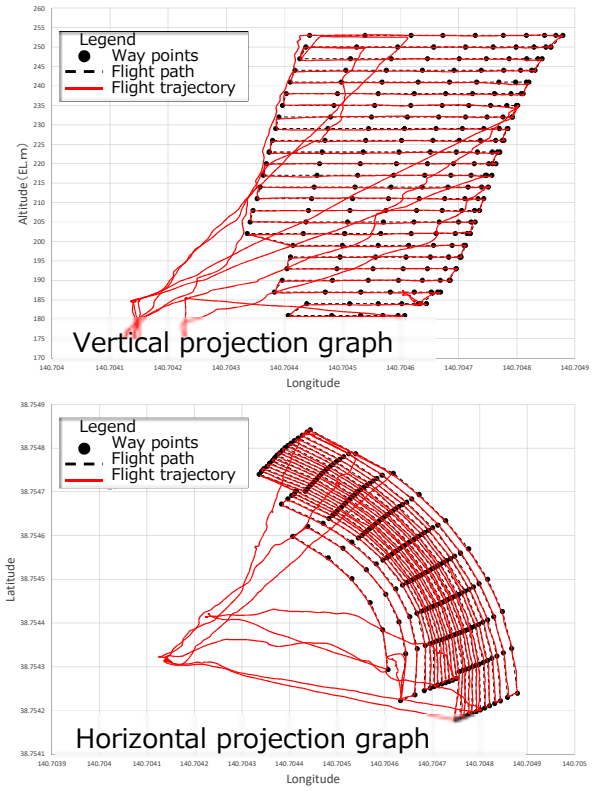

Figure 9. Comparison of WPs and flight trajectory for autonomous UAV flight (Dam-2). The black marker indicates the WPs. The black line shows the planned flight path for inspection. The red line shows the flight trajectory of the autonomous UAV flight.

4.3 Image Quality and Three-Dimensional Reconstruction Accuracy

Figure 10 shows an example of a dam body surface image taken via autonomous UAV flight. Although the absolute width and length could not be measured from the images obtained, it was possible to capture images with a resolution of approximately 1.75 mm/pixel as the vertical joint spacing of the dam is 2,000 mm.

In addition, a three-dimensional model is reconstructed using the SfM software Metashape, as shown in Figure 11. The difference between the three-dimensional point cloud data created by the two different flights was 0.255 mm in the horizontal direction and 0.203 m in the vertical direction; the shape of the dam body was not significantly distorted. As shown in Figure 12, it is confirmed that the use of geotags measured at the total station improved the photograph's alignment. Moreover, this stable and autonomous flight enabled the capture of clear and uniform images; furthermore, the feature point matching between the images taken from two different points is dense and good, as shown in Figure 13.

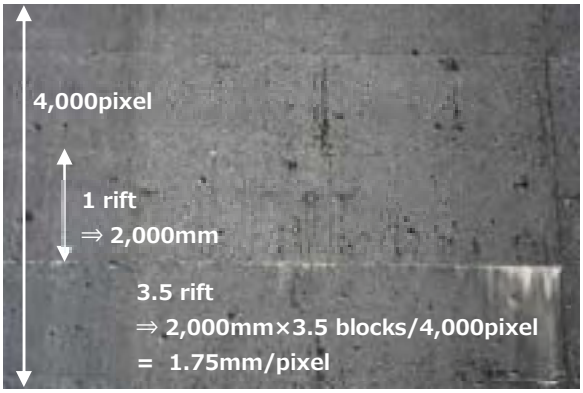

Figure 10. Accuracy verification of image (Dam-1)

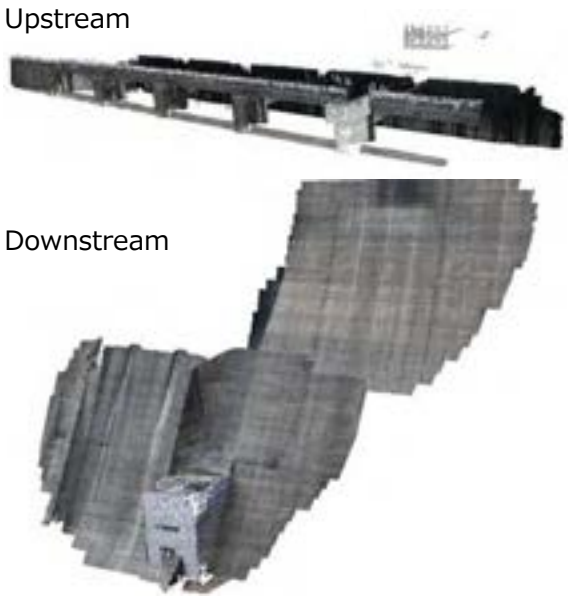

Figure 11. The result of the three-dimensional reconstruction model (Dam-2). The above image shows the view from upstream of the dam body. The image below shows the view from downstream of the dam body.

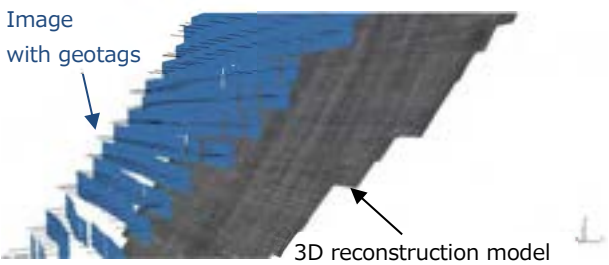

Figure 12. An example of the photograph's alignment (Dam-2).

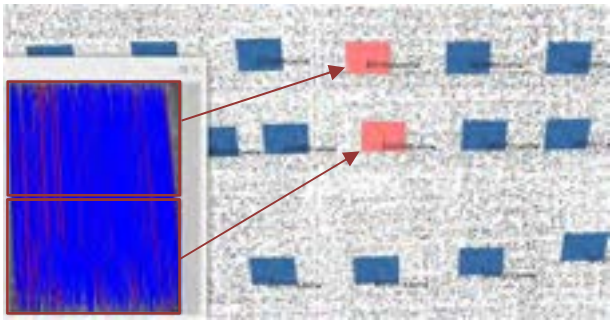

Figure 13. An example of feature point matching between images taken from two different points. The blue lines are a valid match. The red lines are an invalid match (Dam-2).

5 Proposed Flight Opportunity for Aging Detection Using AI Analysis

There are two methods for detecting dam surface aging via AI analysis: supervised and unsupervised learning.

Supervised learning is a method that enables AI to detect even unknown images by learning the teacher information with aging information annotations. Thus, this method is useful only if the observed aging target is obvious as only the annotated teacher information can be detected.

Conversely, unsupervised learning is a method in which AI learns the concept of a normal state and detects information when changes or abnormalities appear. As shown in Figure 14, it is possible to reconstruct a healthy image from a real damaged image and extract the damage from the difference.

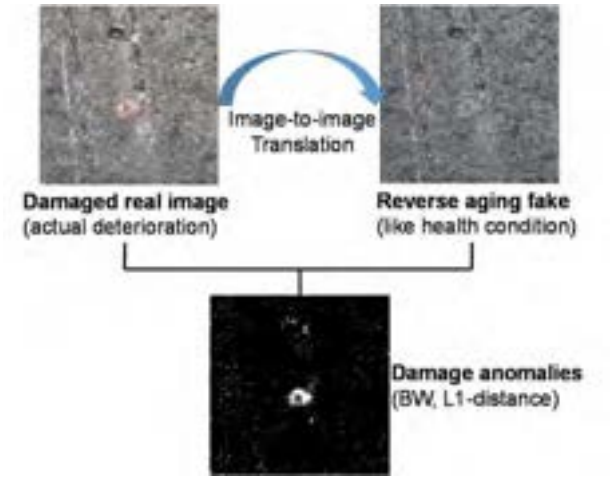

Figure 14. The unsupervised learning image (Dam-2)

There are few abnormal data points on the dam body and it is necessary to extract the various abnormal aging information from a wide range of dam bodies. Thus, unsupervised learning is suitable for the aging detection of dams. Therefore, it is necessary to accumulate images of the dam body during normal times, with uniform quality and accuracy. However, flight opportunities are limited because the dam inspection cycle is very long, i.e., once every few decades. Therefore, using the system proposed in this paper facilitates effective flight and imager accumulation.

6 Conclusion and Future Work

This paper proposes autonomous UAV flight using the dam's total station in non-GNSS environments. In addition, a flight path planning method based on the UAV's flight position, using a total station and geotags that can be added to the image by measuring the flight position at which the image is taken using the total station, which tracks the UAV, is proposed to obtain uniform quality and clear high-resolution images for inspection and management of the dam's body via a digital camera mounted on the UAV.

We implemented a field study and demonstrated the utility of the proposed approach. As a result, we could achieve a high flight accuracy, which is impossible via manual operation. Furthermore, we proposed flight opportunities for aging detection using AI analysis.

Future work is summarized as follows:

- Many field demonstrations will be conducted to verify its practicality.
- To sufficiently reduce the error in three-dimensional reconstruction accuracy, it is necessary to verify the accuracy by changing the lap ratio of the image and correcting it with GCP.
- It is necessary to accumulate images of the dam body surface during normal times.

Abstract -

This paper presents a feasibility study of surface geometry (SG) evaluation and material classification (MC) for robotic spraying. We propose two complementary approaches using point clouds and intensity data provided by a state-of-the-art industrial time-of-flight (ToF) depth camera. The SG evaluation is based on geometric feature computation within local neighbourhoods, which are then used within a supervised classification. The results of this approach are SG classes according to the level of geometric variability of the surface, displayed as SG maps. For MC, active reflectance estimation is investigated and exploited to derive features related to the reflectance and diffusive properties of each material for classification. The result of both approaches can be prospectively used as feedback in digital fabrication for in-line adaptation of the process to improve control of relevant geometrical and material properties.

Surface Geometry; Material Classification; Digital Fabrication; Depth Camera; Machine Learning

1 Introduction

Assuring the required geometric quality of digitally fabricated structures is of high importance not only after but also during the construction process. Recent rapid growth of interest in robotically assisted construction [1] has also boosted the use of sensing technologies to acquire process-relevant information. These works showcased the potential of various sensors in digital fabrication processes and demonstrated ways in which accurately measured 3D information and object parameters extracted from such information can be used for in-line process improvement via feedback control [2, 3]. In order to extract the relevant information for construction processes, appropriate processing algorithms and interpretation of the 3D data need to be employed.

In this contribution we focus on the concept development and feasibility study of algorithms for surface geometry (SG) evaluation and material classification (MC) for robotic spraying applications. The goal is to address the possibility of replacing the manual and subjective SG evaluation and MC processes, currently relying on experts, with novel sensing technology and data analysis. A state-of-the-art industrial depth camera was chosen for data acquisition within this investigation. This sensor technology offers a good trade-off between in-line process acquisition capacity, sufficiently high accuracy and resolution, and areal coverage on the object of interest. It provides not only geometric information of the acquired scene in the form of 3D point clouds (PCs), but also the underlying raw data related to the measured distances and intensities. These data types have potential for extracting various relevant parameters of the observed object by employing a single sensor solution.

SG of structures produced with spraying is important not only for visual and design considerations, but also from a structural viewpoint. The acquired PC data follows the SG of the captured object and implicitly contains its geometric properties. To exploit these geometric properties, i.e. features, it is necessary to carry out a 3D analysis within local neighbourhoods. To achieve this, a processing scheme of four main steps is proposed in this paper: (i) separation of the acquired SG to spatial frequency components, (ii) neighbourhood selection, (iii) feature computation, and (iv) supervised classification. The outcome of this approach are geometry classes according to the level of geometric variability of the surface for different spatial frequencies, displayed as SG maps.

Obtaining adequate information of the early hydration state or local coverage and volume of each sprayed material (e.g. concrete, plaster finish, or paint) requires classifying the materials within the observed scene. This is critical for closed-loop control of the spraying process, such that complete coverage of the surface per material can be ensured. In this context we explore MC exploiting the observations provided by a time-of-flight (ToF) depth camera related to material-specific reflectance properties. The observed differences on repeatable features for the materials used in this initial investigation (i.e. wood, cardboard, metal, and plastic) are then used for developing a simple classifier based on a k-nearest neighbour (kNN) algorithm.

The contributions of this study are twofold. On the one hand, the SG evaluation algorithm can be used within the geometric feedback system of the fabrication in order to

adapt the process accordingly. Chosen SG class ought to be considered as a goal SG, while others indicate areas that need further surface treatment, i.e. either adding additional geometry variation or applying more material to smooth out the dominant SG features. On the other hand, the MC approach can be used within a process of early concrete hydration by distinguishing different states of the concrete and their associated reflectances to automatically regulate the time-window between consecutively sprayed layers.

To introduce this study, a brief overview of the working principle of ToF depth cameras and a basic performance assessment of the one used within this work is given in Section 2. The specific SG evaluation (Section 3) and MC (Section 4) approach is then detailed, including an overview of processing steps, used experimental setups, and datasets. The results of the two discussed concepts are then given and interpreted in Section 5, and the general conclusion and outlook of the investigation are summarized in Section 6.

2 ToF camera

2.1 Measurement Principle

Depth cameras produce 2D depth images of a scene relying on various measurement principles, such as stereo triangulation, structured light, or ToF approaches [4]. With the increase in sensor resolution, the latter have gained attention in recent years for being able to operate over larger ranges with accuracy levels more independent of the scene geometry and background illumination. The most established technique to implement ToF cameras is based on measuring the accumulated phase of an intensity modulated optical signal illuminating the scene and detected independently on each pixel. The illumination is typically produced by one or several near-infrared LEDs driven by a radio-frequency (RF) carrier. The detected signal on each pixel, associated to the illumination signal back-reflected on the corresponding patch of the scene, is demodulated at device level by a dedicated 2D array that computes the correlation of the received signal with an internal reference derived directly from the driver of the emitted modulation. Simplifying the modulation to one sinusoidal component, this correlation $c(\tau)$ can be written as

$$c(\tau) = a \cdot \cos(\tau + \phi) + b, \tag{1}$$

where τ is the correlation lag, a the optical intensity at the modulation frequency, ϕ the phase shift proportional to the propagation delay—and therefore to the range of interest—and b the illumination bias. This correlation is typically computed for four lags regularly spaced with $\frac{\pi}{2}$ rad, so that the obtained correlation samples A_i are

$$A_i = c\left(i \cdot \frac{\pi}{2}\right), \quad \text{with } i = 0, \cdots, 3. \tag{2}$$

The distance-dependent phase can be directly calculated from this correlation samples as

$$\phi = \arctan\left(\frac{A_3 - A_1}{A_0 - A_2}\right) \tag{3}$$

which, considering a sufficiently well-known value of the modulation frequency f_m and assuming a sufficiently accurate approximation for the propagation speed c of the optical signal under typical operation meteorological conditions, can be used to estimate the distance of interest for the given pixel as

$$\hat{d} = \frac{c}{4\pi f_m}(\phi - \phi_0) \tag{4}$$

where ϕ_0 accounts for the systematic delay offset in the correlation process with respect to the mechanical zero of the camera, which should be compensated by calibration. As any phase-based measurement system, these observations are ambiguous beyond one modulation wavelength. This ambiguity is practically solved by performing quasi-simultaneous measurements at several f_m and combining them to resolve a larger unambiguous range. Once computed for each pixel of the depth image, the estimated distances can be used to generate a 3D PC by means of perspective projection [5].

In addition to the accumulated phase, the optical intensity a can also be computed from the correlation samples as

$$a = \frac{1}{2}\sqrt{(A_3 - A_1)^2 + (A_0 - A_2)^2}, \tag{5}$$

being typically used to augment the generated PCs with intensity values. These intensities are proportional to the amplitude of the detected modulated signal, hence independent of the ambient illumination. Given a sufficiently stable illumination and detection efficiency, the measured intensities can be processed considering the spatial distribution of the illumination signal and radiometric attenuation with distance and viewing angle, what enables deriving observations proportional to the material reflectance independently on its position on the scene. By including a prior calibration of scale using a known reflectance standard, these compensated intensities can be in turn extended to absolute reflectance estimations for each point on the scene. Note that such estimations would correspond to the reflectance of the illuminated patch of surface associated to each pixel at the specific angle of incidence (AOI) defined by its relative orientation with respect to the camera.

2.2 Performance Evaluation

An evaluation of the performance using a state-of-the-art ToF camera Helios Lucid [6], has been carried out. The

camera operates based on the measurement principle described in Section 2.1, and its most relevant specifications are given in 2.2. This camera provides both raw correlation samples as directly computed on each pixel according to (2), and on-device pre-processed PC data after averaging multiple frames, correcting of systematic errors, and spatial data smoothing to reduce noise. The ToF sensor used in the camera allows users to access raw data for four modulation frequencies f_M (25 MHz, 50 MHz, 75 MHz, and 100 MHz), however for the processed PC dataset, only 75 MHz and 100 MHz are employed as indicated in Table 2.2.

Table 1. Selected relevant properties of Helios Lucid depth camera, see [6] for more.

Property	Value
Resolution	640 pix x 480 pix
FoV	59° x 45°
Mode	1.5 m (75 MHz and 100 MHz) 6 m (100 MHz)
Precision	<1.6 mm @ 1 m
Accuracy	± 5 mm (1.5 m mode) ± 10 mm (6 m mode)
Illumination	850 nm (VCSEL laser diodes)

Practical limitations on the achievable accuracy of ToF depth cameras are mainly related to sources of variability for the systematic deviations, such as changes of the operating conditions, namely environment temperature, or multipath effects on the scene [5]. Performance assessment procedures of commercial depth cameras primarily addressing those limitations are presented in [7, 4]. Some of these error sources can be mitigated to a large degree by calibration and others further reduced by a careful design of the acquisition conditions and geometry when allowed by the application. Additionally, depth precision is dominated by the signal quality at the sensor level, proportional to the detected optical power and therefore defined mostly by the distance and relative orientation between the sensor and the scene patch, and the reflectance properties of the latter. Precision can only be improved under certain acquisition conditions at the expense of dynamic performance for the given application, by averaging over several measurements of an unchanged scene.

Before using our camera for the data acquisition of our proposed application, We have performed a basic performance assessment to gain a better understanding of the expected data quality and practical limitations. This assessment has specifically addressed stability and noise figure, warm-up effect, and intensity-related depth errors.

The stability and noise characteristics of the raw data were evaluated by computing the Allan deviation of the phases calculated according to (3). This computation was based on a time-series of 8000 samples acquired over two hours on a static scene composed of a flat white plane at a distance of about 1 m using the 1.5 m operating mode. Phase stability was analysed for each of the f_M, using values for a single pixel and is shown in Figure 1. The results indicate a high long term stability on the evaluated time scale without significant low-frequency drifts. A linear fit based on the Allan deviation yields a slope very close to -1, indicating that the noise background is mostly uncorrelated and flat over the evaluated bandwidth—the expected improve by averaging over several acquisitions is therefore approximately proportional to the square root of the number of acquisitions. Computing the distance corresponding to each phase according to 4, the measured precision (2σ) for a single acquisition on each frequency on the evaluated conditions are 5.5 mm (25 MHz), 3.3 mm (50 MHz), 2.9 mm (75 MHz) and 2.3 mm (100 MHz). Precision is expected to increase proportionally to the modulation frequency due to the reduction of distance sensitivity to phase errors. This increase is, however, partly limited by a slight reduction of detected power on faster modulations more attenuated by the sensor bandwidth.

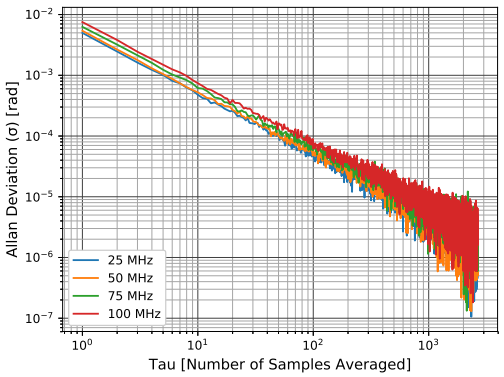

Figure 1. Allan deviation of phase observations for each f_M, using a sample of 8000 measurements for a single pixel.

The internal warm-up of the camera and its impact on accuracy due to temperature-dependent scale errors was evaluated to determine empirically the required warm-up time until reaching optimal performance. Static measurements under similar conditions as described above for precision were carried out acquiring PCs on a flat white plane. This process was initiated immediately after the device was turned on and carried out over three hours with measurements triggered every 20 s. Each PC was used to fit a plane, based on which the maximum and average deviations between the points and the fitted plane were

computed. To reduce the impact of outliers in the analysis, the maximum deviations were computed as the median of the largest 20 deviations. Initial maximum and average deviations were 14 mm and 6 mm, respectively. The results indicate the camera performance stabilizes at about 45 minutes after the camera was turned on, i.e. when the internal camera temperature reaches 36°C. The maximum and average deviations then drop and remain constant at 8 mm and 2 mm, respectively.

The evaluation of intensity-related depth errors due to the spatial inhomogeneity of the illumination pattern were assessed by acquiring PCs using the 6 m operating mode on a white flat surface at distances between 30 cm and 120 cm on 10 cm steps. Deviations to a plane fitted to each PC were computed for each distance. The deviations were grouped in three categories: deviations up to 2 mm, deviations from 2 mm to 4 mm, and deviations larger than 4 mm. These values were chosen to approximate the empirically computed precision discussed in the previous section and its double. The results can be seen in the Figure 2 (left). The figure also shows the area covered by the camera at selected distances. An oscillation patter can be seen within the deviation groups. This pattern agrees with oscillations observed in the distances computed using the raw phase data at 100 MHz (not shown), which suggest a residual uncalibrated cyclic error. Based on the obtained results, it is advised to acquire data at either 40 cm or 80 cm, where the deviations are minimum. Figure 2 (right) shows PCs colored according to the previously defined deviation categories. The most and least optimal PCs were chosen for this representation, being 40 cm and 60 cm respectively. The observed errors could be further mitigated by applying an online compensation taking into account the measured intensity and distance. As a simple approach for the data acquisition during the presented investigation, we have designed our experiment setup geometry and correspondingly cropped the acquired data to exclude the areas with highest deviations.

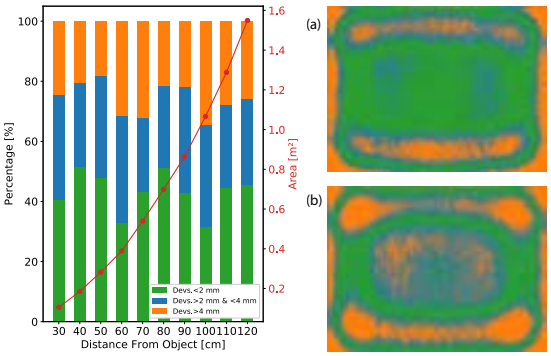

Figure 2. Deviations grouped in three categories, displayed in proportions. Red line represents the area covered by the camera as a function of distance (left). PCs acquired at 40 cm (a) and 60 cm (b) colored according to deviation category (right).

3 Surface Geometry Evaluation

SG captured within the PC can be exploited by local geometric feature analysis. A proposed scheme of assigning points a class of geometry according to the power of change is depicted in Figure 3. The input point cloud is first pre-processed. Then the data is partitioned to three spatial frequency components, and based on a selected neighbourhood, features are computed for each point within the dataset. Next a supervised classification is carried out, outputting the classes for each point which are then spatially filtered. The outcome of this six step processing are SG classes displayed as SG maps.

In general, the presented approach relies on the input data used for model training in the classification step. The observed geometry in the investigated samples is not referenced to a certain absolute definition, but grouped together according to distinctive SG variations.

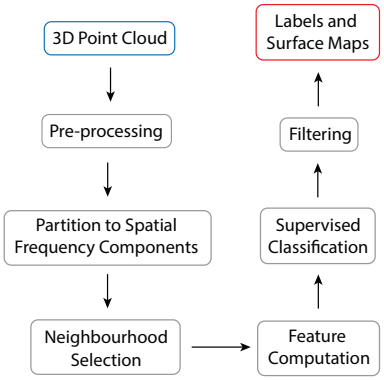

Figure 3. Proposed processing pipeline for SG evaluation.

For the purpose of concept development and evaluation, concrete samples of various geometries were produced using mould casting. Six out of seven sample geometries are shown in Figure 4. These types of geometry were chosen such that they resemble the sprayed surface, since the actual sprayed surface samples were not yet available for this investigation. The chosen dataset is however not completely representative of the sprayed surface and as mentioned, changing the input dataset would lead to different class definitions. Variations in height components (based on Reckli GmBh specifications) are from 11 mm up to 60 mm, therefore covering a wide range of geometric diversity.

The first step after acquiring the data is to pre-process it, which includes two operations: data detrending and crop-

ping. The first operation removes the global linear trend from the whole PC using principal component analysis and reorients it according to the first and second greatest variance of the coordinates. The measured surface might be oriented and at certain angle with respect to the camera, leading to wrong assumptions about a certain geometry. The second operation is to crop the PC and to keep only the central part, which is less affected by intensity related errors compared to the edge parts and therefore displaying higher accuracy (see Section 2.2).

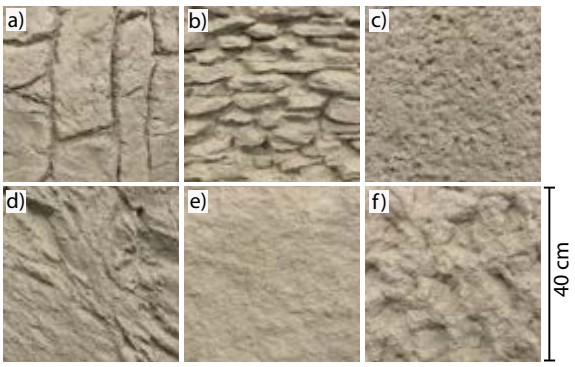

Figure 4. Concrete samples used within the SG evaluation investigation.

3.1 Partition to Spatial Frequency Components

A systematic approach for SG evaluation is adopted based on an existing method for inspection in surface metrology [8], which separates the surface into form, waviness, and roughness components. Typical values for these three components are within a range from microns to a few mm. We have adapted this concept within our SG evaluation and made it representative of the level of geometric variations present in our samples that is both relevant for digital fabrication and observable with the proposed technology, covering a range from a few mm to several cm. We established relative terms, which cover the complete geometric range of the used sample data, namely low- (LSFG), medium- (MSFG), and high-spatial frequency geometry (HSFG).

Two approaches of partitioning the SG to components were employed, making use of either discreet Fourier (FT) or discreet wavelet transform (WT). Since the PC structure is a grid, the transformation can be directly applied to columns and rows of the dataset without any need for interpolation of points. A spatial profile is treated as a time series signal where, instead of time, X- or Y-coordinates are used for rows and columns, respectively. In the first approach, the frequency threshold values between the components of the spectrum were determined empirically based on the observed spectrum in the frequency domain after using the FT. Then Butterworth low-, band-, and high-pass filters were used to partition the signal into three components. An empirically optimized order of the filter was used, which led to more optimal results. In the second approach, using the WT, a selection of a wavelet family and a decomposition level had to be made. Coiflet wavelets and level 5 were empirically selected, since they showed the most optimal results, after trying out different parameter options. The first parameter defines the signal that will be used to convolute the spatial profile, while the second sets the number of levels (i.e. components) that the signal gets partitioned to. In our case LSFG corresponds to level 1, MSFG to levels 2 and 3, and HSFG to levels 4 and 5.

The results of the two approaches applied to a randomly selected spatial profile from surface sample c) are shown in Figure 5. The tree SG components, the original SG, and the reassembled SG are shown. It can be noticed that the results based on the FT approach cannot be reassembled to the original SG profile, while this is successfully achieved for the WT. This confirms that Wavelets perform better on natural signals, i.e. non-stationary signals, as demonstrated in [9]. The FT approach using Butterworth filters does not, on the other hand, perform well on sharp changes in the signal and it tends to smooth over those features.

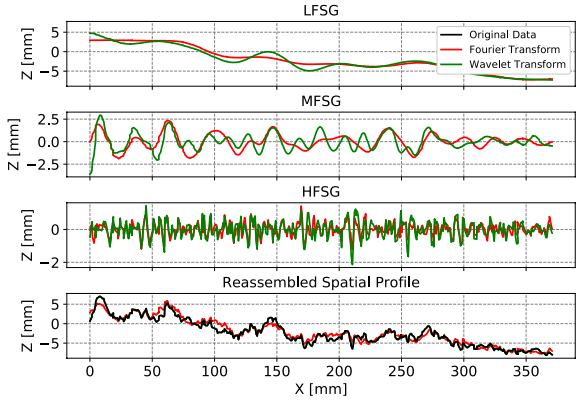

Figure 5. Profiles for each of the three surface components for surface sample c).

The whole PC can be partitioned to components, once this approach is applied to the complete dataset, i.e. all rows and columns. Both approaches are used in this processing, namely WT for partitioning to SG components (see example in Figure 7), and FT for generation of spectrograms. Spectrograms are a visual representation of the spectrum of frequencies of the signal in the time domain, however here shown for spatial domain. A visualization for surface sample b) is shown in Figure 6. The visible information in the spectrograms differs for the dataset ob-

tained from geometries as shown in Figure 4. It can serve to provide additional information of the spatial frequency content of the surface to the user.

The intensity image is obtained by using the same WT approach partitioned to a high- (HFI) and low-frequency intensity (LFI). The LFI component is dominated by the contribution of the camera illumination pattern and is discarded from further analysis. The HFI component, on the other hand, is influenced by small scale features in the observed surface, and can be therefore used to extract small scale features.

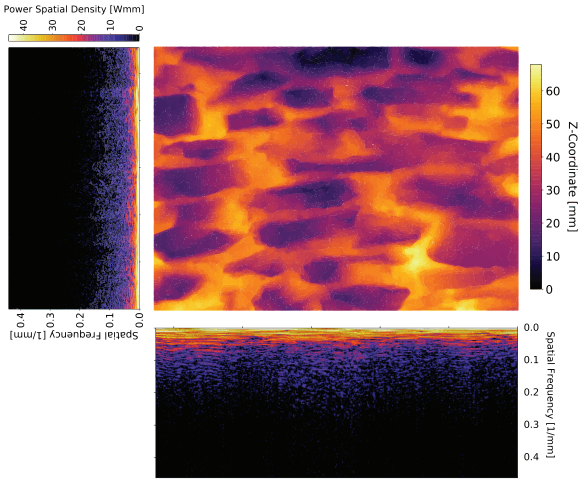

Figure 6. Spectrograms generated for surface sample b) in direction of columns and rows.

Only WT results were used in the end for this investigation, since the results were more optimal compared to the FT. The FT and its results were only used for generation of the SG spectrograms.

3.2 Geometric and Intensity Feature Computation

Each surface component dataset is used for extraction of local geometric features, with features being different for each of the three components. The selected features were handpicked in order to capture the information within the SG components as good as possible. The selection is shown in Figure 7. More information on geometric features that were taken as a starting point in this investigation and on their properties can be found in [10].

The computation of features is carried out for each point within the dataset, using its neighbourhood. Within the implemented algorithm, points are included within a certain neighbourhood based on either the list of indices of the kNN of the anchor point or a query of all points with distances to the anchor point smaller than a given radius. The results shown in this paper were produced based on a chosen radius, being 7 cm, 3 cm, and 1 cm, for LSFG, MSFG, and HSFG, respectively. This makes the classification results independent on the distance from which the acquisition was done.

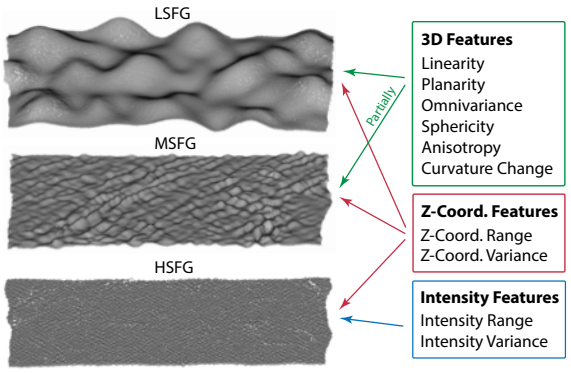

Figure 7. Three SG components (left). A list of features used for computation (right).

The intensity features play a relevant role when analyzing the HSFG component. The goal is to exploit small scale (i.e. sub-mm) features that cannot be captured by the geometry of the PC, due to the accuracy limitation of the used technology. However, the input intensity images of highly reflecting and absorbing local areas could cause intensity variations, in this case the intensity variations would not be related to the geometric but rather to radiometric features.

3.3 Supervised Classification

Once the features for all points are computed, they are normalized per feature to a range of [0, 1], such that none of the feature values dominate on the further processing. Those values are then used within a process of clustering to form groups of points that share similar geometric properties. For this purpose, an agglomerative hierarchical clustering approach was chosen. The algorithm requires a user specified number of clusters. This can be chosen based on a dendrogram, a tree diagram that displays an arrangement of clusters and the similarity between them. The number of clusters was selected as 3 for all components. Only a random subset of about 10% of points with their features was used for model training. It is assumed that the sub-set is sufficiently representative for the whole dataset, which was validated by the result repeatability after selecting different random subsets. The rest of the points is used later on for the evaluation of the model.

Next, the segmentation approach is extended to supervised classification using kNN. The algorithm learns the relationship between the feature value list of each point and assigned cluster indices. The number of clusters from the clustering process and the classification process is there-

fore the same. This classifier can then be applied to another dataset, to predict the closest class label using kNN.

To derive labeling of points with higher spatial regularity, a median filter is applied to the initial class label image. This results into smooth labels and surface maps. Additionally, it is possible to omit patches of areas smaller than the chosen threshold to decrease granularity, however this is not implemented in the proposed approach.

Furthermore, an assessment of each of the features was carried out to understand which have the highest impact on the label outcome. For this the analysis of variance (ANOVA) statistical test was employed, usually used within similar classification tasks. Based on the features and assigned labels, ANOVA assesses how much a class label is dependent on each particular feature and assigns each feature a score of relevance. It then ranks the features based on the calculated score. The most important features were intensity range and Z-coordinate range for HSFG and MSFG, respectively. For LSFG the most important features were change of curvature, omnivariance, and sphericity. The results of the labeling are shown in Section 5.1.

The process of feature computation and classification is computationally intensive, since a set of feature values has to be computed for each point. This makes it unsuitable for a quasi-real-time application. However, this can be overcome by computing features for a subset of points, e.g. every 10th point, classifying them, and then using interpolation of classes on the rest of the points to produce fully classified maps.

4 Material Classification

We have investigated the MC potential of ToF cameras in the context of our targeted applications by developing a MC strategy exploiting active reflectance estimations derived from the raw correlation data. The goal is to propose a processing pipeline to derive information of the reflectance and diffusiveness of the materials in the scene and use it for in-line classification, and to provide a simple demonstration of the feasibility of such approach.

4.1 Experiments and Datasets

An experimental setup for material-related data acquisition was designed making use of the horizontal comparator bench on our calibration laboratory. The ToF camera was mounted on a steel pole in front of the bench and the material samples were placed on a motorized trolley that moves automatically between selected positions measured with a linear Doppler interferometer. This allowed for accurate control of the relative distance changes between samples and camera, which were extended to absolute distances by independently measuring the distance between the camera and the sample at the starting position of the trolley using a laser tracker.

Two experiments were carried out on the described setup using four material samples, namely wood, plastic, metal, and cardboard, chosen arbitrarily as a simple subset of common materials. In the first experiment, each of the four material samples was placed on the trolley and displaced from 0.57 m to 1.6 m on steps of 3 cm. The scene on each position was acquired 10 times sequentially to enable an approximate quantification of measurement dispersion. The complete procedure was repeated for three orientations of the samples (5°, 25°, and 35°) by controlling the orientation with a highly repeatable rotation stage. The values for the distance range and sample orientations were selected to cover the expected working regions of the camera for the envisioned applications, providing sufficient resolution while keeping the effort for the experiments low. In the second experiment, all four material samples were placed on the trolley. The scene containing all materials was then captured for distances between 0.57 m and 1.07 m on steps of 0.1 m, repeating the process for the three aforementioned orientations.

4.2 Active reflectance estimation

Our proposal for reflectance-based MC relies on distinguishing materials based on their reflectance pattern. This approach is based on the estimation of a simple model of the material absolute reflectance as a function of AOI, obtained from calibrated intensity observations of the same surface patch from different points of view. The features extracted from such estimation can potentially provide differentiation for a large number of materials as long as they do not showcase both similar absolute reflectance and diffusive behaviour.

Defining in the simplest case a two-parameter reflectance model R as a generalized Lambertian scatterer

$$R\,(\mathrm{AOI}) = R_0 \cdot \cos^n(\mathrm{AOI}), \tag{6}$$

where R_0 is the material absolute reflectance on normal incidence and n defines the patter directivity; materials can be characterized based on their features R_0 and n. These are obtained from a minimum but sufficient number of two observations of the same surface patch from different perspectives, each observation providing estimations of both the absolute reflectance and the AOI. The AOI can be estimated from the depth map by analyzing the local region of the pixel of interest. The absolute reflectance, on the other hand, can be derived from the intensities calculated from the correlation raw data by applying adequate distance and instrumental corrections. The intensity a measured at pixel px for certain distance d, considering the dominant sources of variability, can be modeled as

$$a\,(d, px) = K_{ill}\,(d, px) \cdot K_{det}\,(px) \cdot G\,(d) \cdot R\,(\mathrm{AOI}), \tag{7}$$

where K_{ill} accounts for the spatial distribution of the illumination signal, K_{det} represents the detection efficiency of the corresponding pixel, and $G(d)$ the overall radiometric attenuation of detected power with distance. These three components can be compensated online using fitted functions or lookup tables obtained by a single calibration process based on acquisitions of a known geometry (e.g. a planar target) with homogeneous reflectance properties over several distances within the range of interest. By additionally including measurements on a material with known reflectance such as a calibrated reflectance standard, the overall scale of the amplitudes can be corrected. The final compensated amplitude provides an estimation of the material reflectance $\hat{R}$ of the surface patch covered by each pixel independently of distance and viewing angle from the camera, thus enabling the generation of absolute reflectance images. Combining these images with the estimated AOI per pixel for pairs of acquisitions allows deriving and mapping the reflectance features R_0 and n for any part of the surface covered on both acquisitions. These features can be then used to classify the materials in the scene by direct comparison with a pre-collected material database.

We have used the data from the two experiments described in Section 4.1 to provide a simple validation of this approach. The correlation data from the first experiment was used to compute the optical intensities per modulation wavelength according to (5). Figure 8 shows an extract of the computed intensities as a function of the interferometric reference distance across all the evaluated materials for the fastest modulation wavelength, with solid lines representing the average of 10 acquisitions per position while shaded areas correspond to the dispersion of those acquisitions in $\pm 1\ \sigma$. These results are good representatives of the overall behaviour of the other three f_M. The analysis of the intensity values indicates unreliable intensity observations due to saturation for some materials at close range. This is specially critical on the metal sample that showcases much higher specular reflectance. This makes the received intensity very high for the 5° orientation, which saturates the sensor for any distance smaller than approximately 1.1 m as confirmed by inspection of the underlying correlation samples. Conversely, the more specular behaviour produces very low intensities for the AOIs on the 25° and 35° orientations. The data derived from saturated observations was excluded from subsequent analyses.

The intensities obtained in the first experiment have been used to generate reference data for the classification. To avoid the need of introducing a reflectance standard, the classification is carried out using relative reflectance values normalized to the average amplitude of wood at 5°. The computed relative reflectances are depicted in Figure 9 for the three evaluated AOIs, where solid and shaded areas represent the average and standard deviation ($\pm 1\ \sigma$) between all wavelengths. The results show that, excluding the regions when the sensor is close to saturation due to high material reflectance and short range, the computed values per material are consistent within a 10% of variability independently from distance. This indicates that features derived from these values hold potential to provide robust classification of the evaluated materials.

Figure 8. Measured intensity at 100 MHz as a function of reference distance for all materials and AOIs.

Figure 9. Normalized intensities at all f_M as a function of reference distance for all materials and AOIs.

The relative reflectances per AOI computed for each material, f_M, and distance have been used to estimate the two parameters R_0 and n of the simple reflectance model in (6), which are to be used as reference features for the classification. Figure 10 shows the resulting features for all frequencies and distances with their associated material class. As seen in the figure, the computed features provide good separability for the evaluated materials.

The data from the first experiment has been additionally used to derive the distance correction $G(d)$, and an additional independent experiment on a planar target at several distances has been used to compute the illumination distribution $K_{ill}(d, px)$. These corrections are used on a scene containing all materials from the second experiment to test

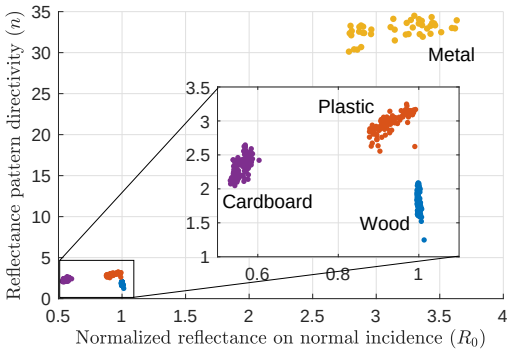

Figure 10. Normalized reflectance features extracted for four materials for all frequencies and distances.

the MC performance against the reference data. The intermediate steps for these corrections and the classification results are shown and discussed next in Section 5.2.

5 Results

5.1 Surface Geometry

The results of the SG evaluation are maps colored according to the assigned classes. Each class signifies the level of geometric variability for each of the spatial frequency components LSFG, MSFG, and HSFG (Figure 11).

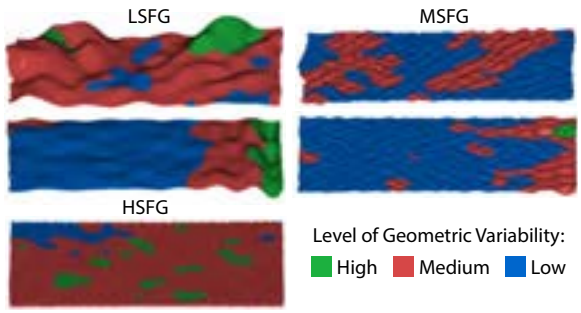

Figure 11. Resulting classified SG map for LSFG, MSFG, and HSFG components.

The results indicate that the proposed evaluation approach works well, with clearly classifying the most similar geometric parts of the datasets in the same class. The differences between classes are obvious and very distinctive. The level of in-class variation is directly related to how many classes were chosen in the classification step. For the given dataset this value has been optimized, to allow only for minor variations within the classes. The selection of the number of the classes should thus be a data driven decision. Due to the unavailability of ground truth data, a plausibility check of the obtained results was done based on subjective evaluation. This resembles standard practice, where SG is evaluated by human inspection.

The results are useful within the process of robotic spraying, where certain classes indicate areas requiring further surface treatment. If the target SG would be a class of medium geometric variability, regions showing high variability imply the need of being filled with more material around it or removed, while regions showing low variability require additional texture.

5.2 Material Classification

A scene containing all four materials seen from two different perspectives (5° and 25° with respect to the camera axis) has been used to assess the MC performance. The intensities as directly computed from the correlation samples are shown in Figure 12.a, for wood (W.), cardboard (C.), plastic (P.), and metal (M.). These intensities were compensated for the impact of distance and illumination spatial distribution with the corrections calculated as described in Section 4.2. The illumination distribution can be seen in Figure 12.c, and the resulting distance- and illumination-corrected intensities are shown in Figure 12.b. The AOI across the scene was calculated geometrically, and the need for calibrating the detection efficiency and overall scale was overcome by computing reflectances normalized to a patch of the scene known to correspond to wood on the 5° acquisition. The two reflectance features were then derived from the computed relative reflectances and compared to the reference data using a kNN classifier. The final results of the classification per pixel after applying a median filter can be seen in Figure 12.d. The results demonstrate high accuracy on the classification of pixels corresponding to metal, cardboard, and wood. Pixels corresponding to plastic get wrongly classified as wood on certain areas. This is caused by wood and plastic being relatively close to each other in the feature space as shown in Figure 11, and suggests the need for a more complex reflection model—thus requiring additional viewpoints—to distinguish materials with similar reflectance properties.

6 Conclusion and Outlook

An exploratory investigation and concept development for SG evaluation and MC using PCs and optical intensity values acquired with a state-of-the-art depth camera was carried out. The results for SG evaluation show that it is possible to classify geometry based on the level of geometric variability that it exhibits, by 3D feature analysis and supervised classification. The generated SG maps are easy to interpret, by both human and computer-aided analysis. Furthermore, the evaluation of the presented MC approach on a reduced subset of materials shows successful classification based on an approximated model of their

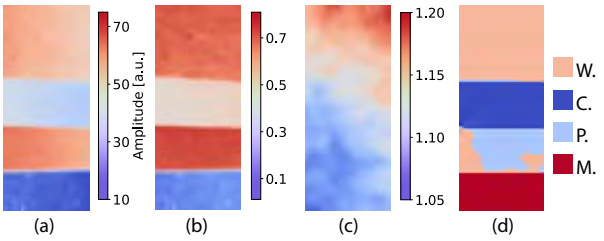

Figure 12. Result and intermediate steps for reflectance-based MC using 100 MHz data at distance of 1.5 m: a) measured intensities, b) corrected intensities, c) illumination distribution, and d) classified pixels, with material initials used for label names.

diffuse reflectance properties estimated from two viewpoints. The proposed method does not require in-situ calibration and can be easily extended to more complex reflectance models—hence potentially increasing classification robustness—by adding measurements from additional viewpoints.

The ultimate goal of the two proposed approaches is their in-line application within the robotic spraying process, providing feedback regarding geometric and material properties to adapt the process accordingly. On the one hand, the SG classes indicate whether further surface treatment in the fabrication process is needed or if the desired SG is met. On the other hand MC results can provide information on local coverage and volume of each sprayed material and also indicate early hydration states of the concrete to automatically regulate the time-window between consecutively sprayed layers.

As a continuation two main further investigations will be addressed. Firstly, the performance of the SG evaluation and MC approaches should be assessed on surfaces actually produced within the spraying process. Secondly, the combination of both approaches for enhanced performance should be explored. The latter means that geometry information (i.e. distances, orientation of the sample, etc.) should be used directly within the MC process where necessary, and vice-versa. Having MC results as one of the features within the SG evaluation, the material within the scene might contain information relevant for the SG classification.

Acknowledgments

This research was supported by the NCCR Digital Fabrication, funded by the Swiss National Science Foundation (NCCR Digital Fabrication Agreement #51NF40-182887).

The authors would like to thank Reckli GmBh for providing the moulds for concrete samples and to Andreas Reusser (NCCR dfab) for the help with concrete casting.

Abstract -

In this paper, Reality Capture technologies are used to reconstruct 3D models of utility excavation holes which can later be visualised in the field, allowing for a more reliable, comprehensive and perceptible documentation and viewing of utilities before excavating to potentially reduce subsurface utility damages. An Augmented Reality (AR) prototype solution was developed and demonstrated for a group of respondents, concluding that visualising reality capturing models in AR would benefit fieldwork before, during and after excavation.

1 Introduction

Most streets in industrial countries are filled with hidden infrastructure beneath ground creating risk of striking underground utilities during excavation work. In the UK the direct cost is estimated at £3600 per utility strike which led to a total cost of approx. £7 Million in 2017-2018 [1]. However, this does not take the indirect cost of strike damages into account, which include project overrun, downtime and social cost such as traffic delays and loss of productivity in businesses. By adding these indirect costs the total cost is significantly higher and has an estimated average ratio between direct and indirect cost of 1:29 [2], thereby increasing cost of each utility strike to approx. £100,000. Similarly, in Denmark it is estimated that the Danish society has lost 2.8 billion DKK over a 10-year period due to underground utilities being damage during excavating [3]. Clearly there is a need for new tools and work processes, preventing underground utility damage.

Poor documentation in terms of quality, accuracy, and access to utility data is often the cause of utility strikes [4] [3]. In best case scenarios utility data is documented in GIS as straight poly-lines with attributes such as elevation and thickness, allowing qualified estimation of where utilities are located. In worst case scenarios the documentation is missing, incomplete or out-of-date and often represent as-planned data instead of as-built data [5]. This form of documentation is, therefore, more a schematic representation of where the utility is placed rather than a representation of its accurate shape where twists and turns can occur along the path [6]. As a consequence, issues often arise when trying to locate utilities before and during excavation. In Al-Bayati and Panzer's survey, (2019) [5], completed by 477 contractors, the most contributing cause for hitting underground utilities was a) the lack of depth information, b) painted markings placed to far from the utilities either because of inaccurate data or the surveyor being rushed or untrained, and c) the temporary state of the marking, i.e. the marking disappears when the top-layer surface is removed or is washed away by weathering. Locating equipment to measure the depth of utilities is, nonetheless available, such as Ground Penetrating Radar, which is often rejected because of the added cost for the utility owner and the limited benefits it provides [5]. Using locating equipment and following good-practice Subsurface Utility Engineering (SUE) is another solution that can be applied to prevent utility strikes [7], it can, however, be very expensive and time consuming. Often this solution does not harmonize with the contractor and utility owner being on a tight schedule and budget [5]. It is clear that more complete and accurate utility data are needed in today's construction industry and also, if not just as important, a more reliable way to display utility information before and during excavation work.

In this paper we showcase a potential solution to reduce utility damage that combines two emerging technologies to deliver a more informed, comprehensible and perceptible visualisation for utility professionals by combining Augmented Reality and Reality Capture. The aim is to visualise point cloud models of previous captured utility excavation holes informing the next person in the field to come.

1.1 AR visualisation of underground infrastructure

One popular solution used to display underground utility information in the field is Augmented Reality (AR). The method was first demonstrated by Roberts et al. (2002) [8] who visualised a 2D projection of underground utility

lines on the surface area. The AR prototype was a rather clumsy setup, compared with today's standards, consisting of a backpack powering a wired and handheld binocular-formed viewing device. Later Schall et al. (2009) [9] improved the concept with a smaller handheld device resembling nowadays handheld mobile devices in form factor. Besides visualising utility lines on the surface the handheld device could generate a geospatial 3D model from GIS utility data and display it at a given elevation value. To aid the users depth perception of the underground placed 3D model, the AR system used a cut-away visualisation technique resembling a virtual excavation. The 3D model was then only visible inside the virtual excavation cut-away volume. According to the authors in later studies this visualisation technique as well as the ability to change between other "x-ray" visualisation techniques, like Ghosting [10] and Shadow Projecting onto the surface, was very useful [11]. The studies further recommended to use comprehensible visualisation techniques to avoid depth perception issues instead of having the user trying to imagining the depth distance between utility pipe and surface [12]. A user study done by Eren Balcisoy (2018) [13] evaluated the vertical depth judgement performance on different x-ray visualisation techniques. It showed that users were performing better in estimating depth of 3D pipelines when using a cut-away excavation box technique compared to a careless overlay and edge-based ghosting technique. A survey by Ortega et al. (2019) [14] similarly showed that the virtual cut-away excavation technique also performed best when compared to other visualisation techniques for viewing of underground infrastructure in virtual environments.

As previously mentioned, other scientific work has primarily focused on visualising 2D GIS data superimposed to the surface or 3D models generated from the existing GIS data and occasionally as-planned 3D models. The latter being more common for large infrastructure projects, such as highway projects [15]. However, not much focus has been directed at using 3D models generated from Reality Capture. In fact to the best of our knowledge this has not before been attempted as a way of visualising underground utility information in the field.

1.2 Documentation of utility assets with Reality Capture

Reality capture is a technology that is used in a wide range of industries and is often used by surveyors to 3D scan constructions such as cultural heritage sites [16], bridges [17] and underground utilities [18].

One popular Reality Capture technique is Close-range Photogrammetry because of the widely available hardware in form of mobile cameras in smartphones and amateur drones as well as a wide range of reliable software. The 3D data output of Reality Capture is most often represented as either point clouds or 3D textured meshes. In this paper we use dense point clouds of underground utilities as our reality capturing data. The point clouds are provided by a Danish utility company and originates from an on-going pilot test made in cooperation with another Danish surveying company to use their Reality Capture technology for documenting underground utilities [19]. Using a smartphone app, workers in the field video-recorded the exposed utilities located in the excavation holes. A dense point cloud was then generated using close-range photogrammetry of the captured video recording. The point clouds were also geo-referenced, ensuring that location and scale were aligned with the existing surroundings. The point clouds serves as improved documentation and can be revisited by the utility company if needed in future activities. The interface view of how point clouds are managed by the utility company is shown in figure 1.

In this paper the mentioned Danish utility company provided access to point clouds from a water distribution renovation project from 2019, in which 14 utility excavations were captured and documented with Reality Capture.

1.3 Research goals

This paper is a preliminary attempt to utilise Augmented Reality as a planning tool allowing both surveyors, inspection engineers and contractors to attain a perceptible visualisations of where utilities are located below ground, based on documentation of previous excavations registered using Reality Capture.

The research presented in this paper consist of the development of an AR prototype and a showcase session for the utility owners and the surveying company, participating in the study. The study demonstrate how captured point clouds can be visualised to inform workers in the field before a new utility excavation project is carried out in the area of a previously captured location.

The aim is to highlight the usefulness of visualising point cloud captures in AR for field workers to prevent damage when excavating as well as assist in other general asset managing tasks in the utility industry. Using Reality Capture in combination with AR has yet to be studied in-depth with regards to obtaining better interaction and visualisations techniques for underground infrastructure in this study.

This paper additionally presents incentives for utility companies to document utility assets with Reality Capture technologies as well as share these 3D captures with other utility owners in the industry.

2 Methodology

2.1 Empirical method

Empirical data was acquired through a series of informal interviews with stakeholders from the utility industry over the span of six months.

Interviews were conducted in two parts. The first part included phone-calls with two stakeholders to attain background information with respect to current practises and experiences with excavation, strike-damages and planning of underground utility work. The second interview partly consisted of a demonstration of the AR prototype developed as part of this research, and partly of an informal group interview evaluating said AR prototype demonstration. The participating respondents were all employees in the already mentioned utility company and surveying company. In all, seven respondents participated, five male and two female with various years of experience in the utility industry.

Empirical data acquisition was based on semi-structured interviews, as described by Brinkman and Tangaard (2015) [20], documented through sound-recordings. A selection of predefined questions were directed to the respondents guiding the interview session whilst follow-up questions were added to the discussion by the interviewer in reaction to the comments given by the respondents, allowing elaboration on comments as well as getting spontaneously occurring questions relevant to the prototype demonstration answered. The questions guiding the interviews were divided into two categories, 1) AR for informed decision-making in the field and 2) AR to prevent utility excavation damage.

Data collected in the interview-session additionally include comments from the respondents from conversations happening during the demonstration of the AR prototype. After empirical data were collected it was analysed and structured through a brainstorming process harmonizing the interview-data gathered with the scope of this paper.

2.2 Prototype development

The AR prototype was developed using Unity3D and ARKit as AR framework running on a 2nd Gen. 12,9" iPad Pro. The dense point cloud models of the utility excavations were managed using Potree created by Schuetz (2016) [21]. By leveraging the octree structure implemented in Potree the rendering process was made efficient to visualise the relative large point clouds (avg. 1-2 million points), for the prototype hardware to handle with a satisfying frame-rate while shown in the AR view. The implementation of Potree in Unity3D was made possible by using a Unity-package developed by Fraiss (2017) [22].

Prior to the demonstration of the prototype tool, markers

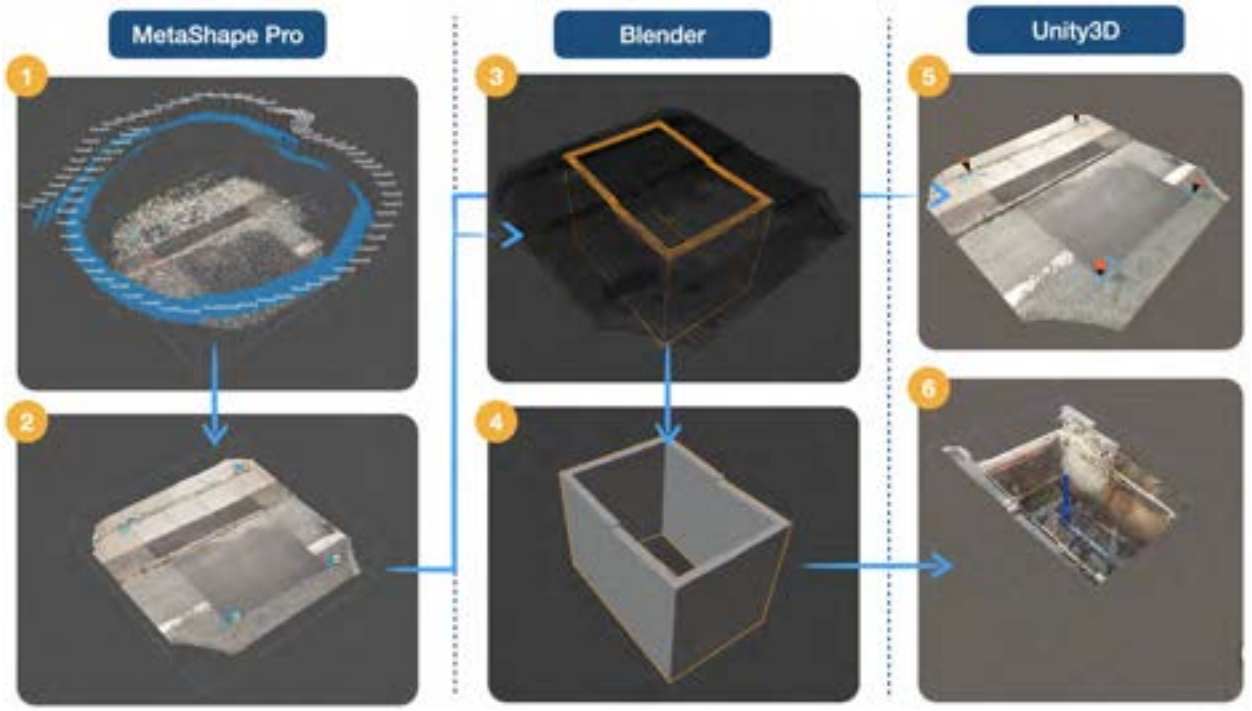

Figure 2. The overall workflow for creating occlusion box

was painted around the ground surface of the previously reality captured utility excavations. By video recording the surface area and surveying the painted markers on the test-site a 3D mesh was generated by using close-range photogrammetry in Metashape Pro. This process is illustrated in figure 2 in step 1 and 2. The surface mesh was aligned with its corresponding utility excavation point cloud. This was done for two reasons.

Firstly, to create an occlusion box around the utility excavation point cloud to keep the illusion of how a physical utility excavation hole would look, i.e. it is not possible to see the outer sidewalls of the excavation as the ground surface occludes it. This was done by modelling a box-shaped 3D model around the utility excavation point cloud using Blender as illustrated in step 3 and 4 in figure 2. The 3D model box was then imported to Unity3D and an occlusion shader was applied as illustrated in the last steps (5 and 6) in figure 2.

Secondly, to manually positioning and orientating the utility excavation point clouds at the correct geo-position in AR. By manually place the point clouds on top of the known markers by utilising ARKits horizontal plane detection and model-free tracking capabilities a stable and robust Six Degrees of Freedom (6DoF) tracking was achieved. This approach was used to obtain a simple and yet reliable AR geo-positioning and tracking solution, satisfying for demonstration purposes.

3 Results

The seven employees from the Utility Company (UC) and the Surveying Company (SC) participating in the demonstration as respondents were given a hands-on demonstration of the AR prototype, as seen in figure 3, before the semi-structured interview was conducted. The participant's roles in the company were primarily team leaders and department managers, all responsible for people with field work, such as planning, inspection and management on site as well as collaborating with contractors responsible for excavation.

In the following section the results from the demonstration and interview are presented, following the structure of the questioning categories presented in section 2. An important aspect to have in mind is that the use of Reality Capture for documentation of utility assets is, a new work process for the UC, as mentioned in section 1, and therefore they are still exploring what value-creation Reality Capture can add to their work routines.

To start the interview the UC first described what current value-gain they have achieved from using Reality Capture. Besides being an additional form of documentation that can be accessed through GIS, as seen in figure 1, the UC also use the point clouds to quality inspect the utility installation work done by the contractors. At the moment only larger water distribution construction projects are documented with Reality Capture, but the UC is confident that

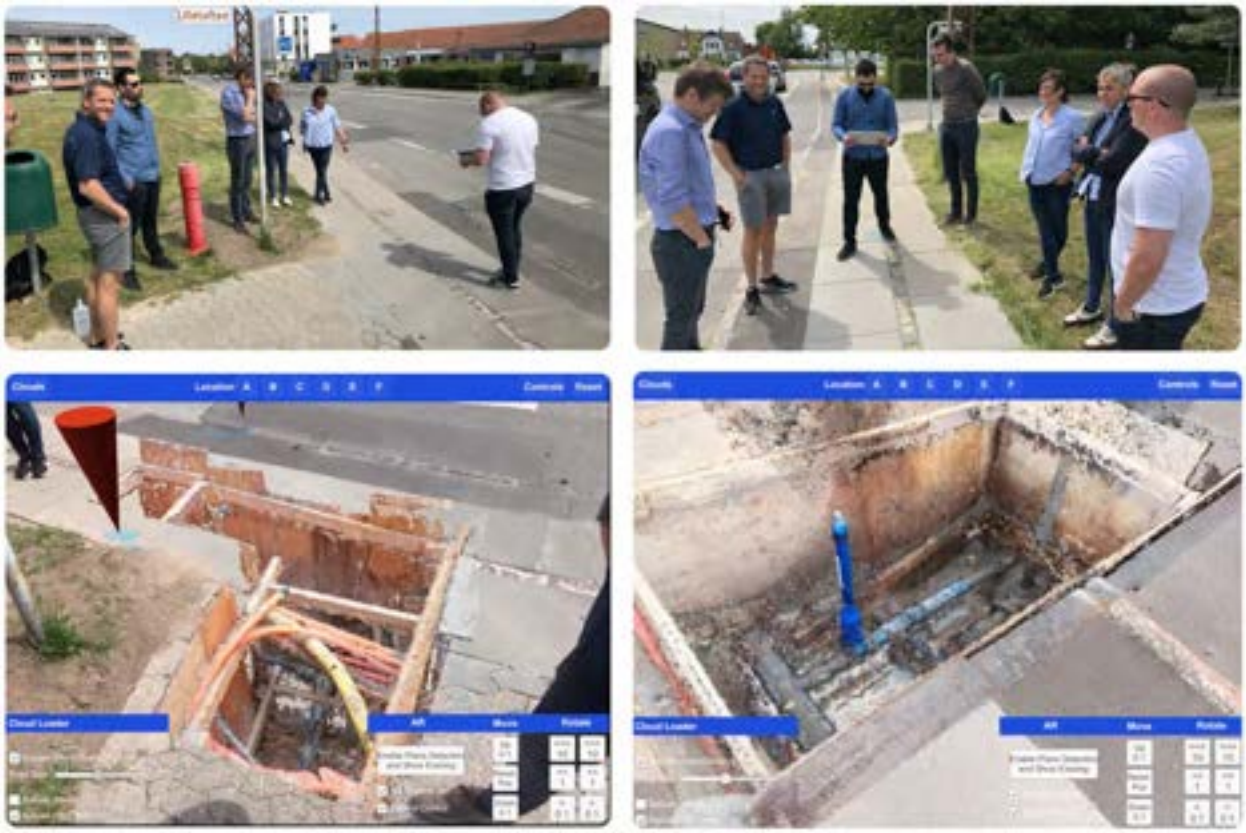

Figure 3. AR prototype in use during the hands-on demonstration seen from AR device view (bottom) and 3rd-person view (top).

it is to be utilised in other types of excavation projects, such as district heating, waste and storm water, in the future. Looking further ahead they believe these point clouds can be useful in the planning phase of new excavation projects near locations of previously reality captured utility assets. In fact, this was one the reasons why the UC was interested to see what their 3D point cloud models would look like when visualised in the field using AR.

3.1 AR for informed decision-making in the field

None of the respondents from the UC has experience working with AR solutions for displaying GIS data to aid fieldwork. The SC, however, is a seller of professional industry AR solutions (currently AugView and Trimble SiteVision) but has not seen Reality Capture 3D models visualised with these systems.

The respondents were asked to discuss what kind of value-creation it would add to their work routines based on their hands-on experience with the AR prototype. All respondents agreed that the ability to view the point cloud models in AR during fieldwork would greatly help planning and coordination with other professionals and non-professionals e.g. in communicating with citizens. The most impressive aspect for the respondents was how perceptibly and comprehensible the virtual utility excavation was visualised in the AR prototype, making it suitable for communicating technical details. For example, to help visualise where a water supply utility is located in relation to cadastre boundary for a house-owner. Another example, could be in case of a water leakage. In such case the UC might have a rough estimation of where the leakage is located based on sensor data. However, entering the field with the ability to look through the surface and see the underground utility pipes with high visual detail, and in context with the physical surroundings, might lead to a faster localisation of the leakage. Ultimately the respondents felt motivated to include the AR prototype in their fieldwork as they agreed it would support a more informed decision-making.

During and after the demonstration the respondents from the UC got so inspired when interacting with the AR prototype that they started to suggest new functionalities. The most requested functionality was distance measuring in the two primary directions: 1) vertical depth from util-

ity to surface level and 2) horizontal distance from utility pipe snapping to horizontal road cross-section features such as center line, drive lane, curbs, bicycle-path, sidewalk, shoulder and road boundary limit. They also would like to have their own 2D GIS utility data visible together with the utility excavation point cloud. When asked about visualising 2D GIS utility data from other utility owners like tele-com and power, they where more hesitant.

3.2 AR to prevent utility excavation damage

When asked if the demonstrated AR prototype could help prevent utility damage during excavation work, all respondents agreed that it would be helpful for the contractor. Again, the main reason is the ability for the contractor to get a perceptible view of what underground utility assets are hidden beneath the surface. This information can then easily be understood by the contractor to plan the digging activity before breaking ground, and reassess during excavation. A particular useful scenario is when multiple underground utilities are buried in the same place, as shown in the utility excavation seen in the bottom left picture in figure 3. In the utility excavation, the flexible and smaller orange and yellow cables are clearly visible, even though the purpose of Reality Capture was only to document the blue water supply pipe laying below. When experiences with utility damages occurring during excavation work was discussed further the respondents agreed that the main cause for utility damages are inaccurate and out-of-date utility data - especially data from tele-com companies. Technical drawings of tele-com cables are often only schematic representation. This can lead to a lot of guesswork for the contractor, when locations of underground cables on the drawings does not correspond to locations in reality. The presented AR prototype solution has great potential to reduce utility strikes, however, as commented by the respondents, this is only useful if previous captured point clouds located beneath or close around the excavation site exist and can be accessed.

4 Discussion

4.1 Reality Capture and AR to incentivise data sharing

The presented AR solution in this paper uses point cloud models of previous reality captured utility excavation to deliver a more informed, comprehensible and perceptible visualisation for utility professionals in the field. Using Reality Capture models as the only data source of visualisation, however, creates the obvious limitation, that the coverage is only as adequate as the number of utility excavations which have been excavated, reality captured and transferred into the AR device. Even though this approach has a weakness in terms of coverage area, it ensures that only accurate utility information is presented for the user. Compared to other AR solutions that use traditionally 2D GIS utility data which are prone to be inaccurate as told by the respondents and others [5]. One could argue that the approach, presented in this paper, is actually a strength by only visualising utility information that are accurate and thus trustworthy for the professionals in the field. Nevertheless, it is clear that the more point clouds the UC can capture, the more relevant the AR solution will become, as the likelihood of revisiting a previous reality captured location increases.

In the future the UC hopes that its neighbouring utility owners will also begin documenting utility assets with Reality Capture. This, they hope, will lead to data sharing between them, which they can all leverage from. For example it is clearly visible from figure 3 that other types of utilities are present in the excavated hole. It is certainly possible that other utility owners have plans to revisit these utilities before the utility owner that originally captured it. It seams only logical to share Reality Capture models. This type of sharing is already a known practice in Denmark as it is mandatory to ask for underground utility information before a contractor starts excavating. However, the utility data is at best only regular 2D GIS utility data and is prone to be inaccurate for some utility types. When documenting utility assets with Reality Capture it automatically documents other utilities appearing in the excavation. This could lead to updating out-of-date data of utilities and cables, benefiting the next contractor to excavate at a previously captured location. Especially if the contractor is able to visualise these virtual utility excavations in the field as demonstrated in the AR prototype presented in this paper. Such sharing of utility data through an AR platform has been proven as an attractive solution for utility owners to engage in as demonstrated by Fenais et al. (2019), although the AR platform was only using regular 2D GIS utility data [23].

4.2 Visualisation of Reality Capture models in AR

The AR prototype used dense point cloud models of utility excavations provided from the utility company. The reason was to demonstrate for the utility company what is possible to visualise in AR with data they already possess. However, that is not to say the point clouds were the optimal Reality Capture model datatype to visualise in AR. In fact it might be more suitable to use 3D textured mesh representations. One of the benefits 3D meshes is that it consist of triangulated faces and therefor occludes the surrounding background when viewed in AR. Contrary, when using point clouds it is possible to see-through where the points are not dense enough which can sometimes break the illusion of AR. In either case, it is interesting to have both point clouds and 3D meshes being optimized for AR

visualisation to be suitable for as many Reality Capture techniques as possible.

5 Conclusion

The aim of this paper was to identify potential value-creation using Reality Capture models of utility excavations, visualised in Augmented Reality for utility professionals in the field. Based on the responses collected in a prototype demonstration and interviews with respondents from a Utility Company and a Surveying Company, it is possible to conclude that visualising Reality Capture models in AR can be useful for field workers for planning of subsurface work, and also during excavations. All participating respondents, furthermore, noted that they wanted to implement a finished version of the prototype-tool demonstrated in this study, in the future.

Many of the respondents had not previously tried AR in an outdoor professional context and was quite overwhelmed with how much sense and value it added. Although visualising Reality Capture models in AR was concluded useful the respondents further noted that more interaction features in the AR prototype, with respect to specific fieldwork tasks and needs. Future work will investigating and develop prototypes to study what value-creation such interaction features can facilitate for utility construction professionals in planning and executing excavation work.

6 Disclaimer

The interview results presented in this paper was collected with participation of the surveying company that provided point cloud models of the utility excavations to the utility company using the survey company's own developed Reality Capture app. The solution and the conclusion of advocating the use of Reality Capture as a way of documentation could therefore be in the surveying company's own interest.

Abstract – Deterioration models significantly contribute to increasing the efficiency of life-cycle planning for highway assets. Therefore, asset managers strive to maximize the accuracy of such models and intensify the efficacy of the life-cycle plan. Even though nearby assets have been thought to have an impact on each other's conditions, usually, such interrelations have not been considered in previous deterioration models. To this end, in this paper, we focused on investigating the impact of considering nearby assets interrelations on the accuracy of prediction models. Our results show that this consideration resulted in more accurate prediction models in comparison to considering each asset individually.

Keywords – Highway Asset Management; Condition Prediction; Logistic Regression; Nearby Assets

1 Introduction

The optimization of budget allocation in highway asset management programs is gaining more attention due to the massive maintenance needs of the existing aged roadways. Furthermore, in recent years, the constrained budget has resulted in an ever-growing backlog of funding. As an example, the amount of budget shortage for preserving the U.S. roadways in a good state of repair was estimated $836 billion in 2017. As a result, this budget deficit emphasizes the need for optimal and smart investments in highway asset management programs [1]. Therefore, in the pursuit of optimal allocation of the available funds, highway decision makers look for procedures that maximize the level of service with minimal expenditure. To this end, information modeling and management are the keys in establishing optimized Life Cycle Plans (LCPs) and maintenance works [2; 3; 4; 5]. In the meantime, the accuracy of deterioration prediction models highly affects the efficiency of LCPs and, in turn, highway asset management programs. Therefore, decision makers strive to increase the accuracy of data-driven deterioration prediction models given the limited extent of available data so that they could better predict possible future deficiencies in roadways.

In a highway system, several asset classes can be found next to each other. According to the first law of geography that specifies there is a relation between everything with nearby elements being more related, it can be hypothesized that the conditions of neighboring assets are correlated [6]. For instance, the condition of neighboring pavements, shoulders, and slopes might be correlated because of the similar impact of the identical temperature variations and precipitation rates that happen in their vicinity. Also, defects in adjacent asset items could be affected by possible interrelations between the degradation of neighboring elements. For example, the deformation of a slope next to a shoulder might cause the shoulder's subsidence.

However, the majority of previous studies developed their condition prediction models when each asset was considered individually [7, 8, 9, 10, 11]. For this reason, the possible interrelations of nearby asset classes have not been fairly considered in previous deterioration models. To address this challenge, the main motivation of this study is to examine the impact of incorporating the condition of neighboring asset classes into condition prediction models on the accuracy of condition forecasts. To this end, we selected flexible pavement, paved shoulder, and slope to perform the analysis. We selected these assets because: (i) they are made of similar materials, (ii) they are located in close proximity, and (iii) similar factors affect their degradation rates. Then, we developed deterioration models for the selected asset types in a case study. We then performed a comparative study to measure the impact of including the conditions of neighboring assets in the developed prediction frameworks for the selected asset items. The following section moves on to the review of the literature in deterioration prediction models of the selected asset items.

2 Background

Several studies targeted developing deterioration models for pavements and bridges. However, other roadway assets have received less attention. In addition, agencies have focused more on measuring the performance of pavements and bridges in comparison to the other assets [12]. Therefore, sometimes agencies do not own enough performance data of other assets such as slopes and shoulders. Yet, in a roadway asset management system, all asset types are required to be considered together under a framework wherein their performance prediction models specify their maintenance investment needs. Consequently, adding the information of assets with abundant data (e.g. pavement) in condition prediction of other assets with less available data could mitigate uncertainties and contribute toward a better budget allocation.

We identified two main shortcomings in previous works. The first found gap is that the majority of prediction models were developed based on the data of a single asset type, where each asset was modeled individually. For instance, [7], [13], and [14] developed prediction models for the condition of pavements only based on the historical data of pavement segments. Another identified shortcoming in the literature is that even though the condition of nearby assets might be dependent, this dependency was not considered in developing prediction models. For example, in spite of the probable impacts of underlying pavements on the condition of pavement markings, the majority of studies investigated their conditions separately [15, 16]. In addition, several studies performed individual investigations of degradations for other asset types, such as signs, barriers, and culverts [17, 18, 9]. Therefore, the possible interrelations between neighboring assets have not been fairly considered in previous studies. However, a few of the past studies partially investigated the mutual impacts of some of the neighboring assets on each other. For example, the impact of drained and undrained base and subbase layers on the condition of pavement were examined in some works, where the outcomes unveiled that the presence of water in the subsurface layer and its surroundings can significantly influence the pavement's stiffness [19, 20]. In addition, [21] studied the role of routine maintenance of paved shoulders on the condition of adjacent flexible pavement. In another study, [22] investigated the influences of shoulders' rumble strip on the pavement condition. Finally, [23] performed a correlational study between the condition of nearby flexible pavements, paved ditches, and paved shoulders. They identified some interrelations that mutually impact the condition of the selected asset items. However, they did not study the possible impacts of these correlations in the condition prediction models of each asset.

To fill the identified gaps in the body of knowledge, the main objective of this study is to examine how including the condition of nearby assets as a predictor in the condition prediction of a particular asset improves the accuracy compared to single asset modeling where the deteriorations are predicted based on the information of each asset individually. The next section moves on to the step-by-step methodology proposed in this study and explains each step in more detail.

3 Methodology

In this study, we selected three asset classes for our analysis: flexible pavement, shoulder, and slope. We used a wide range of contributing factors to degradation in our analysis under three main categories: weather, traffic, and historical asset's condition due to their importance and data availability. We developed the prediction model of each asset in two different scenarios: when the conditions of its adjacent assets were considered (i.e. nearby-asset modeling) and ignored (i.e. single asset modeling). Prior to developing prediction models, we performed a feature reduction step to ensure there was no multicollinearity in the input dataset. Next, we used logistic regression to predict the existence of pothole defects in flexible pavement and shoulder, and erosion and erosion patterns in slope under the scenarios as mentioned earlier.

To measure the capability of the proposed framework, we applied it on 321.4 kilometers of I-81, I-77, and I-381 highways in Virginia as our case study. Selected roadways were split into 84 segments, each of which has a length of 3.2 kilometers (2 miles). The utilized datasets in this study recorded the corresponding values of weather, traffic, and historical conditions between 2015 and 2019. Fig. 1 shows the framework of the proposed methodology. The following sections provide a detailed description of each step.

3.1 Data Collection and Preparation

The utilized data in this study were categorized into three groups: weather, traffic, and condition. First, we collected data from available resources and then audited the data to detect and correct possible errors, abnormalities, and irregularities.

3.1.1 Traffic

The traffic dataset was extracted from a public portal [24]. We performed a cleaning step to identify missing information and inaccuracies in the dataset. Next, in order to prevent the occurrence of bias in the results, we used the min-max scaling in our analysis to linearly map the features between 0 and 1 [25]. We applied this scaler on each feature of the cleaned traffic dataset separately. The summary of the utilized traffic features, as well as

their descriptive statistics, including minimum, maximum, 25th percentile, median, and 75th percentile before scaling are provided in Table 1 and Figure 2, respectively.

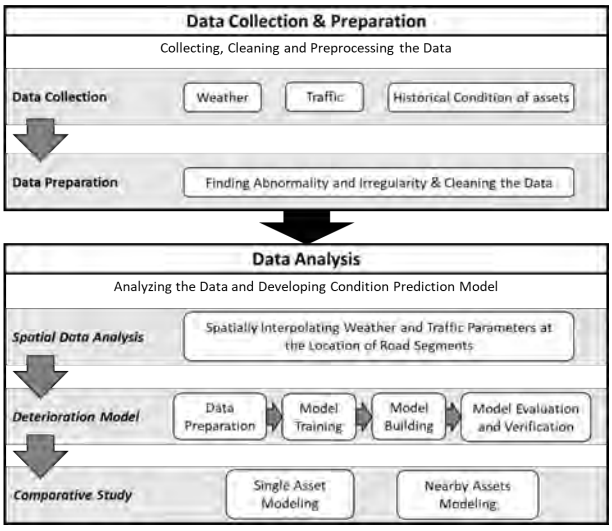

Figure 1. Proposed methodology framework

Table 1. Traffic features

Parameter	Definition
ADT	average daily traffic
AAWDT	average annual weekday traffic
ADT_4	average daily traffic of 4-tire vehicles
ADT_BU	average daily traffic of buses
ADT_TR	average daily traffic of trucks with 1 trailer
ADT_1	average daily traffic of trucks with 2 axles
ADT_2	average daily traffic of trucks with 2 trailers
ADT_3	average daily traffic of trucks with 3 axles

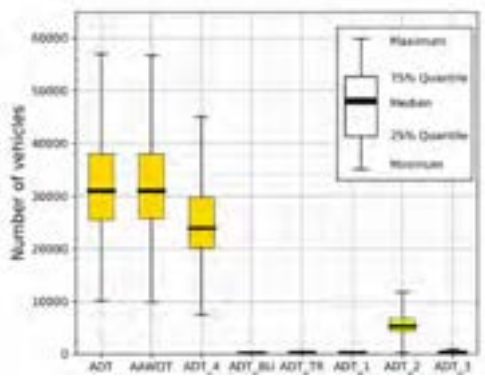

Figure 2. Traffic feature statistical description

3.1.2 Weather

We extracted the weather data from the National Oceanic Atmospheric Administration (NOAA) database. We collected the data from 24 weather stations to cover our case study. Figure 3 shows the selected weather stations and their location with respect to the case study.

Figure 3. Selected weather stations and the case study

We cleaned the dataset to minimize inaccuracies and missing information. We filtered the stations to the ones with more than 250 days of recorded data, which reduced the number of remaining stations to 20. Table 2 provides a summary of the weather features used in our analysis.

We used the ordinary kriging to interpolate the extracted weather features onto each segment. We used this technique due to its acceptable accuracy for weather-related features [26, 27, 28]. In addition to the common weather features, we devised and considered more attributes to incorporate temperature variations. For instance, the average daily maximum-minimum temperature difference in a year, TMAXTMIN, is one of the attributes that we used to take into account the daily fluctuation of the temperature. TMAXTMIN ranges between two extremums: the upper bound, which takes place in desert-like regions, and the lower bound being observed in low-lying humid areas.

Table 2. Weather features

Parameter	Definition
TMAX	annual maximum daily temperature (° C)
TMIN	annual minimum daily temperature (° C)
TMAXMIN	annual average of daily max_min temperature difference (° C)
DWT32	number of days with minimum temperature<0° C (32° F) in a year
DWT80	number of days with maximum temperature>26.7° C (80° F) in a year
DWTMXN30	number of days with Tmax-Tmin>16.7° C (30° F) in a year
DSNW	number of days with snow depth > 2.54 cm (1 inch) in a year
EMSD	maximum annual daily snow depth (cm)
EMXP	maximum annual daily precipitation depth (cm)
PRCP	total annual precipitation (cm)
SNOW	total annual snow depth (cm)

We additionally added another feature to our analysis to include the number of days with maximum-minimum temperature difference greater than 16.7 degrees Celsius (30 degrees Fahrenheit), called DWTMXN30. Then, like traffic data, we used min-max scaling to map the weather data as well. Figure 4 provides the statistical descriptions of the extracted weather features through a set of boxplots prior to scaling.

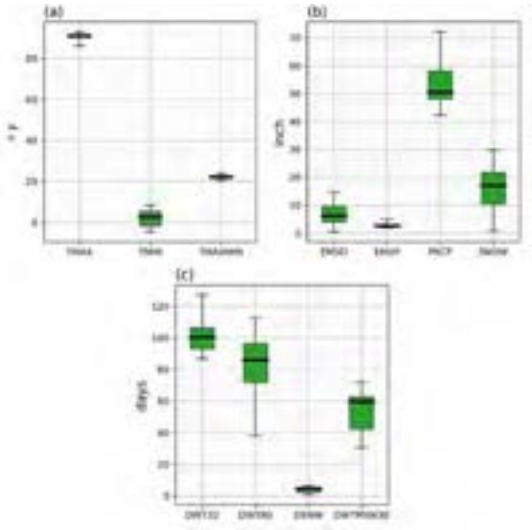

Figure 4. Weather features' statistical description

3.1.3 Condition

The condition of each asset corresponds to its physical characteristics that affect its performance at the time of inspection [29]. We extracted the condition data from a Maintenance Quality Assurance Program (MQAP) that inspected and recorded the condition of the selected assets (i.e. flexible pavement, paved shoulder, and slope) in our case study between 2015 and 2019. The MQAP recorded pothole defects on flexible pavement and shoulder in each segment of roadways, and erosion and erosion patterns in slopes. Being a common defect on flexible pavements and shoulders, potholes pose extreme dangers to vehicles and drivers. Driving over potholes can harm different parts of vehicles and could force drivers to show dangerous maneuvers for avoiding driving over them. Like potholes in flexible pavements and shoulders, erosion and erosion patterns are major probable defects in slopes that endanger their stability. They could cause dangerous failures in slopes. Therefore, we considered these defects in our analysis. The utilized MQAP rated the recorded conditions in 4 classes: very poor, poor, good, and very good. The definitions of all classes of recorded conditions for each asset are provided in Table 3 to Table 6.

Table 3. Condition descriptions for flexible pavement - pothole

Condition	Description
Very Poor	More than one pothole present
Poor	One pothole present
Good	No pothole
Very Good	No pothole or any sign of distressed asphalt such as rutting, heaving, or troughing

Table 4. Condition descriptions for shoulder - pothole

Condition	Description
Very Poor	More than one pothole present
Poor	One pothole present
Good	No pothole
Very Good	No pothole or any sign of distressed asphalt such as rutting, heaving, or troughing

Table 5. Condition descriptions for slope - erosion

Condition	Description
Very Poor	Multiple erosion along slope greater than 8 inches deep
Poor	Erosion along slope greater than 8 inches deep
Good	Less than or equal to 8 inches deep erosion.
Very Good	No slope erosion.

Table 6. Condition descriptions for slope - erosion pattern

Condition	Description
Very Poor	Pattern of erosion that endangers the stability of at least 25% of the slope.
Poor	Pattern of erosion that endangers the stability of less than 25% of the slope.
Good	No pattern of erosion that endangers the stability of the slope.
Very Good	N/A

3.2 Prediction Model

We used logistic regression to develop prediction models and to predict the future condition of selected assets. In developing prediction models, we aggregated the defects into pass or fail classes. This new classification is aligned with trigger levels in maintenance decision making systems that highlights the necessity of repairs for very poor and poor classes. Therefore, in each asset, very poor and poor conditions were merged into the fail class while good and very good into the pass class. As a result, the output of the model would be a binary value (pass/fail), which corresponds to the predicted condition of each asset in the considered segment.

Prediction models in this study were developed in two different scenarios so that the interrelations of neighboring assets could be investigated. In the first scenario, we only considered weather, traffic, and the condition of each individual asset in the modeling (single

asset modeling). The condition feature only contains the recorded condition in the prior year of the targeted prediction time. For example, to forecast the condition of the flexible pavement in 2017, the single asset prediction model uses only the condition of flexible pavement in 2016 as a predictor, as well as other weather and traffic features. Figure 5 schematically shows the single asset prediction modeling used in this study.

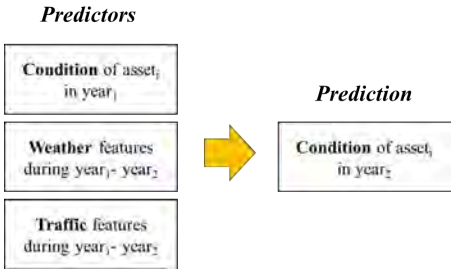

Figure 5. Single asset prediction modeling procedure

In the other scenario, we added the historical condition of the nearby assets in both the prior and the prediction years into the feature space as well (nearby-asset prediction modeling). For instance, for predicting the recorded condition of slope (i.e. slope erosion) in 2017, in addition to weather, traffic, and conditions of the slope (slope erosion and erosion patterns) in 2016, the condition of nearby flexible pavement, shoulder, and the condition of the slope under erosion pattern in 2017 were also included in the modeling. In this way, the interrelations between the condition of neighboring assets in the past and also in the year of prediction are taken into account. Figure 6 schematically describes the modeling process used in this study.

In both scenarios, we first performed a feature reduction step to ensure that the considered features are not highly correlated.

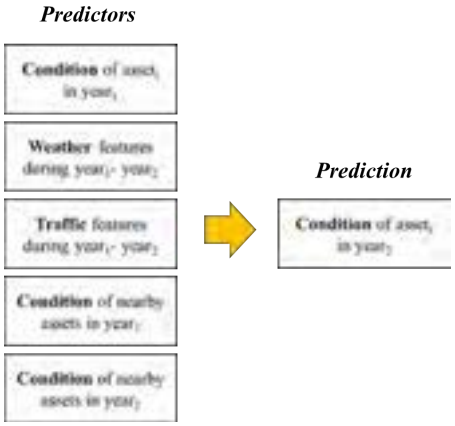

Figure 6. Nearby-asset modeling procedure

3.2.1 Feature Reduction

The efficiency of a multivariable analysis could be highly impacted by multicollinearity among features. Multicollinearity corresponds to the existence of high correlations among some attributes in a dataset, which can bias the result toward correlated attributes [30]. Therefore, we used a correlational investigation to find high correlations between features and to remove multicollinearity.

Given the essence of the considered inputs, we performed the feature reduction in two steps. First, we ensured that there was not any high correlation among continuous features, i.e. weather and traffic, using Pearson correlation coefficients. As a rule of thumb, features whose pairwise absolute Pearson correlation coefficients are more than 0.9 are considered highly correlated [31, 30]. Therefore, we clustered such features and chose only one of them as the only representative of the group.

In the next step, we measured the correlation between the remaining continuous and categorical features, i.e. condition classes, utilizing absolute point-biserial correlation coefficients. Any group of attributes with a more significant correlation than 0.9 were considered as highly correlated and represented with only one of the considered features.

3.2.2 Logistic Regression

After feature reduction, we used logistic regression to develop the condition prediction model, which predicts the probability of each condition category, i.e. pass or fail, for each asset based on multiple independent variables that were available in the dataset, i.e. weather, traffic, and condition. Maximum likelihood estimation was used to evaluate the probability of categorical membership in the binary logistic regression [32, 33]. For example, if y_i is the dependent variable with two categories (0/1), the probability of being in category 1 could be denoted by $\pi_i^{(1)} = \Pr(y_i = 1)$ with the chosen reference category, $\pi_i^{(0)}$. If only one independent variable x_i existed, a logistic regression model would be written as Equation 1:

$$Log\left(\frac{\pi_i^{(1)}}{\pi_i^{(0)}}\right) = \beta_0^{(1)} + \beta_1^{(1)} x_i \quad (1)$$

Wherein $\beta_0^{(1)}$ is the intercept and $\beta_1^{(1)}$ is the regression coefficient. In addition, the probability of being y_i in the reference category (0) is written in Equation 2.

$$\pi_i^{(0)} = 1 - \pi_i^{(1)} = \frac{1}{1 + e^{(\beta_0^{(1)} + \beta_1^{(1)} x_i)}} \quad (2)$$

Therefore, $\pi_i^{(1)}$ can be calculated using Equation 3.

$$\pi_i^{(1)} = \frac{e^{(\beta_0^{(1)}+\beta_1^{(1)}x_i)}}{1+e^{(\beta_0^{(1)}+\beta_1^{(1)}x_i)}} \quad (3)$$

3.2.3 Validation of Prediction Models

After developing prediction models, we validated them using k-fold cross-validation that evaluates and controls the performance of the models over unseen data. We utilized five folds for this purpose.

4 Results and Discussion

This section provides the results that we obtained after applying the proposed methodology to our case study. Figure 7 shows the correlation matrix and corresponding pairwise absolute Pearson correlation coefficients among continuous features i.e. weather and traffic. As it can be observed, traffic features are highly correlated. In addition, TMAXTMIN and DWTMXN30 are highly correlated as well. Therefore, we only considered ADT as the representative of the traffic features, as well as all of the weather features except for TMAXTMIN in the final dataset.

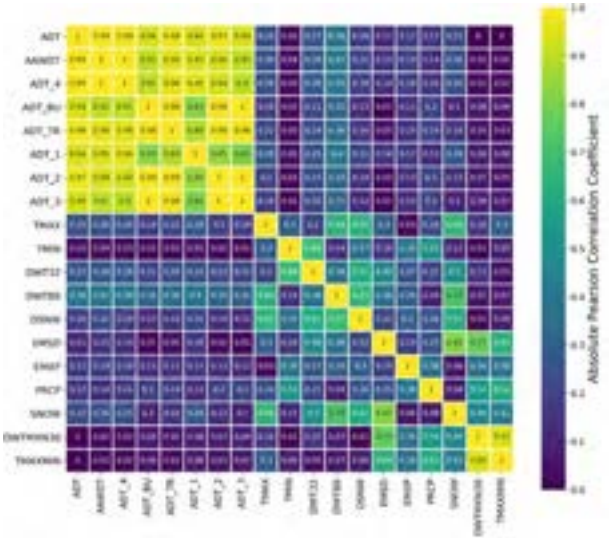

Figure 7. Correlation matrix of continuous features

In the next step, we measured the correlation between the remaining continuous and categorical features (i.e. conditions). The corresponding correlation matrix, using absolute point-biserial correlation, is provided in Figure 8.

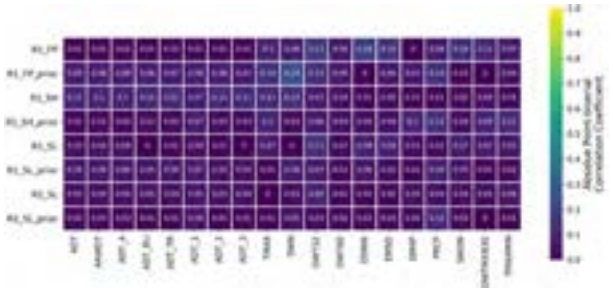

Figure 8. Correlation matrix of mixed features

As Figure 8 suggests, there is not any high correlation in the mixed feature, and we proceeded with the remaining features ensuring that the multicollinearity has been removed.

Next, we fed the reduced dataset into the logistic regression to develop the condition prediction models. We developed the models for each asset in both single asset and nearby-asset modeling scenarios and reported the obtained confusion matrices in Figure 9 and 10, respectively. In addition, the results of the average accuracy of the final validated prediction models for the two considered scenarios are summarized in Table 7. It can be observed that in all cases when the conditions of the nearby asset items were considered in developing the condition prediction model, the accuracy of predictions increased in comparison to single asset prediction models.

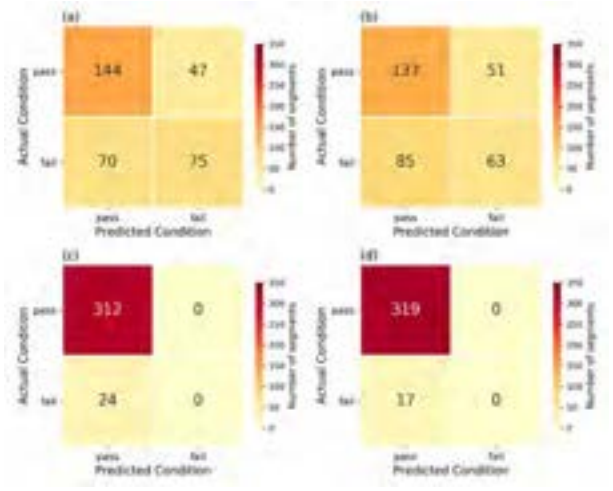

Figure 9. Confusion matrix of single asset modeling: (a) Flexible Pavement-Pothole, (b) Shoulder-Pothole, (c) Slope-erosion, (d) Slope-erosion pattern

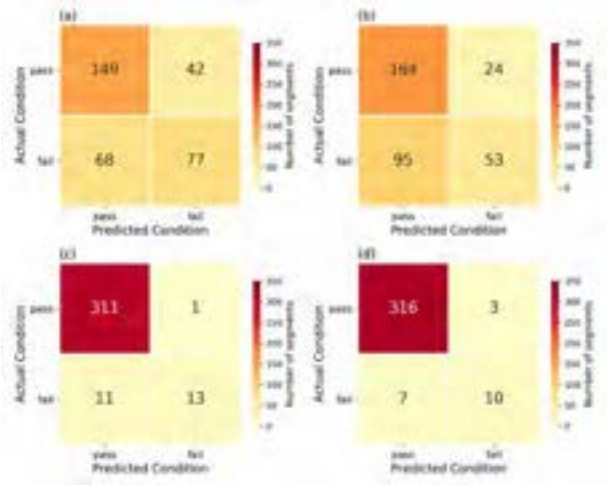

Figure 10. Confusion matrix of nearby-assets modeling: (a) Flexible Pavement-Pothole, (b) Shoulder-Pothole, (c) Slope-erosion, (d) Slope-erosion pattern

Table 7. Summary of the obtained accuracies

Asset/Defect	Accuracy		Improvement
	Single asset	Nearby-asset	
Flexible Pavement-Pothole	65.2%	67.3%	3.22%
Shoulder-Pothole	59.5%	64.6%	8.57%
Slope-Erosion	92.9%	96.4%	3.77%
Slope-Erosion Pattern	94.9%	97.0%	2.21%

5 Conclusion

In this study, we examined the impact of interrelations between nearby assets in the accuracy of their condition predictions. We selected three assets (flexible pavement, shoulder, and slope) to investigate how considering the condition of nearby assets into the condition prediction of each one improves the accuracy of predictions. To this end, we developed prediction models in two different scenarios: when the conditions of nearby assets were and were not considered as a predictor. We then implemented the proposed methodology on a case study in the state of Virginia. The results show that in all of the selected asset items, when the conditions of nearby assets were included in the modeling, the accuracy of condition predictions increased. This highlights the interrelation between nearby assets and its impact on the condition of individual asset items. With potentially increasing the accuracy of deterioration models, the results of this study could benefit the optimization and scheduling of maintenance activities and facilitate planning for an optimum and effective Life Cycle Plan (LCP). In this study, we applied the methodology on three assets. Similarly, the idea could be applied to the other highway asset items with more possible interrelations. Furthermore, we considered weather, traffic, and maintenance as major contributing factors to the degradation of the selected assets. However, other factors such as construction quality potentially impact the condition and could be taken into account in future studies. Another limitation of this study is that we performed the feature reduction using a traditional approach (correlation matrix). It is suggested that future studies utilize other techniques as well.

Abstract –

Unmanned Aerial Vehicles (UAVs) are an emerging technology that serve a range of applications for construction purposes including the creation of site survey maps, jobsite monitoring for routine progress reports, and structural inspections. Though while promising, drones have not yet been widely utilized by the construction industry to their fullest potential and there are still many areas to explore. One such activity is utilizing drones to optimize concrete delivery to a jobsite. Ready-mix concrete is an essential part of many projects, but its quick setting time makes proper delivery planning essential. The purpose of this paper is to investigate the application of UAVs and traffic data in scheduling a concrete delivery and develop an overall framework to optimize this activity. The proposed Automated Construction Data Acquisition and Simulation (ACDAS) framework is comprised of three main steps: collection, simulation, and reporting. To implement the concept, traffic data of a construction site in San Luis Obispo, California was collected and EZStrobe discrete event simulation modelling was used to model three potential routes from a local concrete batch plant to the specified job site. The model was able to predict the most efficient route for concrete delivery in a congested traffic area.

Keywords – Unmanned Aerial Vehicles; UAVs; optimization; ready mix concrete; construction planning, delivery

1 Introduction

A large amount of information is involved in the planning of construction projects and the interdependency among information imposes a heavy burden on planners [1]. Construction projects often involve huge operations, with activities taking place over large areas so one of the major issues that construction practitioners struggle with is having real-time control of the project. This is simply because real-time control requires a high volume of real-time data. Without a comprehensive set of real-time data about all parameters that impact the project, it will be difficult to reach the optimum productivity of construction activities. The most common tools used for recording visual data on construction sites include digital cameras, smart phones, tablets, laser scanning devices, and terrestrial and aerial unmanned vehicles [2,3]. Information that is collected manually generally is not comprehensive and does not relate the data to other parameters that impact the project. In recent years, Unmanned Aerial Vehicles (UAVs) have gained popularity thanks to their demonstrated superiority over traditional methods in various construction tasks by offering an opportunity to capture information for visualizing site layout, planning, and organization in real-time [4]. Drones are currently used in construction to examine terrain at future construction sites, track progress at existing construction sites, inventory the assets, and provide routine facility maintenance [5]. They achieve this by using LiDAR (a detection method utilizing lasers) or a technique called Photogrammetry which uses photography to extract measurements of the environment. Overlapping imagery provides multiple perspectives of the same feature and allows for distance and volume measurements to be taken and provides outputs in the form of "point clouds", 3D images used to render the observed environment in a virtual setting [6]. While drones are a proven powerful tool, they have not yet been widely utilized by the construction industry. This has been partly due to low familiarity and autonomy of project teams with the use of the visual data technologies [7]. Because of this, many aspects of the construction process could still incorporate drones to improve efficiency.

One integral activity that could benefit from UAV incorporation is scheduling concrete deliveries to a construction site. Delivering concrete to a jobsite is an essential step in many construction projects and must be completed with precision. Procuring, delivering, and pouring concrete is a major milestone in many projects as concrete is often the foundation. Propper planning is essential as conflicts between delivery and production

will arise during the execution of plans which can cause chaos in operations management [8]. Planning is especially important for the ready-mix concrete (RMC) industry as it has more potential transport barriers than any other manufacturing industry since RMC has a low value-to-weight ratio and is highly perishable as it must be laid on site before it solidifies [9]. Per ASTM C94, concrete discharge should occur within 90 minutes after the introduction of the mixing water to the cement and aggregates [10]. Going over this threshold can result in the batch being sent back to the plant and essentially wasted. Therefore, optimizing the travel time and distance the concrete travels in the truck is extremely important to ensure the concrete is poured within the 90-minute window.

Unfortunately, this time constraint can pose a problem since transportation of RMC is heavily influenced by current traffic conditions such as traffic congestions [11]. Understanding the access routes available for travel to the construction site and their potentials for congestion. While the traffic impact caused by isolated incidents such as car accidents cannot be predicted, understanding overall traffic patterns can be an important tool in concrete delivery planning. The time chosen for a concrete delivery can have a significant impact on the success of the delivery as the travel time between concrete batching plants and construction sites can significantly fluctuate at different hours of the day and on different days of the week [12]. Therefore, barring the unexpected, historical traffic data is a useful resource in selecting the optimal time to leave. In addition to traffic delays, pedestrian and bicycle traffic can also impact concrete dispatch by increasing the amount of time the concrete is in transport. This issue can be assumed to be especially pertinent to college campuses and city centres, locations often undergoing construction activities. All these hurdles pose the question: how can concrete be delivered efficiently?

This constraint can be referred to as the Concrete Delivery Problem (CDP). The CDP aims to find efficient routes for a fleet of (heterogeneous) vehicles, alternating between concrete production centres and construction sites, adhering to strict scheduling and routing constraints. Procuring and coordinating a fleet is especially important since the amount of concrete requested by a single customer typically exceeds the capacity of a single truck [13]. When multiple deliveries are needed, the temporal spacings between the consecutive deliveries may not exceed certain limits (time lags) to prevent the concrete already poured from partially hardening before the rest of the supply arrives at the site [14]. Therefore, with multiple deliveries (variables) required, optimizing the concrete delivery path is essential to avoid time-induced failure.

2 Background

With such a high level of uncertainty in concrete operations travel times, traditional practices for scheduling concrete production and delivery are largely based on trial and error and depend on the dispatcher's experience [15]. Transitioning from this reliance on human intuition to sophisticated data collection and modelling techniques can help to optimize concrete delivery time. This paper seeks to utilize data collected by UAV, Google Maps, and local transportation departments to model and simulate concrete delivery to a construction site. The model output is expected to impact the construction schedule and provide more reliable dates and times to pour the concrete.

2.1 Traffic Impacts on RMC Delivery

Concrete delivery is an integral part of the construction process. RMC delivery planning is mainly determined by skilled batch plant managers that schedule truck assignments to single deliveries and estimate the vehicles needed such that the total demand can be satisfied. The goal is to plan the whole process optimally to ensure utilization of machinery and workers of the batch plant and construction site [11,16]. A major variable in concrete delivery is traffic. Because of this, traffic patterns and their effects on construction activities have been investigated. Carr 2000 created a Construction Congestion Cost system for the Michigan Department of Transportation to balance construction productivity and traffic delay using 5 excel sheets to produce an output of daily user cost, total user cost, and project cost [17]. Naso et al. 2007 determined that on-time delivery of RMC can be significantly affected by peak-hour and non-peak-hour traffic [18]. Hadiuzzaman et al. 2014 directly utilized traffic information by creating a construction-traffic interdisciplinary simulation (CTISIM) framework based on high level architecture [19]. After determining the optimal arrangement of truck-mixers, their deviation between simulated and requested arrival of truck mixers was reduced by 68.7%, compared to the deviation for the arrangement as in the off-peak hour. In addition, their requested and optimized arrival intervals were all below 5.0 min, showing the feasibility of their integrated simulation model. These studies highlight that any useful simulation model for concrete delivery must consider traffic factors and conditions.

2.2 Simulation Modeling

The construction industry has embraced the power of simulation in recent years. Construction Simulation can be defined as the science of developing and experimenting with computer-based representations of construction systems to understand their underlying

behaviour [20]. Various researchers have utilized this to solve problems related to construction planning and activities.

Simulation modelling has been investigated as a means for optimizing scheduling of various construction-related activities. Maghrebi et al. 2015 investigated six machine learning algorithms tailored to RMC dispatching and compared them to observed human decision data that was employed for a specific case study [21]. While some models worked faster than others, they all were more successful than the human-decision control. Torjai and Kruzslicz 2016 sought to optimize the delivery of biomass from satellite storage locations to a central biorefinery and found that the mean trip duration is a good estimation of the minimal number of required trucks and a schedule without truck idle time was always found even when the number of trucks had been locked at its minimum [22]. Razavialavi and AbouRizk 2017 outline a framework to enable planners to anticipate site layout variables (temporary facilities size, location, orientation) and construction plan variables (resources and delivery plans) to simultaneously optimize them in an integrated model [23]. Khan et al. 2017 describes the implementation of a failure mode, effects, and criticality analysis (FMECA) tool and discrete event simulation to assess supply chain risks, identify vulnerabilities, and measure the impact of disruptions of a ready-mix concrete supply chain [24]. Kim et al. 2020 proposes a dynamic model for precast concrete production scheduling by using discrete-time simulation method to respond to due date changes in real time and by using a new dispatching rule that considers the uncertainty of the due dates to minimize tardiness [25]. The results of these studies indicate that simulation modelling is a viable method for planning and optimizing activities and should be investigated for applying to ready mix concrete delivery.

Although these studies indicate that simulation modelling is a proven tool that can be used to charter the optimal path from a concrete batch plant to a job site, they all share a limitation in that they do not account for the impacts smaller scale factors, mainly pedestrians and bicyclists, can have on deliveries to populated areas and many do not explicitly use data collected by drones, which could prove a beneficial addition.

While there are many studies on the impact construction activities have on pedestrians, no previous studies have been found that investigate how pedestrians and bicyclists impact the construction schedule. While this may not seem like an issue at first glance, underestimating the impacts of non-vehicles on construction can have just as much impact when trying to prevent delays. Take, for example, a model that perfectly simulates the local traffic data in San Luis Obispo, California and schedules the optimal concrete delivery to Cal Poly to arrive at 8:05 AM on a Tuesday. This falls during a passing period where thousands of students will be entering and leaving campus on foot and on bike. This severely compromises the simulation model and what was originally thought to be the best choice based solely on vehicular traffic can end up being the worst when pedestrian and bicycle data is included. Therefore, data should be collected on pedestrian and bicycle patterns around populated job sites; this can be accomplished with unmanned aerial vehicles (UAVs).

3 Methodology

The literature review conducted by the authors revealed both drones and simulation modeling are effective tools for construction practitioners, but they have not been combined for concrete delivery applications. The following is a contribution to bridge this gap. Traffic data and drones can be used to provide data to model the optimal delivery scenarios. The proposed framework is named Automated Construction Data Acquisition and Simulation (ACDAS) and consists of three modules.

3.1 Simulation Model

The following sections detail the framework modules created. The steps in sequence are Collect, Simulate, and Report. Fig. 1 summarizes the steps of this framework.

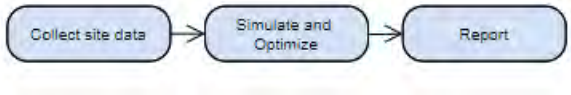

Figure 1. Main Steps of ACDAS Framework

3.1.1 Data Collection

The first step of this framework is to capture relevant traffic data for the potential concrete delivery routes. For this proposal, the data collected is two-fold: traffic data for the roads leading to the site and traffic data immediately on and around the site. Historical traffic data for the roads leading from the concrete batch plant to the job site will be collected from Google Maps, a common GPS system used by drivers (Fig. 2). Google Maps not only provides data for how long a trip will take at the given time; it can also predict the duration of a trip planned in the future based on historical precedents. This allows the eventual model to compare the durations of different paths and different departure times. In addition to Google Maps data, local databases can be utilized to determine information about the roads relevant to the planned delivery. For our experimental study in San Luis Obispo, the County of San Luis Obispo provides Traffic

Counts can provide valuable information to our model [26]. This site lists the peak hour (the time and traffic volume for the highest AM and PM peak hour for the duration of the count) and peak day volume (the day of the week and the traffic volume on the highest day for the duration of the count) for all county maintained roads. This information is compiled for every day of the year from 2015 to present and thus can provide good estimations of historical precedents.

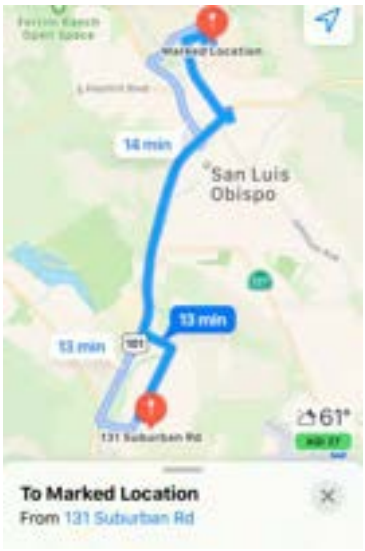

Figure 2. Sample Google Maps routes between a concrete batch plant and construction site.

While traffic data can predict the impact vehicles will have on deliveries, other site-specific factors such as pedestrian traffic and bicycles should be incorporated into the analysis. Drones can be utilized on construction sites to survey conditions around the site to determine when any pedestrian- or bicycle-induced traffic could occur. Drone data collected daily can be fed into the model to determine if there are any patterns in small-scale traffic at specific times in the day to allow the model to account for and avoid these bottlenecks. The following case study is the first iteration of this framework so data from drones was not included but will be the focus of future expansions.

If the collected data is not sufficient, the collection process can be expanded to fill in any gaps. Once all required data is captured and complied, the next step is to input that data into a simulation model.

3.1.2 Discrete Event Simulation Model

The modelling steps of the concrete delivery process are shown in Fig. 3. The first step involved is developing a discrete simulation that depicts the real-world scenario of the concrete delivery process. The model for this study was built using EZStrobe simulation software [27]. EZStrobe is used in the construction industry as a general-purpose simulation system designed for modelling construction processes. However, it is also utilized to model other types of systems because it is domain independent. EZStrobe takes multi-step activities, such as concrete delivery, and models them as just one activity and provides a duration that represents the time it takes to perform all n steps. After the simulation model is generated, it can be run for each of the route alternatives. The model results for each scenario are then analysed and summarized to highlight the most efficient route.

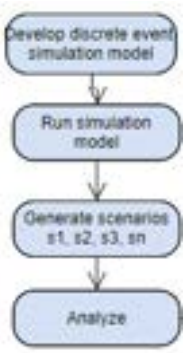

Figure 3. Development of the discrete event simulation model.

3.1.3 Reports

The purpose of this framework is to generate a report that accurately outlines the most efficient delivery path for a truck to take from a concrete batch plant to a job site. The report outputs include: the optimal route to take to the job site, the total delivery duration, the optimal time to start the delivery, the forecasted arrival time, and the number of trucks required. This report will aid Project Managers in planning the concrete pour activities months in advance and will allow the activity to proceed as efficiently as possible when the time comes.

3.2 Experimental Study

The proposed framework was implemented to verify its applicability. The implementation was specifically tried to verify how collected traffic data can help in developing an optimum schedule for the concrete delivery to the construction site. The site investigated in this study is a four-level 102,000 square foot construction project at the California Polytechnic State University campus in San Luis Obispo, California (Fig. 4). This site was selected because it can only be accessed by a limited

Figure 4. An image of the construction site investigated for this study.

number of heavy traffic routes. The goal is to utilize simulation modeling to determine the best route to deliver the concrete to the site to assist the project team in planning this activity efficiently. The preliminary implementation collected traffic data on three routes that started at a local batch plant and ended at the job site; these routes are denoted as R1, R2, and R3 (Fig. 5).

Figure 5. Project site layout before construction with potential delivery routes (Google Maps).

The traffic data collected was sourced using a combination of Google Maps data and local data. This data was fed into a developed simulation model that held the number of trucks available, number of mixing stations, and total amount of concrete required constant for each route (Table 1).

Table 1. Constants used in the simulation model.

nTrucks	Number of Mixer trucks	6
nStations	Number of loading Stati	1
AmtOfConc	Amount of Concrete in CY	720

Three simulations were run to account for each of the three routes. Each analysis follows the life cycle of a single truck and uses statistical modelling to determine the total durations of each step in the concrete pour activity and the total duration of the concrete pour event. The flowchart in Fig 6. summarizes the simulation model created in EZStrobe for Route 1. The circles represent the

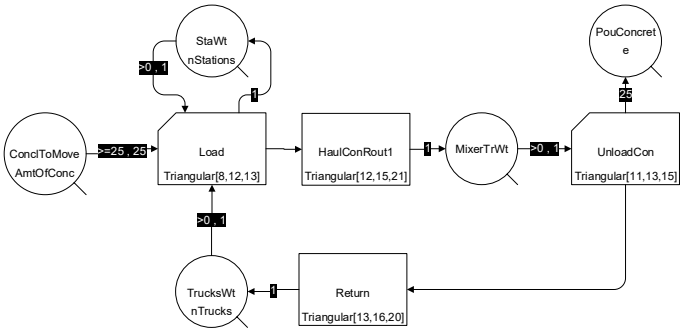

Figure 6. EZStrobe simulation model flow for Route 1.

queuing systems the trucks encounter such as loading and pouring while the rectangles represent the truck entity. When the entity (truck) and its resource (concrete) are two units (i.e. the truck cannot leave until all concrete is loaded or poured) the rectangle has a corner missing and when the entity and resource are one unit (i.e. the truck and concrete traveling together to the job site) the rectangle is intact. The model assumes each truck has a capacity of 25 CY and estimates of the minimum, mean, and maximum durations for each segment in the event (values denoted in brackets in each rectangle). A triangular distribution is used based on these values to determine the overall duration of each 25 CY delivered to the site; this process is repeated until all 720 CY of concrete have been delivered. At the end of the simulation a total activity duration is outputted. The process is repeated for Routes 2 and 3. A summary of the preliminary results for each of the three routes is highlighted in Table 2.

Table 2. Preliminary Results of the Simulation Model

Model Parameters	**S01**	**S02**	**S03**
Number of Mixer trucks	6	6	6
Number of loading Stations	1	1	1
Amount of Concrete in CY	720	720	720
Factory Loading Station Utilization	0.87	0.87	0.85
Mixer Truck utilization	1	1	1
Time of operation in hours	5.9	3.1	5.95
Production rate in CY/hr	133	131	135

The results of this experiment highlight the complex relationship between route selection and delivery time.

Immediately, it is noted from Table 2 that S01 and S03 (R1 and R3) are very similar with total operation times of 5.9 and 5.95 hours, respectively. Conversely, the results for S02 (R2) yield a duration of 3.1 hours, almost three hours faster than the previous two options. Looking at the results for all three routes shows the impact route selection has on the overall duration of a large concrete pour activity. The conclusion that can be drawn from this is R2 should be chosen over R1 or R3 for the concrete delivery in this specific task.

It is important to note that this analysis held the number of trucks present at the jobsite constant at 6 and only compared the different routes. If the number of trucks available were to change this model can quickly show how, if at all, that would impact the optimal route selection. Determining the number of trucks present is another key part of project optimization and is a function of the cycle time of each truck. Because the cycle time is in part determined by how long the trucks are driving from location to location, changing the selected route may (in some cases) allow for additional trucks to be added in the system if their cycle times are reduced substantially. This may be beneficial for projects prioritizing saving time over the incurred costs of expanding the truck fleet. If the number of available trucks is not subject to change under any circumstances this model will still optimize the trucks in their present condition.

Currently, we are working on including UAV data into the simulation model to account for small-scale factors such as bicycle and pedestrian traffic around the job site. Once the university population is back to normal, UAVs will collect data around the job site to determine time frames of peak-traffic. These times are hypothesised to occur in the morning and at passing periods throughout the day when students and faculty are going to and from classes. Our future analysis will reveal the magnitude of influence of these small-scale factors and if they should be considered in future simulation models. Through data collection, simulation, and analysis of multiple scenarios, better construction productivity can be achieved.

3.3 Conclusion

This paper proposes a framework for simulation modeling and drone integration in planning the delivery of a concrete pour activity. This framework is known as Automated Construction Data Acquisition and Simulation (ACDAS) and is achieved through a three-step process. First, the site conditions are quantified using vehicular traffic data and pedestrian and bicycle traffic data, with vehicular data sourced from Google Maps and local databases and pedestrian and bicycle data sourced from on-site UAVs. Second, a simulation model is developed using the collected information to investigate the many possible scenarios the delivery could take. Third, the model determines the most efficient option and outputs the optimal delivery path and delivery time the trucks will take from the batch plant to the construction site. This study will contribute to the construction industry in two major ways. Firstly, utilization of the ACDAS framework in concrete delivery will improve project performance by increasing the efficiency of concrete deliveries to a job site. This will minimize waste and maximize productivity which will lead to lower costs, fewer delays, and less wasted concrete in concrete activities. Secondly, the easy-to-follow nature of the ACDAS steps busts one of the major myths involving using drones (and other advanced technologies) in the construction industry, implementation is too difficult. With this ACDAS path laid out, it will be much easier for interested parties to invest in the new technologies described and utilize their benefits to improve concrete pour deliveries in their projects. Gaining experience in these technologies could also lead to improvements in other aspects of their projects as simulation modeling and drones have proven to be useful for other construction applications.

Our preliminary experiment proved the efficacy of using vehicular traffic data in a simulation model to determine the optimal route for trucks to take while delivering concrete to the jobsite. These findings are not exclusive to just concrete delivery. The constants in our model (Number of trucks, distance of R1, distance of R2, etc.) can be adjusted to fit other activities and routes relevant to the construction process and a similar analysis can be performed to find the optimal course of action.

A limitation of this framework is the lack of a major case study utilizing the ACDAS process in a large-scale construction project. Because of this, while optimization of individual activities has been tested and proven to work, the theorized effects of this framework have yet to be confirmed. Further research is already under way on expanding this topic to include UAV data and future publications will seek to qualitatively measure the efficacy and results of the ACDAS framework.

Abstract –

Steel embed plates are a vital component in connecting steel to concrete members. They are most often used in the construction of tilt-wall concrete buildings, but can be used anytime there is a need to attach steel to a concrete panel or slab. Proper anchorage and connection to concrete should follow the ACI standards. Inspections need to verify the correct location (x, y, z) of steel embeds until concrete placements are finished. Typically, embeds should not affect the positioning of reinforcement, unless specifically allowed in the specifications. Currently, the process of ensuring the position of embeds is completed manually, which is costly, time consuming, and involves errors in complex construction. This paper proposes an approach to ensure embeds are positioned as per the design and within the tolerance limits stated in ACI 117. The proposed approach maps the BIM model geometry into a 3D point cloud of the as-built construction. The mapping process uses different computing platforms that eventually result in a position deviation report in the x, y, and z directions. An experiment was developed and conducted in the laboratory to show the applicability of the method. The results showed high accuracy in capturing the steel plates' deviations from the original position and generated a meaningful report for improving quality control and quick rework.

1 Introduction

1.1 Overview

Steel embeds are an element of precast concrete construction that take the form of pipes, ducts, sleeves, and conduits [1, 2]. Embeds, also known as headed studs, serve as connectors of concrete and steel as modelled in Figure 1. These elements in embedded steel plates connect to structural steel framing, MEP components, and other elements of construction [3]. Embeds are utilized for purposes of ventilation, passing cables, and wherever proper connection to concrete is necessary [3]. Proper implementation results in cleaner and safer construction practices, whereas oversight in the manufacturing process can lead to system failures and construction delays [2, 3].

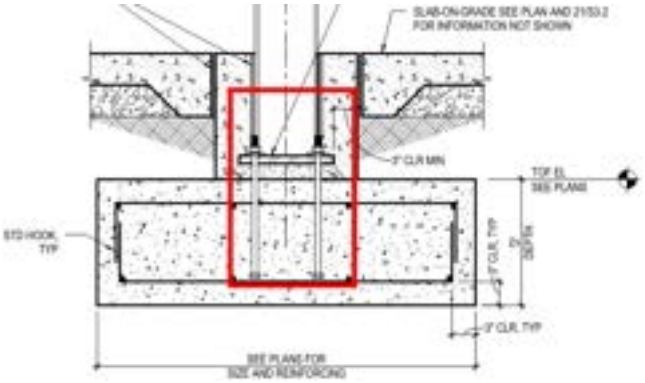

Figure 1. Model of beams connecting to girder at steel embeds.

Per ACI 318, embedment can be manufactured using any material that is not harmful to concrete, and that which is approved by a licensed design professional. Embeds made using aluminium must be coated to prevent corrosive reactions between aluminium and steel. Thus, they are typically manufactured using different materials as designed [1].

1.2 Design

The placement of steel embed plates should follow ACI 318 standards and cannot be implemented where concrete strength is decreased significantly. Proper positioning directly impacts RC strength, such as in the

reinforced concrete beam in a CMU wall shown in Figure 2, and thus guidelines set by ACI 318 and ACI 117 must be followed. Embed placement is permitted where (1) strength of concrete is not significantly decreased, (2) total embedment within a column does not surpass 4% of the area of the cross-section, (3) outside dimensions do not exceed 1/3 of the structure where embedded for pipes and conduits, (4) designed to resist effects of associated materials, temperature, and pressure, (5) not spaced less than three diameters on center, and (6) other limitations in Code 3.6 are maintained [5].

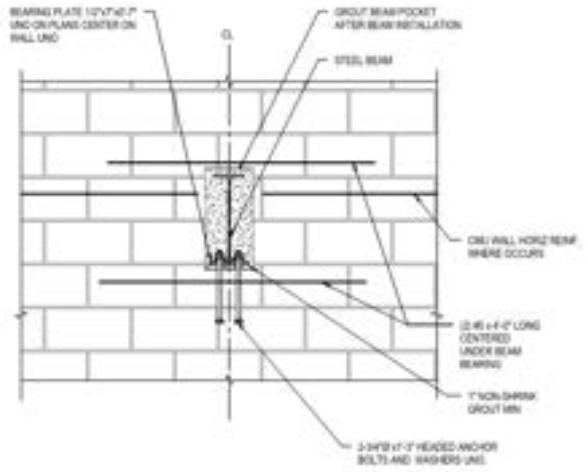

Figure 2. Bearing steel embeds on Concrete Masonry Wall.

Per ACI 117-23, embedment should meet outlined tolerances such that (1) horizontal and vertical deviation from the centreline of the assembly is ±1 in (25 mm), (2) the surface of an assembly from the specified plane for an assembly 12 in. (305 mm) or smaller is ±1/2 in per 12 in (40 mm per m), otherwise, it is ±1/2 in., and (3) anchor bolts and other elements follow through standards outlined [6].

1.3 Coordination and Construction

A careful review of formwork, embed, reinforcing bar, and structural steel drawings should be conducted to regulate work packages from multiple subcontractors [3]. Coordination should run through embed changes guidelines, shipping, on-site operations management, and construction procedures, as well as cover possible conflicts that may arise in any of these fields. Planning should be conducted to reduce potential damage to formwork panels and other structures in the installation of embeds [3]. Clear communication and coordination between parties responsible for design and construction should be the main goal.

Embeds should be placed as per the design. Proper layout reduces discrepancies in as-designed and as-built work. Quality in the field can be preserved by (1) providing sufficient control lines in order to provide accuracy and consistency in layout, (2) checking control lines back to primary control on ground, (3) revising dimensions prior to layout, (4) locating centerline, edges and sizes of embeds, and noting where placement is critical, to name a few [3]. Procedures for layout are outlined by the contractor, but coordination prior to construction is essential to reduce the need for rework in the long run. Installation of concrete should be conducted after all embeds are set, and supervision should be maintained to prevent movement or displacement of embeds as much as possible. Placement of steel embeds in concrete walls or foundations present a great challenge to contractors. The misalignment of these small supports, in addition to non-compliance with code requirements, can result in costly rework and design changes. Hence, it is imperative for contractors to have a tool that allows for a comparison between as-designed and as-built embed locations to capture misplacement or out-of-tolerance variation.

In the past years, smart sensing technologies have gained great interest in the construction sector. Laser scanning and photogrammetry are being used in many aspects of construction. One of them is capturing reinforcement layout and quality of the formwork geometry [4, 7-9]. However, none of these studies address the proper position of concrete embeds prior to concrete casting. Consequently, the objective of this study is to develop an approach to identify the tolerance of the concrete embeds in the three directions (x, y, z).

2 Background

Traditional methods of ensuring embeds are properly placed involve manual inspection performed by quality personnel which is time consuming and costly [10]. Three-dimensional models that capture precise details can be used for planning and coordination of systems like earth retention, safety perimeters, shoring and formwork, post-tensioning, mild reinforcing, embeds, and equipment such as screen walls, tower cranes, and material hoists. Team members at the jobsite can capture value from Building Information Modelling (BIM) by using apps on tablets and smartphones, and workers can transfer coordinates and linework from 3-D models to total stations for concrete layout. The visual nature and the enormous information provided by BIM models help crews understand exactly what they are building and when, while in the field [11]. The approach of directly identifying an object with a laser scanner and comparing it to a uniquely placed object within a BIM model is known as the “Scan-vs-BIM” approach [12]. This allows for a quick and efficient comparison of the as-built state

to the design model to determine if there are any unacceptable discrepancies. This is a common approach used in the relevant research discussed.

2.1 Dimension and position estimation for cast-in-place concrete and other applications

Various studies have been conducted using BIM technologies for quality assurance of concrete structures. Kim et al. describe a holistic approach for dimensional and surface quality assessment of precast concrete elements based on BIM and 3D laser scanning technology. They created a framework consisting of four cores: inspection checklists, inspection procedure, selecting an optimal scanner and scan parameters, and the inspection storage and delivery method. Their BIM and laser scanner quality assessment system were successful in estimating precast panel dimensions with an average error of 2.5 mm and detecting spalling defects with an accuracy of 86.9%. However, their results are limited to precast elements that are rectangular and uniform in thickness and their system did not fully automate the process of comparing the as-built data to the design model [2]. Wang et al. completed a similar study and estimated the dimensions of precast concrete elements with a direct scanning error of 1.7 mm [8]. Kim et al. achieved full automation by developing a non-contact Dimensional Quality Assurance (DQA) technique that automatically and precisely assesses the key quality criteria of full-scale precast concrete elements. They achieved this by developing a new coordinate transformation algorithm to account for the scales and complexities of precast slabs to fully automate the DQA. Precise dimension estimations of the actual precast slab were determined using a geometry matching method based on the Principal Component Analysis (PCA), which relates the as-built model constructed from the point cloud data to the corresponding as-designed BIM model. Lastly, a BIM-assisted storage and delivery approach for the obtained DQA data was proposed so that all relevant project stakeholders can share and update DQA data through the manufacture and assembly stages of the project [4]. Tan et al. used LiDAR and BIM to inspect the geometric quality of individual structural, mechanical, and MEP elements of prefabricated housing units. Their results showed the technique provides inspection results with 0.7 mm and 0.9 mm accuracy for structural and MEP elements [13].

2.2 Related studies on Concrete Embeds inspection

While there are not many studies specifically tailored towards concrete embeds, there has been work done on a similar topic: automated dimensional quality assessment for formwork and rebar of reinforced components. DQA of formwork and rebar is relevant to concrete embeds inspection because embed plate sizes or locations may force altering of formwork tie locations and all embeds should be set before concrete placement — just like the formwork and rebar [3]. Figure 3 demonstrates the interconnectedness of formwork, rebar, and steel embeds as they are all present in the stage of construction that precedes concrete pouring. Because of this, any demonstrated successes in using laser scanners to inspect formwork and rebar can be assumed to have the capacity to inspect steel embeds as well.

Figure 3. Formwork, rebar, and embeds positioned prior to concrete pour.

Kim et al. conducted a study focusing on DQA of formwork and rebar during the fabrication stage. The authors describe a TLS-based automated DQA technique that measures the dimensions of formwork and rebar of RC elements to assess dimensional conformity with design specifications. The proposed method resulted in small average discrepancies in the items measured: rebar spacing (2.15 mm), formwork dimension (2.52 mm), concrete cover (2.18mm), and side cover (3.12 mm). The experimental results demonstrate that the proposed technique yields accurate solutions for the formwork and rebar DQA during fabrication before concrete is poured [10]. Wang et al. developed a system to automatically estimates positions of precast concrete rebar using colored laser scan data. Their technique was successful with the vast majority of differences between the rebar positions estimated by the developed technique and those measured by the manual inspection under 1.5 mm (137 out of 142) and an average difference of 0.9 mm [7]. Gikas combined high accuracy total station and laser scanning surveys to check 3D geometric documentation of the formwork for a highway tunnel in full expansion and compared against the design drawings. The laser

scanner method arc radius of both sides of the formwork deviate from their nominal values by less than 2.0 cm [14]. Turkan et al. used two methods based on extensions of the discussed "Scan vs. BIM" object recognition framework to detect and track temporary structures (formwork, scaffolding, and shoring) and secondary components (rebar). Their experimental results showed it is feasible to recognize secondary and temporary objects in TLS point clouds with good accuracy using their two novel techniques [12].

While the various studies investigated in this literature review are not specifically targeted towards steel embeds in concrete, their demonstrated successes in the areas of rebar and formwork indicate that the technology for high-quality dimensional quality assurance using laser scanners currently exists.

3 Methodology

The proposed components of the approach used to identify the concrete embedded steel plates is shown in Fig. 4. In the following subsections, details are provided on each stage.

3.1 Data Collection

The data of the concrete embed is acquired using FARO Focus 350 [15]. Proper planning of the scan position, resolution, and quality should be completed before conducting the actual scan. A resolution of 1/4 or 1/5 and quality of 4x are reasonable for outdoors in sunny condition scans. The engineer should ensure enough data is collected to ensure enough scans are completed to achieve proper registration with high accuracy.

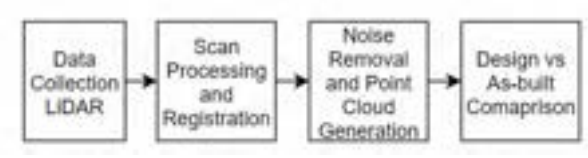

Figure 4. Workflow of identifying concrete embedded steel plates

3.2 Scan Processing and Registration

FARO SCENE software is used to process, register, and generate the point cloud data [16]. Processing the scans is a stage where the captured data is handled to improve the scan quality; this ensures the best results in 3D data. This step is followed by scan registration, which involves aligning multiple scans in a parent coordinate system using reference positions common between scans. These references can be natural or artificial that help in completing the registration.

3.3 Noise Removal and Point Cloud

During the data collection, the required scan parameters are identified. These parameters determine if the scan is acceptable or not. Based on these parameters the scan limit can be defined. Scan points outside of the acceptable parameters are considered "noise." Different filters such as Outlier, Dark Scan Points, and Smooth are available in SCENE software and can be applied to minimize the noise in the data. Once the scan nose is removed from the registered scans, the final step involves generating and exporting the point cloud model that will be used in the analysis and the as-built comparison.

3.4 Design Vs As-Built Comparison

The comparison of the BIM model to the as-built model to determine the deviation can be done in different ways. This step can be completed by comparing the BIM model to an as-built point cloud or comparing old as-built to new as-built. The latter is most widely used in quality control. The analysis of different as-builts is completed using CloudCompare vs2.11.0 [17].

4 Experiment and Results Analysis

The proposed approach involved testing in the lab by building a formwork of a square concrete footing with rebar and steel embed plates. Then, the footing was scanned to generate the as-built point cloud. In the next stage, the steel plate position was modified, and another round of scanning was completed to generate a second as-built point cloud model. In the following sections, more details are provided about the experiment and testing procedures.

4.1 Experiment

The designed BIM model of a concrete footing is shown in Fig. 5a. This plan view shows the dimensions of the footing and distances in relation to the steel plates. The footing itself was designed to be 1.17 m wide by 1.22 m long. The distances from the edge of the steel plates to the short inner edge of the footing are 0.21 m and 0.20 m. The distance between the steel plates is 0.40 m. The distances from the outer edges of the steel plates to the longer inner sides of the footing are 0.48 m and 0.45 m. The footing formwork has a depth of 2 ft and #4 rebar used in both directions. Fig 5b shows an image of the constructed formwork of the footing, steel plates and rebar. Fig 5c shows the point cloud of the scanned footing. This 3D point cloud informs on the dimensions of the actual structure, and the deviations from the intended design. By comparing the constructed footing measurements with measurements obtained from the point cloud model, the results show that a deviation of

0.7 mm is captured for one side and a 0.3 mm deviation between Fig 5a and 5e. The scanner registration accuracy is 0.7 mm as shown in Fig 5d. In conclusion, the scanner achieved high accuracy and can be used to verify the measurement and conduct quality control in construction.

5a) with the as-built point cloud model of the footing (Fig 5c) or, Method 2: compare as-built point cloud model (Fig 5b) to a modified as-built model (Fig 6). In this experiment, we used Method 2. After constructing the footing as per the BIM model, the footing was scanned to

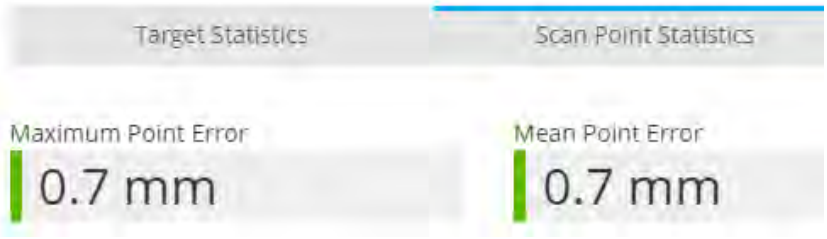
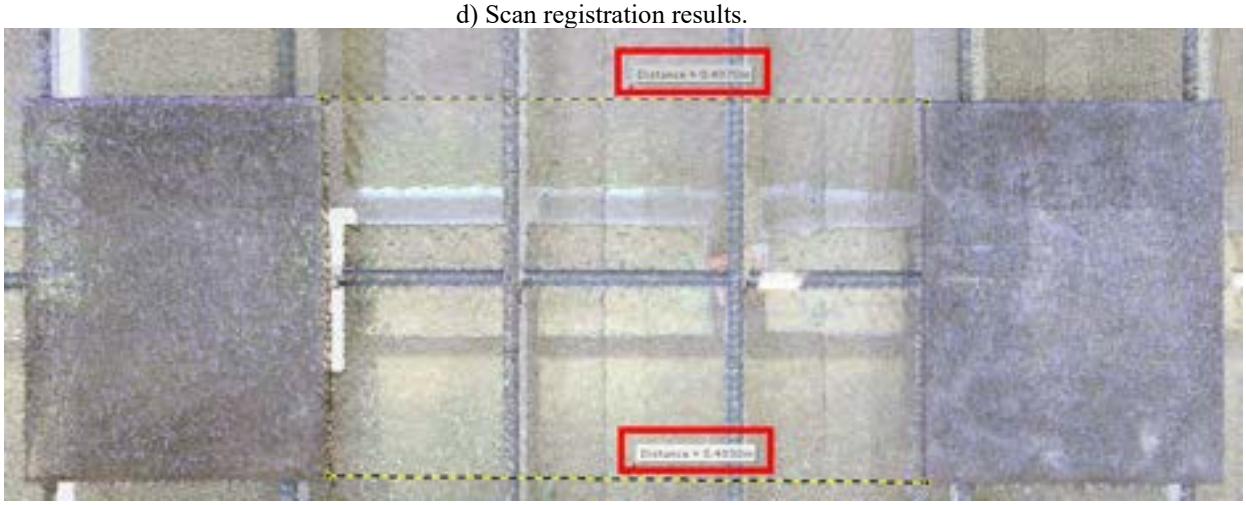
b) Constructed footing

c) 3D Poind Cloud of the footing (as-built 1)



d) Scan registration results.



e) Steel Embed Plates Spacing and Position

Figure 5. Experiment Design and Components

4.2 Results and Analysis

The proposed approach can be verified in two different ways. Method 1: compare the BIM model (Fig

create an as-built model (as-built 1). In the next stage, we modified the steel plates' location, as shown in Fig. 6, and then rescanned to generate another point cloud model (as-built 2). The embed placements were changed from

the layout in Figure 5c to the layout in Figure 6. Each layout was scanned using the FARO 350 laser scanner, and the new layout was compared to the original. Figure 7 shows the two layouts with embeds 1 and 3 denoting the original placements and embeds 2 and 4 being the final positions.

Figure 6. New layout with steel embed plates shifted to the left (as-built 2).

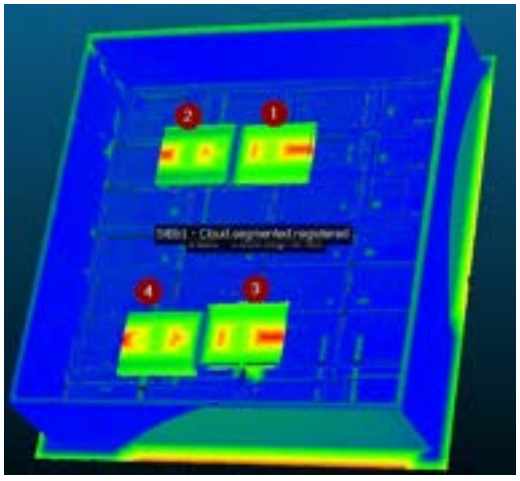


Figure 7. Original embed locations (1 and 3) and moved locations (2 and 4).

Figure 8 shows the heat map that was generated in the model analysis comparing the moved embeds (embeds 2 and 4) to the original layout (embeds 1 and 3). The heat map essentially detects and informs engineers if the embeds are in the correct position by overlaying the as-designed model with the as-built model. For this experiment, the heat map highlights areas in blue to denote negligible change (less than 0.5 mm) between the two scans, which is correct because no adjustments were made there. However, the location where the embeds were moved to is in stark contrast with the surrounding rebar with deviations ranging from 3 cm to 8 cm. This is because the model expected this location to have rebar, but instead it has embeds. Note that the largest deltas, marked with red and orange, occur at the areas that should have open space but now have embed plates. The regions where the embed is on top of rebar still have a difference but the heat map shows a smaller delta because the difference in elevations between the rebar and embed plate is smaller than the elevation changes between the bottom of the formwork and the embed plates.

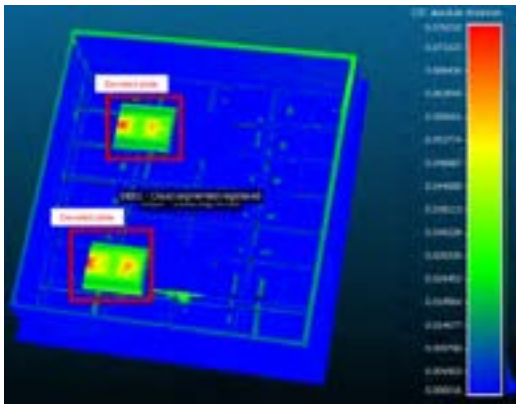

Figure 8. Heat map identifying out of compliance regions.

In addition to identifying which areas are out of compliance, it is also helpful to know how far the items have moved to assist in adjusting the layout to its correct position. Comparing the original and moved layouts provides distance values for how far out of tolerance each embed is. The delta of the left corner of each embed is measured by the software as shown in Figure 9. The shift of the top embeds from location 1 to 2 was 0.262 m horizontally. The shift of the bottom embeds from location 3 to 4 was 0.269 m in magnitude with components in the x, y, and z directions identified. Note that the model can capture differences in a three-dimensional coordinate system which provides precise direction on how far out of tolerance the items are.

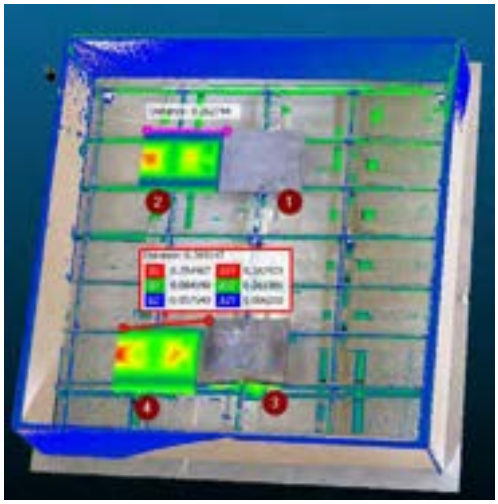

Figure 9. Determination of how far the embeds moved.

This experimental study showed a successful application of LiDAR technology to inspect the as-built conditions of formwork with steel embed plates. The scan created an accurate point cloud model of the formwork and extracted dimensions. CloudCompare vs2.11.0 compared the two scans and generated a heat map that showed the differences between the two. This application can significantly improve rebar and embed inspections, especially for large sites, by linking all the deviations to surveying data to quickly identify what items are out of compliance and where they are.

5 Conclusion

Rework and quality control of steel embed plates installation in construction are difficult tasks for construction professionals. Even small deviations in embeds position can be costly to correct, especially after the concrete hardens. This paper proposed a method to enhance the quality control of steel embed plates installed in concrete and verifies the geometry of the formwork. The method uses a high-quality LiDAR system (laser scanner) and multiple analysis platforms. A 3D point cloud model that is generated from the laser scanner allows for better analysis and reduction of costly rework compared to traditional methods.

The developed method was implemented using a FARO Focus 350 laser scanner. A custom-built 1.17m x 1.22m formwork was built with rebar and steel embed plates placed as per the BIM design that was created. The constructed formwork was scanned to generate an as-built model of the formwork (as-built 1). Then, the position of the steel embed plates was modified and another round of scanning and registration was completed to generate as-built 2. Cloud to Cloud comparison was conducted to capture the deviation the two as-built models in three directions (x, y, z). The experiment showed high accuracy in the results (0.3 mm). This methodology will be especially helpful for capturing the deviation of complex steel embed plates layout so construction practitioners can quickly inspect concrete formwork and embeds. Using LiDAR for concrete embeds inspection will result in increased time and labor savings and can be extremely helpful to construction practitioners.

Future research will focus on developing a tool that automatically captures the deviations once the design and point cloud model are loaded. Currently, the process follow many steps to generate the deviation report. Thus, eliminating steps that require user input will speed up the process and make the framework more user-friendly.

Abstract –

Aging society is not only a crisis in the developed world but also a severe challenge in some emerging economies. However, the awareness of population aging and gerontechnology is far from sufficiently addressed in the architectural design education in universities. Therefore, an interdisciplinary approach in design education is urgently needed to raise the awareness of the aging crisis among the future architects, interior designers, and beyond. This article introduces a novel model of a design seminar offered by a German University, addressing population aging issues in the architecture department. The syllabus, formality, and the expected results of the seminar are revealed in detail. The participants are encouraged to apply interdisciplinary knowledge such as barrier-free architecture, mechanical engineering, electrical engineering, robotics, medicine, psychology, and business to achieve the goals of the seminar. Based on the originality and degree of completion, several students' works are selected and reported, targeting a variety of diseases or syndromes related to aging, such as dementia, immobility, and tremors. Overall, participants of this seminar are motivated and have positive feedback on this seminar, oftentimes claiming that they have seldom studied similar topics in previous architecture education. This enables students from architecture as well as other fields to be better prepared to tackle the upcoming challenges such as labor shortages and infectious diseases in a rapidly aging world. Furthermore, the seminar creates novel concepts that serve as a win-win "honeypot" for both students and their instructors, potentially sparking research topics and start-ups with concepts fostered in this seminar.

Aging-related diseases; Bauhaus 2.0; COVID-19; Dementia; Design education; Gerontechnology; Interdisciplinary

1 Introduction

The worldwide crisis of population aging has drawn the attention of more and more countries. According to the United Nations, the percentage of global older population 60 years or over is expected to rise to 21% by 2050 compared to 13% in 2017 [1]. Many studies pointed out that as the average life expectancy of the world's population increases, the number of people suffering from aging-related diseases increase as well. Therefore, the significance of gerontechnology became prominent in recent years. The terminology of gerontechnology was officially proposed at the 1st International Congress on Gerontechnology, Eindhoven, Netherlands in 1991 [2]. It is a broad interdisciplinary domain that includes subjects such as gerontology, assistive technology (e.g., medical devices, home automation, companion robots, etc.), and inclusive design. Ever since its establishment, researchers and developers around the world continuously made contribution in this field. In architectural design education, however, population aging and gerontechnology does not seem to draw sufficient attention. Furthermore, it is predictable that the ongoing coronavirus pandemic will fundamentally reshape architectural design, challenging doctrines formed since the Modernist Movement such as open plan and shared spaces in order to assist and protect habitants especially the vulnerable elderly [3]. As a result, gerontechnology naturally becomes a powerful tool in this transition. Therefore, future architects and interior designers need to be prepared to respond to the challenges that aging society brings. In conjunction, architecture educators need to provide them with opportunities to study in the related fields.

2 Research aim

This paper reveals an innovative method of teaching interior design seminars in the context of aging society,

mimicking the environment of a business incubator, which distinguishes itself from traditional interior design studios. It involves cross-disciplinary knowledge in inclusive design, mechanical engineering, electrical engineering, robotics, medicine, psychology, and business, based on the key concepts and methods of a large European research project. The results of selected student projects addressing several commonly seen aging-related diseases or syndromes will be presented. Last but not least, the effectiveness and key learnings of this teaching process will be discussed.

3 Methods

Oftentimes, in an interior design or architecture studio, after reviewing exemplary designs, a certain design task is given to the students. Next, students and instructors work together, pushing their sketches iteratively into final plans and renderings. In the end, the design is presented in the form of posters and architecture models.

The seminar presented in this paper entitled "Incubator" is offered to the master level students primarily from an architecture background, also among other fields. Incubators are used in the innovation science and industry to specifically generate innovations or to systemize the innovation process. The aim of the seminar is to let the student study and develop their projects using interdisciplinary knowledge in a simulated environment of an incubator. The key concepts and methods of this seminar are based on the REACH project, a large European interdisciplinary research project aiming at developing customized healthcare systems to promote the elderly's activity level and independence [4]. In REACH, a special type of smart furniture named Personalized Intelligent Interior Unit (PI^{2}U) was developed, which seamlessly integrates the required functions (e.g., unobtrusive sensing and monitoring, training/gaming, nutrition, AI assistant, etc.) into the different living environments. The development process of the PI^{2}Us (including but not limited to PI^{2}U-SilverArc, PI^{2}U-MiniArc, PI^{2}U-SilverBed, PI^{2}U-ActivLife) follows iterative design principles on both hardware and software levels, which allows the project team to optimize the products through prototyping, testing, analyzing, and refining (see Figure 1).

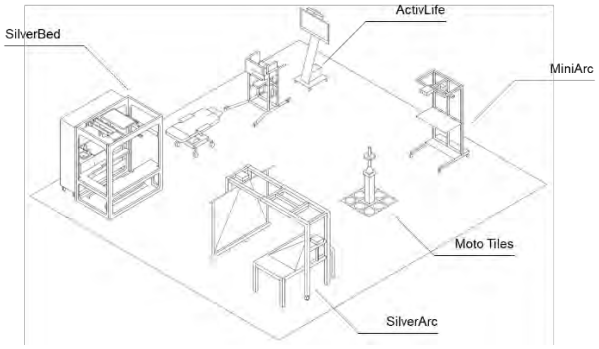

Figure 1. Various PI^{2}Us developed in the REACH project

Based on a variety of PI^{2}Us, the project team proposed a modularized smart home solution, namely the Total Room Assistive Care Kit (TRACK) concept (see Figure 2), which integrates PI^{2}Us and key technologies in REACH to create a complete interior living and care environment for elderly users in different living environments such as home, hospital, and community [5].

Figure 2. TRACK concept including real-life testing of the PI^{2}Us

At the beginning of the seminar, the instructors provide an overview of the key concepts and methods in the REACH project and give various lectures on topics such as the phenomenon of population aging, aging-related diseases, gerontechnology with a special focus on the field of Ambient Assisted Living (AAL), and previous examples from both selected student projects and other relevant research projects such as USA² [6] and LISA "Habitec" [7]. After, specific tasks are defined for all groups with expectations to develop their own approaches and strategies of the solutions based on the abovementioned concepts and methods. The proposed solutions must be interdisciplinary approaches, combining knowledge in barrier-free architecture, mechanical engineering, electrical engineering, robotics, medicine, psychology, and business. Seminar and demonstration sessions are held in the chair's laboratory. By supervising the students' work and evaluating their intermediate presentations, the progress is ensured, and relevant questions are discussed. This process fosters students' awareness of subject-specific problems, and furthermore, uncovers their personal weaknesses and strengths. Through this problem-oriented approach, the course participants are motivated and thus maximize their knowledge gain. The teaching process is highly student-oriented. Work groups are intentionally formed, comprising students from various backgrounds. The instructors actively assist them with both problem solving as well as developing and improving the student's concepts within the project task.

The expected results from the group work are supposed to include 1) an overall study of a specific target disease (or in some cases a series of diseases with certain similarities) related to aging, 2) a systematic and interdisciplinary design solution to assist the target elderly patients to independently perform their activities of daily living (ADLs) in the form of design drawings, mock-ups or prototypes, and/or experiment setups, and 3) business aspects of the proposed solution (e.g., business model generation, a simplified cost-benefit analysis, etc.). At the end of the seminar, students are to present their project solutions in front of the whole class and the course instructors in order to finalize the whole semester's progress and outcomes.

4 Results

As mentioned above, at the end of the semester, student groups are to present their projects in front of the seminar participants and instructors, targeting various diseases or syndromes associated with aging, such as dementia, mobility impairments, and tremors. Several selected works representing a variety of perspectives of diseases are reported as follows.

4.1 Dementia

The word "dementia" comes from Latin, literally meaning "without mind". According to the World Health Organization, dementia is "a syndrome in which there is deterioration in memory, thinking, behaviour and the ability to perform everyday activities" [8]. A large number of the world population is suffering from dementia, and Alzheimer disease is estimated to contribute to 60-70% of the cases. By 2015, roughly 47 million people suffer from dementia and the number is expected to reach 132 million in 2050 [9]. In Germany, for example, more than 1.6 million people were affected by dementia [10]. With no effective treatment currently available to cure it or reverse its progression, the dementia epidemic has a significant negative impact in terms of physical, psychological, economic, and social aspects, not only on the patients themselves, but also on their caregivers, families, and society. Therefore, innovative solutions are needed to mitigate the impact of this disease. In the following sections, three assistive systems, MAK, METIS, and Dooropener are proposed by the course participants to address the severe challenges brought by dementia.

4.1.1 Kitchen for dementia sufferers: Project MAK

The aim of the Modular Adaptive Kitchen (MAK) is to create an Ambient Assisted Living (AAL) concept for a kitchen that supports people who suffer from dementia. Although many ideas that have been implemented to support people with this condition, few holistic concepts fully meet the physical and mental demands of a dementia patient. This project explores an approach that addresses critical challenges by utilizing advanced technologies, such as assistive technology and automation. Eating and drinking are two of the most basic human needs. As a result, daily nourishment is one of the strongest driving fields of human behavior. Due to increased life expectancy, the number of those who suffer from dementia worldwide is also increasing. Among other aspects, this disease is associated with the inability to accomplish everyday tasks. People who suffer from dementia also lose the normal urge to take in nourishment over time. The patients can no longer assess the importance of adequate nutrition and fluids, nor understand the dangers related to malnutrition. In addition to the physical meaning of eating and drinking, food can also influence feelings, evoke memories, stimulate contacts and relationships, and ultimately influence the well-being and quality of the patients' life in a positive way.

Figure 3 depicts the kitchen system, composed of functional modules, a sliding system, and a guidance system. The functional modules ensure high customizability and flexibility for the individual users.

The sliding system not only offers height adjustment and accessibility for both standing patients and users of wheelchairs, but also prevents patients from reaching possibly hazardous products as the disease advances. The guidance system includes symbol stickers to remind the users of the right locations of items meanwhile keeping the integrity and elegance of the kitchen, and a combination of a projector and a motion sensing device (e.g., Microsoft Kinect) which projects a gesture-operable user interface to guide patients' cooking step by step. The advantages of this kitchen system benefit all members of society, especially people with dementia [11].

Figure 3. Modular Adaptive Kitchen for dementia patients (Image: A. T. Braun and M. Zanchetta)

4.1.2 Assistive home system for dementia sufferers: Project METIS

The Multifaceted Equipment to Independence System (METIS) for dementia sufferers (METIS) comprises an assistive home system for people suffering from dementia. After a comprehensive analysis on dementia, including its general specifics, forms, courses, and treatments, a research on caregivers was conducted. The research revealed an increasing number of elderly people affected by the disease within care of informal caregivers and living alone because of a highly important correlation between home and identity. Therefore, a special emphasis was placed on prolonging the independence of seniors and their preferred stay at home on the backdrop of architectural guidelines for physical and cognitive support. The various needs of a person with dementia have to be met in order to ensure their individual comfort. This requires a flexible and modular system, which can adapt to said needs. This system is specifically designed for seniors who live independently or are in home care. Different concepts for health, database, orientation, safety, and process guide yield METIS. One of the key components of the project is the multifunctional floor tiling system. The system features embedded microchips that ensure the interconnectivity, integrated pressure-powered energy generators and storage units that provide electricity for the whole floor titling system, and an embedded RGB LED lighting system that creates an illuminated path to remind the user of his or her daily routes. In addition, the embedded pressure sensors can be integrated with a gaming system to perform various productive games (see Figure 4).

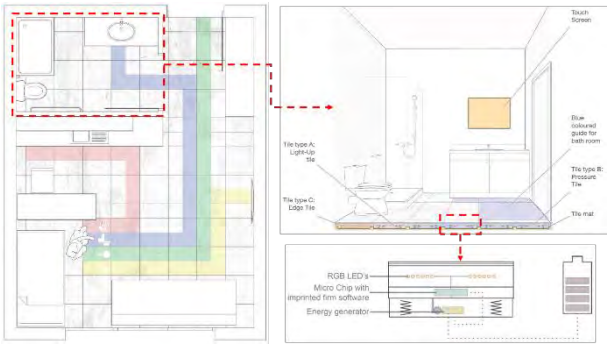

Figure 4. The assistive smart floor tile system (Image: J. Bielski and L. Alsammak)

4.1.3 Smart door handle for people living with dementia

Demographic change is one of the most impactful challenges for our aging population facing new socio-economic, technical and health challenges. We therefore need to find new design solutions to assist older people to stay independently, safe and keep them in a good mood to prevent social isolation. The design of the smart door handle can provide a solution to help older adults to improve their quality of life.

The design responds to the progressive condition of dementia with a modular, as well as adaptive system for three different dementia stages. The three focus aspects of the design configuration variants are mood (for early stage of dementia), independence (for mid stage of dementia) and safety (for late stage of dementia). The system consists of the door, door handle, speaker, passive infrared (PIR) sensor for silent alarm, light module, intelligent switch, security switch and interface (see Figure 5).

Based on the term anticipation, the intent of the project was to design a door system which prevents people suffering from dementia at home and in nursing home from leaving a designated area or building when doing so could otherwise endanger themselves or others. People living with dementia exhibit behavioral disturbances such as mood disorders or wandering,

which can lead to serious safety issues. That is why the system has a few security features such as the security switch, intelligent switch, and speaker to prevent wandering. Additionally, the system keeps them in a good mood through mood nudging with a light module, as well as guarantee their independence through the progressive condition of dementia. The project seeks to combine intuitive technology with a minimalistic form to create a design that can be universally implemented.

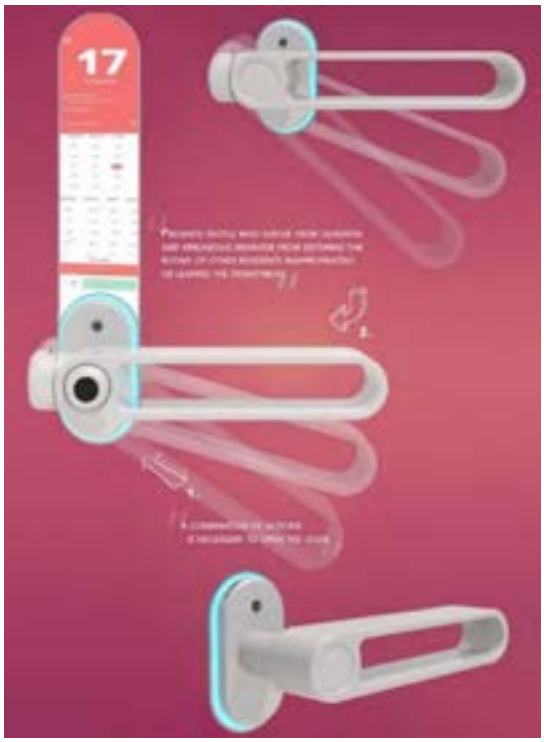

Figure 5. Three configurations for three stages of dementia (Image: M. Schmailzl)

4.2 Mobility impairment

Mobility impairment generally refers to the lack of ability of a person to use one or more limbs in order to move. In general, there are two types of mobility impairments: orthopedic and neurological, both of which have a negative impact on patients' quality of life as well as the healthcare system. Research suggests that among the elderly people aged between 60 to 69 years old, the epidemic of disability in mobility as well as basic and instrumental ADLs is growing at a significant rate [12]. Rosenberg et al. summarized that increasing physical activity has strong benefits on physical, cognitive, and mental health for all age groups, let alone the older adults [13]. Therefore, developing systems that assist patients with limited mobility to move independently meanwhile promoting their activity level is substantially beneficial. In the following sections, such kind of a proposal developed by the course participants will be reviewed.

4.2.1 Interior mobility assistance: Project 3D Movement

Individuals without mobility are exposed to a list of physical and mental problems that affect many of their organs. The 3D Movement system slows the progressive decline of a patient's functions, allowing the users to take care of themselves. Considering the patient's age and physical condition, consistent and intelligent physical activity could reduce or even prevent the degeneration of the patient's state. Researchers have proved that muscular stem cells will decrease with time, but with training, these cells continually regenerate, counteracting the process of aging. The proposed system is designed to support the patient by making movement possible and preventing falls. Assuming the system will be used by people who can stand up on their own, but have difficulties moving independently, the machine allows the patient to regain autonomy in basic daily tasks (e.g., going to the bathroom, cooking, or walking around the living space). Through the integration of a mechatronic system with an appropriate guide-and-support "vest", the system will keep the user in a steady position while preventing the user from falling. When the user intends to move, the force sensor will detect the direction and strength of the movement and move in a safe velocity accordingly. Therefore, the user will be able to move independently while being safe and feeling secure (see Figure 6). As a result, the physical and mental conditions of the patient will improve. The objective of the 3D Movement system is to help people with reduced mobility of all ages, by creating a system that eliminates the use of a wheelchair within confined space. The system can be fitted in hospital rooms and particular types of homes, further benefiting a variety of members of society [14].

Figure 6. Visualization of 3D Movement interior mobility assistance (Image: F. Martini and C. Guernier)

4.3 Parkinson's disease

Being the second most common neurodegenerative disorder, Parkinson's disease (PD) is a progressive nervous system disorder specially affecting the elderly community. It affects about 6 million people around the world, and the number of patients is expected to double over the next generation [15,16]. Without a known cure as of today, PD oftentimes leads to tremors, rigidity, disability, long-term care (LTC), deteriorated quality of life, and eventually premature death, which put increasing burdens on the caregivers and affect the patients and their families both financially and emotionally [17].

Therefore, it is important to create environments that can assist PD patients' activities of daily living (ADL) while minimizing the need for constant care. Therefore, one course participant proposed Project PATRICK ("Parkinson's and Tremor Rehabilitation Interior Care Kit") to empower the PD patients to enhance their ADL through architecture, industrial design, and mechatronics techniques.

4.3.1 Parkinson's and tremor rehabilitation interior care kit: Project PATRICK

This project begins with research into the diseases prevailing in the elderly community. The primary focus is on PD; hence the project is named PATRICK. The research revealed issues with mobility for a large majority of patients, drawing focus on independent movement through the project. The project aims to integrate multiple systems within the architecture of the home, concealing "assistance" and encouraging independence.

Developed through the project focusing on the primary tasks of daily living, there are four systems: the walking assistance, sleeping assistance, fall assistance, and dining assistance. The project creates a secured circulation handrail system for patients within the wall that can extend out when the embedded touch sensors are triggered. The handrail system (walking assistance) is ubiquitous for the entire circulation of the apartment, connected to the sleeping station and eating station. The bed structure (sleeping assistance), maneuvered by a pulley system hidden in the ceiling, can assist the patients to change positions (e.g., lying, sitting, etc.). Meanwhile, the floor and ceiling work together to detect falls and assist the patients with a descending handle. In addition, the dining assistance integrated within the walking assistance features an integrated exoskeleton arm to offset tremors of the user's arm while eating (see Figure 7). In this sense, the entire interior space of the home becomes an assistive robot for the PD patients. The minimalist design ensures that PATRICK can be easily installed and operated within any space, creating a plug-and-play system. Through the research of the disease, understanding its symptoms, investigating current assistive systems on the market, PATRICK make independence possible for PD patients.

5 Discussion

In this paper, the authors presented an interdisciplinary approach in design education to raise awareness of the aging crisis among the future architects and interior designers. Several exemplary results from the participants of this course are revealed in detail.

Experts in related fields already predicted that emerging technologies will have a substantial impact on society, such as replacing a large amount of human jobs [18,19]. Moreover, there is no doubt that emerging technologies will also significantly influence higher education in many aspects in terms of admission, curricula, and organization. Ma and Siau suggested that advanced technologies should be introduced in the curricula of all faculties, not just in STEM majors (i.e., science, technology, engineering, and mathematics), in order to enhance students' ability to adapt to the rapid development in technology [20].

It is widely known that Germany's Bauhaus Movement revolutionarily transformed our world as well as the design education system since its establishment in 1919 [21]. As its founder, Gropius, famously said in the Bauhaus Manifesto [22], the goal of the movement is to "create a new guild of craftsmen, free of the divisive class pretensions that endeavored to

raise a prideful barrier between craftsmen and artists". 100 years have passed since the initiation of the Bauhaus, and facing the severe challenges caused by population aging and emerging technologies today, a "Bauhaus 2.0" Movement, which refers to applying cutting-edge emerging technologies to the education approach of the Bauhaus, is needed to tackle these challenges. To summarize, the key features of both movements can be seen in the following formulas (Figure 8).

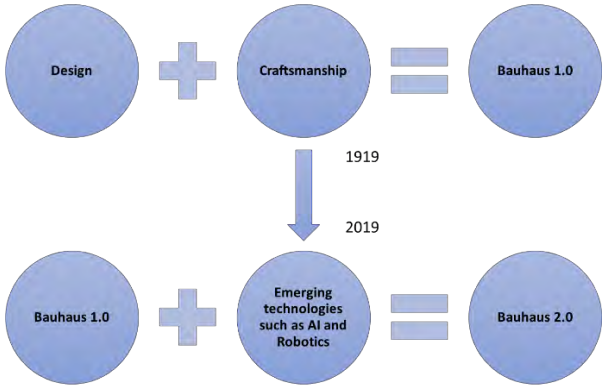

Figure 8. Equations of the Bauhaus 1.0 and the Bauhaus 2.0

As a result, the seminar reported in this paper created a win-win "honeypot" for both students and academic researchers. On the one hand, most students were motivated in the beginning and satisfied in the end of the course because as many claimed they have never experienced such kind of course in architectural education before. The benefits they gain is manifold: the participants obtained a deeper understanding of the impact of population aging through studying various aging-related diseases; they reinforced their design skills in the context of ongoing aging society; they also cultivated an interdisciplinary and flexible mentality in order to better embrace the upcoming age of AI and robotics; more importantly, they learned to collaborate with peers in a simulated business incubator environment. On the other hand, researchers can potentially foster the students to further co-develop their project results into scientific research projects, innovative products, and business startups.

In addition, this approach will inspire educators in the design field to experiment with novel curricula in their teaching practices. Furthermore, the COVID-19 pandemic started in late 2019 has fundamentally changed our society in many aspects. It forces us to rethink the status quo in elderly care today. A trend of applying advanced technologies such as robotics and AI in disease prevention, screening, diagnosis, and operation has already been observed, which especially protects and benefits the elderly individuals who are among the most vulnerable population to the novel coronavirus [23]. Apparently, gerontechnology introduced in the above-mentioned course goes in line with this trend and beyond, making the students better prepared to develop intelligent living environments that promote independent living and well-being of the elderly in the future. The methods and proposals from the past design seminars presented in this paper are by no means an exhaustive range of possibilities. The opportunities for new architectural and technological innovations for aging society are endless, especially with the ever-increasing demand for the young yet promising research field of gerontechnology integrated in the built environment.

Acknowledgements

The research has received funding from *the European Union's Horizon 2020 research and innovation programme* under grant agreement No 690425. In addition, the authors would like to express their gratitude to all participants of the course over the years, especially to A. T. Braun, M. Zanchetta, J. Bielski, L. Alsammak, F. Martini, C. Guernier, and H. Bavishi who share valuable contents to make this paper possible.

Abstract –

With the rapid spreading of digital technology and automated construction applications in architecture, engineering and construction (AEC) society, the current trend is becoming clearer, that automation will change the way we design and build. Robotic Tectonics, as a part of automatic construction methods aiming to achieve the integration workflow from architectural design to finial construction products, emerged from architectural profession for a decade. Avant-garde architects explored the possibility of this new design paradigm through creating the integration of digital design software within the simulation and controlling of robotic construction, and only recently, this completed digital workflow pushes architectural design to re-control the process from initial design conception to finial physical construction, guiding the AEC industry towards a precise, efficient, thus more sustainable development.

However, a success technology innovation is based on the widespread acceptance, where education plays an important role, but in the current architectural education, there is barely no professional courses focused on this. The need to find a framework to integrate the robotic tectonics workflow with architectural curriculum is increasing. Therefore, it became mandatory to integrating and testing of the complete robotic tectonics workflow into architectural curriculum.

In this paper, a pedagogical method of robotic tectonics is defined through a linear scenarios of four stages, based on experiences gleaned from 'Robotic Tectonics' workshops and various other teaching practices. Then this pedagogical method is tested into an architectural curriculum with 135 undergraduate students, for each student, the complete participation of the overall process and questionnaires is required. Results shows this pedagogical method introduces multi-layered interdisciplinary knowledge to architecture students and enables them to using related technologies of robotic arms for automated construction practices, changing the paradigm of architectural curriculum for new design and build processes that will redefine architecture in the near future.

Robotic Tectonics; Architectural Education; Pedagogical Method; Digital Workflow; Architectural Curriculum

1 Introduction

As the industrial revolution replaces manpower with machines to produce large-scale production, it will gradually change our production and lifestyle. Automation technology becomes the key to accelerate transitions of the manufacturing industry from traditional inefficient and labor-intensive mode to present an opportunity to do things more efficiently, accurately, and creatively. As the most representative tool to promote the wave of automation technology, robots have been widely used, especially in the automotive industry. However, like every technological upgrade process, the field of architecture, engineering, and construction (AEC) industry is still in an exploring period of shifting the conventional technology to the advanced technology.

Nevertheless, a bunch of advanced technology applied into AEC industry has enlightened a digital future for the architectural design field, the combination of parametric design tools, design and multi-data simulation, automated construction and robotics. The most advanced technologies start shifting the conventional design methods to the next efficient design workflows. This brings the opportunity to fully realize MacLeamy's curve which advocates shifting design effort forward in the project, frontloading it, in order to archive high-efficiency design process and high-performance architecture eventually (Figure 1). Following the

pavement contributed from the avant-garde architects, like Fabio Gramazio and Matthias Kohler in Zurich, and the demonstration of developing a workflow that challenged the current limitations of computational digital fabrication in design and construction, we believe the relevance of Advanced Architectural Design method with Robotic Tectonics is growing, and it may have the potential to serve as the catalyst for the automation of construction across the diverse architectural field [1,2].

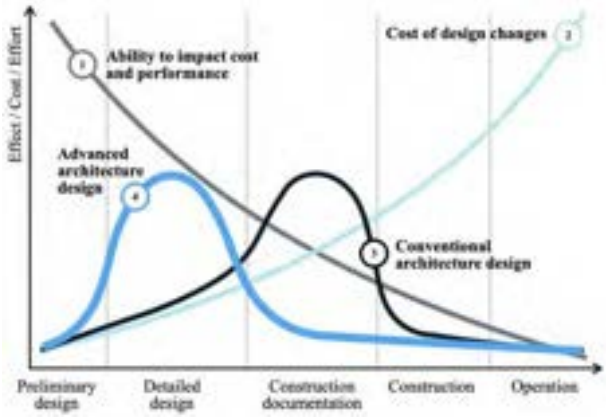

Figure 1. MacLeamy's curve which advocate shifting design effort forward in the project, frontloading it, in order to archive high efficiency design [3].

Therefore, it is necessary to provide future architects in advance with training in new technical techniques and methods suitable for the development of the industry at the educational stage. We believe that successful technology innovation is based on widespread acceptance, where education plays an important role. In recent years, a few of the world's top universities have begun to combine robot manufacturing technology with curriculum design in various forms, such as the representative Harvard University, Carnegie Mellon University, University of Michigan and Princeton University in the United States, University of Stuttgart, ETH Zurich and Delft University in Europe, and Tsinghua University and Tongji University in China, etc. Those are successfully revealed the potential of combining the most frontier advanced robotic technology with the pursuit of humanities and art into the architectural design method under the core concept of architectural tectonics though still at the practice stage. Moreover, we could witness that the ability of robotic tectonics is growing, are advancing in such an efficient and incomparably unstructured environments, as well as has the potential to serve as the necessitated trigger for construction automation in a numerous and diverse field in the future.

From 2015 to the present, we have been eagerly making efforts to find a framework to integrate the robotic tectonics workflow with the architectural curriculum and make it became mandatory to integrating and testing of the complete robotic tectonics' workflow into the architectural curriculum. Thankfully, the feedbacks and opinions collected from students proved that our teaching practice is effective and worthwhile.

2 Pedagogical approach of Robotic Tectonics workflow

with the interdisciplinary requirements and technical difficulty of robotic tectonics, how can we integrate it into architectural education in a simple and understandable way that could allow students to master the necessary skillset while addressing the critical challenge of sustainable development in architecture? As a response to this challenge, we are pushing to establish a novel workflow that can act as a model for a digitally-focused pedagogy and define it within a sustainable framework that combines advanced robotic technology and architectural tectonics. We intend to focus on construction techniques driven by robotics in order to significantly improve material, structural, energetic, and procedural efficiency, all while promoting the aesthetic innovation emblematic of an architectural education. In this linear model, we aim to test the integration of a variety of interdisciplinary techniques in the early design stages, which we believe will aid in the advancement of sustainable development, that changing the paradigm of architectural education. [4-7].

Since its induction in 2016, DAMlab (digital architecture & manufacturing laboratory) has established an experimental teaching platform exploring a myriad of digital tools including 3 KUKA robots (KR120R2700, KR60R2100, KR9R1100) and various CNC machines. Since then, we have hosted several workshops focused on the topic of robotic tectonics. From these last three years of teaching practices, a prominent didactic pedagogical approach has emerged. This new pedagogy is a fully comprehensive robotic tectonic workflow, but it is more easily understood through its four stages – **Parametric Design**: A parametric model-based design conception, **Multi-data Simulation:** robot-oriented multi integral data virtual simulation, **Robotics Application:** Construction-aimed robot end effector development, and **Robotic Construction:** Robotic tectonics represented through automated construction. Within the confines of these individual stages, students can easily break down this overly complex and technically difficult workflow into successive phased steps which each contribute to the learning objectives of this new pedagogy, while simultaneously experience the integrated design to construction workflow which attempting to realize the frontloading concept of

MacLeamy's curve for high efficiency design. (Figure. 2)

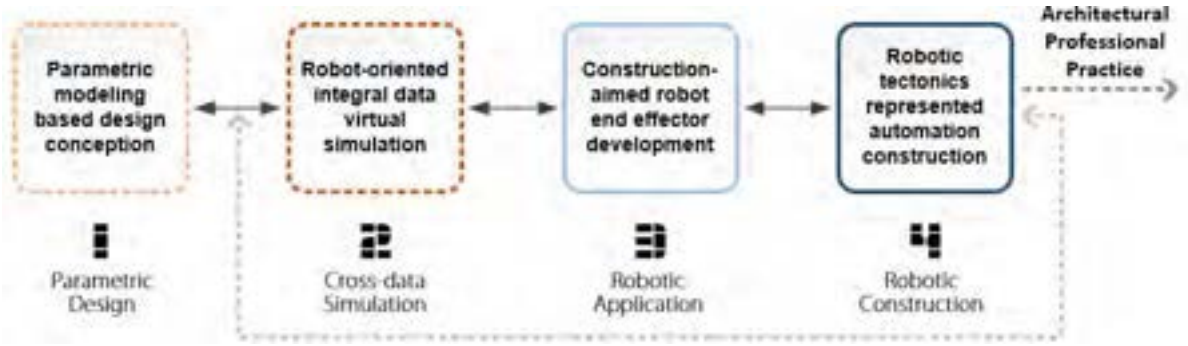

Figure 2. Workflow of the Robotic Tectonics [8]

This pedagogical approach explores the entirety of the typical design and construction cycle, providing the necessary technical skills required to make automated construction into a reality. It expresses a global initiative for students to understand and apply contemporary technology to critical thinking in order to pursue design innovations towards a more sustainable future. Leaders in automated construction practices must be proficient not only in traditional computational and technical skills, but also in a new form of digital materialization which includes a critical understanding of constantly changing manufacturing processes [8].

3 Bricklaying experiment for Robotic Tectonic curriculum courses

The pedagogical method is tested into an architectural curriculum with 135 undergraduate students, for each student, the complete participation of the overall process and questionnaires is required. Our experimental course is conducted in groups. The task of course is to build a columnar brick structure within the range of 0.9m*0.9m*2m, using the standard bricks (200mm*100mm*50mm). The 6-axis KUKA KR30HA robot is applied in this experiment. The robotic arm vertical range of activity is from +35° to -135° with a large turning range of 185°in both directions.

3.1 Pedagogical purpose for bricklaying experiment

The purpose of this course setting is to let students to fully experience the entire robotic tectonic process to systematic understand:

- The theoretical concepts and workflows of "Robotic Tectonic" from design to construction.
- The "Robotic Tectonic" is a combination of Interaction between material and construction, clear and logic structure, and performative architecture.
- The current trends in architectural design and construction technology.
- The modeling and programing techniques, as well as the basic robot working logic and operation skills.

3.2 Experimental content

The four stages of the workflow contents virous works of different levels of interaction, such as information interaction between parametric design and virtual simulation, the parametric design provide geometry generation, program definition, etc. to the virtual simulation process, and get feedbacks as multi-data information, visual configuration, etc. to change design decisions. All these contents are opened reachable for students to experiment with, the whole workflow of experiment contents is illustrated on figure 3.

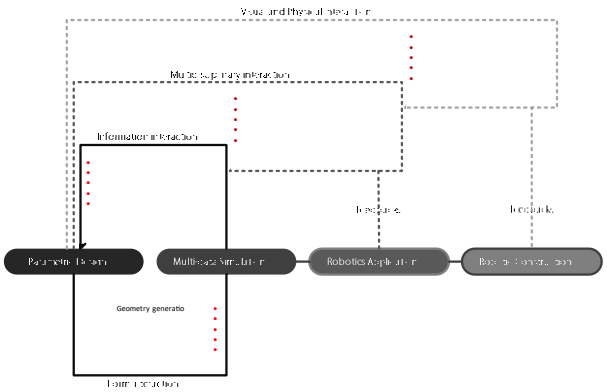

Figure 3. experiment content of Robotic Tectonics workflow

3.3 Bricklaying experiment

3.3.1 Concept and overlapping logic

The priority of a brick structure is to design the overlapping bricks pattern. By deconstructing conventional brick masonry structures, students can learn

the brick overlap logic and its mechanical behaviour, then try to break through the inherent impression of the physical properties of the material itself and further expand the possibilities of the material in design. With the help of digital modelling technology, datum points of curved shapes are generated in Rhino software. After that, a reasonable curve shape is obtained through the algorithm and a curved surface is generated to obtain a basic shape. Then import this basic surface into the parameterized software grasshopper to analyse and arrange the bricks, further optimize the interaction between bricks and bricks by adding functional mapping, object interference and other methods to generate new overlapping logic of the brick structure.

3.3.2 Parametric design for brick structure

The priority of a brick structure design is the overlapping form between bricks. By extracting the logic of brick overlap from the traditional brick structure masonry form, and then by adding function mapping, object interference and other methods to change the interactive relationship between bricks to explore a new spatial logic for the parametric design of brick structure.

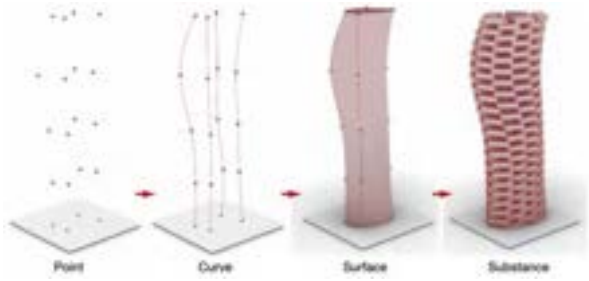

Figure 4. Parametric Design process

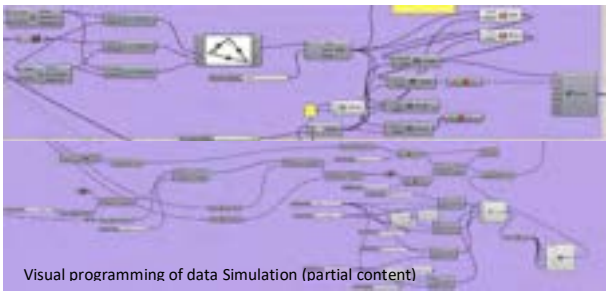
3.3.3 Multi-data simulation for brick assembly

The sequences of picking up each brick, reposition it, gluing at certain area on it, locate into a precise spot, and configure the overall processes for the whole structure's building sequence, are fully considered in this stage. (figure 5) Therefore, not only design factors, but also procedure factor, material information, robot operation data, signals, etc. are all integrated and simulated here.



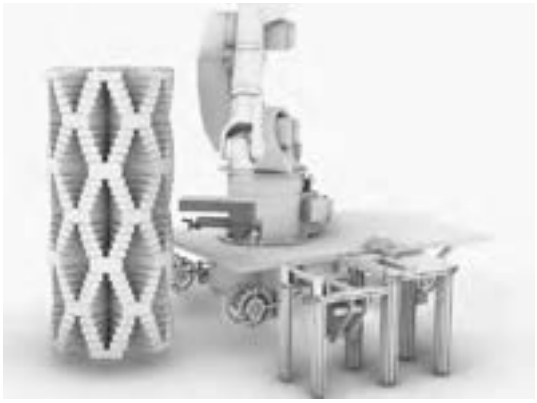


Figure 5. Process of multi-data virtual simulation

3.3.4 Robotics application for bricklaying

Robotics technology of gripper tools, sensing devices, plc components are applied to form a complete end-effector and building environment for the bricklaying.

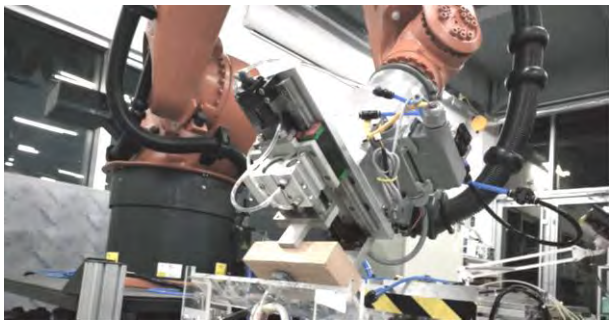

Figure 6. End-effector of robotics application for bricklaying experiment

3.3.5 Robotic bricklaying practice

After setting up the parametric design, multi-data simulation, and robotics application procedures, the final building experiment could be operated (figure 7). During this physical building process, feedbacks could also directly deliver to the previous stages, and manipulate accordingly to the current building situation.

Figure 7. Physical building process

3.4 Experiments results

During the courses, 8 groups of bricklaying experiments are completed, students participate all processes from parametric design to robotic construction. For each stage of the Robotic Tectonics workflow, students have fully experienced through building experiments. Each group of bricklaying project explored virous configurations of robotic bricklaying tectonic, the experiments achievements are fruitful. (figure 8)

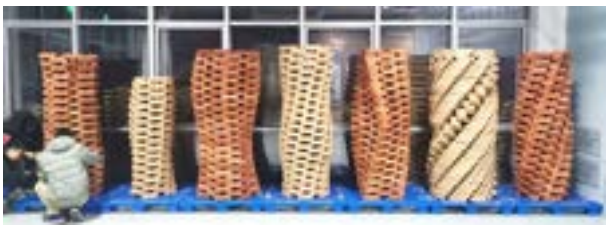

Figure 8. Experiments achievements for courses

4 Teaching questionnaire survey and analysis

To explore the students' perceptions of the proposed pedagogical approach of robotic tectonics and obtain their feedback on teaching effectiveness, we conducted a questionnaire survey of 135 students in the third grade of architecture major who participated in our course. According to the survey, all students' existing relevant knowledge and skill experience of "Robotic Tectonics" has little difference before attending the course. That indicates the feedback information of the questionnaire, which could not be affected by the factor of personal experience, is valid and reliable.

4.1 Comparative analysis between before and after attending the course

The comparative analysis of the results of the questionnaire before and after the course shows in Table 1 that the students have obvious views on the impact of the "Robotic Tectonics" in the AEC industry, the position in the future architectural design and the necessity as the content of the architectural design course. Among them, the proportion of students who believe that "Robotic Tectonics has a great positive influence or plays a dominant approach" has increased from 24.44%, 45.19% (before attending the course) and 42.22% to 68.89%, 75.56% and 54.81% (after attending the course). Similarly, the proportion of students who believe that "Robotic Tectonics has a revolutionary influence or plays an essential decisive approach" has increased from 2.22%, 3.70% and 8.89% to 17.78%, 20.74% and 42.23%, respectively. Then, from the results of internal consistency analysis, the grand mean values of the above set of questions changed a lot from 2.44 to 3.20 and the values Cronbach's alpha increased from 0.442 to 0.791. It means that after experiencing the course learning, the students recognized with more uniform consistency. Most students' opinions have changed from "Robotic Tectonics has a small influence or plays an auxiliary approach" to "that has a great positive influence or plays a dominant approach" on the relevant dimensions of industry, architectural design or professional curriculum.

Table 1. Comparative analysis between before and after attending the course

	Before attending the course		
Questions / Options	Impact on future AEC industry	Role in future architectural design	Role in future architectural design courses
1: No influence / An optional approach	7 (5.19%)	3 (2.22%)	2 (1.48%)
2: Small influence / An auxiliary approach	92 (68.15%)	66 (48.89%)	64 (47.41%)
3: Great positive influence / A dominant approach	33 (24.44%)	61 (45.19%)	57 (42.22%)
4: Revolutionary influence / A necessary approach	3 (2.22%)	5 (3.70%)	12 (8.89%)
Summary of internal consistency	Grand mean	Cronbach's alpha	Sig.
	2.44	0.442	0.000

	After attending the course		
Questions / Options	Impact on future AEC industry	Role in future architectural design	Role in future architectural design courses
1: No influence / An optional approach	1 (0.74%)	1 (0.74%)	0 (0.00%)
2: Small influence / An auxiliary approach	17 (12.59%)	4 (2.96%)	4 (2.96%)

3: Great positive influence / A dominant approach	93 (68.89%)	102 (75.56%)	74 (54.81%)
4: Revolutionary influence / A necessary approach	24 (17.78%)	28 (20.74%)	57 (42.23%)
Summary of internal consistency	Grand mean	Cronbach's alpha	Sig.
	3.198	0.791	0.000

4.2 Improvement of students' design capacity

The analysis of multiple-choice question (Figure 9) finds that the majority of students of (132 people) indicated that the concept of robotic tectonics will continue affecting the architectural design. There are 90 students who reported that their logical thinking improved through the simulation process. There are 86 students considered "human-machine collaboration improves our efficiency". 79 students thought that "robotic tectonics improve the quality of our construction work". 65 students think that their innovative ability improved by using the parametric design method. Few students (29 people) have the view of "It has a positive impact in other areas that are not clear", while only one student thought "it has no help."

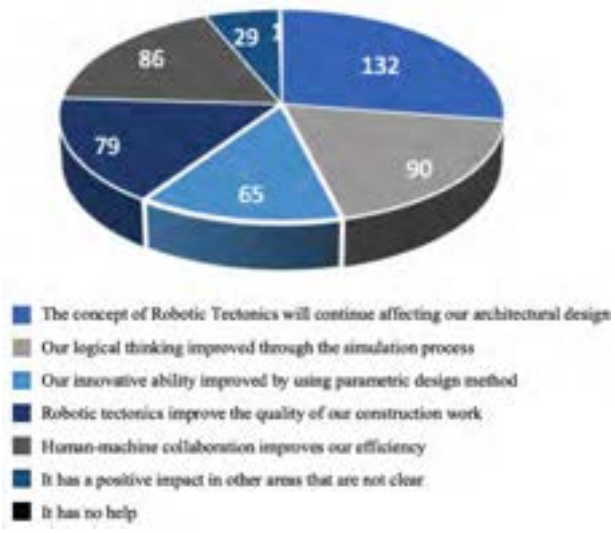

Figure 9. The questionnaire analysis of the improvement of students' design capacity

4.3 Open-ended responses

The students' open-ended responses to the survey questions overwhelmingly provided meaningful improved suggestions and personal reflections about the proposed course. Some specific comments include:

"This is the first time I have manipulated a robot. It is highly professional and requires more systematic learning. I suggest adding related auxiliary courses."

"Compared with the previous manual construction model, the accuracy of the robot construction is particularly high, and it can save labor time."

"For me, it is a magical and surprising experience to compile the design into the program and then let the robot build it into the real thing. I hope to have more opportunities in the future."

"We young people in the contemporary age should actively learn and master this new knowledge and new technology and prepare for the future in advance."

5 Conclusion

Applying the pedagogical method of robotic tectonics into architectural curriculum has significant efforts for the future participants in the AEC industry. It can be considered that the conventional architectural design concept is necessary, but it will allow students to form an inherent thinking, which has a negative effect on the acceptance of new technologies and concepts. Curriculum theory and practical education through reasonable process arrangements are effective for developing students' thinking and perceiving to adapt to the advanced architectural design concepts of the future era. The proposed pedagogical approach and its workflows are reasonable, which can make students fully understand the whole process from architectural design to construction through step-by-step teaching practices and effectively imparted advanced architectural design concepts. All analysis of the questionnaire results quantifies the beneficial effects of this course even are highly recognized and supported by students. The paradigm of architectural education is changing with the integration of emerging robotics technology.

This study reveals a pedagogical approach for future architectural education towards interdisciplinary vision of future sustainable automated construction. All new technologies need widespread for fully acceptance and manipulation, where education always plays an important way. With the digitalization transforming of every field of our lives and societies, students as the future professional participates have somehow generated consciousness for creating brand new ideas of architectural design and construction methods, which could be read through the positive attitude towards future challenges, therefore, adapting to the trends of digitalization and interdisciplinary developing for

architecture, engineering and construction industry is crucial. Searching for the proper pedagogical methods for this changing paradigm are necessary, also, creative and attractive approaches for both students and other participates are indispensable, which always be the future works for our further research.

Augmented Reality Sandboxes for Civil and Construction Engineering Education

Joseph Louis [a] and Jennifer Lather [b]

[a] School of Civil and Construction Engineering, Oregon State University, USA
[b] Durham School of Architectural Engineering and Construction, University of Nebraska – Lincoln, USA
E-mail: joseph.louis@oregonstate.edu, lather@unl.edu

Abstract –

Civil and Construction Engineering (CCE) is a discipline that seeks to engineer the physical world, yet students in classrooms are limited to studying and applying concepts predominantly on paper or computer screens. This paper proposes a framework for the use of augmented reality (AR) sandboxes to bring the vastness of the physical environment that characterizes the problem domains of civil and construction engineering and the students will eventually be working in, into the classroom. Because the surface of the sandbox can be intuitively fashioned to represent a scaled-down version of the wide range of terrain found in the physical world, this tool can demonstrate not just the application of classroom concepts, but even their development from first principles. A description of the AR Sandbox is provided along with the software architecture that is created to enable course delivery to meet the related learning objectives for earthwork planning. This paper presents learning CCE design and analysis concepts that are traditionally presented through diagrams to be delivered through an AR Sandbox. A framework for evaluating the effectiveness of this new mode of instruction is proposed which can inform guidelines on the implementation of novel visualization and interaction technologies in the CCE classroom. Implications of this work include use by earthwork construction teams and professional engineers where AR sandboxes can aid planning and managing large scale construction projects.

Augmented Reality; Sandbox; Heavy Civil; Construction Education; Mass Haul Diagram

1 Introduction

Civil and Construction Engineering (CCE) is a discipline that seeks to engineer and transform the physical world around us, yet students in classrooms are limited to studying and applying concepts predominantly on paper or computer screens. While the technology available in education have increased to many interactive media, CCE as well as many engineering disciplines are slow to implement new modes of learning into modern curricula [1]. The traditional modes and media of instruction, e.g., paper and screens, create a disconnect between the concepts learned in class and their application in the field, e.g., spatial reasoning and broad concept understanding, which is usually bridged only after considerable work-experience in industry. A similar disconnect exists between the designers and builders of civil infrastructure, who necessarily work in two different environments (the office vs. the field).

This paper seeks to bring the vastness of the physical environment that students will be working in, into the classroom, with a tangible interface known as an augmented reality (AR) sandbox. The AR sandbox will serve as an interactive media through which civil infrastructure design and construction concepts will be demonstrated in the classroom. This platform will augment traditional learning tools such as CAD and spreadsheet programs by providing a much needed and appropriate kinesthetic aspect to student learning and engagement. This paper focuses on the development of the physical sandbox and software applications that enable the teaching of various CCE concepts through the AR sandbox. The methodology that will be used to evaluate the effectiveness of the sandbox as a media for education is also discussed in this paper. The concept of mass haul diagraming for earthwork planning and analysis is used as a case study to explore the use of the sandbox in civil and construction education.

A literature review of existing implementations of AR sandboxes for education is first provided to set the context for this research, which is followed by a description of the hardware and software architecture necessary for the working of the sandbox. This is followed by a description of the experimental methods to evaluate the effectiveness of the sandbox for teaching and learning, followed by conclusions of the research.

2 Literature Review

A review of current literature in the field of mixed virtual reality and augmented reality sandboxes is provided to set the context for the research. Following that, a discussion of diverse learning styles is provided to highlight the need for incorporating spatial reasoning into the CCE curriculum, which is provided by the AR sandbox. This sets the stage for presenting the point of departure of this paper from the current state of CCE education and AR sandbox research.

2.1 Augmented and Virtual Reality

Within the commonly used Mixed Reality continuum (Fig. 1), there are two poles, the real world (reality) and the virtual world (virtual reality), where either can be augmented by the other [2]. The augmented reality (AR) is the part of the spectrum where virtual objects are augmented on reality. The augmented virtuality (AV) is the part of the spectrum where real objects are augmented on the virtual environment. In the AR Sandbox, both of these augmentations can occur, sometimes where the virtual representation of the sand is used to generate a virtual topographical map (AR) and sometimes where the sand is meant to augment the understanding of data through exploring how changes in the sand impact a simulation of roadway construction (AV), for example in a cut and fill diagram. These theoretical differences have implications for AR sandbox design and implementation in educational settings. Through understanding the types of tasks to be performed in the mixed reality sandbox environment, the software specifications for AR and AV tasks can be identified. These can aid identification of technology for investigation, design, and analysis tasks associated with spatial reasoning in the civil and construction engineering domain.

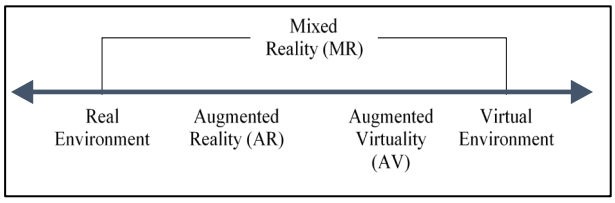

Figure 1. Mixed Reality Continuum

2.2 Augmented Reality Sandbox

The augmented reality (AR) sandbox is a device consisting of a depth sensor, projects, and a physical box filled with sand. It was initially developed at UC Davis to enable a tangible means of manipulating and visualizing spatial data [3]. This device represents a novel application of AR wherein the virtual information is dependent on the physical shape of the real-world sand. Its primary applications thus far have been in providing students with an intuitive understanding of geographic concepts [4] such as topographic maps, and hydrology [5]. Apart from concepts in these fields, other educational and visualization experiences have been created in the areas of natural sciences [6], mathematics [7], and disaster response [8]. The common theme regarding all of the AR experiences implemented in an AR sandbox thus far has been the presence of a strong spatial component relating to vast areas of physical terrain. Furthermore, all of the above experiences only allow one primary means of interacting with the underlying model and visualization, through physically manipulating the sand. For the above applications, the primary concepts under study is the natural terrain, which is can be represented and interacted with adequately by the sand alone.

However, civil and construction engineering concepts involve additional built infrastructure to be considered along with the surrounding terrain. Therefore, this paper builds upon the current capabilities of the AR sandbox interface to provide a more general platform for the sandbox that enables multiple modes of interactivity with the underlying terrain and physical infrastructure under consideration.

2.3 Engineering Education for Diversity

Many researchers have investigated how learning style impacts learning in the STEM fields [9], as well as gender differences in learning style for engineering students [10], suggesting that engineering education be approached with a mixed method approach to incorporate more Active, Sensing, Visual and Global components.

In addition, spatial reasoning has been shown to be a key indicator of engineering education success especially for female engineering students [11]. New trends in VR and AR have added new tools for educators across engineering topics and grade levels [12], [13]. With a large number of new tools, the need for evaluation is expanding into understanding specific interactions, including human-computer interaction (HCI), team interaction, and conventional communication. Previous work has begun to develop metrics to aid researchers in understanding different factors associated with interactive media and teams [14]. Additional tools are needed to understand how both media and interaction play a role in the use of mixed reality in engineering education and how they can assist different learners to succeed in their engineering education. To aid research in this area, research is needed in a new method of incorporating spatial reasoning for engineering education, particularly in the area of civil and construction engineering, where spatial concepts are of critical importance.

It is anticipated that the use of the AR sandbox will provide the spatial component to learning that will enable core concepts in civil and construction engineering to be appeal to a more diverse audience.

2.4 Point of Departure

The point of departure of this paper from current work lies at the intersection of current state of the art in AR sandboxes and the need for enhanced means of incorporating spatial reasoning in engineering educations, especially for civil and construction engineering. Current implementations of the AR sandbox do not consider the interaction of built infrastructure with the terrain, and rather focus on the terrain itself, thereby limiting its application to areas of study relating to geology and hydrology. Therefore the overarching goal of this paper enhance the capabilities to the AR sandbox to enable users to create, visualize, and interact with digital representations of the built environment and infrastructure in addition to the physical terrain that is represented by the sand. Towards this end, the paper describes the development of the sandbox and a case study of developing an application for a specific construction engineering concept taught in the classroom. Furthermore, a discussion of the experimental method for evaluating the effectiveness of the sandbox for education is also provided.

3 Development of AR Sandbox

The AR sandbox used in this research was built from commonly available materials and implemented by the authors and a team of students at Oregon State University. This section describes the hardware and software architecture that comprises the AR sandbox.

3.1 Hardware Design of AR Sandbox

Figure 2 shows a schematic representation of the AR sandbox along with its three primary hardware components: depth sensor, projector, and computer terminal. As can be seen in the figure, the depth sensor and projector are mounted side-by-side on a metal bracket that extends over a box of sand. Both the depth sensor and the projector are connected to the computer terminal.

For portability, the sandbox was mounted on a wheeled double shelf cart, wherein the sand was placed on the top shelf along with the computer terminal. Half inch (1.27 cm) thick clear acrylic board walls were affixed to the sides of the top shelf to accommodate the volume of sand. The picture of the finished sandbox is shown in Figure 3.

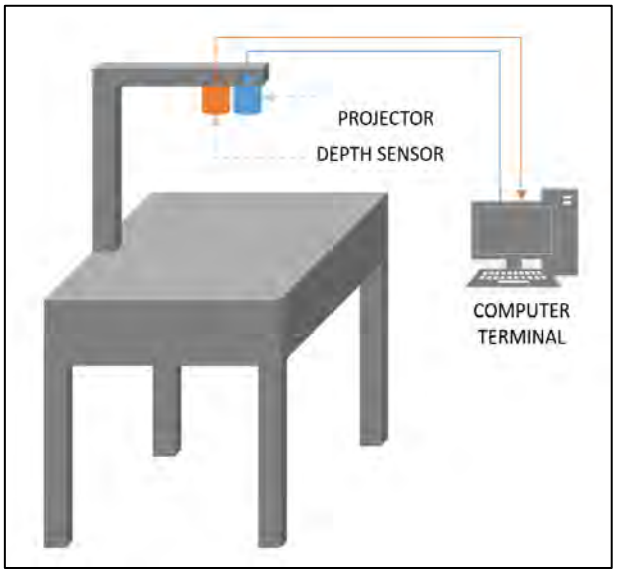

Figure 2. Schematic diagram of AR sandbox

Figure 3. AR sandbox mounted on wheeled cart

The role of the three primary components are the depth sensor, projector, and computer terminal, described below:

3.1.1 Depth Sensor

The depth sensor that was used is a Kinect Sensor by Microsoft. The Kinect is equipped with a 1280x960p full-color camera, and an infrared (IR) emitter and sensor along with an array of microphones and a tilt motor. For this project's purposes, the Kinect's IR sensor and emitter are primarily used and allow us to capture a depth image. This IR system offers a workable range of 0.8m to 3.5m from the target with a data precision of 1cm [15]. When choosing the Kinect, the

most important factors for considerations were the accuracy the sensor and the usability of its application programming interface (API). The Kinect is one of the most accurate depth sensors on the common market and the API created by Microsoft has been created specifically for developers to use when utilizing the sensor for their applications.

3.1.2 Projector

The projector that was used for this sandbox is an AAXA M5 Mini Portable Business Projector. This projector occupies of a volume of 1.5cm x 1.5cm x 4.6cm (6in x 6in x 1.8in) and only weighs 0.86kg (1.9 pounds), while offering a 1280x800p picture at 900 lumens. Allowing for a screen up to 3.81m (150in), this projector allows for a very bright and clear image for its size. The most important factors of the projector are its size, weight, and brightness. Because of the way the projector is mounted above the box, a smaller and light projector was necessary to ensure its stability. With the majority of projectors at this size providing a brightness of 50-100 lumens, the 900 lumens make this projector highly suitable for its intended purpose.

3.1.3 Computer Terminal

To power the AR sandbox, a HP Z240 full tower desktop computer was used which had 16 GB of RAM, a 1TB spinning disk, and an Intel core i7 processor with a base speed of 4.2 GHz. Furthermore, a Nvidia GTX 10XX series graphics card was implemented in the terminal to handle rendering. In regard to the computer terminal, it is necessary to use a full tower desktop since a majority of graphics cards are too big to fit in a small form factor machine. Using a Nvidia GTX graphics card provides the best results for rendering real time graphics at the lowest cost when compared to a similar workstation graphics card. A mouse and keyboard are connected to the computer terminal to enable additional interaction capabilities to the AR sandbox. The output of the terminal is projected on to the sandbox and thus there is no additional monitor that is provided with the sandbox, although one can be easily added for development and debugging purposes.

3.2 Software Architecture of the AR Sandbox

The software architecture of the AR sandbox was developed to provide future developers the opportunity to develop applications relating to core concepts in CCE that could be deployed through the AR sandbox interface without the need to interface with low-level details of the hardware components. Thus, the fundamental functionality that was enabled involved obtaining a depth image information from the depth sensor using Kinect's API and storing that as a heightmap to provides heights on the sandbox at any given x and y location in the sensor region. Also, a geometry interpreter was implemented to convert heightmap data from the depth sensor into a three-dimensional mesh. Apart from dealing with the depth sensor, calibration is required to ensure that the sensor and projector are correctly aligned with each other as well as with the surface of the sand. These settings include adjustments to the area exposed to the depth sensor and to the area covered by the projection. This module continually interacts with the user interface (UI) as it prompts the user with the setting to be adjusted and then stores these settings in the Calibration Settings.

In order to ensure satisfactory graphical performance of the system, this architecture utilizes two pairs of vertex and fragment shaders written in the OpenGL Shader Language (GLSL). The first is responsible for coloring the terrain mesh in order to visually represent height information. The second is used to color road segments to represent cut and fill data. The visual appearance of these shaders will change depending on the current display mode. The rendering subsystem is handled by the Unity game engine and is accessed indirectly through shaders and Unity's UI system.

Finally, a basic application that is enabled to ensure that the system is working correctly is the display of real-time depth information. Display depth is used to visualize the height or altitude of an area. If a part of the sand is above a certain height, then it's displayed using a shade of red. If the sand is below a certain height, then is displayed using a shade of blue. The intensity of the color depends on how far the height of the sand is from a predetermined height. A close up of this display of depth is shown in Figure 4 along with contour lines along sections of equal height.

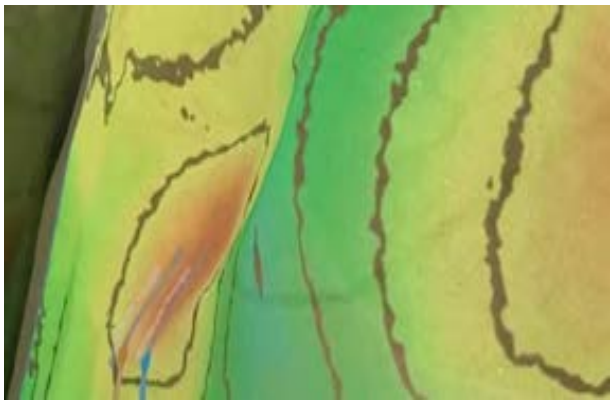

Figure 4. Height map display with contour lines

4 Case Study for Mass Haul Diagrams

Mass haul diagrams are an analytical tool that is used in the planning of horizontal construction projects

like the building of roadways and trenching for pipelines [16]. Mass haul diagrams provide a visualization of the quantities of earth that need to be cut, filled, and moved, along the centerline of the horizontal project. This information is used by project managers to plan for earthmoving equipment fleets and enables them to determine the schedule and cost of the project. Traditional mass haul diagrams are taught to students using a spreadsheet interface which takes as input the elevation profile of the existing ground and proposed pavement and the cross sections of the roadway (or trench) to be built. The output of the analysis is a two-dimensional visualization of cut and fill volumes on the y-axis plotted against the distance along centerline on the x-axis. An example mass haul diagram is shown in Figure 5.

As can be observed from the figure, the information in the mass haul diagram is not intuitive to grasp, especially given its similarity to the input elevation profiles. Another key aspect of the earthmoving that is missing in the current visualization is that it does not show indicate the three-dimensional nature of the volume of soil to be moved. Furthermore, there is no indication of the surrounding terrain as the information is only plotted along a one-dimensional centerline of the road. This can lead to potential misunderstanding of the entire concept.

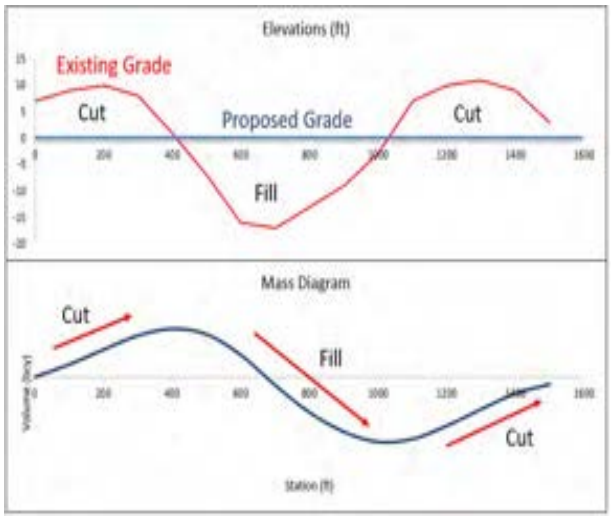

Figure 5. Mass haul diagram for earthmoving

These limitations of the traditional method of instruction of mass haul diagrams present a barrier to the understanding of the core concepts of the method, which essentially relate to the volumes of earth to be moved. Thus, an application was created upon the foundational AR sandbox software architecture described previously for visualizing an interactive mass haul diagram. This application could be run in two modes: Design and Cut & Fill modes.

4.1.1 Design Mode

In the design mode, the user designs the road segment location. The design mode is used to enable the user to create the shape of the roadway segment for mass haul analysis. Specifically, the user can design the horizontal and vertical alignment of the roadway using Bezier control points that provide smooth curves to the shape of the roadways segment. Figure 6 shows an example of the control points (represented as yellow squares) on the alignment of the roadway. This figure also shows the cut and fill representation which will be explained in the following subsection.

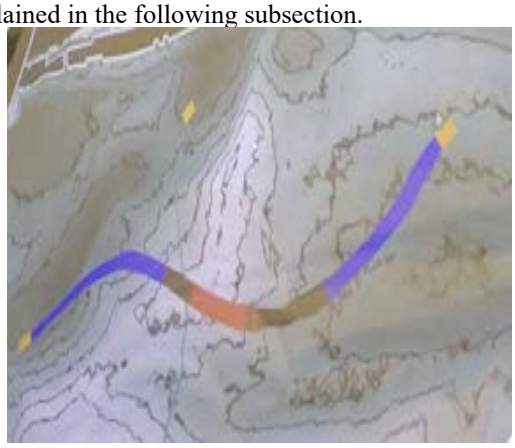

Figure 6. Control points on virtual roadway projected on the sandbox

The user can edit the horizontal alignment of the road by using a mouse to select and move a specific control point. The user can change the vertical alignment of the roadway by selecting and moving a control point and pressing down on the shift key on the provided keyboard. The user can also add and delete control points using UI buttons that are available. Adding a control point enables the user to greater length and curvature to the road segment.

4.1.2 Cut & Fill Mode

Cut and Fill mode is used to visualize the volumes of material that must be added or removed in order to achieve the desired road path. This mode is the default mode and differs from the design mode only in terms of not showing the control points that determine the alignment of the roadway. The cut or fill of a road will be calculated by determining the height of a part of the sand where the road should be, then displaying a colored view of the road. As can be observed in Figure 6, the cut and fill of soil that is required to bring the existing grade of the terrain to the proposed grade of the roadway is displayed visually along the roadway.

Specifically, cut is represented in red and fill in blue. If the elevation of the terrain along the roadway of the proposed roadway, that portion is represented in black color. Apart from providing students with the spatial

context of where the cut and fill areas on the roadway are, moving sand out of cut and into fill portions along the roadway enables them to obtain tactile sensory feedback in obtaining an understanding of the quantity of soil needed to be moved to build a roadway.

Also, the effect of change in terrain on cut-fill sections of the roadway are represented immediately to due to the real-time nature of the depth sensor. This provides students with immediate visual feedback on the effect of physically moving soil from one part of the roadway to another. Quantities are also presented along with the visualization.

4.2 Evaluation of Tasks in AR Sandbox

There has not been a substantial amount of research on the effectiveness of learning using AR sandboxes for CCE. Most evaluation has been on the use of AR Sandboxes in understanding hydrology and topography concepts in Environmental Engineering, with mixed results [4], [17], [18]. The main findings from these studies have found that user experience was positive while statistical differences between learning pre- and post- task have been minimal [19]. Rigorous evaluation of user learning and experience are needed in a variety of task types to understand the value of AR Sandboxes in education. Since previous studies have focused on learning concepts, we propose expanding evaluation to include both unstructured and structured tasks to help understand the use of this technology in both broad understanding of CEE and learning spatial concepts.

The two tasks of the AR Sandbox for CEE, design and cut & fill modes, represent the key tasks for evaluation. As mentioned earlier, spatial understanding has been identified as an indicator for engineering success [4], and this concept is especially important for people with a variety of cognitive styles. In order to understand the benefit of AR Sandboxes in CEE, we propose the collection of data across different task types (design and analysis type tasks), the collection of data on cognitive style, understanding of broad concepts through pre and post-tests, class performance, measures of user perception of the media interaction and potential team interaction during the activity, and comparison with traditional teaching and learning methodologies. For evaluation of AR sandboxes in the CCE education to be valuable, many more studies are needed with enough sample size to produce enough power to have statistical evidence of the value of these systems. Value can be in many forms, including performance, future success, confidence in abilities as an engineer, and enjoyment in education. Additional valuable parameters are expected to arise as researchers evaluate more types of tasks beyond concept understanding, such as unstructured design tasks and cut and fill analysis tasks.

5 Conclusions and Future Work

There exists an inherent dichotomy between the education and practice of civil and construction engineering because the former necessarily happens inside the classroom while the latter is mostly performed out in the real and physical world. This disconnect is usually bridged only after the student has spent sufficient time out in the field and is struck by the inevitable, but much delayed “a-ha” moment - a congruence achieved when abstract concepts are finally placed within their rightful physical context. The AR sandbox, through its seamless blending of virtual content within a tangible interface, has immense potential to deliver concepts to students in an intuitive and engaging manner to assist in alleviating that disconnect. Because the surface of the sandbox can be intuitively fashioned to represent a scaled-down version of the wide range of terrain found in the physical world, this tool can demonstrate not just the application of classroom concepts, but even their development from first principles, through interaction with design and analysis tasks in earthwork planning.

This project specifically provides an alternative means of teaching mass haul diagrams for earthwork planning. Whereas current lessons utilize static two-dimensional profile and plan views of three-dimensional terrain and roadways, this tool enables students to use their own hands to both construct roadways and modify surrounding terrain. The tool then displays the results of the mass haul analysis directly on the physical roadway itself in real-time, to provide an intuitive, interactive, and ultimately effective learning experience for students. The following specific advancements in interactive learning are enabled by the tool. The use of actual sand in the sandbox is anticipated to increase student learning and retention of concepts such as bank, loose, and compacted volumes; and which volumes are to be used during quantity calculations. The provision of a physical terrain and roadway model combined with a dynamically updated mass haul diagram in this project can demonstrate the utility of abovementioned tools for earthwork volumes calculation. The sandbox will serve as a physical medium to aid students in interpreting the design drawings that are provided from an authentic real-world project. The real-time nature of the proposed tool will also enable students to experiment with the terrain to see how it changes the cost and schedule of the operation. The provision of a modifiable scale model of the terrain will enable the testing of different alternatives and scenarios at no expense to the students or instructors.

While the effectiveness of the tools in imparting the lesson has not been evaluated yet, this paper details the experimental process that will be followed for assessment across a series of novel AR sandbox task

types: design and analysis tasks. The results of this assessment can inform educators on the utility of the sandbox and other such novel methods of teaching and guide their plan for implementation.

Future work can also focus on integrating the presented approach of visualizing heavy civil operations with existing means of using virtual reality [20] and augmented reality [21] for visualizing simulated construction operations.

Abstract –

This paper presents the learning outcomes of the Open InfraBIM and Construction Automation workshop in OuluZone motorsport Center, Finland, during October 2019. Totally of 45 students from the University of Oulu, the Oulu University of Applied Sciences, and the Oulu Vocational College were challenged to build the Speedway track by using the latest tools, such as real-time cloud service, work machines with automated 3D control systems, and drones. Furthermore, an autonomous excavator was demonstrated to the participants during the workshop. The students were divided into six groups. Each group had six different interesting tasks of a typical construction site guided by teachers and technology company experts. The idea was to practice real construction site work and problem solving. The feedback from the students, teachers and technology company experts were positive. The practical learning has found to be an excellent way to educate open infraBIM based automation and robotics.

1 Introduction

During last decade, Building Information Modelling (BIM) digitalized the entire construction sector from designing to the implementation and site logistic. Infra BIM is an acronym for Infra Built Environment Information Model, which includes the infrastructure information model and related structures and environment information [1]. According to Costin et al. [2] literature review, many publications have been published since 2002 to 2017 where BIM has studied various infrastructures related to the transport sector, such as bridges, roads, and mass transit. BIM has found to have unlimited potential for improving infrastructure, but there is still challenges interoperation and data exchange.

In Finland, a lot of trial project works have been done to obtain general guidelines and requirements for infrastructure construction since 2010. Building SMART Finland has been published Common infraBIM requirements (YIV2015, now second edition YIV2019), together with the infraBIM Classification and information transferring format [3] that are recommended to use in projects. Instead in Norway, the use of BIM become mandatory in large public infrastructure projects in 2016 [4]. The German Ministry of Transport and Digital Infrastructure (BMVI) aims at establishing the mandatory usage of BIM from 2020 for all building projects in its range of authority. For this reason, many pilot projects have been made [5]. In Sweden, government has assigned in 2012 to the Transport Admiration the task to the implement of BIM throughout of the construction industry. [6] These types of infraBIM piloting, guidelines and exploitations experiences have also been reported in other countries, such as in Spain ROAD-BIM EU-project [7]. As the benefits of BIM in the infrastructure pilots, demonstrations and projects have been found to be significant, it is important to be aware of the need for infraBIM training and education both for professionals and for construction students.

Currently, BIM education in higher education or technical training institutions has been reported providing globally in 17 countries, most in Architecture Engineering Construction (AEC) sector. In the report of NATSPEC 2019 [8], Infrastructure education has been provided only in Finland and Switzerland. History in Finnish infraBIM education was that technology companies involved in the infraBIM projects started to train employees in specific training content. Since 2014 YIV2015 become one of the lecture topics in courses organized for example in Metropolia University of Applied Science, Tampere University of Applied Science and University of Oulu. Since 2015, machine operators have also been trained model-based workflow i.e. infraBIM. Specific infraBIM coordinators training courses, including lectures, learning tasks, e-learning and development task, has been given in university of applied

science level with a collaboration of construction industry started in 2020. [9] Tallinn University of Applied Sciences, Estonia, BIM for Infrastructure course has been developed more for active learning using Moodle for sharing, assessments, and the forum of questions and answers. Students learn by watching, listening, reading and doing step-by-step materials. During the course a number of different software design, construction and visualization tools are utilized in teaching. [10] HSR University of Applied Science Rapperwill, Switzerland, offers the BIM basic education three-day course. The content of the lectures is e.g. Industry Foundation Classes (IFC) and openBIM, and virtual project room (Common Data Environment, CDE) [11] Politecnico di Torino, Italy, has presented their experiences to train professionals to be qualified as infraBIM Managers expert both in the building process and in the parametric digital modelling. During the lectures, individual internship, and the project work students learned that the procedures and processes can be work properly no matter the BIM platform or tool used, the importance of teamwork and the importance of openBIM by presenting previous projects. [12]

In this paper, we present the findings and lessons learning from the practical workshop in Ouluzone 2019. The goal of the workshop was to challenge students to learn open infraBIM and automation by building Speedway track. For example, real-time cloud service, 3D measuring machines, and drones were used as modern tools.

2 Development of the Open infra BIM Workshop

OuluZone workshops were kept in OuluZone, which is a motorsport center owned by the city of Oulu, Finland. OuluZone is located in a place called Arkala, which is around 35 km northeast from the city center of Oulu. One goal of OuluZone is to enlarge its activities and develop it as research, development, and education centre. Currently many research activities have already going on related to drones, robotics, and autonomous excavators. In addition, different workshops have be done for infrastructure technology professionals. The collaboration education week is so called OuluZone – Open Infra BIM and Automation workshop. In the years 2017 [13], 2018 [14], and 2019 workshops were concentrated on educating open infra BIM automation and robotics for students. The objective of the workshop is to provide the latest knowhow, challenges and the future needs in the open infraBIM based automation and robotics to the students. The other goals were to develop teaching and collaboration between organizations. The learning outcomes of OuluZone workshop have been to understand the conceptional and practical knowledge relating to infraBIM technologies, workflows and protocols in the infrastructure construction sites. Each year the teachers met several times to plan the content of the workshop. Depending on the year, the OuluZone workshop week has been contained 2-3 lecture days from teachers and technology company partners, 2-3 practical days in the OuluZone motor center, and finally 0,5-1 feedback day. In the year 2019, the program for the OuluZone workshop week is presented in Table 1.

Table 1. The program of the OuluZone – Open Infra BIM and Automation workshop week 44, 2019 (28.10.-1.11.2019).

Day	Content	Example of the topics
1.	Lectures by teachers and technology company experts	Common InfraBIM Requirements 2019, Infra information modelling, foundations of cloud service system, and automation construction site. Questionnaire
2.	Lectures by teachers and technology company experts	Typical work tasks in construction site such as foreman and designer. Occupational safety, MVR-form
3.	Practical training	Tasks in Ouluzone motor center: training
4.	Practical training	Tasks in Ouluzone motor center: problems solving. Construction site audit. Autonomous excavator show
5.	Summary of the workshop	Results from occupational safety, feedback collection from participants. Questionnaire

2.1 Participants in OuluZone workshop

The Finnish educational system consists of nine-year compulsory comprehensive school, three-year upper secondary education and four to five-year higher education. In OuluZone workshop, the participants came from secondary education provided by vocational college (Education consortium OSAO), and from higher education by the University of Oulu and the Oulu University of Applied Sciences (Oamk). The curriculum of these schools includes infrastructure construction and automation as one field of the study program. For a Masters' Degree students of Technology there is a five-credit course called "Information modelling and automation building construction and maintenance", at the Department of Structures and the Construction

Technology Research Unit at the University of Oulu. For engineering students at the Oulu University of Applied Sciences (OAMK) there is a five- credit course entitled "Infra BIM modeling and building a construction project". The Oulu Vocational College (OSAO) provides three years teaching for construction machinery and lorry drivers as well as logistics instructors. Each workshop had the different number of the participants depending of the year. In Table 2 is presented the number of participants from University of Oulu, Oamk, OSAO and industry in the year 2019. The others are presenting the visitors who were interested to follow and visiting the workshop.

Table 2. The total number of participants was 82 from University of Oulu, Oulu University of Applied Sciences (Oamk), OSAO, and technology company organization as well as visitors.

Organization	Students	Teachers	Visitor
University of Oulu	7	10	3
Oamk	19	3	
OSAO	19	3	
Company		11	7
Total	45	27	10

Before Ouluzone workshop week, each school was preparing their students by different ways. The master's degree students of the University of Oulu had lectures and trainings by teachers and visitor lectors from technology companies in the autumn 2019. In the lectures, students learn how to make a road plan over a measured terrain model using a Novapoint program. Trimble R10 GNSS System was used to produce a terrain model. The measurement guide of Finnish Transport Infrastructure Agency Machine was followed during producing the terrain model [15]. Machine control model for each layer was made by using the 3D-win program. Machine control model is a continuous (3D) surface and/or line model needed for the automation control systems of machines [1]. Inframodel (IM) is Finnish national XML-based application specification which is based on the international LandXML schema [1]. In addition, the students visited to OSAO Haukipudas campus to learn the machine control system is working, and to test the excavator simulator (Tenstar) integrated Leica's 3D machine control system.

Oamk students are either engineering, builders or multiform level. Their lectures were already completed during spring 2019. The topics of the lectures were e.g. infrastructure in society, infrastructure project constructions and contracts, the cost planning of the infrastructure project in a project owners' perspective, construction tasks and good practices ensuring the safety of the constructions projects, and finally general terms and conditions of the construction contract, i.e YSE 1998. After lectures, students had the training period in the construction site.

The third-year students of OSAO practice their earth moving machinery such as excavator and loaders' operator skills and how to actually use 3D-machine control systems first in simulators mention above and then in practice. In Ouluzone OSAO construction driver students were doing their skill tests. The institutes each measured their own students' learning outcomes using appropriate methods.

2.2 Workshop tools during OuluZone

During the OuluZone week, the students continued to build with a help of teachers and technology experts a new Speedway track and its cutting operation in real-world conditions. The Speedway track geometry was designed first in 2D drawings and then in 3D model in open file formats (.dxf and Inframodel). The geometry was designed by using the 3D-Win program presented in Figure 1. The total length of the Speedway track is 437m in with the straight line of 65m. It was calculated that the cutting mass is 7848 m^3, filling mass 7727 m^3, and surplus mass 100 m^3.

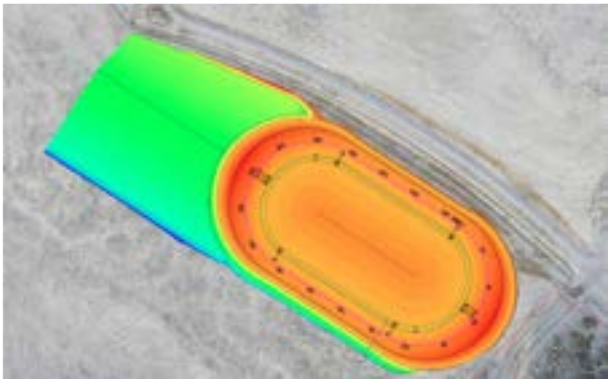

Figure 1. Speedway track geometry designed by using 3D-Win program (Mitta Oy).

The unmanned aerial vehicle (UAV) field measurements were carried out in August 2019.The Speedway track area was photographed using photometry technique to produce the digital surface model (Figure 2). First, the reference points were made by RTK-GNSS Base Station around 50 to 100 meters each other for the area to be photographed. The reference points are searched for in the 200 photos to get coordinates and the margin of error. Similar type of UAV measurements procedure than in Ouluzone were also done in sub-Arctic Mining Site [16]. In Figure 2 is presented the accurate georeferenced dense point cloud based on the targeted photos and reference points. Before workshop 2019, around 30-40% of Speedway track cutting was already made in previous workshops. The cutting operation in workshop 2019 was decided to

continue in the centre of the speedway track.

Figure 2. UAV field measurements made in photometry technique to get Speedway track cutting situation in OuluZone motor center August 2019.

The students were using the latest technology tools at Speedway track construction site. Infrakit cloud service (provided by Infrakit Group Oy) was used as the open infra BIM tool to monitor real-time the Speedway track building progress. Infrakit was selected as cloud service tool based on past experience of its easy of use, and that it can be combined with several devices from different manufactures [17]. In Figure 3 shows the Speedway project view in Infrakit cloud service. For example, during the project, the construction site can be monitored in real-time. The excavator operators are measured the values of the as build point every 20 meters. These as build points are used for the quality control of the dimensional accuracy of structures during work and for monitoring the progress of the work.

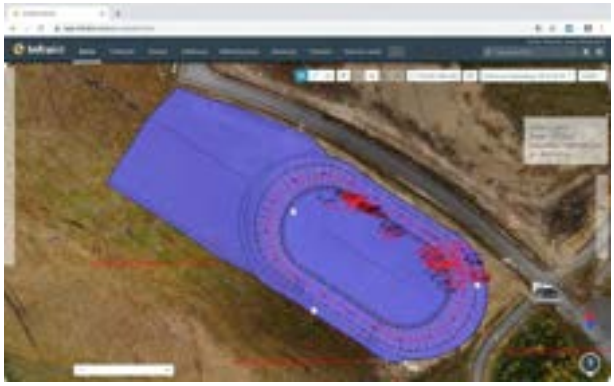

Figure 3. Speedway project in Infrakit cloud service. The combination model is a combination of Speedway track geometry integrated the drone picture.

To build the Speedway track, two excavators and wheel loader with the automatic Leica-3D control system, and two trucks and a dumper with Infrakit-android application were used, too. The other necessary equipment needed in Speedway-track construction site were RTK-GNSS- base station, three to four pieces' reference points around the Speedway track. The coordinates of the reference points were measured using the static GNSS measuring method in ETRS-GK26 map coordinates and N2000 height system [18].

2.3 Tasks in OuluZone

For the Ouluzone practical training, the students were divided into six teams. The number of students in the team was from 5 to 6. The same number of different tasks of a typical site organization were developed where students could practice practicing the work tasks involved. The teachers also organized various change and problem situations in the workshop, which students had to deal with in their various roles. The practical training tasks were:

1. Road designer
2. Speedway -project owner and surveyor
3. Construction' head manager
4. BIM Coordinator
5. Excavators, trucks, and wheel loader drivers
6. Drone-monitoring

Figure 4 shows the time schedule of for each teams 1 to 6. In the Figure Z, numbers 1 to 6 presents task mention above. Both on Wednesday and Thursday at the Ouluzone motor center, the teams followed the same time schedule.

Time	Team 1	Team 2	Team 3	Team 4	Team 5	Team 6
8:30	Arrival, registration and grouping, morning coffee					
9:00	1	2	3	4	5	6
9:50	2	3	1	5	6	4
10:40	3	1	2	6	4	5
11:30	Lunch - cafe			free time		
12:00	free time			Lunch - cafe		
12:30	4	5	6	1	2	3
13:20	5	6	4	2	3	1
14:10	6	4	5	3	1	2
15:00	COFFEE and return of helmets and vests etc					
15:30	Departure					

Figure 4. The time Schedule of Wednesday and Thursday in OuluZone workshop for each team 1 to 6. The number in colored area is the practical tasks: 1) road designer, 2) speedway project owner and surveyor, 3) construction' head manager. 4) BIM foreman, 5) excavators, trucks, and wheel loader drivers, and 6) drone-monitoring.

Occupational safety was monitored by using MVR-form. MVR is used at civil engineering as a method of assessing working conditions and safety and for carrying out statutory weekly inspections. Throughout the

workshop, the safety manager counseled students on if any problems or issues appeared. In addition, the students had the Infrakit app in their mobile phones and a possibility to use Infrakit-support during the workshop. Finally, the students had a possibility to follow the autonomous excavator [19] show provided by the University of Oulu. The tasks were located in Ouluzone in several different places e.g. judge tower and construction site.

3 OuluZone workshop

The Ouluzone workshop 2019 was contained 2 lecture days, 2 practical days in OuluZone and finally the feedback and evaluation day. In this chapter, the results and discussion about the findings and lesson learned about this workshop is presented.

3.1 Lectures

The purpose of the lectures was to go through the various stages of the construction site from the planning to handling over the Speedway track to the project owner. Here is presented few examples of the content of the lectures. Teachers and experts from technology companies prepared their presentation with slides including videos and they explained many real-life examples in their presentations. First, it was explained to students the objectives, organization and general things related to the Ouluzone workshop week. During the lectures was mentioned, Finnish legislation and requirements of the road construction that must be taken into account. Cooperation forum BuildingSMART Finland and its work to disseminate information on infraBIM and to support those in the implementation was presented. In addition, the use of the right documents for example to safety and construction site technical quality requirements (based on InfraRYL) was presented

An integral part of infra information modelling is various geographic dataset such as ground (level) model, and environmental information which can be visualised also in 3D models. Survey control is an essential element in the design and construction survey data. The using correct coordinates and high system is very important and using the correct unit of measure (meter).

Students learned the principles of road construction design and model-based quality assurance. The designer is responsible for the correctness of the initial or source data model. Therefore, it is important that all the term such as lines are defined correctly. The final planning model has gone many rounds from designer to the project owner to ensure quality. The importance of occupational safety issues was emphasized during the lectures before the practical training in Ouluzone. The principle of the MVR-form as a tool for following the safety was gone through.

A simple Kahoot-play questionnaire was conducted to found what student was learned before the workshop. The questionnaire contained 10 questions and there were four answer options in each question. The result of Kahoot-play questionnaire is presented in Figure 5. Based on the correct answers, it can be said that the students had moderate starting knowledge for the workshop.

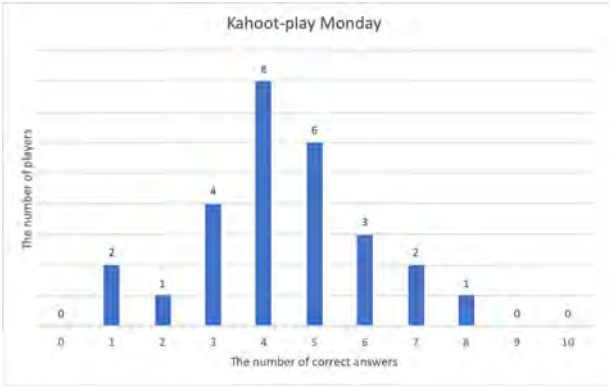

Figure 5. The Kahoot-play questionnaire in the begin of the workshop. The number of answers were 28. The average degree was 4.25 by the standard deviation 1.85.

3.2 Practical training in Ouluzone

The goals of two day practical training in the Ouluzone workshop was to learn open infraBIM-based automation and robotics in practice and problem solving. The construction site of Speedway track contained human resources, digital models, machines and devices, materials and time. It was important that everybody knows their role and responsible to optimize the high quality result. The location of the base station was vital to achieve the best connection to all machines, automation systems and Infrakit cloud service. The learning tools during the tasks were slides, videos, real-life examples, discussions, exercises and demonstrations. In each task, the main responsivities were discussed and how Infrakit cloud service was used. The learning outcomes of students for each practical task can be summarised as following:

1. Road designer: Understanding about model-based road construction work accordance to design and modelling instructions. Describe the documentation procedure to ensure the compatibility of models and absence of conflicts.
2. Speedway-project owner and surveyor: Understanding about decisions and purchase procedures for the preparation and implementation of the project. At each stage of the life cycle, the acceptance the final outcome into maintenance systems is compliant.

3. Construction' head manager: Describe the overall operations (e.g. scheduling, control, implementation, and quality assurance) of the model-based construction site responsibilities.
4. BIM Coordinator: Describe how to use and apply up-to-date information management from the construction site such as ensuring the quantity calculations, a model-based quality assurance procedure, the survey control and preparation of digital handover material.
5. Excavators, trucks, and wheel loader drivers: Understanding about the machine control equipment operation. Describe the model-based quality control procedure in accordance with as build surveys and mappings performance.
6. Drone-monitoring: Understanding about the UAV field measurements procedure to receive the digital surface model, or to follow construction site progress.

The second day at OuluZone was problem solving, and therefore construction site audit was arranged. There were two reasons: 1) the location of the construction site was suspected to be in a wrong place, and 2) the size of the rock found on the construction site. All the participants gathered at the construction site to evaluate and solve the situation.

During the Ouluzone practical days the students were requested to monitor both the positive and negative things at the construction site by using MVR-form. The MVR- form included considerations such as working and machine operation, equipment, electricity and lighting, protection and safety areas, driveways and traffic routes, and ordering and storage.

One possibility for future construction sites is autonomous machinery for example dangerous environments. All the Ouluzone workshop participants were demonstrated, how the automated control of the movements of the excavator (the Smart Bobcat E85 Excavator 6) is working.

3.3 Final day of the workshop week

The final day of the workshop was for receiving the feedback survey both from students and from teachers. The questions were about the successes and development ideas. In addition, the best practical test was evaluated. The participants mentioned time scheduling and getting industry partners as teachers involved as positive things during the OuluZone week. Each group presented their MVR-findings. It was interesting to notice that if the group had any construction site experience, the findings were more accurate. In addition, the debate on the importance of occupational safety was lively.

One of the development ideas was MVR-form as a new practical task was desired, since the discussions with the expert give the new off reinforces perspective. The construction site audit was surprise to students and therefore the problem-solving situation went unclear for some. Thus, the instructions at the beginning of the week should be more exact. This means that there could be even more communication between teachers before workshop week. The best practical tasks were evaluated to be the drone and designer, since teachers were prepared their materials properly.

Finally, Kahoot-play questionnaire was conducted to found what student was learned during the workshop. The questionnaire contained 10 questions and there were four answer options in each question. The results of Kahoot-play questionnaire are presented in Figure 6, in where can be seen that the participants received more correct answers than on Monday Kahoot-play. Therefore, it can be said that the students had good knowledge after the workshop.

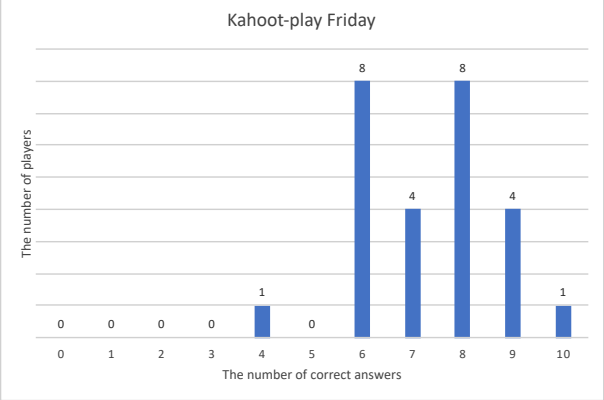

Figure 6. Tue Kahoot-play questionnaire in the final day of the OuluZone workshop. The number of answers were 26. The average degree was 7.31 by the standard deviation 2.32.

4 Summary

The results and findings from the education collaboration workshop week between the University of Oulu, the Oulu University of Applied Sciences (OAMK), and Oulu Vocational College (OSAO) is reported. The goal of the workshop week was to educate Open InfraBIM and construction Automation and robotics to students. During the week students learned from lectures and practical training in OuluZone motor center what are the typical tasks of the responsible person in the constructions site and how they are using modern tools such as automation and cloud service (Infrakit). Practical learning was found to be motivating way to educate students. Technology companies reported that they have received new ideas from the Ouluzone workshop for further product and application development. Based on

good learning experience and the feedback from the participants, the development of Ouluzone workshop will be continued.

Acknowledgements

The authors would like to acknowledgement all the students and teachers from University of Oulu, Oulu University of Applied Science (OAMK), and Oulu Vocational College (OSAO) that took the courses and participating to OuluZone workshop week 2019. Authors are grateful to the experts from construction industry Mitta Oy, Destia Oy, Infrakit Oy, Welado Oy, Ni-Ro Oy, Pointscene Oy, and Novatron Oy for provided the feedback on their experiences and for brought their technology. BusinessOulu is also acknowledged for their great support on this workshop. This OuluZone+ project was financed by European Regional Development Fund (A71660).

Abstract –

Considerable body of literature exits on automated site data acquisition for tracking and progress reporting of construction operations. While GPS-based solutions have been widely investigated in many studies for outdoor tracking of these operations, indoor tracking proved to be more challenging. This paper focuses on indoor material localization and investigates the use of two remote sensing (RS) technologies including ultra-wideband (UWB) and radio frequency identification device (RFID) in order to support automated tracking of indoor operations. The integrated use of these two technologies is proposed to benefit from the capabilities of each technology and to have a cost-effective and practical solution for location identification of the materials on site. The proposed methodology includes two steps. First, tracking of the items located above floor level such as plumbing and HVAC installations. This was performed using accurate identification and 3D-location information generated by an UWB system. A set of experiments were carried out using various filters to improve the localization information. The results indicate that an increase in range distance between UWB tags and receivers increases the mean ranging error from around 20 centimeters to over 50 centimeters. In the second step, an UWB tag is attached to a hand-held RFID reader and accordingly the accurate location of that reader is stored. Then, by using algorithms such as boundary condition trilateration (BConTri) and received signal strength (RSS), the objects that are labelled by RFID tags are localized. Accordingly, this integrated configuration of the sensors eliminates the need for using a large number of RFID reference tags onsite for indoor material localization. The data fusion embedded in the proposed configuration is expected to enhance automated progress reporting. Besides, it is likely to enable identification and measurement of deviations from as-planned models in a timely manner. The experimental data captured in the lab will be analyzed and presented, highlighting the advantages of the proposed method.

Automated progress tracking; RFID system; UWB system; Data fusion

1 Introduction

Progress reporting is a critical part of the project control in which a large amount of as-built information related to a variety of tasks onsite are provided. However, it is not a simple task due to challenges associated with data acquisition and handling a large amount of information for a variety of functions such as scheduling, construction methods, and cost management. Object tracking is an important part of a progress reporting system in which the identification and localization information of the various objects onsite are needed.

The literature reveals a wide range of studies for identification and localization of the objects, as the main parameters of a tracking system. These two types of information can enable us to track an activity in a desired time span. Tracking materials and accessing onsite information can be challenging due to dynamic nature of onsite operations including material delivery and utilization. In fact, material management was identified as one of the areas that has a great potential for improvement on sites [1].

Many researchers have proposed the application of various Remote Sensing (RS) technologies such as GPS, Radio Frequency Identification Device (RFID) and Ultra-wideband (UWB) in tracking of various objects onsite [2]. However, applications associated with outdoor tracking of the materials are mostly based on GPS-based technologies [3-9]. But, this technology is not suited for indoor environment. Besides, due to a wide range of materials and structural objects in an indoor environment, there is a need for a system in which a large number of items can be tracked efficiently.

RFID technology has been used in this respect with

great capability in automatic identification and tracking of tagged objects onsite. It is applicable for both built facilities and during construction due to its non-line-of-sight capability, wireless communication and on-board data storage capacities [10]. Besides identification capability, RFID technology is also used for localization of the tagged objects onsite. There are three main methods to localize an object using RFID sensors including triangulation, proximity, and scene analysis. Range-based localization is usually based on trilateration and triangulation techniques in which the received signal strength index (RSSI), phase-based indicator and time-of-arrival (TOA) are used to measure the range distance from a tagged object. Proximity technique is based on using some reference points with known locations in order to investigate whether a tagged object is close to those reference points or no. Scene analysis uses some algorithms (e.g. k-nearest-neighbor (KNN) or probabilistic methods) to localize tagged objects based on the similarity of received signal with a prior location fingerprints collected from the environment. In the range-based techniques mentioned above, the distance value between a hand-held RFID reader and a tagged object can be measured by converting the RSSI to an experimental range value. Having said that, these received signal strength (RSS) values are unreliable since they are highly dependent on various factors in different environments. However, proximity and scene analysis techniques are not based on the range value between tag-reader, but they still rely on RSS value for localization which makes the localization not reliable enough. Besides, they face additional barriers in terms of system configuration with extra cost and deployment, computing complexity and calibration difficulties [1]. In [1], application of the RFID technology for indoor location identification of the materials was investigated. However, the individual use of RFID sensors faces some difficulties since a high density of reference tags are needed [1,11].

UWB technology is a Real-time Location System (RTLS) which has a performance almost similar to an active RFID system, however, it uses very narrow pulses of radio frequency energy which are occupied in a wide bandwidth for communication between tags and receivers. Various types of UWB sensors use different positioning techniques for localization, including: time of arrival (ToA) or time of flight, angle of arrival (AoA), time difference of arrival (TDoA), and received signal strength (RSS). AoA has some advantages over TDoA as it does not require synchronization of the sensors nor an accurate timing reference. While TDoA is less sensitive to changes in setup calibration, it still requires more cabling to have an accurate timing reference. Several researchers have investigated the possibility of using this technology for location identification of objects to track construction operations. Most of their efforts were focused on evaluating real-time tracking of workers, equipment and materials in indoor and outdoor environments [2,12-15]. Besides, some studies have investigated the effect of the UWB sensors geometry, employment of some filters (e.g. Kalman Filter, particle filters and etc.) and the possibility of using static reference tags in order to enhance the localization accuracy of these sensors [12-13,16-21].Studies have been conducted on integrated use of the RS technologies to overcome their individual limitations in order to achieve a more reliable and economical system in which a large number of objects can be tracked and localized. Examples of these integrated systems for outdoor tracking of objects include systems in which a RTLS such as GPS is integrated with Barcode and RFID to benefit the positioning and identification capability of these two technologies. In [22], a low-cost integrated system of GPS-Barcode was designed for tracking of materials on a storage yard. Furthermore, an integrated use of GPS with RFID technologies could provide better performance for tracking of the resources onsite [2,3,23-25]. For instance, in [23], a system consists of spatially distributed mobile RFID readers equipped with GPS technology was used to track a set of mobile RFID tags. Besides, boundary constraints were introduced to facilitate RFID-based localization applications to overcome the challenge associated with unknown tag-reader distance.

Applications of indoor location identification of objects in construction industry include the real-time progress reporting, safety, materials management, and productivity analysis [26]. This paper aims to introduce a new technique in which an integrated use of the UWB and RFID technologies helps to efficiently track the materials in an indoor environment. Besides, a large number of objects are localized in a more economical way which can enable us to recognize and measure deviations from planned models by having both time and location of the available objects associated with each activity. This can result in a more enhanced and timely progress reporting onsite, which is essential for an accurate earned value analysis (EVA) and project estimating.

2 Experimental Performance of the UWB System

In a set of experiments in the Construction Automation Lab. (CAL) in Concordia University, performance of the Trek1000 UWB Evaluation Kit which is an off-the-shelve product is investigated. These sensors utilizes an atomic timer embedded in their PCB board that provides a high positioning accuracy in the range of a few decimeter. This product is almost eight times less expensive than the available commercialized

sensors, however, it is still not a final product with a protected enclosure.

The initial setup of the experiment includes a system of four receivers and one tag. The data rate of this setup is fixed on 110 kb/s and in Channel 2. This is the standard setting defined by the manufacturer for maximum range measurements. For calibration and measuring the accuracy of this system, a grid on the floor with tiles in size of 90 cm × 90 cm was marked in order to define the 65 ground-truth test points which covers both Line-of-Sight (LOS) and None-Line-of-Sight (NLOS) scenarios. The anchors were put at height of 1.65 m except one of them at the height of 2.15 m, and a moving tag at height of 1.35 m. The experimentation consists of moving one mobile node to 65 different ground-truth locations. For each tie point, a time interval of 30 seconds was considered, so each tests lasted 32.5 minutes (i.e. 65X30 s=1950 s). However, 10 seconds before and after each displacement was rejected in order to guarantee a good ground-truth data. Figure 1 shows the good performance of this system. As we expected, all data points are above diagonal line which indicates the positive aspect of error due to the NLOS dispersion since there should never be range measurements shorter than the real straight path.

2.1 Range Measurement Accuracy of the UWB System

Range measurement is important since the location of the tagged objects are achieved based on their values. One way to improve ranging measurement is to remove the clearer outlier measurements from our estimation. A comparison of the methods to mitigate localization error associated with NLOS situation and the situations in which they can be employed are discussed in reference [26]. For the case of this research, there are technically two groups of objects which need to be tracked and localized by the UWB system. The first group is stationary objects which are tagged by UWB sensors. The second one is a moving RFID reader. For the first application, since the objects are stationary (or semi-stationary such as plumbing and mechanical facilities) a tailed UWB-ranging measurement model is used which is fitted to a histogram of the ranges error in NLOS situation (Figure 2). For simplicity, the same particle filter was used for the moving RFID reader.

In this experiment, first any outlier reading ranges in NLOS situation with the error value more than 0.8 m are removed from the initial data. Then, the testing ranges are split into three intervals with step of five meter (0-5,5-10,10-15). Finally, the remained reading ranges in middle of 10-second out of 30-second stop in each tie point are averaged to calculate the tag's location in each time step. Figure 3 illustrates the mean range error and standard deviation for each ranging interval with and without omitting initial outliers.

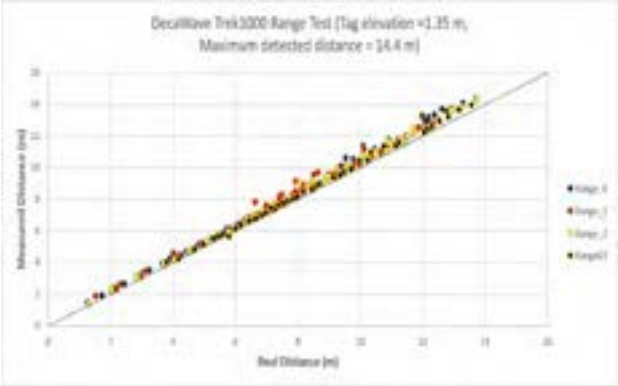

Figure 1. Real versus measured ranges.

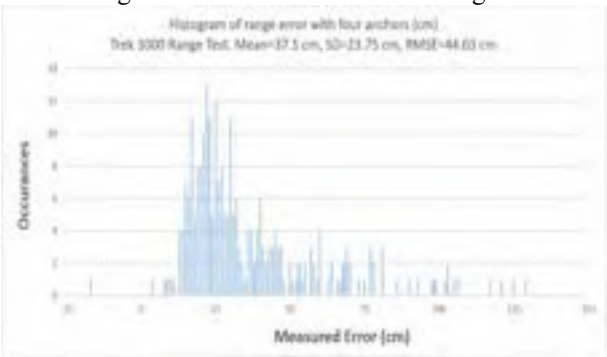

Figure 2. Error histogram in NLOS.

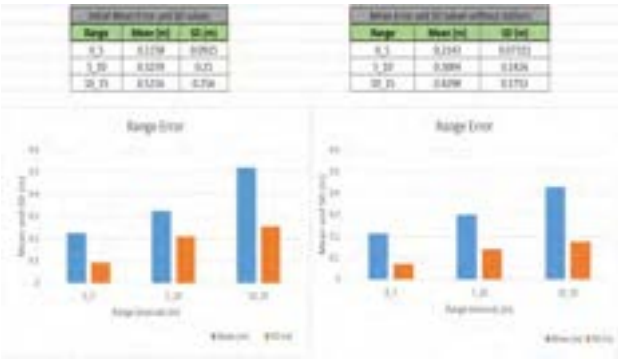

Figure 3. Mean and SD error values with outliers (left) and without outliers (right).

2.2 Localization Accuracy of the UWB system

In this research experiment the 3D location of the critical elements in elevation are tracked by UWB tags attached to these elements such as installations and critical spools in plumbing system. Besides, it is possible to localize and track the items which are tagged by RFID tags. For that, the real-time location of the hand-held RFID reader is acquired by the UWB tag attached to it (section 3.1).

From various techniques to mitigate the localization error [16,26], for tracking stationary (or semi-stationary) objects tagged by UWB sensors, a tailed UWB ranging measurement model is fitted to the experimental

measurements presented in the last section. In fact, this model combines a Gaussian distribution (for the LOS measurements), a Gamma distribution (for the NLOS cases) and a constant value to cope with additional uncertainty and spurious measurements. By creating a measurement model using the error histogram in NLOS situation (Figure 2), it is possible to alleviate in-excess range measurements. Then, a particle filter with three states (i.e. X, Y and Z) is used to change the weight of each particle. Finally, the location of the moving object is obtained by computing the weighted mean location of all particles [16].

3 Proposed Methodology

There are various techniques for localization of the objects by using a RFID system. Since in this experiment a roving RFID reader (s) with known location is used, the application of a range-based technique is investigated to localize stationary tagged objects. Here an integrated system of both RFID and UWB sensors is designed. In fact, it is not economically practical to use only UWB tags for tracking objects onsite. While, the reasonable price for RFID tags make them a good choice for object identification and localization. However, the calibration of the system in this approach is problematic since the RSSI varies over time and it is highly dependent on the site environment. Plus, there is no direct relationship between this RSS value and a conventional ranging formula which results in low positioning accuracy [27].

In another approach, the tagged objects are localized by using a boundary condition-based algorithm in which the maximum reading range of a hand-held RFID reader helps to localize those objects which can satisfy the condition of appear in-out in that range limit [24,28].

Using only RFID tags for localization of the objects in an indoor environment needs to employ a large number of RFID reference tags [23]. Saying that, for outdoor tracking of materials, an integrated system of RFID and GPS-based sensors was proposed in previous literatures which eliminated the need for reference tags [23,25]. It was basically based on finding the location of the RFID reader (s) by a GPS receiver and then finding the tags location through trilateration technique. Unfortunately, in an indoor environment the performance of the GPS sensors are highly degraded since they need a direct access to the sky to receive signals from satellites. In this way, the UWB system can be replaced with GPS system to localize RFID reader in each time span.

3.1 Integrated UWB and RFID Technologies

An integrated system of the UWB and RFID sensors helps to benefit from positioning capability of UWB sensors for localization of RFID reader (s) in an indoor environment. In fact, by knowing the location of the RFID reader (s), it would be possible to localize RFID tags by using a Boundary-condition Trilateration (BConTri) algorithm or a received -based technique. In the boundary condition-based algorithm, a tag location is measured by solving three (four) lateration equations (Equation 1) in which the intersection of three circles (four spheres) for 2D (3D) localization is needed. While, the RSS-based algorithms estimate the tag location as an average weighted over received RSSI of the three (four) corresponding reader locations under the boundary condition (Equation 2) [23].

$$(x - X_{i,t})^2 + (y - Y_{i,t})^2 = r^2 \quad (1)$$

$$(x,y) = \left[\frac{\sum_{i=0}^{2} X_{i,t^*}\, rs_i}{\sum_{i=0}^{2} rs_i} + \frac{\sum_{i=0}^{2} Y_{i,t^*}\, rs_i}{\sum_{i=0}^{2} rs_i}\right] \quad (2)$$

Where (x,y) are unknown target tag coordinates, $(X_{i,t}, Y_{i,t})$ are the RFID reader location at time t which are measured by UWB sensor (i=0, 1, 2 for three different RFID reader locations), r is the range distance between tag and reader and rs_i is received signal strength indicator of reader i.

In BConTri technique, the initial value for r is set to the nominal range value of the RFID device (r_0). However, this value needs to be corrected until achieving an acceptable area of intersection between three circles for 2D localization. In this way, an even virtual distribution of points in all three circles is considered. If there is no common intersection area between these circles (number of the virtual points are less than a defined value), then this radius should be increased. In contrary, if the intersection area is more than a defined value, the radius should be decreased. Finally, the estimated location for each tag is calculated by averaging the points available in the intersection area.

It is worth mentioning that since here the tagged objects are static, a few number of readers would be fine for location identification of the items. However, in case of tracking moving objects, a large number of RFID readers would be required. To localize a tag, a set of acceptable boundary reader points (BRPs) should be identified. Around 10 points would be enough for an experimental assessment to localize a tag. Then, three (four) out of ten points are selected to solve the trilateration equations for 2D (3D) localization. Since selection of these three (four) points combination can affect the location accuracy, the combination with the highest value of dilution of precision (DoP) is preferred. In fact, in a GPS system the localization accuracy will increase when visible satellites are far apart which results in a higher DoP and geometry is stronger. Saying that, unlike GPS system, RFID system is not working based on clock offset (using the time difference to measure distance). In this way, a new approach to consider the effect of the RFID reader locations on the localization

accuracy is needed. In fact, besides measuring the accuracy of the system to localize the RFID tag (s), a calibration model for distribution of the RFID reader (s) is also needed. Similar to the DOP factor in GPS system, this model can enable us to measure the variance for various three (four) combination of the BRPs. Each of these variances are corresponding to an average error value in localization of the tag. In this way, each combination of the BRPs is equivalent to a specific accuracy in measurement which can be used as a standard for selection of the reader (s) distribution.

3.2 Schematic Design of the RFID and UWB Data Fusion Model

Below shows a schematic diagram of the methodology to integrate the UWB and RFID systems in order to achieve a more practical and cost effective technique for indoor location identification of the materials onsite (Figure 4). This information can be used for automated progress reporting and a more timely earned value analysis.

The first part of the tracking system is based on using UWB tags to track objects above floor level. For this type of objects, the UWB tags are used to provide 3D identification-location information of the objects. However, due to high cost of UWB tags it would not be reasonable to tag all objects for tracking each activity. This issue can be addressed by tagging critical objects to track critical activities.

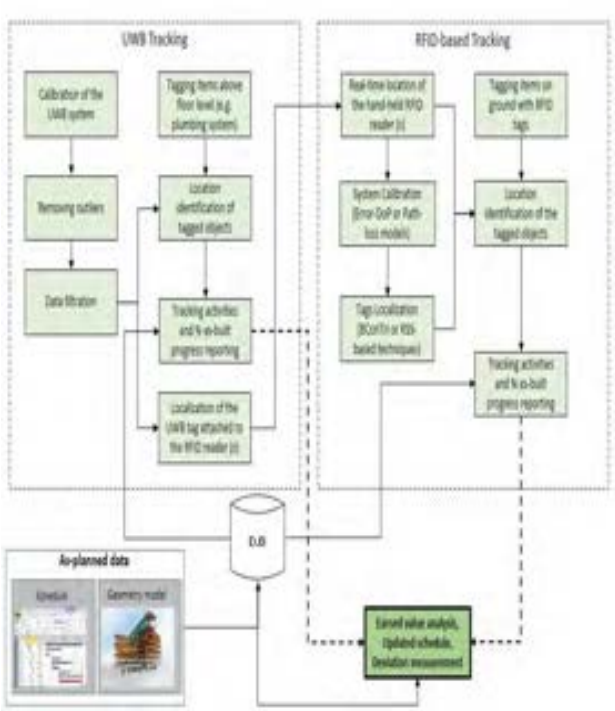

Figure 4. Conceptual overview of the location identification material tracking system.

In the second part of the tracking system, the integrated use of RFID and UWB systems is proposed to track a larger number of objects but in a cost effective manner. In fact, by attaching an UWB tag to the hand-haled RFID reader (s), it would be possible to localize the RFID reader by using the data acquired by the UWB system. By knowing location of the mobile RFID reader (s) and using a localization technique (e.g. BConTri or RSS-based technique), it is possible to localize objects with the attached RFID tags. As mentioned, system calibration should be conducted before tags localization. In the following subsections, after a brief review on some protocols for data acquisition, the calibration and localization modules are elaborated.

3.2.1 Data Acquisition protocol

The data acquired by integrated RFID-UWB sensors should be time-stamped. Saying that, the UWB system have a timer with ms accuracy, while the timer accuracy for RFID system is in second.

a) Data acquisition for system calibration: to achieve the path-loss model required for the RSS-based range measurement, the RSSI received from 10 RFID reference tags on the ground are recorded. Since the exact position of all the tie points and the 10 reference tags are known, it would be possible to measure the range distance between the reader and each reference tag. The RFID reference tags are located at the height of 1 m, while the hand-held RFID reader output is set to 22 dbm (with an approximate reading range of 3.5m). Here we move forward on the 35 tie points (the same tie points for UWB system calibration) every 30 seconds. After deducing the first and last five seconds in each step, the data read by the RFID reader are analysed. In another scenario, the real-time location of the hand-held RFID reader is estimated by the UWB tag attached on it. In this way, there is no need to move on any tie-points, however, a time-step (such as one second) should be considered for matching RFID and UWB data. To enhance the accuracy of the UWB tag in localizing the RFID reader, we should ask the surveyor to stop moving when triggering the hand-held reader.

b) Data acquisition for the RFID tags localization: in order to meet the condition required for localization based on the BConTri algorithm, some protocols for data acquisition need to be respected by the surveyor. In fact, an acceptable reading for a tag in this algorithm is based on a roving RFID reader moving to different directions in each time step. For that, we should ask the surveyor to not stop moving when pushing the trigger of the hand-held RFID reader. Plus, for better performance of the hand-held reader, it is needed to put it in rest mode every minute in which the surveyor should stop moving.

3.2.2 Calibration Module

To calibrate the system for localization of the tags by the hand-held RFID reader, first a set of acceptable readings for localization need to be selected. The acceptable reading data can be varied depending on the algorithm we use for localization. Here, both BConTri and RSS-based algorithms are tested to evaluate the accuracy of each of them for localization. For instance, in BConTri algorithm the acceptable readings are those in which the event appear in-out happens for each tie point. For the RSS-based algorithms, on the other hand, there are some factors that may affect the accuracy of the localization measurements. This includes factors associated with the RFID devices such as operating frequency, the hand-held RFID device power and distance between the tag (s) and reader. The results of an experiment showed that if the distance of the reference tags from each other is half of the device reading range (0.5RR) then a better detection rate is resulted [28]. The factors associated with indoor environment also influence the RSSI signal such as free space loss factor, multipath reflection, and interference effects [29]. As mentioned above, by putting some reference tags with known locations, it would be possible to evaluate the accuracy of the measurements. Figure 5 illustrates the various steps for the system calibration.

a) In BConTri-based technique: for this method, the combination of RFID reader locations with the highest value of Spatial Dilution (SD) is preferred in order to achieve better localization accuracy. Saying that, the SD value refers to the distribution of a number of objects in space and their geometric configuration, mostly used as an indicator of the locating accuracy for systems which are working based on the ToA and AoA positioning techniques. In fact, it is equivalent to the mathematical variance and DoP in GPS-based systems. In this case, for each combination the SD factor for hand-held RFID locations and the corresponding error in identified reference tags location are calculated. Then, the SD can be normalized into a ratio of the SD (RSD) by diving its value to the highest tag-reader distance to omit the effect of range distance in estimation. The details of the mathematical calculations are provided in [25].

After repeating the steps above for all possible combinations of the RFID locations geometry, a linear regression is assigned to the points achieved in a graph in which the error value (m) and RSD are the variables in vertical and horizontal axis respectively. This graph can be used as a standard for standard value of DoP and the corresponding accuracy. The standard value is used as a threshold for selection of the data in localization of other tagged objects. In fact, only the RFID reader location combinations with SD value more than the standard SD value are accepted.

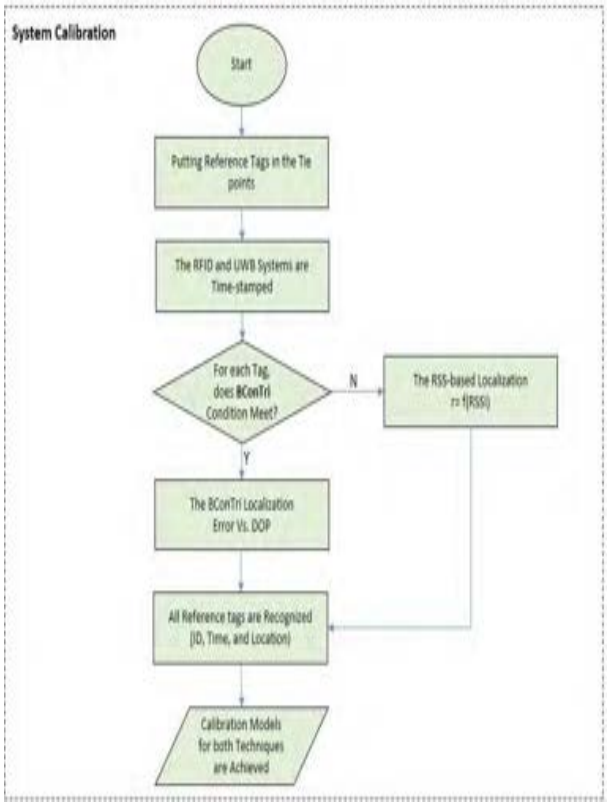

Figure 5. System calibration diagram.

b) In RSS-based technique: to use this technique for tags localization, a path-loss model is needed. In fact, based on the RSSI recorded for each reference tag and the corresponding distance range value (DRV), the model would be achieved (Equation 3). Then, by knowing the location of the RFID reader recorded by UWB sensor attached, the location of the each RFID tag is calculated by solving three distance equations (Equation 4).

$$DRV = - 0.5617\ RSSI - 39.9337 \quad (3)$$

$$DRV = [(x_{r\_uwb} - x_i)^2 + (y_{r_{uwb}} - y_i)^2]^{1/2} \quad (4)$$

In which (x_{r_uwb}, y_{r_uwb}) are the location of the hand-held RFID reader (s) which are acquired by UWB device attached to it. And (x_i, y_i) are the coordinates of the identified RFID reference tags with known locations. For each identified tag, an average of the RSSI values and the calculated range value are recorded.

The result of the system calibration to achieve the path-loss model is shown in Figure 6. It depicts the RSSI versus the distance between the reference tags and the reader in each tie point. In fact, the average of the RSSI for each tag identified in each tie point is calculated. Then, for assigning a regression model to the data acquired, the data are again averaged for every 5 cm increments. Details of the best regression model and their accuracy can be found in [26].

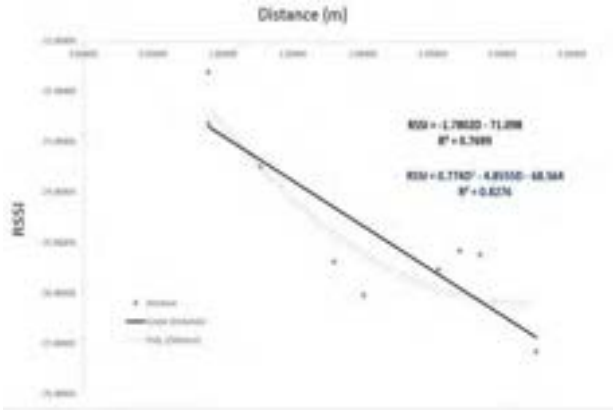

Figure 6. RFID system path-loss model.

3.2.3 Localization Module

After conducting the calibration, it is time to localize the tags location by using the standard spatial dilution (SD_{st}) or the path-loss model to localize tags in BconTri and RSS-based techniques respectively.

a) Localization through BConTri technique: to localize a tagged object, the location data achieved from the selected combinations of SD (SD> SD_{st}) for each identified tagged object are averaged.

b) Localization through RSS-based technique: to localize a tagged object, first the location of the hand-held RFID device in each time span is achieved from the UWB tag attached to it. Then, by using the path-loss model achieved in the calibration step, the range of the tagged object from the hand-held RFID is calculated. The results for the sample RSSI received from 10 target tags indicated an absolute average error of 0.94 m.

4 Summery and Concluding Remarks

This paper investigates the possibility of tracking objects in an indoor environment by doing both identification and localization of a set of tagged objects onsite. For objects in elevation, the performance of the UWB tags were investigated. However, to track a larger number of objects, the integrated use of UWB and RFID technologies was proposed. For that, a hand-held RFID reader was tagged with an UWB sensor in which the location of the RFID reader was acquired by the UWB system. A two-step algorithm developed including calibration and localization modules. In fact, the calibration was based on using some tie points with known locations in order to provide calibration models. After achieving the calibration models for both BConTri and RSS-based techniques, the tagged objects were localized in plane surface. However, the efficiency of this algorithm for 3D localization of the tagged objects need to be investigated more in future.

4.1 The Methodology Contributions

The tracking system proposed can provide identification and localization information for a set of objects in an indoor environment. The use of low cost RFID tags made it possible to track and localize a larger number of objects in comparison with systems in which the individual use of UWB tags were proposed in previous studies. The two-step algorithm developed for localization of the RFID tags would make it possible to have less missing data of the tagged objects in cases that the tagged objects cannot meet the BConTri required condition. In these cases, the object will be localized by the RSS-based technique. Besides, the integrated use of UWB-RFID technologies solved the problem of using a large number of reference tags for localization of the hand-held RFID reader that was proposed in previous studies.

4.2 The Methodology limitations

The localization algorithm provided in this experiment has some limitations. First, to localize a tag in BConTri algorithm, it is needed that at least three (four) readings happens for that tag in which the tag should appear and disappear to be considered as an acceptable reading. This condition may not be possible especially for 3D localization in an indoor environment with a cluttered distribution of the objects. To mitigate this problem, the tags were localized by RSS-based techniques in case that the BConTri requirement is not met. However, the accuracy of the RSS-based localization is still less than the BConTri algorithm.

Another limitation is the difference in reading rang of the RFID sensors in which considering a circular (spherical) profile for reading range may get biased if the direction of the hand-held RFID reader to the tag differs. Finally, the accuracy of this localization method is highly dependent on the calibration of the system in each environment. For that, an accurate positioning of the reference tags (tie points) is required.

Abstract -

This paper presents an integrated raw-wood fabrication workflow using an industrial robot arm and a laser scanner. The research is situated in a Swiss mountain forestry context where timber in its natural form could be applied locally without relying on large centralized timber industries. While local saw-mills relies on the standard processing tools to transform raw-wood into regular beams and boards, an automated robotic application could exploit timber in its natural form directly for construction. The research proposes a digital fabrication workflow that links industrial robot arm and laser scanning to adapt timber joinery tool-paths to irregular raw-wood such as straight, bent and forked tree trunks. The application employs ABB IRB6400 robot and Faro Focus S150 laser scanner. Several methods are developed for the point-cloud processing including flat-cut sectioning, mesh reconstruction and cylinder fitting. The methodology is tested in two stages: a) scanning a set of tree trunks b) continuous integration within robotic fabrication. The findings compare the scanning method in regards to calibration, pointcloud processing, time needed to communicate between the robot controller, the accuracy of the application. The results show that is possible to perform robotic cutting and scanning interchangeably and the speed of the scanning application is proportionally fast (3-4 min) considering the overall robotic cutting time (60-90 min) depending on the study case.

1 Introduction

Timber as a construction material is commonly unified into engineered timber products such as panels, boards and beams of regular sections [1, 2]. However, these techniques could be avoided by employing machining tools that help to transform raw-wood into a building material with a minimal processing time. CNC and robotic arms can have a computer-vision, cutting and assembly techniques to adapt to the irregularity of the tree shapes [3, 4, 5].

The scanning methods of timber are applied in sawmills, ranging from fast laser scanners [6, 7] to volumetric CT scans [8, 9, 10]. In the industrial context, the geometry acquisition is used to optimize the cutting pattern of trees into boards, identify timber knots and disregard crooked timber. The process is often well structured using a digital data-base to track the maximum use of material, its age, species, and location where the wood is harvested from [11]. This data is applied only at the scale of the saw-mill companies and is not transferred for a design use.

The introduction of industrial robots arms in the architectural research environments helped to change the notion of a standardized-timber and apply its original form for construction. There is a series of scanning methods that gives a vision to the industrial fabrication methods and informs design decisions such as manual measurement, markers and tracking devices, photogrammetry, camera sensors, laser scanning, virtual reality applications, and volumetric scanning.

1.1 Manual Measurement

Trees are primarily inspected using manual measurement tools and selected based on physical dimensions needed [5, 12, 3, 4]. The selection criteria depends on a geometrical data: length, radial parameters i.e. axis and diameter, curvature, and topology i.e. straight, bent, bifurcated tree trunks. The fabrication process could also be assisted by a visual measurement employing a teach-pendant when coordinates are transferred to a digital model [13]. For example, 3 points could be taken to visualize an end of a beam in a form of circle fitting.

1.2 Markers and Tracking

The marker-tracking system is a lightweight geometric method that allows a fast positioning of an irregular tree trunk. Markers or positioning points could ease the fabrication process if a 3d scan has already been performed. There are several possible solutions to position a log within a fabrication setup: (i) aligning two point-clouds by targets captured during a design stage (ii) pre-drilling dowel holes that match a machining setup [4] (iii) employing point tracking system i.e. (OptiTrack) [11]. The reference of markers is determined by probing and matching reference features both found in a digital data-set and the actual raw-woods.

1.3 Photogrammetry

Digital models of raw-trees could also be obtained by taking multiple photos with a low-cost camera [5]. The process requires a slow post-processing technique to translate the photos'pixel-data to a point-cloud or mesh repre-

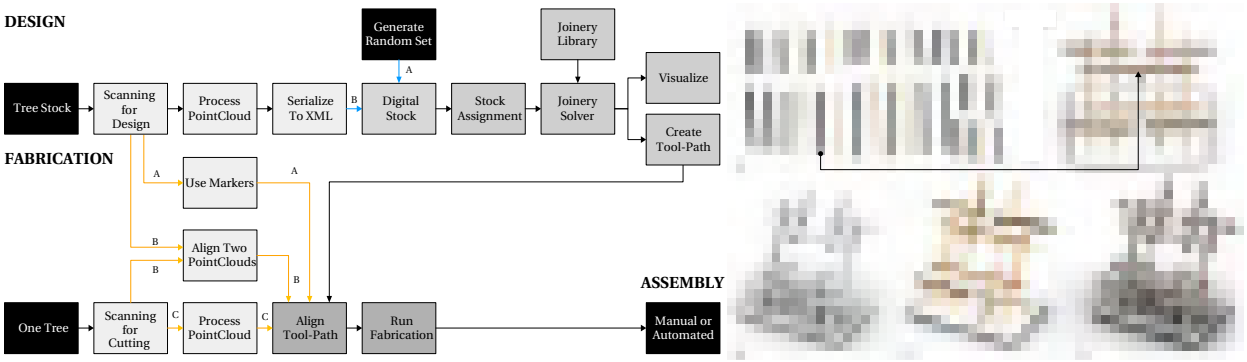

Figure 1. The workflow focusing on design-to-fabrication methods (left). Design method (right) of raw-wood assignment (A) to a digital model (B) that is adjusted for fabrication considering trees radial parameters (C-D).

sentation. The scanning could be combined with a photographic selection and 2D post-processing technique [14] for a large set of forks and only scanning trees that are chosen for a fabrication [4]. When a scanned object is relatively small i.e. tree branches, a rotary table, cylindrical supports, camera, and AR markers could be employed [13, 15]. This is an inverse application when a camera is stationary and the object is rotated in small increments to get a 3d representation.

1.4 Camera Sensors

Camera sensors often employ structured light techniques by projecting a known light pattern to an object [16]. The deformation of the pattern relates to a calculation of depth and surface information in a scene. In a raw-wood context, the most common application is a Kinect sensor [12, 17, 18] due to low-cost and open-source SDK. The technique is subject to light conditions and may require scanning to be performed indoors [12] for a better registration process.

1.5 Laser Scanning

The method combines controlled steering of laser beams with a laser range-finder. Due to the high speed of light, this technique is not appropriate for high precision sub-millimeter measurements, where triangulation and other techniques are often used. This technology has already been successfully applied to scan parcels of forest in Kielder Water and Forest Park (UK) by ScanLAB [19] and a forest in Each Sussex by Universal Assembly Unit. Also, laser scanning could be used for analyzing tree biomass regardless of noise data added by small tree branches [20, 21, 22]. There are several raw-wood applications employing the laser-scanning method for fabrication as well. The method is used with a motion tracking system to guide the raw-wood manufacturing process [11].

1.6 Point-cloud Processing

After the scanning process is finished a skeleton extraction has to be performed to change a high-resolution model to a minimal 3d representation. The tree central-axis and radial-parameters are key elements both for visualization and fabrication. These parameters could be obtained by sectioning a closed mesh [4], 2D projection method following local radii [13], contouring [15], point-cloud sectioning [11]. Then the centers of the sections of the scan are connected to form a central-axis. The axis is used for orientation transformation in design-to-fabrication workflows Figure 1 by analyzing the curvature or topology of a tree trunk. When the geometrical data is collected, a tree database could be constructed containing 3D models and a spreadsheet of tapering diameters, changing curvature, best sawing positions, and markers for positioning.

2 Context and Objective

2.1 Contribution of the Study

While automation in scanning applications and robotic controllers is a well studied field and there are readily available commercial products that could collect the scanning data in real-time i.e MetraScan, Artec RoboticScan, Hexagon, Sick, there is a lack of integration in the raw-wood fabrication and timber design. In the research applications (sections 1.1 - 1.6) the process is based on manual point-cloud processing and the scanning is separated from the robotic control. Commercial practices in raw-wood construction make use of the standardized fabrication that requires a minimal skilled labour to complete the projects by local workers such as Unilog / TTT (New Zealand) and FEEL (Japan). Crooked timber is applied in practice as well i.e. WholeTrees with manual carpentry and stationary scanning i.e. Faro Focus. Moreover, raw-wood could be machined using robot cells i.e. Balmer Systems (Canada) along with scanning Mobic SA (Belgium). A

collaboration is built with the later enterprise to employ a scanning application with a robot controller[23] that could gather pointclouds within 4-5 min. using linear movements of a robot for a tree in 5 - 10 m length and diameter of 40-70 cm. The hardware could be optimized further using high-precision and long-range stationary scanners i.e. Faro Focus S 150 and applying a faster communication between a robot controller and the scanner. However, there is a lack of reliable point-cloud processing tools for crooked wood because the current practices do not consider such timber as a valuable resource. Consequently, there is a minimal development of the machining tool-path integration. Small radius straight, tapered, bent and forked beams has a strong structural advantage and could be exploited while developing and automating the workflow between architectural design, digital fabrication and tree harvesting.

2.2 Mountain Forestry

The tree harvesting process is assisted by a collaboration with a mountain forestry in Rossiniere and Lausanne. The Spruce trees are harvested in the Swiss Alps using a cable system due to a high terrain, then brought to a temporary processing site where trees are cut to 5 meters length for the transportation and saw-mill processing Figure 2. In the Swiss forestry context, the raw-wood economic value no longer covers the harvesting costs. Therefore, there is a need to exploit timber in a closed circular economy where wood is not sold to large sawmills but applied locally. Currently, the sawmills rely on the traditional cutting tools and the digital fabrication workflow is absent.

Figure 2. Scans showing a local mountain forestry context: a high and steep terrain where large Spruce trees are cut to fit to a small truck size for transportation to neighbour sawmills.

2.3 Raw-wood Workflow

The research employs ABB IRB6400 industrial robot arm and Faro Focus S150 stationary laser scanner. The scanning of whole-timber is part of a design-to-fabrication system including a laser-scanning, joinery solver, and fabrication techniques for the assembly of irregular timber elements in circular sections Figure 1. The objective is to scan the raw-wood for a design and fabrication using an automatic tool-changer that enables to perform different tasks interchangeably such as scanning, vacuum-grip, and cutting (mill, saw-blade) Figure 3. The scanning is needed because the orientation and position of the work-piece is not known in relation to machining-space. Also, the geometry acquisition is needed for a design scope when a group of selected trees are scanned to create a digital stock. The stock informs the design target - a structural roof system when central-axes of the tree trunks are assigned to a digital model. Afterwards, the timber joints are created depending on a curvature of a beam axis-and radii. Consequently, the fabrication tool-paths are oriented to machining space.

Figure 3. A laser scanner is mounted on a robot vacuum gripper and the $TCP_{Scanner}$ is not known.

3 Methods

The methodology focuses on a scanning application to automate a stationary laser scanner that can be used both for scanning parcels of forest and employed in a digital fabrication. The data acquisition is composed of following parts: physical setup of a scanner mounted on the robot, calibration of the scanner to know the relative position to the robot end-axis, standalone application of the Faro LS 150 SDK (software development kit), its integration within the robot control software (Rhino, Unity), point-cloud processing to obtain radial parameters of harvested timber, serializing data for further design and tool-path alignment for cutting Figure 1.

3.1 Setup of Industrial Robot Arm

The scanner is mounted on a vacuum gripper Figure 4 for safety reasons. The communication between the scanner and computer is enabled by a wi-fi. Then the SDK is applied and .NET application is made to send and retrieve signals from a scanner. The application could trigger following methods: connection, synchronization of scanning parameters, start, pause and stop scanning, send and read data. The power is supplied by 5 hour lasting batteries or a 19 V cable. The files are stored inside SD card that could be sent to computer via the robot-controller. The field-of-view of the scanner is 0◦ × 360◦ in the horizontal and -150◦ × 150◦ in a vertical rotation.

Figure 4. Laser scanner is positioned on a vacuum gripper. When the scan is finished the tool is automatically changed to the spindle

The raw-wood mounting setup is built as a rail-system that has three reference points. The rails are made from L-shape profiles that are fixed to stands to hold a tree trunk. Four steel Y-beams ensures the stability of the setup. Two parallel stands are used for a straight beam fixation and a third one is employed for forks. A beam is fixed to the setup by straps and pre-drilled holes helps to reduce a rotation during the fixation Figure 4.

Figure 5. Cutting process using spindle and milling while the scanner and gripper is removed.

3.2 Control of Robot and Laser Scanner

The robot control is based on a software interoperability between the CAD/CAM application (Rhinoceros) and the cross-platform game engine (Unity). One software is utilized for geometry processing algorithms that could be applied to define the robot tool-path while the other is used to simulate the robot‘s movements physically and digitally. Each software has different coordinate systems that has to be matched to get an exact representation. The notation of rotation (Quaternion) and position (XYZ) is translated as following R_{ABCD} to R_{BDC-A} and T_{XYZ} to T_{XZY}. The match between two coordinate systems is found by computing all possible permutations for rotations and positions. The text interface with a robot controller enables to move robot in absolute and linear movements, change tools and tool-holders, perform scans, retrieve and process pointclouds. The cutting process is connected within a design-scanning workflow where a series of fabrication tool-paths are generated considering saw-blade cutting, milling and drilling. Each scan is triggered when the robot reaches a target and then the next pose is taken when the scan is finished.

3.3 Calibration of Laser Scanner

The laser scanner has to be calibrated in relation to the end-axis of the robot to know a pointcloud location at each scan. This process helps to avoid point-cloud processing and registration because the position of the scanner is already known in the robot world space Figure 6. The unknown (1) is a transformation matrix X of a scanner TCP_S that is relative to the end of the robot 6th axis TCP_R.

$$TCP_S = TCP_R + X \tag{1}$$

When a scanner is calibrated, a list of scan points P_i in a world-space is found by multiplying the rotation matrix XR_R^W and the translation matrix XT_R^W of the robot in the world space with points p_i that are positioned relative to the scanner rotation XR_S^R and position XT_S^R that is mounted on the robot arm (2).

$$P_i = XR_R^W * (XR_S^R * p_i + XT_S^R) + XT_R^W \tag{2}$$

While the robot and laser scanner is fixed, a calibration accuracy limits the alignment of scans (3). Several calibration methods were applied including: (a) the multi-scan registration on a sphere, (b) alignment to a robot base, (c) employing an external scanner device and (d) sharp tool manual reference, (e) 4TCP method for the scanner holder measurement. The precision T of the scanning technique depends on a scanner tolerance T_S (±0.1-0.5), marker detection precision T_M, robot accuracy T_R (±0.5-1.0), a calibration method precision T_C (3).

$$T = T_S + T_M + T_R + T_C \quad (3)$$

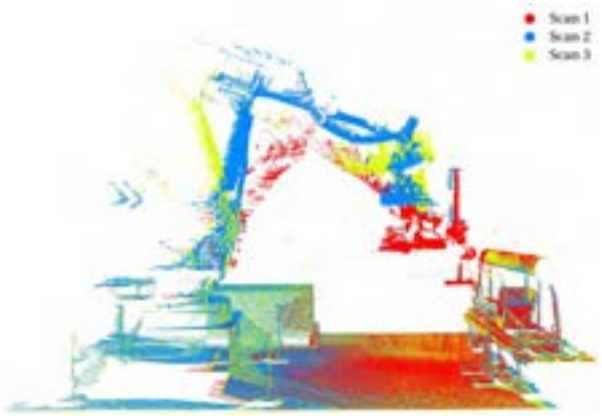

Figure 6. Result of the calibration using Faro Focus S 150 laser scanner.

3.3.1 External Scanner Device

First calibration test was made by employing Faro Arm Figure 7 D to measure the end-flange of the robot and laser-scanner. The result was inaccurate and only gave an approximate position of the scanner. The imprecision varied between ±1.0-2.0 cm in translation and ±1.0∘ in an arbitrary rotation. While the Faro Arm is a precise measurement tool, the reflective surfaces and possible laser-scanner tilt in relation to the tool-holder could have resulted in such a high inaccuracy.

Figure 7. Calibration methods. A - 4TCP Toolfolder, B - Robot-base scan, C - Multiple scans on a sphere, D - Faro Arm

3.3.2 Reference Points

A reference point calibration using an engraver tool and checkerboard markers proved to gain a sufficient tolerance. Robot is moved manually using the Teach Pendant to the centre of each target within several tries. The tolerance of manual measurement ranges between ±0.25-0.75 mm. Then the robot is moved to the highest reachable position and the scan signal is triggered from the robot controller. When the scan is finished, the data is sent to computer where it is processed to detect the positions of the markers. The scan position is oriented by a plane-to-plane transformation. The plane of the measured points is defined from 4 points and the target plane is retrieved from the detected markers. Four planes are created from the points, that are averaged by planes‘ origins and axes to obtain a better fit. The same procedure was tested using 12 targets to increase the tolerance. The resulting precision is between ±1.5-2.0 mm which is good enough for detecting the raw-wood trunk position for the manufacturing of timber joints.

Figure 8. Targets are measured by a sharp-tool and captured by the laser-scanner.

3.4 Point-cloud Processing

When multiple scans are taken and sent to computer, they are processed to obtain the radial parameters and central-axis of the tree. The duration of scanning depends on point-cloud density, measurement accuracy, connection type, the file transfer and geometry processing. The geometry survey could be divided in two parts: (i) creating a tree stock for a design and (ii) a tool-path alignment within the fabrication setup. Three methods were developed to obtain the radial parameters including (i) Flat-cut Sectioning, (ii) Mesh-skeletonization, (iii) Cylinder-fitting.

3.4.1 Flat-cut Sectioning

The method for calculating central-axis and radial-parameters from straight or curved logs is based on a point-cloud sectioning and assumption that every beam has two flat-circular ends Figure 9. The workflow is divided into following parts: get minimal bounding-box of a

point-cloud using PCA (Principal-Component-Analysis), get two smallest planes of the bounding-box, find the closest-points within the two planes, perform RANSAC (RANdom-SAmple-Consensus) algorithm to identify the flat-cuts of the beam [24], interpolate planes from the RANSAC, cut the point-cloud by a closest-plane method, fit sections to circles, draw axis between circle centers, serialize the data to XML file. The method will fail if the robot cannot move far enough to obtain he flat cut or the beam is not cut flat on the both ends.

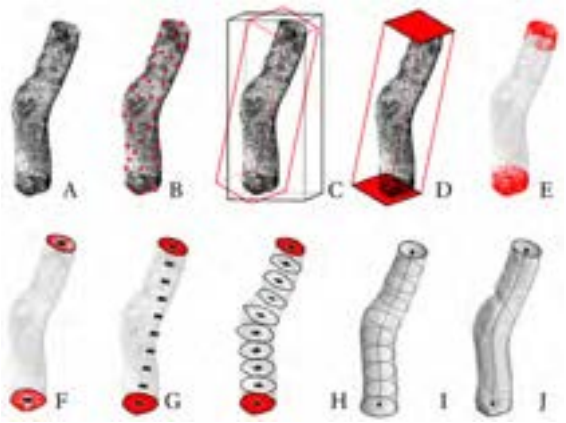

Figure 9. Flat-cut Sectioning method: A - Point-Cloud, B - Sub-sampling, C - PCA, D - two smallest faces, E - closest points, F - RANSAC plane, G - interpolation, H - 2D Convex-hull, I - circle-fit, J - surface representation.

3.4.2 Mesh Reconstruction

The method is based on a surface reconstruction from a point-cloud [25] and the closed mesh skeletonization [26]. Unlike the Flat-cut Sectioning method, it can be applied to the tree forks as well as bent or straight trees. Poisson surface reconstruction is chosen to retrieve a closed mesh from point coordinates and normals. The normals are approximated by fitting points to a plane using a least-square method. Structured point array simplifies the normal estimation because the orientation point (scanner position) is already known. The local radii of a log is found by sectioning the mesh by planes that are tangent to the skeleton-axis. The method is implemented as part of the robotic framework and tested within a series of bifurcated trees Figure 10 G-H.

3.4.3 Cylinder Fitting

The third method employs a cylinder fitting of the point-cloud. The list of points is projected to a 2D plane to approximate an outline of the point-cloud using the Marching Squares algorithm. Afterwards, the axis is extracted from

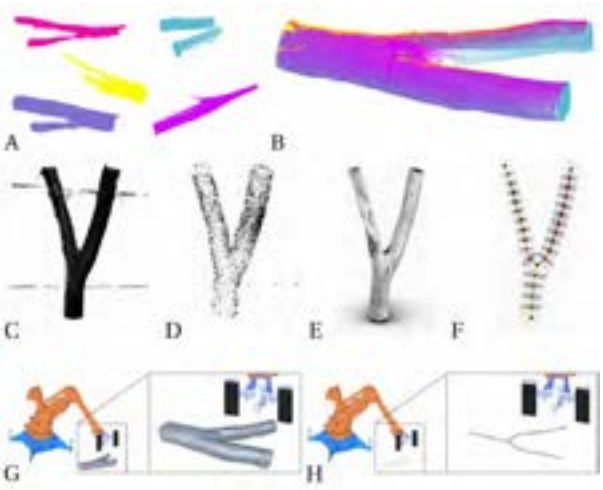

Figure 10. A - Individual Scans, B - Aligned Point-clouds. Mesh Skeletonization method: C - Point-Cloud, D - Normals Estimation, E - Poisson Mesh Reconstruction, F - Mesh-Skeletonization, and implementation in the robotic workflow G - mesh, H - skeleton.

a 2D curve using Zhang-Suen thinning algorithm. Then the axis is projected to the initial list of points by measuring the local radii of axial points. Consequently, cylinders are fit along each line of axis. The method was tested for both bent and bifurcated beams that contained noise from scanning and external objects such as straps of the fabrication setup and robot parts Figure 11.

Figure 11. A - PointCloud, B - Projection, C - 2D Thinning, D - Cylinder-fit, E - Radial parameters, F - Application in straight, curved and forked trees.

3.4.4 Fabrication Tool-path Alignment

When the point-cloud is processed, it is serialized for a digital timber stock and machining alignment. While the setup seems almost equal between beams Figure 12, each position changes up to 3-5 cm because of manual positioning, beam properties and rotation during the fixation

within an already small radii beam. The minimal model of a scan allows to position the timber joinery following the radius and tangent direction of the axis. There are several ways to reference a digital and analog model such as: a) alignment of a beam to the scanned object before the machining starts Figure 5 b) employing markers that have a distinctive reflective color that are captured during the scanning process.

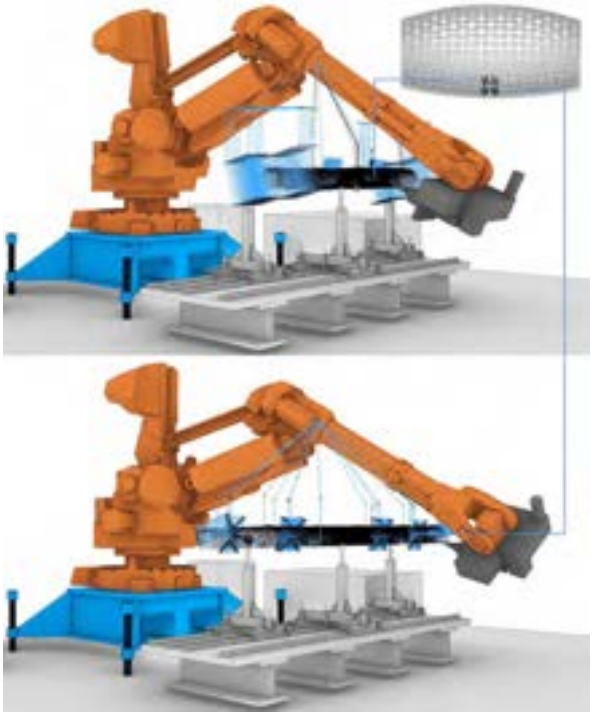

Figure 12. The tool-path is oriented from the design model to the machining space.

3.4.5 Validation Process of Results and Outcomes

The proposed methodology was applied in the realization of a first prototype made from 13-16 cm diameter logs Figure 13. A second one is planned as a tree fork truss to validate other tree topologies. The first model is composed 24 elements. The cylinder-fitting was applied repeatedly before cutting each beam and resulted in the successful model realization even if beams were small, crooked and bent. The scanning application itself is relatively fast in comparison with the milling and saw-blade cutting (60-90 min). Nevertheless the application could be optimized further by controlling the scanner via the automation adapter to send CAM messages and connecting the device with the robot controller to avoid latency in w-lan communication. Furthermore, the helical-scan could be connected with the robot movements to capture the point-cloud data in one step instead of two separate stages.

Figure 13. First prototype in small radius round-wood made using the applied methodology.

4 Discussion

The SDK of the Scanner, software of the robot control and tool-changer allowed to automate the scanning and fabrication workflow. The scanning precision was expected to be higher considering the specifications of the scanner due to the manual calibration, target detection and robot tolerance. Nevertheless, the precision needed to machine the raw-wood is sufficient enough because the imperfection of wood such as branches, chain-saw cuts, cracks is discarded. Multiple point-cloud processing algorithms were tested and the cylinder-fitting method was proved to be the most successful because it works when a point-cloud is incomplete and if there are outliers within the fewer scan taken per one tree. The challenge of the raw-wood integrated workflow is to speed the cutting process which takes the longest time comparing to the scanning and standardized timber products.

5 Conclusions

The laser-scanner and the industrial robot arm made the geometry acquisition of irregular timber faster from 45 min manual process to the 3 min automated solution, including robot movement, scanning and point-cloud processing. 24 beams were scanned without additional manual processing that directly guided the machining process. The scanning method was necessary to get a position of a tree trunk that helped to position cutting tool-paths within ±1.5-2.0 mm tolerance. The prototyping demonstrated the feasibility of the proposed workflow for low value tree trunks harvested from the local forests.

Abstract –

In order to teleoperate excavators remotely, human operators need accurate information of the robot workspace to carry out manipulation tasks accurately and efficiently. Current visualization methods only allow for limited depth perception and situational awareness for the human operator, leading to high cognitive load when operating the robot in confined spaces or cluttered environments. This research proposes an advanced 3D workspace modeling method for remotely operated construction equipment where the environment is captured in real-time by laser scanning. A real-time 3D workspace state, which contains information such as the pose of end effectors, pose of salient objects, and distances between them, is used to provide feedback to the remote operator concerning the progress of manipulation tasks. The proposed method was validated at a mock urban disaster site where two excavators were teleoperated to pick up and move various debris. A 3D workspace model was constructed by laser scanning which was able to estimate the positions of the excavator and target assets within 0.1 - 0.2m accuracy.

Keywords –

Pose estimation; laser scanning; excavator

1 Introduction

Robotic agents have enormous potential to be used to perform manipulation tasks for excavation, sample collection and repair work in remote areas. In hazardous environments such as nuclear power plants or post-earthquake disaster sites, it is common for these robots to be teleoperated by human operators from a remote location [1,2]. Such challenging conditions require a high level of situational awareness from the operator. It is difficult for human operators to efficiently and accurately carry out manipulation tasks through a teleoperation medium without clearly perceiving the pose of the robot and objects around it.

Research and field studies at major disaster relief operations such as the World Trade Center collapse showed that when mobile robots were deployed in confined spaces, the lack of perceptive data processing capability reduced the robotic skill set and added to the operator's cognitive responsibilities [2]. Armed with only a raw video feed with noisy and blurry images, operators and rescuers were unable to keep track of where the robots searched and the conditions during the deployment [2]. This problem of deficient perceptive information is amplified in the case of grasping tasks. Conventional teleoperation systems [1,3,4] make use of only a video camera that provides 2D images to the operator and the lack of depth perception makes it difficult for the operator to estimate the size and distances of unknown objects. Moreover, visual cameras do not work well at night or in adverse weather conditions. As a result, operators require a significant amount of trial and error to correctly control the robot to complete a grasping task.

An integral part of intelligent perception is transforming sensor data into knowledge and expressing that knowledge as information for use by other members in a human-robot team [5]. The idea of workspace modeling is to create a 3D representation of the robot and its surrounding environment [6–8] containing both semantic and geometric information that can be shared among all human and robotic agents in the operational team. The workspace model is constructed in real-time by processing the raw sensor data, organizing it, and labelling relevant objects [9]. Then the workspace model is used to provide visual feedback to the operator on the

task progress.

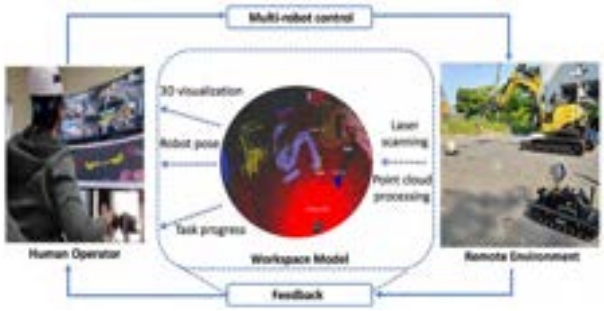

Figure 1. Feedback loop for teleoperation with 3D workspace modeling

This research proposes a context-aware 3D workspace modeling of remote equipment to improve perception and situational awareness for efficient teleoperation (Figure 1). In contrast to contemporary methods [1,4] which only provide views of the environment from the camera viewpoint to the remote operator, this research proposes a third-person viewpoint with automated state estimation and visualization of the relative pose between the end effector and salient objects. In addition, this research was validated at a large-scale outdoor environment with real construction equipment, compared to existing methods which were more focused on small to medium scale indoor environments [10,11]. To summarize, the contributions of the proposed work are as follows:

- designed a 3D workspace modeling and visualization scheme for teleoperated construction equipment
- developed an accurate algorithm for pose estimation of articulated equipment without prior dynamic models
- demonstrated the effectiveness of the 3D workspace modeling system with field trials using a multi-excavator system teleoperated in real-time

2 Literature Review

2.1 Remote Excavator System

Demand has recently been increasing for unmanned robotic excavator systems to carry out dangerous construction operations or disaster relief work. In such hazardous environments, direct human operation of excavators is unsafe due to the threat of rollover accidents, collisions, or radioactivity in the case of nuclear disaster sites. If the excavator could be robotized and teleoperated from a remote location, this would lead to a safer work environment for the human operators involved.

There are several teleoperation systems for excavators that have been studied in the literature. For example, [12] developed a excavator teleoperation system using the human arm, where sensors are attached to the operator's arm in order to detect movements so that command signals from sensors can be transmitted to the excavator. It is also possible to perform motion control with the teleoperation system by using posture sensor devices for receiving the kinematic information [13,14]. In these existing teleoperation systems, operators receive feedback either in the form of visual feedback [15,16] or force feedback [17] to monitor the interaction between the machine and the environment. More advanced excavator teleoperation systems [18,19] make use of a modular system such that a single operator can control multiple excavators with multiple end effectors at once to carry out more complex manipulation tasks. In such cases, effective feedback for teleoperation becomes even more important due to the higher risk of collision and other confounding factors such as occlusion and requirement for a larger field of view.

2.2 Workspace Visualization Systems

In a general teleoperation scenario, there are multiple ways to provide feedback to the remote operator including video feeds [3], laser scans [7], and haptic feedback [13]. In spite of these options, conventional teleoperated robots [1,4] mostly rely on a single video camera due to its simplicity and ease of use. Even when additional sensors are installed on the robot, they are poorly utilized due to the lack of information processing [2]. This causes the remote operator to have a limited field of view of surrounding objects and have limited depth perception.

There are several strategies in the literature to improve the visualization system for robot operation. [3] used a separate robot arm for visualization to overcome occlusions while performing visual servoing. However, being a primarily visual system, it still had limitations in terms of field of view and depth perception. [10] and [11] used RGBD-cameras paired with interactive visualizations to allow the operator to customize the 3D view. However, these works only considered the case of a single robot on an indoor, tabletop environment without any base displacement. [6] used 3D laser scanning to track the motion of construction equipment, but only modeled the construction equipment itself without visualizing the surrounding objects. [20] employed a multi-sensor system using four fisheye cameras and a 360◦ laser scanner to continuously reconstruct a 3D model of the surroundings with Simultaneous Localization and Mapping (SLAM). However, the method was only tested in static, indoor environments. Moreover, these methods have no automated object recognition or annotation of task-relevant entities,

leading to difficulty in identifying objects in cluttered or confined spaces. For the case of construction equipment, there exist algorithms for recognition [21,22] and pose estimation [23–25], but they still lack integration into a complete workspace visualization system.

3 Methodology

This research proposes a workspace modeling framework for teleoperation of remote construction equipment. As shown in Figure 1, the workspace model enables a feedback loop where the remote operator is able to simultaneously observe the effect of control inputs and interpret the remote environment from a 3D visualization interface, thus improving the situational awareness and efficiency for performing complex manipulation tasks. The workspace modeling procedure is designed to be independent from the equipment control such that the visualization and pose estimation process can remain the same regardless of any control configuration changes. The following subsections will provide details for each component of the proposed framework.

3.1 GHOST teleoperation system

This research makes use of the GHOST teleoperation system [19], which retrofits construction equipment such as excavators to be operated remotely. The manipulators are controlled wirelessly from a remote operation room equipped with monitors, joysticks and pedals. In general, each excavator can receive six different types of control signals which are assigned to the boom, arm, bucket, cabin, left track and right track respectively. Since the combination of one set of joystick and pedals is sufficient to transmit six control signals, the complete system allows a single operator to control two excavators at the same time.

However, teleoperating multiple excavators at once using conventional visualization methods is challenging even for experienced operators. Besides problems with the limited field of view and limited depth perception, the remote operator has to continuously monitor for multiple events including coordination between the excavators, occlusions, risk of collisions and risk of rollovers. This leads to a high cognitive burden for the operator, potentially causing lower efficiency and higher risk of accidents. To overcome this problem, this study implements a remote laser scanning system to provide 3D visualization of the environment surrounding the excavators, which will be described in the following sections.

3.2 Remote laser scanning system

Figure 2 shows the remote laser scanning system used to acquire a 3D reconstructed model of the excavator workspace. The VLP-16 LiDAR was mounted on a small teleoperated tracked mobile robot and utilized to acquire real-time laser scans of the site. The VLP-16 has a range of up to 100 meters with ± 15° vertical field of view. This means that the vertical angular resolution is only 2° because the VLP-16 has only 16 scan lines (channels) in the vertical direction. Thus, the scanned point cloud will be overly sparse for regions far away from the scan origin. For this reason, this study implemented an improved scanning system by installing the VLP-16 at 90° sideways and spinning it continuously with a stepper motor (refer Figure 2). In this way, the limited vertical resolution (now horizontal resolution) can be mitigated by rotating the scans horizontally, thus creating a higher resolution point cloud.

The effectiveness of 3D workspace modeling depends heavily on the point cloud update rate and resolution, which can impact the subsequent object recognition and pose estimation [26]. From the rotation mechanism discussed previously, the LiDAR scanner can generate a 360° point cloud of the surrounding environment after spinning about the vertical axis for half a revolution [27,28]. The update interval, between which the point cloud is updated to capture changes in the environment, is thus determined by the time it takes for the LiDAR scanner to spin for half a revolution. There exists a tradeoff between the rotation speed and resulting point cloud resolution due to this rotation mechanism of the laser scanner. When the rotation speed of the laser scanner is increased, the update rate increases but the point cloud resolution degrades because of the larger distance covered between consecutive scans. In contrast, when the rotation speed of the laser scanner is decreased, the point cloud resolution improves but the update rate decreases.

To find the best rotation speed, a simulation was carried out to determine the generated non-overlapping vertical scan lines when rotating the scanner. Based on this simulation, the average angle between the vertical scan lines as well as the maximum angle between the two adjacent vertical scan lines were calculated as shown in Table 1. From these results, the rotation speed corresponding to a 2.4s update interval was selected to minimize the update interval while maintaining a high horizontal resolution. This means that it is difficult for the scanner to capture rapid motions in the environment, but the higher resolution is necessary for object recognition.

Using this rotation setting, the resulting laser scanning system has a 0.25° resolution in the horizontal direction and a 0.4° resolution in the vertical direction, generating 324,000 points per update. The individual scans within each update are registered by multiplying by a rotation matrix, calculated from the rotation angle of the stepper motor. The laser scan data is published

wirelessly to the operation room as a ROS (Robot Operating System) message.

Table 1. Relationship between update interval and horizontal angular resolution

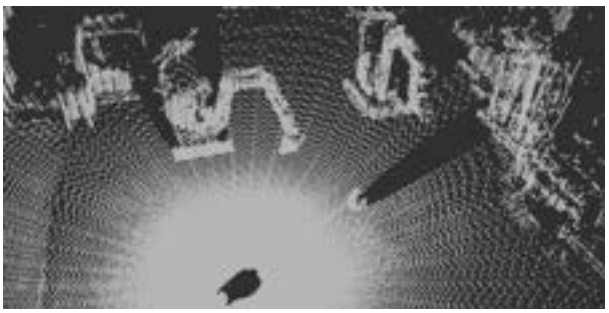
Update Interval	1.2s	1.4s	2.1s	2.4s	2.5s	2.9s
# vertical lines	374	447	641	720	523	927
avg. horiz. resolution (°)	0.48	0.40	0.28	0.25	0.34	0.19
max. horiz. resolution (°)	0.50	0.43	0.29	0.25	0.40	0.28

Figure 2. Remote laser scanning system

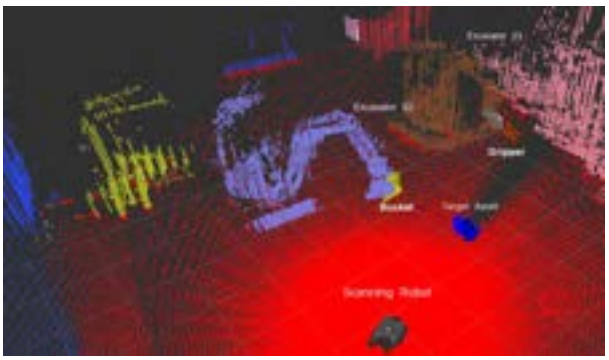
3.3 Point cloud pre-processing and segmentation

Processing the point clouds in real-time is challenging due to noisy sensor data, limited resolution of the laser scanner (refer Section 3.2), limited data bandwidth, and motion blurring of objects. Moreover, the point cloud is dynamically changing due to the movement of equipment and in the scene, meaning that it has to be processed incrementally.

A voxel grid filter is first used to equalize the point cloud resolution to 0.1m throughout the scene. This serves a dual purpose of allowing more consistent segmentation as well as speeding up the processing time by downsampling the point cloud. Next, the point cloud scene is segmented into smaller units corresponding to individual objects to enhance visualization of the scene. To meet the real-time constraint, the fast segmentation method of [29] is used. The ground plane is first segmented using the RANSAC algorithm [30] to estimate the 3D plane parameters. Alternatively, for the case of non-flat ground, the ground segmentation algorithm from [21] can be used. From the remaining points, Euclidean clustering is used to form clusters consisting of points that neighbor each other within a margin of 0.15m. As new scan points are acquired, they are matched to the closest existing clusters and each cluster is then updated. New scan points also cause new clusters to be initiated if no neighboring clusters are found. This allows the segmentation process to occur incrementally, similar to the method used in [31].



(a) Raw point cloud acquired by laser scanning



(b) Segmented point cloud showing relevant entities

Figure 3. Point cloud segmentation results for a scene with two excavators and a single target asset

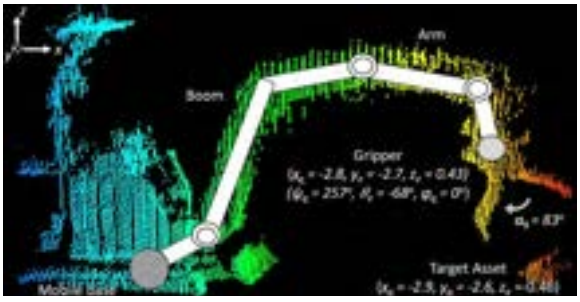
Next, the following relevant entities are automatically labeled in the scene: (i) laser-scanning robot, (ii) construction equipment, and (iii) target assets for manipulation tasks. The position of the laser-scanning robot can be easily determined as the origin of the point cloud scan. On the other hand, the positions of various construction equipment can be determined by using the method in [21], where a feature descriptor is computed for each point cloud cluster and classified with a pre-trained classifier. Finally, the point cloud clusters for objects lying on the ground close to the construction equipment are labelled as potential targets for manipulation.

Figure 3 shows an example of the segmentation results for a scene with two excavators and a single target asset. The segmentation results are additionally overlaid with CAD models of the end effectors (bucket or gripper) and other relevant entities (e.g. target asset and scanning robot) to enhance the visualization. From Figure 3, the

raw point cloud data is extremely blurry, and it is difficult to keep track of the movement of objects in the robot workspace. However, with automated segmentation and annotation of the point cloud data, the remote operator is able to better perceive the robot workspace.

3.4 Point cloud-based pose estimation

(a) Model parameters for excavator joint configuration



(b) Pose estimation result for a gripper and a target asset

Figure 4. Excavator pose estimation

Figure 4a shows the model of the excavator joint configuration used in this study. For each excavator, the robot pose can be described in terms of the following variables: (x_b, y_b, z_b), position of the mobile base; α_1, rotation of the mobile base with respect to the z-axis; α_2, rotation of the boom relative to the mobile base; α_3, rotation of the arm relative to the boom; α_4, rotation of the end effector relative to the arm. Similarly, the pose of the end effector can be described in terms of the following variables: (x_e, y_e, z_e), the position of the end effector and (ψ_e, θ_e, φ_e), yaw, pitch, roll angles of the end effector with respect to the world frame. In addition, the variable α_5 is used to describe the opening angle of the end effector if a gripper is used.

To perform pose estimation on articulated equipment such as excavators, the strategy used is to approximate each joint as a line segment and use line detection algorithms to extract corresponding segments from the point cloud. Due to the noisy nature of the point cloud, robust parameter estimation methods such as RANSAC [30] and PCA [32] are used. Then the tangent direction of each line segment is used to estimate the joint rotation angles α. Empirically, using RANSAC for detecting the boom and PCA for detecting the arm gives the best results. Next, the end effector points are segmented by taking the rightmost points of the excavator after correcting for rotation. (x_e, y_e, z_e) is calculated by taking the centroid of this segment whereas (ψ_e, θ_e, φ_e) can be inferred from the internal joint angles. The gripper opening angle, α_5, is estimated by taking the width of the end effector segment after correcting for rotation. On the other hand, to perform pose estimation of a target asset for manipulation, the position, (x_a, y_a, z_a), is first estimated by taking the centroid of the corresponding point cloud segment. Then the orientation, α_a is estimated by extracting the convex hull and solving for the minimum bounding box [33]. Each step of the pose estimation process also employs error correction using the smooth motion constraint. That is, if a new prediction differs from the previous prediction by more than a predetermined threshold (e.g. due to outlier data), the new prediction is discarded.

Figure 4b shows an example of the point-cloud based pose estimation result for an excavator equipped with a gripper. The segmentation can be computed in 0.05 - 0.1s whereas the pose estimation can be computed in 0.02 - 0.03s. The delay in showing the 3D visualization depends on network latency, but is usually within 1s. The final 3D workspace model is displayed through an interactive user interface. The remote operator is allowed to select the target asset of interest for manipulation. The user interface will then display task progress in terms of grasping the target asset.

4 Results

4.1 Experimental setup

Figure 5. Experimental setup of two excavators at a mock urban disaster site.

The experimental setup consists of two robotic unmanned excavators deployed at a mock urban disaster site (Figure 5). The operator has two options to remotely

monitor the test environment: (i) 2D images from cameras mounted on the excavator roof and (ii) 3D visualization obtained from the mobile laser scanning system. One excavator is equipped with a gripper as the end effector whereas the other excavator is equipped with a bucket. Using one or both of the excavators, the operator is tasked with carrying out various manipulation tasks such as picking up miscellaneous wreckage and moving them to a specified location. The accuracy and effectiveness of the proposed workspace modeling and visualization system is then validated using the pose estimation accuracy.

4.2 Pose estimation accuracy

The pose estimation results are visualized as shown in Figure 6. Note that this evaluation only considers a single excavator, but the proposed system is able to estimate the poses of multiple excavators simultaneously. The left 4 columns show results for a propane tank as the target object whereas the rightmost column show results for a plastic container as the target object. From the 2D images of the operator view, it is difficult to perceive whether the gripper is in line with the target object and the distance of the gripper to the target object. On the other hand, the 3D visualization provides helpful information in terms of physical distances and poses that can assist the remote operator in decision making.

As shown in Table 2, the pose estimation accuracy is measured using three metrics: (i) error in estimating the distance from the center of the end effector to the center of the target asset, d_1, (ii) error in estimating the distance from the center of the end effector to the ground, d_2, (iii) error in estimating the distance from the center of the end effector to the center of the excavator body, d_3. The accuracy of the proposed method is compared against two baselines methods: (i) simple line-fitting with linear least-squares regression [34] and (ii) Iterative Closest Point (ICP) [35] to fit the end effector model to the scanned point cloud. Results show that the proposed method achieved lower pose estimation errors compared to the two baseline methods. This is because the scanned point cloud is too noisy and has low resolution for simple line-fitting or ICP to work, whereas the proposed method is able to estimate the pose parameters from point clouds more robustly.

Table 2. End effector pose estimation error

Method	d_1 error (m)	d_2 error (m)	d_3 error (m)
Simple line-fitting [34]	0.93±1.06	0.39±0.50	0.15±0.07
ICP [35]	0.15±0.11	0.10±0.07	0.24±0.26
Our method	**0.13±0.07**	**0.09±0.09**	**0.10±0.08**

5 Conclusions

In summary, this research proposed a workspace modeling system for teleoperated construction equipment based on laser scanning. Through field tests at a mock urban disaster site, the constructed 3D workspace model was demonstrated to be able to estimate the positions of the excavator and target assets accurately and improve the performance of human operators on manipulation tasks. This represents an important step towards achieving the goal of improving the efficacy of remote robot operation, reducing human operator needs, and reducing the operator's cognitive burden during teleoperation. For future work, the method will be extended to more types of heavy equipment such as

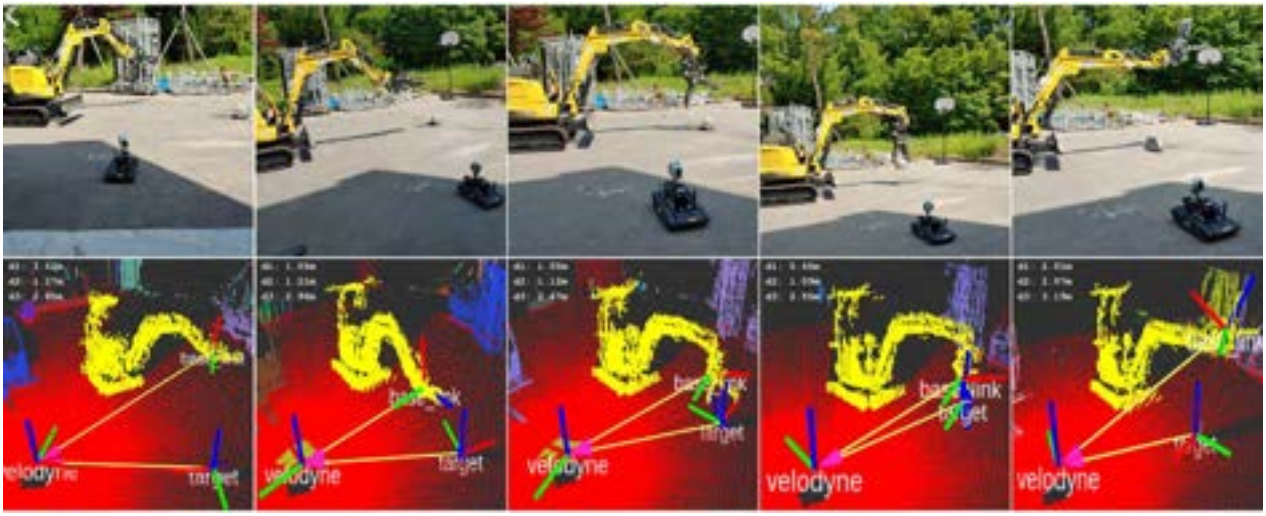


Figure 6: Visualization and pose estimation of excavator workspace. The top row shows 2D images of the scene whereas the bottom row shows the corresponding 3D visualization

loaders and dump trucks and further evaluated in more challenging manipulation scenarios.

Abstract -

Automation for retrieving relevant contents without human interventions has been considered as an essential task in the construction industry. Computer vision has grasped attention to be employed for providing rich data from the surrounding environment and automation of such critical tasks. Nonetheless, various challenges, including the detection of complicated and changing interactions and processing large-scale data remain unresolved. Deep learning methods have led to satisfactory achievement in providing progress monitoring systems, especially with detecting complex human motions and activities in construction scenes. However, further research contributions for vision-based safety monitoring are required to determine existing limitations and gaps in the construction and infrastructure field. In this paper, through some bibliographics and scientometrics analyses, more research backgrounds are suggested for application of computer vision and especially, deep learning, in construction robotics. Moreover, the accuracy of various computer vision methods is analyzed and compared by considering publishing year, countries, institutes. This demonstrates that Deep Learning application is still premature in the construction context, and current researches lack robust and swift image processing techniques.

Keywords -

Automation; Computer Vision; Construction; Deep Learning

1 Introduction

Automated methods have been considered as a vital task intended to retrieve relevant contents and features without any human interventions in the construction robotics [1]. In this regard, machine vision has drawn attention since several critical tasks, including continuous object recognition, monitoring of motion behaviour [2], productivity analysis [3], health and safety monitoring [4], require automation in their procedure [5] . It is worth noting that a major prerequisite for applying computer vision methods is data collection. Despite their importance, current methods of on-site data collection are still time-consuming, costly, and error-prone [6]. In addition, having large-scale database for most of industrial projects is another challenge for computer vision methods. In the recent years, several studies have been carried out in the construction field to evaluate unsafe conditions and acts. Despite the relative success of the research conducted by [7], some unresolved gaps and challenges remain in construction and infrastructure Civil Engineering, including the recognition of activities in complicated and varying conditions, multi-subject interactions and group activities.

Computer vision has achieved satisfactory performance in providing progress and quality monitoring systems and identifying unsafe conditions and actions in ongoing works, especially by detecting human motions and activities in construction sites [8, 9] In fact, color-based techniques such as the detection of workers, equipment, and materials in the construction sites are commonly used in various object detection [10] A behaviour based safety approach can be used to observe and identify people's unsafe actions in order to modify their future behaviour [11, 12] The advent of deep learning in machine learning field provides solution to the problems of manual observation of unsafe actions. The Convolutional Neural Network, CNN, based methods have been widely applied to a variety of problems that are encountered in construction [13, 14]. Object detection using deep learning algorithm can be employed for identifying construction components, counting objects, and objects size determination [15]. Furthermore, motion detection can be deployed in cameras via deep learning computer vision methods for surveillance purposes. In [16], a deep CNN is developed by integrating optical flow and gray stream CNNs to automatically recognize motion on construction sites.

By searching through the database of publications, 11 review articles are found which have put their effort on this area of interest, among which, from 2017, four papers have been published. This is important since what has developed from 2017 changes in data science interaction with construction and civil infrastructure fields. In Table 1, the information of the published review papers in this field has been demonstrated. From 2015 to 2016, five review articles have focused on this field of research, trying to provide bibliographic information,possible solutions and gaps on computer vision with share keys including progress monitoring, condition assessment, image-based 3D reconstruction, computer vision, and building information modeling;

Table 1. Analysis of published review papers on application of computer vision in the construction field.

Review Papers	Analyzing Date	Review Style	Reviewed Papered
[10]	2009-2019	bibliometric	97
[5]	1999-2019	scientometric	375
[19]	2000-2018	scientometric	216
[20]	1990-2018	bibliometric	235
[21]	2005-2016	scientometric	614
[22]	2010-2015	bibliometric	40
[6]	2000-2015	bibliometric	101
[23]	1995-2015	bibliometric	96
[24]	1995-2015	bibliometric	121
[25]	2005-2015	bibliometric	104
[26]	2000-2015	bibliometric	139

the most published articles belong to the journal of Advanced Engineering Informatics. Nonetheless, what has been considered has chiefly changed in recent years. As a case, one of the gaps in review papers was referred to the lack of suitable tool for processing and interpreting of high value of images and videos which was addressed in several articles, including [17, 18], by introducing deep learning methods in civil and infrastructure construction fields. It is worth mentioning that the relation between ontology and deep learning application in Civil Engineering has been analyzed in [19] which leads to suggestions for analyzing background detail and employing ontology in order to improve the accuracy of computer vision methods in monitoring and safety. Nonetheless, what has totally been off the topic in the scientometric analysis is the role of accuracy of different computer vision methods in the future of the construction field. None of the review papers has scrutinized and demonstrated the possible reasons and trends in the accuracy of computer vision methods from sceintometrical view point.

Therefore, further studies are required to find out existing limitations in order to boost the adoption of the advanced techniques. Several practical challenges could be identified in studies including a lack of robust and swift image processing techniques in industrial settings, considering the varying and dynamic conditions which are demonstrated in construction and civil infrastructure sites. Moreover, the review papers neglected the recent improvements and achievements in the general computer vision and machine vision. Hence, more researches are required for computer vision that involve the state-of-the-art deep learning findings in the construction field in order to provide the practitioners with more accuracy in identifying conditions resulting in inferior quality, productivity and safety performance. In this regard, using of a computational light convolutional network such as MobileNets [27], ShuffleNets [28], ResNets [29] seems necessary.

This research has tried to analyze this topic from different view point, that is more or less related to the data science field. In this paper, different methods of computer vision have been analyzed considering their application in the construction field. In Section 2, the way of acquiring bibliographical records of articles in the fields of machine vision and construction is explained. Thereafter, in Section 3 the recent achievements in the aforementioned fields are categorized and the most leading and cutting-edge articles in the field of application of computer vision in construction are extracted. Section 4 is devoted to the more detailed scientometrics analysis of the selected articles. Finally, discussions and future trends are included in Section 5.

2 Data acquisition

In this section, the method of acquiring bibliographical data is explained. In this research, the Dimension platform is employed as the basic search platform which offers more advantages[30, 31], such as proving plentiful research options, easily extracting research results, access to profiles at author and journal level, awarded grants and patents. In this regard, journals and conference papers are selected as the research option, since several highly cited documents have been published in both publication types. Moreover, the surveyed date has been set to 2000-2020 which contains the most published papers in the field of construction and machine vision. A suitable research keyword for application of machine vision in the construction and Civil Engineering might be as follows: ("Computer vision*" OR "Machine vision*" OR "Vision systems*") AND ("building*" OR "construction*"). Based upon the aforementioned settings for carrying out search in the platform, 2515 documents have been found for the rest of the research.

3 Bibliographical Analysis

In this section, the literature of computer vision application in construction is analyzed from bibliographical point of view. In this regard, VOSviewer software [32] possesses useful features in the text mining and bibliometrics analyses, which provides researchers with graphical way of literature data-set presentation. Considering the bibliographical results, demonstrated in Figure 1, four main clusters have been identified in the graph. The graph contains top 160 documents by total link strength. The first cluster, which has been demonstrated with yellow color, is mostly related to the articles belonging to implementation of conventional computer vision methods in construction. The leaders of the cluster [33, 9, 34, 16] share similar keywords, i.e., Support Vector Machine (SVM), computer vi-

and Civil Science. Therefore, the articles from clus
and #2, with the number of 110, have been analyze
scientometrics section, from different aspects of s
metrics, especially accuracy of computer vision m
data base, and co-occurrence. Nonetheless, there are two other main clusters that have been found in the bibliographical results in Dimensions search platform. One of these two clusters with red color, #3, has focused on the general computer science field with shared keywords, computer vision, classification, and object recognition, while the another with blue color, #4, has put the attention on Civil Engineer, 3D reconstruction, and building model. As a results, excluding these articles from main articles based on the titles and abstract in the bibliographics is impossible; only by employing methods such as the bibliographical coupling analysis, these clusters are separable. In the Scientometrics section, these two clusters are not analyzed since those are relatively far from the main topic of this research.

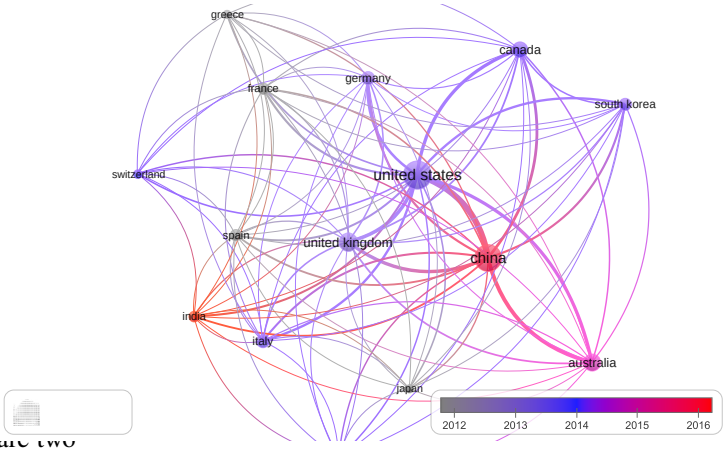

Figure 2. Overlay visualization of countries of published documents respecting to average publishing year via bibliographic coupling analysis.

Based on the bibliographical data from Figure 2, the United States, China, United Kingdom, South Korea, Australia, and Canada have mainly attempted to contribute in construction and vision fields of researches. The graph nodes are scaled by total link strength in which minimum number of documents of a country is set as 20, minimum number of citation of a country is chosen as 10, and top 15 countries are visualized considering total link strength. Moreover, the graph demonstrates that from 2016 till now, China, Australia, and India have attempted to extend the application of computer vision in Civil Engineering. On the other hand, the focus of researchers in the United States and United kingdom is mostly respected to the span of 2012 to 2014 on average, and predicated upon the citation records, their researchers had received enormous attention

and citation.

4 Scientometrics Analysis

In this section, the aforementioned extracted articles from clusters #1 and #2 of Figure 1 are analyzed through varied points of view. From 2015, a brand new way of literature review, namely, scientometrics analysis, , has been introduced [38] which detects the correlation between keywords and the most repetitive words through co-occurrence analysis. Consequently, by combining the bibliographical information of the selected articles with the extracted data such as accuracy, source of database, abstract and so forth, the scientometrics analysis has been carried out in this section in order to focus on surveying the published articles in the field of computer vision and construction. Employing corpus and scores files, composed by integrating abstract and keywords of the selected articles, the demonstrated graph in Figure 3 is obtained. The graph shows top 20 of most relevant and important terms scaled weight by Occurrence, with minimum number of occurrence of a term as 10. Based on the graph, Deep Learning as a representation for complex image processing methods and SVM as one for conventional image classification toolbox have been mentioned more than other methods.

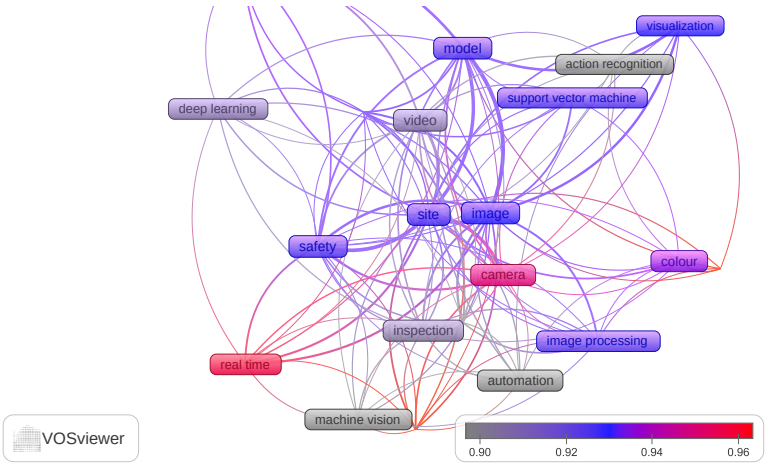

Figure 3. Overlay visualization of occurrence analysis of abstract and keywords of selected articles with respect to average accuracy timeline.

In the clusters #1 and #2 of Figure 1, representing fields of construction and machine vision, 3 publication journals have mostly contributed from volume of published papers point of view. In Table 2, several information have been presented on the publication resources, namely Automation in Construction, Advanced Informatics, Computing in Civil Engineering, and Computer-Aided Civil and Infrastructure Engineering and the corresponding details.

Table 2. Scientometrics analysis of the publication sources of selected articles.

Publication Journal	Percentage	Average Published Year	Average Citation	Dominant Method
Automation in Construction	37.04%	2016	91	Deep Learning
Advanced Engineering Informatics	14.81%	2013	92	Deep Learning
Journal of Computing in Civil Engineering	13.89%	2012	117	Edge Detection
Computer-Aided Civil and Infrastructure Engineering	8.35%	2012	193	Edge Detection

Table 3. Scientometrics analysis of the first author countries of selected articles.

Institution	Percentage	Average Published Year	Average Accuracy	Dominant Method
Huazhong University of Science and Technology	10.19%	2018	0.895	Deep Learning
Georgia Institute of Technology	12.04%	2012	0.938	Tracking Method
Yonsei University	6.48%	2014	0.967	Edge Detection
University of Illinois	9.26%	2011	0.982	Motion Detection

The focus of Automation in Construction and Advanced Informatics has been shifted toward applying deep learning methods in the construction field from 2016 [17, 35]. Nonetheless, the journal of Computing in Civil Engineering and Computer-Aided Civil and Infrastructure Engineering have published the articles, mostly employing edge detection methods, in the construction and civil engineering [39, 40].

From the countries point of view, the United States, China, Canada, the United Kingdom, and Australia are pioneers in applying computer vision in the construction field. In Table 3, it is shown that 4 institutions have had more contributions in publishing their results in the relevant journals. The average publishing year for Georgia Institution [8] and the University of Illinois [9] is around 2012; tracing methods and motion detection, respectively, are employed which have led to highly cited articles, but their focus has been shifted away from this field since

2014. On the other hand, several papers such as [41, 42] have been published from Huazhong University that contributes in this field by applying CNN and deep learning in the object and human recognition. These papers have been specialized in such a narrow topic that limits the citation while the average accuracy of the deep learning methods is less than the aforementioned institutions in the United States.

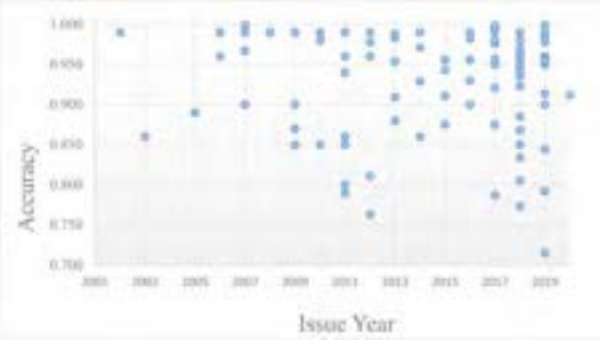

Figure 4. Scatter plot of the issue year of selected articles versus the accuracy of computer vision methods.

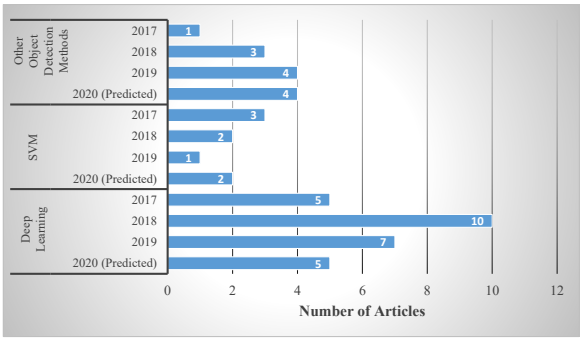

Figure 5. Comparing the applied dominant machine vision and classification methods in selected articles respecting to the issue year of articles.

Since 2008, by deployment of computer vision in the construction industry, the number of published papers in this field rouse by gaining appropriate accuracy of the object and edge detection methods. For instance, in Figure 4, one can observe that from 2008, more articles have achieved high accuracy in vision methods of construction mostly due to the advancement in face recognition and object detection methods. However, it is worth mentioning that one can find several articles including [41, 43] that cannot achieve expected accuracy, that is above 95 % on average, since the volume of processing data has increased as well. Consequently, in this field, the span of accuracy

Table 4. Scientometrics analysis of the dominant machine vision and classification methods in selected articles.

Method	Percentage	Average Published Year	Average Accuracy	Average Citation
Deep Learning	20.37%	2018	0.908	68
SVM	14.81%	2015	0.905	2120
Other Object Detection methods	12.04%	2015	0.955	49
Other Edge Detection methods	9.26%	2010	0.887	136

that publications in the construction field has gotten bigger whilst the bold part of this span is still on the highest possible accuracy of computer vision. Most importantly, the rate of published research paper in this field has accelerated since 2017. This has happened mostly due to attention that deep learning methods have received. Based on what has been demonstrated in Figure 5, since 2018, more research articles such as [44, 14] have put the base of their concentration on Deep Learning and big data science field. Face recognition, object detection, and huge amount of data classification methods are eventually possible to be carried out by deep learning methods. This trend decreased in 2019 which might be respected to the existing gaps of deep learning in the construction and safety field which will be discussed later in Section 5. Meanwhile, SVM method, which represents fast classification of data, fails to receive more credit in comparison to what has happened in 2015 [45, 46], according to Table 4. This shows that the focus of automation in construction has been shifted from speed toward the accuracy and processing of huge database information.

5 Discussion and Future Trends

In the recent years, the vision-based tasks have improved due to the need for automation in the construction field. Some of the researchers have tried to extend the volume of image processing, from motion and object detection tasks towards activity recognition. This has led to increasing complexity of the space of data regressors while the conventional methods lack the ability to conform to big data process. As a result, more complicated and powerful tools in learning patterns and data are required to solve the problem. However, based on what has been illustrated in Table 4, it is clear that deep learning methods could not achieved the accuracy that has been achieved in the

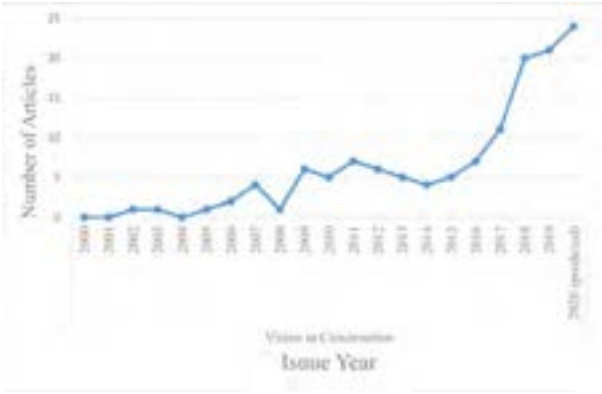

Figure 6. Number of published articles on the application of machine vision in construction respecting to the issue year.

vision field [18], that is approximately 95 %. Moreover, it is demonstrated that the achievement of conventional vision methods in the object detection, motion detection, classification reveals better accuracy in comparison to the deep learning methods [47]. The existing gap among the capabilities of deep learning in the construction field, employing pre-trained networks in non-similar contexts and lack of experience and background researches, decrease the possible success in obtaining successful results in the vision methods. In fact, setting AI field techniques such as MobileNets [27], ShuffleNets [28], ResNets [29] in construction and infrastructure civil field are demanding and time-consuming. Therefore, the upcoming articles must be inclined to increase the accuracy and efficiency of deep learning methods. By doing so, the predicted number of published articles on application of machine vision in construction, demonstrated in Figure 6, will be realizable.

Another important topic is the way of acquiring database for application of vision in construction industry. Most of researchers in this field have employed specific database. Based on the scientometrics data, the majority of the analyzed published documents in this field possess their own construction images database. Some of review papers, especially [19], believed that considering the copyright rules and respecting the privacy of workers in construction site often lead to the fact that most researchers do not publish their researches database in the publications. In this regard, there is rare published well-known database of construction images and the authors are obliged to put more of their effort and resources on acquiring images from a construction site. This may be the key point why researchers have put less effort and attention on improving the efficiency of computer vision methods, especially in deep learning-based recognition method, in the recent years. Furthermore, lacking general image databases in the construction field makes validation of the results in this field even harder. In other word, the precise comparison between application of varied machine learning methods in construction and infrastructure Civil Engineering is not mainly feasible since each articles applied the method on a specific database which is not accessible for other researchers and authors [17, 42]. In this regard, the average accuracy has been employed in this paper in spite of applying machine learning methods on each case study of construction field. As a future trend, a general database of construction sites must be formed respecting the privacy of involved people and the copyright rules, which surely involves more researchers in the applications of machine learning in the construction field.

E-mail: wmh17@mails.tsinghua.edu.cn, lin611@tsinghua.edu.cn

Abstract -

Construction robots have drawn attention in research and practice for decades. Considering most of the construction robots are not fully automated and humans are always involved in the construction process, how humans and robots collaborate has a great impact on the total productivity. Unlike collaboration systems between human-human, human-device and robot-robot, human-robot collaboration process has its complexity and uniqueness. Thus, this paper starts with analysis of human-robot collaboration system in construction, then provides an agent-based approach to simulate the process in bricklaying with emphasis on its complexity. A real project in Beijing is utilized to validate the feasibility of the proposed method. Besides, managerial insights useful for the workers to better utilize construction robots can be drawn from the results, which shows the effectiveness of the proposed model. This research contributes to the body of knowledge an agent-based approach to modeling, simulating, and analyzing the human-robot collaboration process in construction sites. This research serves as a foundation for further in-depth investigation in this area.

Keywords –

Construction robots; human-robot collaboration; agent-based simulation; communication mode; human factor

1 Introduction

Construction robots have drawn attention in research and practice these years to cover the shortage of conventional construction. In terms of the entire industry, its productivity has been declining in recent years and the conventional construction paradigm has reached the technological performance limit[1]. In terms of workers in this industry, construction tasks are usually of high physical demand, and sometimes are harmful to their health[2]. Therefore, construction robots have aroused increasing interest in the last 15-20 years because it can improve the productivity while replace workers from doing heavy duties and dangerous tasks[3]. The application of robots involves nearly every construction-related tasks, including glazing[4], beam assembly[5], earthmoving[6], concrete wall fabrication[7], etc.

However, construction industry cannot be fully automated currently even with the aid from robots[3]. As a result, various operations and tasks still need to be fulfilled by human workers. In other words, human-robot collaboration is a critical part of the construction process.

Agent-based (AB) modeling, a simulation approach to model systems by using virtual agents to imitate the behaviors and interactions of participated individuals[8] is commonly used to simulate construction scenarios to understand and further optimize the process. Multiple collaboration systems between human-human[9], human-device[10] and robot-robot[11] in construction have been studied. However, human-robot collaboration system has its specific complexity and uniqueness comparing to other collaboration systems, which calls for further investigation.

This research starts with analysis of human-robot collaboration system in construction, then chooses bricklaying process as a typical application in the construction domain, and adopts an agent-based (AB) modeling approach to simulate human-robot collaboration process with emphasis on its characteristics. Managerial insights are drawn to show the applicability and benefits of the proposed model. The remainder of the article is organized as follows. Section 2 introduces the methodology used in the research. Section 3 provides the analysis for human-robot collaboration systems in construction. Section 4 proposes the development of the AB simulation model. Section 5 presents case studies and draws managerial insights. Section 6 summarizes the research and discusses possible future investigations.

2 Methodology

The objective of this research is to model human-robot collaboration in bricklaying with an AB modeling approach. To achieve the objective, AnyLogic© (version 8.5.0) is used as a simulation platform. A six-step

methodology is utilized (Figure 1), which contains system analysis, model scope determination, simulation environment determination, agent property definition, data collection and scenario application.

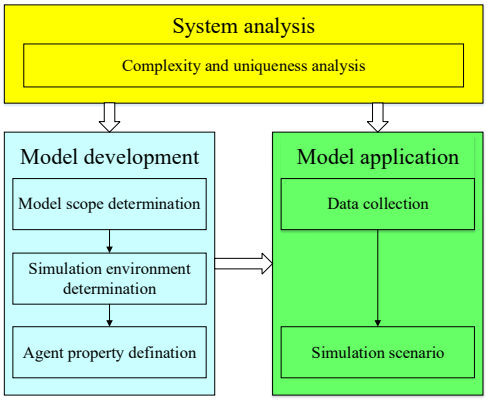

Figure 1. Overview of the research methodology

At the very beginning, the human-robot collaboration system in construction is analysed. Its complexity and uniqueness comparing to other collaboration systems are further stressed, which is the foundation of all the rest steps. In model development, model scope is first determined. Robot agents, worker agents, brick agents, and recorder agents are incorporated. A real project in Beijing is used as the simulation environment. Acting behaviors are captured to define the agents' property. Then, agents can act spontaneously in the experiments. The model is further applied to a case study to test its applicability and draw managerial insights. Data collection should be done at first to determine parameters in the model. Considering the practical applications of bricklaying robots are still limited, the parameters cannot directly be acquired from real bricklaying robots. To address this, the parameters are based on theoretical and empirical evidence, including previous papers and video records. However, it is important to mention that the parameters can be easily adjusted to other values when needed. Considering the randomness in experiments, the simulation scenario is simulated three times and outputs are set to the average value.

3 Analysis for human-robot collaboration systems in construction

3.1 Collaboration system

Collaboration systems are classified by participants. In construction, collaboration systems between human-human, human-device, robot-robot and human-robot are common (Figure 2). Human-human and robot-robot collaboration refers to the collaboration among workers and machines respectively. The difference between human-device collaboration and human-robot collaboration is that human conducts a mission by manipulating a device (i.e. infrared cameras in bridge inspection[12]) while human and robots can work on different tasks side by side[13].

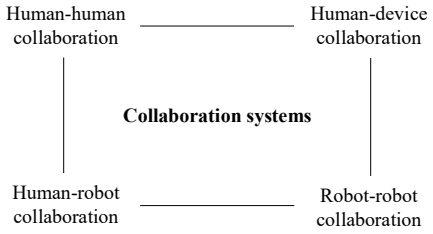

Figure 2. Classification of collaboration systems

Several communication modes are involved in collaboration systems[13] (Table 1). These modes are originally used in human-robot collaboration, but they can be generalized to other collaboration systems as well. Therefore, agents are used to represent the participants, corresponding to the AB approach.

3.2 Complexity and uniqueness of human-robot collaboration system

3.2.1 Traditional collaboration system

Traditional collaboration systems between human-human, robot-robot and human-device are involved in simulation scenarios of previous papers. Table 2 summarized the scenario, collaboration type, communication mode of representative works. For example, in bridge inspection process[12], on one hand, preparation and inspection are conducted in sequence by technicians. Technicians use voice to communicate, which is considered a form of RCI. On the other hand, technicians move with the devices in the inspection process, and since technicians need to set or program the devices first, the communication mode is ME.

It can be concluded that traditional collaboration systems only involves a simple communication mode, either RCI or ME. This is reasonable since humans only need to communicate by voice; robot-robot system as a fully automated system only needs electronic signals to send messages; while device as a passive object only need to be programed.

3.2.2 Human-robot collaboration system

Comparing to traditional collaboration systems, human-robot collaboration is complex and unique in the following three aspects. All three aspects will be further illustrated in Section 4. (1)Simultaneously involving

multiple communication modes: since many robots in construction is not fully automated, they still need to be installed, programmed or manipulated (ME, TL) like devices; however, robots have much higher autonomy and independence as a collaborator rather than a passive tool, which provide possibility for more communication modes (RCI, DPI). (2)Safety requirement: for extremely complicated and distributed environment like construction site, it will be very hard to set up fence to separate workers and robots. Since human workers are exposed to robots, human-robot collaboration system needs some safety requirements such as safety distance[14]. Safety issue is seldom considered in traditional collaboration systems. (3) Different characteristics between participants: the two participants, human and robot, have different characteristics. For example, human workers will forget or feel tired, but robots will not. This is unique as well. For human-device collaboration, when humans are tired, the efficiency of device will also be effected as it is manipulated by humans.

Table 1. Communication modes in collaboration systems[13]

Communication mode	Description
Direct physical interaction (DPI)	One agent's body contact with another in order to perform a task
Remote contactless interaction (RCI)	Agents contact by interfaces (e.g. voice, camera)
Teleoperation(TL)	Workers directly drive a machine with interface
Message exchange(ME)	Information is exchange using digital signals transmitted through physical button

Table 2. Traditional collaboration systems in previous work

Paper	Scenario	Collaboration type	Communication mode
Seo et al.[9]	Bricklaying	Human-human	RCI
Abdelkhalek et al.[12]	Bridge inspection	Human-human	RCI
Zhe et al.[15]	Pump maintenance	Human-human	RCI

Jung et al.[10]	Lift system	Human-device	ME

4 AB model development for human-robot collaboration

After having an understanding of the complexity and uniqueness of human-robot collaboration system, this section provides an AB model to simulate this process.

4.1 Model scope

Model scope determines the content of agents. Four kinds of agents are involved in this model, robot agents, worker agents, brick agents and recorder agents. The first two agents will work together to fulfil masonry tasks. Four agent states are introduced to capture the working condition of both robots and workers: (1) working state refers to an agent working on a given mission; (2) idle state refers to agent being in idle without missions; (3) moving state refers to workers moving robots or robots being moved; (4) operating state refers to workers and robots doing preparatory works. Bricks are considered as passive agents for robots and workers to manipulate. Besides, in order to record the agent state at any time, a kind of dummy agent, recorder, is introduced to the model. Each recorder agent has one corresponding robot agent or worker agent. It will record the state and the corresponding time when the state has changed.

4.2 Simulation environment

The simulation environment is the construction site where agents are acting and interacting with each other. In this research, a typical residential project in Beijing is used to provide references to the design of the simulation environment. Several assumptions are made to simplify the original layout of the construction site without losing generalization. One of the buildings in the layout is picked as the construction object. The corner of the site is assumed to be Long-term Store Place to deposit construction materials, such as bricks. A small place near

the building is considered as Temporary Store Place for workers' convenience. A rectangle area that envelopes the building is assumed to be Work Zone. Besides, a small rectangle place near Temporary Store Place is set to be Robot Store Place. The simplified layout of the simulation environment is shown in Figure 3. It is then imported to the simulation model in Anylogic© using real-world plotting scale to ensure the reliability.

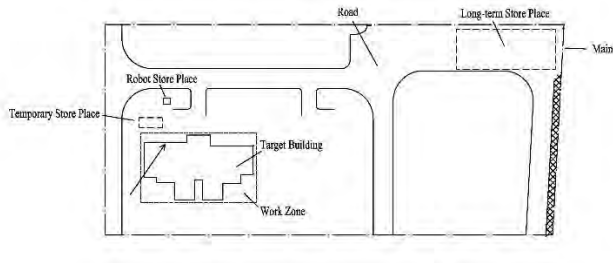

Figure 3. The simulation environment of the model

At the beginning, all bricks are deposited in the Long-term Store Place. The robot is placed in the Robot Store Place, while all the workers are randomly placed in Work Zone. In this research, we mainly focus on the situation with one robot. It is assumed that three workers are needed to move the robot. Therefore, the simulation environment contains 3 worker agents and 1 robot agent.

4.3 Agent properties

In AB models, agents have two types of properties, attributes and variables, to regulate their performance[17]. Attributes are fixed properties, while variables may change in the process.

4.3.1 Robot agent

The main job for robot agents is to construct brick walls. Conventionally, brick walls function as infilled walls that locate between columns. Two dummy nodes, start node and end node, are extracted to represent the endpoints of each wall. The set of all nodes, Node Set (NS), is introduced to record all the start nodes and end nodes. It represents all the construction tasks for the bricklaying robot. One attribute, Number of Nodes (NN) and one variable, Number of Completed Nodes (NCN), are applied correspondingly to capture the number of all nodes and completed nodes in NS. Another attribute, Number of Layers (NL), is introduced to determine the number of layers in each wall.

The robot agent will pass through four stages during the whole construction process. (1): Robot agents start waiting for workers at Robot Store Place, so it is classified as idle state. (2): After moved and installed by workers, the robot is working in Work Zone, and is classified as working state. Although there are several types of bricklaying robot existing in industry or academic [2, 18-23], most robots share the same process of laying one brick. Therefore, SAM100 is chosen as an example to model the laying process. For SAM100[24, 25], the whole process can be summarized into the iteration of two procedures, moving to target position and bricklaying. Bricklaying is a generalized process that contains plastering on the surface, grabbing one brick and laying it on the mortar. Two attributes, Moving Velocity in Working (MVW) and Brick Laying Duration (BLD) are critical in this stage. The first attribute captures the velocity as robots moving to the target position, and the second attribute captures the duration for the bricklaying process. When one layer is finished, the robot will return to the start node. For safety reason, it is assumed that the robot will not start the next layer until the worker responsible for extra mortar removing (introduced in the next section) finishes this layer. (3): After all layers are finished, the robot will automatically move back to the start node and stop operating. It is classified as idle state. Meanwhile, the start node and the end node for this wall will be labeled as "Complete" and NCN will increase by two. (4): Because several bricklaying robots has a pipe to deliver mortar[25], it is assumed that the mortar is always sufficient. However, robots probably will still run out of bricks that are stored inside. When this happens, the robot will pass to Stage 4 and stop operating, therefore the state will change into idle state. The attribute, Robot Storage Capacity (RSC), is applied to determine the maximum number of bricks that can be stored inside the robot. When the bricks are supplemented, the robot will start operating again and continue the previous task.

4.3.2 Worker agent

In this model, workers are responsible for three kinds of tasks in the whole process. First, workers need to carry the robot to target locations, called Robot Moving and Installing (RMI). Second, considering when robots squeeze a brick on the mortar, the robot arm will also push some mortar beyond the below brick's edges[23], this extra mortar is supposed to be removed by one human worker. This task is called extra mortar removing (EMR). Third, when robots run out of bricks in their storage, one worker is responsible to supplement bricks[26]. This task is called Brick Supplement (BS). For the three worker agents in the model, one is responsible for BS and RMI (called the BS worker), one is responsible for EMR and RMI (called the EMR worker), and the last one only need to participates in RMI (called the RMI worker).

RMI task can be divided into two parts. (1): At the very beginning, workers first move to Robot Store Place. Their moving speed is determined by the parameter Walking Velocity (WV). Some preparation works need

to be done before they move the robot. Then, workers will carry the robot to Node 1. Another attribute, Robot Moving Velocity (RMV), is introduced to capture this moving speed when carrying loads. Then, workers need to install it on the work site. These two processes, determined by Preparation Duration (PD) and Installation Duration (ID), belong to operating state. (2): When the robot finishes the bricklaying work for one wall, workers will judge whether there are other unconstructed walls. If so, they will move the robot to the next unfinished node in NS. Otherwise, workers will move the robot back to Robot Store Place.

EMR task is the iteration of moving to target brick and removing extra mortar on the brick. Since the worker is not carrying loads, it is assumed that the moving speed is WV as well. An attribute, Mortar Removing Duration (MRD), is introduced to determine the time for the worker to remove mortar on one brick. To ensure that the EMR worker has a safe distance with the robot, it is assumed an at least 10 bricks length separation distance.

Since the EMR worker is beside the robot, he will inform the BS worker when the robot runs out of bricks and stops operating. Then, the worker will go to Temporary Store Place or Long-term Store Place to supplement bricks, depending on the number of bricks at Temporary Store Place. If it is larger than RSC, he will grab, move and add these bricks to the robot. Otherwise, the BS worker will first transport five times RSC bricks from Long-term Storage Place and drop them to the Temporary Storage Place. Three time-related attributes, Grabbing Duration (GD), Dropping Duration (DD), and Supplement Duration (SD) are introduced to determine the duration the BS worker needs to grab, drop and supplement RSC number of bricks. Besides, Carrying Velocity (CV) is introduced to decide the moving velocity for the BS worker when transporting bricks. Besides just waiting for the information from the EMR worker, it is assumed the BS worker will check the number of remaining bricks periodically. If the BS worker finds that bricks in the robot are less than Supplement Limit (SL), he will start the supplement process directly. Check Interval (CI) is introduced to determine the checking frequency.

Two ergonomic behaviors are incorporated.

(1) Forgetting: Because the BS worker may repeat checking many times a day, he is very possible to forget some checks. To capture the forgetting behavior, the variable Forgetting Possibility (FP) is introduced. FP is determined by the following equation[15]:

$$FP = e^{-0.01CI} \quad (1)$$

(2) Muscle fatigue: In bricklaying process, several tasks have physical work load on masons [27], which leads to muscle fatigue. To address this, we reference a dynamic fatigue model proposed by Seo et al. [9]. A worker will take a voluntary rest when his current level of muscle strength is lower than the physical demand in the following work element, and will not perform the task until the former is at least 10%MVC higher than the latter. MVC refers to the maximum muscle strength. Relation of current muscle strength and work load is shown in equation (2), and muscle strength in the recovery process can be explained in equation (3).

$$\frac{F_{cem}(t)}{MVC} = e^{-\frac{F_{load}}{MVC}d} \quad (2)$$

$$F_{cem}(t_b) = [1 + r \times (b - a)]F_{cem}(t_a) \quad (3)$$

$F_{cem}(t)$ represents the currently available maximum force at time t. d refers to the duration of the task, and F_{cem} refers to the average physical demand of a work element. Only four work elements that have physical demand are considered based on Seo et al. [9]. The physical demand for extra mortar removing is 0.1%MVC; while the physical demand for grabbing bricks, dropping bricks, and adding bricks to the robot are 0.4%MVC. Besides, r equals 5%MVC per 1 min when F_{cem} is lower than 90%MVC, and equals 0.3%MVC per 1 min otherwise.

4.4 Characteristics of human-robot collaboration in the AB model

This section introduces how the characteristics of human-robot collaboration mentioned in Section 3.2.2 is embedded in the AB model.

Table 3 shows the communication modes related to the bricklaying process. It shows that the human-robot collaboration simultaneously involves three communication modes except TL. These there modes are successfully captured by the proposed model.

Table 3. Involved communication modes in AB model

Communication mode	Scenario
DPI	BS supplements bricks for the robot Workers move the robot
RCI	Communication among workers The Robot waits EMR for next layer
TL	/
ME	Workers install the robot

As mentioned before, the robot will not start laying the next layer until the EMR worker finish the layer; the minimum distance between the robot and the EMR worker is required. These two rules represent the safety requirements. Other requirements can be embedded to the model as well in the same way. Besides, the different characteristics of human and robot are modelled by considering two human factors.

5 Model application and demonstration

5.1 Data collecting

The simulation model is set up based on a range of parameters, including attributes and variables. Attributes are given default values, and variables can be calculated from attributes. Attributes in the model are classified into four types. (1): NS, NN, NL are defined by the construction tasks; (2): PD, ID, MVW, BLD, RSC are related to the robot type; (3): RMV, WV, MRD, GD, DD, SD, CV are determined by the workers' capacity; (4): SL, CI represents the inspection policy. This research aims at providing a modeling approach, without focusing on specific robots, workers or policies. Therefore, the attributes are decided in Table 4 based on theoretical evidence, empirical evidence and necessary assumptions[18, 24, 28]. Triangular distributions with a 20% variance are applied to PD, ID, MRD, GD, DD and SD to capture workers' random performance[29].

Table 4. Default value of attributes

Robot agent		Worker agent	
Attribute	Value	Attribute	Value
PD	10min	RMV	0.33m/s
ID	10min	WV	0.75m/s
MVW	0.2m/s	MRD	5s
BLD	8s	SL	100 bricks
RSC	300 bricks	CI	15min
		GD	30s
		DD	30s
		SD	10s
		CV	0.67m/s

5.2 Case study

This scenario gives a demonstration of the output in order to shed light on a better understanding of the proposed model, while draw useful managerial insights from the output. The construction task for this scenario is the first wall with ten layers, which is labeled with an arrow in Figure 2. Therefore, NS contains two nodes, NN equals two and NL equals ten. Other attributes equal default values.

5.2.1 Recording duration data

The model is capable of recording total and classified construction duration for both robot agents and worker agents. Based on the duration data, the proportion of working time and idle time can be calculated. Duration data for robot agents are shown in Table 5. The construction duration, together with proportion of working time and idle time can serve as an indicator of the productivity of the construction process.

Table 5. Duration data for robot agents

	1	2	3	average
Construction time (h)	5.07	5.10	5.04	5.07
Working time(h)	2.78	2.77	2.77	2.77
Idle time (h)	1.58	1.57	1.54	1.56
Moving time (h)	0.06	0.06	0.06	0.06
Operating time (h)	0.66	1.57	1.54	0.67
Working proportion		/		54.6%
Idle proportion		/		30.8%

5.2.2 Generation of state-to-time variation

Based on the data recorded by recorder agents, figures that show state-to-time variation can be generated. In the figures, different states are labeled with different numbers (2 refers to working state, 1 refers to idle state, 0 refers to operating state, -1 refers to moving state). This grading approach can capture the divergence of states from working state. The state-to-time variation of primary agents, including the robot agent, the BS worker agent and the EMR worker agent are showed in Figure 4.

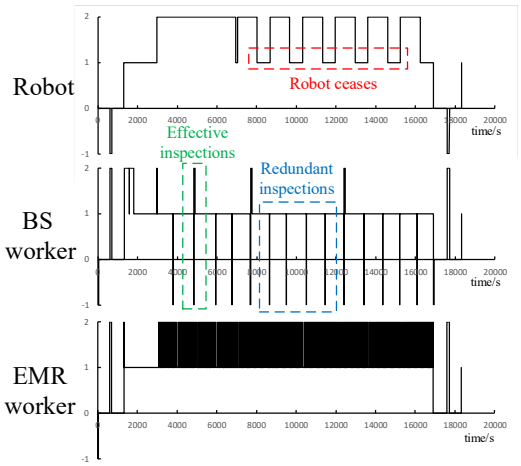

Figure 4. State-to-time variation of main agents

The state-to-time variation clearly shows the working condition of each agent, therefore it is considered to be a good tool to examine the productivity of the process. For example, it stresses the impact of inspection policy on total productivity. Beside effective inspections labeled with the green rectangle, the BS worker has several redundant inspections labeled with the blue rectangle, which infers CI should be adjusted longer than the default value to achieve better effectiveness. Besides, the robot still ceases several times labeled with the red rectangle due to the fatigue of the EMR worker. It is clearly shown in Figure 6 that all the pauses happen after the F_{cem} of the EMR worker reached 0.11, 10%MVC higher than the physical demand of his tasks. Another important managerial insight can be drawn to address this. At the

early stage, workers' strengths match well with the robot. However, when the construction is carried forward, workers become incompetent due to muscle fatigue. At this time, some managerial actions (i.e. shifts) should be taken to regain the balance between workers and robots. The proposed model can indicate the best time to shift the EMR worker, which is labeled by red line in Figure 5.

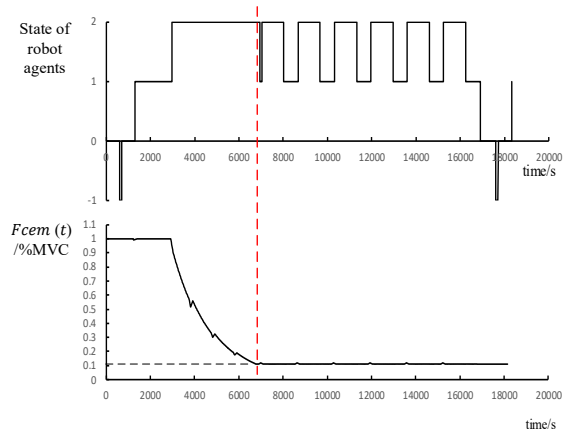

Figure 5. Impact of fatigue on productivity

6 Conclusion

Comparing to collaboration systems between human-human, human-device and robot-robot, human-robot collaboration is complex and unique because it involves multiple communication at the same time; it has special safety requirements; its participants, human and robot, have different characteristics. In this research, an agent-based approach is applied to simulate human-robot collaboration process in typical bricklaying scenarios, in order to provide a bottom-up approach to help understand and further optimize this complicated process.

The proposed model fully integrates the behaviors of both workers, robots and their interaction. The effect of muscle fatigue and forgetting is incorporated as human factors to further emphasize the differences between robots and workers. The AB model is capable of recording total and four types of classified construction duration corresponding to the four states, and is able to capture state-to-time variation. Development of the simulation model is based on a range of parameters to capture the quality of both workers and robots, which is further based on theoretical and empirical evidence, including previous papers and video records. The result confirms the potential of AB modeling for analyzing human-robot collaboration process in construction. The results also draw some managerial insights: (1) inspection policy can be adjusted to achieve a higher effectiveness; (2) shifts in workers are highly recommended to retain the strength balance between workers and robots to maximize the productivity, since muscle fatigue will greatly hamper workers' capacity.

Further research can be conducted to improve and utilize the proposed model. Although the proposed model reflects the coexistence of different communication modes, it will be very meaningful to abstractly model the four communication modes, which can guide the establishment of future simulation models related to human-robot collaboration. Besides, currently only forgetting and muscle fatigue are considered in the model. However, other human factors (i.e. communication errors etc.) and ergonomic behaviors (i.e. muscle fatigue increases the forgetting possibility etc.) can be incorporated. Furthermore, many parameter values in this research are not based on actual robots due to the limited practical application. As construction robots become more prevalent, parameters can be adjusted to actual values.

Abstract –

Medical facilities in the United States (US) are facing growing demands due to shifts in patient demographics, healthcare policies, costs of care, and medical technologies. An emerging trend is the growing importance of outpatient and ambulatory care relative to inpatient care. Whereas the term "inpatient" involves a patient needing admission into a hospital over an extended period of time, ambulatory care (i.e., outpatient clinics, dialysis clinics, ambulatory surgical centers, etc.) generally involves medical and surgical services performed outside a hospital environment, with the overall patient visit duration typically lasting less than a few hours. Changes in healthcare policy and advances in medical technologies are driving the need for ambulatory facilities to be more flexible in terms of functionalities and environmental qualities (e.g., light, acoustics, etc.). Responsive environments, as a design approach focusing on how spaces can change in response to user and environmental input (e.g., user interfaces, sensors), can uniquely address these changing and contemporary needs of medical practices. Architectural robotics, a key element of responsive environments, can facilitate rapid changes in building component configurations, such as interior wall, display screen, and furnishing layout, enabling spatial flexibility for medical staff. In this paper, we envision a novel application of responsive environments in the context of outpatient clinics and ambulatory care facilities. We present two ambulatory practice scenarios demonstrating architectural robotics use cases, based on preliminary observations of six ambulatory care medical staff and their patterns of interactions with existing technologies, building spaces, and navigation between spaces. Virtual environments, modeling those two scenarios, have been scripted and tested with an initial group of nine medical professionals activating architectural robotic transformations and experiencing the changes in configurations, with feedback collected through a follow-up questionnaire. Collected data on participants' feedback on the scenarios' applicability to healthcare practice and usability are presented in this paper. We expect to develop subsequent responsive environments to serve specialized medical practices as we identify them by shadowing a larger cohort of medical staff. Outcomes will be helpful for design practitioners as our findings suggest updates to the typical medical building layouts given digital technology advancements in healthcare practice. This work serves as an initial proof of concept for how responsive environments and architectural robotics can improve the spatial flexibility of future ambulatory care settings in particular and medical facilities overall, and how these are positively perceived by medical staff.

Keywords –

responsive environments; immersive virtual environments; healthcare; architectural robotics

1 Introduction

Medical facilities in the United States (US) face numerous challenges amidst a changing landscape of policy, demographics, and technology. An emerging trend is the growing importance of outpatient and ambulatory care relative to inpatient care. Inpatient care typically refers to hospitals, where a patient stays for an extended period of time under significant levels of monitoring and treatment. Outpatient and ambulatory care (i.e., outpatient clinics, dialysis clinics, ambulatory surgical centers, etc.) generally involves medical and surgical services performed outside a hospital environment, with the overall patient visit duration typically lasting less than a few hours. Within the last fifteen years, the number of outpatient facilities in the US has increased 51% due to numerous factors including an aging population, changes in US healthcare policy, and rising costs of inpatient care [1] [2]. These trends motivate us to specifically focus within the context of healthcare on improving the built environment of outpatient and ambulatory care facilities. While the terms "outpatient" and "ambulatory" have nuanced definitions in medical research, for the purposes of simplicity, this

paper use "outpatient clinics" to refer to both terms.

Outpatient clinics are starting to involve new digital technologies, raising questions of how the existing and future facilities can be better designed. For example, the predominant use of electronic health records (EHR) has created a challenge for physicians to balance their attention to EHR computer screens while making sure the patient still feels a sense of connection [3]. This has led to various investigations in how the built environment can be better designed with optimal positioning of furniture and EHR screens within an exam room [4]. EHRs are also getting integrated with wearable health technologies to capture more data on patients and streamline medical staff workflows [5]. Telemedicine has changed the relationship between people and the built environment, allowing patients to check in with their doctors without having to visit an outpatient care facility [6] [7]. Driven by these changes in technology, expectations of patients, and medical staff workflows, outpatient practices need flexibility in terms of the amount of space, variations in environmental qualities (e.g. lighting, acoustics, temperature), and ability to use the same space for multiple purposes [2]. The need for flexibility in outpatient clinics compels us to re-evaluate what medical staff and patients currently require from their environments.

Updating medical staff and patient requirements on the usage of facilities will inform the design of outpatient clinic environments that work in conjunction with the information technologies being used. In fact, those same technologies that reduce the number of in-person visits also present an opportunity for improving outpatient clinic environments for situations when an in-person visit is necessary. As technologies become more interconnected, more ubiquitous computing ecosystems and cyber-physical systems may become possible to incorporate into the design of outpatient clinic environments. We anticipate that these new technologies can enable the spatial and environmental flexibility desired by current outpatient practices through a responsive environment design approach.

Specifically, we see potential for architectural robotics to be involved in medical staff workflows, allowing for greater functionality within a given floor area. We present in this paper preliminary demonstrations of architectural robotics in virtual environments of outpatient clinic spaces, use cases of space transformations that were identified through field observations in medical facilities, and evaluate the feedback we received from medical professionals who navigated within those VEs. Overall, these VEs provide a means for evaluating whether the needs of outpatient medical staff are well identified and addressed.

For this study, we performed preliminary ethnographic studies observing medical staff working in current outpatient care facilities. Based on those observations, we developed two scenarios of how architectural robotics can transform clinic spaces. We then present feedback from nine medical professionals after they walk through virtual environments demonstrating those two scenarios. While the focus of this paper is on outpatient and ambulatory care facilities, we expect that the findings are applicable to medical facilities in general.

2 Related Work

2.1 Responsive Environments

While the term "responsive environments" has varied over time and different contexts, it generally refers to elements of a built environment that react to a stimulus of social (e.g., a person) or environmental (e.g., air temperature) nature [8]. Within these responsive environments, a range of explicit (e.g., a person turning on an air conditioner) and implicit (e.g., a thermostat determining space cooling needs) interactions providing that stimuli are possible [9]. A more specific definition of interest to our research is a responsive environment that can perceive people's changing needs through a system of sensors [10] [11] [12]. Past research in responsive environments has developed means of modulating visual and auditory stimuli in office environments [13].

At the same time, forward thinking designs of outpatient clinics has focused attention on the static placements of digital screens and medical devices in the patient-centered experience [14] [15]. While much research has focused attention on optimal environmental features (e.g., lighting, noise levels, color, optimal room layouts, etc.), not much has been investigated on how those features could change in response to changes in people's needs [3] [16] [17]. Similarly, past research has investigated flexibility strategies for inpatient medical facilities, presenting a gap in how responsive environment design approaches can improve outpatient clinic environments [2] [18]. Our work seeks to develop responsive features that enable dynamic interactions between users of outpatient clinics (e.g., medical staff and patients) and their surrounding environment. This approach will integrate clinics' emerging technologies and ultimately enable more flexibility in how spaces can serve users' needs.

2.2 Architectural Robotics

We consider responsive environments as an overall design approach. Architectural robotics, a term referring to intelligent machines at the scale of built physical environments, can be considered a cornerstone of

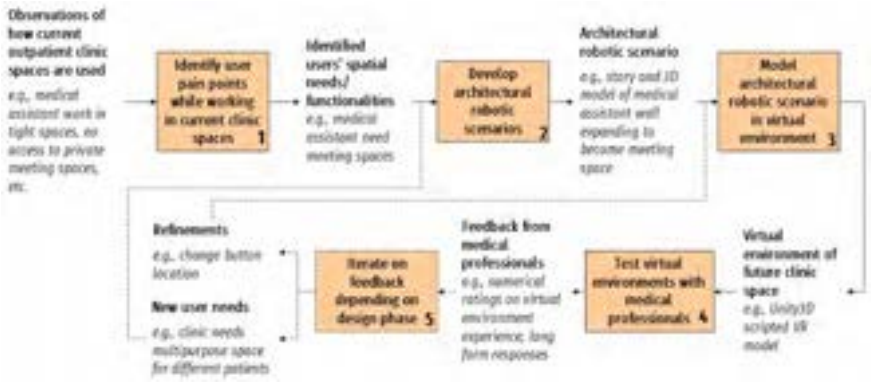

Figure 1. General process followed to identify architectural robotics use case scenarios for future outpatient clinics. Dashed lines indicate steps that lie beyond the scope of this paper to be pursued in future work.

responsive environments [12] [19] [20]. Architectural robotics, as a concept, proposes a connection between conventionally analog building features, such as interior wall partitions, and technologies typically categorized as building control systems (BCS). Two notable works serve as a point of departure for our vision in this paper. Houayek, et al. developed physical architectural robotic prototypes for novel work environments for designers in response to emerging technologies within the architectural design and office work domains [21]. In the context of healthcare, Threatt et al. envisioned an ecosystem of architectural robotics for a rehabilitation inpatient setting [22]. In contrast, our study focuses more on the needs of outpatient clinic spaces and developed architectural robotic use cases in response to emerging technologies in the healthcare domain.

It is important to emphasize that this paper concerns the role robotics can play beyond anthropomorphic (i.e., human-like) forms and outside of heavy surgery and intensive care applications in healthcare. Numerous research work has been done on how human-like robots can assist with healthcare, both as standalone assistants and arms for robotic surgery [23]. The term "architectural robotics" is used here to refer to autonomous and ubiquitous computing available for transforming the built environment [24]. Our study focuses on understanding the unique requirements of outpatient healthcare settings and how robotics at the scale of the built environment can satisfy them.

2.3 Virtual Environments

One major barrier to the implementation of architectural robotics is the cost of prototyping and mockups. While early/rapid prototyping is deemed essential for iterating on design options, designers are limited by the time and costs to produce high fidelity prototypes and mockups. Virtual reality (VR) is aptly suited for creating game-like environments for stakeholders to preview how to interact with architectural robotics in outpatient care facilities. Early virtual environment (VE) walkthroughs by medical staff can clarify their workflow requirements and point to better use cases for architectural robotics in outpatient care. Later in the design process, these virtual environments can inform specific usability and interface decisions (e.g., should a button be placed on a wall?) (Figure 1).

Notable among virtual environments research in healthcare is the study by Dunston et al., which used a cave automatic virtual environment (CAVE) set up to preview mockups of a hospital patient room [25]. Previous studies have used virtual environments for developing robotic prototypes both for healthcare and outside that domain [26] [27]. Our study utilizes virtual environments for testing architectural robotics and responsive environments, beyond the physical scale of human-like robot forms. Virtual environments afford designers the opportunity to test room-scale interactions, rather than passively previewing an architectural design.

3 Methodology

Steps taken to identify how architectural robotics could improve outpatient clinics are summarized in Figure 1. First, we set out to understand how current outpatient clinic spaces are used through firsthand observations of medical staff. These observations focused on how people interacted with the built environment (e.g., space usage patterns, sequence of navigations between spaces, etc.). Based on these observations, key workflow pain points were pinpointed using the identified patterns of interactions with existing technologies, clinic spaces, and space-to-space navigations (Figure 1, box 1). If multiple pain points all indicated a particular subset of clinic spaces, a scenario would be developed outlining how the architectural robotic transformations could resolve those pain points

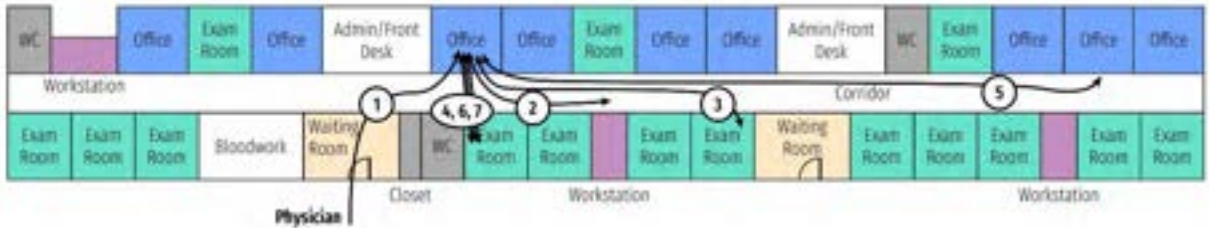

Figure 2. Navigation pattern mapping of physician in primary care clinic.

by changing a room's layout from one space type to the other (Figure 1, box 2). Two scenarios developed from this process are presented in this paper: *Scenario 1:* a physician's private office transforming into a patient exam room; and *Scenario 2:* a medical assistant work area transforming into a larger meeting space. Virtual environments demonstrating these scenarios were then built in a game engine platform, showing the transformations and user interactions needed to trigger them (Figure 1, box 3). Finally, an initial group of nine medical professionals were invited to test the scenarios in the virtual environments and provide feedback on the transformations enabled, its potential value to healthcare practices, and specific usability issues (Figure 1, box 4). This study utilizes virtual environments to test two specific architectural robotic use case scenarios in outpatient clinic spaces. Future studies will refine those designs to be more practical and usable while also identifying additional use cases, based on medical professionals' feedback (Figure 1, box 5).

Regarding the first step of observations, the research team conducted in-person observation of a primary care physician and his medical team over the course of an afternoon at an outpatient clinic. Field notes were taken recording the physician's actions and general notes about how the space was used by all medical staff. Observations focused on tracking the navigation patterns between spaces in anticipation that future spaces could minimize the time medical staff need to spend walking between spaces and improve their work efficiency. The physician's walking patterns within the outpatient clinic were recorded as shown in Figure 2 on the floor plan of the medical facility. Each line in Figure 2 shows an approximate walk path direction, labeled in the chronological order taken during the workday. Paths 3, 4, 6, and 7 show the physician walking between exam rooms to see patients. Path 2 occurred when the physician needed to check on a patient's status with a medical assistant at their workstation. Path 5 occurred when the physician's colleague needed help finding an empty office for a private meeting. These trends illustrate how the physician needs to primarily walk to exam rooms but also other areas for impromptu tasks. Field notes obtained from a different research study examining computer screen and equipment usage in an obstetrics and gynecology (OBGYN) clinic were also analyzed for identifying the patterns of how spaces were used. The walking paths of various staff (physician, physician assistant, etc.) were plotted onto the clinic floorplan (Figure 3). Similar to Figure 2, it was also observed that the physician primarily walks between exam room and office spaces as shown with red colored paths. Unlike the primary care physician, however, the OBGYN physician also occasionally sees patients in their office. Figure 3 also examined the walk path of other clinic staff. Physician assistants (Figure 3 in purple) and medical assistants (Figure 3 in blue) tended to also converge at the exam rooms, while surgical coordinators (Figure 3 in pink) remained in their office during the observed period.

These observations and navigation pattern mappings directly informed the development of architectural robotic scenarios for user testing. *Scenario 1: Office to Exam Room* was developed in response to alleviate the physician's need to walk between office and exam room, as illustrated in both Figures 2 and 3. By combining office and exam room into a single reconfigurable space, physicians can potentially save time walking. In *Scenario 1*, with a press of a button on the physician's desk, a sliding partition opens to reveal an exam table, consult desk, and display screen. The exam table reclines into a seated position and the display screen turn on automatically, providing an area for the physician to consult the patient while viewing electronic health records. Pressing the button again returns the room to the original office layout. *Scenario 2: Workstation to Meeting Space* was developed from observations in the primary care physician's clinic, where medical assistants

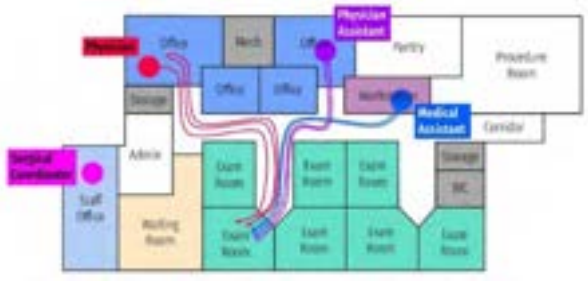

Figure 3. Navigation pattern mapping of medical staff in OBGYN clinic.

use the empty offices for privacy during lunch breaks and individual staff meetings. These pain points collectively suggested a need for medical assistants to have spaces to meet, especially given the smaller spaces given to medical assistant workstations (Figure 2). In *Scenario 2*, the medical assistant can press a button to activate a sliding partition wall, expanding their small workstation area into a larger meeting space. The expansion necessitates the adjacent office space to be compressed, requiring the office desk to fold up and chairs to be clear of the sliding partition wall before the transformation can be completed. The user is expected to press the button twice: once to begin the overall transformation, and again after confirming the office space area is clear and ready to be compressed. The same logic applies to returning the rooms to their initial layout but in reverse. Table 1 summarizes the details of these transformation sequences Both scenarios were developed from related paint points involving a pair of spaces (office/exam room, workstation/meeting space), which indicated the potential to be combined into a single reconfigurable space using architectural robotics. Scenarios were developed initially as stories defining a premise (i.e., when do medical staff need spatial transformations to occur) and a transformation sequence (e.g., "desk folds up, chair moves, etc.") (Table 1). The scenarios were then modeled in a 3D modeling software, where the exact sequence of transformations was planned to fit within spatial constraints (e.g., chairs fit through door, desk folds to provide more space, etc.). Both scenarios were modeled to occur within the same general area of a hypothetical outpatient clinic, with room sizes based on the floor plan of an existing outpatient clinic familiar to the research team. The 3D models were then imported into a game engine software, where the exact movements of the architectural robotic elements and interactions were scripted.

Nine medical professionals (8 physicians, 1 nurse informaticist), were invited to walk through the VEs demonstrating the two scenarios in individual testing sessions. During the testing sessions, participants ran the application on their own personal computer while sharing their screen to a researcher over web conference. Participants went through a training scene before the two

Table 1. Scenarios demonstrating future clinic spaces utilizing architectural robotics.

Scenario Name and Description	***Transformations***
Scenario 1: Office-to-Exam Room ***Premise:*** Participants were asked to imagine themselves as a *physician* in their private office. With all exam rooms full, the physician can transform their private office space into an exam room to consult patient. ***Transformations:*** (1) User presses button, office desk folds up. (2) Hidden partition wall slides up. (3) Exam table, consultation table, and large display screen comes out of hidden wall partition. (4) Exam table reclines upwards for patient to sit while facing display screen. (5) Display screen turns on showing health information and teleconference consult.	***Plan View*** *Initial* *Intermediate* *Final*  ***First Person Point-of-View (POV)*** *Initial* *Intermediate* *Final* 
Scenario 2: Workstation-to-Meeting Room ***Premise:*** Participants were asked to imagine themselves as a *medical assistant* at their workstation. With conference and meeting rooms all occupied, they must convert their space to a small group meeting room. ***Transformations:*** (1) User presses button, office desk folds up. (2) Office chairs move automatically towards the wall. (3) User presses button again, workstation-office wall partition moves. (4) Office chairs move automatically into place, grouped with medical assistant chairs. (5) Large display screen automatically turns on.	***Plan View*** *Initial* *Intermediate* *Final*  ***First Person Point-of-View (POV)*** *Initial* *Intermediate* *Final* 

scenarios to get acquainted with the VE interface (e.g., arrow keys for movement, how to press buttons, etc.). On screen instructions indicated possible actions to the participants while the researcher guided them through the transformations. Participants could stand, walk around, or sit in chairs to get a sense of space in as much time as they wanted before moving on to the next scenario. Afterwards, participants filled out a standard questionnaire to provide feedback on the robotic transformations, their potential value to healthcare practices, and point to possible scenarios to explore in the future. Initial findings are provided in this paper. Overall, the study focused on evaluating whether the architectural transformations met the needs of medical staff. Future studies may refine specific robotic features in each scenario, such as button interactions and self-moving furniture, to determine which are needed and practical for medical professionals to use.

4 Results and Discussion

Nine medical professionals gave feedback on the two scenarios. A majority (N=6) of the participants were primary care physicians. Two participants considered themselves specialist physicians (e.g., pulmonary medicine, etc.), one listed themselves as a nurse informaticist. Most participants (N=6) have more than 15 years of professional experience beyond medical school, while the rest had less. The questionnaire asked them to also specify the percentage of their time spent in various clinic space types (e.g., exam room, private office). An aggregated percentage of time spent by all the participants is presented in Figure 4. Participants spent a majority of their time (81%) in an exam room, private office (i.e., a room used only by the participant), or shared office (i.e., a room used by multiple people simultaneously or different times over a workweek). Only 2% of the clinic workday was spent by all participants at an auxiliary workstation like the starting space for *Scenario 2*. When asked on their experience with 3D modeling/game applications, most participants stated having some experience (N=6) while the rest stated no experience (N=3).

When asked to rate the statement "I find the transformations presented in both scenes to be a necessity, given limited space within current clinics and trends in medical practice," 55% of participants strongly or somewhat agreed (N=5), and 44% neither agreed or disagreed (N=4). When asked specific questions about each scene's transformations' potential value to healthcare practices, participants had consistent responses as seen in Figure 5. A majority of participants agreed (strongly/somewhat) the premise of *Scenario 1* (N=7) and *Scenario 2* (N=6) were commonly observed in

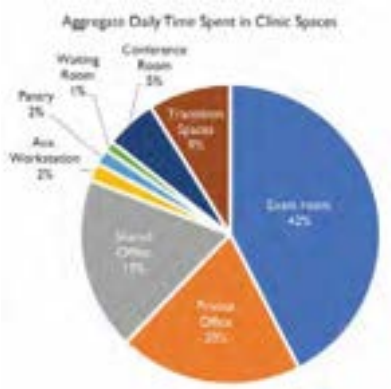

Figure 4. Percentage of time spent in clinic spaces by all VR user test participants.

their clinics. A majority (N=8) of participants agreed that *Scenario 1*'s transformations could provide a better experience for patients, but some (N=3) questioned whether the scenario would help physicians work more efficiently. Six of the respondents felt that *Scenario 2*'s transformations would help staff with finding meeting space and work together, and hence improve work efficiency (Figure 5).

Long form questions asked participants to elaborate on their ratings of overall experience and applicability to healthcare and their responses were generally positive. One participant especially liked *Scenario 1*'s concept, noting from their experience that patients tend to feel more comfortable speaking to their physician in a private office. Those who disagreed that *Scenario 1: Office to Exam Room* (N=2) would help physicians work efficiently stated concerns that the folding desk would have to be clear of items before the transformations began, and exam table surfaces would need to be sanitized after patient visit, per common health safety practices. While they noted that they see an increasing prevalence of "multiuse spaces" over private offices, some questioned the relevance of these scenarios given COVID19 and the prevalence of telemedicine. Though some participants saw *Scenario 2: Workstation to Meeting Space* as potentially helpful to nurses and medical assistants, others raised concerns regarding how the transformations could be used for natural ad hoc meetings and maintaining privacy. These responses conveyed that while participants found the general idea of space transformations valuable and applicable, they questioned the two specific scenarios presented in the virtual environments.

Overall, the virtual environment experiences spurred participants to point to other clinic use cases to consider at larger scales, such as how these transformations could assist the rest of the patient experience beyond the exam room and the entire clinic floor space. These suggestions indicate while there is a general positive interest among medical professionals in responsive environments, there

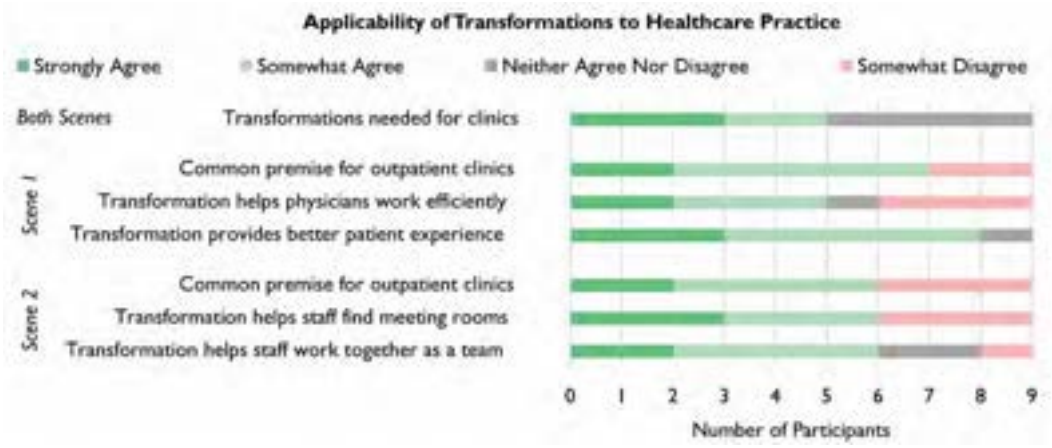

Figure 5. Participant responses on how applicable architectural robotic transformations are to healthcare.

are potentially other architectural robotic use cases that can better address the needs of outpatient medical staff. Additionally, scenarios demonstrated here are examples of explicit interaction between users and environments, where changes in layout are activated by button presses. New use cases in outpatient clinics and implicit interaction mechanisms for changing environment layouts will be developed and presented in future publications.

5 Conclusion

Responsive environments and architectural robotics have a potential to address the need for greater flexibility in medical facility spaces, especially in outpatient and ambulatory care settings. Our preliminary study showed a positive interest among medical professionals for the applicability of responsive environments and architectural robotics in medical settings. Their feedback provided specific concerns and suggestions, which prompt us to investigate other potential use cases in clinic spaces in future studies, beyond the two scenarios presented here.

Abstract -

The majority of fatalities and traumatic injuries in heavy industries involve mobile plant and vehicles, often resulting from a lapse of attention or communication. Existing approaches to hazard identification include the use of human spotters, passive reversing cameras, non-differentiating proximity sensors and tag based systems. These approaches either suffer from problems of worker attention or require the use of additional devices on all workers and obstacles. Whilst computer vision detection systems have previously been deployed in structured applications such as manufacturing and on-road vehicles, there does not yet exist a robust and portable solution for use in unstructured environments like construction that effectively communicates risks to relevant workers. To address these limitations, our solution, the Toolbox Spotter (TBS), acts to improve worker safety and reduce preventable incidents by employing an embedded robotic perception and distributed HMI alert system to augment both detection and communication of hazards in safety critical environments. In this paper we outline the TBS safety system and evaluate it's performance based on data from real world implementations, demonstrating the suitability of the Toolbox Spotter for applications in heavy industries.

Keywords -

Workplace Health and Safety; Hazard Detection; Computer Vision; Human Machine Interface (HMI)

1 Introduction

In 2018 there were 99 fatalities in the heavy industries of Transportation, Agriculture, and Construction alone in Australia, accounting for 69% of all workplace fatalities across all industries [1]. The vast majority of these (71%) were directly related to vehicle collisions and impacts with other moving machinery.

ToolBox Spotter (TBS) is an embedded robotic perception and distributed alert system for use in heavy industries that works to supplement existing safety procedures in these critical environments. It addresses both the detection of hazards that may result in a collision or injury, as well as the effective communication of these hazards to vehicle operators and nearby pedestrians. The TBS is a modular system consisting of local sensor nodes, a central processing node (CPN), and distributed alert devices. This forms an intelligent detection system and alert network for use on vehicles, mobile plant and machinery, and on infrastructure as a safety control measure.

Figure 1. *The Toolbox Spotter (TBS) hazard awareness system in use on heavy machinery at a construction site. The sensor node (highlighted in blue) is alerting the operator to the presence of the two people standing in the vehicle's blind spot.*

Existing approaches to safety include the use of a hierarchy of controls which aim to eliminate and mitigate risks where possible through the use of standard policies such as task isolation and the use of personal protective equipment (PPE). Whilst these procedures can be effective when correctly employed, it is not always practical to completely remove a risk during normal operations. Additionally, worker distractions and lapses of attention can greatly reduce the effectiveness of these approaches. Recently, proximity based collision detection devices combined with wearable RFID tags have been used in safety systems in construction [2]. However, these systems cannot always differentiate between objects when RFID tags are not worn and crucially rely on human behaviour and supervision to ensure this.

In this work we describe our solution to the problem

of safety around moving vehicles and plant in heavy industries, the ToolBox Spotter. Section 3.1 provides an overview of the components of the TBS system.

We also evaluate our proposed system in Section 5 on three diverse datasets of real world video clips, chosen to reflect current implementations of the TBS on construction sites. We outline the performance of the system as well as addressing usage of the system with consideration of its application as a human in the loop safety system.

2 Background

2.1 Safety in Heavy Industries

A comprehensive study of occupational safety in the construction industry [3] detailed that the primary conditions influencing safety performance in a workplace were not just the organisational procedures and policies in place, but the individual attitudes towards safety, including personal engagement, the taking of responsibility, and prioritisation of safety. Whilst the proper use of control procedures are critical in the elimination of avoidable risks, there will always be situations in which a degree of inherent risk is unavoidable. In these cases there is a clear need for safety controls that are not dependent on individual behaviours, such as the use of PPE.

Previous approaches to reducing vehicle collisions in heavy industry have made use of proximity sensors, including RADAR and ultrasonic based systems [4, 5]. These devices have less capability of differentiating between different types of objects, and so have been used alongside body tags, using RFID or magnetic fields [2]. Whilst these systems can work effectively to reduce the risk of collisions they again depend on individual behaviours, requiring each worker to wear the tag as additional PPE. These signals are also significantly impacted by conductive materials and can be obstructed by nearby vehicles and human bodies [6].

2.2 Computer Vision based Safety Systems

The use of computer vision object detection in safety systems is well established in areas including automotives and manufacturing, where these systems are integrated into the vehicles or fixed infrastructure [7, 8]. Similar systems have also seen recent application in mining vehicles, where they are used for both personnel and vehicle detection in less structured environments [9]. These systems have been shown to effectively detect hazards in heavy industries, but are generally used within a completely automated process, rather than forming a human in the loop system that communicates these hazards to relevant workers. Additionally, these safety systems are often built in to the hardware in which they are used, minimising their capability to be retro-fitted to existing vehicles and infrastructure or be used in a portable manner. Other applications include the use of computer vision technologies for safety management, in which the detection of workers' locations, activities and behaviours from surveillance cameras is used to inform management strategies for mitigation of future risks [10]. Whilst these approaches can help decrease incidents over a longer time period, they do not communicate immediate hazards to vehicle operators or workers.

Human in the loop safety systems require a thorough understanding of the interaction between humans and automation [11]. The system's behaviour should be intuitive to the human and not cause extra cognitive load. An example of intuitive behaviour is to only alert an operator of the presence of a distant person when the person is approaching the operator, not when the person is moving away. This example only holds for distant objects, as all close objects should result in an alert to the operator. Behaviour of a human operator will be influenced to be more positive and safe in a well-designed human in the loop safety system.

Our TBS system can communicate with human operators via haptic, visual, and audio alerts. Additionally, a halo-light can be placed on top of a vehicle to alert people approaching the vehicle to the detection of their presence. This acts to enhance 'positive communications', a procedure where a person walking behind or alongside a construction vehicle must establish that the operator is aware of their presence.

3 System Details

3.1 Overview

The TBS is composed of a network of connected devices, including a single Central Processing Node (CPN), multiple camera sensing nodes, and a Human Machine Interface (HMI) consisting of distributed AlertWear alert devices and a user interface (UI) tablet device. Each sensing node passes 2D images to the CPN where the Alert Pipeline, outlined in Figure 2, is used to determine when to send an alert to the distributed AlertWear devices. The behaviour of the Alert Pipeline is configurable by the operator using the UI device, allowing the setting of which types of hazards to be alerted to, including people, light vehicles, heavy vehicles, and demarcations such as traffic cones and bollards. Additionally, the operator is able to configure exclusion zones within each sensing node's field of view, in order to define alerts to a region of interest.

3.2 Alert Pipeline

The main components of the alert pipeline are outlined in Figure 2. Input images are first preprocessed, including

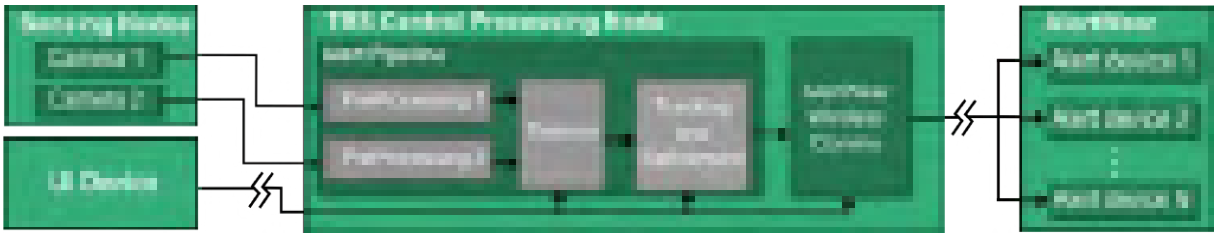

Figure 2. *Network architecture of the TBS system, illustrating communication between sensing nodes, central processing node (CPN), UI device, and distributed AlertWear devices. Alert Pipeline is detailed in Section 3.2*

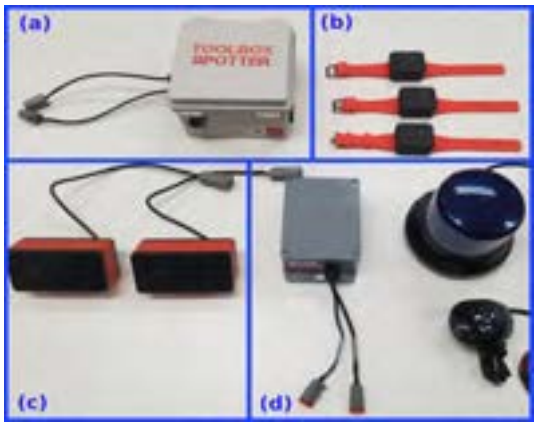

Figure 3. *The physical TBS system, showing the Central Processing Node (CPN) (a), Alertbands (b), Sensing Nodes (c) and additional AlertWear devices (d) including the Alertbeacon (top right), halo-light (bottom right) and expansion node (left) which allows connection to external devices.*

a check of image quality used to advise operators if the quality is outside operating conditions via the UI device.

Object detection in the camera frame is performed using convolutional neural networks (CNNs) [12, 13, 14], which have been pretrained as per Section 3.3. In order to minimise duplicates and false detections, improve detection localisation accuracy, smooth alerts, and to determine the final confidence of each detection, the output is further processed before alerts are communicated to the operator. Objects are tracked between frames and if an object's confidence exceeds the user defined threshold, an alert is issued to each connected AlertWear device. Tracked objects are finally filtered based on selected class types in the UI, and by region of interest, if an exclusion zone is being used (see Section 3.4).

3.3 Application Specific Training

We make use of a proprietary dataset of 15870 labelled construction specific scenes to fine-tune our models after pre-training on publicly available datasets, e.g. [15]. To evaluate detection performance, the dataset is split randomly into a train and a test set. Dataset balance and labelling quality is critical to the trained model performance. Data augmentation is performed during training, allowing the model to generalise better to new unseen data. When our system is implemented in new environments, images from the new environment are added to the train and test dataset. Semi-automatic human-in-the-loop labelling is performed using the existing model to provide labels.

3.4 HMI

AlertWear

The purpose of the AlertWear system is to communicate detected hazards and risks to all relevant workers in a clear and non-intrusive manner. This system involves a wireless mesh network (IEEE 802.15.4 std) of devices which can expand to accommodate user selected devices.

The main means of communication is an Alertband, worn by workers which vibrates to communicate various alerts. This interface was chosen based on initial pilot studies conducted of the system on a major construction company's operational sites, in which users deemed visual and audible warnings either too distracting or not noticeable enough, leading to the misuse and non-use of the system. From these studies it was found that a two second pulsed vibration was the most effective means of communicating an alert. The AlertWear system also supports visual and audible warnings through the use of the halo-light, which can be mounted on vehicle to illuminate exclusion areas, and the Alertbeacon which can provide area wide alerts, as shown in Figure 3.

Operator Interface

A UI app has been developed to allow configuration of each device, including checking sensor field of view, selection of detection classes, setting of any exclusion zone and the changing of Alert Pipeline settings. Alert Pipeline settings are input by using sliders which allow configuration of the detection and tracking thresholds. Changing these values will alter the false positive and false negative rate.

In this work we have tested three different alert modes based on different configurations of these sliders: (1) *Default*; (2) *Reactive*; and (3) *Certain*, where *Reactive* aims

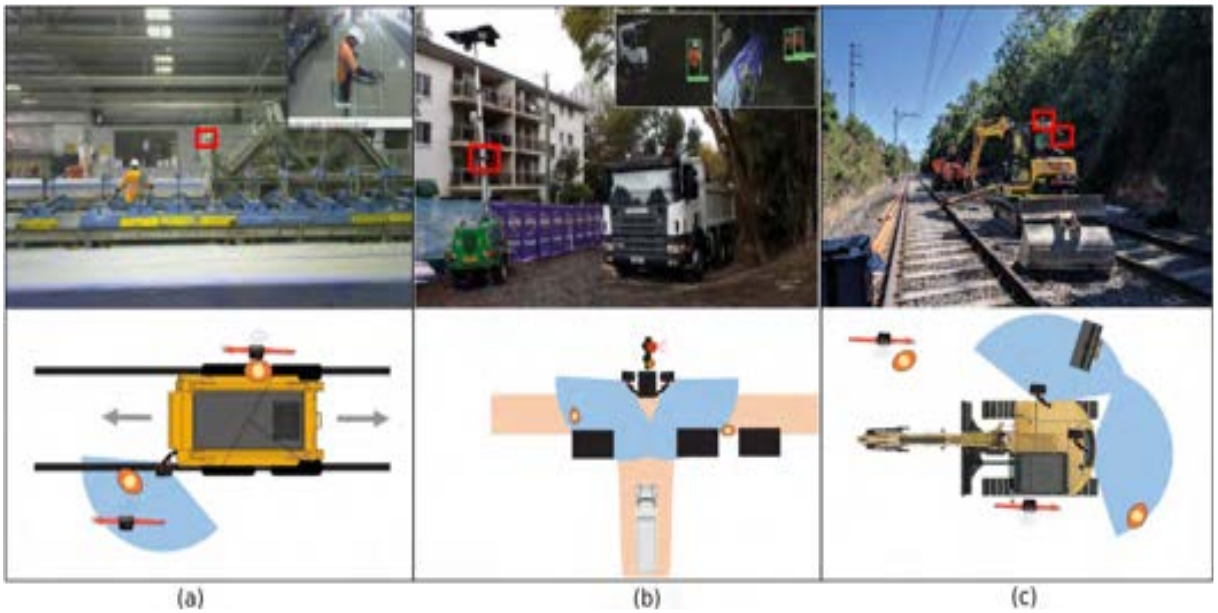

Figure 4. *Real world use cases of the TBS are shown in the top row, with the location of sensing nodes highlighted in red and camera views as inset if available. The bottom row is a top down illustration of the setup, showing the location of sensing nodes, AlertWear, and objects, as well as the field of view of each sensing node in blue, and people as orange ellipses . Example (a) demonstrates a single sensing node on a manufacturing line covering a blind spot of the mobile machinery from the operator's viewpoint. (b) shows two nodes and an Alertbeacon installed on infrastructure at intersection alerting oncoming traffic to the presence of hazards around a blind corner. (c) shows two nodes covering a rail vehicle's blind spots.*

to minimise alert delay, *Certain* minimises false positives, and *Default* aims to strike a balance between the two other modes. This UI also allows the setting of user defined exclusion zone, which can be used to limit alerts to detections that intersect with an area of interest in the camera frame. An example of an exclusion zone is shown in Figure 5 (c).

4 Empirical Evaluation

Evaluation of the overall TBS system has been conducted in order to determine performance across a variety of real world scenarios and visual variations. This evaluation has been done specifically with the class type of people, rather than other hazards and vehicles in the images for the sake of clarity and to to provide an indicative example of performance on the highest priority class.

4.1 Datasets

The TBS is currently implemented across a number of real world heavy industry sites, including construction, mining, agriculture and manufacturing. Within these implementations the TBS is being used on vehicle, on infrastructure or buildings, and within manufacturing lines.

Figure 4 provides examples from each implementation, showing both the system in use and a top down diagram of installation. The datasets used in this work have been chosen to reflect these real world use-cases, and include:

1. **Vehicle**: On vehicles in an off-road environment
2. **Indoor**: On mobile machinery for indoor use.
3. **Infra**: On infrastructure in a road environment

The Vehicle dataset contains a total of 17 clips, Indoor dataset 10 clips, and Infra dataset 7 clips. Each clip contains approximately 20 seconds of video. Example images from each dataset are shown in Figure 5. These clips cover the following range of visual variations, encountered during real world implementations of the TBS:

- Overexposure and glare
- Varying target obstruction
- Image degradation (blur and dust)
- Varying target distance
- Varying clutter in image

Additionally, a second subset of clips has been created for supplementary testing, which we refer to as 'Outlier Clips'. This subset was compiled based on a subjective measure of how difficult it was for a human labeller to initially identify the person in the clip and includes examples

Figure 5. *Example TBS viewpoint images from each of the test datasets as outlined in Section 4.1, illustrating the visual variance tested. (a) is mounted on a vehicle in an outdoor environment, (b) on moving machinery indoors, and (c) on stationary infrastructure on road. Example (c) illustrates how a user defined exclusion zone (shown in red) is displayed in the UI, as described in Section 3.4.*

that the average user would not be expected to see within a reasonable length of time.

These examples are a result of:

- The sensing node being set up without a clear view of the area of interest
- The person of interest being very heavily occluded or located very far from the sensor
- The person of interest appearing in an unexpected area of the frame
- Extreme visual aberrations including glare or usage at night

Testing on the 'Outlier Clips' subset is detailed further in Section 6. Figure 7 provides two typical examples of images from this data subset.

4.2 Metrics

Performance of the TBS system has been measured on the following metrics for all datasets:

- **Precision** - True positives over all detections
- **Recall** - True positives over ground truth occurrences
- **Alert %** - Proportion of people resulting in an alert
- **Alert Delay** - Time from first appearance to initial alert for each person

Precision and recall have both been calculated on a frame-wise basis. Alert % is calculated based on the number of completely missed alerts. For instance, a clip containing a single person walking through the scene would score 100% if an alert was sent whilst the person was in frame, or 0% otherwise. Alert Delay is calculated based on the time between a person entering the frame and the an alert being sent. Testing has been repeated for each of the three detection modes outlined in Section 3.4 determined by the system configurable parameters, including: (1) *Default*; (2) *Reactive*; and (3) *Certain*. Testing has then been repeated 5 times for each dataset.

4.3 Implementation

During testing each recorded dataset has been played by an external host computer over an ethernet network. This has been done using the ROS framework, duplicating the logged video over two separate streams to replicate usage of two sensing nodes. The output of the TBS has then been taken prior to the TBS CPN passing the alerts to the AlertWear wireless comms module. Alerts were then streamed back to the host using the same network.

Measured round trip network latency between host computer and TBS (83.0ms) has been deducted from all alert delay calculations and replaced with the measured real world sensing latency of the used cameras (67.0ms). Additionally, the time taken to send an alert over the AlertWear network has not been included in measures of alert delay. As this network uses IEEE 802.15.4 standard, we instead refer to previous testing which has shown a round-trip latency of 18ms for a 'single hop' less than 100m line of sight and 100ms for 4 hops. [16].

5 Results

Both *Default* mode and *Reactive* mode were able to correctly detect all people present in each clip, whilst *Certain* mode achieved an average accuracy of only 96.67%. The *Reactive* mode was also able to increase recall compared to *Default*, meaning that more frames containing a person were correctly identified as such. However this came at a cost to precision, meaning that false positives grew significantly. Conversely, *Certain* mode was able to increase precision at a cost to recall.

Figure 6 illustrates the distribution of delays for each tested mode across all datasets. Both *Default* and *Reactive* modes achieve significantly less delay than *Certain* mode, with peaks of 200ms compared to 1000ms. This equates to over 50% of all alerts occurring with a delay of

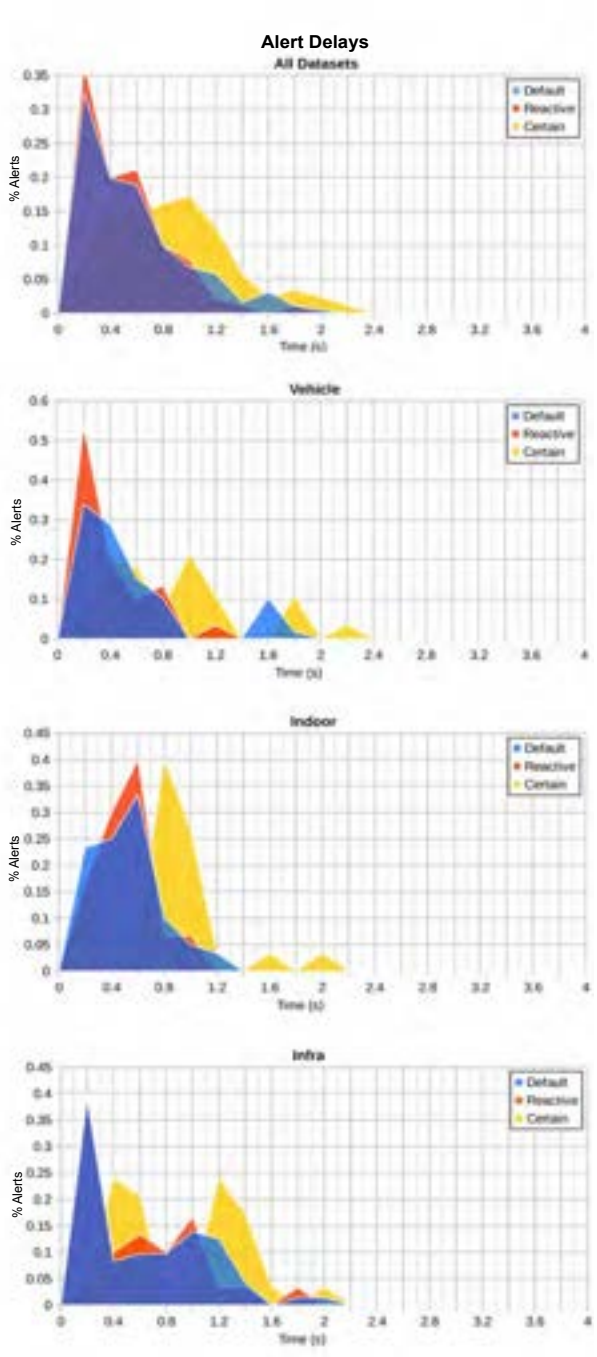

Figure 6. *Delays for each tested mode across all datasets. Delay refers to time between an object becoming present in the camera frame until the time at which an alert is passed to the TBS AlertWear. Combined result for all datasets is shown on top.*

less than 600ms for *Default* and *Reactive*, and 1000ms for *Certain*. This delayed response is due to the increased requirement that *Certain* mode has with regards to detection confidence. An alert will only be sent when the system has gained increased confidence in the likelihood that there is a person present. Whilst this does lead to slower reaction times, it also greatly reduces the number of unnecessary alerts, as reflected by the increased precision in *Certain* mode. It should be noted that the Infra dataset yielded a large number of delayed alerts for all modes. As the Infra dataset is significantly smaller than either the Vehicle or Indoor datasets (see Section 4.1), it is likely that some significantly harder clips have a greater detrimental influence on the resulting metrics. This can also be seen to a lesser extent in the Vehicle and Infra datasets in which minor second peaks occurs.

	Dataset	Mode		
		Default	*Reactive*	*Certain*
Precision	*Vehicle*	0.845	0.826	**0.891**
	Infra.	0.751	0.547	**0.863**
	Indoor	0.925	0.868	**0.955**
	AVG	0.841	0.747	**0.903**
Recall	*Vehicle*	0.771	**0.961**	0.660
	Infra.	0.829	**0.849**	0.726
	Indoor	0.872	**0.925**	0.796
	AVG	0.824	**0.912**	0.727
Alert %	*Vehicle*	**100.00%**	**100.00%**	93.33%
	Infra.	**100.00%**	**100.00%**	96.67%
	Indoor	**100.00%**	**100.00%**	**100.00%**
	AVG	**100.00%**	**100.00%**	96.67%

Table 1. *Performance of TBS on all datasets. Alert % refers to the number of correctly alerted people per clip. Both the Default and Reactive mode are able to correctly detect all occurrences. Certain mode significantly increases precision, resulting in fewer false positive alerts, at a cost of Alert %. Consideration of the cost of false alarms versus missed alerts is required in real world usage.*

5.1 Difficult Scenarios and Failure Cases

Performance on the 'Outlier Clips' set (described in Section 4.1) is shown in Table 2 and Figure 8. As expected, the performance is significantly lower than that on the three main datasets, however the system still detects the majority of occurrences in *Default* and *Reactive*, with the majority of these alerts having a delay of <1s. This performance would still be beneficial when used to augment existing safety measures, especially considering the difficulty that a human has in perceiving a detection in these examples. Additionally, these results highlight the importance of correct installation, as situations where the camera's field of view does not line up well with the actual area of interest can result in similar cases to Figure 7.

6 Discussion

The TBS was able to successfully detect and alert the user to the presence of all people in the test dataset in both *Default* and *Reactive* modes. However, there is a clear trade off between alert delay and frequency of false

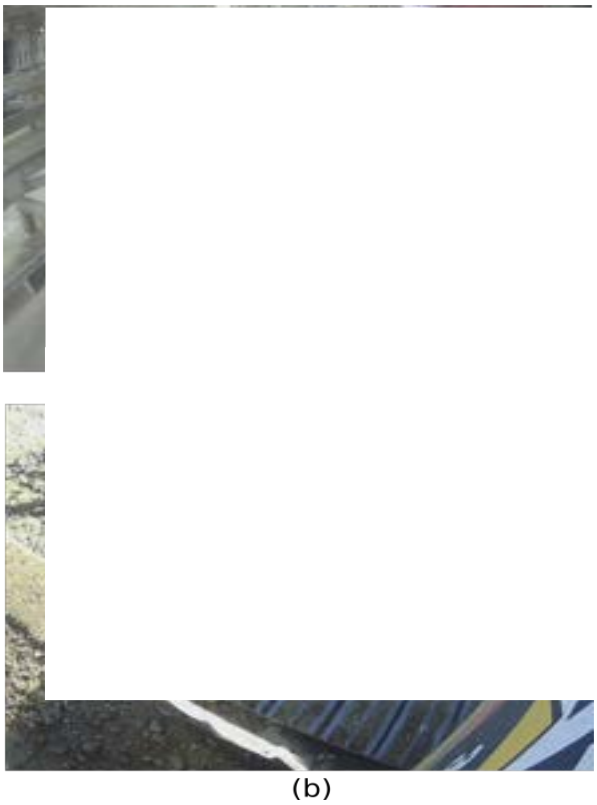

Figure 7. *Example frames from videos in 'Outlier Clips' set with the person highlighted in each frame. Both (a) and (b) are the frame selected by a human labeller as being the easiest frame in each respective clip to identify the person.*

positives that must take into account the actual usage of the system in the real world. The TBS is a human in the loop safety system that does not operate in isolation, but instead augments the existing perception of workers with regards to their ability to detect hazards in their working environment. Human reaction time to a visual stimulus in perfect conditions has been shown to be between 200-250ms [17, 18]. This time grows significantly in the presence of distractions, with the addition of just two coloured images alongside the target image of a stop sign increasing reaction time to over 550ms [19]. In the presence of tasks requiring significant mental focus, such as those carried out in all heavy industries, workers can even experience inattentional blindness, resulting in the complete missing of hazards altogether [20]. The *Alert Delays* reported in this work are comparable to those of a human applying their entire focus on the task of detecting a hazard without any distractions. The results from this work are taken from real world use cases in which the system is currently being applied, and involve cluttered and distracting environments in which human reaction time has been shown to greatly deteriorate. The TBS can achieve these results whilst not suffering from fatigue of lapses of attention.

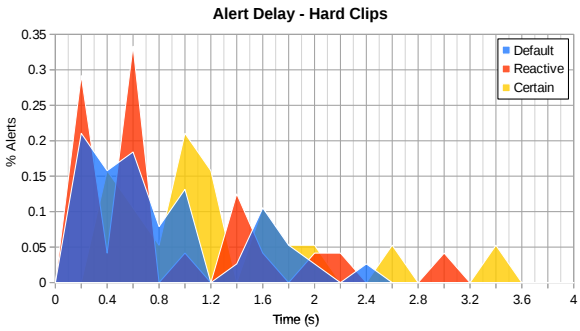

Figure 8. *Delays when testing on the 'Outlier Clips' data subset, displaying noisier alerts as expected.*

Outlier Clips	**Mode**		
	Default	*Reactive*	*Certain*
Precision	**0.915**	0.771	0.884
Recall	0.463	**0.482**	0.378
Alert %	**53.3%**	**53.3%**	46.7%

Table 2. *Performance of TBS on 'Outlier clips' (detailed in Section 4.1) which have been chosen by a human labeller as being difficult to identify any person in the video.*

An understanding of how the system is used is required when considering the importance of each metric reported in this work. Recall, a measure of how many frames were correctly classified for each person, is not as important in pratice as the metrics of alert % and delay due to how the alerts are interpreted by a human user. As each alert sent across the AlertWear network results in a two second window of notification, as described in Section 3.4, any incorrect classifications during this time are filtered out and not noticed by the user.

The results of this work additionally highlight how different modes are appropriate for different use cases. *Default* and *Reactive* both suit safety critical situations where delayed response to hazards is the crucial factor, while *Certain* would be more useful for less time pertinent uses, such as security or site access control in which false positives would want to be minimised. Whilst a number of alerts were missed in the 'Outlier Clip' set, these examples were based on videos in which a human labeller operating in perfect conditions struggled to identify the hazard, and so would likely have also been missed by a worker.

7 Conclusion

We have evaluated the performance of the TBS system for the detection of people in safety critical environments, validating its use as a tool for improving situational awareness in heavy industries. Evaluating the TBS system as

'fit for purpose' cannot be achieved by simply comparing Detection % on the test datasets to a given acceptable threshold. Instead, as the system is intended to augment a human's perception in real world use, it should be evaluated based on it's ability to improve this perception. It is clear when we compare the performance of TBS to human workers operating in similarly demanding environments, as discussed in Section 6, that the TBS provides a significant benefit with regards to the detection and communication of hazards in safety critical environments, and is able to do so without being subject to issues of fatigue and attention.

With the benchmark set in this paper, future work in testing the complete TBS will involve evaluation of additional detection classes and validation of additional sensing nodes, and will be conducted on a larger and more diverse dataset.

Abstract –

This paper introduces a navigation algorithm of mobile indoor unmanned ground vehicle (UGV). The navigation methodology with AR markers is presented and demonstrated in detail. In the navigation algorithm, the mobile indoor UGV can make 2D or 3D map inside the structure. From the driving test, it has seen that the navigation algorithm with AR marker is essential to control the attitude of the UGV and drive autonomously. The proposed navigation algorithm is very important to drive UGV autonomously inside building.

Lastly, for investigating the capability of Simultaneous Localization and Mapping (SLAM) data, the 2D and 3D maps are evaluated by comparing to traditional survey and structure from motion (SfM). In conducting the map, slowing the speed of UGV affects the 2D map negatively, while it has positive impact in 3D mapping. Using visual SLAM with LiDAR makes 3D map very easily and rapidly as compared to SfM.

From these results, the proposed navigation algorithm and manufactured prototype UGV with the mapping device for 2D and 3D are useful for studying the inside buildings even in the developing countries.

1 Introduction

Many research topical issues, about technologies in specific, which related to construction industry have only been discussed to some extent in the context of industrialized nations. Usually it is considered that these technologies do not matter the developing countries. This research paper addresses some of the issues about construction technologies from the perspective of developing countries in basic and industrialized countries as well. It starts with some construction and maintenance problems which usually seen as a concern of only developing countries, but also relevant to industrialized nations. It then proceeds to discuss the navigation of unmanned ground vehicle (UGV) and data collection for making 2D and 3D.

Construction problems can be discussed according to the existing situations. In general consideration some construction problems can be financial problems, lack of skilled man power, construction time delay, project management problems, human resource problems, technological problems etc.

The use of technologies has been limited only to the manufacturing industry. Recently the interest of using these technologies in construction industry growing. But this interest is limited to big companies which can afford these technology easily in any cost. Since construction industry is labor-intensive by nature, it is profitable to use technologies like robots [1]-[12].

Similar to the construction problems, there are also common maintenance problems of buildings. Some of these problems include: Lack of proper management, financial problems, lack of engineers or specialists, lack of human resource, lack of technologies etc. These problems can be defined in the same manner of construction problems. Many kinds of building maintenance has been discussed by researchers. This paper is more related to making 2D and 3D for maintenance which consists of elementary tasks (data collection, inspection, surveying, etc.) that needs brief training. So, these tasks can be held by ordinary people in the support of some technologies. Especially historical structures may not have proper design plan and it needs to collect data for preparing 2D or 3D plan.

In an effort to address the need for surveying and data collection, this paper introduces a navigation algorithm of mobile indoor UGV. The navigation methodology with AR markers is also presented and demonstrated. With the navigation algorithm, the mobile indoor UGV can make 2D or 3D map inside the structure. Lastly, for investigating the capability of SLAM data, the 2D and 3D maps will be evaluated by comparing to traditional survey and structure from motion (SfM).

2 Devices for 2D and 3D Mapping

In this research, two types of the mapping device sets shown in Figure 1 are used. Each mapping device set consists of three elements: light detection and ranging (LiDAR), IMU and the depth camera. LiDAR is used for measuring the scale of the structure component and making the map. The IMU device provides the 3-axis accelerations, roll, pith, yaw and 3D orientations form the 3-axis accelerometer, gyro and magnetometer. To use these information, the ROS package estimates the 3D pose of the depth camera and the LiDAR. The mapping device with Slamtec mapper shown in Figure 1(a) utilizes IMU inside Slamtec Mapper [13], [14]. Using URG-04LX shown in Figure 1(b) employs 9DOF Razor IMU. The depth camera is used to obtain 3D information, which are image, distance and point could data. Both devices employ the RealSense Depth Camera D435i. Properties of D435i is shown in Table 1. LiDARs used in this research are Hokuyo URG-04LX UG01 and Slamtec mapper. The characteristics of LiDARs are shown in Table 2.

For making 2D map, Simultaneous Localization and Mapping (SLAM) algorithm is utilized. Many kinds of SLAM algorithms are developed by many robotics researchers. Many of these SLAM algorithms need the wheel odometry information, which means the velocity of wheel, the motor speed and so on. Inside of the building, there are various friction and load conditions on the floor surface. So, it is difficult to implement the wheel odometry information to the SLAM algorithm. Based on this fact, SLAM algorithms which do not require wheel odometry information to conduct map are used in this research paper. For mapping device with Slamtec mapper shown in Figure 1 (a), the 2D SLAM algorithm produced by Slamtec is employed. SLAM algorithm of Slamtec mapper uses IMU information inside the device and not need the wheel odometry. For the other device with URG-04LX, the Hector slam [15], [16] is used with the 9DoF Razor IMU. For conducting map by using Hector slam, the Odometry information is not necessary.

To conduct 3D map of the point cloud data, Rtabmap [17]-[19], which is one of the visual SLAM, is employed for both devices. To make the point cloud data, Rtabmap uses the 3D pose information of the depth camera calculated by 2D SLAM using Slamtec mapper or URG-04LX. For estimating the accuracy and the usefulness, SfM using Agisoft Metashape is also used. For SfM, the photographs are taken with Cannon camera. Its properties are shown in Table 3.

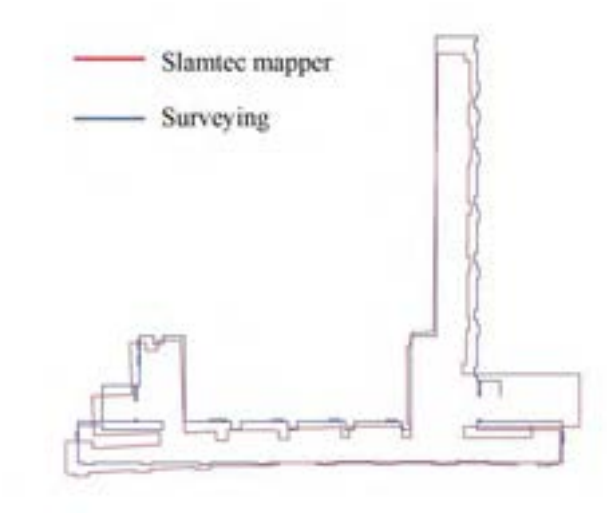
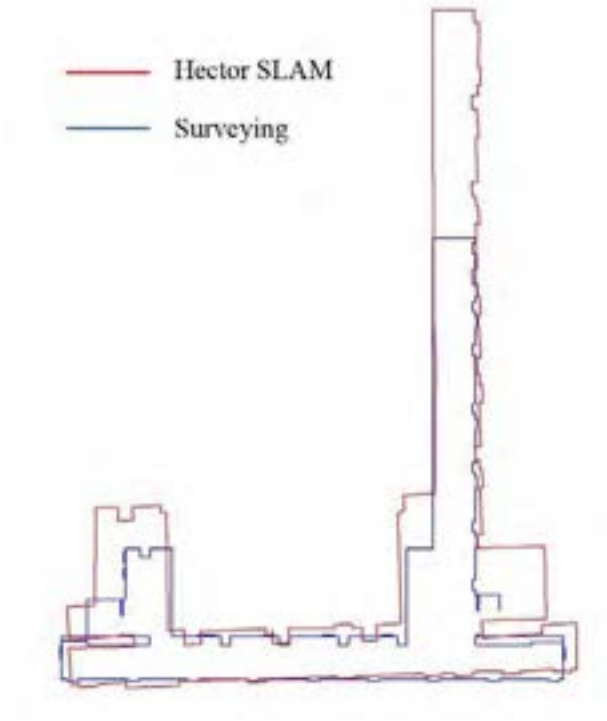
3 Results of 2D and 3D Mapping

To measure and determine the scale and layout of the structural components and openings, demonstration for



(a) Slamtec Mapper

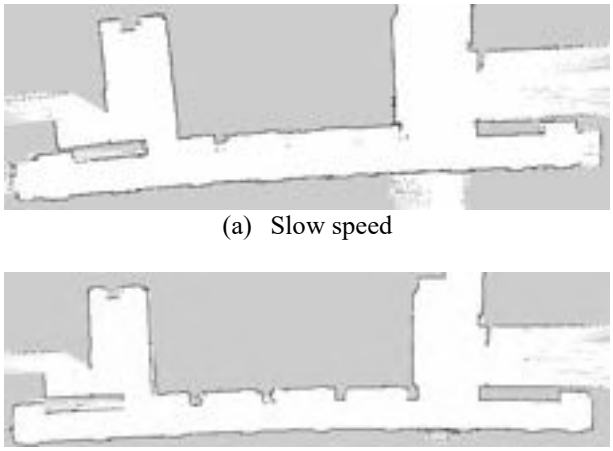


(b) Hcetor SLAM with IMU

Figure 2. 2D Mapping made by SLAM

2D and 3D mapping were carried out within the buildings of Ashikaga University. The mappings were performed in passer-free environments.

Firstly, 2D maps utilized SLAM are evaluated by comparing to traditional survey results for investigating the accuracy of the 2D mapping. The compared results for Slamtec mapper is shown in Figure 2 (a) and Hector SLAM with URG-04LX and IMU is shown Figure 2(b). Figure 3 shows the result of Slamtec mapper with different moving speeds. From Figure 3 it is clear that the



(a) Slow speed

(b) Suitable Speed

Figure 3. Slamtec Mapper with different speed

Slamtec mapper with slow speed can not specify the location and shape of columns. Throughout the experiment results, the accuracy of 2D mapping depends on moving speed of mapping device. Slow speeds are not good for creating 2D map, but 3D mapping needs slow speed. And the length of the corridor is difficult to measure, because the corridor generally has few features. From Figure 2, Slamtec mapper can estimate the length of corridor and gives more accuracy on 2D mapping compared with Hector SLAM. The length using Slamtec mapper is about 0.96 times of actual, and using Hector SLAM is about 1.51 times.

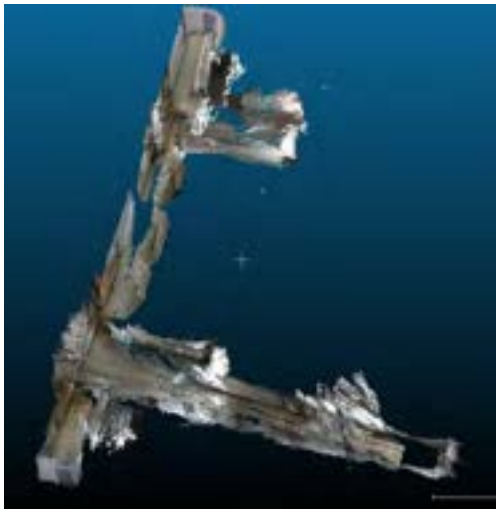
Next, 3D mappings utilized by Rtabmap, which is one of the visual SLAM, are evaluated. The 3D results of Rtabmap are shown in Figure 4. And Figure 5 shows the projection maps of Rtabmap. In Figure 5, the projection maps using Hector SLAM and using the depth camera only estimated the length of corridor in lateral direction longer than actual length. The estimated length using Slamtec mapper is almost same as actual length. From these facts, 3D mapping using SLAM data are more accurate compared with the result using the depth camera only. And scale of 3D mappings using Slamtec mapper creates more accurate than using Hector SLAM. From these results, the pose information of UGV from 2D SLAM is important in making 3D mappings. Comparing to SfM, Rtabmap makes it easy to create an entire 3D layout inside building. But, SfM can provide more detailed 3D mapping.

From these results, SLAM and visual SLAM with mapping devices easily makes 2D and 3D mapping compared with traditional methodologies.

4 Navigation Algorithm

Inside the building, the navigation algorithm can not use the GPS signal. Even it is difficult to use the navigation tool of SLAM as the layout of the building is

(a) RealSense Depth Camera D435i only



(b) D435i with Slamtec mapper

(c) D435i with Hector SLAM

Figure 4. 3D Mapping conducted by Rtabmap

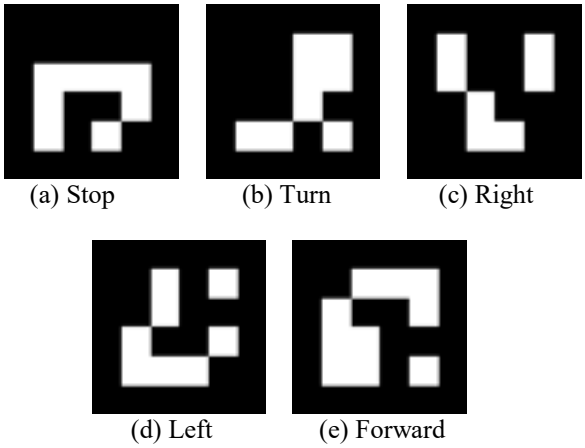
Figure 5. Projection Mapping of Rtabmap

Figure 6. Result of SfM



(a) Stop (b) Turn (c) Right

(d) Left (e) Forward

Figure 7. AR Marker

changing frequently. Hence, it can be understood that developing navigation algorithm without the use GPS and the navigation tool of the SLAM is needed [20]-[23]. This paper propose the navigation algorithm that utilizes AR markers on the floor. AR markers are used for two purposes. One is attitude control of UGV and the other is command to the robot, which are "turn" and "stop". The used AR markers are shown in Figure 7. The schematic figure of navigation algorithm with AR markers is shown in Figure 8. In this proposed navigation algorithm, the size of x axis coordinate and angle of AR marker in the image are important for attitude control and command. The size of AR marker in the image is measured by using Eq.(1).

$$L = 0.5 \times (x_2 - x_1 + x_3 - x_4) \quad (1)$$

in which (x_1, y_1) = coordinates of upper left corner; (x_2, y_2) = coordinates of upper right corner; (x_3, y_3) = coordinates of lower right corner; (x_4, y_4) = coordinates of lower left corner. And the x axis coordinate, x_M, and angle, y_{dif}, of AR maker is detected from Eq.(2).

$$x_M = 0.25 \times (x_1 + x_2 + x_3 + x_4) \quad (2)$$

$$y_{dif} = 0.5 \times (y_1 + y_4) - 0.5 \times (y_2 + y_3) \quad (3)$$

The need of controlling the attitude of the UGV is to keep AR marker at the middle of the camera view and parallel to the X-axis. The concept of the attitude control of UGV is shown schematically in Figure 9 and 10. When Eq.(4) is satisfied,UGV will firstly move in horizontal direction to satisfy Eq.(5). Eq.(4) indicates the range of the control.

$$L > \gamma \quad (4)$$

$$|x_c - x_M| \leq \alpha \quad (5)$$

in which x_c = center X-axis coordinate in the image; γ=threshold value of AR marker size; α = threshold value. If $x_c - x_M$ is the positive value, UGV moves to

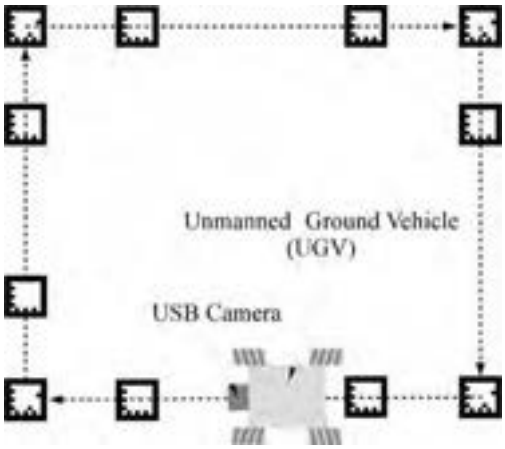


Figure 8. Navigation Algorithm using AR Marker

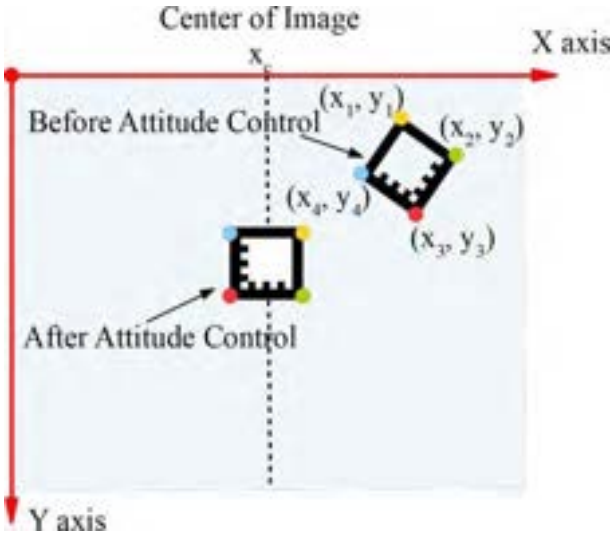

Figure 9. Schematic Figure for Attitude Control

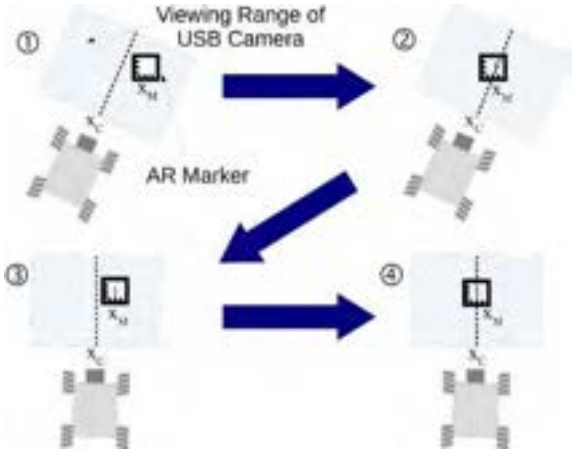

Figure 10. Attitude Control Utilizing AR Marker

the right direction. If $x_c - x_M$ is the negative value, UGV moves to the left direction. Next, when Eq.(4) is satisfied, UGV will rotates so as to satisfy Eq. (6).

$$|y_{dif}| < \beta \quad (6)$$

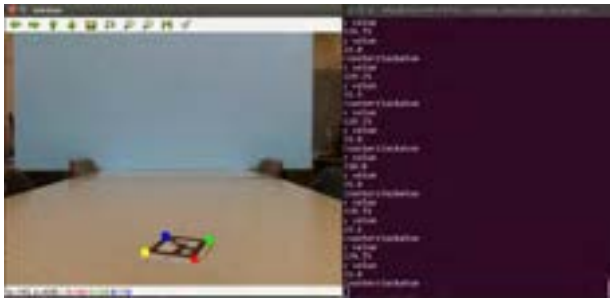
in which β = threshold value. If y_{dif} is the negative value, UGV turns to counter clockwise. If y_{dif} is the positive value, UGV turns to clockwise.

For command control, four different AR markers are used for ordering "Stop", "Right Turn", "Left Turn" and "Turning with 180 degrees". In this control, UGV is commanded when Eq.(4) is satisfied.

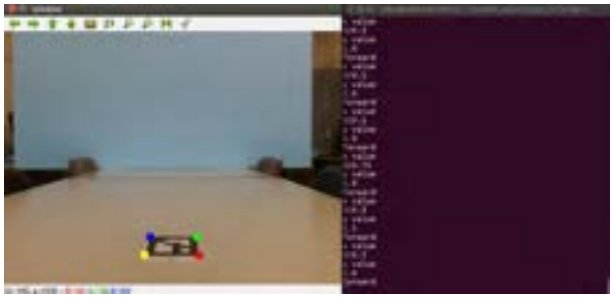
To investigate the capability of the proposed navigation algorithm, AR maker detecting tests are conducted. In Figure 11, UGV detects the AR marker and controls the attitude of UGV. After the attitude control, UGV is ordered to move "Forward". In Figure 12, AR maker commands UGV to turn the "Right".

5 Prototype of UGV for Mapping

From the results of Section 2 and 3, two prototypes of the small UGV with SLAM function is manufactured for measuring and determining the scale and layout of the inside building components. Manufactured UGVs are shown in Figure 13. The main components of the prototype UGVs are: UP board, Arduino board, the mecanum wheels, Intel Realsense camera D435i, which is depth camera and LCDpanel. UGV shown in Figure 13(a) employs the Slamtec Mapper as LiDAR and IMU device. In Figure 13(b), URG-04LX is used as LiDAR while as 9DOF Razor IMU is used for measuring the pose of the UGV. The UP board with the Intel x86 processor has the higher performance of the calculation than the Raspberry pi, which is one of the famous small Linux computers. The UP board is installed "ROS", that is useful robot OS. On the "ROS", two kinds of program

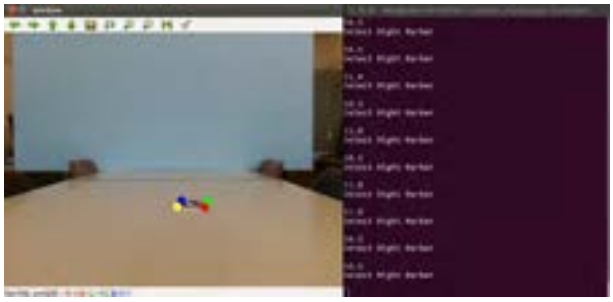


(a) Turning in attitude control



(b) Forward moving

Figure 11. Detecting AR Marker in Attitude Control



(a) Out of Range

(b) Right Turn

Figure 12. Command Control

are running. The first one is the proposed navigation algorithm to detect and follow AR markers. The second one is 2D and 3D SLAM algorithm for measuring the scale of the structure components. Arduino board controls the motors of UGV depending on the control signal from the UP board. For moving in any direction,

(a) With Slamtec Mapper (b) With URG-04LX

Figure 13. Two Prototypes of UGV for Mapping

the UGV uses the mecanum wheel. Although, mecanum wheel is better to adjust the attitude of the UGV easily for setting the measured location. The total cost of the UGV components is about $2,500, which can be reasonable for developing countries to afford.

6 Conclusion

To measure and determine the scale and layout of the inside buildings, this paper introduces a navigation algorithm of UGV and manufactures the prototypes UGV for 2D and 3D mapping.

Firstly, to evaluate the accuracy and usefulness of the 2D and 3D mapping conducted by two type of the mapping device, the 2D and 3D mapping results of the mapping devices are compared with traditional surveying and SfM. In conducting the maps, the speed of UGV has significant influence in making 2D and 3D maps. Slamtec mapper can estimate the length of corridor and create more accurate 2D and 3D maps as compared with Hector SLAM. Using Rtabmap with LiDAR is easy way to make 3D map as compared to SfM method.

Secondly, the navigation algorithm utilizing AR markers is proposed. From the demonstration tests, AR markers in the navigation algorithm are used to control the attitude of the UGV and drive autonomously. The proposed navigation algorithm is very useful to drive the UGV autonomously inside the buildings.

Finally, the prototype of UGVs with two kinds of mapping devices are manufactured for measuring and determining the scale and layout of the inside buildings. The approximate cost of the UGV components is around $2,500, which is reasonable cost for developing countries

From the discussion of the research results, it can be conclude that the proposed navigation algorithm and manufactured UGV prototype with the mapping device can be used for studying inside buildings in the developing countries as well.

Abstract –

Collisions between workers and operating vehicles are the leading source of fatal incidents in the construction industry. One of the most prevalent factors causing contact hazards is the decline in construction workers' auditory situational awareness due to the hearing loss and the complicated nature of construction noises. Thus, a computational technique that can augment the audible sense of a worker can significantly improve safety performance. Since construction machines often generate distinct sound patterns while operating at the construction sites, audio signal processing could be an innovative solution to achieve the goal. Unfortunately, the current body of knowledge regarding automated surveillance in construction still lacks such advanced methods. This paper presents a newly developed auditory surveillance framework using convolutional neural networks (CNNs) that can detect collision hazards by processing acoustic signals in construction sites. The study specifically has two primary contributions: (1) a new labeled dataset of normal and abnormal sound events relating to collision hazards in the construction site, and (2) a novel audio-based machine learning model for automated detection of collision hazards. The model was trained with different network architectures, and its performance was evaluated using various measures, including accuracy, recall, precision, and combined F-measure. The research is expected to help increase the auditory situational awareness of construction workers and consequently enhance construction safety.

Keywords –

Machine Learning; Sound Surveillance; Hazard Detection; Construction Safety

1 Introduction

According to the Occupational Safety and Health Administration (OSHA), the annual fatality rate in the construction industry in the United States is relatively high compared to that in other industrial sectors [1]. Most of these fatalities occurred when workers being struck by a construction vehicle. This is because the nature of construction sites often includes potential hazards during the situation that construction workers and heavy mobile equipment are in proximity [2]. The critical factor leading to collision hazard was reported as the decline in auditory situational awareness of construction workers due to the hearing loss [3] and the complicated nature of construction noises [4]. Therefore, a novel audio-based technique that can augment the audible sense of a worker needs to be developed to improve safety performance.

The use of advanced computational techniques in auditory signal processing for hazard detection is motivated by strong acoustic emissions coming from hazardous situations. Hence, it is possible to extract much useful information from sounds at job sites. For example, construction machines often produce unique sound patterns while performing certain activities [5], [6]. Moreover, the detection of acoustic events is further complicated by the heterogeneous sound types of construction equipment operations generated from diverse working environments [7], [8]. In this case, the detection tends to fall under the categorization of construction equipment-related activities. Therefore, abnormal acoustic events that can cause collision hazards are classified as mobile equipment, and normal acoustic events are identified as stationary equipment. This is especially the case when one of the most common causes of construction accidents was "struck by moving vehicles" [9]. Thus, such auditory

surveillance of potential accidents would significantly improve construction safety.

However, sound sensing in the construction field for safety has received little attention from the academic community in the past decade. A majority number of related studies were only focused on tracking various activities of construction equipment to reduce operating costs and the identification of working and operation activities [5], [6], [10], [11]. To address these existing issues, we propose a novel audio-based machine learning model for automated detection of collision hazards at construction sites. The study specifically has two primary contributions: (1) a new labeled dataset of normal and abnormal sound events relating to collision hazards in the construction site, and (2) a CNN model for automated detection of collision hazards.

The remainder of this paper is organized as follows: Section 2 surveys recent related work on the applications of auditor surveillance, and the use of CNN for the detection of abnormal events; Section 3 describes the novel audio-based machine learning model for automated detection of collision hazards; Section 4 describes the setup of an experiment in which we compare the performance of CNN across various datasets; Section 5 discusses the results of this experiment; and, finally, Section 6 summarizes the paper and proposes directions for future work.

2 Related Work

Auditory surveillance technologies in the construction industry help support the construction industry's safety performance since lack of excellent visibility was the principle factor leading to fatalities [1]. However, there is still a lack of such research in the field. Most of the sound-based surveillance technologies were only focused on monitoring construction work activities and equipment operations. For instance, a hybrid system for recognizing multiple construction equipment activities was proposed [11], and a supervised machine learning-based sound identification algorithm was implemented to enhance construction site activity monitoring and performance evaluation [12]. A few studies attempted to develop new approaches for conducting an audio-based event detection system for safety, but some limitations still existed. Experimental trials were designed to deploy sensing technology to provide alerts to proximity detection when heavy construction equipment and workers are in close proximity [2]. Nonetheless, the devices were installed on construction equipment only, not equipped on construction workers. Another approach using a machine learning algorithm can categorize sound events and make construction workers aware of possible safety risks and hazards [7]. Still, the sound data relating to collision hazard was only collected from a particular worksite. Such an approach is restrained because the sounds emitted by the equipment from various construction sites may differ. To address the gap, there is a need to investigate the surveillance approach to detect collision hazards from the perspective of construction workers using the sound collected from multiple construction sites.

Auditory surveillance has been extensively applied for the detection of abnormal events in various contexts and achieved promising results even in environments with complicated noises. For instance, some researchers developed a technique for detecting shouting events in a real-life railway environment [13]. Additionally, efforts have been made focusing on the detection of crimes in elevators [14], and the detection of human emotions based on verbal sounds during hazardous situations in public spaces [15], [16]. Other researchers also implemented signal processing for the surveillance of healthcare facilities, including a system for medical telesurvey [17], and a framework that detects older adults' falls [18].

Previous machine learning approaches to recognize and classify the auditory events typically used conventional machine learning models such as Gaussian Mixture Models (GMM) [19], [20], Hidden Markov Models (HMM) [12], [21], [22], and Support Vector Machine [11], [18], [23]. However, those techniques have been proved to underperform deep learning methods, such as Deep Neural Networks (DNN), in a variety of tasks for sound classification [24]-[26]. Recently, several studies have used a more complex architecture of DNN, such as Convolutional Neural Networks (CNN), for audio classification [27]–[30]. In sound processing, CNN can learn filters that are shifted in both time and frequency so that it can cover numerous input fields [29]. It was also found that the performance of CNN networks for signal classification is highly regulated by the optimum number of convolutional layers [28], [30]. CNN models can also be trained with a back-propagation mechanism that consists of two processes, including the pattern creation process and the testing process [31]. Motivated by these recent impressive performances in auditory surveillance, we applied CNN to the detection of hazard collisions in raw audio.

3 Novel Audio-Based Machine Learning Model for Automated Detection of Collision Hazards

Hereby, we present an innovative framework using supervised deep learning for sound detection associated with the recognition of mobile equipment. This framework is based on processing audio signals

generated at construction jobsites. The overall process, including three main steps, is illustrated in Figure 1. First, audio files are collected and labelled as abnormal and normal types. Then, acoustic features are extracted using the Fast Fourier Transform (FFT) function. Those features are the input of the CNN model, which is trained on the labelled data to detect acoustic events.

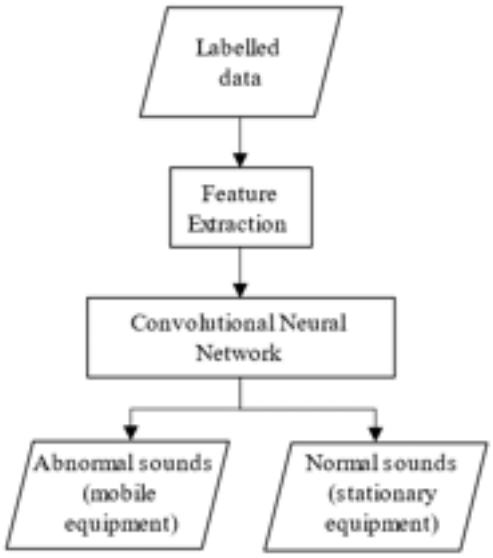

Figure 1. Overall flowchart for automated detection of collision hazards

3.1 Labelled Data

Given the goal of creating an audio event detection of collision hazards, we need to define the set of events the system should recognize. Thus, the sound sources originated from construction equipment-related activities need to be classified as a set of classes. This set of classes will allow us to collect labelled data for training and evaluation. Since the occurrence of abnormal sounds is an essential indicator of dangerous situations requiring quick safety responses, collected sound events are labelled into normal and abnormal types.

3.2 Feature Extraction

This step aims to extract the acoustic features in both time and frequency domains from audio signals by using different extraction functions. In this work, the most commonly used Mel-Frequency Cepstral Coefficients (MFCCs) are extracted by the FFT. They are mainly used to depict the spectral envelope in a significant number of audio processing applications. Through feature extraction, the components of the sound signals that are good for identifying the sound contents are recognized. In other words, the feature extraction process transforms the raw signals into feature vectors in which specific properties of audio signals are emphasized.

To obtain MFCCs from a discrete audio signal, the audio signal undergoes a pre-emphasis process, where the extraction function FFT is employed to convert the signal to the frequency domain. Then, the spectrum of the frequency domain is fed into mel-filter banks. Each filter has a center frequency called the filter bank energies. This compression operation makes the acoustic features match more closely to what humans hear. In the following step, the Discrete Cosine Transform (DCT) is applied to filter bank energies. The output coefficients of DCT are called Mel Frequency Cepstral Coefficients (MFCCs). It is worth noting that only 13 MFCC coefficients are extracted in our work, as recommended in several studies in sound classification [32]–[34]. This is because the higher MFCC coefficients represent fast changes in the filter bank energies, and it turns out that these fast changes actually degrade sound classification performance. The MFCCs extracted from the sound signal are stored as an array of values. The vertical axis represents the number of MFCCs calculated in order and the horizontal axis represents the number of frames available.

3.3 Convolutional Neural Network

After the feature extraction is completed, the CNN model is developed for sound detection with the array of the MFCC values as the input. The deep CNN architecture proposed in this study is comprised of four convolutional layers, as depicted in Figure 2, followed by a max-pooling layer, a dropout layer, a flatten layer, and two fully connected layers to get the output. The activation function used for convolutional layers and dense layers is the Rectified Linear Unit, which is most commonly used in deep learning models. The function returns zero if it receives any negative input, but for any positive value, it returns the same amount back. The Softmax activation function is applied to the output layer. The output is a prediction of which class an audio belongs to.

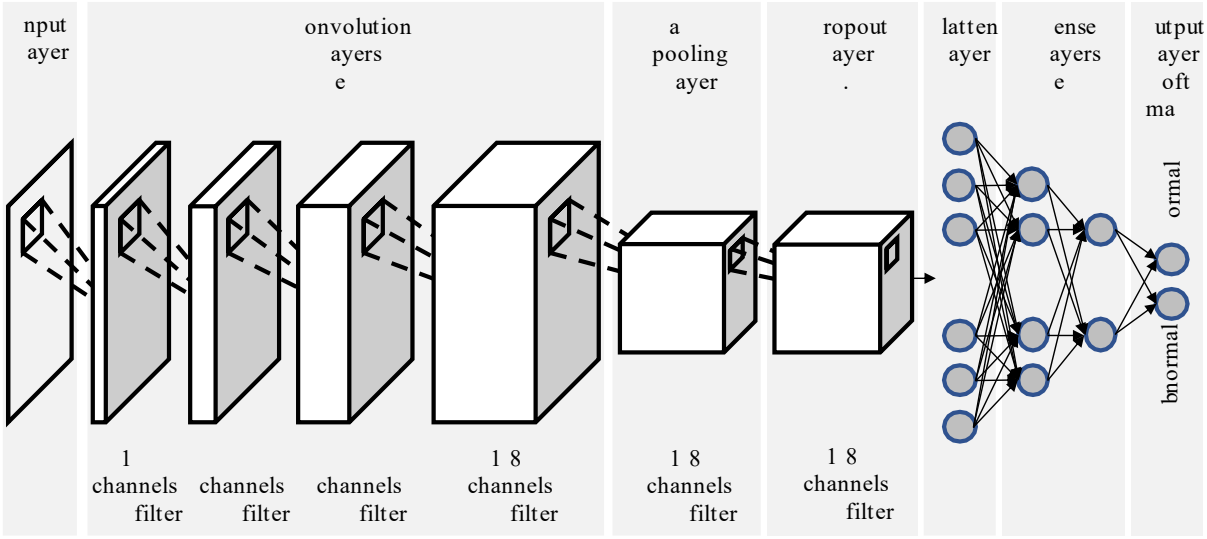

Figure 2. Detailed architecture of the convolutional neural network

The prediction is achieved through several steps in training the neural network. The first step is convolution, which is a process of taking a small matrix of numbers, called filter, then passing it over our input and transform it based on the values from the filter. Subsequent feature map values throughout convolution layers are calculated. The following steps are achieved through Max-pooling and Dropout layers. While the Max-pooling layer selects a maximum value from each region and put it in the corresponding place in the output, Dropout works by randomly setting the outgoing values to 0 at each update of the training phase to prevent overfitting. Then the shape of the data is changed from a two-dimensional matrix to a one-column vector, which is the correct format for dense layers to interpret in the last step. Each dense layer consists of neurons represented by nodes. Each node of the previous layer is connected to all nodes of the next layer. This connection is defined as a scalar value called weights. The model adjusts its weights by a training process called backpropagation. The backpropagation process can be separated into four distinct steps: the feedforward pass, the loss function, the backward pass, and the weight update. At first, the weights are randomized, and the feedforward pass is implemented. Then, the backpropagation is processed with a loss function. In this work, a loss function is represented as categorical cross-entropy, which is a great measure to distinguish two discrete probability distributions. To achieve the correct prediction, the amount of loss needs to be reduced. Therefore, the model finds out which weights most directly contributed to the network's loss and adjusts the weights so that the loss decreases. Finally, all the weights are taken and updated.

4 Experimental Setup

4.1 Datasets

Since the videos on YouTube, which is the most popular video sharing website, have become a treasure of data, the audio files of the dataset prepared for this research were extracted from this abundant source. To extract high-quality sounds from the videos, the authors avoid noisy backgrounds by using only videos that enable a broad view of recordings to ensure that no other irrelevant sound sources affect the sound quality. The audio files were then converted into wav format at 44.1 kHz sampling rate, 16-bit depth, and mono channel. An extensive set of acoustic signals in the construction site were finalized, as shown in Table 1. This dataset consists of two classes: the abnormal class includes sound excerpts from nine mobile equipment, and the normal class includes sound excerpts from seven stationary equipment. The original audio files extracted from YouTube videos were segmented into smaller frames with an equal length of 3 seconds and 2/3 overlapping. The total duration in seconds of audio files in each subset of the abnormal class, the normal class is summarized in Table 1. At this stage, the total number of the whole dataset is 3,629 audio files.

Table 1. Number of original examples in each subset of data

Abnormal class		Normal class	
Type	Total duration (s)	Type	Total duration (s)
Excavator	522	Pneumatic tamper	459

Bulldozer	387	Concrete pumper	180
Grader	1185	Pile driver	174
Front end loader	558	Pneumatic breaker	312
Forklift	123	Steel welding	1533
Compactor roller	855	Hammer	291
Scraper	2712	Saw	807
Water truck	147		
Crane	642		

The audio files were artificially mixed with background audio from two backgrounds, the wind noise, and the street noise. The mixture has the purpose of evaluating the CNN model performance to see if the model is more difficult to detect in one environment than the other. A noisy training dataset was created to enable the model the ability to detect acoustic events among noisy background. Specifically, the audio files were mi e d at different "signal-to-noise" ratios s (-15dB, -5dB, 5dB, 15dB). As a result, two different datasets with wind-noise background and street-noise background were created. Each dataset has a total number of 14,516 samples.

4.2 Model Training

The authors trained the CNN model on each dataset. 64% of the samples in each dataset were used for training, and the remaining 16% and 20% of the samples were used for validation and testing, respectively. With each dataset, the training procedure was stopped after 15 epochs when the good performance was achieved on the validation set. Various measures, specifically accuracy, recall, precision, and F1-score, are used to evaluate the sound detection performance. Accuracy is the number of correct predictions divided by the total number of predictions. While precision quantifies the number of positive class predictions that actually belong to the positive class, recall quantifies the number of positive class predictions made out of all positive examples in the dataset. F1-score is the weighted average of Precision and Recall. Therefore, this score takes both false positives and false negatives into account.

5 Results

The system correctly classified almost all audio files. The performance of the proposed CNN model on the two datasets is shown in Table 2. We found that the CNN model performed good predictions on both datasets, with "wind" and "street" backgrounds. Besides, the results show that the ability of the model to detect collision hazards is affected by different acoustic environments. As can be seen that the accuracy of the model slightly varies across the different acoustic scenarios, with 98. % and 97. 9% in the "wind" and "street" scenarios, respectively. This concludes that the model detects the abnormal sounds relating to collision hazards better in the wind-noisy background with no missed "abnormal" detection the precision of "normal" detection = 1.00).

Table 2. Measures for the performance of the proposed CNN model on each dataset

Dataset	Wind background		Street background	
Class	Ab-normal	Normal	Ab-normal	Normal
Precision	0.98	1.00	0.97	0.99
Recall	1.00	0.96	1.00	0.93
F1-score	0.99	0.98	0.98	0.96
Accuracy	98.52%		97.49%	

6 Conclusion and Future Work

In this paper, the authors applied a machine learning technique for automated detection of collision hazards. The presented framework was tested using multiple audio files collected from YouTube videos, and the results are profound. As the first stage of this research project, we found that the proposed CNN model trained on two datasets accurately recognizes sound patterns of sounds from mobile equipment.

The limitation of this research is that the model was not developed to work on more sorts of background noises provided that a construction site is considered as noisy workplace. Besides, the system could not capture the localization of mobile equipment provided that a mobile vehicle moving toward a worker is a risk and a mobile vehicle moving away the worker is considered as safety. As the plan for future research, the authors intend to develop a model that can operate across different noise backgrounds, such as rain and ocean wave sounds or the noise from people talking, and consider the factor of localizing the sound source. This work is a great start to build more realistic models that can work on detecting collision hazards under the complicated nature of construction noises.

Abstract -

Building assets surveys are cost and time demanding and the majority of current methods still rely on manual procedures. New technologies could be used to support this task. The exploitation of Artificial Intelligence (AI) for the automatic interpretation of data is spreading throughout various application fields. However, a challenge with AI is the very large number of training images required for robustly detect and classify each object class.

This paper details the procedure and parameters used for the training of a custom YOLO neural network for the recognition of fire emergency assets.

The minimum number of pictures for obtaining good recognition performances and the image augmentation process have been investigated. In the end, it was found that fire extinguishers and emergency signs are reasonably detected and their position inside the pictures accurately evaluated.

The use case proposed in this paper for the use of custom YOLO is the retrieval of as-is information for existing buildings. The trained neural networks are part of a system that makes use of Augmented Reality devices for capturing pictures and for visualizing the results directly on site.

Keywords -

YOLO; Neural Network; Asset inventory

1 Introduction

Facility Management (FM) is the most costly phase of the building lifecycle, accounting for up to 80/90% of total costs [1]. For this reason, improving efficiency of FM processes can lead to significant savings. To establish an asset management system, component inventory has first to be conducted [2][3]. But, this process still relies on manual procedures that make it time-consuming, expensive and prone to errors and omissions. Construction industry is increasingly moving through digitization, consequently is growing the awareness about the value of integration of new technologies such as AI, in process automation. Component inventory is an area that could certainly benefit from this. The automatic acquisition of geometric and semantic data of built assets has been pursued, principally through point cloud collecting technologies, photogrammetry and image processing. But computer vision, especially object detection using artificial intelligence (AI) has seen limited exploitation in that field, despite being aggressively pursued in others engineering fields: from autonomous driving to automated fruit picking. AI systems, and more specifically Deep Learning frameworks, generally require large datasets for training [4][5]. A challenge about this is that it is never obvious what the minimum number of pictures is for developing a well-performing neural network. You Only Look Once (YOLO) networks [6][7][8] are state-of-the-art real-time object detection and classification systems, demonstrating to be fast and accurate. The aim of this research is to investigate and detail the training process for customized YOLO Convolutional Neural Networks (CNNs).

This first development of a customized NN is part of an on-site application project which allows to automate surveys using mixed reality. NNs are exploited for automation of object detection while localization is performed by means of sensors and algorithms embedded in the augmented reality device. On site collected data can be immediately verified through the use MR device that shows information overlapped to real world and the possibility of adding semantic data directly on site avoiding long post processes phases.

2 Scientific Background

There is an increasing need to have structured and semantically enriched "as-is" 3D digital models of buildings in order to handle, more efficiently, maintenance, restoration, conservation or modification. Especially, as far as existing buildings are concerned, it is necessary to develop an efficient approach to generate a semantically enriched digital model. Various digital tools for building capture and auditing are available, such as 2D/3D geometrical drawings, tachometry, laser scanning or photogrammetry, but they need increased modelling and planning efforts of skilful personnel. Approaches that

process point clouds are beginning to appear for the semi-automatic identification of objects [3][9].
There are also systems like the one by [10] that exploit images rather than point clouds. However, these methods consist of complex processing operations that not only require long processing time and therefore high costs, but they are also pursued not on site with major difficulties in comparing collected data and real conditions. This leads to an error prone process and difficulties in the interpretation of gathered data.
Machine learning techniques have been widely applied in a variety of areas such as pattern recognition, natural language processing and computational learning [11]. Particularly, the field of image recognition, and object detection especially, has seen an increase in development in the recent years. In the automotive industry, for example, the use of deep learning algorithms has allowed self-driving cars to recognize lanes and obstacles without the need for more expensive and complex tools [12]. Object detection is a problem of importance in computer vision. Similarly to image classification tasks, deeper networks have shown better performance in detection. At present, the accuracy of these techniques is excellent. Hence, they are used in many, diverse applications, touching all engineering fields [13]. [14] studied an application of machine learning for the construction industry to categorize images of building designs. [15] proposed a similar approach towards the recognition of 3D BIM environments. [16] used NN for the automatic recognition of house spaces. Some interesting applications of ML regard diagnostic issues such as in [17] where semantic segmentation networks are used to recognize wall cracks on both stone and plastered walls. [18] proposed a system for the automatic detection of formworks in construction site images acquired with a Unmanned Aerial Vehicle (UAV).
Despite their huge potential NNs have not been wholly exploited in the AECO sector, partly due to the challenge of developing specific domain labelled datasets. In this paper the use of YOLO CNN for is considered along with the creation of a dataset for fire protection system components. In particular, an investigation is reported on the sufficient number of images for YOLO customization. Two objects classes have been implemented: fire extinguishers and emergency signs. This research work starts from the retrieval of specific images for the creation of multiple datasets with different number of pictures, then the setup of the whole training system has been specified. Finally, the trainings results are exposed and commented.

3 Methods

3.1 Training environment settings

In order to train the network, it is necessary to have a training environment. Since this project involves the use of YOLO neural network it has been decided to use the training platform advised by the developer of the network itself: Darknet-19 [13]. Darknet is an open source neural network framework written in C and CUDA. It supports CPU and GPU computation [8]. In order to install Darknet it is necessary to set the proper environment. The following ones are all the necessary requirements [7][19]:

- Windows or Linux;
- CMake >= 3.8 for modern CUDA support;
- CUDA;
- OpenCV >= 2.4;
- cuDNN >= 7.0;
- GPU with CC >= 3.0;
- on Linux GCC or Clang, on Windows MSVC 2015/2017/2019.

The development system is Visual Studio installed with its default options. The dependencies are CUDA, cuDNN and OpenCV. Starting from CUDA, the version installed is the 9.1. This installation requires also the installation of the NVIDIA Graphics Drivers if not yet on the pc. The second installation to be done is cuDNN version 7.0. Finally, it follows the installation of OpenCV 3.4.0. After having done all these installations, Darknet needs to be compiled with the following procedure:

1. Start Microsoft Visual Studio
2. Open the darknet.sln
3. set x64 and Release
4. Include cudnn.lib in your Visual Studio project
5. Build > Build darknet.

At this moment the darknet.exe is generated inside the folder. Finally, darknet needs to be prepared for using OpenCV, CUDA and cuDNN. The bin file has to be placed in the same folder of darknet.exe. Bin and include folders have to be inserted also in CUDA folder if they are not already there. Finally, a new Windows variable cudnn has to be created.

3.2 Dataset creation

The dataset to train the network to recognize a specific object must have specific features. Shape of the object, lighting conditions and varying viewpoints are aspects to take into consideration when gathering the images. According to the COCO dataset approach, choosing images with the object in context improves the recognition of it in real scenarios [20]. The presence of multiple objects in the same pictures is another parameter that improves the

performance of the network. For this reason, pictures with the objects in their common context have been preferred in this research.
The network capability of recognizing the object at first sight and with a high level of confidence depends, among other factors, upon the quantity of pictures in the dataset, although a minimum number is not suggested in the literature.
Collecting original images is always a time consuming task. Pictures can be gathered using various methods, including:

1. crowdsourcing;
2. web scraping.

Generally speaking, crowdsourcing regards all the possible processes to obtain information or input into a particular task or project by enlisting the services of a large number of people, either paid or unpaid, typically via the Internet. Unlike datasets shot in controlled environments crowdsourcing brings in diversity which is essential for generalization [21]. In this case, the task was not conducted using internet sources, but was spread among people in the department and acquaintances outside the university. In the case of web scraping three popular sites have been exploited: 1. Google; 2. Flickr (already used in other research like [22]); 3. Instagram. In this research, the three sources were exploited. Using keywords, images were manually searched and downloaded from Flickr and Instagram. For Google, a python script has been used for web scraping images through keywords as well [23]. To further increase the size of the dataset at low cost, a common technique consists in the usage of both original pictures, from real buildings in this case, and graphically reedited photos; a process called Data Augmentation. Data augmentation introduces additional variety during training, producing robustness in the model to various inputs. The percentage of original images and modified images has been studied in order to obtain a trained network with good performances [24]. In this work the augmentation involves the modification of pictures with the help of a custom MatLab script, to automatically modify the photos, choosing what transformations must be performed, the starting dataset and the number of images to be created. The custom script applies the following transformations: resize, shifting, additive noise, rotate, zoom, crop. The creation of the dataset involves also labelling all the images. Creating the label involves both the design of the bounding box around the object to recognize and attaching the correct label to it. This operation is performed in this thesis using VoTT, a tool that supports the manual drawing of the bounding box [25]. This tool gives the possibility to choose the right output format according to the kind of network chosen. The output for the YOLO network is a .txt file, with the coordinates of the boxes and the label attached to them. The final task to complete the dataset is the definition of the training and testing sets of images. We allocate 80% of the images to training, and 20% to testing. Anyway in this study the same testing dataset has been used so as to can better compare the data. Specifications about the testing process can be find in Section 5.

3.3 Training process settings

After having created the dataset there are some files to set before starting the training: the .cfg file of the network chosen; the .data file; the .names file; the .weights file. The parameters to customize in the cfg file are: batch = 64, this means we will be using 64 images for every training step; subdivision = 8, the batch will be divided by 8 to decrease GPU VRAM requirements. If one has a powerful GPU with loads of VRAM, this number can be decreased, or batch could be increased. The other parameters to change are classes = 1, the number of categories we want to detect; filters = (classes + 5)*5 [19][26].
The .data contains all the paths to the other necessary files for the training process. The .names file is the file that contains the name of the tag inside the images of the dataset.
The weights have to been chosen according to the network that one wants to train. Choosing the weight file means that the network used is a pre-trained network with a general dataset (CoCo, PascalVoc or others). It would be possible also not to choose any weights file and in that case the network will be trained from scratch and it will not profit from transfer learning, which is valuable particularly for low level feature learning.
The output of the training process is:

- the chart with the Mean Average Precision (mAP) progress and the Aerage loss progress;
- the log file with all the operations executed to train the network. It contains the report of all the epoch, with the avg and mAP values;
- the backup folder which contains the weights of the trained network saved at predefined stages.

The question "when the average loss is low enough?" does not find its answer in existing literature. As a rule of thumb, according to what is stated in other customizing network processes, when the first decimal digit reaches 0 it is low enough (e.g. 0.02).

3.4 Validation metrics

To compute the mAP, the Precision and Recall are required. Precision is the ratio of correctly predicted positive observations to the total predicted positive observations. Recall is the ratio of correctly predicted

positive observations to all the observations in actual class. (Equation 2) [27][28][29][30][22].

$$Precision = TP/(TP + FP) \quad (1)$$

$$Recall = TP/(TP + FN) \quad (2)$$

Figure 1. From left to right: emergency sign door, emergency sign man, emergency sign.

True Positives (TP) and False Positives (FP) are the number of objects correctly and incorrectly predicted, respectively, as the object of interest. Similarly, True Negatives (TN) and False Negatives (FN) are the number of objects correctly and incorrectly recognized as background. Because the precision and recall rates cannot be reported for scenes without any actual positives, the images taken into consideration contain at least one instance of the objects of interest [28].
For each class, a Precision/Recall curve is obtained by varying the threshold parameter from 0 to 1. The average precision is defined as the area under the curve. The mAP is computed by averaging the AP value for all classes. This process is applied to obtain the AP for each class [24]. Besides the calculation of Precision and Recall also the F1 parameter has been measured. This metrics is frequently used in pattern recognition performance assessment [30]. F1-measure is a measure that combines Precision and Recall, using a sort of weighted average (Equation 3).

$$F1 = 2 * ((Precision * Recall)/(Precision + Recall)) \quad (3)$$

4 YOLO trainings

Training a customized neural network starts from the creation of the dataset which has been achieved through the method explain in 3.2. In this research two objects have been introduced into the datasets: fire extinguisher and emergency signal. Among the pictures referring to emergency signals there was a distinction between different types 1: Emergency sign; Emergency sign door and Emergency sign man. In 1 the original pictures have been reported.

The network chosen for the training sessions has been the tiny YOLOv2. This choice depends upon the further uses of the customized network, which has to be compatible with other components. The chosen network came from a training with CoCo dataset and thus pre-trained weights have been used. In 2 all the training sessions for fire extinguisher category have been detailed. In this table, TRAINING 2 uses the same dataset as TRAINING 1 but a network that is not pre-trained. 3 reports the list of all the training session for emergency signs.
Finally, a training (TRAINING 17) with a combined dataset has been done using 500 original pictures of fire extinguishers and 581 images of emergency signs. In this case, the mAP = 71,98%.

5 Testing the networks

The testing process of all the trainings has been pursued through the calculation of the metrics exposed in 3.4. This process has been done using the same test dataset, composed by 100 original pictures, so as to make the tests comparable. 2 shows the output of the tests and the evaluation about the result for the calculation of precision and recall. The third column shows the confidence score for every single object detected marked by its bounding box. At test time YOLO defines the confidence score as P(object) * (intersection/union) between the predicted box and the ground truth which provides class-specific confidence scores for each box. These The confidence score threshold for the testing process has been set equal to 60%.
Since the trainings produced a new weights file every 1000 iterations for every test it has been selected the weights closer to the number of iteration that had obtained the higher mAP. The test has been performed for the most relevant networks as shown in 4.
On the other hand, Figure 4 displays the values of precision, recall and F1 in a graph. Following these calculations it is possible to express some observations:

- it can be seen that all the F1 values are acceptable since they are higher than 80%;
- a high percentage of image augmentation deeply worsen the performances of the network, as can be seen in TRAINING 13;
- moderate percentage of image augmentation are still acceptable as suggested by TRAINING 15.

Moreover, from these tests it is evident that the higher the number of pictures the better the performances is not true, with or without augmentation.

Table 1. Dataset composed by original images.

Object	Dataset	Number and origin of images
FIRE EXTINGUISHERS	Dataset 1	175 from Polytechnic University of Marche and Flickr
	Dataset 2	118 original images from University of Edinburgh
	Dataset 3	286 images from Google
	Dataset 4	127 images from Google
	Dataset 5	270 images from Google
	Dataset 6	24 images from Instagram
EMERGENCY SIGNS	Dataset 7	45 images from Polytechnic University of Marche
	Dataset 8	536 images from Google

Table 2. Fire extinguishers training sessions.

Training	Dataset	mAP
TRAINING 1	1000 original pictures using all fire extinguisher images	89%
TRAINING 2	1000 original picture using all fire extinguisher images	90,80%
TRAINING 3	100 original pictures taken from Dataset 1	89,11%
TRAINING 4	200 original pictures taken from Dataset 1, 6 and 2	92,86%
TRAINING 5	300 original pictures taken from Dataset 1, 6 and 2	98,91%
TRAINING 6	400 original pictures taken from Dataset 1, 6, 2 and 3	99,30%
TRAINING 7	500 original pictures taken from Dataset 1, 6, 2 and 3	73,43%
TRAINING 8	600 original pictures taken from Dataset 1, 6, 2 and 3	82,73%
TRAINING 9	700 original pictures taken from Dataset 1, 6, 2, 3 and 4	82,73%
TRAINING 10	800 original pictures taken from Dataset 1, 6, 2, 3, 4 and 5	76,68%
TRAINING 11	900 original pictures taken from Dataset 1, 6, 2, 3, 4 and 5	78,13%
TRAINING 12	175 original pictures from Dataset 1 and 175 pictures coming from augmentation	94,95%
TRAINING 13	4000 pictures, only 175 original	16,43%

Table 3. Emergency signs training sessions.

Training	Dataset	mAP
TRAINING 14	1373 pictures, 539 original and 834 from re-edited photos	86,40%
TRAINING 15	581 original photos	80,98%.
TRAINING 16	310 original photos, 155original and 155 from augmentation	84,46%.

Table 4. Training testing results.

Training	Precision	Recall	F1
TRAINING 1	97,83%	97,83%	97,83%
TRAINING 2	97,08%	96,03%	96,55%
TRAINING 3	89,51%	98,56%	93,81%
TRAINING 6	97,08%	96,03%	96,55%
TRAINING 7	97,09%	96,39%	96,74%
TRAINING 14	86,57%	93,98%	90,12%
TRAINING 15	84,80%	91,77%	88,15%
TRAINING 16	81,97%	89,29%	85,47%
TRAINING 17	83,19%	89,31%	86,14%

With the aim of testing the network in real world conditions it has been performed a test inside the Polytechnic University of Marche premises. The customized network was the one able to detect fire extinguishers only. The chosen building is a three-floor construction and the fire extinguisher were 32, 15 at the ground floor, 11 at the first floor and 6 at the basement floor. Performances with real and unfortunate light condition have been test in this case, especially using the Hololens for taking the pictures while in the aforementioned tests the pictures had been taken with phone camera. This real world test has been done with an embedded system composed by the Hololens for taking the pictures, a raspberry and a neural compute stick to run the network locally. In this case the network has been always able to recognize the object although with different level of confidence. Less than 10% of the object have obtained a value of level of confidence lower than 60%. In 9 cases the recognition did not worked at the first attempt. This was due not to light condition but to the chosen point of view. When the white label usually on top of fire extinguisher was not visible the network struggled in recognize the object at the first attempt.

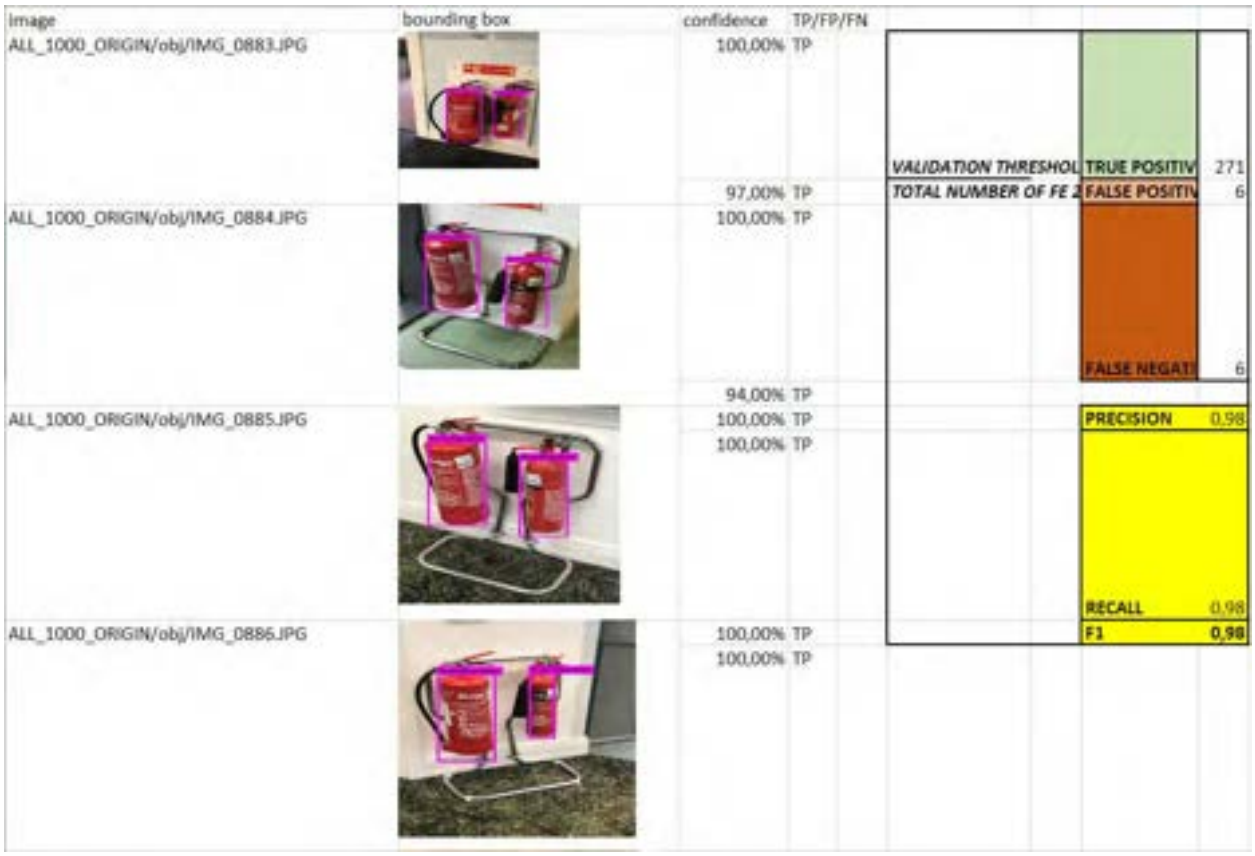

Figure 2. Testing sheet reporting the obtained bounding box, true positive, false positive, false negative and calculating performance indexes.

6 Conclusion

In this paper a study about the creation of a customized YOLO CNN for fire safety system object recognition has been proposed. Details about the training processes and indications on the right number of images for good performances have been provided. The results show that there is not a minimum number for all the purposes and categories. Furthermore, this research tried to investigate the role of augmentation for creating datasets that provide good trainings which result in good performances. A deeper analysis can be carry out exploring different proportion between original and re-edited pictures.
This application of CNN represents a part of an automated method for system components inventory exploiting AI and augmented reality so as to perform data collection and interpretation directly on site.

Improvement of 3D Modeling Efficiency and Accuracy of Earthwork Site by Noise Processing Using Deep Learning and Structure from Motion

N. Yabuki[a], Y. Sakamoto[a] and T. Fukuda[a]

[a]Division of Sustainable Energy and Environmental Engineering, Osaka University, Japan

Abstract –

Nowadays, we can relatively easily create 3D models of earthwork construction sites by taking many pictures from multiple viewpoints using Unmanned Aerial Vehicles (UAV) and by applying Structure from Motion (SfM) technique to the pictures. However, since many construction machines are moving at the construction site, they become noise or disturb the model when generating a 3D model. Thus, it is necessary to take measures such as removing the noise, i.e., construction machinery after surveying, stopping construction work during the survey, or surveying on weekends when all machines are parked at proper places, which can result in reduced efficiency and productivity. On the other hand, object detection technology using deep learning is making great progress. Therefore, this research proposes an efficient and accurate UAV photogrammetry system that generates high-precision 3D models by detecting and removing construction machinery from UAV aerial images in advance. First, the object detection method by deep learning is used to detect the construction machinery. Next, the parts of the construction machines are removed from the images, and the removed parts are completed by image interpolation or compensation. Finally, a 3D model is created using SfM. We developed a system based on the proposed methodology and applied it to an actual earthwork construction site. The result showed that accuracy and efficiency have been enhanced by using this system.

Keywords –

Photogrammetry; Unmanned Aerial Vehicle; Structure from Motion, Deep Learning, Object Detection

1 Introduction

It has become easy to take multi-viewpoint images thanks to the Unmanned Aerial Vehicle (UAV) technology. In addition, photogrammetry technology that combines aerial images taken by UAV and the Structure from Motion (SfM) that generates a 3D model from multi-viewpoint images was developed. These technologies have been used in various fields, such as forest management, situational assessment at the time of disasters and construction field. Application to progress management and soil volume management using 3D models is expected to contribute greatly to productivity improvement. However, many construction machines are working at the construction site. When photogrammetry is performed by UAV and a 3D model is generated in such a situation, the working construction machine causes errors and noise. Therefore, it is necessary to take measures such as surveying with construction work stopped, surveying during weekends, or removing noise manually after surveying, resulting in low efficiency. Also, surveying with UAV takes several hours, so it is difficult to do it frequently.

On the other hand, object detection technology using deep learning is making great progress. While various high-accuracy methods have been proposed, many studies have been conducted to apply the detection results to various systems.

In this study, the object detection method using deep learning is adapted to the construction site by fine tuning, and the construction machinery is automatically detected, removed, and complemented from UAV aerial images in advance. As a result, we propose a system that can generate 3D models with high accuracy even under construction work. Also, verify the detection accuracy of construction machinery.

2 Literature Review

2.1 Research on Utilization of 3D Modeling of Construction Sites

Many methods using 3D models for construction site

management and surveying have been proposed. In recent years, with the spread of SfM technology, it has become possible to easily generate a 3D model by taking a large number of pictures with a digital camera. The use of 3D models is expected to improve productivity at construction sites.

Omari et al. [1] proposed an efficient method to generate a 3D model of a construction site by combining a 3D laser scanning and photogrammetry. In surveying using a laser scanner, it is necessary to measure at many points. Efficient surveying was made possible by reducing the number of surveying points and making up for the lack of scanning by using photogrammetry. The proposed method succeeded in reducing 75% of the time required for surveying the construction site.

Gore et al. [2] proposed a photo-based 3D modeling method for space planning to improve construction site safety and productivity. With the conventional visual inspection and space planning method that relies on 2D drawings, the construction site is usually very complicated and difficult to capture, therefore we proposed a method for generating 3D models from multi-view photographs.

Yamaguchi et al. [3] proposed a system for efficient photogrammetry using UAV. The system automatically detects and removes construction machinery from UAV aerial images, and generates a highly accurate 3D model using SfM. An object detection method based on the features in the image was used to detect construction machinery. Detection was performed for each construction machinery using the Joint-HOG feature value generated by Real AdaBoost in two steps from the HOG feature value, which is a co-occurrence table of the feature value histograms of the gradient direction of the brightness of the local region. Construction machinery was classified into six classes: backhoe, wheel roller, heavy dump, hydraulic breaker, bulldozer, dump truck, and learning was conducted, accuracy was verified, the average detection rate by object class was 54.5%, which was low.

2.2 Object Detection Method

In recent years, various high-precision object detection methods have been proposed and are expected to be used in a wide range of fields such as application to automatic driving technology of automobiles. Many object detection methods using classifiers based on convolutional neural networks such as SSD [4] and YOLO [5] have been proposed, and each has high detection accuracy. The feature of SSD is that it is designed to be able to detect multi-scale from various output layers. However, at the stage of prediction at the low layer, there is a disadvantage that the accuracy is lowered because the feature quantity obtained in the subsequent layers cannot be captured. YOLO is a fast object detection algorithm. Since the object can be detected by looking at the entire image, the possibility of misrecognizing the background as an object has decreased, but it is difficult to detect when many small objects are included.

In the construction field, to improve productivity, attempts are being made to detect construction machinery using these evolving object detection algorithms and to develop systems that utilize the detection results.

Yabuki et al. [6] proposed a system for improving the efficiency of managing many photos taken at construction sites and disaster areas. The system detects various construction machines, workers, and signboards in photographs and automatically classifies them into folders. By using SSD for object detection and transfer learning, we obtained high accuracy from a few learning data sets.

Kim et al. [7] detected objects of construction machinery from photos to improve the accuracy of the vision-based construction site monitoring method to capture the situation at the construction site in real-time. R-FCN was used as the construction machinery detection method, and high accuracy was obtained from a few data sets by performing transfer learning.

While object detection based on deep learning from UAV aerial images has also been attempted. Matija et al. detected an airplane from UAV aerial images using the object detection method YOLO of a convolutional neural network. The detection accuracy is 97.5%, and the object detection method based on deep learning is useful for detecting objects from aerial images.

In this paper, an object detection method based on a convolutional neural network is used for construction machinery detection from UAV aerial images, aiming to enable more accurate detection and removal than when using Joint-HOG.

3 Proposed System

3.1 Overview of the Proposed System

The flow of the system proposed in this study is shown in Fig. 1. First, UAV is used to photograph the construction site under construction work. Next, construction machinery is detected from all photos. Next, the detected construction machinery part is masked and image complementation is performed. Finally, the goal is to create a highly accurate 3D model efficiently by creating a 3D model using SfM.

3.2 Detection of Construction Machinery

In this paper, You Only Look Once v3 (YOLOv3)

[8], which is an object detection method based on a convolutional neural network, is used to detect construction machinery. YOLOv3 has high precision and detecting small objects in images with high accuracy. In addition, YOLOv3 uses Feature Pyramid Network (FPN) to cope with the detection of different scales and aims to improve accuracy by capturing more features. For example, SSD does not use FPN, and the feature obtained in subsequent layers cannot be used in lower layers, but YOLOv3 overcomes this problem.

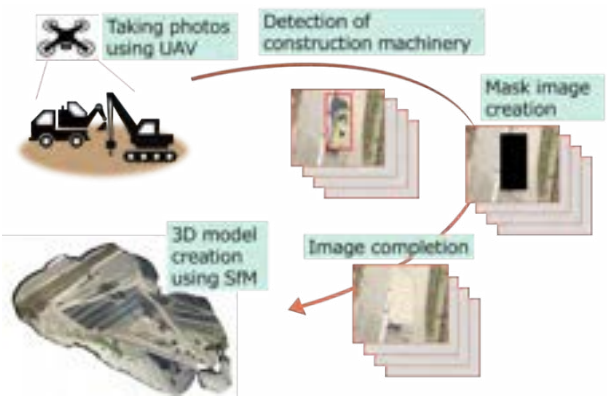

Figure 1. The Flow of the Proposed System

From the study of Matija et al. that YOLO is useful for detecting objects from UAV aerial images, it is expected that high detection accuracy can be obtained even in the detection of construction machinery by using YOLOv3, which was developed from YOLO. Also, because photogrammetry using UAV aerial photography is performed from a high altitude, the construction machinery that is the detection targets of this study often appear small. Therefore, YOLOv3, which is good at detecting small objects and has high detection accuracy, is considered an appropriate detection method.

In YOLOv3, learned models of general objects such as people and dogs are released. In this study, detection is performed by creating and fine-tuning construction machinery data set using the publicly learned model.

3.3 Detecting Object Types and Creating a Dataset

In this paper, 6 types of construction machinery are detected. We defined six classes: backhoe, bulldozer, road roller, dump truck, mixer truck, and car (Fig. 2). The class of 'car' was defined as passenger cars or light trucks moving in the construction site. By visual identification from UAV aerial images, 6 types of construction machinery were classified as shown in Table 1.

Based on the classification, a dataset was created from the UAV aerial images. There were 2,182 images included in a training dataset and 219 images included in a test dataset.

(a) backhoe (b) bulldozer (c) road roller (d) concrete mixer truck (e) dump truck (f) car

Figure 2. Examples of construction machinery to be detected (a) backhoe (b) bulldozer (c) road roller (d) concrete mixer truck (e) dump truck (f) car

Table 1. The numbers of classified objects

Object class	Number of objects
backhoe	213
bulldozer	19
road roller	24
dump truck	185
mixer truck	18
car	350

3.4 Fine Tuning of YOLOv3

YOLOv3 was fine-tuned using the data-set described in Section 3.3. By using this result, the construction machinery is detected from the aerial image from UAV.

4 Validation

4.1 Detection accuracy verification method

An index called mean Average Precision (mAP) was used for verification. The mAP is an average value for the entire class, calculated from Average Precision (AP), which calculates the precision for each defined class. When evaluating using mAP, it is necessary to obtain Intersection over Union (IoU). IoU is the index that shows how accurately an object is detected. It can be calculated that the common part of the ground truth and the prediction area divided by the area of sum (Fig. 3).

$$IoU = \frac{area(B_p \cap B_{gt})}{area(B_p \cup B_{gt})} \quad (1)$$

where

B_p: Predicted bounding box

B_{gt}: Ground truth bounding box

In order to calculate the mAP, the relationship between the ground truth area and the prediction area is important. These two relationships can be divided into four types True Positive (TP), True Negative (TN), False Positive (FP), and False Negative (FN) (Fig. 3). TP indicates a state in which an object existing in the image is correctly detected. FP indicates a state in which an object that does not exist in the image is detected (false detection). TN recognizes that the object does not exist and indicates a state in which it does not actually exist. FN indicates a state in which an object actually exists in the image but is not detected.

In this paper, when IoU $\geqq$ 0.5, it is defined as TP, and AP and mAP are calculated. First, the precision AP for each class is calculated. Then, mAP which is the average value of the whole is calculated.

$$AP = TP/(FP + TP) \quad (2)$$

$$mAP = \frac{1}{M}\sum_{i=1}^{M} AP \quad (3)$$

where

M : The number of classes

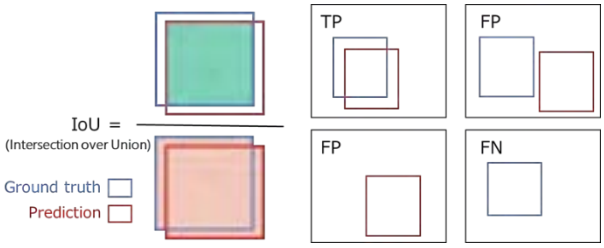

Figure 3. Image of IoU and the relationship between ground truth area and prediction area

4.2 Verification of Construction Machinery Detection Accuracy by YOLOv3

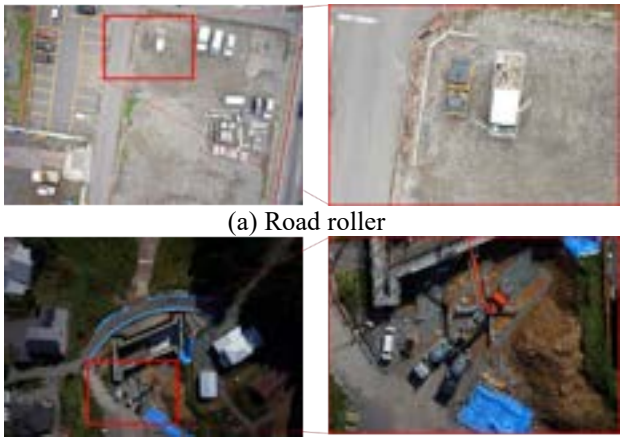
The accuracy of fine tuning was verified using mAP. The test data set created. Which is described in Section 3.3 was used for verification (Table. 2).

The mAP was 92.20%. For the five classes of the backhoe, bulldozer, road roller, dump truck, and car, high accuracy of over 90% was obtained, but for concrete mixer truck, the accuracy was relatively low at 71.43%. The road roller with the same number of objects in the data set has a detection rate of 100%. Therefore, the cause of the decrease in accuracy is considered to be due to the characteristics of the image. Many images included the road roller has a clear hue difference from the background and are considered easy to detect. On the other hand, compared to the road roller image, many of the concrete mixer trucks are not clearly different in hue from the surroundings, which may have led to a decrease in the detection rate. Fig. 4 shows examples of test data sets including concrete mixer truck and road roller. Fig. 5 shows examples of construction machinery detection based on the obtained learning results

The test data set is images that are not used for learning of YOLOv3, but it can be confirmed that construction machinery has been detected. In addition, even if the construction machinery in the image is small because of UAV aerial images, they can be detected.

Table 2. YOLOv3 construction machinery detection accuracy

Object class	Number of objects	Average Precision (%)
backhoe	187	98.40
bulldozer	16	92.73
road roller	22	100.0
dump truck	180	97.12
mixer truck	21	71.43
car	299	93.51
mAP		92.20



(a) Road roller

(b) Concrete mixer truck

Figure 4. Examples of test datasets

Figure 5. Example of construction machinery detection by YOLOv3

5 Conclusion

In order to perform photogrammetry with UAV, it is necessary to stop construction work or to remove noise manually after creating a 3D model. We proposed a system for efficient UAV photogrammetry by detecting construction machinery by deep learning method and removing them that causes noise.

For the detection of construction machinery from UAV aerial images, YOLOv3, which is an object detection method based on convolutional neural networks, is used. 2182 training data sets are created for the construction machinery to be removed and performed detection and accuracy evaluation using 219 test data sets. As a result, it was found that the detection of construction machinery with a high accuracy of 92.2% compared with previous studies. Since the construction machines shown in the UAV aerial images handled in this study are often small, the usefulness of using YOLOv3, which is good at detecting small scales, were confirmed. On the other hand, the detection rate of mixer truck was relatively low among the classes we tried to detect in this paper. This is thought to be due to the characteristics of the images used for training. Increasing the detection rate is expected by adding various mixer track images to the training data set.

As future work, the construction machinery part detected by YOLOv3 should be masked and complemented, and a 3D model should be generated by SfM, aiming at completion of a system that enables high-precision UAV photogrammetry even under construction work. We will examine an image completion method suitable for this study and verify the accuracy of noise removal after generating the 3D model. Further, the robustness of the system against environmental changes of sites should be evaluated.

Abstract –

Workers in a construction site may be exposed various hazards and risks and may work with excessive demands beyond their physical abilities. It is important for construction companies to sustain a workforce in the work environment that does not sacrifice worker safety and health and maintains the required productivity. The purpose of this study was to develop a method for real-time estimation of the workload risk of individual workers at a construction site. Based on previous studies, we developed a workload model that includes behavioral information and physical characteristics of workers in addition to heart rate reserve (%HRR). Recent wearable devices have sufficient performance for measuring biological and physical load data without interfering from their work. In this case study, heart rate and physical activity were measured using smart wear equipped with a biosensor, an acceleration sensor and IoT system developed in our research. Using a logistic regression analysis as the statistical methods and SPSS as the analysis tool, we analyzed the risk caused by the workload. As a result, it became clear that the physical activity and the heart rate will be the important parameters for estimating workload risk in construction works. However, worker age and body mass index (BMI) did not have a significant effect on estimating workload risk. In the construction site, types of works and skills of workers will change according to the progress of the project. In order to ensure a stable workforce and productivity, it is necessary for construction industry to manage workers' health and safety. In conclusion of this paper, we propose that the real-time monitoring of heart rate and physical activity during construction work can be used for human resource management (HRM). With the development of this study, it will be possible to determine how the workers' workload affects productivity. It is believed that this research will be useful as an element of the integrated management technology of the entire construction site using ICT tools.

Workload estimation; Heart rate reserve; Wet bulb globe temperature; Construction hazards; Worker safety

1 Introduction

The construction industry serves as the base for several other industries in every country and contributes significantly to the national economy. In order to maintain the industry's productivity, it is essential to ensure the safety and health of its workers [1,2]. Characterized by poor working environments, such as poor scaffolding, aerial work platforms, high humidity at high temperatures, and a worksite adjacent to heavy construction equipment, construction sites often contribute toward increasing the physical workload of construction workers [3,4]. A high-temperature or highly humid work environment and long-term physical workload expose workers to chronic fatigue, injury, illness, and health risk, and thereby reduce a site's productivity [5].

This study uses heart rate to understand the impact of the physical load of a job as well as that of the personal and environmental factors [6,7]. Since it is difficult to identify the important factors affecting workers' health in every situation, an analysis based on workers' heart rate can be useful for understanding their work capacity. As an indicator, the heart rate reserve (%HRR) has been reported to be a major predictor for estimating an individual's workload capacity [8,9]. This method assumes resting HR resting (i.e., minimum HR

during resting) as a level with no physical load, and calculates a percentage of the difference between working and resting HRs among HR reserve (i.e., HR reserve indicates the difference between HR max and HR resting) [8-10]. Considering the health risks of workers, workers with more than 40% HRR should not undertake any heavy workload exceeding 30 minutes [9,10]. In this study, workers with more than 40% HRR were considered to be at health risk. Although %HRR is a useful determination method, most studies often identify HRR based on certain activities such as walking, jogging, or treadmill. Given the frequent inflow and outflow of workers at construction sites, it often becomes difficult to use specific activities to measure the HR max and HR resting for each worker precisely. Hence, it is difficult to use %HRR as an indicator of workload at construction sites.

It uses a model composed of workers' movement acceleration, age, body mass index, and the wet bulb globe temperature (WBGT), which take into account temperature, humidity, and radiant heat. By using the model, the impact of workload risk is estimated through the worker's %HRR. In order to formulate strategies to manage workers and improve their productivity, it is important to determine the impact of workload on their health using simple and accurate methods.

2 Materials and Methods

2.1. Measurement system

In order to evaluate the type of work environment, the study measured the air temperature, relative humidity, and WBGT; HRR and acceleration (ACC) detected from the respiratory rate (R-R) interval in ECG were measured in order to determine the workload.

We measured the heart rate and the physical activity of workers on the basis of the ECG signals captured using the smart clothing worn by construction workers, as shown in Figure 1., a is heart rate and acceleration sampling sensor (WHS-2), b is smart clothing (COCOMI) and c is Data acquisition device (CC2650).

The smart clothing is an underwear-type shirt integrated with biometric information sensor (detection of heart rate) [11-13] and a 3-axis acceleration sensor. Since the smart clothing is made of stretchable fabric, stretchable ECG electrodes were integrated with the hardware for measuring the heart rate [14]. The heart rate was detected by detecting the R-R intervals in the ECG signals. HRRs during load and rest were obtained by converting the detected R-R intervals. We attached a small heartbeat sensor device (WHS-2) to the smart clothing; we monitored the heart rate and the amount of physical activity by taking the 3-axis acceleration showing the spacing between the R-R waves of and the physical activity the subjects [15]. Using a Bluetooth low energy device, the heart rate and 3-axis acceleration data were sent to the data acquisition device used by the workers (Texas Instruments, Inc. CS2650). Subsequently, data from the data acquisition device were transmitted to and stored on the server installed on network using the established wireless access point (data transfer device) in the work area.

Based on the data provided by workers on their height, weight, and age, we calculated their BMI; the WBGT was calculated based on their labor time. In order to grasp the temperature and the relative humidity of the work environment, the WBGT was measured at 5-minute intervals.

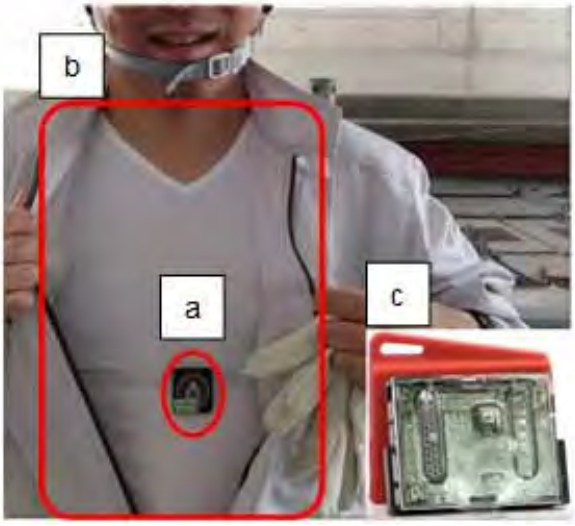

Figure 1. Picture of measurement equipment.

2.2. Measurement method

Table 1 shows the measurement parameters and techniques used in this study. The participants were expected to be aware of their body measurements as they worked in construction companies that conducted these measurements on a regular basis. We asked questions related to age, height, and body weight of the subject and, subsequently, used the responses to determine the BMI. As per a study [16] on an East Asian cohort, people with a BMI between 22.6 and 27.5 had the lowest death risk, whereas people in a higher BMI range were at a higher risk of deaths from cancer, cardiovascular diseases, and other causes. The BMI was added to this study's explanatory variables to examine worker health risk.

Heart rate during work ($HR_{working}$) was determined by the average value of the heart rate measured every 5 minutes for each worker. Thus, the heart rate during work denotes the average of the data collected every 5

minutes; this data has been corrected by deleting null data or outliers [17,18]. An accurate measurement of the HR_{max} is not suitable for construction workers who are often in flux. Therefore, the HR_{max} was predicted using the equation of Tanaka [19]. In order to confirm the stability of the heart rate at rest time, the subject's heart rate at rest time was measured more than thrice at 5-minute intervals; the lowest average heart rate was used to determine the $HR_{resting}$.

Table 1. Measurement parameters.

Measurement parameters [unit]
$BMI = weight / (height)^2$ $[kg/m^2]$
$HR_{working}$ = average heart rate in 5 minutes during working hours [bpm]
$HR_{resting}$ = average heart rate in 5 minutes during the rest hours [bpm]
$HR_{max} = 208 - 0.7 \times age$ [bpm]
$\%HRR = \frac{HR\ working - HR\ resting}{HR\ max. - HR\ resting} \times 100$ [%]
$ACC\ [mG] = \sqrt{(A_{X_n} - A_{X_{n-1}})^2 + (A_{Y_n} - A_{Y_{n-1}})^2 + (A_{Z_n} - A_{Z_{n-1}})^2}$

By using the 3-axis acceleration sensor for continuous monitoring, the physical activity level of the subject was evaluated to get ACC [20] of the three axes (the longitudinal axis: X, the lateral axis: Y, and the vertical axis: Z); the resulting ACC, which is physical activity, was calculated by an average value generated during the 5-minute intervals. The intensity level of the physical activity is shown to be a predictor of good health [21]. The 3-axis acceleration method observed the strength of each worker's overall movement during the working hours. Unlike office workers, construction workers can provide a more detailed operating data than those derived from the measured parameters; this data may include data on their capacity to lift load up the stairs. In other words, the method captures the intensity of the workers' movement between the work activities (for example, walking, standing, and crouching) performed during the working hours.

2.3. Participants

The data were collected at the water injection pump construction sites of a construction company in the following dates of the year 2018: May 25th, June 29th, and November 16th (Kumagai Gumi Co., Ltd.). The participants were tasked with the dismantling of the steel scaffolding. Specifically, eight steeplejack workers performed repetitive tasks (of those involved in the demolition) and four assistant workers carried out indirect work such as equipment installation. These 12 participants were notified of their selection as subjects in the experiment.

2.5. Data collection

Table 2 shows the dates of data collection, ages of the subjects, work tasks, and body measurements each subject. The data were measured from 8:30 am to 5:00 pm, and the data were collected during the entire period or at any of the 5-minute interval in the time zone of half of the period of the working day. All the subjects were men; they were asked about their age, job title, and the provision of information about their body and weight. Since the cardiopulmonary function aims to eliminate the unhealthy subjects from the measurement, the subjects were also asked about the presence or absence of the history of cardiovascular disease and their current health condition (for example, whether they suffer from chronic cardiovascular disease). Among the 13 workers who expressed a desire to participate, 1 subject with arrhythmia did not participate in the experiment. Except for the preparation time for data collection, 5 minutes were given to each of the 882 datasets collected from 12 subjects.

When measuring the subject, we checked for the Hawthorne effect [22]. In this experiment, we did not monitor the activity of the subject; we waited a little farther from the work area and recorded and photographed the work with the help of two cameras installed in the work area. In general, manual laborers performing high-load work have their own health concerns; they also focus on the physical workload resulting from their daily operations. Hence, before starting the measurements, we instructed the subjects not to depart from the usual work patterns; they were also informed that the study did not intend to measure their productivity but their physical workload.

Table 2. The Collected Data on the Subjects.

ID#	Age (years)	Main job task	Height (cm)	Weight (kg)
S1	20	Scaffolder	159.0	57.0
S2	39	Scaffolder	179.0	74.0
S3	32	Scaffolder	177.0	93.0
S4	25	Scaffolder	182.0	82.0
S5	41	Scaffolder	176.0	70.0
S6	40	Scaffolder	176.0	75.0
S7	36	Scaffolder	170.0	68.0
S8	22	Scaffolder	165.0	55.0
L1	43	Worker	168.0	70.0
L2	50	Worker	174.5	87.5
L3	27	Worker	170.5	62.5
L4	59	Worker	169.0	76.0

2.6. Model development and statistical analysis

The independent variables comprised subjects' ages, BMI, the amount of physical activity during labor, and the WBGT in the field environment. The binomial logistic regression was used to analyze the health risks determined by the level of %HRR. Logistic regression assessed the value of new medical treatments. It is one of the regression analysis methods evaluating the factors affecting a problem surrounded by controversies [23]. Logistic regression modeling is not limited to the study of physiological medicine, but it is also used in biology, engineering, ecology, health policy, linguistics, and business and finance [24]. Regression analysis has become an integral element of data analysis for describing the relationship between the independent variables and one or more of the explanatory variables.

A prediction model considering the parameters of these independent variables improves the accuracy of risk detection; in this study, we observe a strong correlation between risk factors. Therefore, it is necessary to consider the possibility of multicollinearity while conducting the statistical analysis. When developing the statistical model, the Pearson's correlation coefficient and variance inflation factors (VIF) were calculated for determining the physical activity ACC, AGE, and BMI of the subjects and WBGT in the work environment.

Table 3. Correlation matrix for workers' risk.

	ACC	BMI	AGE	WBGT	VIF
ACC	1.00				1.17
BMI	0.02	1.00			1.48
AGE	0.33^{***}	0.42^{***}	1.00		1.43
WBGT	-0.07^{*}	0.39^{***}	0.05^{*}	1.00	1.20

Table 3 shows the results obtained with respect to the correlation coefficient and the VIF between independent variables. A p-value less than 0.05 (typically $\leq$ 0.05) is statistically significant, *** indicates $p \leq 0.001$ and * indicates $p \leq 0.05$. A weak negative correlation coefficient (-0.33) was observed between physical activity ACC and the AGE of the subjects, while there was no correlation against the BMI and WBGT. The BMI of the subjects was slightly positively correlated (0.42) with the AGE and weakly correlated with the WBGT (-0.39). Furthermore, it was observed that the AGE of subjects was hardly correlated with the WBGT. The VIF serves as a reference for checking multicollinearity; the values of all the independent variables were the extent of the value 1-2, indicating a low likelihood of multicollinearity [25].

3. Results

3.1 The relationship between ACC and %HRR

Figure 2 shows the results of the %HRR for the ACC measured in each subject. The relationship between the ACC and the %HRR is shown in linear approximation; Table 5 describes the correlation coefficient $r_{L1\text{-}L4}$ of L1-L4 and the correlation coefficient $r_{S1\text{-}S8}$ of S1-S8. In all the subjects, the %HRR increased according to the increase in the ACC, and the correlation coefficient r of the ACC and the %HRR was at about 0.7–0.9. When compared to assistant workers, the higher heart trend of the scaffold workers shows their exposure to a high physical workload. During the break time, the workers' ACC and %HRR were relatively low and their physical activity and heart rate at rest time were stable.

Figure 2 also shows that, despite an increase in ACC from S5 to S8, the %HRR tends to be relatively large. S1 recorded the highest ACC among all subjects because S1 not only placed the dismantled steel materials under the scaffold stairs but also carried them to the collection location. It is presumed that there was an increase in the transportation task between the unloading location of the scaffold stairs and the collection location, which led to an increase in both %HRR and ACC. S1 is the youngest among the subjects; as HR_{max} increased by the calculation based on age, there is a possibility that even same $HR_{working}$ is no longer conspicuous when compared to the other subjects. Conversely, although relatively high-age assistant members, such as L3, had a relatively low ACC without a big movement behavior, S1's %HRR was seen to be higher than the other assistant workers. This can be attributed to the fact that HR_{max} obtained for L1's age is lower than that for the other subjects.

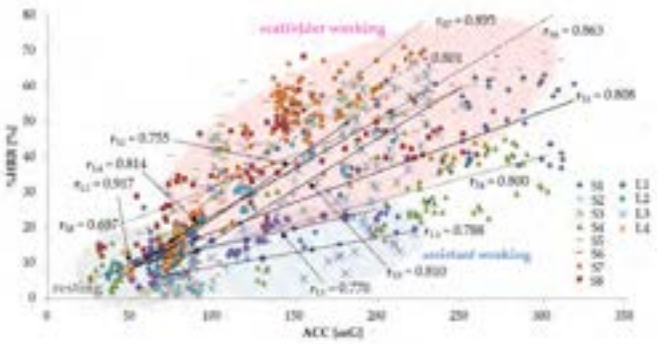

Figure 2. Relationship between ACC and %HRR (Scaffolder $_{S1\text{-}S8}$, Assistant worker $_{L1\text{-}L4}$). $\mathbf{r}_{S1\text{-}S8}$ denotes the correlation coefficient of the relationship between ACC and %HRR for S1-S8, and $\mathbf{r}_{L1\text{-}L4}$ is the correlation coefficient of the relationship between ACC and %HRR for L1-L4.

3.2. Logistic regression model

Logistic regression analysis was performed using the statistically significant ($p < 0.05$) independent variables in Table 4. The logistic model formula used in this study is shown below.

Workers' health risk (≥%40 HRR: 1, <%40 HRR: 0)
= f（ACC、AGE、BMI、WBGT）

where the objective variable is 1 for the worker's health risk (≥40% HRR), and it is 0 for no health risk (<40%HRR).

The independent variables are physical activity ACC, AGE of subjects, BMI calculated from height and weight, and WBGT in the work environment. Using the HR max and HR resting of each subject and calculating their %HRR, the independent variable was estimated by whether HRR ≥40%.

Table 4 shows the estimation results of the model on the health risks of workers examined in this study. In the Model 1, ACC, AGE, BMI, and WBGT were independent variables. By p-value, the ACC, AGE, and WBGT of the subjects of the work environment were statistically significant, but the BMI of workers was not significant. Wald χ^2 shows the contribution of each variable to the model, and it indicates that the larger the value, the higher is its importance [26]. In the Model 1, compared to AGE and WBGT, the contribution of the ACC was relatively high. To determine the influence of the dependent variable, we use the odds ratio in the logistic regression. It is indicated that independent variable increases due to an increase in the odds when OR>1; hence, the odds ratio can be a measure of a likelihood of a decline in independent variable with an increase in the odds when OR <1 [23,24,27].

Table 4. Estimation by logistic regression model.

Model	Variables	Coeff.	*p*-value	95% CI for Odds
Model 1	Constant	-25.6	< 0.001	–
	ACC	0.041	< 0.001	1.04 – 1.05
	AGE	0.074	< 0.001	1.04 – 1.12
	BMI	-0.035	0.548	0.86 – 1.08
	WBGT	0.705	< 0.001	1.67 – 2.44
Model 2	Constant	-28.1	< 0.001	–
	ACC	0.041	< 0.001	1.04 – 1.05
	AGE	0.066	< 0.001	1.04 – 1.10
	WBGT	0.742	< 0.001	1.82 – 2.43

When the odds ratio is larger than 1, while the lower limit of the confidence interval (CI) is not less than 1, the ACC, AGE of workers, and WBGT in the work environment are independent variables. However, the BMI of workers is the independent variable whose odds ratio is less than 1—the lower limit does not exceed 1. By the results, without BMI, the Model 2 examined a model based on independent variables ACC, AGE, and WBGT. It is indicated the statistical significance of the three independent variables; AGE, ACC, and WBGT may be high to show the health risks of workers, which is important for the Model. Furthermore, according to the odds ratio, the influence of the WBGT on the health of workers was the largest.

Concerning the estimation results of the model, Table 5-1 shows predicted results by model and Table 5-2 show the suitability index of the model due to its goodness of fit (GoF). The positive discrimination rate by the estimation of Model 1 was 88.9%; the positive discrimination rate by the estimation of Model 2, except the BMI that did not have statistically significant results, increased to 89.2%. Three indicators were determined to test the significance of the model by GoF. Akaike's information criteria (AIC) = -2logL + 2k were defined, and AIC were considered as indicative of the model fit [28,29]. Here, k denotes the number of parameters in the model; the first term model represents the true goodness of AIC, and the second term represents the penalty due to an increase in the variable. The values of the AIC are small. According to the obtained AIC, the adaptation of Model 2 was slightly better than the Model 1. The Cox-Snell R2 corresponds to determining coefficients of a linear regression analysis R2, referred to as pseudo-R2. The fit of the model becomes better as the Cox-Snell R2 becomes larger; the Cox-Snell R2s of Model 1 and Model 2 are 0.4-0.5, while the fit of the independent variable for the dependent variable was not very high [30,31]. However, when Nagelkerke R2 approaches from 0.5 to 1, the fit becomes higher [32-34]. The fit of the independent variable for the dependent variable of Model 1 is 0.590 and the one of Model 2 is 0.589. Both of them were high. Both the fit of Model 1 and Model 2 were good by these results.

Table 5-1. Estimation of subjects' physical load.

Model (independent variables)	Observed		Predicted Risk 0	Predicted Risk 1	Percentage (%)
Model 1 (ACC, AGE, BMI, WBGT)	Risk	0	487	53	90.2
		1	45	297	86.8
	Overall				88.9
Model 2 (ACC, AGE, WBGT)	Risk	0	486	54	90.0
		1	41	301	88.0
	Overall				89.2

Table 5-2. GoF of Estimation.

Model (independent variables)	GoF		
	AIC	Cox-Snell R^2	Nagelkerke R^2
Model 1 (ACC, AGE, BMI, WBGT)	57.5	0.435	0.590
Model 2 (ACC, AGE, WBGT)	59.5	0.434	0.589

4. Discussion

This study shows that a continuous measurement of the physical load of construction workers can change work conditions and increase an understanding of their health conditions. It measures the load fluctuation of the workers by using data collected from the smart clothing; this fluctuation corresponds to workers' age, the temperature of the working environment, and working conditions (e.g. foreman and the real workers and the difference between the assistants and the scaffold workers). In line with the results of previous studies, this study shows that the physical demands differs in case of each worker; hence, results seen in previous studies on wearable devices (wristband-type devices) correspond [4,34] to this study.

Based on the work patterns (dismantling, transportation task, and the percentage of work activities, including preparation work), the physical demands of the workers vary even in the same construction site. In order to understand the health risks of workers, there is a need for continuously measuring a work in progress.

When measuring the subjects, we observed that the physical demands should not be sustained for a longtime. Concerning the workplace and physical demands, specific guidelines were created. (i.e., the work activities that increase the %HRR beyond 40% should be limited to 30-60 minutes [10].) Based on these guidelines, as shown in the subjects S5 and S7 (Table 5 and Figure 2), there were several workers with more than 40%HRR who continued to work throughout the day. Therefore, in order to reduce the high physical demands of these workers, some intervention must be implemented. This study provides insights on the appropriate interventions required for managing excessive physical requirements.

Most studies determine %HRR based on typical activity patterns and experimental environments, and there are very few cases that consider an actual construction site. Concerning the application of methods for determining %HRR of construction workers, it is difficult to measure HR max and HR resting [35] in advance for workers, and it is likely that %HRR will interfere with actual use as the indicators.

The important finding of this study is that it proved its hypothesis on the impact of physical workload on the %HRR of workers, by using the covariates in logistic regression. The relationship among these covariates influence the heart rate of workers [36]. WBGT has the largest odds ratio among all the covariates and the impact on workers' %HRR was significant [16]. To the best of our knowledge, this is the first study to report how the physical activity, workers' age, and WBGT could be used to determine workers'physical workload without calculating their %HRR. Concerning ≥40%HRR, the accuracy rate is about 89.2%, based on the estimation of the judgement model of the health risks of workers. Thus, in an environment where HR max and HR resting cannot be measured, it was indicated that the health risk could be judged by %HRR.

We have several limitations in our study. First, the sampled Japanese construction company had only 12 workers in total. Due to this limited number of subjects, the dataset used the average of the physical activity and heart rate collected at 5-minute intervals. We recognized that the observation period is sufficient for analyzing workers because previous studies have used data on heart rate and physical activity collected at about 30-minute and 5-minute intervals, respectively [8-10,18,37]. However, since the measured values are averaged, rapid changes in the worker's condition could not be observed. Second, some physical activity and heart rate data were missing, which might have led to measurement errors. However, almost the same results were obtained even when these outliers were included in the analyses (data not shown in table). These outliers may slightly affect the heart rate mean or standard variance. To avoid these technical errors, there is a need to monitor more accurately the heart rate and physical activity. Third, the study used a self-reporting method that could result in differences between workers' information on their height and weight. Future research should seek to include observable data to better understand the potential impacts of the physical workload on workers. Finally, this study provides an insight into the degree of contribution of the physical activity and other variables for estimating workload. Workers' health is very fragile, and it is affected by their physical workload, mental state, and lifestyle. Hence, it is necessary to carry out further study in this regard. Further studies in other working conditions are required to accumulate more evidence and assure the accuracy of the models.

5. Conclusions

In this study, the heart rate and physical activity, the age, BMI, and WBGT of the working environment were measured for workers of a Japanese construction company. Given the high workforce mobility in the construction industry, this study developed a new judgement model of workers' health risks as an alternative to %HRR. By using workers' physical activity, age, BMI, and WBGT of the work environment as independent variables, it can be easily observed the physical load of worker without preparation such as HR max and HR resting. It measured the heart rate and physical activity of construction workers by using a smart clothing equipped with biological and acceleration sensors. By logistic regression analysis, the risk to health by physical workload was analyzed. The results showed that physical activity, age and WBGT are important parameters of workload estimation. However, BMI of workers was not statistically significant, and hence it did not have a significant impact on the estimation of the health risks posed by the workload.

This study aimed to develop a method to facilitate a practical estimation of the workload risk of individual workers at a construction site in real-time. The use of a lightweight wearable device in this study has important theoretical implications in that it presents a real-time monitoring mechanism for examining workers' health condition. This monitoring mechanism is very easy, without special preparation. It can also be adopted by firms to minimize the workers' health damage.

In managing the health and safety of workers, it is useful to assess workers' workload and health state quantitatively. Although there are several studies on workforce management [38-40], few studies focus on using workers' individual heart rate, physical activity, and body measurements. Further research on the use of these attributes can improve the identification of the health risks of workers quantitatively and promote the productivity of workers at construction sites.

Acknowledgments

This study was conducted with financial support from the Ministry of Land, Infrastructure, Transport and Tourism of Japan. The authors would like to thank all the construction workers who completed the questionnaires.

Abstract –

With the development of the construction industry, many problems such as human safety are remaining unsolved. The construction holds the worst safety record compared to other industrial sectors, approximately 88% of accidents are related to workers' safety. The high complexity of the construction site compare to the ordinary living environment is also a major factor that cannot effectively protect the safety of workers. In this paper, an integrated sensor network method is proposed for the safety management of construction workers. The main signals collected in this paper are visual signals and electronic signals. The compatibility issues caused by cooperation between different types of signals will also be discussed in this paper. At the same time, a multi-signal automatic correction method is used to improve the accuracy and efficiency of our proposed method.

1 Introduction

"Smart City" concept is widely known by people around the world for many years, the main purpose of it is using information technology to help to improve city service. Currently, Smart City is applied in transportation, citizen management, urban resource allocation and so on, they all perform well compare to traditional methods. Along with the rising of Smart City, the concept of "Smart Construction" is also proposed recently, many well applied methods from other fields are poured into construction area. But due to the differences in management mode and implementation, those methods perform not so well. There is a lot of room for development of Smart Construction.

Speaking of which, construction industry field still holds a worst record in safety compare to others. In Japan, death number in construction accidents is twice that of Germany and 3 times that of UK from data since 2003 to 2005 [1], and haven't improve well during the last 20 years [2]. Comparing to other developed countries, accident monitoring efficiency is the main reason that workers cannot be found and rescue in time.

The main causes of workers' injuries and deaths are heat stroke, hitting by heavy objects, felling from a height and so on. Some of the injuries are caused by accident, some of them happened because of the unsupervised unsafe acts of workers' own due to cost, time pressure and other reasons. Normal monitoring system such as web camera requires manual operation, it is inefficient because of human neglect, obstacle and other factors. A more efficient and accurate safety management and monitoring method is needed.

Camera-based monitoring method is widely used and researched around the world, it has a lot of benefits, such as low cost, easy to be assembled, and so on. Yet more disadvantages are unavoidable, such as unable to solve occlusion problem, low accuracy in weak light or dark environment. Other methods concentrate on changing RGB frame to RGB-D frame by adding depth into the picture, such as Kinect and Realsense. RGB-D is more accurate to detect human and object comparing to RGB's pixel crop, it also works well even in weak light environment. However, due to the limit of working distance, reflective surfaces and relative surface angles, depth maps in RGB-D frame always contain significant holes and serve noise, as shown in Figure 1, these errors limit the practical usage of RGB-D frame in real applications, thus depth maps restoration in hole filling and noise removing becomes a necessary step in depth-camera-based monitoring system.

Monitoring method based on Inertial Measurement Unit (IMU) sensors is also a hot topic in recent years, because of its undoubtable benefits compare to other methods such as visual camera. IMU sensors are nonintrusive, lightweight and portable measuring devices, they can overcome the sensor viewpoint and occlusion issues, once they were attached on subject, the activities can be detected in a non-hindering manner [4], [5], [6]. After pre-processing of the motion for activity

Figure 1. Depth map (top) and infrared frame

recognition, discriminative features are then derived from time and/or frequency domain representation of the motion signals [7] and used for activity classification [8]. Although there are a lot of benefits of IMU sensors, there are also some disadvantages, first, it is not intuitive, not easy for manual recheck, second, model complexity is hard to control especially when precise motion capture is needed.

In order to fix injuries problems in construction field, we propose a safety management method based on multiple sensor network. This method aims at using data of workers from different kinds of sensors to detect human motion and movement more accurately, sensors such as depth camera and IMU sensor will be used, and by cooperating them to decrease the error rate and improve efficiency in accident alert and injury rescue.

The main contributions of this paper are as below:

1. Improve the accuracy of multi-type sensor fusion based motion recognition in specific motions in construction site environment;
2. Multi-type sensor fusion based motion recognition correction method.

The remaining sections are organized as follows. Related works are reviewed in Section 2, including camera-based, depth camera-based and IMUs-based methods. The proposed methodology is introduced in Section 3, visual sensor-based human recognition, IMU s-based human recognition and sensor fusion method will be introduced. The simulation and experiment details and hardware parameters will be introduced in Section 4. The conclusion is drawn in Section 5.

2 Related works

2.1 Camera-based human modeling

Commercial camera-based human detection method requires subjects wear markers and depend on multiple calibrated cameras mounted in the environment. [9], it is inconvenient, to overcome these constraints, other researchers focus on developing marker-less approaches from multiple cameras, yet some of these methods require offline processing to achieve high quality results [10], [11]. But some other real-time approaches have been proposed [12], these approaches typically fit a skeletal model to image data. Other approaches to real-time performance include combining discriminative and generative approaches [13]. However, multi-view approaches assume stationary and well calibrated cameras, therefore they are not suitable in mobile scenarios.

2.2 Depth camera-based depth map restoration and human modeling

As for regular camera, RGB-based depth prediction normally uses large body of literature, training exclusively using ground truth metric depth, [14,15,16,17,18]. As for depth camera, many methods have been proposed for restoring depth maps by Kinect, these methods can be classified into two types: filtering-based and reconstruction-based. Filtering-based methods use different filters to restore captured depth maps. Lai et al. [19] applied a median filter in RGB space to fill holes in depth map recursively, however this method will blur sharp edges obviously. To preserve sharp edges, Camprani et al. [20] applied a joint bilateral filter in depth map iteratively. Matyunin et al. [21] considered using temporal information to restore depth map, but this method occurs delay because it uses multiple consecutive frames to restore target depth map. Reconstruction-based methods use image inpainting techniques to fix missing values in depth maps. Telea [22] proposed FMM (Fast Marching Method) for image inpainting. Miao et al. [23] proposed a texture-assisted method in which the texture edge information is extracted for assisting depth restoration. These methods can remove noise and fill small holes in depth maps, however when it comes to large holes exist in depth map, such as holes in Figure 1, the results are unsatisfactory.

About human modeling, Anguelov et al. [24] introduced SCAPE, a data-driven method for building a human 3D model than spans variation in both shape and pose. It shows that given a high-resolution range image from a single view, the SCAPE model can be used to observe data. Based on SCAPE parameterized model, Weiss et al. [25] combined multiple views of person and several low-resolution scans to obtain an accurate human 3D model. Liao et al. [26] introduced prior of human body pose and shape, then proposed a human 3D modeling method based on a monocular depth camera.

2.3 IMUs-based human modeling

Roetenberg et al. [27] used 17 IMUs equipped with 3D accelerometers, gyroscopes and magnetometers, fused together using a Kalman Filter. Assuming the measurement are noise-free and contain no drift, the 17 IMU orientations completely define the full pose of the subject (using standard skeletal models). However, 17 IMUs are very intrusive for the subject, long setup times are required, errors such as placing a sensor on the wrong limb are common, which makes it difficult to reproduce. Marcard et al. [28] compute accurate 3D poses using only 6 IMUs. They take a generative approach and place synthetic IMUs on Skinned Multi-Person Linear Model (SMPL) body model [29]. They solve for the sequence of SMPL poses that match the observed sequence of real measurements by optimizing over the entire sequence. But this method relies on computationally expensive offline optimization, which is also hard to reproduce. Therefore, a smaller number of IMU sensors and less computation complexity is the key of future IMUs-based human modeling and motion detection.

3 Methodology

In this paper, we propose an integrated sensor network method for safety management of construction workers. This method mainly uses depth camera, IMU sensor, and environment sensor to collect data from workers and construct human model to analyze human motion, gesture and some physical index such as temperature and air pressure. This method concentrates on multiple sensor cooperation, by using different kinds of sensor to decrease the errors caused by sensor defects, to increase the accuracy of detecting and improve efficiency.

3.1 Depth camera-based human recognition

Yin et al. [3] proposed a two-stage stacked hourglass network based on Varol et al. [30] to get high-quality result of human depth prediction. Instead of using RGB image directly, this method uses RGB image and human part-segmentation together to predict human depth. It consists of convolution layer, part-segmentation module, and depth prediction module. First, RGB image input goes through the convolution layer and turns into heat maps, then enter the part-segmentation module, after then, heat maps turn into human part-segmentation results, these heat maps are summed as the input of the following depth prediction module with previous layers features, finally human depth prediction results are outputted.

Algorithm 1 GradientFMM

1. **Procedure** GradientFMM (*depthmap*)
2. *Known* ← all pixels with known values in *depthmap*
3. *Unknown* ← all unknown pixels adjacent to *Known* in *depthmap*
4. insert all pixels in *Unknown* into min-heap
5. **while** *Unknown* not empty **do**
6. p ← root of min-heap
7. calculate p's value using *depth value equation*
8. add p to *Known*
9. remove p from *Unknown*
10. perform down heap
11. **for** each neighbor q of A **do**
12. **if** q not in *Known* and *Unknown* **then**
13. add q to *Unknown*
14. perform up heap
15. **end if**
16. **end for**
17. **end while**
18. return *Known*
19. **end procedure**

The algorithm above is called GradientFMM [3], it propagates depth from known pixels to unknown pixels. After the process, every pixel in depth map in the unknown region has a depth value. In order to mark useful pixels in depth maps to predict possible human skeleton, we use GradientFMM as our pre-treatment method in human depth prediction.

The resolution of collected image from depth camera is 848x480 and 30 frames per second. In our method, firstly we apply GradientFMM algorithm to analyze each frame and get data of human depth maps, next, we consider frame platform and depth direction as a 3D coordinate, and collect all coordinate data of each pixel inside depth map. At the same time, well-trained image processing algorithm will be used to identify skeleton based on depth map, in this research, we use OpenPose or Intel skeleton tracking SDK. After human skeleton is detected, the 3D coordinate changes of specific parts of human (head, hand, foot) and required parts (arm, waist) will be recorded, and compare with collected database, to find out the best match and output. Frames with skeleton will be used as input for further image processing to improve accuracy of skeleton mapping.

3.2 IMUs-based human recognition

This part introduces IMUs-based human motion detection, IMUs can measure triaxial (3D) accelerations and triaxial angular velocities. It is also easy to obtain information directly without numerous restrictions.

In our proposal, we mainly consider the motion capture while workers are working, so the upper body will be observation focus. 3 IMU sensors will be used to detect movement changes, two will be attached on outer arms, another one will be attached on front waist.

Not only can IMU sensors collect movement data, but also, they are able to collect workers' surrounding environmental factors such as temperature, height, air pressure and so on, by doing data exchange with environment sensors, to ensure that workers are in proper working environment.

IMU motion recognition is based on Dehzangi et al. [31], this paper introduced a human activity recognition method in normal environment, the activities they considered are walking, walking upstairs, walking downstairs, sitting, standing and sleeping. In our proposal, due to the difference of subjects, new motions are added: uplift (one or two arms up), pick up heavy object (the swing amplitude of both arms is reduced and stiff), hold up heavy object (the arms are partially angled and stiff), arms raised (arms at right angles to body), regular cyclical movement (arms turn the roulette), bend over (lean forward or backward).

The framework of IMU-based human activity recognition system is: first, collecting relevant data through users; then, in the learning phase, relevant features are extracted from the time-series raw data. Model complexity is reduced by applying Feature selection/ Dimension reduction technique. Recognition model is created from the dataset of selected features. Then, in the testing phase, this model is used to evaluate raw signal and create an activity label. Finally, raw data will be outputted as labeled motion.

IMU sensors attached in 3 parts will continuously record data, and using motion recognition method to analyze amplitude changes. At the same time, when there is a dramatic change during the process, the differences between triaxial accelerations and angular velocities before and after the change will be counted and recorded as change graphs. Finally, the differences will be compared with motion database and find out the best match.

3.3 Multi-type sensor fusion and analysis

Normally, visual signal and IMU electronic signal are quite different, it is hard to make a comparison between them. In our proposal, both visual camera-based method and IMU sensor-based method can perform results individually, but when it comes to some special occasion such as partly occlusion, using only one kind of signal will cause high error and effect the whole system.

In this research, we try to cooperate two kinds of signal, by educe the advantages and disadvantages of them to further improve accuracy of this method. We consider the whole area as a huge 3D coordinate system, as shown in Figure 3, depth camera is placed on one side of the system, IMU sensors are also calibrated before loading to make sure they are consistent at time 0.

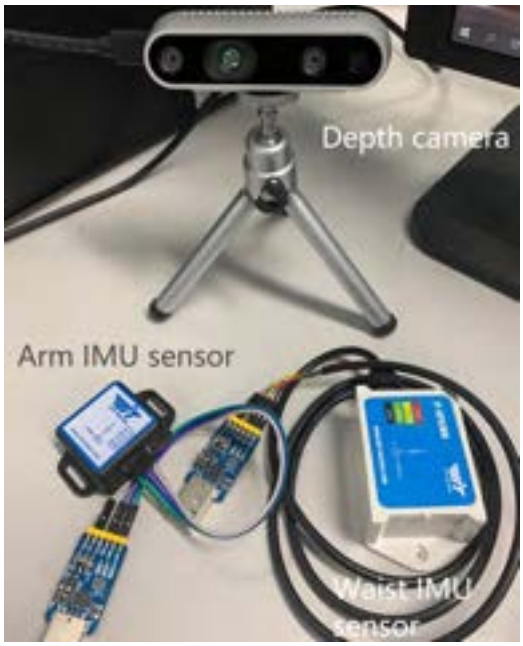

Figure 2. Depth camera and IMU sensors

As introduced in previous sections, when record starts, both camera and IMU sides will generate constant 3D coordinate changes. As for depth camera side, the variation and value of specific point can get from the coordinate made by depth map and frame platform. As for IMU sensor side, during the movement, three axes will change in different accelerations, based on the origin set at time 0, the path changes and distance can be calculated by double integral:

$$\vec{S} = \int(\int(\vec{a})\mathrm{dt})\mathrm{dt} \quad (1)$$

where $\vec{S}$ represent directional distance, $\vec{a}$ represent average acceleration during time period t.

Although the unit, distance and size are quite different between depth map coordinate and IMU sensor coordinate, we can describe the change amplitude curve between specified coordinate points (in this case, points of two arms and waist), by considering the weight of each kind of sensor, we can get a more accurate result to make comparison with database, and gaining a higher reliability on human motion recognition.

The equation of final degree of change is:

$$\Delta P = (\Delta P_v / P_v^0 \cdot \alpha + \Delta P_I / P_I^0 \cdot \beta)/2 \quad (2)$$

where ΔP_v is the change of motion from visual side, ΔP_I is the change of motion from IMU sensor side, P_v^0 and P_I^0 are the initial states of the current time segment, α and β are weight coefficients for visual and IMU sides.

The directional distance of each axes in each sensor can be calculated by Equation (1), and the degree of change in each sensor can be evaluated by Equation (2).

4 Experiment

This section makes experiment to validate the feasibility of our proposal. It includes the following aspects:

(1) Using depth camera to detect human skeleton and motion based on our visual recognition method, and record the 3D coordinates of depth maps;
(2) Using attached IMU sensors to detect human upper body skeleton and motion based on our applied motion recognition method, and record the coordinate differences of each sensor;
(3) Using our multi-type signal fusion correction method based on weight to generate coordinate differences from each frame and frequency. And output final accuracy.

In order to get the depth maps of subjects, an Intel Realsense D435i camera is settled, and shooting from one side of our experiment area. The picture of camera is shown in Figure 2, it can achieve a smooth video streaming with 848x480 resolution and 30 frames per second. Possible detecting range is from 0.3 m to 16 m.

In order to get the 3D motion data of subjects, 3 Witmotion IMU sensors are attached on subjects' two outer arms, and front waist. The arm sensor model is BWT901CL, the detectable parameters are acceleration, angle, velocity, magnitude, temperature. The waist sensor model is WTAHRS2, the detectable parameters include above and air pressure, height, which can make sure the surrounding environment of workers is stable and comfortable.

The experiment area is settled as Figure 3, depth camera is placed in front of the whole area, IMU sensors are attached on worker's outer arms and front waist, the worker will continue making different gestures in front of the depth camera.

Before the beginning of experiment, the database of actions to be tested which also is the control group will be prepared. In this experiment, several motions will be considered, including normal motions such as stand, sit, and sleep (lie down), other specific motions in construction site such as uplift, pick up heavy object, hold up heavy object, arms raised, regular cyclical movement and bend over will also be included.

The experiment process will be introduced as follows:

First, experiment subject (worker) will be attached with sensors, and stand in the proper position inside experiment area;

Next, experiment subject will make corresponding actions in order, there will be a break between each two motions;

Then, depth camera-based method will generate depth map, all pixels' coordinate information will be recorded, human skeleton will be generated based on image processing, human parts will be labeled and

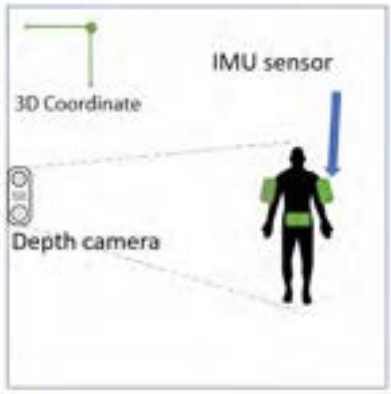

Figure 3. experiment area layout

corresponding to pixels, the coordinate amplitude of these parts will be recorded as well;

Next, IMUs-based method will collect data changes from 3 sensors, during the process, a low pass filter will be settled to eliminate redundant noise;

Then, the acceleration changes of each sensors will be used to calculate path changes by double integral;

Next, the changes of points of three human parts from visual side and IMUs side will be calculated separately to obtain degree of change within a certain period of time;

Then, degree of change from visual and IMUs side will be used to calculate the weight average, the result will be compared with database to find the best match;

Meanwhile, origin degree of change from visual and IMUs side will be compared with database separately;

Finally, the similarity from visual side, IMUs side and sensor fusion side will be compared, to prove if the sensor fusion method shows the best result.

As for the degree of change for IMUs, we set experimental steps as follows:

1. Calibration procedure: remove the output offset component of the acceleration sensor because of the presence of static acceleration (gravity). The method is to average the acceleration when there is no motion in accelerometer. (the more samples we collect, the more accurate the calibration result will be)
2. Low pass filtering: eliminate signal noise in accelerometers (both mechanical and electronic), to decrease the error while integrating the signal.
3. Mechanical filtering: when in a stationary state, small errors in acceleration will be treated as constant speeds, it indicates a continuous movement and unstable position, which will affect the actual motion detection. A mechanical filtering window will help to distinguish the small errors.
4. Positioning: the acceleration of each time period is known, we use double integral to obtain distance

information. The first integral gains speed and the second gains position.

In our simulation, we suppose 9 motions have their own perfect degree of change, includes vector changes from left arm, right arm and front waist:

$$M_n = \begin{bmatrix} \overrightarrow{L_n} \\ \overrightarrow{R_n} \\ \overrightarrow{W_n} \end{bmatrix}, n \in [1,9] \quad (3)$$

$$\overrightarrow{L_n} = \left(\Delta x_n^L, \Delta y_n^L, \Delta z_n^L\right) \quad (4)$$

$$\overrightarrow{R_n} = \left(\Delta x_n^R, \Delta y_n^R, \Delta z_n^R\right) \quad (5)$$

$$\overrightarrow{W_n} = \left(\Delta x_n^W, \Delta y_n^W, \Delta z_n^W\right) \quad (6)$$

where $\vec{L}, \vec{R}, \vec{W}$ represent the change of motion from left arm, right arm and front waist.

Generated data are divided into 2 groups, on visual side, the vector changes will be found by pixels and depth, on IMUs side, through the acceleration of three axes and time, Equation (1) will be used to obtain the distance in all directions, thereby obtaining the vector change. Then, assign a weighting coefficient to vision and IMU part through standard normal distribution, next, we will use Equation (2) to calculate the integrated vector change:

$$F = \begin{bmatrix} (L_v/L_v^0 \cdot \alpha + L_I/L_I^0 \cdot \beta)/2 \\ (R_v/R_v^0 \cdot \alpha + R_I/R_I^0 \cdot \beta)/2 \\ (W_v/W_v^0 \cdot \alpha + W_I/W_I^0 \cdot \beta)/2 \end{bmatrix} \quad (7)$$

where L_v is the left arm vector change on visual side, L_I is the left arm vector change on IMU side. F will be compared with M_1 to M_9 in Equation (3) to find out the best match.

100 pairs of sample data for each motion are generated based on our database by adding random interferences and white noise, to simulate deviations caused by the effects of real data collection. Weight coefficients obey standard normal distribution. By comparing our modified data with real motion data, the result of accuracy is shown on Figure 4. We can see that some similar motions such as standing and pick up heavy object, hold up heavy object and arm raised, sometimes are indistinguishable, this may become a more serious problem in real world sampling. Our simulation on 900 pairs of motion samples in total shows that averagely the accuracy of motion recognition by multi-type sensor fusion is about 97%, although the number of samples is not large, but this result shows that multi-type sensor fusion is possible to improve the accuracy of specific motion recognition in construction site condition. In real world experiment, due to other unexpected interferences and noises, the result may

real motion / detected motion	stand	sit	sleep	uplift	pick up heavy	hold up heavy	arm raised	regular cyclical	bend over	total
stand	95	3			2					
sit		96			1					
sleeping			100							
uplift				98			1

arm raised				2	1	8	94			
regular cyclical								100		
bend over									100	
accuracy	95%	96%	100%	98%	96%	92%	94%	100%	100%	97%

Figure 4. simulation result.

change a bit, but due to the large number of samples, we expect the result to be as good as our simulation result.

5 Conclusion

In this paper, a new method is proposed for motion recognition and safety management of construction workers by using integrated sensor network, in order to effectively ensure the safety of workers in complex environment of construction site. We improve the motion recognition with depth maps, we also proposed several new motions that are usually shown in construction site and generate the database of each new motions' degree of change in relative 3D coordinate system. We proved that using multi-type sensor fusion to recognize human motion is possible, and our simulation shows that the accuracy is quite high compare to some related works.

We also noticed several problems during our research, such as distinction of similar motions. In the future, we will consider to add more special motions to expand recognition range, we will also improve the accuracy of skeleton interest point movement to decrease detection error from similar motions. IMUs-based motion recognition method is considered to be improved as well, meanwhile, a remote VR-based motion recognition system is included in our consideration.

Data-Driven Worker Detection from Load-View Crane Camera

Tanittha Sutjaritvorakul, Axel Vierling and Karsten Berns

Department of Computer Science, Technische Universität Kaiserslautern, Germany
E-mail: {tanittha,vierling,berns}@cs.uni-kl.de

Abstract -

Cranes as an essential part of the construction machinery, are one of the prominent sources of fatalities in the construction sites. The camera assistant system can contribute significantly to the safety of the crane operation particularly in blind lifts tasks, where the operator highly relies on the load-view camera. In this paper, we address the worker detection from an off-the-shelf load-view crane camera using a data-driven approach. Due to the difficulties in collecting data, we generate five training datasets via a simulation platform to build up the synthetic samples to improve the state-of-the-art detector. Despite the fact that only the simulation data is used as training datasets, the trained network demonstrates the average precision of up to 66.84% in two real-world scenarios.

Keywords -

Construction safety; Crane simulation; Worker detection; Visibility assistance

1 Introduction

The number of crane accidents caused by visibility remains high. The load-view crane camera is essentially used to widen the operator's field of v iew. However, it is hard for operators to keep observing hazards from merely a seven-inch monitor with no semantic information such as the position of the worker with respect to the crane or load. This work presents an analysis of a data-driven worker detection from a load-view camera using solely synthetic data in the learning procedure. The large volume of synthetic data is created by the simulation platform.

According to visibility-related fatalities, struck-by accidents contribute to 87.7% of all construction equipment accidents [8]. Cranes, which are the main machines in the construction, carry out the major activities in the building construction industry. Falling loads or struck-by loads are the most common and most dangerous crane-related hazards. The workers can be struck or hit by any moving load while they are working in close proximity to the crane. The poor visibility or blindspot causes the operator has difficulties to identify any personnel or objects in the work zone. Unlike in the street environment, the construction site is complex and unstructured. Workers and machines work side by side. The operator simultaneously monitors many things e.g., load radius, workers-on-foot, and spotter. Automated localizing workers or objects surrounding the load allows operators to understand the situation, and make decisions and actions accordingly.

Figure 1. Crane load-view camera circled in red.

Not all sensor types are suitable to monitor objects from the load. Numerous crane safety assistance methods are presented in previous studies. The proximity warning is prevalent. Many sensor-based technologies have been adopted for construction safety assistance. These sensors can be installed on the site, workers or machines themselves to recognize objects. To increase spatial awareness of the operator, the load sway monitor can be observed using IMU or a camera [4, 5]. Similarly, hook motion tracking can measure the working radius in order to avoid collision [28, 12, 17]. Wearable devices such as bluetooth, RFID, and ultra-wideband (UWB) tag on safety helmet which provides the position can be irritating and privacy-intrusive to the workers [25, 29]. The operator mainly depends on the load-view camera during lifting tasks. It allows the operator to inspect the distance between the load and obstruction without occlusion among other objects. The view provides the top perspective from the camera mounted at the boom head pointing down to the ground. Information from any sensors installed on-site or on the cabin itself can be insufficient for the operator

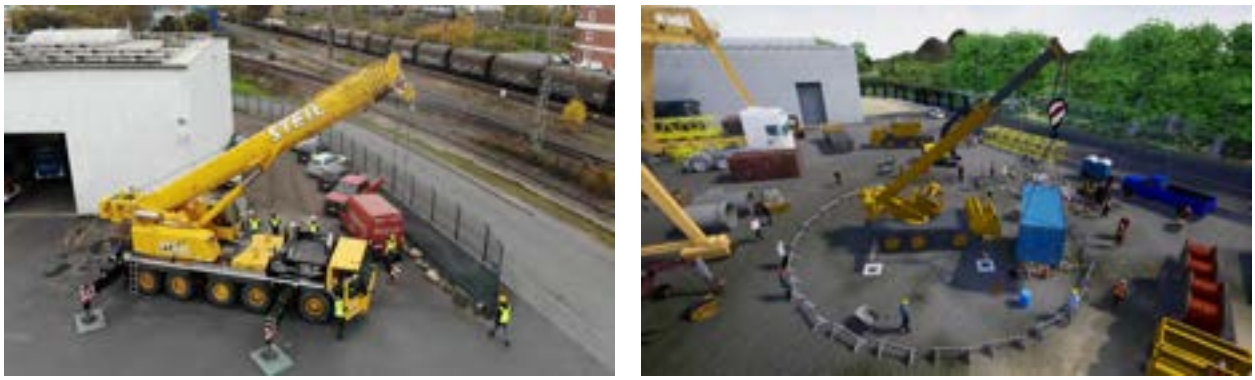

Figure 2. Comparison of real (left) and virtual (right) view at the experimental site in Trier, Germany.

during lifting materials over or into the building. The operator is unable to directly observe any adjacent objects due to the obstruction.

Detecting workers from the load-view is challenging. There is a lack of research on this topic. Traditional worker detection methods are based on simple features like helmet and color of high visibility vest [18, 26, 24]. In fact, most workers do not regularly wear protective clothes. The average of 87 percent of construction workers is reported as Personal Protective Equipment (PPE) noncompliance [20]. Thus using PPE information, the high-visibility color of helmet or vest, as a feature to detect workers may not be adequate. In general, it is very hard for a human to notice the small-sized workers from the top view, see Figure 3(f) which explains the high fatality rate in crane operation and necessitates the application of load-view worker detection. The construction area is cluttered and dynamically changing over time.

With the outstanding results, the construction domain also employs the data-hungry learning methods into worker recognition. The following studies of detecting workers from load-view camera or similar use deep learning approaches. Yang et al. [34] use Mask R-CNN to detect workers from a tower crane and identify if the workers are in the safety distance. Hu et al. [9] use YOLOv3 to detect non-complaint worker without a helmet. Vierling et al. [30] propose an automatic zoom load-view camera based on the working zone and load occlusion. The authors train the convolutional neural network with the load-view image and current zoom level, then result the optimal zoom level for the operator.

There is an intensive shortage of training data in the construction domain. The performance of deep learning methods is highly dependent on the existence of ample training samples. The self-driving car datasets publicly exist in great amount [11]. However, these datasets are not applicable to load-view object detection due to the frontal viewpoint. In addition, Unmanned Aerial Vehicle (UAV) datasets [23, 33, 1] could not be used as an alternative because of an uncluttered and static background, unlike the construction area. The pose or activity of the worker and the pedestrian are not identical, which can lead to different image features.

Data collection is crucial. Gathering data consists of two main steps, namely data recording, and annotation. Recording data from a car is relatively straightforward as opposed to a huge construction machine. The sensors can be easily mounted and adjusted. The driver does not require any additional specific skills. Image annotation techniques can be manual, semi-automatic, and automatic. Manual annotating data is tedious. The annotator required the knowledge to fulfill the task e.g., occlusion constraints, object representation, and boundary [2]. For a very large scale dataset, there exist crowd-sourcing platforms, such as Amazon Mechanical Turk (MTurk), to gather image annotation possible. Regardless of the verified annotated data, Zhang et al. [35] show the localization errors of original annotation in Caltech dataset.

Besides the benefits of using simulation as a construction robot test platform or vocational training, simulation also helps to augment data while reducing localization error and time from the manual labeling. Vierling et al. [31] develop the automated data generation tool in a game engine. Soltani et al. [27] propose automated annotation using synthetic images of construction resources is able to reduce the annotating time while improving the detection accuracy. The synthetic data can be used as an additional option to generate the training samples. Several studies [19, 32] demonstrate the synthetic data, which is generated from a game engine, can be used in a real-life scenario. With the rendering capability, the game engines like Unreal Engine[1] can generate the photorealistic environment and human characters. The virtual characters

[1]A game engine developed by Epic Games (www.unrealengine.com)

should behave naturally. Jan et al. [7] modelled and validated the usage of virtual characters in Unreal Engine for pedestrian-vehicle interaction system for an autonomous vehicle.

This paper aims to detect workers from a load-view crane camera using a data-driven detection approach. Worker detector can semantically provide information about what is happening nearby the load for the operators. With promising performance of DNN, RetinaNet architecture [14] is selected as a worker detector for our experiment. In order to cope with the absence of data, we generated the synthetic training data from virtual environment which is similar to the real experimental site. Special attention is given to construct the worker appearance, clothing and movements.

2 Methodology

Our approach consists of two main parts, data collection, and worker detection. First, the data collection describes how we gather the dataset from the real scenario and simulated platform. The second part explains the choice of detection algorithm and training strategy. The test crane used in this work is a telescopic crane (Liebherr LTM1130) while the testing took place in Trier, Germany. The standard crane load-view camera (Motec MC5200) is used in detecting workers. It is mounted at the boom end via pendulum bracket, looking downward, see Figure 1. The hardware used in detection experiments is NVIDIA GeForce GTX 1060, 3GB GDDR5.

(a) UT0 (b) UT1 (c) UT2 (d) UT4 (e) R1 (f) R2

Figure 3. Sample datasets for worker detection.

2.1 Data Collection

All collected data is listed in Table 1. The sequence name with a prefix of *R* is collected from the real mobile crane at the experimental site while the one with prefix *UT* is data generated by Unreal Engine. Examples of the data can be found in Figure 3. In a real-world scenario, the data is taken from the crane using 3-7 participants in the scene. The estimated distance of the camera to the ground (D_{cam}) is 25-35 meters, which refers to a 6- to 8-floor building. The crane performs basic lifting task—hoisting, extending, retracting boom, etc. In sequence R2, the test load is a wooden pallet. The annotation is done by hand which took about 14-20 seconds per frame.

For the synthetic data, we use a simulation system that developed in [32, 6]. The platform exploits the game engine features which allow us to create alike environment as the experimental site, see Figure 2. It provides large, diverse data with accurate annotation in an instant. The datasets contain workers, with and without PPE on diverse appearances and activities e.g., talking on the phone, standing upright, driving in the truck, carrying, pushing the wheelbarrow, or working with the device. Similar to the real world, construction machines, equipment, and material are present. Within the same scenario, different weather conditions can be rendered. The load-view camera setup is installed in the same manner as the real hardware. We generated 5 virtual image sequences, UT0-UT4 under daylight conditions. The sequence number of the synthetic data defines the level of boom arm extension e.g., UT0 means no boom extension and UT4 means the crane extends the boom up to 4th section. The main boom angle to the ground of all synthetic sequences is 60 degrees. In each sequence, the images are randomly captured while the turret is rotating from 0 to 360 degrees.

2.2 Worker Detection

Choosing network architecture is a difficult task because of speed–accuracy trade-offs [10]. With the great achievement of the deep neural network (DNN), it has been widely used and takes over the traditional image recognition methods. Regarding the requirement of visibility assistance, the operator should be alarmed about any surrounding

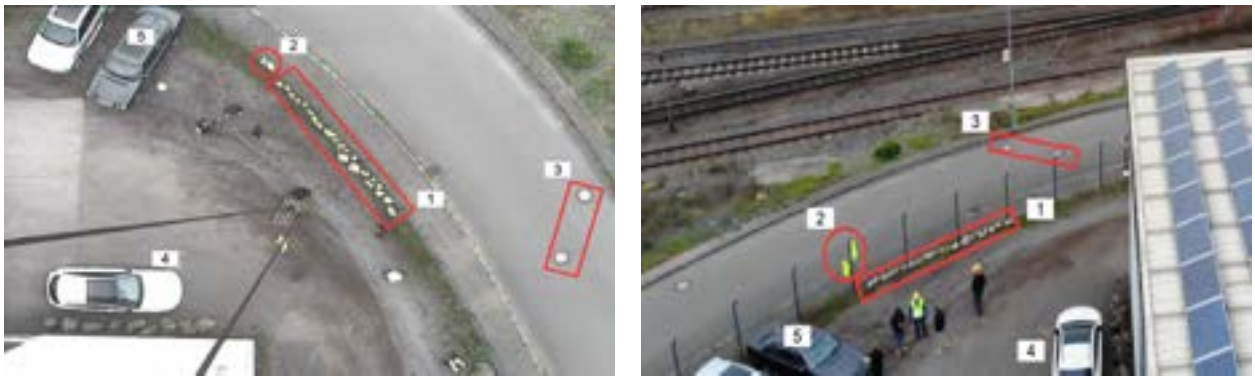

Figure 4. Comparison of the top view perspective between load-view camera (left) and drone camera (right). The identity of each object in both images is defined by the same number tag in the scenario. Number 1 is a rock border next to the fence. Number 2 is two green emergency vests hanging on the fence. Number 3 is two road manholes. Number 4-5 are cars.

Table 1. Dataset Summary.

Seq name	Frames	Resolution	D_{cam}(m)	Average object instances per frame	Total object instances
UT0	120	1600x1200	12	2	283
UT1	300	1600x1200	19	3	753
UT2	303	1600x1200	26	5	1636
UT3	501	1600x1200	33	9	4463
UT4	1110	1600x1200	39	8	8448
R1	713	720x480	25	3	2139
R2	400	720x480	35	7	2795

workers-on-foot in order to be aware of the hazards in (near) real-time.

Object detectors based on the DNN can be mainly categorized into two groups, two-stage detector, and single-stage detector. Two-stage detectors, such as all R-CNN model series [22], are mainly based on regional proposal network (RPN). In the first stage, the model proposes a set of sparse regions of interest by RPN or selective search. The candidates are later classified in the second stage. The accuracy of these models results relatively high but is typically slower. On the other hand, one-stage detectors, SSD [16], YOLO family models [21], and RetinaNet [14], propose the candidates from the input image directly without region proposal step. This leads to simpler and faster model architecture while lessening the performance slightly.

In this paper, we select the object detector based on RetinaNet for our experiments. It is introduced to handle objects in different scales and accurately localize dense objects. The focal loss in RetinaNet tackles an extreme imbalance between background which contains no object and foreground which has objects of interest. In other words, there are a very large number of negative samples and only a few positive samples. Therefore, RetinaNet works well in detecting small targets and high density such as the view from the UAV or load-view crane camera. The backbone network of RetinaNet is the featurized image pyramids which allow detecting object in multiscale [13].

To create the synthetic data closely resembling the target dataset (i.e., R1 and R2), the synthetic data are pre-processed by image filtering. We notice that the target images have more motion blur than the training samples because they tend to come from the swing movement of the camera, the vibration of the machine, or video interlace. For this reason, the motion blur is added to the synthetic data. In practice, the averaging filter with the kernel size of 10x10 applies to all simulated data in order to blur the images. The original synthetic datasets are denoted as UT0-UT4 and the blurred datasets are denoted $\overline{\text{UT0}}$-$\overline{\text{UT4}}$.

The ResNet-50 model is used as a backbone network. We initialize our weights from a pre-trained checkpoint of the COCO dataset [15]. All synthetic data, $\overline{\text{UT0}}$-$\overline{\text{UT4}}$ are combined and randomly shuffled into training and validation sets. The train set and the validation set consist of

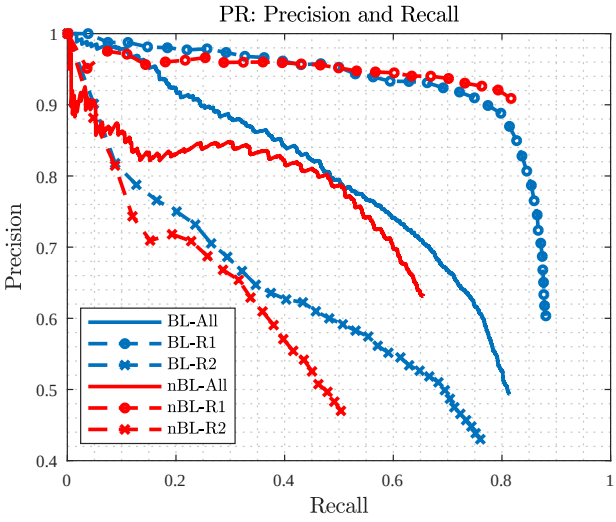

Figure 5. Precision-Recall curves of the experiments. AP in Table 2 can be achieved by the approximation of area under PR curve.

10907 and 4675 objects respectively. The test set with 4934 objects are from R1 and R2. The network is trained until the optimal point with a learning rate of $1e-7$. The sizes of anchors are set to {32, 64, 128, 256, 512} and the strides to {8, 16, 32, 64, 128}.

3 Results and Analysis

We conducted two main trials. In the first trial (BL), we trained the network with the blurred images ($\overline{\text{UT0}}$-$\overline{\text{UT4}}$) and for the second trial (nBL) the non-blurred images, UT0-UT4, are used for training. In each trial, we validate the network with two test sets, R1 and R2. Our detection evaluation metric is adopted from PASCAL Challenge [3] with Intersection over Union (IoU) threshold of 0.5.

$$IoU = \frac{B_p \cap B_{gt}}{B_p \cup B_{gt}} \quad (1)$$

B_p is predicted bounding box and B_{gt} is ground truth bounding box. Average Precision (AP) is widely used in measuring the accuracy among object detectors. The metric is based on the precision-recall (PR) curve. Figure 6 presents several predicted frames from both test sets. APs of the trials are listed in Table 2. The AP is obtained by the approximation of areas under PR curve.

First, we evaluate the networks, which are trained with blurred and non-blurred images on the test sequence R1. Both of them, $BL-R1$ and $nBL-R1$, yield nearly the same results (AP≈78%). The workers in the sequence most often can be recognized by both networks. Despite the low-light condition, the workers were wearing the high-visibility color vest and hard helmet which can be visible

Table 2. Results of AP on each dataset.

Trial	Test seq name	AP@0.5 (%)	Average inference time (ms per frame)
$BL-All$	R1,R2	**66.84**	-
$BL-R1$	R1	78.10	150.0
$BL-R2$	R2	**50.10**	152.7
$nBL-All$	R1,R2	53.13	-
$nBL-R1$	R1	**78.20**	155.6
$nBL-R2$	R2	38.26	151.7

to the networks. Afterward, we assessed the second test sequence R2 for the trial $BL-R2$ and $nBL-R2$. The detector trained with blurred images, $BL-R2$, shows a positive outcome. As a result, the overall AP of the network is higher when trained with the blurred datasets ($\overline{\text{UT0}}$-$\overline{\text{UT4}}$), compared to the non-blurred ones (UT0-UT4), check the AP values for trial $BL-All$ and $nBL-All$ in Table 2. The difference in the average predicting times among trails is minor.

In fact, R2 is a difficult sequence. It is recorded in higher elevation and thus it is hard to recognize the worker. Figure 4 shows the comparison of the same objects from two different camera angles. Apparently, the white rocks (number 1) and manholes (number 3) are almost identical to the person wearing the safety helmet. The workers' appearance form a similar color and shape view as of the ground. For the green emergency vest, we notice that the load-view camera is unable to reproduce the same color as shown in the drone camera or being visible to the human eye. Instead, it displays as white pixels, see Figure 4. This could be caused by the variant brightness, low image resolution, etc. In addition to the issue of the traditional detectors using only PPE color features mentioned in Section 1, color inaccuracy shown in the load-view camera can worsen these detectors because those color feature ranges are normally predefined. These negative samples can likely lure the human to misjudge as well as the detector.

Furthermore, we had prior experience in training the load-view worker detector with UAV data whose detail is not included in this work. The data are initially expected to be used as an alternative to augment the training dataset for load-view worker detection. However, the prediction results were unsatisfactory. Evidently, the workers in the drone camera in Figure 4 can be seen fully while only the heads and shoulders of the workers in the load-view camera are visible. Consequently, using artificial data to train a DNN model is beneficial. The model acquires the image features and is able to yield good performance without seeing none of the real-world data.

Figure 6. Predicted results of trial *BL* on the test sequence R1 in the first row (frame 30, 219, 632) and R2 in the second row (frame 40, 297, 348). The blue bounding box is the detected target with confidence score label while the green box is groundtruth.

4 Conclusion

In this paper, we demonstrate the worker detector from a load-view camera using RetinaNet. This one-stage detector is able to localize and classify small-sized objects in dense areas. Two test image sequences are collected from the real crane. Regarding data shortage and complexity in data collection, we created the five image sequences from different altitudes by the simulated platform in Unreal Engine. The platform allows us to generate plenty of data in an accurate and fast manner. The datasets are synthesized with the motion blur and later fed into the learning procedure. There are two networks trained for evaluation. The first network is trained with preprocessed images and the second is trained with the primitive images. Finally, the detector ran on the two test sequences were taken from the real crane. Blurred virtual data appears to make data more realistic to the learning algorithm.

For future study, worker tracking and activity recognition could be added to reduce misinterpretation between non-object and object. Different synthesized techniques can possibly experiment on the images for training, such as video interlace and synthetic image refiner. Using synthetic data still requires more effort to study because the synthetic data sometimes looks realistic to a person but it can appear to be unrealistic to the learning algorithms.

In conclusion, the worker detector can be used as additional information for risk assessment for each worker. Visualization of workers nearby in 2D or 3D with respect to the crane including the risk level of each worker can be useful for the situational awareness of the operators. This can provide support to the crane operators to identify hazards during operation.

Abstract –

Spotting indications of unsafe human behaviour, a leading cause of an accident, is critical in providing a safe workspace. Among factors affecting human behaviour, stress and overload are the most significant ones, where limited knowledge exists on their underlying causes. Tracing physiological signs caused by stress and overload might be a feasible approach in detecting a specific neurological status leading to unsafe human behaviours, such as disobeying safety rules, standards, and instructions. In this paper, we present a deep learning technique to recognize distinctive neurological status by assessing physiological signals such as temperature and heart rate. An open database of non-EEG physiological signals was used to train and test the model. The database includes electrodermal activity, temperature, acceleration, heart rate, and arterial oxygen level signals of 20 healthy subjects through relaxation, physical, emotional and cognitive activities. A robust automated pattern recognition method, using deep learning, was used to predict and identify stress and overload. The experimental results indicate that the model can detect neurological status with higher accuracy than the traditional classification-based methods.

Deep Learning; Pattern Recognition; Stress; Overload; Safety

1 Introduction

Despite the ongoing safety studies and policy recommendations in construction, the extent of injuries is still significant. Based on the Canada Work Injury, Disease, and Fatality Statistics from Association of Workers' Compensation Boards of Canada (AWCBC/ACATC 2018)[1], each year, around 200 people die in construction sites. There are about 28000 time-loss injuries in construction-related accidents. The number of Canada's fatalities in 2018 shows that the construction industry has the highest number of fatalities among all sectors and accounts for almost 20 percent of the reported fatalities. So, improving safety and discovering the leading causes of accidents are still considered significant contributions to the construction industry.

In Eskandar et al. 2019 [2], three major categories of social, physiological, and cognitive human factors that influence the safe behaviour in construction were studied to guide future research around improving safety in construction. From a physiological perspective, stress and overload presented to have a high-level association with unsafe behaviour among construction workers, which motivated many researchers to detect stress in the work setting.

Stress can be described as the response of the body to the pressures on the human nervous system [3], which have been measured through subjective tests and questionnaires to collect individual responses [4], [5] . Moreover, stress can be measured through variations in human physiological features such as heartbeats, body temperature, and respiration [6]–[8]. With the advances in wearable biosensors and real-time data collection, many researchers focused on the physiological effects of stress on the human body to build a stress detection model. Several supervised learning algorithms were employed to detect stress and overload by detecting patterns of stored physiological signals during experiments.

Below, we first look at the stress and overload of construction workers and relevant physiological information that could guide their identification. Then a deep supervised learning model is proposed to classify different stress-inducing neurological states by processing physiological signals.

2 Stress and Overload

Stress (including physical and psychological) is among the contributing factors that lead to unsafe behaviour [9], [10]. Examples of stress factors in construction setting

were presented as (1) physical stressors like noise, vibration, lighting, boredom, fatigue, cold or heat, and (2) social psychological stressors like fear, uncertainty, anxiety, mental overload, and time pressure [10]–[13]. Overload as an essential stressor that affects human behaviour was selected to focus on due to the nature of manual work in a construction environment that causes workers to exceed their capacity of handling the job.

Tracking symptoms of stress and high mental overload with multiple physiological features give us insight into a human's neurological state. Most physiological measurements come from a network of sensors in which become easier to collect in an unobtrusive real-time manner. Currently, the human body's vital signs can simply be recorded through wearable biosensors and health gadgets (e.g., smartwatch, earbuds, headset). Many researchers used sensors to measure specific physiological conditions to study factors that affect individual neurological statuses such as stress [14], sleep deprivation [15], fatigue [16], and social aspects [17].

Among different measuring methods that could reflect stress and mental overload, Electroencephalogram (EEG) sensors have been commonly applied in many studies [18]–[20]. EEG is a valuable source in identifying brain activities to measure electrical activities of the brain by electrodes positioned on the scalp, and they capture neurons in the brain by electric potentials. However, there are limitations in applications during physical activities as these signals are sensitive to face and body movements (e.g. eye blinks), which makes them impractical for application in construction safety [20]–[22]. Considering the EEG limitations, viable biosensors that could detect and reflect the stress in construction were presented in [14] as; Photoplethysmography (PPG), Electrodermal Activity (EDA), and peripheral skin temperature (ST), that are sensitive to extrinsic and intrinsic artifacts which require extensive filtering.
In addition to the feasibility of data collection in construction, data should reflect the sign of stress and overload. In an open-source database from a Birjandtalab et al. [23], that was conducted on subjects while confronted by stress and overload; seven different non-EEG physiological signals were collected during the experiment. In the current study, the above-noted database (Non-EEG dataset) was used as a source of information to study and train a stress and overload detection model. This database provides us with useful insights over the physiological features of individuals while confronted with overload and stress. This paper is distinct from previous studies by focusing on the physiological impact of mental stress and protecting the model against biases other than the ultimate goal, such as; not including 3-axis acceleration, which leads the model to movement recognition.

3 Non-EEG dataset

A non-EEG physiological signal from [23] includes acceleration (Ax, Ay, Az), electrodermal activity (EDA), temperature, heart rate, and arterial oxygen level (SpO2) signals of 20 healthy subjects during relaxation, physical, emotional and cognitive activities. This dataset includes individual responses while facing different stress-inducing activities. The experimental procedure includes: (1) Five minutes of relaxation, (2) Physical stress by walking on a treadmill at 1 mile/hr. For two minutes and jogging at 3 miles/hr for two minutes, (3) Relaxation, (4) Cognitive stress by counting backwards by sevens from 4285, and then performing Stroop test while alerted by a buzzer, (5) Relaxation, (6) Emotional stress by watching clips from a horror movie, (7) Relaxation.

Figure 4 displays a time-series for the Subject1 during the experiment collected by wrist-worn biosensors. The data file was in the WFDB (WaveForm DataBase) format, which can be read using its associated software package [24]. Records were labelled through ".atr" annotations file format (i.e. red stars on the a_x signal), which indicate a change in the activity of a human subject (i.e., moving from one step to another in the experiment steps).

The data files contain two records per person; one is recorded 3D acceleration, temperature, and electrodermal activity (EDA) with a frequency equal to eight (Figure 1). Another measurement technology recorded heart rate (HR) and arterial oxygen level (SpO2) with a frequency of one reading per second (Figure 2) [23].

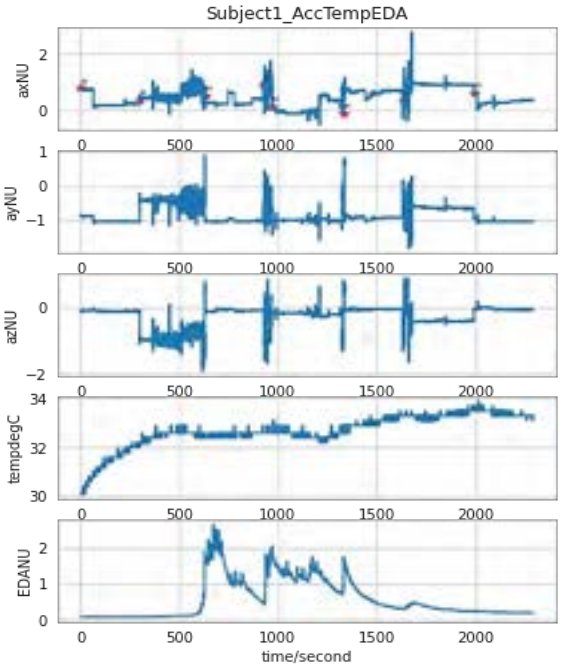

Figure 1. Acceleration (Ax, Ay, Ax), Temperature, and EDA recorded time-series for Subject1.

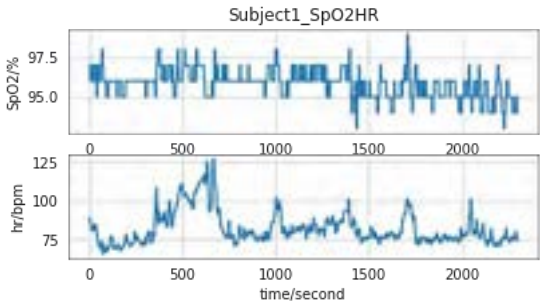

Figure 2. SpO2 and Heart rate recorded time-series for Subject1

3.1 Preprocessing

3.1.1 Aligning

Before analyzing and preprocessing the recorded data, we need to align data of different frequencies from different devices. There are two strategies for resampling and aligning: (1) Upsampling the lower frequency by repeating or interpolating data between reading samples, (2) Downsampling the higher frequency data by replacing extra readings with mean or median. The following graph (Figure 3) shows the difference between Downsampling (with median) and original reading for an accelerometer-x signal. Whether we need to maintain a precision of the higher frequency or not, we can align data of different frequencies. Downsampling signals might result in loss of data, and upsampling the lower frequency reading was chosen to align readings from two separate measuring devices (Figure 4).

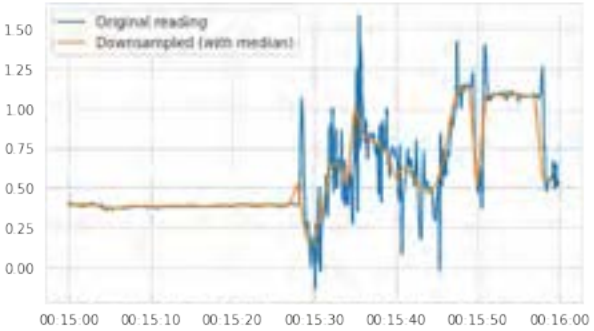

Figure 3. Accelerometer-x down sampled (with median) side-by-side to the original high-frequency

3.1.2 Feature scaling

As it is visible in Figure 4, recorded signals are from different range and amounts. So it is essential to scale all data and perform feature scaling before any processing. Mainly, in classification problems, the majority of algorithms perform based on the distances, scaling the features before processing is necessary.

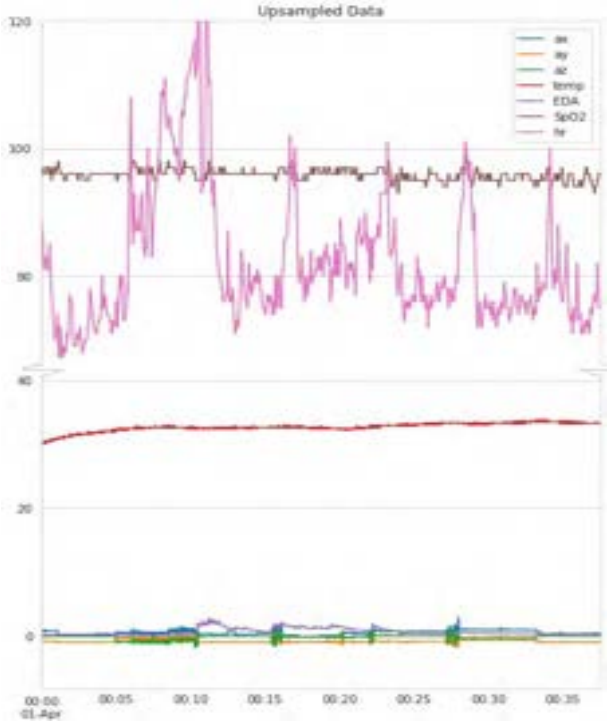

Figure 4. Aligned signals using the upsampling method (with interpolation) for SpO2 and Heart rate

3.1.3 Feature selection

In the preprocessing stage, it is essential to study correlations between different features. In Figure 5, the Pearson r correlations coefficient matrix has been shown to measure the degree of the relationship between linearly related variables to indicate whether two variables are strongly dependent or independent as a part of preprocessing. Based on the Pearson correlation coefficient and Cohen's standard, there is a significant association between acceleration signals (Ax, Ay, and Az). However, temperature and electrodermal activities (EDA) are independent.

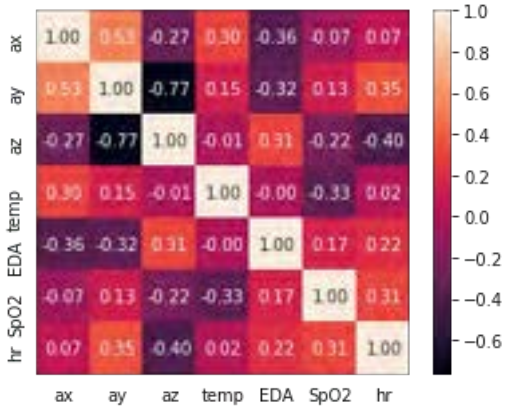

Figure 5. Correlation matrix calculated using the Pearson method

Processing the correlation between features and eliminating those attributes that are unrelated enables a robust feature selection. Feature selection is a critical part of any machine learning pipeline, which leads to the accuracy in the models. Also, having perfectly correlated features increase a chance that the model performance obstructed by Multicollinearity (i.e. when one part can linearly be predicted from the others with a high degree of accuracy, in this case, Ay and Az are negatively correlated). High accuracy cannot be achieved without applying different methods of feature selection, such as Pearson or Spearman correlation matrix, Chi-squared, or Recursive feature elimination. Here, based on the Pearson correlation, features that are highly correlated decrease the performance of the model.

In the current research, in addition to the highly correlated features, it is required to remove three signals of accelerators. Acceleration in different directions is beneficial for activity and movement detection, not the stress and mental overload, which is the focus of this study. Especially in a construction setting due to the physically demanding nature of work, eliminating data regarding movement and activities protects the model to biases, and it focuses on the ultimate goal of stress and mental overload detection.

Since the recorded signals are continuous reading over time, slices of data during a window of time were selected as a separate entry to the model. The optimal window size was detected by calculating the accuracy of the model for different window sizes. Moreover, in classification models, it is essential to have balanced classes for training a model. So, a similar number of windows representing each class were selected as the input to the model.

3.1.4 Feature extraction

After the feature selection stage, a feature extraction tool is needed to provide the training stage with more information regarding data distribution. For this matter, a convolutional neural network (CNN) layer was added at the beginning of the model pipeline.

4 Model

For time-series pattern recognition and classifying different neurological statuses (i.e., relaxation, physical, emotional and cognitive stress), long short-term memory (LSTM) algorithm was selected for training purposes. Long short-term memory (LSTM) is a form of recurrent neural network (RNN) in the field of deep learning. LSTM has feedback connections in addition to the standard feedforward processing. These features enable LSTM to process entire sequences of data and make it accessible in time series data. At the beginning of the model pipeline, convolutional neural network CNN extracts features from signals, and it prepares input for the pattern recognition stage, which was conducted through sequential LSTM layers. Three different LSTM layers were added to the model to give more depth into the calculation, which provides a model with a better chance of prediction. Then, two fully connected layers at the final stage of training prepared the processed data for classification. Different classifiers can be applied to the final stage, namely: Bayes classifier, Hidden Markov Models, Random Forest Classifier, and Ensemble algorithm classifier (meta-algorithms that combine several methods into one model to decrease bias and variance and improve predictions). Adam classifier was chosen for the proposed model as the best fit.

There are multiple hyperparameters (e.g., number of units in each layer, number of dense layers, type of classifier, and number of epochs) in the proposed model, which requires a hyperparameter tuning for selecting the best match for the model. By defining a search area and training a model for several combinations, the best combination was chosen for training a model. For instance, by applying different window sizes, a window of 20 continuous reading of the signal was selected as an optimum number for the proposed model.

For training and testing processes, twenty percent of data were kept unseen for testing and from remaining samples, twenty percent was allocated to the cross-validation for backward propagation.

Figure 6 depicts the categorical accuracy and validation loss during the training session.

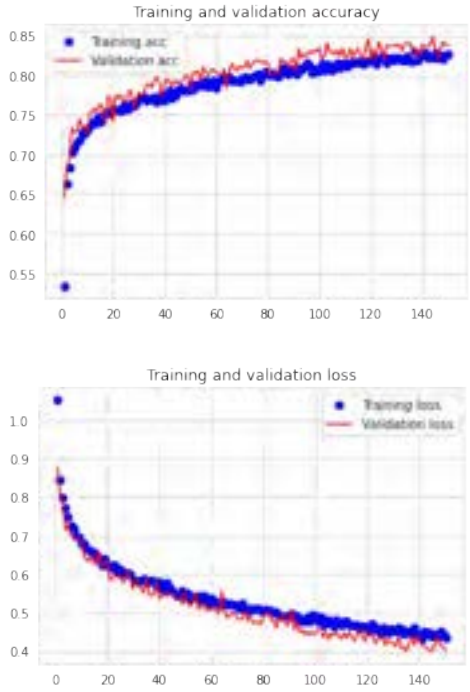

Figure 6. Training and validation accuracy and loss

Figure 7 presents the proposed model classification results that achieved an overall 85 percent accuracy for the test data set. Based on the f1-score (i.e. is a balanced amount of precision and recall) in the following report, we can conclude that the trained model is robust toward detecting physical stress and has more limitations in cognitive stress detection.

Classification Report

	precision	recall	f1-score	support
CognitiveStress	0.71	0.90	0.79	487
EmotionalStress	0.89	0.81	0.85	510
PhysicalStress	0.94	0.94	0.94	506
Relax	0.89	0.75	0.81	481
accuracy			0.85	1984
macro avg	0.86	0.85	0.85	1984
weighted avg	0.86	0.85	0.85	1984

Figure 7. Model classification report

In Figure 8, the confusion matrix for four different classes represents the actual classes in vertical and predicted classes in a horizontal direction.

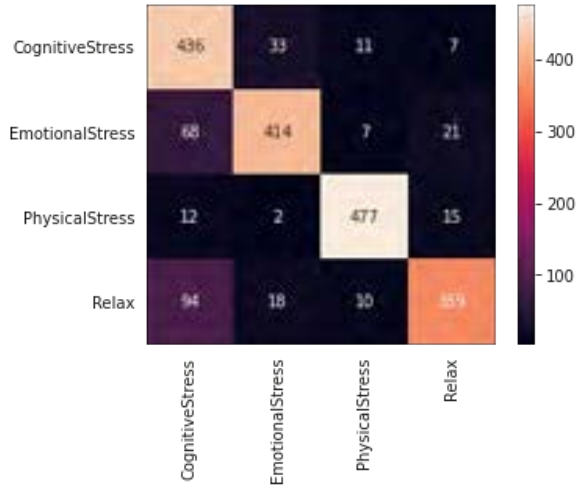

Figure 8. Confusion matrix

5 Results discussion and conclusions

In this research, efforts were taken to detect stress and mental overload, not only by employing deep learning techniques but by knowing the inputs of the model and removing preconceptions of the experimental study. The presented trained model in this study achieved 85 percent accuracy over unseen samples, which is a distinct improvement compared to using traditional methods of manual feature extraction (e.g., calculating the median, range, and standard deviation over the time series), combined with classifier algorithms.

Based on the confusion matrix, the trained model has difficulty recalling the Relax state, which needs more improvement in the data-gathering stage for future studies. Inputs to the proposed model were heart rates, temperatures, electrodermal activities, and arterial oxygen levels of subjects during an experiment, in which Ax, Ay, and Az accelerations were removed to enable the model to detect mental overload and stress instead of activities and movement detection. In addition to the importance of input to the model, the level of personal capacity while confronted with stressors has to be considered as individuals have different capacities under pressure.

Furthermore, for detecting stress and overload, multiple sub-classes should be considered to represent different levels of neurological status. For this matter, the severity of the neurological state uncovers, and only the higher level of stress in each category is considered hazardous.

Abstract –

Accurate information on workers' behavior is important for safety and productivity management on construction sites. In recent years, some methods for estimating construction workers' behavior using sensing data have been proposed to collect the data based on scientific evidence. Due to the limitations of previously proposed methods that usually relied on expensive devices such as motion capture systems, the huge amount of investment on the system installation and human resource costs are required. This paper proposes a method for estimating workers' posture with Long Short-Term Memory (LSTM) by using terminals that have already been introduced to construction sites, taking into consideration the operational cost and issues in the previous studies. Moreover, we also propose and evaluate a data augmentation method for utilizing limited training data sets. The experiment results for a reinforcing bar worker indicated that the proposed method could estimate not only the forward-leaning and squatting postures with 79% or more F-measure but also the number of rebar binding points by the acceleration data. Besides, we confirmed that the data augmentation method improved the accuracy of posture estimation by 5%.

1 Introduction

While the number of labor accidents at construction sites in Japan is decreasing, the number of serious accidents continues to be higher than in other industries [1]. Therefore, it is necessary to take improvement measures in consideration of both the organization and the technology through a meeting among construction-related people. Moreover, as construction demand is expected to be stabilized in recent years, there is a concern that the labor force will be insufficient due to a decrease in the number of young employees and the aging of skilled technicians. Thus, regarding labor productivity as well, it is necessary to formulate efficient construction plans by saving labor costs while also considering the safety of workers [2].

In recent years, for managing construction plans that consider safety and efficiency at construction sites, the introduction of construction support systems that have the function of visualizing the situation of workers and equipment on the site from past accumulated data has been promoted [3]. At such time, it is important to collect the condition data of the workers by using informative equipment such as sensors and cameras and convert them into information that is practical for site management such as the behavior history of the workers.

Video data acquired by RGB cameras and sensing data from wearable terminals are used to gather behavior data of construction workers. In this study, we employ a method using sensing data that enables data acquisition in consideration of the obstructions on the site and personal privacy and estimates the workers' behavior [4]. Also, it has been reported that supervised learning can be used for behavioral estimation based on individual characteristics.[5]. By applying these methods to workers at construction sites, the estimation of tools used by workers [6] and the work estimation of reinforcing bar workers [7] have been performed. Furthermore, smartphones with built-in inertial sensors or motion capture systems that attached multiple inertial sensors to the joints of the workers were also proposed to estimate their behavior [8]. However, these equipment costs are not easily achievable and besides, it is also essential to prepare the human resources for security and maintenance of these devices. Therefore, it is necessary to consider constraints such as project size and budget when applying it to the field.

In this study, thus, we propose a construction worker behavior estimation system that considers the limitations when introducing it to a construction site by using monitoring devices that have already been used at the construction sites. Our method considers constraints such as sampling frequency when collecting data by adopting a model corresponding to time series data as a behavior estimation algorithm. Besides, we propose a data

augmentation method because it is labor-intensive and costly in order to prepare a high amount of training data for the behavior estimation model. Finally, we verify the posture estimation accuracy of the proposed system by conducting a verification experiment using the sensing data of the workers acquired at the actual construction site.

2 Literature review

Human behavior estimation technology has gained attention in recent years such as in medicine and engineering scopes [9]. Data collection for human behavior estimation can be separated into two types: a vision-based method, in which video devices are used to collect data from a target person at a distance, and a sensor-based method, which utilizes a device with a built-in sensor directly attached to the target person. In this section, we summarize the applications of each method that have been implemented on construction sites.

2.1 Vision-based methods

Video data is used in various fields because it is easy for humans to intuitively understand and obtain useful information from the images by looking at them directly [10]. In recent years, due to cost reduction, downsizing, and high resolution of video equipment, it has been introduced to the construction sites as well, and research on data collection of worker status and construction machines' positions have been conducted [11]. In particular, recent research has been carried out to apply computer vision technology using deep learning. Some of the studies were to automatically identify which task a worker is engaged in [12] and to verify the appropriate utilization of safety devices such as safety belts [13]. In those studies [12-13], the practitioners use cameras to track the workers. However, hiring extra staff to work on these tasks increases the cost of the project. A fixed-point camera-based method [14] has also been proposed. However, on the construction sites where workers and equipment are densely packed, the target workers may be hidden behind the equipment and the data cannot be continuously collected.

In recent years, a method using a depth camera for behavior estimation[15] has also been reported. Depth information makes it possible to correctly reproduce the human posture that occurs in the real space. However, the depth camera cannot accurately obtain depth information of distant objects and may face some difficulties when some objects are exposed to sunlight.

2.2 Sensor-based methods

The sensor-based method is proposed to eliminate the weaknesses of behavior estimation using video data. The posture and motion can be estimated by attaching a terminal with built-in inertial or biometric sensors to the human body and performing the calculation on the sensing data. This method can compensate for the shortcomings of vision-based method because it can continuously collect data without being affected by surrounding obstacles, light sources, and sight distance [4]. Also, sensor-based method can collect data in consideration of the privacy of the subject [4]. Behavior estimation using sensing data has been applied in a variety of fields, as the recent spread of micro-electro-mechanical-systems (MEMS) technology made it possible to easily develop behavior estimation systems [9]. In the construction sector, a motion capture system using multiple inertial sensors attached to human body to prevent Work-Related Musculoskeletal Disorders (WRMDs) was proposed at a construction site, and verification experiments have shown the effectiveness of the warning function [8]. However, the motion capture systems are hardly affordable and attaching many sensors to the human body is intrusive. With respect to productivity management, smartphone-based methods have been proposed to estimate tools handled by workers [6] and work estimation for rebar workers [7]. It is cost-effective to use personal smartphones for data collection which are ubiquitous these days. Nevertheless, the recent diversification of smartphone models and specifications leads to an increase in the burden for system administrators. Thus low-cost, nonintrusive and uniform equipment is suitable for installation to construction sites.

2.3 Objective of this research

Considering the constraint for installing the equipment as shown through the literature review, we adopt the monitoring devices for the workers that have already been installed to construction sites. The devices meet the requirements of low-cost, nonintrusive and uniform. Then, we propose a system for estimating workers' posture using a machine learning-based estimation algorithm and a data augmentation method corresponding to the sensing devices.

3 Proposed method

3.1 Overview of the proposed method

In this study, we propose a behavior estimation method for construction workers that uses a helmet-mounted terminal, which has already been installed on actual construction sites. Figure 1 shows an overview of the proposed system. The terminal with a built-in composite sensor provides sensing data including acceleration and positional information obtained by positioning system every second. These data are stored in

the terminal's memory. The stored data are transferred to the database in the laptop by connecting the terminals to the equipment installed at the site. Then, we construct a system to estimate the postural state of construction workers from the stored sensing data by utilizing a neural network model that is trained using past behavior data of workers.

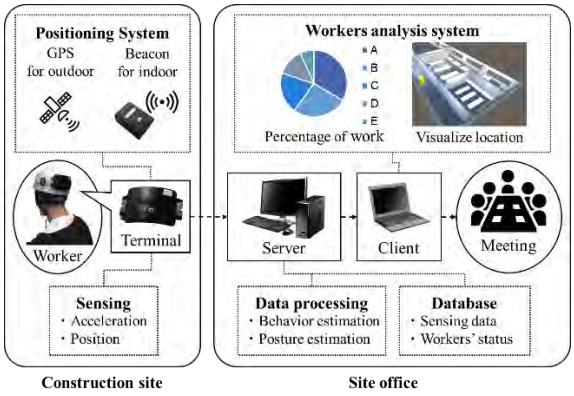

Figure 1. Overview of the proposed system

3.2 Data Acquisition by terminals

We use the "Construction Site Operation Monitoring System [16]" developed by Hitachi, Ltd. as a terminal for acquiring sensing data. The positional information is provided by Beacon or Global Positioning System (GPS) and sensing data, including triaxial acceleration, barometric pressure, and temperature are stored in the terminal's internal memory every second. The stored data are transferred to a server PC by connecting to the cradle installed on the site at the end of workday. The collected data are used to confirm the walking path of each worker verifying whether or not there are dangerous movements through the aforementioned system.

The monitoring system has functions such as detection of approaching the dangerous area and falling, and calculation of worker's posture based on the triaxial acceleration values obtained every second, but it does not have a function to estimate worker's behavior considering the change of worker's condition over time. Therefore, it is not possible to use the results obtained from the estimation of worker's behavior for productivity analysis or safety management measures.

3.3 Behavior estimation using sensing data

3.3.1 Data processing flow

Focusing on the fact that the workers' behavior estimation function is not implemented in the monitoring system, the proposed system employs a posture estimation method based on acceleration data and its time-series. Figure 2 shows the flow of the behavior estimation process in the proposed system. After the processing starts, input data for estimation are read from workers lists and sensing data registered in the database. In the preprocessing phase, acceleration data are extracted and formatted to suit the input of estimation model. Then the posture state of the target worker is estimated and processed as the posture data of the worker at that time by inputting the extracted data into the estimation model inside the system.

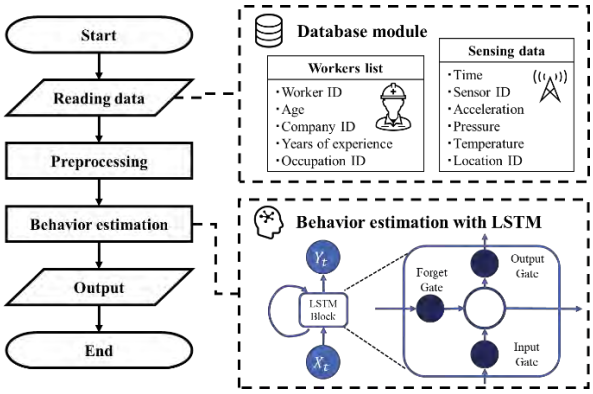

Figure 2. Data processing flow in the proposed system

3.3.2 Reading data and prerprocessing

The structure of the dataset used in this method for posture estimation and training of the estimation model is shown in equation (1). After reading sensing data from the database module, the time-series data is converted to the right side of the matrix in the equation (1). We assume that the worker's condition at time t is determined from the worker's condition before time t and the acceleration values around time t. Then, we define the dataset as a mapping between the posture label P_t at time t and the acceleration values around time t.

$$P_t \leftrightarrow \begin{bmatrix} x_{t-n} & y_{t-n} & z_{t-n} \\ \vdots & \vdots & \vdots \\ x_t & y_t & z_t \\ \vdots & \vdots & \vdots \\ x_{t+n} & y_{t+n} & z_{t+n} \end{bmatrix} \quad (1)$$

where

P_t: Posture label at time t
x_t, y_t, z_t: Acceleration value of each axis at time t
$2n+1$: Time window width

3.3.3 Posture estimation with LSTM

In the posture estimation phase, a feature and classification algorithm should be selected in consideration of the terminals used for sensing and the

behavior characteristics of individuals [4]. We implement a neural network model that automatically extracts and learns features from the input training data to perform posture estimation for various occupations and individual differences in this study. We also use Long Short-Term Memory (LSTM), which has been reported to have a high performance in predicting time series data among neural network models [17]. The structure of the LSTM employed in the system is shown in Figure 3. LSTM is a kind of recurrent neural network, which replaces the hidden layer in the recurrent neural network (RNN) with a module called LSTM blocks. LSTM addresses the gradient vanishing problem, where the value of the hidden layer is decayed and lost, which is inherited by the next time layer by adopting the LSTM block. It is known that LSTM performs better than RNN for the problem of predicting time series data with long-term dependency [18].

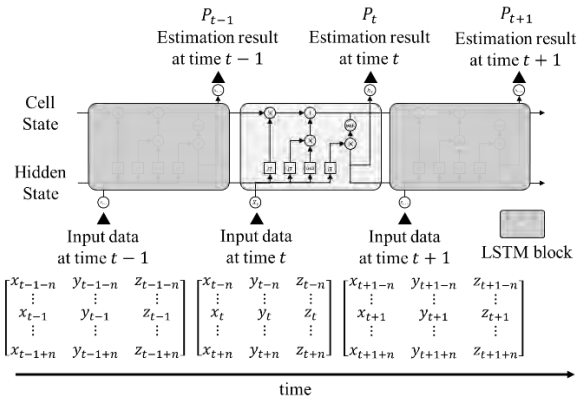

Figure 3. The structure of LSTM network for behavior estimation

3.3.4 Data augmentation

The data labeling should be done referring to data other than sensing data, such as video data, as shown in Figure 4, in creating datasets for behavior estimation. In the labeling of time-series behavior data, video data are commonly used to label behavior conditions [19]. On the other hand, this method is costly and labor-intensive, and inadvertent mislabeling may occur. In order to eliminate these tasks, previous works sharing human behavior data focusing on basic actions in daily life have been done [20]. Nevertheless, studies providing behavior data on specific workers such as construction workers have yet not been made. Therefore, we implement a data augmentation method for sensing data and propose a method to utilize limited data collected in the field as training data.

The conceptual diagram of the data augmentation proposed in this study is shown in Figure 5. While most of the studies on action recognition using inertial sensors use a sampling frequency of 25 Hz or higher, the terminals used in the proposed system have a low sampling frequency of 1 Hz. Taking this condition into consideration, the proposed method restores the acceleration waveform using the interpolation formula for the data discretized by sensing. After that, the number of data sets is artificially increased by cutting out data from the interpolated acceleration waveform at equal intervals. By using this method, it is possible to add diversity to the training data while maintaining the correspondence between time-series information and posture labels, which can be used to generate models with high generalization performance. Indeed, our low-frequency sampling system and this method are inappropriate for instantaneous motion classification problems such as gesture recognition. However, we adopt this method because of the postures targeted in this study record more stable data in the long term than gestures.

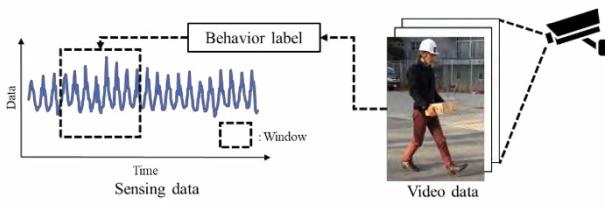

Figure 4. Conceptual diagram of data labeling

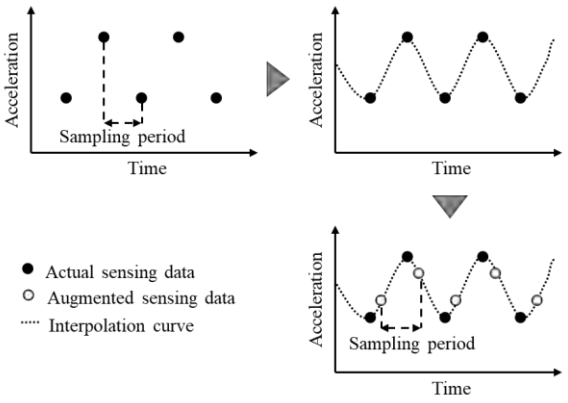

Figure 5. Conceptual diagram of data augmentation for sensing data

4 Verification of the proposed system

We evaluated the accuracy of posture estimation, verified the effectiveness of data augmentation, and estimated the number of binding points of rebar using acceleration data for a rebar worker at an actual construction site.

4.1 Experiment

4.1.1 Target work setting and data collection

A reinforcing bar worker (male, in his 50s, 37 years of experience) who works on binding rebars of floor slabs was asked to wear a terminal and recorded the working state together with the sensing by the terminal. In the work of binding the reinforcing bars of the floor slab, because the transition from the standing state to the forward-leaning posture and the squatting posture occurred repeatedly, the burden on the lumbar region of the worker was large, which caused a disorder of the musculoskeletal system. Because our system can be used for planning preventive measures against musculoskeletal disorders by quantifying and estimating the posture state. This criterion was also utilized for verification.

The rebar binding work is a typical repetitive work of moving to the rebar binding point, preparing a binding wire at a hand, transitioning to the forward-leaning or squatting posture, binding rebar, and moving to the next binding point. Figure 6 shows the flow of the work for binding the reinforcing bars of the floor slab. Unevenness and excessive reduction in repetitive work times are important information for ensuring an appropriate working environment for workers.

In this experiment, forward-leaning and squatting postures for a long time would be counted as rebar binding. The relationship between the posture and the rebar binding work of the floor slab is defined as shown in Figure 7. The number of rebar binding points is estimated based on that. Subsequently, by counting the number of binding points visually based on the actual video data and comparing the estimation results with the actual number, we consider the possibility of applying the proposed system to estimate the number of binding points of the reinforcing bars.

4.1.2 Datasets preparation

After acquiring the terminal record, the correct posture labels (hereinafter called ground truth label) were extracted from the video in every second. Then, the sensing data and correct labels were associated with each other to create data sets. Typically, the time window width is set to have a 50% overlap with respect to the sampling frequency [6], but in this experiment, given the low sampling frequency, we set it to 5 seconds with an 80% overlap. Then, the acceleration data for 5 seconds before and after was associated with the posture label P_t at time t. Three types of postures, standing, leaning-forward, and squatting, were extracted as the static state from "The Nagamachi Work Posture Classification [21]", which defines postures from the ergonomics point of view based on the magnitude of the load applied to the lumbar region of the human body in each work posture.

For dynamic states, we set two categories: transitioning of posture states such as forward-leaning posture from standing posture and walking. Table 1 summarizes the aforementioned posture categories and their definitions in this experiment.

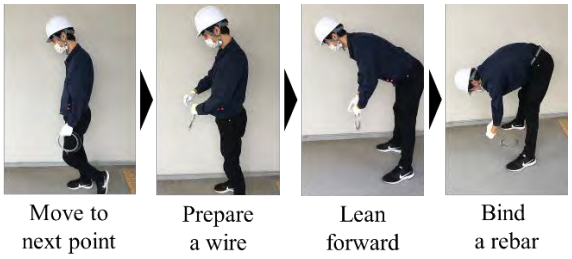

Figure 6. The workflow for binding the reinforcing bars of the floor slab

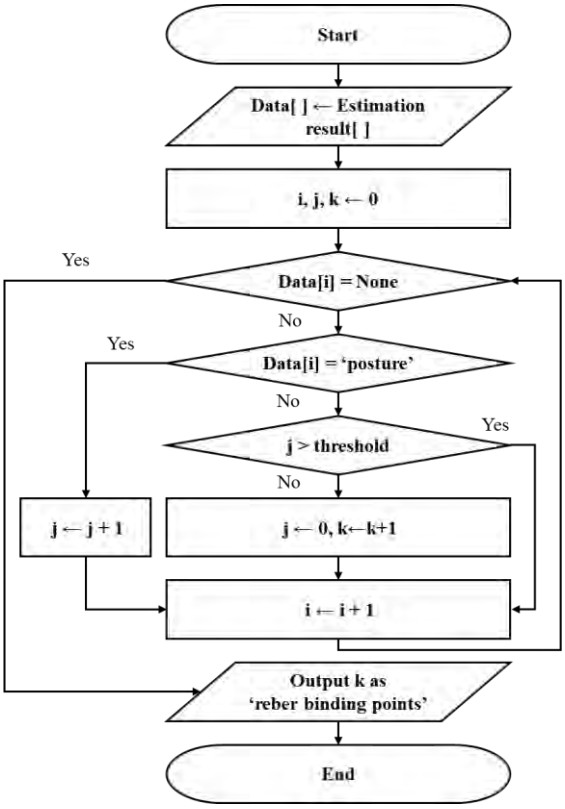

Figure 7. The flow of the estimation for the number of rebar binding points

Table 1. Posture classification of workers in the verification experiment

State	Posture	Definition
Static state	Standing	Upright posture with knees extended
	Forward-leaning	Posture with the waist bent by 30° or more with knees extended
	Squatting	Sitting on the heels posture
Dynamic state	Transitioning	State during changing posture
	Walking	State of advancing step by step

4.1.3 Estimation of accuracy indicators

After the data sets were created, they were divided into training data and test data. The estimation model was trained based on the training data, and the estimation accuracy was calculated based on the test data. Table 2 shows the breakdown of these data in the verification experiments. We allocated the correct labels and estimation results to the confusion matrix shown in Table 3 and calculated the precision, recall, F-measure, and accuracy from Equation (2) to Equation (5) to evaluate the accuracy of the posture estimation.

Table 2. The breakdown of datasets used for accuracy verification

Posture	Training data	Test data
Standing	160	16
Forward-leaning	607	40
Squatting	502	46
Transitioning	344	53
Walking	106	6
Total	**1719**	**161**

Table 3. Confusion matrix in two-class classification

		Estimation result	
		Positive	Negative
Ground truth	Positive	True Positive (TP)	False Negative (FN)
	Negative	False Positive (FP)	True Negative (TN)

$$Precision = \frac{TP}{TP + FP} \quad (2)$$

$$Recall = \frac{TP}{TP + FN} \quad (3)$$

$$F - measure = \frac{2 \times Precision \times Recall}{Precision + Recall} \quad (4)$$

$$Accuracy = \frac{TP + TN}{TP + FP + TN + FN} \quad (5)$$

4.2 Results

4.2.1 Evaluation of data augmentation

Table 4 shows the estimation results with the data augmentation ratio as a comparison when generating the estimation model. For the data augmentation ratio, 1x (without data augmentation), 2x, 4x, and 8x values were used, while linear interpolation was also implemented with the waveforms for the augmentation. The results in Table 4 indicated that the F-measures in each posture, increased and decreased as the ratio of the data augmentation was increased, while the accuracy tended to increase as the ratio was increased. It was confirmed that forward-leaning and squatting postures could be estimated with the F-measure of 79% or higher for all data augmentation ratios.

Table 4. The estimation accuracy at each data augmentation ratio

	Posture	Data augmentation ratio			
		1x	2x	4x	8x
F-measure	Standing	0.73	0.60	0.62	0.60
	Forward-leaning	0.82	0.88	0.85	0.87
	Squatting	0.80	0.79	0.82	0.83
	Transitioning	0.41	0.51	0.60	0.65
	Walking	0.40	0.14	0.33	0.22
	Accuracy	**0.68**	**0.70**	**0.73**	**0.73**

4.2.2 Evaluation in time-series

Figure 8 shows a time-series evaluation of the ground truth labels and the estimation results at the data augmentation ratio of 8x, which recorded the highest accuracy in the estimation results as shown in Table 4. It was confirmed that the accuracy increased when the same posture continued for a long time. On the other hand, the accuracy tended to be lower if the posture changed frequently in a short period.

Figure 8. Time series evaluation of posture estimation

4.2.3 Evaluation of rebar binding points estimation

Table 5 shows the results of the estimation of the rebar binding points based on the results of the estimation flow of the binding points shown in Figure 7. The results of the posture estimation are shown in Figure 8. The condition that the rebar is bound while the forward-leaning or squatting posture was continued for more than 5 seconds was set. The number of binding points, the total time required for rebar binding, and the time spent on binding each point were also calculated.

Table 5. Evaluation of rebar binding points estimation

Input data for estimation	Posture estimation	Ground truth posture
The number of binding points	6	8
Total binding time (sec)	72.0	83.0
Binding time per point (sec)	12.0	10.4

4.3 Discussions

The results in Table 4 show that the proposed system can estimate the worker's posture correctly up to 73% accuracy based on the triaxial acceleration. The accuracy of the proposed system was increased from 68% to 73% by using the data augmentation method. It was also confirmed that the F-measure of 79% or more was able to be achieved for the forward-leaning and squatting postures. Their accuracies are higher than the other gestures in every data augmentation ratio. This is because the LSTM network learned the change in direction of the gravitational acceleration caused by the tilt of the worker's head as effective feature for posture estimation. In the posture classification based on the influence on the musculoskeletal system [21], forward-leaning and squatting postures are set as the level of 5th and 6th out of 10th respectively. Therefore, calculating the cumulative frequency of these levels enable improvement of working environment using quantitative indicators. For further improvement of accuracy, we need to use positional information that was not used in this experiment and add small devices that consider intrusiveness of wearing. According to the results shown in Table 5, the number of rebar binding points were estimated, and six of the eight points were correctly estimated from the posture estimation results. By comparing these estimated results with the quantities of components extracted from product models such as Building Information Modeling (BIM), site stakeholders will be able to understand the progress quantitatively.

5 Conclusions

This paper proposed a system for estimating workers' posture using a helmet-mounted terminal, which is already in use at a construction site to collect worker's behavior data. From the results of posture estimation using triaxial acceleration data acquired at the terminal, it was confirmed that five different postures could be estimated with an accuracy of up to 73% by using LSTM and the data augmentation method. In particular, the system was able to detect forward-leaning and squatting postures with high accuracy, which indicates the system can be used to improve the ergonomic work environment, such as quantifying the load on the body, by calculating the cumulative time of those postures. It was also confirmed that the results of the posture estimation can be used to predict the number of rebar binding points.

Future work includes collecting data to expand the range of jobs and postures to be estimated and improving the accuracy of posture estimation by linking with other types of sensing data such as positional information. We also aim to develop a management system that links behavior estimation with geometric and attribute information of the BIM model.

Abstract -

Fatal accidents occur at construction sites. Incidents involving dangerous situations but not reaching the category of fatal accidents also take place. When an incident occurs, workers typically generate an on-site physiological reaction. In this paper, an automatic detection system is proposed to automatically identify incidents by measuring biological signals related to emotions of on-site workers, such as heart rate and the masseter muscle. In the first stage of this study, some virtual reality (VR) video-based experiments were conducted with some wearable sensors to confirm whether the aforementioned biological signals are suitable to detect incidents. While watching the VR videos, biological signals of the subjects were measured using different wearable sensors. The experimental results corroborated that the proposed sensing method is suitable to detect construction-site incidents.

Construction site; Safety; Biological signals; Incident detection

1 Introduction

According to a survey by the Ministry of Health, Labour and Welfare, there has been a slight increase in the number of occupational accidents in Japan. In particular, more fatal workplace accidents occur in the construction industry than in other industries [1]. The reasons for this are the shortage of workers caused by the decline in the population due to the low birth rate, and the aging of the on-site workers. Therefore, the need to establish a safer working environment is becoming urgent. To this end, we need to detect an "incident", i.e., a situation in which there is a risk of an accident or other danger, and conduct an analysis of the cause of the problem.

There are two main methods for detecting incidents, as shown in Figure 1: detection from the external environment through devices such as a camera, and detection of hazards perceived by field workers. For the latter method, biological signals related to physiological responses are often used to detect and register dangerous situations perceived by the workers at the site. In this study, this method was used because we finally would visualize the hazards perceived by the field workers not only for incident detection but also for removing the mental burden of the workers in the future.

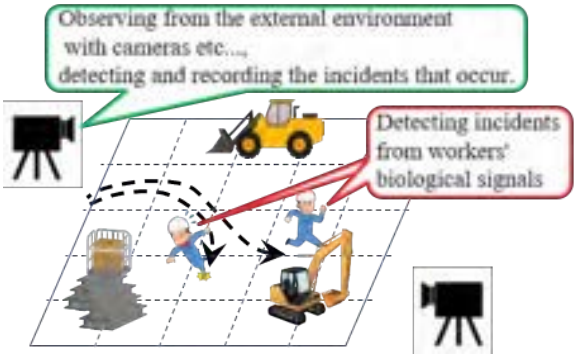

Figure 1. Two main methods for detecting incidents.

Previous studies related to ours reported a construction-site incident detection method based on the heart rate [2]. In this study, the subjects' heart rate was measured using a chest-belt smartwatch, and incidents were detected using the measured heart-rate variability. There are also previous studies for traffic incidents, where the heart rate of drivers is used to detect incidents[3][4]. The heart rate varies according to the activity of sympathetic and parasympathetic nerves [5]. This is related to a person's mental state. Remarkably, the sympathetic nervous system is dominant during tension, resulting in a higher heart rate. In other words, the heart rate is higher when the user feels in danger. However, it is generally known that the heart rate increases not only during mental tension but also during exercise[6]. At construction sites, workers often carry heavy materials and perform other tasks that require strenuous exercises. Therefore, the problem of uncertainty about whether an elevated heart rate is caused by exercise or worker ' s unsafety feelings is expected to occur.

In this study, to solve the aforementioned problems, we aimed to detect incidents at construction sites by using various biological signals related to physiological responses in addition to heart rate. To achieve this, we created virtual reality (VR) videos that simulated incidents that can occur at construction sites. We also conducted experiments using the VR videos. Subjects were asked to watch the VR videos while their physiological responses were measured in terms of heart rate and electromyography (EMG) of the masseter muscle. The detectability of construction-site incidents using these biological signals was verified.

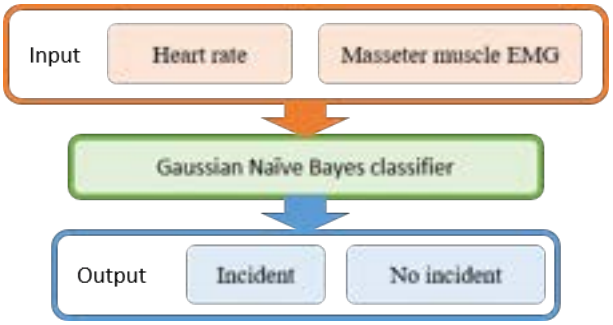

Figure 2. Outline of the proposed method.

2 Proposed Method

2.1 Biological Signals Used

The final goal of this study was to detect situations where workers feel in danger in the field through a wearable sensor. The sensor measures their biological responses and correlates them with the work content. To achieve this, it is necessary to select the biological signals for detecting the scene where a worker feels in danger. Typical biological signals related to human emotions include the heart rate and the masseter muscle.

The heart rate fluctuates according to sympathetic and parasympathetic, i.e., autonomous, nervous activity [5]. This activity is related to the human psyche and is associated with a higher heart rate owing to the dominance of sympathetic nerves during tension. In other words, it is believed that the heart rate increases when the worker is in a tense state due to potential danger to himself.

Facial muscles, such as the masseter muscle, are known to be related to human emotions [7]. Therefore, it is possible to estimate workers' emotions toward danger by measuring the activity of the masseter muscle.

Overall, heart rate and EMG of the masseter muscle can constitute physiological indicators to detect situations where a worker feels danger. In this study, we used these indicators as candidates for the biological response. We conducted indoor VR experiments to test whether these candidate biological signals can be used to detect construction-site incidents.

2.2 Detection Method

In this study, heart rate and EMG of the masseter muscle were used as features, and a Gaussian naive Bayes classifier was used to detect construction-site incidents, as shown in Figure 2.

As in previous studies, we used the average heart rate h at a given time t as a feature of heart rate [2]. Given that the maximum amplitude is generally used for the evaluation of EMG, the masseter EMG feature in our study was the maximum amplitude f at a given time t. The feature vector $\mathbf{x}$ used in this study is expressed as follows:

$$\mathbf{x} = (h, f)^{\mathrm{T}}. \tag{1}$$

Using this $\mathbf{x}$ as inputs, a Gaussian naive Bayes classifier, which is often employed to classify time series data such as those generated in this study, was used to determine whether an incident occurs at a construction site or not. A Gaussian naive Bayes classifier assumes the independence of each feature and simultaneously estimates the probability from each feature. The label with the highest probability constitutes the output. The classifier is expressed according to the following formula:

$$\hat{y} = \mathrm{argmax}[p(y|\mathbf{x})], \tag{2}$$

$$= \mathrm{argmax}[p(y)\prod_{d=1}^{D} p(x_d|y)], \tag{3}$$

where $\hat{y}$ is the output label, $p(y|\mathbf{x})$ is the posterior probability of correct label y given the input vector $\mathbf{x}$, $p(y)$ is the prior probability of correct label y, $p(x_d|y)$ is the likelihood, x_d is the feature in the d-th dimension, and D is the dimension of $\mathbf{x}$.

To use the classifier, we need a unique parameter for each probability distribution. The optimal value of the eigen-parameters is found by maximum likelihood estimation, with the feature matrix of the training data as $\mathbf{X}$ and the corresponding correct label vector as $\mathbf{y}$. The maximum likelihood function $L(\mathbf{X}, \mathbf{y})$ is expressed as follows:

$$L(\mathbf{X}, \mathbf{y}) = \prod_{n=1}^{N} p(y_n)p(\mathbf{x}_n|y_n), \tag{4}$$

$$= \prod_{n=1}^{N}[p(y_n)\prod_{d=1}^{D} p(x_{nd}|y_n)], \tag{5}$$

where N is the number of training data, y_n is the correct label in the n-th training data, $\mathbf{x}_n$ is the feature vector in the n-th training data, and x_{nd} is the feature in the d-th dimension of the n-th data.

A Gaussian naive Bayes classifier assumes that the likelihood $p(x|y)$ follows a Gaussian distribution and finds the optimal value of the intrinsic parameters such that the likelihood function $L(\mathbf{X}, \mathbf{y})$ is maximized for each event. The Gaussian distribution is represented by the following equation:

$$p(x|y) = \frac{1}{\sqrt{2\pi\sigma^2}}\exp(-\frac{x-\mu}{2\sigma^2}), \quad (6)$$

where σ^2 is the distribution of the feature x when the correct label is y and μ is the mean of the feature x when the correct label is y. A Gaussian naive Bayes classifier estimates the correct label from the input features by computing the above equation.

In this study, the aforementioned methods were used to classify whether incidents occur at a construction site.

3 VR Experience

3.1 Outline of Experience

In this study, we conducted experiments in which subjects watched a simulated environment of a construction site through VR videos and simultaneously obtained biological signals from a wearable sensor. Subjects sat in a designated position in the laboratory, wore a wearable sensor for biometric measurements, and watched a VR video. To understand which scenes subjects felt as dangerous, we gave them a controller and instructed them to press the button on the controller when they felt a situation as dangerous; we recorded the time when they pressed the button. This experiment was conducted with the approval of the Ethics Committee of the University of Tokyo.

3.2 VR videos

In the construction industry, personal injuries involving contact between workers and construction equipment or machines such as automobiles are very common [8]. Therefore, in this study, we prepared VR videos of incident scenes where a subject and an excavator are likely to come into contact. Specifically, we prepared the following eight videos.

- Two types of incident scenes in which a hydraulic excavator moves backwards unaware of the presence of a worker and almost comes into contact with the worker, changing the stopping position (long-distance backward and short-distance backward)
- Two types of incident scenes where a hydraulic excavator turns unaware of the presence of a worker and the tip of the bucket almost comes into contact with the worker at different distances (long-distance turning and short-distance turning)

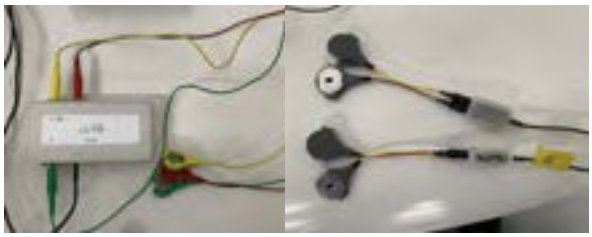
Figure 3. Example of VR image.

- One type of non-accident scene where a hydraulic excavator waits at a long enough distance from a worker (standby)
- One type of non-accident scene where a hydraulic excavator turns in the opposite direction with respect to a worker (non-accidental turning)
- One type of non-accident scene where a hydraulic excavator moves forward and away from a worker (forward)
- One type of non-accident scene where a hydraulic excavator crosses at a long enough distance from a worker (crossing)

In addition, we prepared videos so that the subject could see papers near the subject's hand, simulating that the subject is working at a site while looking at papers such as instructions. The subjects were instructed in advance to look at the papers before them and to pay attention to the construction machines in front of them, as if they were in a construction site. An example of such prepared VR images is shown in Figure 3. These VR images were filmed at the Public Works Research Institute using Ricoh Theta V, operated by Hitachi Construction Machinery ZAXIS120.

3.3 Devices

The wearable sensors used in this experiment are shown in Figure 4. The S&ME DL-310 was used to measure the heart rate, as shown in Figure 4a, and the S&M DL-140 was used to obtain the EMG, as shown in Figure 4b. The S&ME's DL-310 amplifies the R wave of the cardiac signal detected by the sensor with a filter amplifier, and outputs this pulse. EMG of the masseter muscle was measured by the S&M's DL-140 with electrodes attached to the temporal area of the face. The biological signals acquired



(a) S&ME DL-310 (b) S&ME DL-140

(c) S&ME DL-3100

Figure 4. Sensors employed in the experiments.

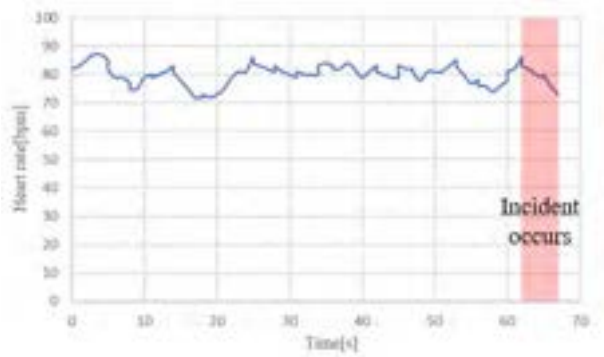
from these sensors were recorded in an S&ME data logger (DL-3100), as shown in Figure 4c. This S&ME DL-3100 has a sampling frequency of 1000 Hz and 16-bit A/D conversion resolution and can store measurement data in its on-board memory.

Vive Cosmos was used to present the VR videos. This head-mounted display is also equipped with headphones; thus, subjects could hear the sound recorded at the time of filming and watch the video.

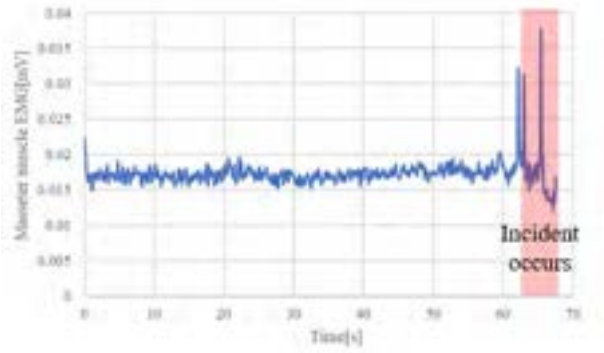
3.4 Biological Signals Processing

After applying a bandpass filter in the frequency range from 0.16 to 500 Hz to the cardiac telegraphic signal in the amplifier section, the biometric information was transmitted to the receiver and recorded in the device. Simultaneously, a pulse waveform synchronized with the R wave was generated in the amplifier section and was recorded in the biometric device concurrently with the cardiac signal. Given that the synchronized pulse rises at the time position of the R wave, the R-R interval was calculated from the time position of the rise of the pulse, and the heart rate was calculated from the inverse of the pulse. The time at the midpoint between consecutive R waves was used to record the heart rate.

In this study, the root mean square (RMS) method was used, which is commonly used for analyzing an EMG of the masseter muscle. Considering the frequency range of EMGs in previous studies, a 5-Hz high-pass filter was used to process the EMGs [9]. Given that humans usually chew in a range from 0.1 seconds to several seconds when they chew, the frame length in this study was set to 100 ms and the interval between frames was set to 1 ms. Denoting the value of RMS at sample point n as $S(n)$, we obtain the



(a) Heart-rate variability in subject A.



(b) EMG of the masseter muscle in subject A.

Figure 5. Biological signals of subject A.

following equation:

$$S(n) = \sqrt{\frac{1}{N}\sum_{i=0}^{N} f^2(n+i)}, \tag{7}$$

where N is the frame length and f(n+i) is the signal of the masseter muscle at sample point n+i.

3.5 Result

Three male students in their twenties were the subjects of this study.

As an example of experimental results, the variations of heart rate and EMG of the masseter muscle for subject A while he was watching the short-distance turning VR video are shown in Figure5. Figure5a shows the heart rate of subject A. The horizontal axis represents the time of the VR video and the vertical axis represents the heart rate. Figure5b shows the variation of the EMG of the masseter muscle for subject A. The horizontal axis shows the time of the VR video and the vertical axis shows the amplitude variation of the EMG of the masseter muscle. The area in red in both Figure5a and Figure5b is the interval of the incident. Figure5 shows that the heart rate ranged from 73 to 86 bpm during the incident, and there was only a slight

difference from the time before the incident occurred. In contrast, the amplitude of the EMG of the masseter muscle reached up to 0.38 mV, which is approximately twice as large as before the incident occurred. This suggests the possibility of detecting incidents from the EMG of the masseter muscle.

In this study, among the experimental data of 3 subjects watching 8 VR videos, 3 subjects watching 4 VR videos (short-distance backward, short-distance turning, standby, and crossing) were used as training data, and 3 subjects watching the remaining 4 videos (long-distance backward, long-distance turning, forward, and no-accident turning) were used as evaluation data. Correct labels were assigned for the experimental data as incidents at the time of the simulated incident in the VR video and no incidents otherwise.

The detection of construction-site incidents by the proposed method was evaluated using accuracy and recall. Accuracy was calculated by comparing the estimation results of the proposed method with the correct labels of the test data and dividing the number of correct answers by the total number of test data. Thus, it provides the percentage of correct estimation results. Recall is calculated by dividing the number of test data correctly detected as incidents by the proposed method by the number of test data actually labeled as incidents. Thus, it indicates the completeness of the incident detection. The equations for accuracy A and recall R are as follows:

$$A = \frac{D^C}{D^T}, \tag{8}$$

$$R = \frac{D_I^C}{D_I^T}, \tag{9}$$

where D^C is the total number of correct data, D^T is the total number of evaluated data, D_I^C is the number of correct data detected as incidents, and D_I^T is the number of data labeled as incidents.

The accuracy and recall of the proposed method are shown in Table 1. In addition, for comparison, the accuracy and recall obtained by the method of estimating only the heart rate as a feature are also shown in Table 1. Accuracy was 0.48 for the proposed method and 0.87 for the heart-rate-only method. Therefore, the accuracy of the heart-rate-only method was higher. By contrast, recall was 0.57 for the proposed method and 0 for the heart-rate-only method. Therefore, the recall of the proposed method was higher. The purpose of this study was to detect incidents, and it is important to detect incidents comprehensively for achieving a safe construction-site environment. Therefore, it is desirable to have a method with high recall and accuracy. Given that the recall of the heart-rate-only method is 0, it is assumed, according to such method, that no incidents were detected at all. The proposed method is more effective than the heart-rate-only method because the recall is higher and more comprehensive, even though the accuracy of the proposed method is lower than that of the heart-rate-only method. The reason why we could not detect an incident using the heart-rate-only method in these environments may be because heart rate responds after a short period of time after an incident occurs. Generally, the heart rate is known to respond about 10 to 20 seconds after an incident occurs, but in the VR video used in these experiments, the video ended within 10 seconds after the incident occurred. It is thought that we could not detect incidents using the heart-rate-only method. In the future, we will consider creating a VR movie with more than 20 seconds left after an incident and using it for experiments.

Table 1. Accuracy and recall of the proposed method and heart-rate-only method

Method	Accuracy	Recall
Proposed Method	0.48	0.57
Heart-Rate-Only	0.87	0

4 Conclusion

In this study, a method for detecting construction-site incidents through a Gaussian naive Bayesian classifier using heart rate and masseter EMG as features was developed. Indoor experiments in which subjects experienced the simulated environment of a construction site through VR videos were conducted to obtain biological signals. The performance of the proposed method was evaluated using the data obtained from the experiments. A comparison between the proposed method and a heart-rate-only method confirmed that the proposed method was more effective in detecting incidents comprehensively. In the future, we will aim to establish a method for detecting incidents in which workers and construction machines are close to come into contact with each other through verification of experiments using VR videos.

Abstract –

Learning by doing creates a marked impact on a trainee's cognitive ability. Technologies such as Virtual Reality (VR), Augmented Reality (AR) etc. aid in developing platforms to enhance the learning experience of users. These technologies can be particularly effective in construction sites which are complex and contain hazards difficult to foresee. These technologies can enable the formulation of robust safety training procedures that will enhance awareness among workers about workplace risks and help to mitigate the same. Currently, the customized development and expense in execution of these digital platforms are major deterrents in its practical deployment and optimum utilization.

In this study, a framework is proposed for the design and development of a VR platform for safety training. The proposed framework classified as Decision-Making Accident Scenario (DMAS) - produces an information skeleton which is derived out of an assessment of potential accidental situations emerging out of a functioning construction site. This skeleton works as a design document to conceptualize the accident scenario as per the identified accidental situation. In each scenario, trainees need to analyze simulated situations, identify risks, and make informed decisions about the mitigation measures which create alternate outcomes. Immersive VR experience of the scenario is built with the help of a gaming engine Unity and Google VR SDK. Smartphone-based VR platform is suggested for user interaction as it is economical to deploy. A pilot study to evaluate this proposed framework was experimentally executed by developing cases related to an ongoing project and synthesizing the different scenarios and storylines into the VR platform. This was tested on three users, and preliminary findings empirically indicated that that safety training using the aforementioned digital platform was significantly more effective in creating better understanding of safety practices on-site.

Virtual Reality (VR); Unity; Decision Making Scenario; Construction Safety Training

1 Introduction

The advancements made in the field of construction have facilitated the implementation of more complex projects in the sector. However, the complexity of a construction project also resulted in making the workplace more prone to accidents and injuries. Despite the industry's sustained efforts to train and educate its workforce about safety practices in the workplace, the construction industry continues to record the highest number of work-related accidents and injury. The USA Occupational Safety & Health Administration (OSHA), reports "out of every 5000 private-industry worker fatalities, 20% are in the construction industry, which means that one out of every five workers deaths is construction related" [1]. This data is based solely on officially reported injuries, and it is widely known that a majority of the workplace injuries go unreported [2]. Such statistics reveal how dangerous and potentially unsafe the construction industry is.

From the perspective of project performance, any on-site accident or injury can cause substantial project delay and cost overrun [3]. To avoid such uncalled for circumstances, the industry follows various protocols, standards, and systems established by the concerned regulatory body of the respective government of the country. The industry also ensures that basic safety training is given to its workforce and generally employs conventional methods for the same which are based on videos, presentations, lectures, and apprenticeship programs [4]. Though this approach gives an insight to the construction practitioners about risk identification and mitigation measures, its effectiveness is limited as it does not prepare them for anticipating and appropriately addressing hazard scenarios [5].

Research has shown that Virtual Reality (VR) has the potential to serve as a training platform, especially

in applications that require visualization. It combines 3D vision and sound; and allows active participation by evoking a sense of the presence of the user [6]. Based on the capabilities of VR, it is proposed to develop a detailed framework to identify and analyze experiences of various accidental situations of a construction site. A platform to implement the framework that enables interactive scenario-based safety training VR application for a smartphone is also proposed. It is expected that the immersive experience of accident scenarios derived from the analysis of the accidental situation will enhance the trainee's ability of risk identification and enable suitable precaution selection.

This paper is organized into seven sections. The following section discusses the existing literature, related work and current gaps in VR based safety training. Sections 3 and 4, present the proposed solution: DMAS based VR training platform and the methodology to develop it. A pilot study to develop and apply the prototype is presented in Section 5. Section 6 shows the analysis of the results obtained after testing the prototype on users, and Section 7 presents the conclusions of the study along with the future work.

2 Related work

This section presents the methods of conventional safety training followed on-site and their limitations. It also discusses the existing VR based safety platforms along with potential and current limitations.

2.1 Conventional Training Method

Safety awareness gets imbibed in workers primarily through field experience and safety training exercise among others. The construction industry has well-established systems for imparting safety training by using methods and platforms like videos, PowerPoint presentations, lectures, or safety toolbox meetings [4]. A survey was conducted on 121 construction practitioners who completed an OSHA 10-hours construction safety training course to check their perception about the efficacy of existing training programs [7]. The survey shows that most of the participants were dissatisfied with the way the training was given. Another study shows that trainees faced problems in being able to visualize construction tasks and activities. In a way, though the videos enabled visualization, the passive role of the trainee in the training procedure renders this method tedious and insufficiently engaging [8]. Thus, these conventional training platforms failed to give the desired results and time and again resurfaces and reinforces the need for a better and effective training program. The inclusion of digital advancements like VR in safety training, can go a long way in devising the potential solution to this problem.

2.2 VR Based Construction Safety Training

The use of VR in the training and education field is widespread. Its first implementation was to train the aircraft pilots by using a flight simulator. In recent years, VR has also become popular in the construction field. Many researchers have tried different ways of using VR for safety training purposes and found largely satisfactory results.

The main advantage of VR lies in the fact that it enables visualization. One study tried to verify this aspect by comparing hazard recognition and risk perception skills of two sets of test subjects: one, who worked with photographs and documents and the other who visualized the situation using VR [9]. Results show clearly that the test subjects from the VR set were able to identify most hazards correctly.

Another study tried to solve the visualization problem faced by the safety management team in risk identification [5]. In this, gaming technology was used to develop the Virtual Safety Assessment System (VSAS). This system simulated high-risk activities and asked complicated multiple-choice questions related to the activity, where the trainee had to think and observe before opting for any option. Such platforms managed to cover various aspects of general safety training. However, VR is not limited to just this. Researchers tried to train a group of students and workers about general safety training as well as task-specific safety training like safety in cast-in-situ concrete and stone cladding work [10]. Task-specific training simulation consisted of various accident scenarios that could arise because of the possible mistakes committed by the trainee while performing the assigned task. The results from the study suggests that the VR platform had a clear advantage in task-specific training, while no significant improvement was seen in the case of general safety training. It also verifies that VR training is indeed very effective as it required the trainees to maintain a high level of alertness and engagement for the entire period.

A social/collaborative VR-based framework was developed to make the workers aware of the critical elements in a collaborative task on-site. Here the students were given an opportunity to learn about construction safety measures by doing experiments on 3D virtual world space [8]. The prototype allowed the student to play an active role while collaborating with other students. The results clearly indicate that it improved the students' involvement, ability to collaborate with other students.

Although research in the field of VR has grown rapidly in the last decade; most of the existing VR platforms for construction safety training still have certain limitations. Some of these are as follows:

Currently, existing VR platforms, while proving useful, lack a well-defined framework and

methodology, which tends to generalize the process of VR based construction safety training platform development.

Most VR simulations teach about risk identification but seldom provide scenarios on how to mitigate the risk.

The cost associated with any VR based safety training platform is very high as a result of which deployment across construction sites gets limited.

3 Proposed DMAS Based VR Training Platform

Based on the above limitations, a Decision-Making Accident Scenario (DMAS) based VR android application platform was proposed which was economical and didn't require high-end VR devices. This platform was prompted by a requirement to focus on improving trainee's ability of risk identification as well as identifying suitable mitigation techniques. It would consist of various accident scenarios, which would be the modified replica of identified accidental situations in a real construction site.

The trainee would be introduced to these scenarios in a virtual environment. Based on observations and assessment, the trainee would need to identify the correct risks associated with the scenarios and try to mitigate those risks by suggesting appropriate precautions. After making those decisions, the trainee would need to verify the safety of that scenario's location by testing it. Identifying risks correctly and suggesting corresponding precautions accurately would be the parameters for evaluation. While testing, it might result in an incident/accident, if the trainee make errors in taking all necessary and correct precautions. These simulated accident outcomes would create a significant and much needed impact on the trainees in raising awareness about how a wrong judgment on site could lead to severe danger.

4 Methodology

To develop a DMAS based VR training platform, a detailed methodology, as shown in Figure 1, was designed and developed. The first step was to develop a detailed Risk Identification Framework (RIF) having the same structure as shown in the first part of Figure 1. This framework was used to classify general types of accidents that could occur on-site into standard categories (A), along with its root causes (R) and precautions (P) to mitigate it. For developing the RIF, safety manuals and accident case studies were referred.

After RIF preparation, the second step was to assess the specifics of the site and identify where training is required. The site visit was intended to identify and analyze various Accidental Situations (As), which might lead to an accident in case of negligence. The Possible Accidents (PA) in those situations were classified as per pre-classified accident categories (A), as shown in the second part of Figure 1.

The third step was to form a DMAS information skeleton. This skeleton was a design document that conceptualized the VR visualization of DMAS. As sketched out in the third part of Figure 1, there were two variables: what accidents should be framed and what corresponding precautions should be suggested for that Framed Accident (FA). The analysis of the accidental situation (As), as shown in the second part of Figure 1, would become the base for deciding the first variable as well as a storyboard (S) and surrounding environment in VR world space. The list of both the correct and incorrect precautions (CP/IP) for the other variable could be derived from RIF, as shown in Figure 1.

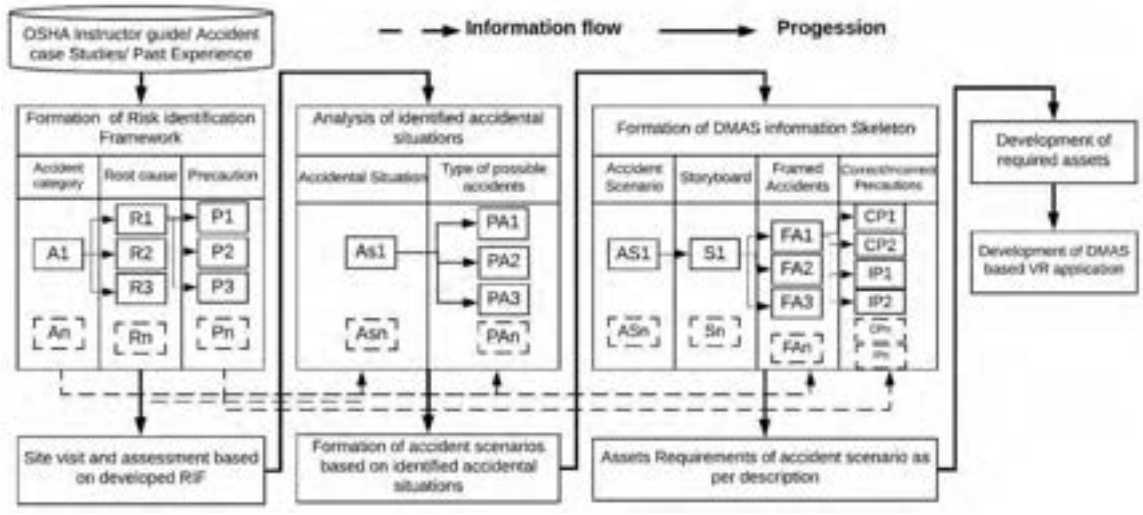

Figure 1. Framework for development of DMAS based VR safety training platform

In the fourth step, the DMAS information skeleton had specified a list of required assets (3D models, etc.). Later, these 3D models were developed with the help of modeling software. Then these all developed models were brought together on a single platform to create VR experience of DMAS where the trainee could experience the outcome of the Framed Accidents (FA).

5 Pilot Study

5.1 Risk Identification Framework (RIF)

This pilot study was executed in the sequence described in the Figure 1. This RIF was based on OSHA's four instructor guides (Construction focus four) for construction safety training [11]–[14]. The RIF output is depicted in Table 1.

The first column classified all possible types of accidents which could occur in any construction site into five general accidents categories (A) (fall from height, struck-by, caught-in or between, electrocution and scaffold collapse) along with its minimum basic requirements to occur.

The second column had root cause analysis (R) for each accident category with the possible reasons which might cause that particular accident. The third column had a set of common suitable precautions (P) suggested and recommended by OSHA, which could eliminate the cause as well as the risk. This given RIF in Table 1 is limited to including only those accident categories which were identified on-site and further used in VR simulation development. Shaded cells in Table 1 highlight the used elements of RIF.

5.2 RIF Based Site Assessment

The site selected for assessment was a commercial office building project. The project consisted of multiple towers which were in different stages of construction. Activities like wall cladding installation and concreting on the top floors were in progress. RIF was used to identify hypothetical accidental situations based on ongoing work.

Table 1. Risk Identification Framework (RIF)

Accidents category (A)	Root Causes (R)	Precaution (P)
Fall from height (Location's elevation higher than 6fts)	Unprotected roof edges, roof, scaffolds, and floor openings, and leading edges, etc.	Provide guardrail systems
		Provide safety net
		Wear Personal Fall Arrest Systems (harness or lanyard)
	Improper scaffold construction	Check for proper access, full planking, and guard railing.
	Unsafe portable ladders	Check for stable footing and the proper angle.
		Choose the correct ladder in good condition for the task Check for surrounding hazards,
Electrocution (Location has any electrical equipment or power lines under or above it)	Contact with overhead power lines (in case of Cranes, other high reaching equipment, Mobile heavy equipment, Ladders, and Material storage)	Maintain a safe distance from overhead power lines
		De-energize the Utility company and visibly grounded the power lines or installed insulated sleeves on power lines
		Check for Flagged warning lines installed to mark horizontal and vertical power line clearance distances
	Contact with underground power lines (in case of excavation)	Check for the markings from underground line location service before digging
		Hand dig within three feet of cable location.
		Use ground-fault circuit interrupters (GFCI)
	Contact with energized sources (live parts, damaged or bare wires, defective equipment)	Use gloves and appropriate footwear
	Improper use of extension and flexible cords	Inspect portable tools and extension cords
		Use power tools and equipment as designed
Scaffold collapse (Location has scaffold)	Improper construction	Check for safety tag (Scaffold Identification Tag)
	Use of parts manufactured in different organizations	Use same manufactured part from one organization
	Instability	Check for unsupported overall height to length of the shortest side of the base
		Check for the firmness of soil under the scaffold
		Check for weather conditions (Wind & Rain)

Figure 2. Accidental situation (As)

Even though four hypothetical accidental situations were identified, this paper focuses on the observation, illustration, and analysis of one of such accidental situations. The situation formulated is based on a new scaffold that was erected for the installation of the formwork, as shown by red arrows in Figure 2. However, the scaffold installation was incomplete and didn't have a suitable platform to work. Also, it wasn't verified by the safety engineer and hence had a red safety tag. Table 2 depicts the performed analysis of Accidental Situation (As) based on RIF. Furthermore, these observations and analysis of Accidental Situation (As) were utilized for creating Accident Scenario (AS).

Table 2. Analysis of Accidental Situation (As)

Possible Accident (PA)	Possible Worker's Negligence
Fall from Height	Workers could perform a task on that platform without any fall protection.
Scaffold collapse	Worker could perform a task on the improperly erected scaffold.

5.3 DMAS Information Skeleton

The Accident Scenario (AS) was a modified VR replica of the identified Accidental Situation (As). The analysis of the identified accident situation resulted in two possible accident types. Since there are many cases of electrocution while working on the scaffold platform, this accident type was also included in the skeleton. A list of correct and incorrect precautions was also prepared for each framed accident with the help of RIF. This was mapped into a detailed storyboard. The prepared DMAS information skeleton for this scenario is shown in Table 3.

5.4 DMAS Based VR Application Development

Figure 3 shows the followed system architecture and its information flow for VR application development. As shown in Figure 3, the first step for developing a VR application representing DMAS was to create all required 3D models, shown in Table 3.

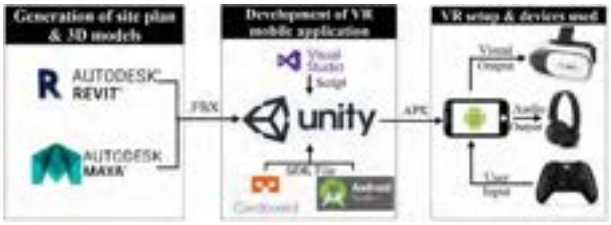

Figure 3. System architecture and technical integration

Autodesk Revit was used for creating models such as under-construction building, transmission tower etc. However, models like a safety net, harness etc., required more flexibility in modeling their shapes. Since Revit was not a non-uniform rational B-spline (NURBS) modeler, which generally helped in manipulating 3D curves and surfaces of any object, it couldn't be used for creating these models. For these models, Autodesk Maya (a NURBS modeling software) was used. After creation, these models were exported into .fbx format

Figure 4. Visual representation MainScene of DMAS

As shown in the second step of Figure 3, these 3D models were imported into Unity where it was navigable. In the Unity environment, all models were located as on-site, so that the overall view of the GameScene (MainScene - Figure 4) could present the prepared Accident Scenario (AS). Animation and user-controlled movement of the character were added to make the static GameScene functional. The dynamics of these models were customized, and conditions were levied on the models, by adding scripts created in Visual Studio using C#. Multiple outcomes for the framed accidents (fall from height, Electrocution, Scaffold Collapse), were also developed in a similar way in various GameScenes. Physics engine, visual effects in the form of Particle System Prefab, and audio effect in the form 3D sound were added to augment the reality quotient of these Outcome GameScenes. The options of correct/incorrect risks and precautions, were empanelled in the form of buttons inside User Interface (UI).

The MainScene was then interlinked with the Outcome GameScene, so that the trainee could be directed to the respective Outcome GameScene based on his responses in MainScene. The Plain visual output of the MainScene was converted in stereo screen format by using Unity Package - Google VR SDK. It was decided to use a smartphone-based VR platform as this is economical to deploy. Android SDK was utilized to process the Unity output for a smartphone-compatible application in .apk format.

Table 3. DMAS Information Skeleton of the accident scenario

Description	A scaffold having a platform higher than 24 feet will be erected. It will be having red safety identification tags with some unprotected platform openings without any fall protection system. A power cable from the transmission tower will be going just above the scaffold platform in proximity to the workplace.
Storyboard (S)	A workforce is going to start work on the newly erected steel scaffold platform. Its tasks include welding and reinforcement fixing. Look carefully and identify the possible accidents and suggest suitable precautions.

Framed Accident (FA)	Correct Precaution (CP)	Incorrect Precaution (IP)	3D Model Required
Fall from Height	Provide edge protection Provide safety net Cover scaffold's opening Wear harness	Do nothing Clean the area Wear safety shoes Wear eyeglasses Wear safety gloves Deny to work	Wooden plank to cover scaffold openings Edge protection Safety nets Harness Under-construction building
Scaffold Collapse	Check for safety-identification tag Call the supervisor	Wear harness Wear safety gloves Work and walk slowly	Scaffold with openings Safety tags
Electrocution	De-energize the cable Wear safety gloves Wear safety shoes	Wear eyeglasses Clean the area	Transmission tower Power cables Safety Gloves Safety Shoes

As shown in the third part of Figure 3, the visual output and audio output of the application were received by Google Cardboard and headphones, respectively, and a gaming pad was used to give user input for controlling the character's movement in 3D world space.

5.5 System Evaluation

Feedback from users was obtained on the basis of their experience of using the platform in order to enable an evaluation of the application. For the evaluation, the user was first introduced in the form of an avatar at a predefined location in virtual space. Within this space, the user explored the site with the aid of navigation options and made informed decisions regarding potential hazards and ways to mitigate it as per options available in UI. The scenario got modified depending on the user response. Figure 5 showed how users could mitigate fall from height risk by selecting the options such as provide edge protection, provide safety net, and provide cover for scaffold openings in UI of the MainScene.

After the user had taken all the precautions to secure the situation, he/she was asked to verify the efficacy of the selected precautions. If all correct precautions were taken for the identified potential risks, then work should progress as planned, with minimal chances of any untoward incident occurring in the virtual space. However, if the user happened to miss one or more of the recommended precautions for a risk in hand, then the user would have faced the accident outcome linked to the missed precautions. The VR accident experience-of typical framed accident (scaffold collapse) is shown in Figure 6.

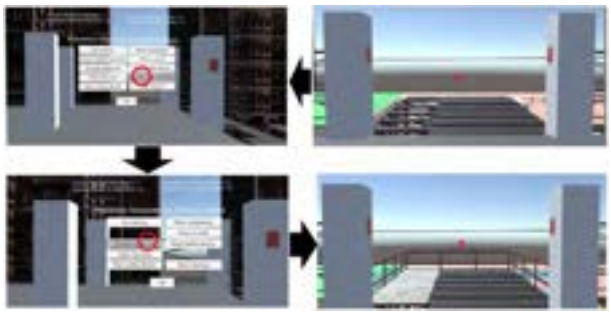

Figure 5. Modification of scenario as per the options selected by the trainee

The scenario presented to the three users had a total of 3 correct, 2 incorrect risk situations, and 9 correct and 11 incorrect precautions. The user responses to the scenario experience is recorded in the four outcomes:

Number of correct risks identified
Number of incorrect risks identified
Number of correct precautions taken
Number of incorrect precautions taken

This prototype application was evaluated based on feedback collected from three students of the civil engineering department. Each of these students had already worked in a construction site before and had taken a course on construction safety thereby having an introductory understanding of the safety practices to be

adhered to on-site.

Figure 6. VR experience of scaffold collapse accident

6 Results & Discussions

The results of the training test and the feedback survey are presented in Table 4 and Table 5.

Table 4. User response records of training test

User no	Risk Identified		Precautions Taken	
	Correct	Incorrect	Correct	Incorrect
1	2 of 3	0 of 2	4 of 9	1 of 11
2	2 of 3	1 of 2	3 of 9	4 of 11
3	3 of 3	0 of 2	6 of 9	4 of 11

Observations of Table 4 show that only user 3 was able to identify all risks. User 1 and 2 were not able to identify all the risks, specifically electrocution. The conversation after the training test revealed that these users neglected the electrical hazard near the scaffold as they were not anticipating this. This confirms that though VR could definitely help in visualization it doesn't necessarily improve risk identification ability, as this ability requires site experience as well.

Table 4 also shows that there were many events where even after identifying the correct risks, users had failed to identify the appropriate precautions recommended for the same. An analysis of two similar events post their occurrence are discussed further. User 1 and 2 failed to take two precautions from the list of recommended precautions to mitigate fall from height as listed in Table 3. They missed covering the scaffold openings because they thought wearing the harness and providing edge protection with safety net would be sufficient to ensure safety. In the event of electrocution, two potential sources of this risk were framed. The first one was emanated from the power cable coming from the transmission tower, the second from the welding task assigned to the trainee as per the storyboard of the scenario. User 3 verified the effectiveness of the selected precaution just after de-energizing the power cable, but he forgot to wear safety shoes and gloves which were essential for the welding task.

In the risk scenario of scaffold collapse wearing harness was one of the incorrect precautions chosen by the users. Similarly, for fall from height - safety shoes and gloves were incorrectly identified as a precaution. Committing such mistakes however made the user reflect on his knowledge gaps and raised awareness about chances of negligent behavior in such situations.

The feedback survey in Table 5 evinces that DMAS based VR training significantly enhanced responsible behavior and improved decision-making ability of the user. This is largely because the simulation of the vivid accident scenario gave the user an opportunity to experience the accidents and hence take cognizance of negligent behavior that causes the same in a graphically visual form. Besides this, the experientiality of these virtual scenarios helped to create a deep and long-lasting impression on the user, thereby enhancing their decision-making ability in the face of such situations at the site in future.

Further, the survey evinces that the VR training boosted the user's confidence and significantly enhanced their safety knowledge and awareness. This can be attributed to the real-time scenario that the platform was capable of simulating, which was crucial to reinforcing the importance of applying the correct precaution and gave the user a chance to witness and realize immediately why his selection of precautions were incapable of mitigating the risk completely. Thus, this platform helped to identify and bridge the gaps in the user's knowledge thus enabling him to make more informed and confident decisions.

The main limitation of the smart-based VR platform was its unpleasant experience as the user felt VR sickness during the test. Despite this limitation, all users agreed that this training would go a long way in helping them to avoid accidents on site and strongly recommended the importance of such training in the future also.

7 Conclusion and Future Work

It was found that of all the steps in the proposed methodology, RIF preparation was the most crucial and time-consuming step. The high level of detail involved in developing RIF enhances its efficacy to identify a sizeable range of accidental situations on-site and also ensures that a high quality of training is maintained. The RIF used in this study is limited to general safety training, but it can be extended to develop site-specific or task-specific training.

Site assessment or analyzing the identified accidental situation is also another vital step. The analysis of the accidental situation should be done rigorously, and all possible outcomes need to be identified and taken into account as it formulates the scope of DMAS information skeleton.

Table 5. Feedback of the users

Questions	User 1	User 2	User 3	Avg
To what extent this training affected your knowledge about safety?	8	9	9	8.7
To what extent will you remember what you've learned a year from now?	9	7	9	8.3
To what extent will training affect your behavior on a construction site?	9	8	9	8.7
To what extent was learning a pleasant experience?	4	3	1	2.7
To what extent, this training improved your confidence in identifying risks on the construction site?	9	9	10	9.3
To what extent, this training improved your decision-making ability?	10	8	10	9.3
Will the training help you avoid accidents on the site?	Yes	Yes	Yes	*
Do you want to have similar training in the future?	Yes	Yes	Yes	*

The skeleton of this study is based on only one accidental situation, but it can be expanded and made more informative by merging various accidental situations of multiple sites thus opening up significant scope for a wider range of training.

The study concludes that the proposed framework made the development process of VR application-based training platform more intuitive, perspicuous, and pragmatic. Moreover, unlike the existing literature on the safety training using VR, the proposed framework isn't limited to this presented scenario, but the same can be further utilized to develop various other scenarios covering all broader aspects of general safety training.

Furthermore, the final product architecture and the prototype VR platform performed well in terms of giving a virtual experience of accidents, identifying gaps in existing knowledge, teaching the immediate applicability and thereby reinforcing the significance of the precautions recommended, and enhancing the confidence of users. However, extended usage may cause VR sickness, and this may be addressed by sophisticated technological improvements.

The DMAS based VR training platform is presently limited to general safety training. This study could be extended to encompass and develop a safety training module for task-specific and site-specific training as well. Further, these DMAS related to task-specific training can be prepared for multi-user environments also. Such environments will enable the participants to play collaborative roles on site and bring the virtual experience even closer to the real scenarios.

Abstract –

Researches on the combined platform of unmanned vehicles, especially aerial, and artificial intelligence can be executed on hobbyists' level with a low budget along with inside multi-billion-dollars technological laboratories. This flexibility has allowed UAV to attract financial potentials and even to migrate them from another technological field. Nowadays, UAVs are used in many industrial fields such as photogrammetry, cinematography, monitoring, cloud seeding. In this paper, we present our work on using UAV to generate a 3D model for a construction site. The purpose of the 3D model is to analyze day-by-day the development and progress on-site, to reconfirm the construction planning, discover opportunities and eliminate potential risks.

Keywords –

Construction site; Unmanned Aerial Vehicle; Artificial intelligence; 3D model

1 Introduction

There are different methodologies to generate 3D models. Mostly are based on Odometry and Photogrammetry algorithms [1-6]. The latter consists of obtaining information on a certain object by using recorded videos or pictures. The sources of the visual information vary depending on the purpose of the 3D model. For instance, it is possible to superimpose LIDAR scanning data [7-13] on infra-red and thermal pictures to detect cracks on the building and identify which construction material (type) has been exposed to damage. The value of photographic interpretation is well-founded in other medical and technical fields such as the Roentgen Stereo Photogrammetry. The application of this method in the construction field is called a computer stereo vision. It allows comparing information about a scene from two vantage points, for instance, obtained by satellite scanning and actual UAV recording.

The advantage of such an approach is to extract 3D information by examining the relative positions of the objects in two different panels. Often this method is used to assess a shore suffered previously by a damaging cyclone [6]. The hidden risk of micro motion displacement can only be identified many years later. Using the Stereo Photogrammetry on a frequent basis will allow the identification of such risks and mitigate them prior to their occurrence.

On the other hand, the inconvenience of using such a method is the embedded high cost and a huge amount of data to be stored and processed. Researchers in photogrammetry field are proposing a different solution for data compaction, however, most frequently the same is leading to decrease pictures quality, hence the generated model, or introducing additional processing noise due to combination of multiple algorithms and working desks.

For a construction field with a limited budget, the generation of a 3D photogrammetric model using UAV is cost-effective and serves the purpose of monitoring, activity planning, and progress control. In this paper, we present our work in generating a rendered 3D model based on orthomosaic and mesh model.

2 Mathematical foundation

In space, the unmanned aerial vehicle has six degrees of freedom, and its motion is described by six differential equations of motion (Euler equations). The solution of these equations in the general case would make it possible to determine the nature of the spatial motion of the UAV at any moment of time, and, in particular, defining the operator's influence on the controls, and would also make it possible to judge the stability of this flight.

However, the direct solution of these equations presents certain difficulties even when using modern computing machines. If we use a straight-line steady flight without sliding for the initial flight mode and consider the deviations of the motion parameters from the initial values to be sufficiently small, then due to the

symmetry of the UAV, the system of six equations of motion can be divided into two independent systems of equations that describe the motion of the UAV with an unknown degree of accuracy longitudinally and laterally.

It should be noted that for the photogrammetry task, the mathematical model will have three different referential axis systems (fig. 1): The Fixed-Earth system, the UAV or body-axis system, and the Camera system.

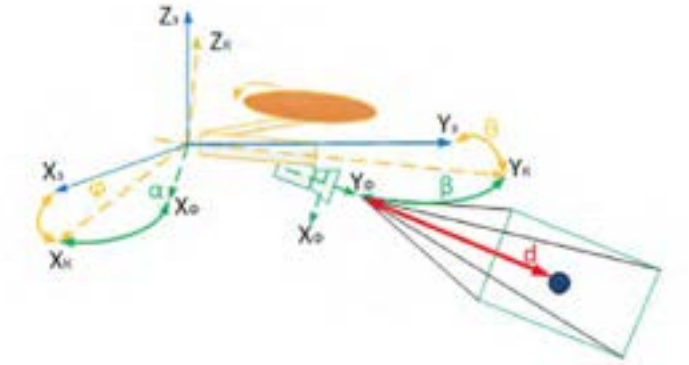

Figure 1. Representation of different systems for photogrammetry task

It is possible to establish mathematical equations for the transition between camera reference system and body-axis system. This is done using the following equations:

$$X_{\text{п}} = \frac{x}{\Pi x}.\cos\left(\arctan\left(\frac{H_B}{H_{\text{г}}}\right)\right); \qquad (1)$$

$$Y_{\text{п}} = \frac{y}{\Pi y}.\sin\left(\arctan\left(\frac{H_B}{H_{\text{г}}}\right)\right),$$

$$\rho_x = \sqrt[2]{{X_{\text{п}}}^2 + {Y_{\text{п}}}^2} * cos(arctan\left(\frac{H_B}{H_{\text{г}}}\right)); \qquad (2)$$

$$\rho_y = \sqrt[2]{{X_{\text{п}}}^2 + {Y_{\text{п}}}^2} * sin(arctan\left(\frac{H_B}{H_{\text{г}}}\right)).$$

Where, $X_{\text{п}}$ and $Y_{\text{п}} -$ are the pixel coordinates corresponding to linear motion, x and $y -$ are the Earth-Fixed axis coordinates; Πx and $\Pi y -$ are the scale coefficients, ρ_x and $\rho_y -$ are the pixel coordinates representing the rotational motion (roll and pitch angles); $H_{\text{г}}$ and $H_{\text{B}} -$ are the horizontal and vertical distance to Earth-axis coordinate in 2D mode.

3 Application of Photogrammetry

The following initial data were taken into consideration prior to launching the photogrammetry task. The construction plot is 416 Km^2, the average ground sampling distance or the distance between two consecutive pixel centers measured on the ground is 3.39 cm. The bigger the value of the image Ground Sampling Distance (GSD), the lower the spatial resolution of the image and the less visible details. The GSD is related to the flight height: the higher the altitude of the flight, the bigger the GSD value. The median of key points per image or the key points that are characteristic and can be detected on the images are 38981 key points per image. In total 1542 images were taken.

Based on equations (1) and (2), it could be retrieved that 1536 out of 1542 pictures could be processed considering the 60-degree angle introduced to install the camera on the UAV-axis. As such 0.94% relative difference between initial and optimized internal camera parameters can be computed (fig. 2).

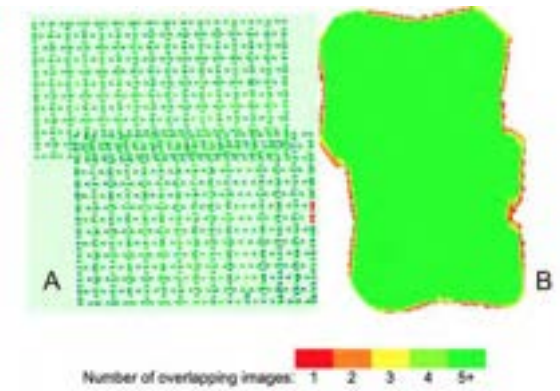

Figure 2. Offset results

Fig. 2 (A) shows the offset between initial (blue dots) and computed (green dots) image positions as well as the offset between the Ground Control Points (GCPs) initial positions (blue crosses) and their computed positions (green crosses) in the top-view (XY plane), front-view (XZ plane), and side-view (YZ plane). Red dots indicate disabled or uncalibrated images. Dark green ellipses indicate the absolute position uncertainty of the bundle block adjustment result. (B) shows the number of overlapping images computed for each pixel of the orthomosaic. Red and yellow areas indicate low overlap for which poor results may be generated. Green areas indicate an overlap of over 5 images for every pixel. Good quality results will be generated as long as the number of key point matches is also sufficient for these areas.

Fig. 3 shows the computed image positions with links between matched images. The darkness of the links indicates the number of matched 2D key points between the images. Bright links indicate weak links and require manual tie points or more images. The absolute geolocation variance shows the following:

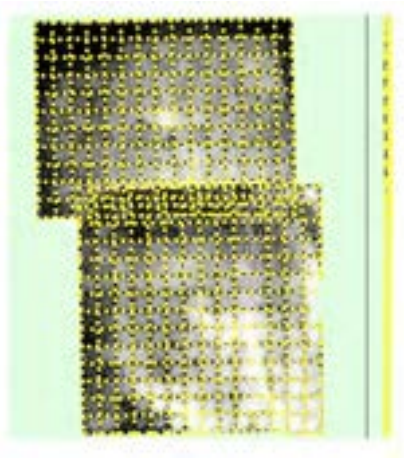

Figure 3. Links between matched images

Table 1. Absolute Geolocation Variance

Min Error [m]	**Max Error [m]**	**Geolocation Error x [%]**	**Geolocation Error y [%]**	**Geolocation Error z [%]**
-15	-12	0	0	0
-12	-9	0	0	0
-9	-6	0	0	0
-6	-3	0	0	0
-3	0	0.39	0	1.24
0	3	47.79	54.62	50.26
3	6	51.17	44.79	46.94
6	9	0.65	0.59	1.56
9	12	0	0	0
12	15	0	0	0
15	-	0	0	0
Mean [m]		**0**	**0**	**0**
Sigma [m]		**1.2513**	**1.2472**	**1.324**
RMS Error [m]		**1.2513**	**1.2472**	**1.324**

Where, Sigma is The standard deviation of the error in each direction (X,Y,Z) and RMS is the Root Mean Square error in each direction (X,Y,Z).

As the geolocation error is the difference between the initial and computed image positions, it should be stated that the image geolocation errors do not correspond to the accuracy of the observed 3D points. Min Error and Max Error represent geolocation error intervals between -1.5 and 1.5 times the maximum accuracy of all the images. Columns X, Y, Z show the percentage of images with geolocation errors within the predefined error intervals.

Table 2. Geolocation RMS Error

Geological Orientational Variance	RMS [degree]
Omega (roll)	2.006
Phi (Pitch)	1.901
Kappa (Yaw)	4.575

The geological orientational variance can be computed to define the Root Mean Square (RMS) in terms of degrees for the roll, pitch and yaw angles. Geolocation RMS error of the orientation angles identifies the difference between the initial and computed image orientation angles.

Figure 4. Orthomosaic Model of Construction Plot

4 Conlusion

The translating results from 2D orthomosaic to 3D Mesh shows several results. Firstly, as the proposed capturing angle is 60 degree and it is not assisted with any other capturing devices such as NADIR, the calibration of the images will be limited to the rendering algorithm. The first step is to produce mesh points obtained in Fig. 2 and Fig. 3 respectively. The result is shown in Fig. 5 along with the mesh textures.

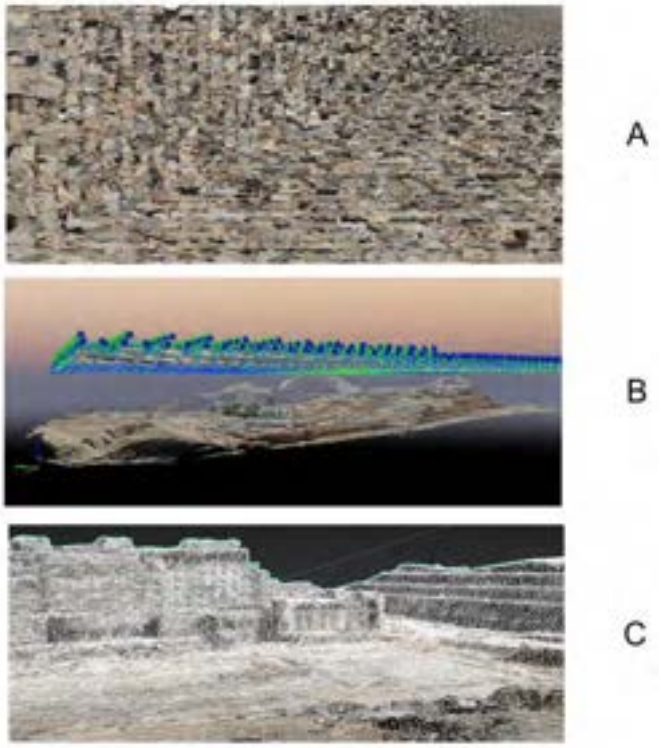

Figure 5. 3D Mesh and Texturing

The latter will be used to skin the mesh geometries, so the façades of the orthomosaic will reflect the actual status of the construction site. Lastly, the 3D model is rendered and illustrated in fig. 6.

Figure 6. Rendered 3D model

Abstract –

To inspect Road Tunnels every five-years is obliged in Japan, because for managing base the LCC (Life cycle cost). However, there are serious issues that not enough of engineer and budget to maintenance, so new technology for growing inspect efficiency is desired.

To solve these issues, we developed Tunnel full section inspection system within Crack measurement unit, Hammering unit and Protective frame. Our target tunnel of this system was one-lane on one side road tunnel, so especially protective Frame was designed for this kind of section. On the other hand, it needs to huge modify the frame to apply for another shaped section tunnel for example two-lane on one side road or train tunnel.

Therefore to expand application these inspection system, we developed the tunnel inspection system to apply varied tunnel section with mounted on aerial work vehicle. In this paper, we report the result of field application at two different shaped section tunnel with this system.

Keywords –

Inspection; Tunnel; Field application

1 Introduction

In Japan, many infrastructure face ageing issue. Especially half of road tunnels will over 50 age in 2033. Now in Japan, road tunnel must be inspected every five-years based on the road laws, because for managing base the LCC (Life cycle cost) [1]. However, there are serious issues that there are not enough of engineer and budget to maintenance, so new technology for growing inspect efficiency is desired.

From these background, we developed Tunnel full section inspection system (hereinafter, referred to as Full-Section-System) within Crack measurement unit, Hammering unit and Protective frame as in Figure 1 [2] [3]. Our target tunnel of Full-Section-System, especially the shape and size of Protective frame was designed for one-lane on one side road tunnel, because this size of road tunnels are major type at country areas in Japan.

Full-Section-System has advantages as follows.

- Protective frame secured space through which the vehicle can pass.
- To inspect full section of tunnel at one time.
- To avoid accident with falling concrete piece or another material under inspection by Protective frame.

On the other hand, Full-Section-System was designed for one-lane on one side road tunnel, therefore it needs huge modify to apply another shaped section tunnel for example two-lane on one side road. Add another thing, component parts of Full-Section-System are huge, so high transport cost and long preparing time at inspection site are taken.

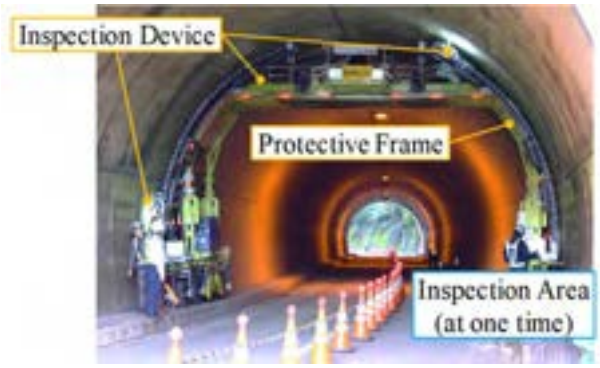

Figure 1. Full-Section-System

Figure 2. Half-Section-System

We thought these are the weak points of expansion of application. So to apply this system to many shaped section tunnel, we started to develop another type of frame as second generation system. The concept of development for second generation are as follows.

- To design flexible rail that easy to adjust for many section types of tunnel.
- Decrease component parts for easy to transport.
- Reduce preparation time at inspection site.
- To increase mobility, use truck based vehicle, instead of Protective frame.

The Gen2 of tunnel inspection system (hereinafter, referred to as Half-Section-System) as in Figure 2.

2 Outline of System

Functions of Half-Section-System are as follows, specifications of Half-Section-System are as in Table 1.

2.1 Flexible Rail

A number of curved rail are connected, top of rail is flexible and rail angle can be adjust by jack mechanism to fit tunnel shape as in Figure 3. Flexible rail and base frame need be compatible to stiffness and lightweight, so there were designed with FEM analysis as Figure 4.

2.2 Transferring Mechanism

Inspection devices are mounted on the tram, and the tram can move up and down by winch as in Figure 5. The caster of tram rolls on inner of lip channel steel, transferring condition is smooth, silent and stable.

2.3 Inspection Device

Crack measurement unit and Hammering unit are mounted on the tram as in Figure 5. We can obtain information of cracks and efflorescence by Crack measurement unit, and we can obtain information of spalling concrete by Hammering unit, these information are detected automatically.

2.4 Base Vehicle

The frame of Half-Section-System mounts on base vehicle with boom and roller type outrigger, it can be easy to set and adjust inspection device to tunnel surface and can drive without storing the outrigger and boom.

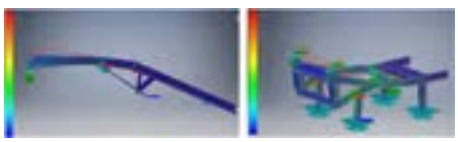

Figure 4. FEM analysis for Rail and Base Frame

Table 1. Specifications of Half-Section-System

Item	Specification
Rail Length	10.2m *1
Applicable Tunnel Inner Radius	R3.5~6.5m *1
Weight	Total 800kg *2 Device 50kg *3
Inspection Speed	9.0m^2/min *4
Inspection Width	600mm/scan
Resolution of Crack Width	0.2mm
Width of Hammering Interval	150mm *5

*1 Rail length and radius are adjustable if needed.
*2 Frame, inspection devices, control board are included, without aerial work vehicle.
*3 Transportable device weight by Tram.
*4 Set up time is excluded.
*5 Hammering interval can be adjustable.

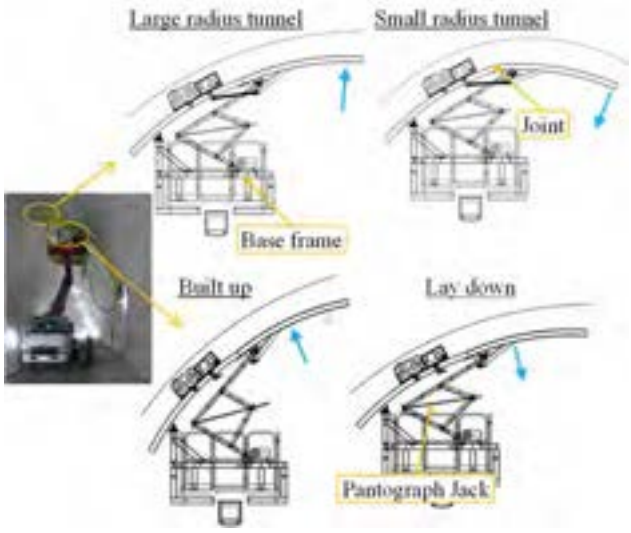

Figure 3. Function of Flexible Rail

Figure 5. Mechanism of Inspection Device Transfer

3 Outline of Inspection

We applied Half-Section-System to two types of tunnels. Type A is wide section for road tunnel, Type B is tall section for train tunnel. To compare the inspection results, conventional methods inspection by engineer was conducted at same time. Both of them were inspected as completion inspection. These tunnel's specifications are as in Figure 6, 7 and Table 2, 3.

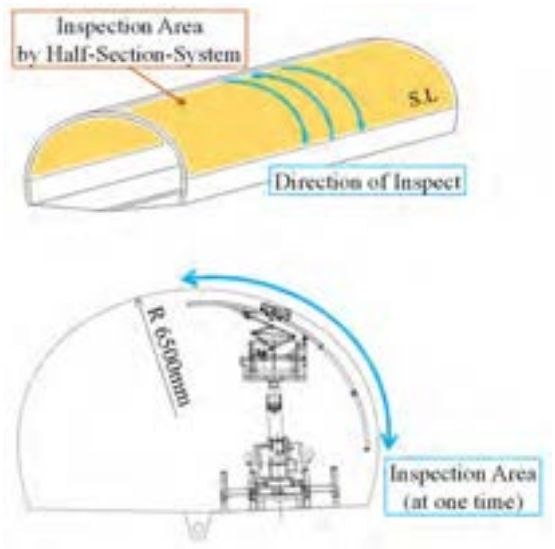

Figure 6. [Type A] Inspect area and Appearance

Application	Train
Construction Method	NATM
Condition	New construction
Road condition	Pavement surface
Inspect area by Half-Section-System	Around the Joint of Lining Concrete *1

*1 the other area was inspected by another methods.

4 Results of Field Application

We inspected two types of Tunnel by Half-Section-System, and we evaluated the results about flexibility, mobility, inspection results comparison between system and engineer and work efficiency (Field work, office work) as follows.

4.1 Flexibility and Mobility

One of concept of Half-Section-System is general versatility, so we designed the frame and flexible rail could be mounted on base vehicle. Then we could inspect two different types of tunnel by one type rail with adjustable mechanism.

Frame, rail and control box of Half-Section-System are compact, so we could transport and assemble by one truck with crane. And another thing, lower section of rails are foldable without crane or another heavy machine. Half-Section-System was able to fold rail and U-turn in the tunnel, so we confirmed that Half-Section-System has high mobility. System transport, assemble and foldable rail are as Figure 8. Results from field applications, we make evaluation that flexibility, stiffness and mobility of Half-Section-System is generally well.

Figure 8. System Transport, Assemble and Foldable Rail of Half-Section-System

4.2 Inspection Results Comparison

We made an inspection results report inspected by Half-Section-System example of tunnel type A as Figure 9. There was no defect, so we reported as no cracks and no defected area.

Tunnel type B, there were few defects, so we compared results by Half-Section-System and by conventional methods (visual inspection and hammering by inspection engineer) as Figure 10.

For comparison, inspection result by Full-Section-System in 2018y is shown as Figure 11. This inspected tunnel is different from type A and type B.

By the comparison, cracks and spalling concrete were detected at same area in both inspection. In report of Half-Section-System, three cracks were detected. It was assumed that crack I and II were connected at out of inspect area and were same as crack A by conventional methods. We assumed that maximum width of crack A was out of inspect area of Half-Section-System, this was the reason that width had difference in between crack I, II and A, we thought.

It was assumed that spalling concrete Ⅳ and spalling concrete B were the same. However the detected length of both were difference (Ⅳ: 0.6m, B: 2.8m). In this case, the detection of spalling concrete was judged by hammering inspect. However, hammering point of Half-Section-System was approx.65mm near the edge of joint. So, if the spalling concrete was located on less 65mm area from edge of joint, it had possibility to be undetected by Half-Section-System. We thought this is the reason detected area of Half-Section-System was shorter than detected by inspector.

We assumed that crack 3 and spalling concrete C were same defect, though both of them were detected another category. In fact, this defect had step and ditch near the joint, so Crack measurement unit could find this spalling concrete as crack. However, Hammering unit could not detect this defect, because spalling concrete was too near to the joint to hammering.

There are some difference in inspected results between system and engineer, however accuracy of inspection results by Half-Section-System are enough to judge the soundness of tunnel.

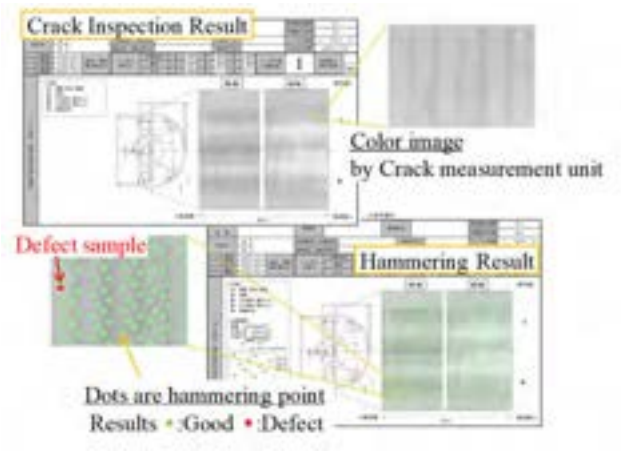

Figure 9. [Type A] Example of Inspection report

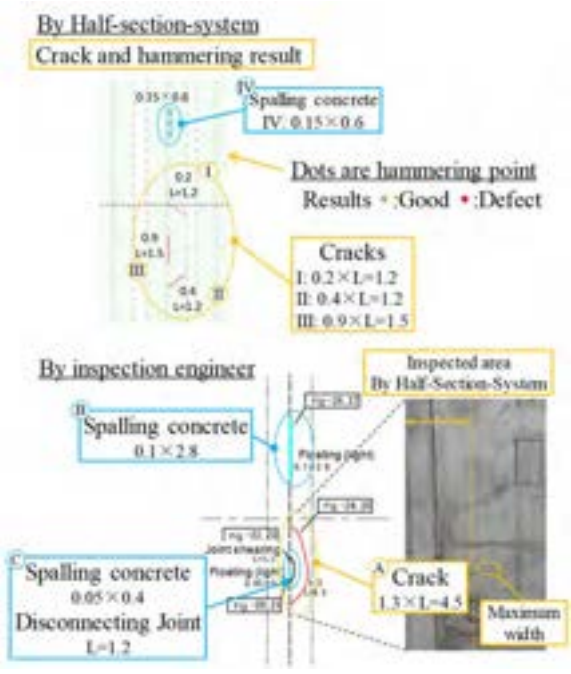

Figure 10. [Type B] Comparison results between by Half-Section-System and by Inspection Engineer

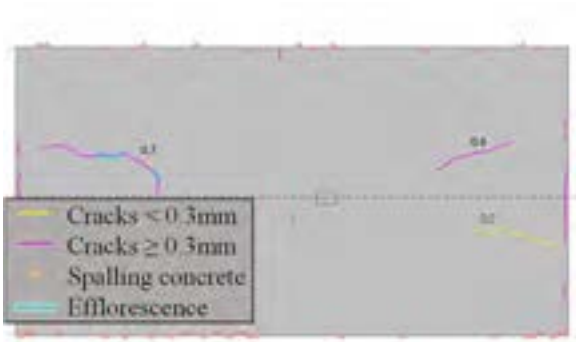

Figure 11. Example results by Full-Section-System in 2018y

From comparison results between Half-Section-System and Full-Section-System, the minimum detected crack width are 0.2mm, so we assume the preciseness of inspection are almost equal between two types of systems.

4.3 Work efficiency (Field work)

We evaluated work efficiency of field work by comparison with estimate and actual work time as Table 4. In table 5, we compared about assemble/disassemble time with Full-section-system and Half-section-system, and compared about inspection time with conventional methods at type B tunnel and Half-section-system.

Especially "Reduce preparation time" was one of the target of Half-Section-System. Working time of assemble and disassemble were shorter than Full-section-system, it means almost satisfied with our target, however actual inspection time were longer than conventional methods.

So we analyzed inspection time of Half-section-system about two types of tunnel as Figure 12. In this chart, "Inspection" means inspection time only. "Drive/Positioning" includes time to drive the vehicle and to position to prepare to inspect next line. "Adjust/Preparing" includes preparation before start working, warming up the system, maintenance the system and daily cleanup. "Fixing" includes repair the system or replace to spare parts if trouble.

"Drive/Positioning" time of Type B is longer than type A, because total drive distance of type B is longer than type A. However, we think "Drive/Positioning" time is too long, Type A is almost 15% of total inspection time and Type B is over 40%, and this process has room for improvement.

" Fixing" time of type B took long, because hammering unit had a breakdown about inner connection trouble of control unit in large part. So it is necessary to improve reliability about these trouble.

Table 4. Detail of work time (Half-section-system)

	Item	Working hours (Hrs.) Estimate	Actual
Type A	Assemble	4.0	5.8
	Inspection (Total)	56.0	99.1
	Inspection	-	48.0
	Drive/Positioning	-	13.8
	Adjust/Preparing	-	31.8
	Fixing	-	5.5
	Disassemble	4.0	3.5
Type B	Assemble	4.0	4.0
	Inspection(Total)	80.0	120.9
	Inspection	-	20.9
	Drive/Positioning	-	51.7
	Adjust/Preparing	-	19.4
	Fixing	-	28.9
	Disassemble	4.0	3.0

Table 5. Working time comparison

For comparison	Working hours (Hrs.)
Assemble	
Full-section-system in 2018y	7.6
Half-section-system [Type B]	4.0 (-47%)
Inspection	
Conventional methods [Type B]	96.0 *1
Half-section-system [Type B]	120.9 (+26%)
Disassemble	
Full-section-system in 2018y	4.8
Half-section-system [type B]	3.0 (-38%)

*1 3teams × 4days (8Hrs/day)

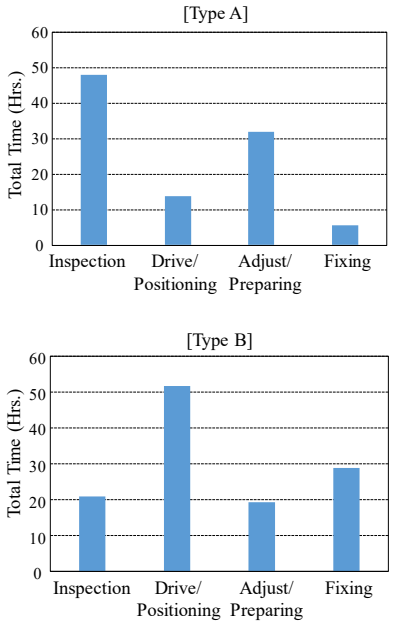

Figure 12. Breakdown of Inspection Time

There are some points need to improve to reduce "Drive/Positioning" time, especially positioning process, as follows and Figure 13.

- Add the target by laser marker line, to help positioning at tunnel lining wall.
- Add angle-meter to notice tilt of rail to operator in control monitor by value.
- Add distance value to inspected data measured by road measure, to help to prepare inspection report by automatically.

Figure 13. Improvement Plan for Reducing Work Time

4.4 Work efficiency (Office work)

We obtained defect information, cracks by Crack inspection device and peel at surface layer by Hammering inspection device, by Half-Section-System automatically. However the office work for preparing inspection report is almost manually, so there is few merit for office work at this time.

We think that automation of inspection report creation is essential for social implementation. So we will plan to prepare inspection report automatically.

5 Conclusion

In this paper, we evaluated Half-Section-System at two types of tunnel and concluded as follows.

- Working time of assemble/disassemble at field was approx. 40% shorter than Full-section-system of it.
- Confirmed general versatility, flexibility and mobility of Half-Section-System.
- Obtained inspection results enough to judge the soundness of tunnel, and preciseness of inspection is almost equal as Full-Section-System.
- Working time of inspection was approx. 26% longer than conventional methods (inspect by engineer). So especially positioning process needs to improve to reduce work time at field.
- Automation of inspection report creation is essential for social implementation.

In the future, we will develop work efficiency at field and at office.

On field work, our plan is to add sensor and target to frame, our target time of positioning process is half than current process. By this improvement, the working time of Half-section-system will be shorter than conventional methods.

On office work, our plan is to make software, our target is automatic process of making inspection report. That means, first input to software the data inspected by device, then picture and defect data are arranged automatically by software, finally inspector analyses and determines the soundness of tunnel by arranged data.

Our goal from these improvement is, total inspection cost of Half-section-system will be competitive than standard cost of conventional methods, so Half-section-system will solve the tunnel inspection issues that not enough of engineer and budget of inspection.

This result is part of accomplishment supported by Council for Science, Technology and innovation, "Cross-ministerial Strategic Innovation Promotion program (SIP), Infrastructure maintenance Renovation, and Management" in 2014-2018. (Funding agency: NEDO)

Challenges in Capturing and Processing UAV based Photographic Data From Construction Sites

Saurabh Gupta[a] and Syam Nair[b]

[a,b] Department of Civil Engineering, Indian Institute of Technology Kanpur, India
E-mail: saurabg@iitk.ac.in, syamnair@iitk.ac.in

Abstract– Construction industry is going through a paradigm shift where remote data collection approaches are replacing manual processes that are presently being followed in construction related activities. Unmanned Aerial Vehicles (UAV) are being engaged in various construction applications, like real-time supervision, progress evaluation, surveys, mapping, safety evaluations etc. The paper discusses some of the typical challenges related to operations, data acquisition, and post-processing of data collected using UAV when used in civil engineering applications. Issues related to obstructions, reflection, illuminations, lighting condition, blurred image data, inaccuracies in georeferenced image data etc. are discussed and possible solutions suggested based on a field study. A DJI Phantom 4 Pro V2.0 was used in data collection and the solutions for various issues identified from literature were evaluated and discussed based on collected field data. Feasible solutions for the above mentioned problems are also discussed and presented.

Keywords– Image Recordings; Recording Challenges; Construction Site Monitoring; Photogrammetry; UAV data processing challenges

1 Introduction

Over the last decade, use of Unmanned Arial Vehicles (UAV) in civilian activities have increased rapidly which ranges from infrastructure development to surveillance, goods delivery, agricultural, mining and many more [1]. Infrastructure development sector has started using UAVs in construction related activities like progress monitoring, surveying, aerial photography and surveillance, visual inspections, safety inspections, quantity take-off and estimation, defect and damage detection etc. [2]. Visual monitoring using camera equipped UAV is being used in earthwork measurement, damage assessment on structure, archeological site survey, safety planning and monitoring in high rise building construction, pavement distress detection, bridge inspections etc. [3, 4, 5, 6, 7, 8]. Utility of UAV data is not limited to construction monitoring at large, but can be extended for use in ortho-mapping, model development (digital elevation model, digital surface model), augmented reality models, 3D plans for structure, mesh model etc., using point cloud data generated from digital images [9, 10]. Use of UAV based photogrammetric data has now become the preferred option for civil engineers due to the diverse utility, accuracy, cost effectiveness and pace of data collection when compared to manual survey options used earlier. Efforts to adopt new and innovative technologies often encounter issues related to implementation, processing and data extraction which needs to be identified and solved in order to inculcate these approaches in construction activities. The objective of this study is to enumerate operational, data collection and post processing challenges while working with UAV data and to identify and evaluate feasible solutions from literature using field data.

2 Methodology

Challenges while working with UAV can broadly be classified into three categories (Figure 1). Section 3 of the paper addresses operational challenges which primarily include challenges in flight planning, like trajectory planning for cost minimization, avoiding data redundancy, occlusions, etc. [4]. Trajectory decisions often depend on the chosen flying height and required image overlay, details of which are included in section 3. Section 4 discusses the data collection issues related to occlusion, reflection, shadows etc. Issues encountered while working with blind spots, poor lighting conditions, similarity in object texture etc. during image processing is also discussed. Post-processing issues like blurred image, coordinate errors etc. are discussed briefly in section 5 of this paper.

3 Operational Issues

Flight planning for data collection involves trajectory planning, selection of data collection mode (manual or auto), deciding coverage area, selecting required image overlap etc., while accounting for logistical issues like, flight time, clearances, climatic issues etc. Trajectory is the path followed in data collection which often is the shortest route that can capture all required details along the project location. Selection of trajectory is often based

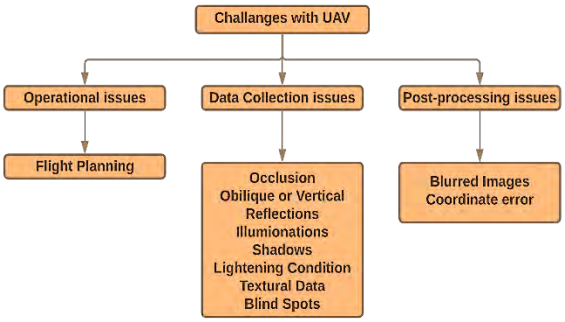

Figure 1. Classification of Challenges on working with UAV [4][5].

on optimizing coverage with minimal occlusions at the site. Even though trajectory is meant to cover maximum feature points of components falling in field of view (FOV) of UAV, pertinent details sometimes gets occluded as observed in schematic diagram (Figure 2). Semsch et al. (2009) in their study using multiple UAVs tried to identify the shortest trajectory that covers maximum feature points. After determining the starting points of UAVs, a surveillance algorithm which runs independently was used without any further coordination between the two trajectories. The occlusion-aware control mechanism developed during the study can be effective in trajectory planning for UAV-based data collection [11].

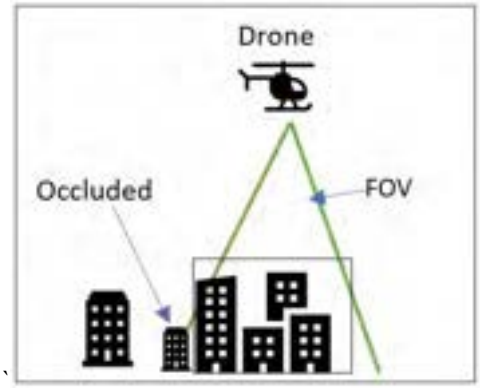

Figure 2. Graphical representation of occlusion in the FOV.

Parameters like shortest trajectory, battery constraints are also variables that need to be considered during trajectory planning which are often equipment specific due to variations in pay load capacity, flying time etc. Factors like lighting conditions, speed and shutter timing, and relative location of light source etc. need to be accounted for before actual data collection. Logistics issues like obtaining flying clearances, permissions based on the size and weight of different UAVs, etc. often varies across countries, details of which are explained and compared by Shrivastava et al. (2019). Information/details required while seeking permission for aerial survey from concerned authorities are also addressed by the authors [1].

4 Data Collection Issues

Issue related to data collection is discussed below with probable solutions.

4.1 Occlusions: Clutter, Auxiliary equipment's

Construction sites are often congested and cluttered with equipments which can lead to occlusions while collecting data remotely. Occlusions can be of two types (a) static occlusions and (b) dynamic occlusion [12, 13]. Static occlusions include missing data points due to stationary objects like formwork, scaffolding etc. whereas missing data points due to movement of workers, moving construction equipment's etc. can be considered as dynamic occlusions as illustrated in figure 2 and 3 [6] [7].

Construction sites are dynamic in nature which can lead to poor registration of dataset during progressive data collection. Given in Figure 3, is an issue related to dynamic occlusion while capturing data for foundation work at a construction site. While calculating quantity of earthwork from day 1 and day 2, occlusion due to auxiliary equipment in captured data set can lead to errors in estimated quantities. The data is also difficult to register with previously collected data set.

Figure 3. Example of dynamic occlusion

Images presented in Figure 4 explains issues related to dynamic occlusion in data collected for construction monitoring at site. Some of the ground control points (GCPs) is covered with construction materials, while few are occluded by clutters. Randomness, prompted by ease of construction, in positioning and arrangement of materials at construction site can lead to dynamic occlusions and difficulties in registration. Manual data processing techniques can address these errors to certain extent by eliminating identical objects with variable data sets from captured images or by registering only common points in both the data sets. However, issues may arise

especially while using automated or unsupervised data processing algorithms.

Figure 4. (a) Marked GCP at construction site and (b) GCP occluded due to site activities.

Solution: Researchers presented different solutions to address dynamic occlusions ranging from 2D image processing to 3D photogrammetric techniques. The data collected for generating meshes and point cloud may have disturbances due to similarity in colors of objects at site, say, scaffoldings vs other structural components. Xu et al. [8] presented a solution for eliminating similar issues using fast point feature histogram (FPFH) and random forest classification algorithms. Point cloud data were classified with linear fitting algorithm and by using the signature of histograms of orientations (SHOT) algorithm to detect the shape to make the results more accurate. Golparvar-Fard et al. used an alternate approach where instead of the fixed camera location, photographs were captured in a random/unordered manner from nearby locations to avoid occlusion. Using structure from motion (SfM) technique thereafter helps removing small occlusion automatically, and the generated point clouds will not require any post-processing [9].

Tuttas et al. (2014) used construction logics and precedence charts, which assume completion of severely occluded construction elements based on the completion of dependent elements [10]. Another option in addressing dynamic occlusion is through point picking method where the selected points can be easily recognized and registered when executed manually. The approach works around locating common points in different images and use them as tie point for creating dense point cloud. Photogrammetric software's that can automate point picking approach are also available which saves time and can register more feature points. This method is further modified by Kim et al. (2013) using machine learning (ML) approach for comparing as-built vs. as-planned data sets. They used supervised learning Lalonde feature (which is a 3-dimensional vector that can be used to detect linearity, surface uniformity, and scatter of a 3D data set) and extracted structural components out from the data set. The assessment is based on the extracting data set of structural components only and neglecting feature points related to an auxiliary equipment causing occlusion [11].

Since construction sites and too complex and dynamic to handle, researchers have attempted many pre-processing and post-processing strategies to overcome clutter and dynamic occlusions while processing captured data. A simplified approach followed during data collection is to alter the time of data collection, subject to construction schedule, so that dynamic occlusion such as moving personnel and equipment can be avoided [6]. Another approach is to consider dynamic occlusion as a static if they are stationary in multiple data sets. A good example would be a welding machinery for steel construction held in one location for many days while working personal uses it for nearby locations. Approaches mentioned below to remove static occlusions can be applicable in this case.

Static occlusion on the other hand can be solved by adopting proper flight planning techniques and recording strategy. Trial and error approach are also being followed in many cases, where trial trajectories are used to identify areas where potential static occlusions may affect the registration. Trajectories are then modified to cover maximum details pertaining to objects relevant for assessment. A simulation study by Semsch et al. (2009) shows possibilities of managing occlusion, by testing trajectory even before flying. A good example would be AgentFly UAV simulation testbed which can be used to model a real world to create a framework for flight planning and collision avoidance [4]. Figure 5 shows a similar issue related to static occlusion in field which was overcome by using multiple trajectories.

Another approach in reducing registration inaccuracies is to ensure a large overlap between two data set, which helps increases the number of feature points. The feature point are higher in figure 6(b) as the number of occlusions reduced by changing the trajectory of the UAV [5].

Figure 5. (a) Occlusion due to structural component, (b) occlusion avoided using different UAV trajectory.

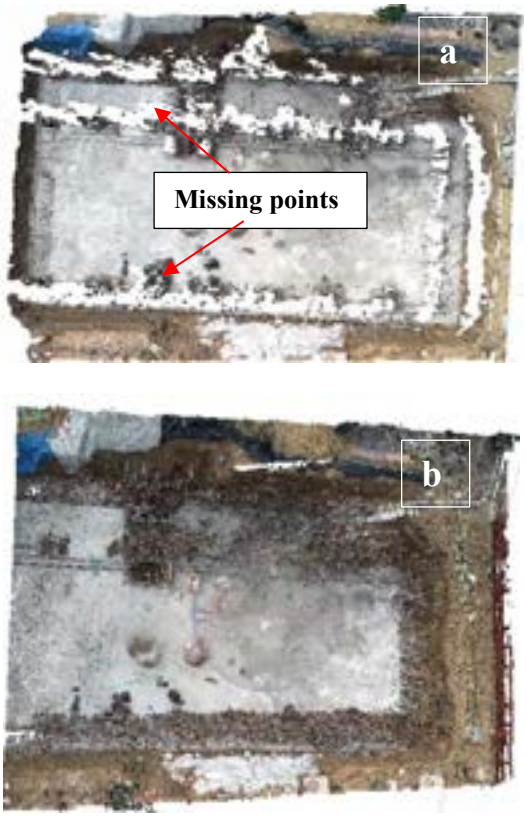

Figure 6. showing (a) missing cloud points due to occlusion (b) missing point filled up using images from modified trajectory.

4.2 Issues related to camera positioning

Aerial photographs captured using UAV can either be vertical or oblique. A vertical photograph can be taken by keeping the camera's optical axis in a direction perpendicular to the ground surface, whereas in oblique photography the camera's optical axis carries a depression angle (angle at which the optical axis is depressed below the imaginary horizontal line drawn along the camera axis) between 0º and 45º [12] [13]. Figure 7 shows a schematic representation for vertical and oblique photography.

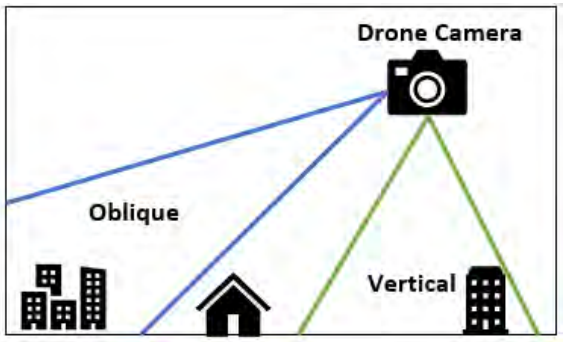

Figure 7. Representation of vertical and oblique coverage.**Solutions:** Vertical photography is beneficial in creating ortho-images that can be superimposed on the digital plan of structure for comparison. Oblique image is useful in capturing facades of structure. For vertical photography, the scale always remains a constant whereas oblique photography can have a variable coverage depending on the inclination angle of camera. If GPS or RTK option is available in UAV, images can be geotagged which eliminates scaling issues in oblique images. Rao et. al. (2018) observed 3D model reconstructed from oblique photography to be more precise and less noisy when compared to models based on vertical photogrammetry [14]. Table 1: Comparison between points generated by oblique and vertical images.

Parameters	Vertical images	Oblique images
No. of images	4	4
Processing time	49 sec	60Sec
Accuracy	Medium	Medium
No. of points	1531286	1648910

Table 1. above shows details of parameters used in capturing images using a stationary UAV to develop point cloud showing differences in data set generated due to camera positioning. Point cloud data shown in figure 8 was generated using oblique and vertical images captured using a DJI Phantom 4 Pro V2.0 with 3-axis (pitch, roll, yaw) gimbal flying at a height of 30 m.

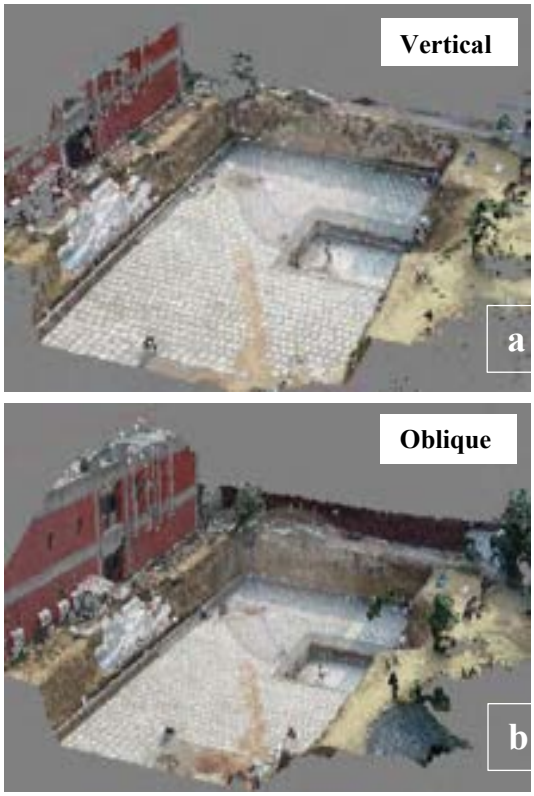

Figure 8. 3D point cloud model of the vertical and oblique images.3D point cloud model shown in Figure 8 suggest models developed using oblique images to have more coverage and feature points. The number of data points generated were also high in case of oblique images as shown in table 1. The results are in agreement with observations by previous researchers where the angle between ground and the camera was found to significantly affects the density of point cloud generated [21, 22]. Aicardi et al. (2016) and Chen et al. (2017) recommend using an inclination angle of 0° to 30° for obtaining dense data clouds as the points density start decreasing for angles above 30°.

4.3 Illumination, Reflections & Shadows

Processing reflections and shadows in photographic images poses another challenge while working with these datasets. Illumination and reflections may arise due to light scattering, textural properties of materials, or differences in site conditions. These can affect the final data at the time of processing, due to pixel value changes on similar objects leading to inaccurate point cloud generation. Shadows generated due to location of light source can also influence the accuracy of final data set.

Solutions: There are no literature available, to the best of our knowledge, towards addressing issues related to reflections and shadows in captured images. Since reflections are primarily dependent on the position of light source, use of SfM approach can be a feasible option to address this issue (figure 9 [a, b]). Selection of vertical image capturing option instead of oblique photography can also be effective in certain cases. However, the final solution is very much site dependent and the choice has to be made on a case by case manner.

However, Partama et al. (2018) suggested an alternate post processing approach to eliminate reflections and shadows, where videography was chosen over photographs, and ideal frames were extracted for processing. Since the UAV was moving continuously, the frames obtained from the video had different extrinsic properties where pixel values of objects at a given location keep changing in extracted frames. The discrepancy was adjusted using a temporal minimum filter algorithm to extract data points with smaller RGB pixel values, thereby eliminating the effect of reflection leading to an increase in RGB value [15].

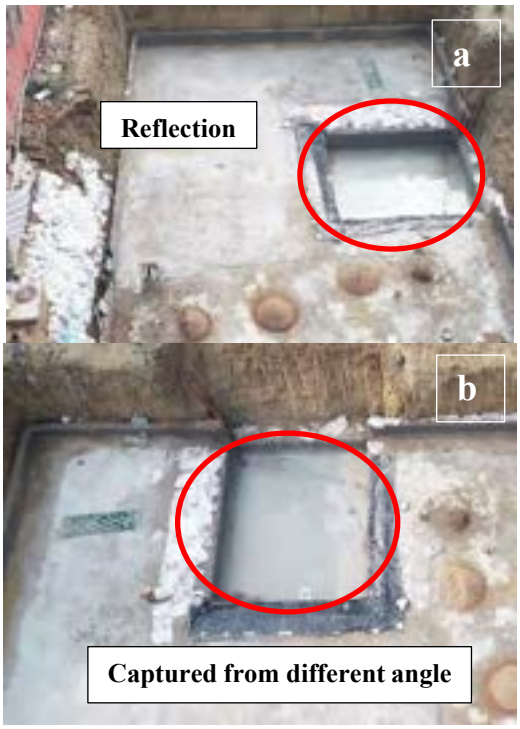

Figure 9. (a) reflection due to water (b) reflection avoided by trajectory modification

Since there are limited options available to address the issue related to shadows, two simplified approaches are generally followed during data capturing where trajectory modifications or camera positioning are altered to minimize the effect of shadows on the data set. A comparison of images collected using trajectory modification approach is included in figure 9 [a,b]. Even though selective post-processing strategies are being used to eliminate the effect of shadows, the process is time consuming and computationally heavy [16]. In summary, since the efficacy of strategies adopted to address reflection, shadows and illuminations can vary depending on site conditions, suggesting a unique

solution to address the problem may not be possible.

4.4 Lightening condition:

Difference in lighting condition can arise locally due to weather conditions or due to local features restricting light availability. Wierzbicki et al. (2015) observed a 25 percent reduction in point cloud density on using data from ortho-images collected during poor weather conditions [17].

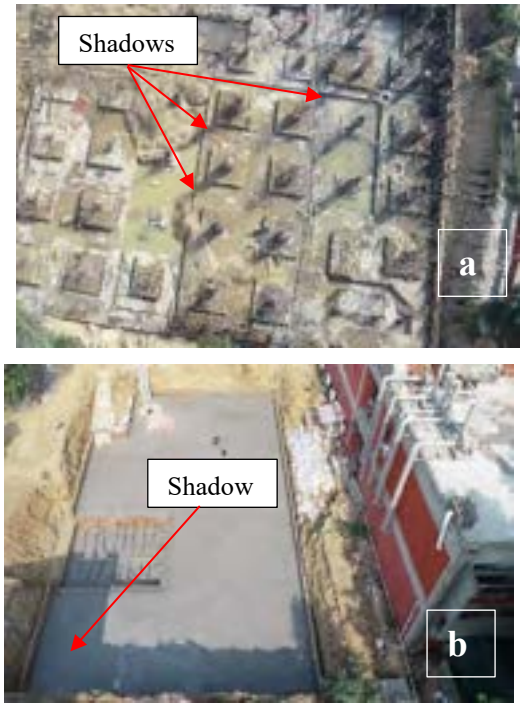

Figure 10. (a) Multiple shadows due to structural elements (b) Shadows due to adjacent structures

Since lighting issues can affect quality of the collected data, a common approach followed is to increase ISO values of photographs. This approach may not be feasible for UAVs as the proportionate increase in image capturing time can result in noise generation or motion blur due to stability issues in UAVs. Differences in lighting condition can also result in over/under exposure of images from FOV resulting in quality issues on point clouds generated.

Solutions: Even though artificial lightning can be a solution, the idea may not be feasible for all locations and often not cost effective (Perfetti et al., 2017). Efficacy of vehicle mounted lighting will also depend on power/battery/payload constraints of the UAV used. Improving quality using artificial lighting can have range limitations, as it can give a better quality image of elements in the foreground as against a noisy image for background elements. Other option is to increase ISO sensitivity and slowing down the shutter speed. ISO sensitivity represent the camera's ability of capturing light. The captured light is then converted into electrical signals, and by amplifying the signals the ISO sensitivity can be increased. Even though ISO changes allow us to capture images with many feature points, a reduced shutter speed slow down the data collection process (due to the additional time taken by cameras to adjust to the changes). Increase ISO can also lead to noise, grains, and blur which also get amplified with the signals. Method of changing ISO may not always be beneficial while aligning images for processing as the available feature points vary significantly with luminosity factor due to differences in captured pixel properties [18]. Use of High Dynamic Range (HDR) techniques can result in motion blur due to the longer exposure time required for capturing images. Hence the option may work reasonably only in cases were vehicle movements can be controlled manually.

4.5 Textural data

Properties of pixels in raster image captured from UAVs is dependent on texture of the object. Processing images of objects with quasi-uniform color, say concrete, is often challenging as distinctive feature point are hard to obtain. Hence feature points are often identified along edges and corner of the element which has different pixel values from the rest of the surface. The mesh generation and reconstruction from these data are often less accurate due to decrease in point cloud density.

Figure 11. 3D point cloud model of the under-construction foundation work.

Solutions: During field experiments, the authors came across issues due to reduced point density while performing dense reconstruction of objects with poor texture properties. Textural issues were also found to be dependent on lighting conditions as the quality of images reduces with deterioration in lighting as observed in point cloud data given in figure 11.

4.6 Blind Spots

Accessibility issues can create problems during data collection. Data collection on open construction sites like pavements are easier in comparison with data collection

on complex residential structure due to accessibility issues. The field of view (FOV) for UAV is limited and typically lies between 70° to 95° [19]. The coverage of an area also depends on the inclination angle of camera used during data collection. Figure 12 shows an example of a blind spot encountered by the author during field study.

Figure 12. Blind spot encountered during the field experiment.

Solutions Perfetti et al. (2017) suggested the use of wide angle lenses such as fisheye to enhance the FOV during data accusation [18]. However, the level of details achievable using this approach is often less than what is required for generating a dense point cloud. Use of vertical camera positioning instead of oblique positioning may help getting more feature points than by using a wide-angle lens.

5 Post-processing issues

5.1 Blurred Images

Since UAVs fly at a height of more than 30m to capture images, the captured data is often affected by wind, vibration and stability issues of UAV. In Blurred images, pixels get distorted; the RGB values and vectors of the image changes, which can all affect the quality of point cloud generated.

Solutions: Haar algorithm (HAAR), intentional blurring pixel difference algorithm (IBD), SIEDS (saturation image edge difference standard-deviation) are some of the available techniques to detect and remove blur from the images. Nobert et al. (2011) evaluated the effectiveness of SIEDS algorithm on two data sets collected using UAV and found the algorithm to be reliable in detecting blurred images [20][21].

5.2 Coordinate errors

Modern UAVs often have on board GPS that can create geotagged images and thereby generate geo tagged cloud points. However, problems can arise due to differences in latitude or longitude data for a given location in the dataset collected during multiple runs as the GPS may link with different set of satellites during individual runs.

Solutions: Use of real-time kinematics (RTK) in post-processing of data or use of local coordinate system instead of the global coordinate system can help overcome this issue [20].

6 Conclusion

Construction sites pose several challenges during collection and photogrammetric processing of images collected using UAVs. Use of occlusion-aware control mechanism developed by Semsch E. et al. (2009) may be an effective option for flight planning operations. Issues related to static and dynamic occlusions during data collection can be addressed in part by changing trajectory and angle of capturing data or by using machine learning approaches during post processing to remove irrelevant data points. Cloud density was observed to be higher when oblique images were used in point cloud generation when compared to vertical images. Even though density of point cloud may be compromised, mesh generation and reconstruction using edge and corner based feature points appears to be the only available option to segregate objects with similar textural properties. Discrepancies arising from differences in GPS coordinates may be addressed either by using RTK or a local coordinates system.

Abstract –

In 2014, a regular inspection of public infrastructure facilities (bridges, etc.) once every five years be-came a legal system. Of the approximately 730,000 bridges nationwide, 530,000 are small-scale bridges with a bridge length of 2-15m. These bridges are often not easily accessible by inspection engineers. Therefore, in this study, for the purpose of studying inspection methods as an alternative to visual inspection for small-scale bridges, development of inspection robots, examination of efficient methods for creating 3D CAD data, inspection using 3D models. We examined the results from four viewpoints, the management system of results and the extraction of damaged parts from photographs by AI. As a result of the research, we conducted demonstration experiments several times, arranged the scope of technology application according to the usage scene, and clarified the definition of functional requirements. This can be expected to contribute to the development of more efficient inspection, improvement of productivity, safety, etc. in future small-scale bridges, as a material for development for actual operation.

1 Introduction

In 2014, the Japanese Ministry of Land, Infrastructure, Transport and Tourism (MLIT) put in place regulations requiring periodic inspections of public infrastructure facilities (e.g., bridges) once every 5years [1]. This meant that municipally managed bridges that were not previously subject to regular inspections, were inspected all at once. Many of these bridges are relatively small and difficult to inspect. Provisions were often made for sites that could not be approached without risk to inspectors, such as use of various inspection equipment or adjustments of inspection timing, but even this was insufficient for some sites, resulting in “inspection impossible” categorization.

There are about 730,000 bridges in Japan, of which around 530,000 are small structures measuring 2–15 m in length. Many such small bridges are not easily accessible to inspectors, making visual inspections according to the designated procedure impossible. In 2019, the MLIT revised the inspection procedures, allowing them to be based primarily on close-up visual inspections, and permitting the use of new technologies for complementing or replacing close-up visual inspections by inspectors [2]. These revisions allowed conditional use of drones or robots for inspecting conditions at sites that are otherwise difficult to approach. Further, there are plans to develop guidelines on the use of new technologies, which requires the development of efficient inspection technologies and investigation into their scope of application.

2 Objectives and Methodologies

In this study, we conducted proof-of-concept experiments targeting various issues and risks for small bridges with the aim of investigating the scope of application of technologies according to usage scenarios, clarifying functional requirement definitions, and providing material for developments toward actual

operations.

We develop a robot for use in place of human visual inspections at sites that cannot be entered, or where entry is possible, but space is insufficient for inspections. Such a robot would likely be effective for application to various civil engineering structures, but in this study, we focus on its application to small bridges.

The implementation plan and focus of this study are as follows. To investigate and extract various issues and the scope of application, we conducted proof-of-concept experiments such as robot operation tests, data acquisition via mounted equipment, and post-processing tasks using the acquired data, and provided comments regarding their implementation.

2.1 Development of an inspection robot

Concerns surrounding safety, labor shortages in the construction industry due to low birthrates and the aging population, and a shortage of engineers in local governments have prompted active research and development of inspection robots for the purpose of more economical inspections. The MLIT has published materials on inspection support technologies [3], but most are related to the use of drones and target relatively large bridges. In this study, we developed a robot capable of entering beneath bride girders in place of a human.

2.1.1 Conditions

Based on our knowledge accumulated over 20 years of experience in bridge inspections and surveying tasks, we set the primary specifications for the robot as follows. A height of 70 cm is sufficient to allow human inspectors to enter the space beneath bridge girders but make it difficult to look up at the girders (slabs) that are the target of inspections. Figure 1 shows the state of inspection tasks for a bridge of the same scale as the bridges targeted in this study.

- The robot must be capable of entering and exiting a 70 cm space beneath bridge girders.
- It must be possible to mount cameras or other devices capable of recording damage.
- The robot must be capable of traversing over small rocks, mud, and other surface irregularities of up to several centimeters in size.

2.1.2 Implementation plan and focus

In developing the robot, we first selected usage scenarios for various issues such as expected operational environments, communication environments, and robot operations under low visibility situations. We next investigated what equipment should be installed. In proof-of-concept experiments, we first verified factors such as the operational performance of the robot, wireless communication quality between it and its controller, and the mounting position of the mounted devices, and then we varied and investigated types of mounted devices, their mounting positions, and settings for data acquisition methods. Figure 2 shows the robot developed in this study, and Table 1 lists its primary specifications.

Figure 1. Status of inspection work on small bridges

Figure 2. Developed robot and 3D CAD

Table 1. Primary specifications of the robot developed in this study

Specification	Value
Size	Width: 498mm/Depth: 592mm /Height: 375mm
Weight	4.0kg
Transmitter device	Futaba 14SG
Receiving device	COOLTECH R7008HV
Tire	140mm Off-road tires
Athletic performance	4WS

2.2 Efficient method for 3D model data creation

The MLIT has been carrying out common information model (CIM) tasks since 2012 and has confirmed information sharing and safety improvement effects among stakeholders using three-dimensional (3D) models during infrastructure design and at construction sites. Based on the CIM model creation specifications, Yamaoka et al. [4] , [5] verified usage methods in maintenance management using precise CIMs created at the design stage. Further, Shimizu et al. [6] developed a system for managing photographs taken during inspections in a 3D model. They also proposed a method for constructing 3D models by parametric modeling, and this method is highly effective for newly creating 3D models of existing bridges that are undergoing

maintenance and for which models do not exist. However, humans or drones generally take photographs in these cases, and there are no examples of creating 3D models from photographs taken beneath the girders of small bridges using an autonomous robot.

In this study, we therefore investigated methods by which data obtained from a robot entering the space beneath bridge girders can be easily and efficiently applied to creation of 3D model data. In bridge inspections as well, there are increasing opportunities for converting 2D image data into 3D point group data through "structure from motion" (SfM) processing, allowing creation of 3D model data. Specifically, a fixed laser scanner is used to interpolate complex forms that could not otherwise be acquired. These are conditions like those of the small bridges targeted in this study.

2.2.1 Conditions

Bridges are built in various forms, but we limit our focus to girder bridges with reinforced concrete slabs and box culvert bridges, which account for the majority of small bridges.

2.2.2 Implementation policy and focus

As an initial point of interest, it is important to acquire still images with sufficient overlap for performing SfM processing. We performed proof-of-concept experiments to investigate how such images can be acquired not by humans, but by robots. Specifically, we established photo acquisition methods (for still images and video), photo resolutions, overlap ratios, distances to the target structure, view angles, and the presence or absence of feature points, and evaluated accuracy for point cloud data generated through SfM processing under various environments.

For our second point of interest, we created 3D modeling data from the generated point cloud data. Currently, computer-aided design (CAD) engineers must select (click) arbitrary points among point cloud data to create line segments and surfaces based on their experience and knowledge of bridge construction and combine these to create 3D model data. This is a bottleneck because the process requires huge amounts of time and labor. We therefore investigated methods for performing this task more efficiently and with less effort.

2.3 Inspection results management using 3D models

We constructed a prototype support system for 3D damage map creation as a management method for accurate and reliable sharing of structural lifecycle information among facility managers, inspectors, and repair workers, and investigated its necessary functional requirements. As the development environment, we used Unity [7], an integrated game development environment by Unity Technologies that can handle 3D models.

Table 2 shows the performance requirements. It is important to confirm the system's use as a platform that allows information sharing between stakeholders in different positions.

Table 2. System function Lists

No	Function
1	Bridge Specific Data Registration
2	Specifications Data of bridge Registration/Browse/Editing
3	Data Search
4	View and Operation of 3D model of bridge
5	Damage Data of bridge Registration/Browse/Editing
6	Narrowed-down display of damage information (Part of Member/Damage Kind/Damage Rank level)

2.4 Application of AI to detection of damage in photographs

We investigated conditions for application and operation of artificial intelligence (machine learning) to extract training data for automatically discovering damage from among the huge amounts of image data acquired by robots that are unable to distinguish between soundness and abnormalities.

Inspectors apply machine learning using as training data photographs of damage taken as in conventional inspection methods from near the structure, thereby creating a discriminator. This discriminator is used to identify damage in photographs taken by the robot and consider the results.

3 Implementation

3.1 Development of the inspection robot

3.1.1 Mounted equipment

Primary mounted equipment consists of a camera for robot operations, a camera for photographing damage (we compared two models, a Panasonic GH5S and a GoPro Hero7), and LiDAR (Velodyne VLP-16 Hi-Res) for position tracking.

3.1.2 Robot dimensions, maneuverability, and operability

Table 1 shows robot data, such as its dimensional specifications. The requirements call for an ability to enter beneath a bridge girder of height 70 cm and to acquire images of its underside, so as to ensure a constant view angle; the design is for a 15 cm distance from the

tire contact surface to the baseplate on which the equipment is mounted. We must also consider possible obstacles to the robot's undercarriage as it advances beneath small bridges, such as sediment (mud and sand), gravel, pebbles, dead leaves, and vegetation. Therefore, to improve its operability and obstacle avoidance performance, we adopted four-wheel steering (4WS), a steering method that allows independent setting of steering angles for each wheel of the robot. Further, we set the tire diameters to 140 mm to allow operation in small amounts of water. We attempted use of continuous track propulsion in preliminary experiments but leaves and twigs frequently became caught in the treads, immobilizing the wheels, so we adopted tires instead. For the battery, we used a small, lightweight, high-power lithium polymer battery, and allocated sufficient space in the robot's middle for mounting a battery with capacity for 1 hour of continuous operation. In terms of image transmission between the operator and the robot that has entered a narrow space, we confirmed that transmissions were not interrupted from beneath the target bridges with which we conducted our experiments. We further confirmed that image transmissions were uninterrupted during gradual movement of the operator's position about 20 m upstream and downstream from the center of the road surface and beneath the bridge. We did not conduct tests from farther distances because 20 m was considered sufficient for the small bridges targeted in this study.

3.1.3 Proof-of-concept experiment I

We performed this experiment with a bridge of length 2.0 m, width 4.5 m, and 80 cm clearance beneath girders. We confirmed positioning of onboard devices, the quality of SfM processing results using acquired images, and the possibility of position tracking by the LiDAR. Tables 3 and 4 list parameters investigated in each proof-of-concept experiment.

When investigating parameters related to SfM processing, we used two camera models to confirm differences in camera image quality and view angle. We also confirmed differences arising due to turning the high dynamic range (HDR) setting on or off in each installation direction and when using or not using wide-angle mode. To investigate whether substitution of the equipment used for normal inspections as a photocontrol point improves the results of SfM processing, we also used the presence or absence of photocontrol points as a parameter.

When setting LiDAR-related parameters, to verify any differences due to the incident angle of the laser on the structure and the reference object, we investigated three horizontal installation angles, using the presence or absence of a reference object as a parameter.

Table 5 shows primary specifications for the bridge used in this proof-of-concept experiment, and Figure 3 shows a photograph of the proof-of-concept experiment being carried out. Figure 4 shows the installation angles. Figure 5 shows conditions for camera installation directions.

Figure 3. Demonstration work status

Horizontal direction Vertical direction

Figure 4. LiDAR installation angle

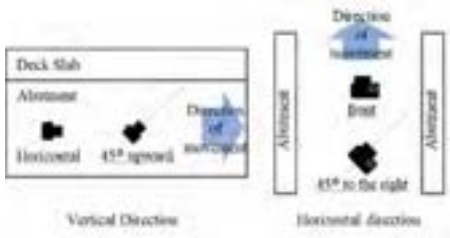

Figure 5. Camera installation directions

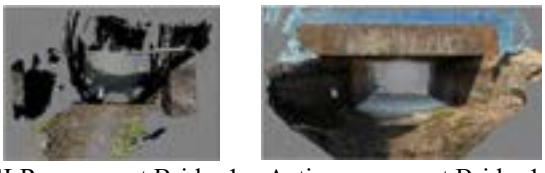

SLR camera at Bridge1 Action camera at Bridge1

Figure 6. SfM processing results

The results of this experiment showed that when performing position tracking using the LiDAR, the bridge form was not reproduced in any case where the reference object was not installed on a side face of the bridge. Also, form replication tended to improve when the LiDAR was installed horizontally. This is likely because the ability of a laser to capture the installed reference well is more effective for shape reproduction than for capturing the bottom surface of slabs.

However, installing plates for use as reference objects during inspections would be labor intensive and time-consuming, making inspections highly inefficient. Further, wind could blow plates over, which is a potential task hazard.

We next confirmed generation of 3D forms through SfM processing using robot-acquired image data. Figure 6 shows the results of SfM processing using image data for the same bridge as acquired by a single-lens reflex (SLR) camera and an action camera. The SLR camera could partially capture forms before entering beneath girders but capturing structures beneath the girders was nearly impossible. In contrast, the action camera could capture the entire form, including beneath girders. Due to this difference, there were many omissions in point cloud data created using the SLR camera. One effect likely influencing this is the difference in brightness when entering the dark environment beneath the bridge compared with the bright environment outside. Figure 7 compares still images captured by the SLR and action cameras. The action camera automatically and immediately changes brightness settings when entering beneath the girder, allowing capture of clear images while operating there. It is of course possible to change brightness settings for an SLR camera, but considering operability during inspections, the ease-of-use of an action camera likely makes it better suited to inspection tasks. Such cameras are also superior in terms of their small size and low weight.

Table 3. Study parameters (SfM)

	Value	Note

No	Length	Width	Height of under the girder	Structure type
1	2.0 m	4.5 m	85 cm	RC Deck Slab bridge
2	2.2 m	4.0 m	70 cm	RC Deck Slab bridge
3	13.0 m	1.8 m	85 cm (Inner)	Concrete Box Girder bridge

3.1.4 Proof-of-concept experiment II

Based on the results of proof-of-concept experiment I that concerned LiDAR-based position tracking, in proof-of-concept experiment II we verified whether equipment used in conventional inspection tasks or inspectors themselves could substitute for the reference object. To confirm any influences of surface shape or size of the

reference object, we investigated cases where an aluminum staff and an inspector were used as reference objects. Figure 8 shows a photograph of the installed reference object.

In proof-of-concept experiment II, we set investigated parameters with a focus on photography conditions for the action camera, and we considered what effects these might have on the generation of 3D forms.

To confirm the conditions inferred from the results of proof-of-concept experiment I, we set investigated parameters in consideration of improved operability, efficiency, and safety of inspections, confirmed whether similar trends were reproduced in experiments performed on two bridges of similar type, and investigated the validity of the inferred conditions.

The results suggested that parameters minimizing defects in the 3D form were a fisheye lens mode, horizontal installation direction, and illumination turned on. No differences were seen between still images and video capture. Because video capture has improved on-site operability, and clipping intervals can be adjusted for still image extraction in post-processing, video capture is likely most appropriate.

3.2 Efficient methods for 3D model data creation

In LiDAR-based form measurements beneath a bridge girder was possible to capture the form of bridge1 and bridge2, but not bridge3. This was likely because it was impossible to maintain continuous recognition of the installed reference object.

We constructed an algorithm for generating 3D model data from 3D point cloud data. Table 6 describes an overview of processing, investigation content, and processing content in each step. First, we prune the point cloud data to improve processing speed. We next perform clustering to estimate planar regions in the target object. The existence of point cloud data other than those belonging to the modeled bridge lowers modeling precision, so we remove such data and perform 3D labeling before processing for planar-surface fitting. When planar surfaces are formed, their intersections with other planes are taken as edges. We created an algorithm that creates a surface model from the vertices generated up to this point, and then a triangulated irregular network (TIN), finally converting data into a specified CAD format.

Table 6. Process overview and examination/process details of each process

No.	Process	Overview	Investigation/Processing
1	Point cloud data pruning	Reduce point cloud data acquired by SfM	Pruning processing is sped up by using an octree data structure.
2	Normal vector clustering	Group the resulting point cloud data for each generated plane	Generate planes from points in a given space by the least squares method and perform clustering by the K-means method using the angle formed by the Z-axis and the normal vector for each plane.
3	3D labeling	Remove point cloud data not subject to modeling	For all spaces in the space octree, merge connectable grids (labeling by distance), leaving only spaces containing point cloud data, and remove labels that do not correspond to some minimal volume.
4	Planar fitting	Generate fitted planes for each label	Use the least squares method for fitting. Planes determine the outer region within the range including the projected points.
5	Edge extraction	Generate surface model vertices	Search for intersections between a given plane and other planes; where intersections are found, update boundary as edges.
6	Surface modeling	Generate surface model from generated vertices	Generate a TIN using Delaunay triangulation. Convert the TIN into a specified CAD format and output.

To confirm the utility of the algorithm, we performed trials using highly accurate point cloud data as verification data and confirmed that the 3D model data were generated as expected. We used a ground-based laser scanner (Focus S350; FARO Technologies, Inc.) to generate ideal point cloud data for verification. Further, we performed SfM processing using image data acquired by the robot, performed verification using the generated data, and were thereby able to construct a model. By calculating root mean square values for planes in the

generated 3D model data and the point cloud data, we confirmed that accuracy was within the LiDAR catalog value of ±0.030 m. This can be considered as sufficient accuracy for 3D model data applied to the maintenance management that is the objective of this study.

No method for quantitatively evaluating SfM-generated point cloud data has been established. Therefore, there is need for performing various verifications in the future to establish evaluation methods and confirm robustness in actual operations.

3.3 3D model-based inspection results management system

We constructed a prototype support system for 3D damage map creation to allow stakeholders to intuitively and accurately grasp and share locations and states of damage and identified and organized application ranges and issues for various parties.

The Windows application maintains a database of bridge specification data, damage information, and damage site ID numbers. The Unity application displays 3D model data on a screen. This system has functions for superimposing damage data on model data and for confirming and editing damage information.

The system is designed to maintain minimal information on bridge specifications, assuming there are components such as a ledger system already managed by the local government. Similarly, for inspection information, we prepared a database table using a damage location identifier as its key to represent damage locations, assuming a connection with an existing system.

Table 7 lists the main issues as indicated by persons responding to a survey that involved 200 visitors to an exhibition. Figure 9 shows the main screen of the constructed prototype system and the damage data input screen. In future work, we will develop a mechanism or device that allows efficient association of damage sites on the 3D model data.

. Many small bridges in Japan have a low maintenance cost per bridge. Therefore, the current situation is that there is almost no cost to newly create 3D model data. How to efficiently create 3D model data is important.

In this study, it was found that the structure and shape of a small bridge is simple, and it is difficult to understand the damage situation if a damage map is expressed by a 3D model.

In such a case, the use of CAD data as 3D model data, rather than using CAD data with colored point cloud data or textures attached, improves the grasp of damage conditions.

In future R&D, it is necessary to add a function that can read such data to the system.

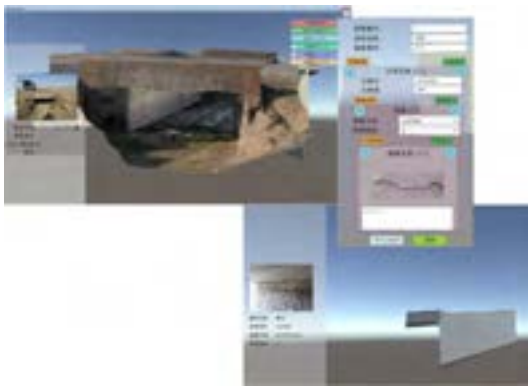

Figure 9. System screen and damage data registration/browse screen.

Table 7. Main issues as indicated by persons

Role of each persons	Main issues
Facility manager	Support function to make an optimal maintenance plan. Interoperability with the existing road management system (ledger system).
Bridge Inspectors	Output function for inspection reports. Automatic registration of damage location.
Repair workers	Optimal repair method and construction planning support. Automatic calculation of construction quantity.

3.4 AI application to identification of damage sites from photographs

We investigated algorithms and prepared an environment for introduction of AI methods. For training data, we used photographs previously taken by the authors or other inspectors judged as indicating damage.

For damage photograph labeling, we compared cases of labeling performed by inspectors and those by inexperienced persons provided with samples.

The results of discrimination in robot-acquired images included misidentification of cracks, peeling, and rebar exposure, an overall lack of recognition of peeling, and differences in scopes of occurrence. The results thus included many misidentifications of locations, scopes, and types of damage to be extracted. However, we obtained knowledge about constructing a learning environment and learning data, which enabled identification of requirements for condition setting. The following are items we identified as being particularly important development policies:

- Ensure consistent labeling of training data and prepare learning data that are high-quality (annotated) as well as abundant. Document how inspectors think for conversion from tacit to formal knowledge and identify what should be learned and how.
- Clarify relations between the required learning data scale and classification performance for each target damage class (e.g., damage type and degree) to be identified.
- Develop and formulate tools, interfaces, and operation processes that are linked with tasks so that learning data can be collected without placing burdens on primary tasks.
- Manage training data not as individual image files but matched with bridge specifications and other related information.

4 Conclusion

In this study, we summarized the requirements for robot development that can enter the girders of small bridges and acquire necessary and sufficient data for post-process work from the viewpoints of technological trends, development and maintenance costs, and versatility.

We have developed a robot that enters and exits under the girder of a small bridge with a space below the girder height of 70 cm or less. In addition, we performed a comparative verification of the conditions and installation methods of the equipment mounted on the robot and proposed an efficient method for 3D model data.

Regarding the 3D damage map creation support system, the system requirements and issues were organized from the perspective of the relevant parties (facility managers, inspection operators, repair work operators, etc.). In addition, it is also important to propose activities to replace the current 2D drawing management method with the proposed method.

Regarding damage extraction by AI, the requirements for a series of maintenance up to the introduction of AI have been arranged.

In the future, further verification in various bridge types and under girder environments will be required for actual operation.

Abstract –

In recent years, deterioration of concrete structures such as floating and delamination has occurred. These damages can lead to the falling of concrete pieces. It may cause damage to third parties such as vehicles or pedestrians passing under the bridge. Therefore, the concrete damages need to be detected and repaired early.

Japanese highway companies conduct hammering tests on concrete structures once every five years to detect damages such as floating and flaking. However, the inspector must be near the bridge to perform the hammering sound inspection, which requires work at a high place and a lot of time and cost. Also, when using aerial work vehicles, traffic regulation under the bridge is required which may cause traffic congestion and accidents.

Infrared thermography is a non-destructive inspection technique that detects areas of floating or delamination by imaging a unique temperature distribution on the concrete surface using an infrared camera. The inspection cost of infrared thermography is significantly lower than that of hammering test. Since it is a long-distance non-destructive inspection, work at heights and traffic restrictions are not required. However, it is difficult to ensure the accuracy of damage detection because the peculiar temperature distribution acquired by infrared thermography includes an abnormal temperature distribution caused by something other than damages.

In this study, by using deep learning, we improved the accuracy of the unique temperature distribution imaged by infrared thermography and ensured detection accuracy that can be used practically. We also report on the construction of an automatic discrimination system that implements the deep learning discrimination algorithm on a cloud server.

Deep Learning；Infrared Thermography；Cloud Computing System

1 Introduction

Aging of concrete structures has been escalating recently, and there have been several reports of concrete piece falling accidents due to fractures of PC reinforcement rods and PC stranded wire in prestressed concrete, or corrosion of reinforcement steel rods. For instance, On April 3, 2009, the cover concrete with a length of 1 m, a width of 100 mm, a thickness of 260 mm, and a weight of 6 kg fell due to the corrosion of the rebar installed in the drainage unit of Tooridani bridge in Shikokuchuo-city. If flaky concrete hits a passer-by, it can cause a secondary disaster, so such accidents should be prevented as much as possible.

Several nondestructive inspection (NDI) techniques are available for the task [1][2]. In our project, we have decided to establish a detection technique of areas with floating and delamination based on the passive infrared thermography method, which would not limit the target bridges and should be able to inspect the target remotely and entirely.

The infrared thermography method has already been applied in the detection of floating of building tiles, but currently, it has not been applied to the inspection of floating and delamination of the concrete structures that have been put to practical use[4][5]. That's because the detection rate is significantly lower than conventional hammering tests. To enhance the detection rate, we first

examined infrared cameras by comparing their performances. As a result, the most suitable type was a cooling type camera, which has a shorter measurement wavelength range. We also developed a method to analyze the acquired thermal images and detect damages thoroughly. Specifically, it enables the machine to detect damages through machine learning, which has learned both anomalous forms in the areas of temperature alteration and the texture within the target areas.

2 2 EQUIPMENT AND METHOD OF INSPECTION

2.1 Equipment

ASTM D 4788 (Standard Test Method for Detecting Delaminations in Bridge Decks Using Infrared Thermography) requires the following conditions in thermal imaging [3].

1) Targets that are in constant contact with water, ice, or snow should not be applicable for shooting; they must be dried at least for 24 hours.
2) The condition with over 25 km/h wind velocity should not be applicable for shooting.
3) Thermal imaging at night should be taken in fine weather.

It also requires specific weather criteria for shooting as shown in the following table.

Table 1. The weather criteria for thermal imaging.

The weather condition of two hours before the test start	Determination
Fair	Possible
Fair with occasional clouds	Possible
Cloudy with occasional fine weather	Possible
Cloudy with temporary fine weather	Impossible
Cloudy	Impossible
Rain	Impossible

It is also critical to select the right infrared camera to get accurate detection results. Some of the essential specifications for an infrared camera should be its pixel resolution, detecting element, measurement wavelength, noise equivalent temperature difference (NETD), or frame rates, in which NETD is the most important. Regarding NERD, the infrared camera candidates we evaluated for our investigation were roughly classified into two groups; 0.02℃-NETD and 0.06℃-NETD. To determine the selection criteria for the thermal camera, we need to confirm the temperature difference in the target floating/delamination areas. Considering the fact that the typical cover of the bridge's upper structure is 40mm, it is essential to select the camera capable of detecting cracks and voids 40mm below the surface. We built some model structures to investigate thermal cameras' detection capability and weather conditions and selected one that could detect the cracks and the voids 40 mm below.

2.1.1 Building Model Structures and Photographing Conditions

We built cubic concrete model structures. Each model has a void with the size of 100mm x 100mm (t=10mm) in a different depth from the surface; 20mm, 30mm, 40mm, and 60mm, respectively (Fig. 1). In order to avoid the influence of daytime sunshine, a model was installed in the shade under the bridge on the Takamatsu Expressway and photographed at night (23:00) under weather conditions with a daily difference of 10°C or more.

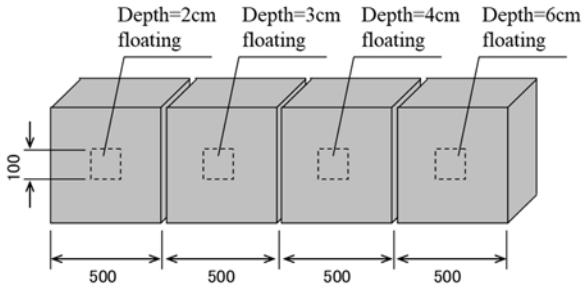

Figure 1. Concrete model structures and locations of voids.

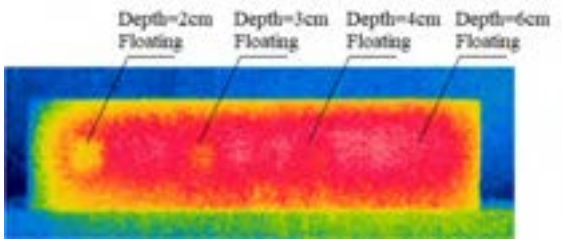
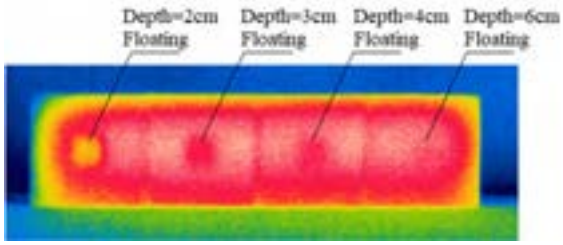
2.1.2 Thermal Images of Each Infrared Camera

We used three cameras with different measurement wavelength and NTED in photographing model structures. We set two cameras of different NTED in line and photographed model structures simultaneously. Photographing with the camera of the minimum thermal sensitivity below 0.06℃ could not detect the void. The thermal images of the camera with minimum thermal sensitivity of 0.025℃ or less succeeded in detecting the void up to the depth of 40mm. We also learned that even the camera with below 0.025℃ minimum thermal sensitivity could not detect the void in 60mm deep, due to signal-to-noise ratio (SNR) of the camera. The result suggests that the camera with minimum thermal sensitivity below 0.025℃ is applicable for inspection of the upper structure, but not for lower structures with much thicker covers.



(a) Thermal sensitivity below 0.06℃



(b) Thermal sensitivity below 0.025℃

Figure 2. Thermal images of concrete model structure

2.2 Thermal Environment Suitable for Infrared Thermography Method

The infrared thermography method requires the generation and the retention of heat flow inside the target object for several hours. Usually, Equation 1 should calculate the required time for the operation. However, due to heat transmission from the area around the target, it takes longer than the time derived from Equation 1 before the surface temperature of the floating/delamination area changes. In our experiment, the temperature change appeared in the condition with 2℃ difference continuously for an hour between object and air temperatures.

$$d = 2\sqrt{\frac{\lambda t}{\rho c}} \quad (1)$$

where

d: Heat transmission depth (m)

λ: Heat conductivity (W/mk)

t: Time of appearance (sec)

ρ: Density (kg/m^3)

c: Specific heat (J/kg K)

3 3 EXAMINATION OF THERMAL IMAGE ANALYSIS METHOD

3.1 Necessity and outline of the thermal image analysis method

Some of the problems with infrared thermography measurements are the risk of overlooking and false detection of floating and delaminations by inspection personnel. Therefore, we have built an automatic detection system for floating and delamination based on machine learning.

However, the analysis requires preprocessing of the target images. Due to the different thickness of components in concrete structures, external influences such as solar radiation cause temperature differences in the components depending on the component thickness (Figure 3).

Figure 4 is a model showing a unique temperature distribution under different thermal conditions, that is, detection in uniform temperature and detection with temperature gradient. If the temperature of the target structure is uniform, not only the amount of temperature change but also the size of the damage can be easily detected. However, in reality, the surface temperature of the target concrete structure has a significant temperature gradient due to the difference in component thickness, which makes it harder to detect damages than in stable temperature conditions.

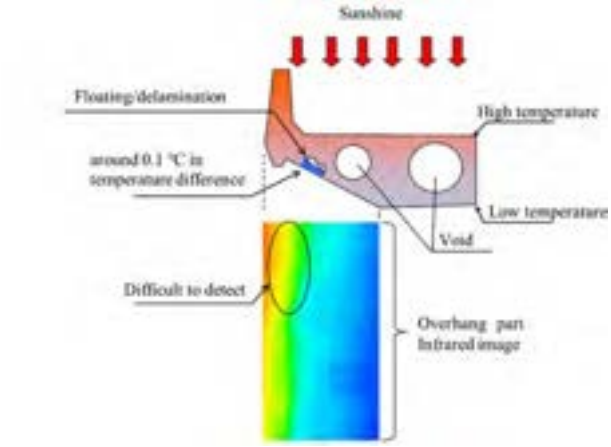


Figure 3. Thermal image example of RC hollow bridge with temperature difference

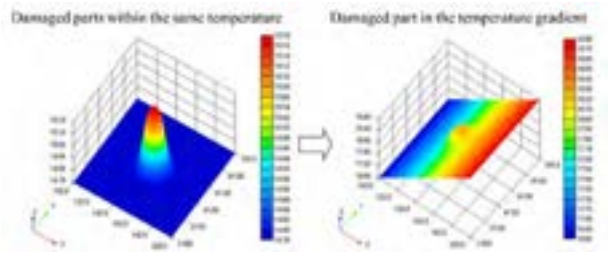

Figure 4. Concept of thermal change in the damaged area

In our study, to eliminate the influence of temperature gradient in concrete structures, we calculate the moving average of temperature distribution and subtract the target pixel temperature. It enables damage detection in concrete structures under the influence of temperature gradient; the detection result should be free from the temperature gradient in the target structures.

After the abovementioned preprocessing, we have constructed a system by machine learning to detect floating/delamination from thermal images. Machine learning requires training data, for which we collected through infrared thermography measurement, as well as the full-scale hammering tests on RC, steel and box-girder bridges that has been in service for 5 to 38 years. As for the infrared thermography, we conducted the measurement at night on the day when the diurnal range exceeded 10°C. Detecting singular temperature distribution with infrared thermography does not always mean the detection of floating/delamination. For instance, there are several factors that affect the temperature distribution of the target, such as free limes piled up by rainwater infiltration and roughness of the target surface itself. The following Table 2 shows the list of factors that cause temperature irregularity. Each is described in the following sections.

Table 2 Factors of temperature irregularity

Floating area
Delamination area
Adhered slag
Foreign substances
Repair marks
Free limes
Color irregularity

3.2 Factors of temperature irregularity

3.2.1 Floating area

The floating area, in this case, is an area where noise is generated in the hammering test, but the concrete surface is still intact. Comparing with the thermal image of the healthy area where a foreign object attached, the temperature distribution image on the floating area is not distinct.

3.2.2 Delamination area

The delaminating area, in this case, is an area where concrete flakes should fall when the hammering tests are conducted. Compared to the thermal image of the floating area, the image of this area distinctively shows a singular temperature distribution.

3.2.3 Adhered slag

The delaminating area, in this case, is an area where Slags remain on the joint form marks after the initial concrete placement turned to a thickness of 2-5 mm; thus, they are detected distinctively as thin linear singular temperature distributions that run along with the joint form marks by infrared thermography.

3.2.4 Foreign substances

If foreign materials such as wood chips are mixed in the concrete of the covered components, they are detected as temperature irregularities by infrared thermography. Because the mortar plastered on top conceals the wood chips, it is impossible to detect from the visual image whether the foreign materials are mixed in it.

3.2.5 Repair marks

The standard repair procedure of the floating/de-lamination of concrete due to rebar corrosion is to remove that areas and fill the damaged sections with materials such as shrinkage-compensating mortar. If the thermal conductivity of the materials used for repair is different from that of concrete, they appear as singular temperature irregularities.

3.2.6 Free limes

Free limes adhering to the concrete surface appear as singular temperature irregularities in thermal detection. The difference in reflectance or thermal conductivity between free limes and healthy concrete surface or the existence of gaps in between free limes and concrete surface would be the cause of the detection.

3.2.7 Color irregularity

The color irregularity causes a singular temperature irregularity detection in the thermal image.

3.3 Full-Scale Hammering Test Results Summary

Figure 5 shows thermal images organized according to characteristics in detection shapes. We collated organized images with hammering test results to confirm significant characteristics in the shape of areas with singular temperature irregularity in the following five types; 1) delamination, 2) floating, 3) slag, 4) foreign substances, and 5) healthy area. Table 3 shows each characteristic. If we can calculate the value expressing the shape of the temperature irregularity area (shape features), we determined that it is possible to classify using these five types of machine learning.

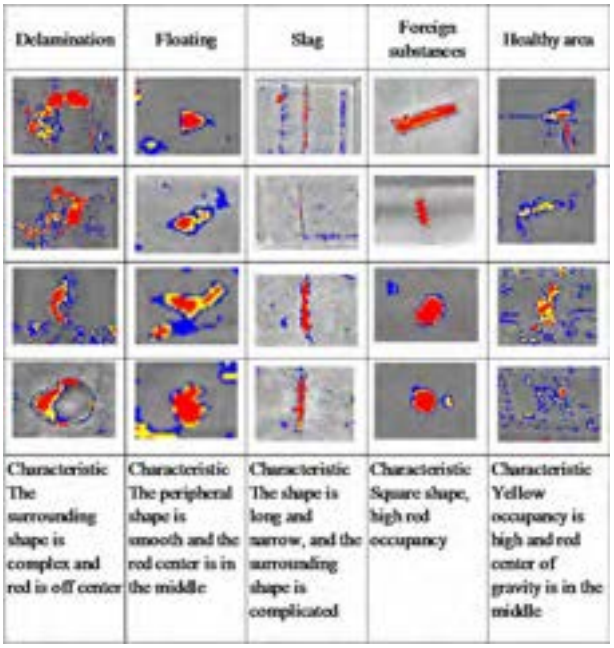

Figure 5. Relationship between hammering test results and image processing

Table 3 Relationship between hammering test results and detection image shape characteristics

Sounding result	Unique temperature area shape characteristic	note
delamination	The red area is off the center of the whole area	Knock down
Abnormal sound only	The red area is at the center of the whole area	floating
foreign substances	Square shape, high red occupancy	False positive
slag(t=2～5mm)	The occupancy rate of red is high and the shape is square, but the periphery is more complicated than foreign substances	False positive
healthy area（Reflection）	High yellow area occupancy	False positive

3.4 Discrimination Index Using Geometrical Features in Thermal Images

In this study, we have examined the image filtering process that ternarizes the thermal images. Based on the emphasized index, we set the threshold values of ternarized red, yellow, and blue as follows; over 0.11 as red, over 0.08 and less than 0.11 as yellow, and over 0.04 and less than 0.08 as blue, respectively.

Considering the results in the previous section, the positional relationship between the red, yellow, and blue areas is important. If the red area appears near the center of the blue area, the detected image is probably a floating area with abnormal sound alone. On the other hand, if the red area appears at the location apart from the center of the blue area, the detected area could be a delamination area. Thus, the distance between the centers of each area should be calculated as a feature for the discrimination index.

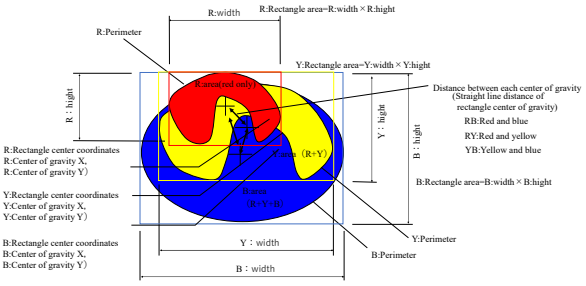

Figure 6. Concept of shape feature calculation of ternarized thermal images

The Shapes of red, yellow, and blue areas are also significant. In the thermal images of false detection, if its edge is smooth, it could be a floating area. Therefore, we examined shape features of red, yellow, and blue areas. The number of pixels represents circumference and dimension of the area. Occupancy rate, degree of shape complexity, and circularity level of each shape are calculated by the following equaitons, where L is the circumference and S is the area.

$$\text{Occupation rate (O)} = \frac{S}{R(height) \times R(width)}$$

$$\text{Degree of shape complexity (C)} = \frac{L}{S} \qquad (2)$$

$$\text{Circularity level (CL)} = \frac{4\pi A}{L^2}$$

In addition to the above values, we use the co-occurrence matrix[6][7][8], which is an image texture analysis method that can quantify changes in image contrast. The co-occurrence matrix firstly derives the matrix that uses the P-value of the target contrast in a specific position δ = (r, θ) away from the point i should be the contrast j, Pδ = (i, j), as its element (hereinafter referred to as stochastic matrix) to calculate several features by the matrix as shown in Figure 7. Values of the stochastic matrix represent frequency to each sample image, but practically we normalized them so that all numbers should be 1.

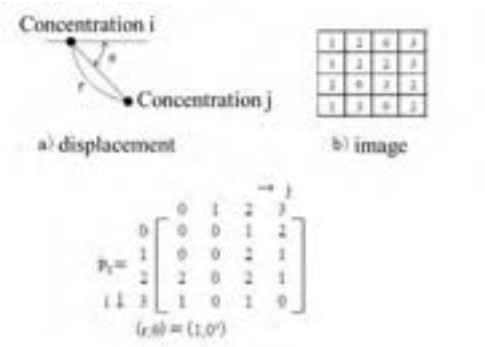

Figure 7. Co-occurrence matrix sample

We calculated following 14 features in total by the co-occurrence matrix mentioned above; Angular second moment, Contrast, Correlation, Sum of square variance, Inverse difference moment, Sum average, Sum variance, Sum entropy, Entropy, Difference variance, Difference entropy, Information measure of correlation 1, Information measure of correlation 2, Maximal correlation coefficient. We also set the position value δ as r = 1, 2 and the angle value θ as 0, 45, 90, 135, 180, 225, and 270. As for the contrast, we set it in 32 levels of gray, and we generated the co-occurrence matrix.

3.5 Deep neural network

We used hammering test results as the training data for the deep neural network[9][10][11] developed in this study based on shape features obtained from analyzed images in the previous section. The shape features are ternarized areas, their positional relations, and those obtained by co-occurrence matrix. The data amount was 2,353 cases (hammering test results from 2008 to 2010).

In this study, a deep neural network with one input layer, six hidden layers, and one output layer was developed. The number of nodes in hidden layers are 453, 500, 600, 400, 300, and 100. The drop-out layer is also sandwiched between these layers. In this paper, the number of layers of the hidden layer for high accuracy is investigated by grid search. It is probably not the optimum value, but it is almost the optimum value and there is no problem in practical use.

4 RESULTS AND CONCLUSION

4.1 Results

Table 4 shows the accuracy of the deep neural network model. The overall accuracy was 88.7 % (2,086/2,353). In addition, 800 data which were not used for the learning were prepared, and the analysis by this method was carried out. As a result, Over 97% of the hammering results are in the top two of the prediction results, which proves that this system is highly accurate.

Table 4 Analysis results of training dataset

sounding results / analysis results	Delamination	Floating	Slag	Healthy area	Foreign substances	total
Delamination	**111**	2	0	32	2	147
Floating	2	**116**	2	12	0	132
Slag	1	0	**34**	6	0	41
Healthy area	64	71	17	**1,732**	42	1926
Foreign substances	3	0	0	11	**93**	107
total	181	189	53	1793	137	**2353**

4.2 Conclusion

It has been confirmed that the temperature gradient generated in the structure is removed by the image filtering process of the thermal image taken by the infrared camera, and the damage detection rate is improved. In addition, the image filtering process should be sufficient to deal with the influence of temperature differences around bridge appendages.

We also succeeded in building a deep neural network model that evaluates the presence and type of damage due to temperature changes. As inputs of deep neural network model, 14 feature quantities obtained from co-occurrence matrix, etc. were used. As a result, the accuracy of 88.7% was realized. Furthermore, the high accuracy was obtained even in the data set which was not used for the training. As a result of this study, floating/delamination can be remotely evaluated, which is considered to contribute to drastic improvement in efficiency of present inspection that depends on hammering sound.

5 Automatic detect system using a cloud server

5.1 Introduction of the system

Statistical analysis software is required to perform the damage detection described above, but such software can only be used by a limited number of users. Therefore, we have built a cloud server that can automate the damage detection for many users, and are currently conducting trial operations as shown in Fig. 8. This system is based on the machine learning system described above and can automatically detect damages based on infrared measurement and hammering test result data. Figure 9 shows an example of the use of an automatic detect system using a cloud server.

1. The thermal image (Figure 9(a)) is loaded into the analysis software “J-system” and ternarized areas, and their positional relations, and those obtained by

co-occurrence matrix are automatically output.
2. Upload the output to the cloud server.
3. Users download the results of the damage detection by the cloud server (Figure 9b).

The results of the infrared measurement are summarized in the above procedure. Figure 12c shows an example of delamination in a hammering test. This was the damage the proposed system determined to have a high probability of damage.

Figure 8. Automatic detect system using a cloud server

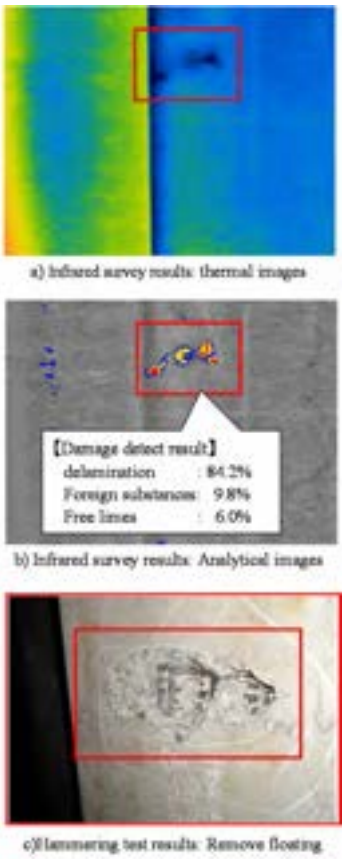

Figure 12. Example of Automatic detect Results from a Cloud Server

Utilizing a highly accurate system that automatically detects damages from infrared measurement results, the individual differences of surveyors are eliminated. The more data this system has, the more accurate the system will be at determining damages. When users of J-system perform the infrared survey and use the cloud server, the survey data will be stored on the cloud server, and as a result, the accuracy of the automatic detect system will be improved.

5.2 Introduction result

The J-system has been evaluated as a "non-destructive inspection technology that can detect floating and delamination of concrete structures" by the Bridge Maintenance Subcommittee of the Committee for Verification of Robots for Next Generation Infrastructure.

In addition, the J-system has been installed in the Shikoku branch of NEXCO West Japan since 2008 as a hammering sound screening system for periodic bridge inspections. It has also been used by NEXCO Central Japan, NEXCO East Japan, and Honshu-Shikoku Bridge Expressway, and has been introduced on a trial basis on bridges owned by the national government since fiscal 2015. The total survey area that West Nippon Expressway Engineering Shikoku Co., Ltd. received an order for is 2.55 million square meters (as of the end of FY2017). We will continue to develop a high-precision infrared measurement system so that it can be widely used for bridge inspection and surveys, including prevention of damage to third parties.

Abstract –

In order to ensure the safety of construction workers during the construction process, supervision of violations of safety regulations and control of hazardous situations not recognized by the workers are continuously required. However, due to the dynamic nature of the construction site, the hazardous situation is always changing and there is a limit to managing all these risk situations in a manual manner by the supervisor. To address these limitations, various computer vision-based researches are being conducted that can automatically identify and manage risk factors. The aim of this study is to propose a system for detecting potential horizontal and vertical risks of moving or static objects around workers by measuring distance between objects using Stereo Vision. Proposed system consists of motion detection, object detection and distance measurement between objects using depth image from stereo camera. It synthesizes images from multiple cameras into one and uses motion-detection and object-detection to identify the movement of objects in a vertical or horizontal position. Then, based on the depth information of the stereo camera, the distance is calculated to identify whether a worker is in the hazardous zone. The proposed system was implemented in the lab environment to verify the proposed functionality. The lab test results indicate that the proposed system can detect vertical and horizontal hazards. It is expected to contribute to the prevention of possible accidents by detecting and controlling the dangers around the workers in real time.

1 Introduction

Despite various efforts to reduce the number of accidents and fatality in construction sites, construction Safety accidents are occurring continuously. Safety in construction remains a critical issue. Among various types of accidents, this study aims to focus on ways to manage risk situations that are not recognized by workers.

Based on the KOSHA database, the accident cases that happened during 2016-2018 have reported 1345 fatalities in construction. The reported three years of data have been analyzed to find the proximity and collision-related accident cases. As a result, 222 cases are identified related to proximity risks, either horizontally or vertically, that account for 12% of the total fatalities that happened during that interval of time.

For instance, the accident that happened during vertical simultaneous work is a case in which a worker hit by fallen rebar lifted by a crane, hitting by the fallen pipe from the upper floor while working near the window, and hitting by the falling temporary structure while working at the basement. The accident happened during horizontal simultaneous work is a collision happened with a moving car while cleaning up the site, falling into an opening during the site inspection.

These fatal accidents may occur because the worker is not aware of the dangerous situation, but in some cases, the accident is caused by the worker ignoring the dangerous situation. The main purpose of this study is to propose a stereo-vision based system that can determine in real time whether a worker is exposed to a dangerous situation by measuring the distance between the worker and the risk factors. Through this, it is possible not only to control the dangerous situation, but also to identify how often workers are exposed to the danger at the site, and to provide information that can be reflected in future safety management plans.

2 Related Work

2.1 Sensor-based Proximity Risk Detection Systems

The complex nature of the construction site and dynamic movements of construction entities tend to produce many struck-by hazards. To avoid collisions

between the objects, the proximity warning system (PWS) is widely used [1]. The PWS operates based on the spatial relationships between the interested entities, and their performance depends on the type of object's tracking technology, for instance: radio frequency (RF) sensing, ultrasonic, radar, global position system (GPS), and magnetic field [2]. To determine the proximity between the objects, the radiofrequency sensing technology emits the electromagnetic signals from a mounted device on objects [3]. This technology uses predefined rules to generate an alert based on signal strengths between the device and objects with the attached tags. Based on the power source in the tags, RF technology can be grouped into three classes:(1) active RF technology and (2) passive RF technology [4]. The active technology needs a power-source for long-range detection. For instance, a type of active RF technology, Ultra-Wideband (UWB) robustly transmits the signals using comparatively low power for tracking the objects, with the errors of centimeter-level [5]. However, passive RF technology requires a power source for the RF device in the shorter-range detection. Passive tags are less expensive, powered by the radio waves from the reader, and have a range of up to 30 feet [4]. Since the RF-based PWS only requires signals strength adjustments and data processing step, thus, it can be easily implemented in the construction site [5]. However, RF technology requires additional work of putting tags on every interested object. Moreover, their signals could be interfered and disturbed by the multipath fading effect [1].

On the contrary, the Global Positioning System (GPS) is employed to recognize the absolute location of objects [3,6]. The GPS sensor identifies the latitudinal and longitudinal coordinates of the objects which required to be monitor. To detect the proximity risk of the entities, the heading direction and speed also need to be considered and extracted [1]. GPS can be used to cover large scale area; thus, many researchers have extensively studied this technology for the practical implementation in the large construction sites [2,7]. However, previous efforts revealed various limitations such as manual input from the supervisor to limit the access to a hazard zone by using risk zone information [8], and accuracies dependent cost ranges of the GPS sensors. Moreover, the additional significant limitation is the strength of the signals, which could be blocked by buildings or other objects.

2.2 Vision-based Proximity Risk Detection Systems

To detect the proximity risks in construction, previous studies have used object tracking techniques for monitoring the trajectories of the localized objects in a series of images [7,9,10]. The primary step for object tracking and action recognition includes the detection of objects. Once the entities of interest are successfully recognized, the location of the bounding boxes in a frame with respect to time could be traced by utilizing the object tracking algorithm [11]. The localization of objects takes place based on their pixel information, changes in brightness, intensity, and other local features. Detection of the sudden slope failure is possible based on the change in pixel intensity [12]. The extracted location information is then used to identify unsafe actions and conditions.

Compared to sensor-based tracking techniques such as RFID tags, UWB, and GPS, Computer vision as a technique has the capability to identify multiple object's information form construction worksites using images only, without human involvement or any additional devices for instance, tags or sensors. Furthermore, the camera can cover large area, thus, multiple objects can be simultaneously captured and easily tracked. Location and detailed information such as types and velocity of the objects can also be acquired. However, the performance of the vision-based systems may vary under poor light conditions, snow, rain, or dusty storms.

3 Proposed Methodology

The purpose of this study is to propose a stereo vision-based risk detection system that can identify how close a worker is to vertical and horizontal hazards and determine whether they are dangerous. Figure 1. illustrates the operating process of the proposed system.

The system consists of motion detection, object detection, and object depth and distance measurement technology using Stereo vision. This system is designed to use the stereo camera's depth calculation in a way that works only under certain conditions, so that it can be used in real time even on low computing resources. First, motion detection and object detection algorithms are applied to the stereo video information to determine the movement and presence of objects in the air and on the ground, and to check the possibility of a dangerous situation. After that, the distance between objects is measured based on the depth information of the stereo camera to determine whether the distance between objects located on the ground is a dangerous situation horizontally and whether an object located in the air poses a danger to objects on the ground.

This system is applied Motion Detection technology that detects motion compared to the current frame and previous frames, YOLO V4 Object Detection algorithm that enables stable real-time detection, and the depth measurement technology of the object using INTEL RealSense Stereo Camera. This stereo camera measures the depth of a specific pixel value through operation using video taken from two or more different angles and additional infrared or RGB color image sensors. When

using a general camera, more computation is required at the same resolution, which increases the consumption of computing resources. Thus, the proposed method is designed to minimize depth calculation by utilizing the stereo camera (Intel RealSense) so that it can operate in real time even with low computing resources. For this purpose, motion detection and object detection are designed to operate sequentially in one video information, which identifies the movement and presence of objects in the air and on the ground, and identifies the possibility of dangerous situations. Then, after calculating the distance based on the depth information of the stereo camera, it is determined whether a specific object is in a dangerous situation.

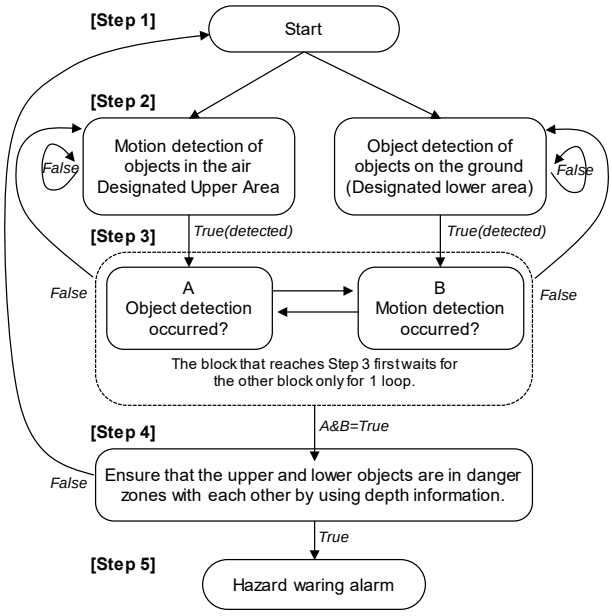

Figure 1. Overview of the proposed process

4 Lab Test and Results

4.1 Lab Test Process

Lab test was conducted on two conditions for determining vertical and horizontal hazards (Figure 2). In the case of horizontal hazards, the distance between a worker working on the ground and a dump truck was measured, and in the case of vertical hazards, the distance between a worker working on the upper area and a worker working on the ground was measured. The risk level was set to be dangerous when the distance between vertically and horizontally located objects is within 2 m, caution when 2 to 4 m, and safe when 6 m or more. For the lab test, a 1/20 scale model was used.

Depth estimation using stereo vision from two images (taken from two cameras separated by a baseline distance) involves three steps: First, establish correspondences between the two images. Then, calculate the relative displacements (called "disparity") between the features in each image. Finally, determine the 3-d depth of the feature relative to the cameras, using knowledge of the camera geometry [13]. The typical stereo vision geometry for depth measurement is illustrated in Figure 3. The stereo depth camera used in this study, RealSense 435i, uses two infrared sensors to measure the depth value.

The procedure for measuring the distance between two objects by utilizing the measured depth values is as follows. (1) The full width of the camera Field of View (FOV) at a specific distance from the camera to the object is applied at an absolute value. (2) The total horizontal length of the camera FOV is calculated from the position of the object in front of the objects to be measured in proportion to the previously applied value. (3) Obtain the depth value of the object in front through Object Detection (Set to X). (4) Set the difference between depth values between objects to Y. The distance R between objects is calculated by following equation [R^2 = X^2 + Y^2].

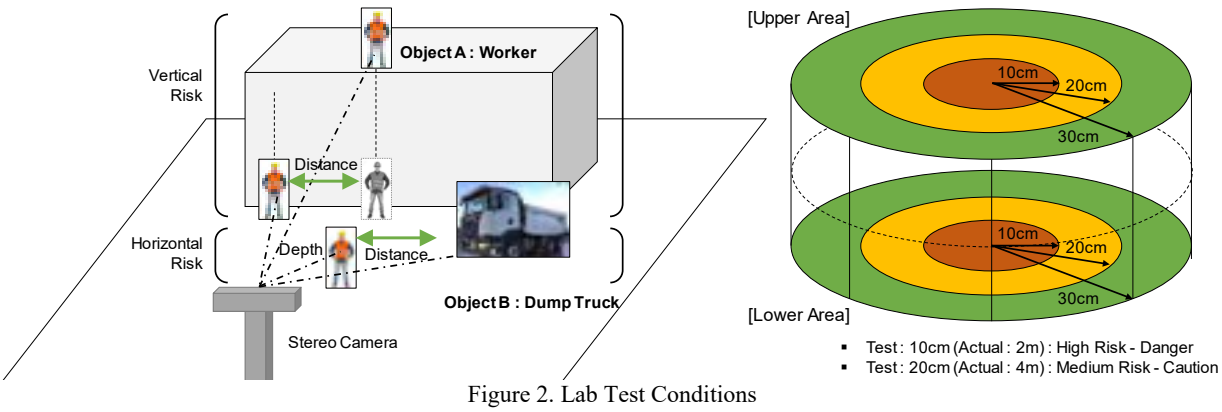

Figure 2. Lab Test Conditions

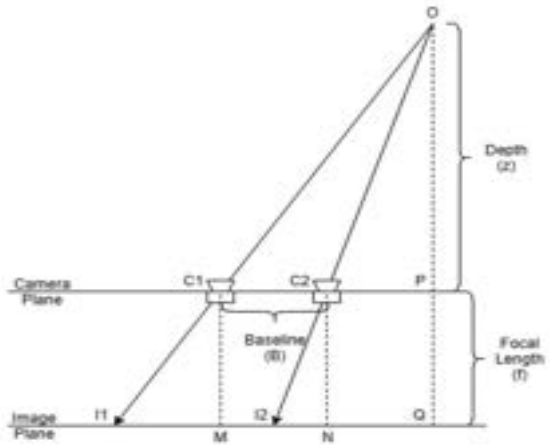

Figure 3. The Stereo Vision Geometry for Depth Measurement [14]

4.2 Lab Test Results

Lab test was performed on the laptop system with specifications as follows; Intel Core i7 8700K, 16 GB RAM, GTX1080TI VGA, Intel RealSense435i, Ubuntu 18.04, and Tensorflow 2.1.0.

As shown in Figure 4, the horizontal risk level (danger, caution, and safe) was determined in real time according to the set risk area as the worker approaches the dump truck.

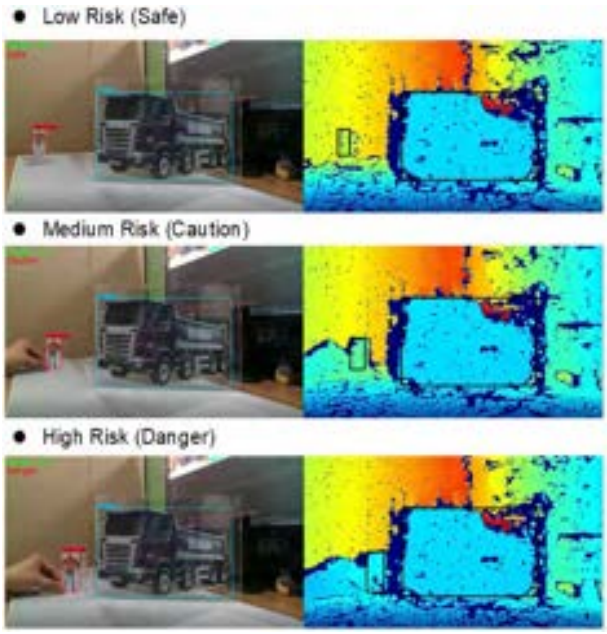

Figure 4. Example of Real-time Horizontal Risk Checking

As shown in Figure 5, motion detection determines the motion by comparing pixel changes between the current frame and a certain number of previous frames.

Figure 5. Example case of a motion detection

As described in the system process, when an object that moves at the top of the video frame is detected, the object detection algorithm is applied to determine the risk based on the distance between objects. In this test, the position of the lower worker was fixed and the upper worker was approached toward the lower worker. The difference between the X-axis value of the left pixel of the upper worker and the right pixel X-axis value of the lower worker was calculated as the horizontal distance.

As shown in Figure 6, the vertical risk level (danger, caution, and safety) was determined in real time according to the set risk area as the upper worker approaches the lower worker.

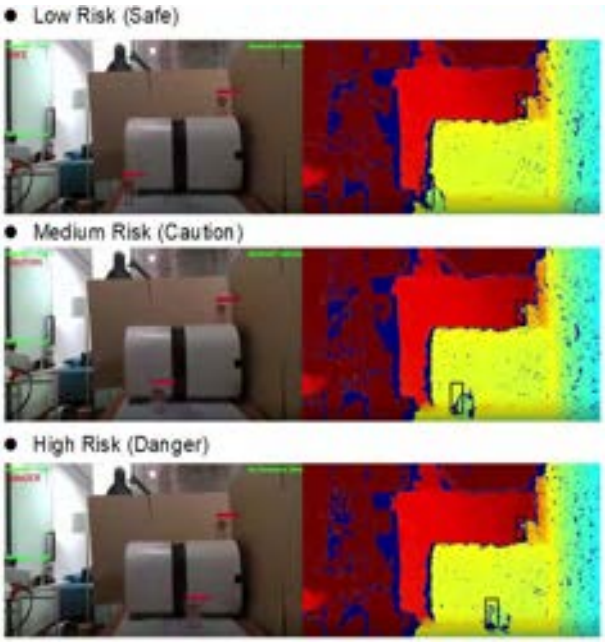

Figure 6. Example of Real-time Vertical Risk Checking

Table 1 and 2 show the results of vertical and horizontal risk level measurement. Tests were performed by measuring the depth and distance values by placing objects on the basis of the risk level (10 cm, 20 cm, 30 cm).

In the horizontal hazard test, when the distance between the worker and the dump truck was placed at 30cm, the measured distance was 31.6cm, with an error of 5.3%, but when placed at 10cm, the measured distance

was 8.81cm, with a slightly larger error of 11.9%. The size of the 1/20 scale model used for the test was small, so close-up shots were taken, which caused the infrared sensors to be unstable.

Table 1. Results of Horizontal Risk

Actual Distance (Risk Level)	Depth Measurement		Distance between Objects	Error
	Worker	Dump truck		
10cm (Danger)	30cm	25cm	8.81cm	11.9%
20cm (Caution)	40cm	25cm	18.5cm	7.5%
30cm (Safe)	55cm	25cm	31.6cm	5.3%

In the horizontal hazard test, when the distance between the workers was placed at 30cm, the measured distance was 29.7cm, with an error of 1%, but when placed at 10cm, the measured distance was 9.8cm, with an error of 2%. In the case of vertical hazard determination, the error was relatively low because the distance was measured using the RGB image-based pixel information, not the infrared sensor-based depth measurement method.

Table 2. Results of Vertical Risk

Actual Distance (Risk Level)	Depth Measurement		Distance between Objects	Error
	Worker (Lower Area)	Worker (Upper Area)		
10cm (Danger)	45cm	57.4cm	9.8cm	2%
20cm (Caution)	45cm	52.8cm	20.5cm	2.5%
30cm (Safe)	45cm	50cm	29.7cm	1%

5 Conclusions

This study proposed horizontal and vertical risks detecting system around workers by measuring distance between objects using stereo vision technology, with the goal of preventing accidents caused by unrecognized hazards such as material drop during lifting and collision with construction vehicle. In this paper, motion detection and object detection are designed to operate sequentially in one video information to minimize computing resources.

The proposed system is tested in the lab environment. Test results showed that objects moving horizontally and vertically were detected in real time, and hazard levels were also determined in real time. However, the accuracy of the measured distance was low due to the size of the scale model utilized in the lap test and the narrow distance between the infrared lenses of the camera used.

In the future research, in order to increase the accuracy and applicable range of distance measurement between objects, we intend to test the measurable distance and viewing angle by using various stereo depth cameras on the actual field.

Abstract

Fire poses an enormous threat to human safety; many people get injured or die due to fire accidents each year. As permanent firefighting equipment usually available in a build building, they do not exist in many construction job sites, so they merely depend upon the portable firefighting equipment (PFE) to keep the fire damage limited and minimum. To ensure the proper functionality of the PFE in the case of fire, perfectly located and in-good order are the two vital factors for the PFE. According to standards specified by safety regulations, PFE inspection and maintenance are required to ensure the perfect location and good order of the PFE. Currently, the PFE inspection and maintenance includes the safety auditor from the government and safety manager from the concerned companies. Moreover, the PFE inspection and maintenance process depends on the paper-based manual reporting and recording system, which is time-consuming, cumbersome, and can be easily manipulated. To automate the process of PFE inspection and maintenance, this study will propose optical character recognition (OCR) and Blockchain-based reporting and recording system. A mobile application is developed to validate the proof of concept. One of the artificial intelligence techniques, the optical character recognition (OCR) is adopted in the mobile application, which automatically converts the image tag or report of the PFE inspection and maintenance to the text. The text data is encrypted in a hash using encryption scheme SHA 256 of online service with open API, named as truetimestamp. The generated hash will signify the date inside of the file, which will be immutable and incorruptible. Moreover, the coordinates of the captured image will be extracted from the device to ensure the location of the PFE. It is expected that the proposed system will decrease the paperwork, reduce the burden of the safety manager, with increased efficiency and reliability of the PFE inspection records. The collected inspection record data could also be used to evaluate the safety performance of the concerned contractors.

Artificial Intelligence; Blockchain; Inspection Data Records: Portable Firefighting Equipment

1 Introduction

The construction industry includes many unhealthy activities that are perceived as the causes of workers discouragement, project progress delay, additional cost, low project productivity, damage to reputation, and ultimately human fatalities and injuries [1]. The inherited features of the construction industry itself have potential threats of accidents since its unique nature, open space, working at height, fire risks, exposure to severe weather, confined spaces, unskilled labor involvement, working with toxic and explosive materials, physical and psychologically vulnerable working conditions, and occasionally tight project duration with high productivity demand [2]. Academic researchers and industry professionals have been devoted vital attention to enhance construction safety for many decades. Despite much efforts, construction job sites are still known to be hazardous worksites with high accidents rate, thus, safety in construction remains a vital issue in many countries.

Many people become seriously injured or die due to fire accidents each year [3]. Fire incidents came into existence after its discovery and are intimately proportional to the progress and development of human civilization [4]. World Health Organization (WHO) report for fire-induced burns revealed more than 300,000 deaths annually. Unfortunately, annoying statistics are that 95 percent of these deaths are happening in low-income and middle-income countries [3]. The report from the U.S Bureau of Labor Statistics in 2018 divulge the death of 66 construction workers each year due to fires and explosion [5]. The five years (2010-2014) study by National Fire Protection Association (NFPA) revealed $280 million in direct damage to the property annually in renovation or under construction residential projects (discounting one- and two-units projects) [6].

The quantity of industrial and civil construction projects are swiftly growing due to socio-economic

development policies in many countries [7]. The growing challenges for fire safety with respect to economic progress have significantly supported the evolution of fire science and technology [4]. Initially, fire science and technology's primary intention was to save large factories, properties and evade sweeping fires conflagration [8]. Extensive research has been carried out in the domain of fire safety monitoring and early detection. Many studies have focused on the detection of smoke and heat by using various tools and techniques such as Dual infrared (IR/IR) spectral band flam detection, very early smoke detection apparatus (VESDA), linear infrared flammable gas detection, and fiber optic attached to distributed temperature sensing (DTS) [4,9,10]. Apart from fire safety monitoring and fire detection, several studies have also focused on fire safety and evacuation planning for existing as well as under-construction buildings and tunnels [11–14].

Fire safety management is a significant issue for every business; however, it is notably vital in construction due to several reasons that engender grim fire risks frequently. Firstly, workers are exposed to combustible substances in many construction job sites, and the presence of wind around the unfinished buildings can immediately cause a fire. Secondly, as under-construction sites do not possess permanent and adequate fire protection system, so, PFE or sometimes water tanks are the only preventive measures which they can adopt. With this regard, the Occupational Safety and Health Administration (OSHA) stipulates that a site-specific safety plan should include a fire protection plan for every construction project. Since many construction job sites depend on the PPE as a preventive measure, the vital factors which need to be considered are two: (1) perfect location of PFE, and (2) good working order of PFE [15]. The former is addressed in the previous study using a visual programming approach [16], while the latter is considered in this study. To ensure the maintenance of the fire extinguisher and overcome fraud or modifications in inspection records, this research work proposed an android app that uses optical character recognition (OCR) and blockchain technology for inspection data recording system PFE for maintaining the right order of the equipment.

2 Current Issues in Recording Safety Inspection of PFE

In the past, people typically have to depend on themselves or rely on their nearby vicinity for rescue operations in case of fire [17]. However, based on the necessities, new tools and techniques are developed over time. Many buildings, tunnels, or any other workplaces are currently using fire extinguishers (portable firefighting equipment). To maintain the PFE, frequent interval inspection and maintenance are required. In the past, the essential inspection information about these types of equipment was often dispersed between the stakeholders, which sometimes could lead to data loss [18]. Another significant issue is filling the documents or tags of PFE falsely with the same pen and the same pattern of dates [19]. To sort out the issue, a BIM-based approach has been introduced, which could store the necessary information about these devices such as device name, manufacturer name, maintenance staff, type, equipment warranty, last repair/inspection time, exterior features, and other specifications, as well as the location of fire-fighting equipment, equipment status [15]. However, to take the inspection data recording system to the next level, a much reliable and transparent system is inevitable to make the PFE in order and ultimately use it as a performance evaluation metric in the bidding process.

3 Blockchain and optical character recognition technologies applications

The rapid evolution in the internet of things (IoT), artificial intelligence (AI), and blockchain technologies have witnessed unprecedented contributions to the current world. This has resulted in many automated devices, time-saving, cost reduction, and a paradigm shift from the real world to the digitized world. Blockchain technology offers encrypted, distributed, and secure logging of digital transactions that could revolutionize many areas, mainly where transparency and privacy are essential [20]. As the name indicates, the blockchain can be regarded as a series of blocks (virtual cubes) in a vertical structure, aligned linearly, where each block contains a specific amount of data in the form of ciphers and codes [21]. Once the block's data is completed and validated, the said block is then permanently locked, which cannot be modified. This technology has the potential to address some problems that discourage the construction industry from using new technologies such as BIM, for instance, confidentiality, disintermediation, provenance tracking, non-repudiation, inter-organizational recordkeeping, change tracing, and data ownership [20]. Considering optical character recognition (OCR) with blockchain, previous efforts depict extensive research on recognizing characters through optic vision. OCR intends to convert handwritten or typed texts in the image to encoded texts [22]. Compared to typed or printed texts, recognition of handwritten text is challenging. Generally, an individual's handwriting style varies from others; thus, handling these variations is vital in OCR [23]. The OCR techniques include image acquisition, pre-processing, segmentation, feature extraction, classification, and recognition [22–24]. Previous efforts witnessed of OCR and blockchain technologies in construction safety

inspection and record keeping. Therefore, the innovative and useful approach for the construction safety inspection data recording system pertaining to PFE is presented in this research work.

4 System Development

This study proposed an android app for the inspection data recording system pertaining to PFE. The research was initiated with the analysis of fire-related accidents in the construction industry. Since PFE was determined as a significant measure for the first quick response to the fire emergency in the construction job site, therefore, pivotal attention is inevitable to make sure the good location and good order of PFE. Traditional inspection of PFE and its manual recording process were studied. The roles responsible for the safety inspection data recording and conformance were identified. Optical Character Recognition (OCR) and Blockchain technology were adopted to develop the proposed approach. This android app was developed in android studio using Java and Extensible Markup Language (XML). Streaming API for XML (StaX), which is considered dominant to Simple API for XML (SAX) and Document Object Model (DOM), was used in Java 6.0 for parsing XML documents. Java was used for backend business logic, while XML was used for the front end design. An objected-oriented language, Java, is user-friendly, which is platform-independent to operate; however, it is compiled in bytecode with the support of Dalvik Virtual Machine. To extract the ID of PFE and other relevant information from the tag, this system integrated the open-source google OCR library, named as, Vision API that extracts and detects text from images. The Vision API executes feature detection on an image file through sending the contents as abase64 encoded text. The database was designed in MySQL for storing the user's information and record saving. To make the server and Android App layers separate from each other, REpresentation State Transfer (REST) API was utilized to interact with the reside database and share information between them in JavaScript Object Notation (JSON). REST API was developed in PHP to make communication between the app and the server. An open-source blockchain service TrueTimeStamp (truetimestamp.org), is used as a proof of existence for each transaction. When an image of PFE's tag is submitted, the complex mathematical formula converts the file into a string of numbers and characters. Two different submissions, even with a slight variance, would generate a different hash. The system then uploads that hash, not the image, to the TrueTimeStamp Service, where it is then stored in the database. The transaction can then be verified by going to the TrueTimestamp website and putting the same hash in the verify box. The confirmation of time and date when it was initially being updated can then be seen. Moreover, the network-based location service API from google was also integrated into the app, which determines the location based on Wi-Fi access point or cell tower available in the area.

5 Process description of inspection data recording system for PFE

In this study, an application for reliable and transparent recording of PFE's inspection is developed that runs on the Android device. The entire system can be delineated in Figure 1. The developed application process includes two major stages, such as OCR and blockchain time stamping, as portrayed in Figure 1.

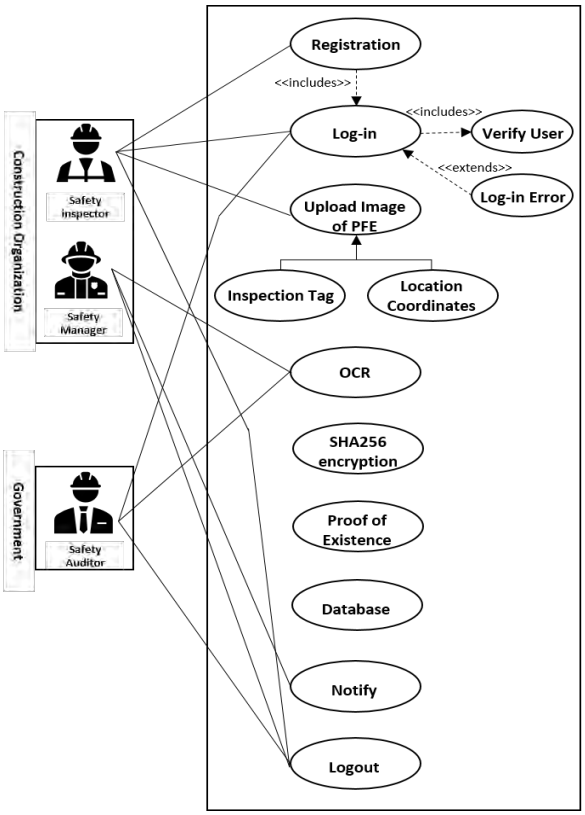

Figure 1. A use case diagram for the developed application

Figure 2 explains the process for users to register and access the functions and database of the application. The associated stakeholders must be registered in the system before they need to use this application. In the OCR process, image taken by built-in camera of the smartphone will go across three phases, including localization (region of test is located), segmentation (extraction of each symbol), and recognition

(reconstruction of words and numbers using contextual information). Next, the system will extract the ID of the focused PFE and will match it with the corresponding input ID for submission to the database. Matching extracted ID and input ID will ensure the exact tag image of the given PFE, which will reduce false reporting. The submission process would be smoothly done if both the IDs are identical, and a hash value would be allocated to the uploaded image using the Secure Hashing Algorithm (SHA-256). This hash value is a digital signature that provides cryptographic proof to avoid any modification or reproduction. As Figure 1 depicts, the uploaded image will be store in the database, and the generated hash value will be recorded on a server using truetimestamp service. All the associated stakeholders, particularly the safety auditor from the government agency can see the stored records and verify any transaction from the server.

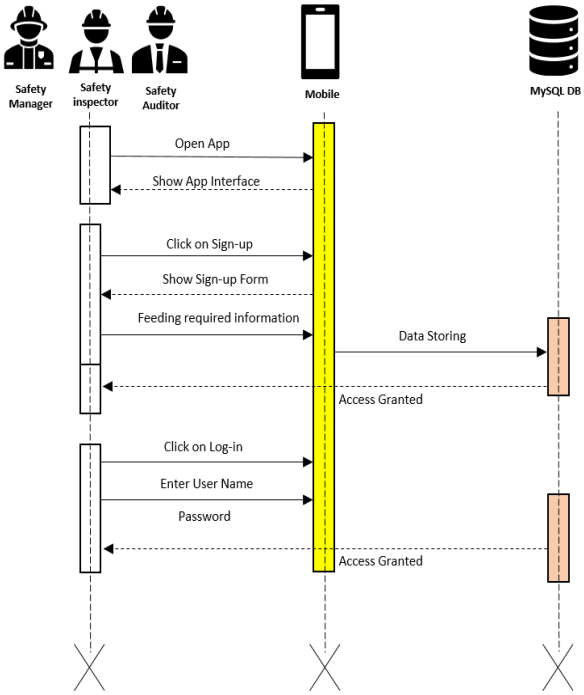

Figure 2. The sequence of users registration

6 Case testing of developed application

This section presents a case study for the Optical Character Recognition and Blockchain-based inspection data recording system pertaining to PFEs. This case study intended to validate the concept; therefore, the second-floor corridor in the Department of architecture engineering building (208) was selected for the experiment (see Figure 3).

Figure 3. Location of a case study for the developed application testing

The app users consist of three major participants, such as a safety auditor from the government agency, a safety manager, and a safety inspector from the given company. Figure 4. explains the registered roles using the sign-up process for the developed app and database. Following the exhibited procedure in Figure 2., three emails have been registered against the corresponding roles (see Figure 4). A new project named "Construction Technology Innovation Lab (ConTIL)" is registered in the project list (see Figure 4-(b).) using the safety inspector account (see Figure 4-(a).). Tags after inspections were assigned to each PFEs, and images of those tags were captured and uploaded to the database with the ID of each PFE, as shown in Figure 4-(b). The embedded OCR technology in the app extracts the ID from the image and matches it with the manually entered ID. Next, the blockchain-based proof of existence service allocates a unique hash value (a digital signature) to each record and will store that on the server using the procedure discussed in the previous section. In our case, several images have been uploaded to the server, however, one of the tag's image is exemplified in Figure 4-(b) and the hash value generated for this specific inspection can be seen in Figure-(c-2)., which is "b5f4687aff73ba6418d15ecb2f2eb3bc3a3ea90d358a0b036d67f9e9105764b6". As depicted in Figure 5-c, the safety auditor from the government agency or safety officer from the company can remotely check and verify

the inspection done by a safety inspector through logging-in to their concerned accounts. The respective transaction of each PFE's inspection associated with the enlisted projects can be verified by clicking on the "VERIFY TIMESTAMP" button in their corresponding interval is inevitable to ensure the good order and location of PFE. Currently, the PFE inspection process depends on the paper-based manual reporting and recording system. So, during the government agency's scheduled visits of safety auditors, the manual and paper-

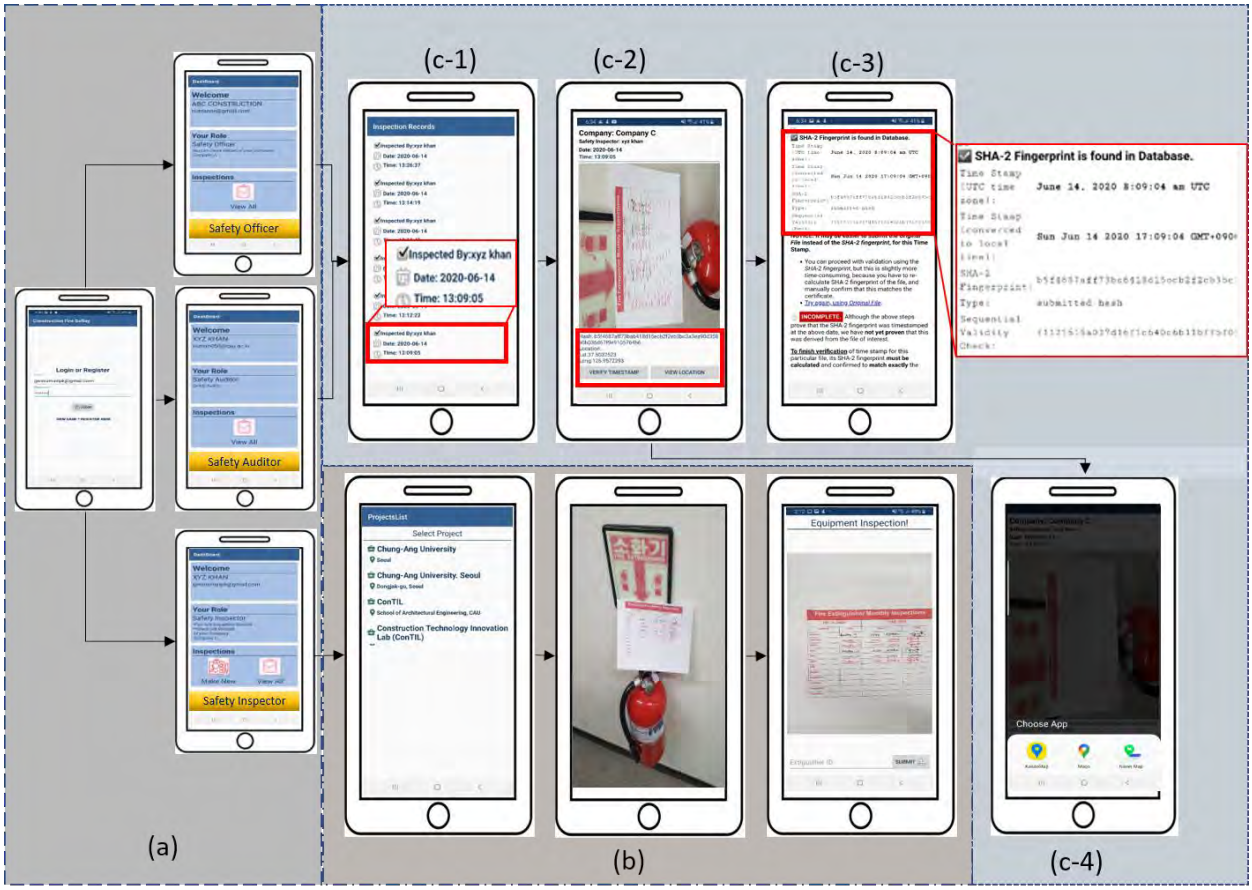

Figure 4. Screen shots of the andriod application depicting data flow and functions

dashboards. For instance, in our case, the inspection done by xyz khan on dated 2020-06-14 at 13:09:05 is verified, and the results regarding the record are visualized in Figure 4-(c-3)., which shows that SHA-2 Fingerprint is found in the database", with the same hash, date and time. In addition to verifying the transaction, the location can also be traced using different maps such as kakao, Naver, or google.

7 Conclusion

In construction, numerous workers get injured or died due to fire accidents each year. To keep the fire damage limited and minimum, many construction sites solely depend on PFE due to the absence of permanent firefighting equipment during the construction stage. Therefore, appropriate inspection with an identified based records can be easily manipulated. To address this issue, this study has developed an android mobile app that utilizes OCR and Blockchain technology for reporting and recording data. The OCR intends to automatically detect the ID from the captured tag image and the blockchain assigns a digital signature to the image.

A simple case study within the campus has been carried out to validate the concept that confirms the functionality of the developed app. It is anticipated that this app will enhance transparency, minimize the usage of paper, decrease the burden of the concerned stakeholders, and reduce the physical visits of safety auditor and safety manger, which is significantly required in the current situation of COVID-19 pandemic.

In the future, a comprehensive system will be designed to collect PFE inspection records and other

inspections or reported unsafe behavior data for the safety performance evaluation of the concerned contractors in the bidding process.

Development of Field View Monitor 2

-An assisting function for safety check around a hydraulic excavator using real-time image recognition with monocular cameras

Abstract –

We have developed a function to process the images of three monocular cameras mounted on a hydraulic excavator in real time, and to notify the user of any human-like images on the monitor and by sound. This function is composed of the following four functions. (1) Detection of the human head by random forest, (2) Normalization of the region of interest, (3)Evaluation of human presence based on luminance gradient features, and (4) Tracking based on the human and the excavator motion model. The algorithm is implemented in a FPGA unit, and the 3-camera images are input into the FPGA unit and processed by time-division manner to achieve both high-speed processing and low-cost.

Keywords –

Excavator; Image recognition; Human detection; Electronic Control Unit

1 Introduction

Hydraulic excavators are large, heavy, and fast-moving, and they do not only run but also turn. Operators are required to check the surrounding area reliably and over a wide area in order to ensure safety at sites where workers and obstacles are mixed in. However, there are many blind spots in the rear and right side of the vehicle that are not directly visible to the operator, because the engine hood and counterweight block the view from the operator's cabin at the front left of the vehicle. Therefore, it is necessary to make it possible to check the surroundings with mirrors and cameras. We developed a function to process the images of three monocular cameras mounted on the hydraulic excavator in real time. After processing the images, the function notifies the operator of any human-like images with a monitor display and sound. An image of the function is shown in Figure 1.

Figure 1. An example of the image recognition function.

The conventional function developed by us [1] [2] consists of three monocular cameras with wide angle, high sensitivity and wide dynamic range at the rear, right and left sides of the hydraulic excavator, which are combined in real time and displayed on a monitor in the operator's cabin. This function allows the operator to see 270 degrees view behind the excavator at a glance while

sitting on the operator's seat. An example of the camera arrangement and a composite image is shown in Figure 2. The pipeline processing using FPGA allows for the composite display of images without frame rate degradation. In 2011, this function was first sold as an option for hydraulic excavators and later it becomes standard equipment.

Figure 2. An example of a three-camera arrangement and image composition

However, the timing of when operators check the monitor is different depending on the operators. For example, it is assumed that workers in the vicinity may approach the hydraulic excavator while you are concentrating on your work and taking your eyes off the monitor. We developed a function to recognize camera images and notify the operator of the presence of human-like images with a monitor display and sound so that, the operator checks the area. The development's goal was to achieve a low-cost system configuration with only a monocular camera and to process the composite image that covered the entire 270-degree rearward area. In this paper, we introduce the technical issues and solutions to realize these problems, as well as examples of actual operations.

2 Targets and issues

The development goals were set as follows. This chapter describes the technical challenges for achieving the goals.

Target 1: Evaluation of the human presence using only monocular image recognition

Target 2: Processing of camera images with three different directions at least 10 times per second.

Target 3: Development compact and inexpensive in-vehicle equipment

2.1 Apparent change of a person in an image

The apparent appearance of the person in the image changes in a variety of ways, such as the color contrast of the background and the clothing, clothing with different colors for the upper and lower body, personal belongings, position and orientation to the camera, and pose. In addition, since the camera is mounted on the top of the hydraulic excavator body, which is taller than the person's height, the ratio of the image of the head to the body changes when the person approaches the camera and when he or she moves away from the camera. An example of this image is shown in Fig. 3. Although we assumed that only pedestrians appear in the images in this development, it is still difficult to manually design an algorithm to quantify human-like appearance by assuming all kinds of apparent changes of pedestrians.

Figure 3. Examples of changes in the appearance of a person on an image

2.2 Distortion of the wide-angle camera image

A wide-angle camera is used to capture the boundary between the rear camera and the side camera without any gaps, and it is installed at an angle downward to cover the entire distance from the very near to the far side of the excavator. As a result, the image of an object may be tilted at the left and right ends of the field of view, while the image of the excavator may be reflected at the lower end of the field of view. An example of the image is shown in Figure 4. When we set the region of interest to evaluate the human presence if there is a human in the area, a part of the attention region might be outside the image or covered by the excavator. This means that image information is missing.

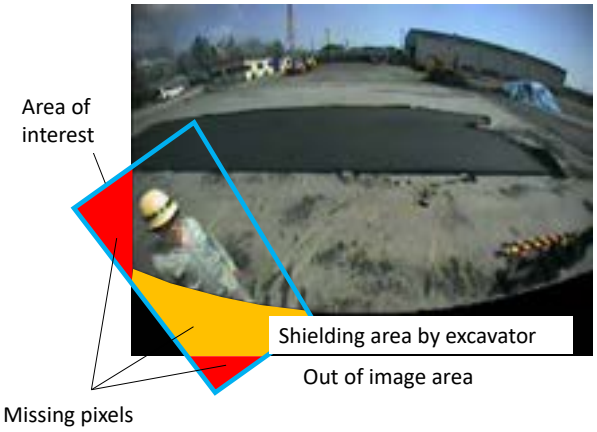

Figure 4. The missing pixels at the edge of the field of view

2.3 Faster and more stable image recognition processing cycle

It is necessary to keep executing image recognition processing, which requires a large number of computations, at a stable time cycle; FPGA can be used for stable processing time, but low-cost FPGA is limited by resources such as multipliers and internal memory.

2.4 Dense placement of the attention area

Even if the area of image for the human detection is limited to reduce the computations, thousands of regions of attention are still needed for each camera to evaluate human presence. But if we evaluate the human presence for all of regions, it is too computationally intensive to achieve the target processing cycle.

2.5 Reduction of substrate area

If the FPGA or CPU that implements image synthesis and image recognition processing is mounted separately, the board area becomes larger and more expensive, and the external appearance of the device becomes larger and more difficult to install in the excavators.

3 Evaluation of the human presence by Monocular Image Recognition

We adopts an evaluation model based on machine learning technique for the technical issues from 2.1 to 2.2 in this development. However, publicly available databases and evaluation image cropping methods [3] are not configured to address the issues described in 2.1 and 2.2, especially when a person comes directly under the camera.

In order to obtain the evaluation model for human presence in machine learning technique, a large number of supervised images are required. To collect the supervised images, we assumed a simulated environment where there is a hydraulic excavator equipping a laser sensor and a camera. The camera images were collected while the laser sensor measured the position of a person. Thousands of images were collected in the simulated environment, varying the background, weather, people's clothing, time of day, season. Then, based on the measurement results of the position of the person, a region of interest was set on the camera image, and the image was cropped and stored in the database. The position of the person in relation to the camera, the date and time of shooting, the background images and the weather, the region of interest outside the image range or the image of the car, and the original camera image were also stored in the database.

We divided the database into two categories. Category one is for the data taken very close distance from the camera, and category two is for the data taken away from the camera. We randomly selected samples from the data of the two categories. The supervised images for human detection were obtained by excluding pixels of outside the image range from the sample images or removing sample images with a large proportion of pixels of the excavator. This is to prevent the learning of pixels outside of the image range or the image of an excavator body as a characteristic of human. It is also possible to generate and use separate training models for the vicinity of the camera and for other areas to accommodate differences in the way people are reflected. The non-personal images are randomly selected by setting an arbitrary region of interest in the image without a person.

We tried to increase the number of combinations of clothing and backgrounds for supervised images, but there was a limitation. Therefore, as a preprocessing method for machine learning, we performed a feature vector transformation based on the distribution of the luminance gradient direction and normalized it for each 84-segmented partial feature vector to make it less susceptible to effects such as the contrast between background and clothing and clothing with different colors in the upper and lower body. Machine learning is ensemble learning in which the normalized sub-feature vectors are selected for a maximum of 99 logistic regressions.

4 Image recognition processing and overall structure

For the technical issues 1.3 to 1.4, we have adopted the overall structure shown in Figure 5.

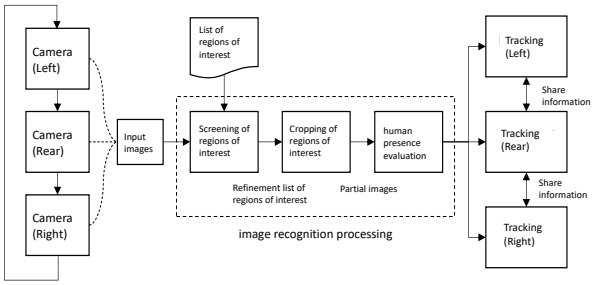

Figure 5. Overall structure of the image recognition process

The region of interest is the rectangle that surrounds the person in the image. The position of rectangles are calculated in advance for each position of the person in relation to the camera.

The image recognition process is the FPGA module that inputs grayscale images extracted from the camera images and outputs information on the area of interest that is judged to be human-like. It includes the processing of area of interest screening, the area of interest cropping, and the human presence evaluation.

In the screening of regions of interest process, all the region of interest in the field of view are input and the candidates are narrowed down by simple image recognition without trimming the area. In this case, we assume that there is a human-like image in the region of interest and transform the feature vectors of the region corresponding to the human head based on the luminance distribution. After that, we evaluate the image recognition with a machine learning model. The machine learning model is a lightweight random forest.

The region of interest extraction process extracts the pixels in the region of interest narrowed down by the region of interest screening process and normalizes them to a partial image with a uniform size.

The human presence evaluation process applies the human presence evaluation model described in Chapter 3 to the partial image generated by the region of interest cropping process, and judges whether the image is humanness or not by comparing it with the threshold value.

The tracking process obtains the location, time and camera ID of the region of interest that is determined to be humanness. The position of the region of interest is determined to be within the range of a human movement by comparing it with the results of the judgement made up to the previous time. This movable range is calculated from the relative speeds of the man and the excavator. If the judgment is positive, the positional information of the region of interest is output. This positional information is a rectangle that surrounds the object in the image and is fine-tuned to take into account the deformation of the edge of the field of view and the speed of movement. It can be done. In addition, as the person may move between cameras, a function to share location information between adjacent cameras is provided. The system is equipped with a function to select a person in the same field of view in order of near distance from the camera if more than one person is detected in the same field of view. When two or more persons are detected in the same field of view, a function to select them in the order of their distance from the camera is provided. This set of processes is a lightweight algorithm that applies a histogram filter [4] and does not affect the speed of overall image recognition cycle.

5 System Configuration and Hardware

In this development, the structure shown in Figure 6 was adopted to solve the technical problem of 2.5. The outline specifications of the configuration are shown in Table 1.

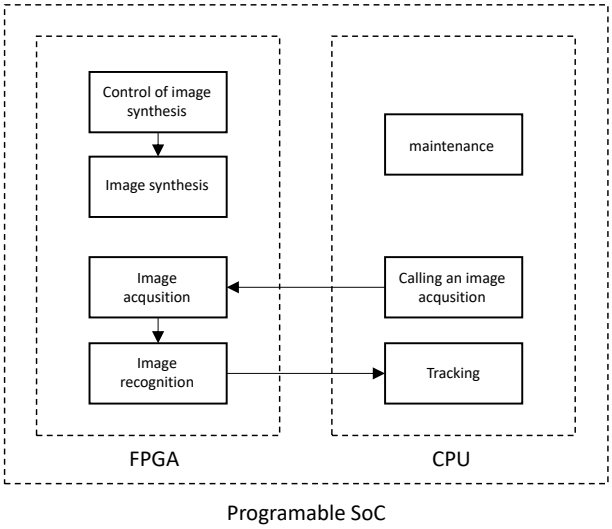

Figure 6. Overall configuration using a programmable SoC

Table 1. System specifications

In-vehicle unit	Specification	
Image Signal form	NTSC	
CPU	800	MHz
RAM	DDR3L SDRAM 2048	MB
Image synthesis memory	SDR-SDRAM 64	Mbit
Dimensions	Width 215	mm
	Length 128	mm
	Height 36	mm

The programmable SoC consists of the FPGA part, a CPU and a microcomputer part with various peripheral interfaces in the same chip.

In the FPGA part, an image synthesis module, a control module, an image recognition module, and an image acquisition module that supplies grayscale images to the module are integrated. In the microcomputer, a software that calls the image acquisition module, tracking software, and maintenance software for setting and adjusting each FPGA module and software were installed.

The evaluation of various scenes was based on the part of the database described in Chapter 3. Scenes in which people were present in the vicinity of 2 m from the camera and should be correctly detected were selected as the dataset for human detection evaluation. In addition, scenes that did not contain people were selected as a dataset for false alarm evaluation. While analyzing the processing results of these data sets, we adjusted the balance between the sensitivity to detect people and the false alarm rate. As shown in Figure 10, we were able to detect people with simple backgrounds with almost no misses. On the other hand, as shown in Figure 11, when the background contains high contrast and complex edges, the number of missed images and false alarms increases. Specifically, this includes the shadows of the excavated ground, plants and trees, other work equipment, cars, and man-made objects such as drums and benches.

Figure 7. Dataset for human detection and evaluation

Figure 8. Dataset for false alarm evaluation

6 Examples of system operation

Figure 9 is an example of a monitor display of the recognition results for various orientations and distances of people from the camera, and for various types of clothing and backgrounds. If there is a human-like image, we can see that the image can be displayed on the monitor regardless of the change in appearance on the image.

Figure 9. Perceptional results of people with diverse appearances

Figure 10 is an example of a monitor display of the recognition result when a person is approached by walking along the boundary between adjacent cameras. Even if the image appears to be tilted near the edge of the field of view, if there is a human-like image, it can be displayed on the monitor because of the image distortion of the wide-angle camera.

Figure 10. Recognition results at the edge of the field of view

Figure 11 is an example of the conventional function of displaying recognition results on a composite image. The system not only allows the operator to check the rear 270 degrees of the excavator at a glance, but also notifies the operator of any human-like images on the monitor display, and at the same time the system notifies the operator by sound, etc., which can be a trigger for the operator to check the area around the excavator.

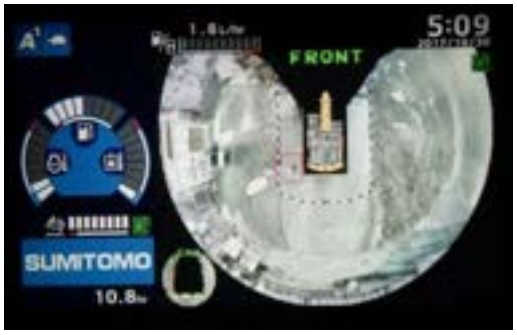

Figure 11. Display of recognition results on the composite image

Figure 12 is an example of the monitor display of the recognition result when a non-human object is judged as a human.

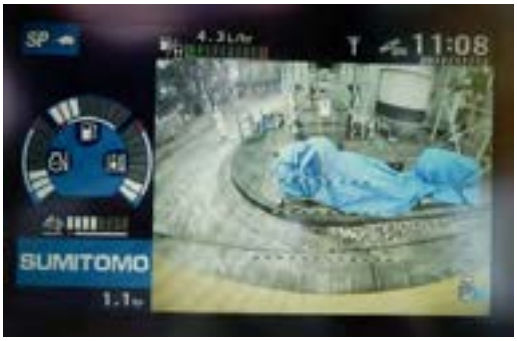

Figure 12. Examples of not being a person, but recognizing a person as a person

7 Conclusion

We have developed and put into practical use a function that recognizes images from a monocular camera mounted on a hydraulic excavator and notifies the operator of any human-like images with a monitor display and sound, giving the operator the opportunity to check the surroundings. The system was also approved for registration in the New Technology Information System (NETIS) [5].

Abstract –

Visual inspections of underside of concrete superstructures of piled piers are usually carried out by inspectors on small boat or divers. it is not easy to ensure work safety in such a narrow space because of affection by waves and tides during inspection work. And, in-service facilities require to carry out the inspection work efficiently within a limited amount time and period. Therefore, the authors developed a ROV type inspection device with various support functions that takes images of the underside of the pier superstructure for improving the safety and efficiency of the inspection work. Moreover, we also developed a software to support documentation of the inspection and diagnosis of pier superstructures.

In this paper, a developed ROV for visual inspection of concrete pier superstructure and cooperation between various support functions are described.

Keywords –

Visual inspection; Concrete pier superstructure; ROV; Work support functions

1 Introduction

In typical periodic inspections, visual inspections of underside of concrete superstructures of piled piers are usually carried out by inspectors on small boat. If there is insufficient clearance to access the underside by boats, divers carry out the inspection work. However, it is not easy to ensure work safety in such a narrow space because it is affected by tidal and wave conditions during work. In addition, inspection work should be carried out efficiently so that it does not interfere with the mooring or cargo works.

For the purpose of improving the safety and efficiency of such inspection work, our R&D group has been developed a ROV (Remotely Operated Vehicle) type inspection device that takes images for diagnosis of the underside of the pier superstructure by remote control from land since 2014. We have been conducting the ROV demonstration tests since 2017, and the ROV was equipped with various work support functions at each development phase in order to reliably navigate and operate the ROV in the environments described above. Typical support functions are a positioning under the pier superstructure without using GNSS (Global Navigation Satellite System), shooting position management, a collision avoidance for obstacles, and a shooting history presentation for preventing shooting omissions. Moreover, we also developed a software for documentation of inspection and diagnosis to support in-house work.

In this paper, a developed ROV for visual inspection of concrete pier superstructure and cooperation between various support functions are described in detail by citing references of each development report.

2 ROV for Visual Inspection of Concrete Pier Superstructure

The ROV for visual inspection of concrete pier superstructure, named ROV-PARI, consists of an underwater vehicle platform and the camera system intended for concreate superstructure shooting. This is a semi-submersible ROV with a camera mounted on the top of the underwater vehicle platform and floats on the side. With this configuration, the distance from the center of buoyancy to the center of gravity can be extended, and so the ROV ensured stability against hull fluctuation.

The underwater vehicle platform is a movable body with payload part and a device extension function. It is equipped with an underwater camera and six underwater propulsor units, and can be also used as a general ROV that can dive up to 200m by itself. The underwater camera of the underwater vehicle platform and the two aerial cameras in front and behind make a wide field of view when operating as ROV-PARI.

The camera system intended for the superstructure shooting is equipped with one GigE camera for preview and image processing and one digital single-lens reflex camera (DSLR) for inspection images facing upward. It is as tolerant to low-light and deposits as humans.

In addition, ROV-PARI is equipped with LRF (Laser Range Finder) in order to grasp the situation of obstacles around itself, and a directional gyro is installed for the

ROV's own heading estimation. The scanning results obtained from the two LRFs are combined to form the omnidirectional scanning result and be imaged, and pier piles are detected by image processing, and its position information are used. The positions of these detected piles and the piles in the map database are collated, the collated piles are regarded as landmarks, and the ROV's own position and heading seen from the position of the landmarks are estimated by inverse calculation. In the case that the number of collated piles is less than two, the ROV's own heading is estimated by the directional gyro. Moreover, the ROV's own position and direction are measured using a GPS compass on the sea outside piers.

Therefore, attaching the position information to the obtained pictures, it is possible to manage the inspection position. Figure 1 shows ROV-PARI, and Table 1 shows the specifications.

3 Work Support Functions

3.1 Software for In-situ the ROV-PARI Operation

The ROV is remotely operated while confirming the shooting position on the software for in-situ ROV-PARI operation onshore. Figure 3 shows the screenshot of the software used by operators.

In order to support the operation and navigation of the ROV by the operator, the software presents the ROV position information and surrounding obstacles information in real time. This figure is a screenshot while actual operation in the field verification test. Operation panels are prepared on the left side of the window, and various support functions can be used by checking the necessary functions. The main functions are described below:

- CamConPanel: Shooting interval setting. Checking “HIGH” is 1 second, and “MIDDLE” is 2 seconds.
- INSTRUMENTS: Power control of each of the following devices: “CAMERA (all upward cameras)”, “O-GYRO (optical-gyro)”, “LRF (Lase Range Finder)”, “DISTANCE (distance meter)”. LRFs and distance meter are indispensable devices for making after-mentioned “COLLISION AVOIDANCE” and “FOOT PRINT” work.
- GPS COMPASS: Checking “GPS”, it is possible to measure the position and heading of the ROV on the sea outside piers. Mainly used for initial position setting before approaching under pier.
- A-CAS: Autonomous Collision Avoidance System. Measuring positional relationship with obstacles detected by LRFs, the ROV avoids collision with obstacles autonomously. The avoidance action is added to human operation. Checking “UP LINK”, onshore equipment and the ROV are connected. Checking “COLLISION AVOIDANCE”, the function is working.
- REC: Recording logs. Checking “REC LOG”, log recording and interval shooting are started.
- SHOOTIN: Shooting functions. Blue line rectangle is shooting area calculated by shooting distance and optical system of camera, and fill the shoot area. Checking “FOOT PRINT”, shooting history is presented. On “ERASE EP” button down, shooting history is reset. On “ONE SHOT” button down, one picture is shoot manually.

On the lower left side of the screen, an image of the underside of the pier superstructure taken by the GigE camera for preview described in Chapter 2 among the two upper cameras installed is constantly displayed. This shooting area is slightly narrower than the area of DSLR for inspection images.

On the lower right side of the screen, the all-around scanning image obtained by LRFs is displayed. Namely, measuring the relative positional relationship with surrounding objects and obstacles obtained by all-around scanning is calculated, and the result is always displayed in heading-up. Using the relative position information of the closest and second closet piles, shown in Figure 3 as pink and orange piles respectively, the position of the ROV is estimated from the relative position with the closest pile, and the heading is estimated from the angle between the line segment of the closest-the second closet piles and the ROV itself. The positioning function is described in Section 3.2.

In addition, since the all-around scanning result using LRFs are obtained while the positioning process, not only the piles but also the surrounding obstacles are observed. The collision avoidance direction and the level are presented by measuring the relative positional relationship with surrounding objects, and the autonomous collision avoidance behaviour is performed based on this information. The autonomous collision avoidance function is described in Section 3.3.

On the top of the screen is a map created from the prepared pile placement information. By displaying the ROV on this map based on the previous positioning result, the operator can grasp the current position of the ROV under the pier superstructure, and the reliable operation of the ROV along the pre-planned inspection route is possible. Blue line rectangle is shooting area, and filled it is presented as shooting history. In the figure, the filled area in light grey is the captured area. It is possible to easily distinguish captured area and the uncaptured area underside of the pier superstructure in real time, and toto present the omission of shooting. The shooting history presentation is described in Section 3.4.

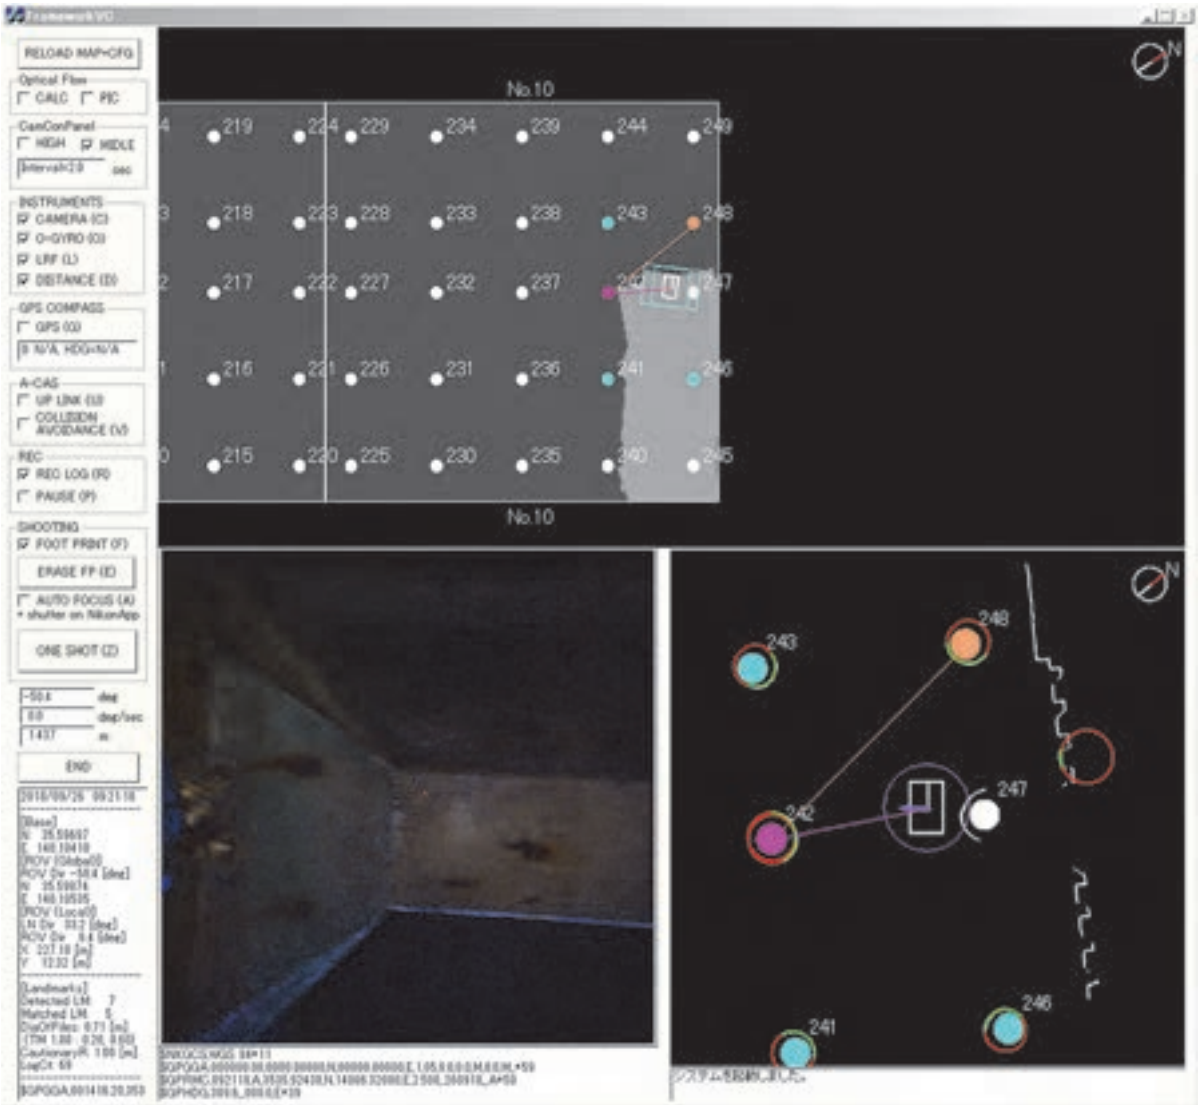

Figure 3. Screenshot of software for in-situ ROV-PARI operation

3.2 Positioning under Pier Superstructures

First, the scanning results obtained by the two LRFs are combined to make an all-around scanning result and is imaged. Next, the piles are detected from the image by image processing, and the position information are used. In fact, the positions of these detected piles and the piles in the map database are collated, the collated piles are regarded as landmarks, and the ROV's own position and heading seen from the position of the landmarks are estimated by inverse calculation.

When there are two or more Matched piles that succeeded in matching the position of the "detected objects" of circular cross-sectional shape by image processing from the scanning image with the position of the piles in the map database, the matched pile proximate to the ROV is "reference point for positioning" (Pink circle in Figure 3) and positioning of the ROV's own position is conducted relative to the point (Pink line in Figure 3). Next, the matched pile secondly proximate to the ROV is the "auxiliary point for azimuth estimation"(Orange circle in Figure 3.), and the heading of the ROV is estimated from the angle between the baseline connecting the positioning reference point and the azimuth estimation auxiliary point (Orange line in Figure 3) and the ROV. In case that the number of matched piles is less than one, the heading estimation is switched to the gyro-base. In case that there is no matched pile, the position estimation of the ROV is allowed to be switched to inertial navigation.

The mathematical presentations of the positioning are shown in the following sections. The first and second axes of the ROV coordinate system are the Roll and Pitch axes on the horizontal plane, and the third axis is the vertically downward Yaw axis, respectively.

The first and second axes of the local map coordinate system are the axis parallel to the face line of the wharf and the orthogonal axis that land side is positive on the horizontal plane, and the third axis is vertically upward, respectively. The first and second axes of the world coordinate system are north latitude and east longitude, and the third axis is vertically downward, respectively. However, all coordinate systems are positive-oriented.

3.2.1 Position on a Local Map Coordinate System

Each positional vector of the piles is defined in Equation (1). Here, the left-superscripts of the variables represent the coordinate systems, and the right-subscripts of the variables represent the objects. Bolds represent vectors or matrices.

$$
\begin{aligned}
&{}^{\mathrm{ROV}}\boldsymbol{P}_{\mathrm{MAP}_k},\ {}^{\mathrm{MAP}}\boldsymbol{P}_{\mathrm{MAP}_k} &&: \text{Piles positions}\\
&{}^{\mathrm{ROV}}\boldsymbol{P}_{\mathrm{RES}_j},\ {}^{\mathrm{MAP}}\boldsymbol{P}_{\mathrm{RES}_j} &&: \text{DP positions}\\
&{}^{\mathrm{ROV}}\boldsymbol{P}_{\mathrm{RES}_{P_i}},\ {}^{\mathrm{MAP}}\boldsymbol{P}_{\mathrm{RES}_{P_i}} &&: \text{MP positions}\\
&{}^{\mathrm{ROV}}\boldsymbol{P}_{\mathrm{MAP}_{Q_i}},\ {}^{\mathrm{MAP}}\boldsymbol{P}_{\mathrm{MAP}_{Q_i}} &&: \text{MP positoin on the local map}
\end{aligned}
\tag{1}
$$

Here, the position of the detected pile j is compared with that of the pile k on the map database, and if the norm between them is less than or equal to a threshold, the detected pile j is regarded as the pile k, and is becomes the matched pile i. In addition, P_i is an index which sorted i in near order to the ROV, and Q_i is the index corresponding to P_i on the map database. After that, P_1 and Q_1 are the index of the proximate matching piles to the ROV, and regarded as positioning reference points, then P_2 and Q_2 are the index of the secondly proximate matching pile to the ROV, and are regarded as auxiliary points for azimuth estimation. The heading and positional vectors of the ROV are defined in Equation (2).

$$
\begin{aligned}
&{}^{\mathrm{ROV}}\theta_{\mathrm{MAP}}: \text{Angle btween first axes of ROV and MAP}\\
&{}^{\mathrm{MAP}}\theta_{\mathrm{ROV}}: \text{Angle between first axes of MAP and ROV}\\
&{}^{\mathrm{ROV}}\theta_{\mathrm{RES}_{P_1\to P_2}}: \text{Angle between ROV and segment RES}_{P_1\to P_2}\\
&{}^{\mathrm{MAP}}\theta_{\mathrm{MAP}_{Q_1\to Q_2}}: \text{Angle between MAP and segment MAP}_{Q_1\to Q_2}\\
&{}^{\mathrm{ROV}}\boldsymbol{P}_{\mathrm{ROV}},\ {}^{\mathrm{MAP}}\boldsymbol{P}_{\mathrm{ROV}}: \text{Positioal vectors of the ROV}\\
&\boldsymbol{R}_1(\theta): \text{Rotation matrix. The subscript is rotational axis}\\
&\qquad \text{, and the argument is rotational angle.}\\
&\text{where,}\quad {}^{\mathrm{ROV}}\boldsymbol{P}_{\mathrm{ROV}} \equiv \boldsymbol{O}
\end{aligned}
\tag{2}
$$

From the above definition, if there are two or more matching piles, heading of the ROV ${}^{\mathrm{MAP}}\theta_{\mathrm{ROV}}$ in the local map coordinate system can be estimated by using the positioning reference point and the auxiliary point for azimuth estimation from Equation (3) [1].

$$
\begin{aligned}
{}^{\mathrm{ROV}}\theta_{\mathrm{RES}_{P_1\to P_2}} &= \operatorname{atan2}\left(\frac{{}^{\mathrm{ROV}}y_{\mathrm{RES}_{P_2}} - {}^{\mathrm{ROV}}y_{\mathrm{RES}_{P_1}}}{{}^{\mathrm{ROV}}x_{\mathrm{RES}_{P_2}} - {}^{\mathrm{ROV}}x_{\mathrm{RES}_{P_1}}}\right)\\
{}^{\mathrm{MAP}}\theta_{\mathrm{MAP}_{Q_1\to Q_2}} &= \operatorname{atan2}\left(\frac{{}^{\mathrm{MAP}}y_{\mathrm{MAP}_{Q_2}} - {}^{\mathrm{MAP}}y_{\mathrm{MAP}_{Q_1}}}{{}^{\mathrm{MAP}}x_{\mathrm{MAP}_{Q_2}} - {}^{\mathrm{MAP}}x_{\mathrm{MAP}_{Q_1}}}\right)\\
{}^{\mathrm{ROV}}\theta_{\mathrm{MAP}} &= {}^{\mathrm{ROV}}\theta_{\mathrm{RES}_{P_1\to P_2}} - {}^{\mathrm{MAP}}\theta_{\mathrm{MAP}_{Q_1\to Q_2}}\\
{}^{\mathrm{MAP}}\theta_{\mathrm{ROV}} &= {}^{\mathrm{MAP}}\theta_{\mathrm{ROV}_{inc}} = -{}^{\mathrm{ROV}}\theta_{\mathrm{MAP}}
\end{aligned}
\tag{3}
$$

If Equation (3) cannot be used because the number of matched piles is less than 1, it is possible to seamlessly switch the heading source from Equation (3) to ${}^{\mathrm{MAP}}\theta_{\mathrm{ROV}_{inc}}$ and to estimate ${}^{\mathrm{MAP}}\theta_{\mathrm{ROV}}$ by initializing the heading ${}^{\mathrm{MAP}}\theta_{\mathrm{ROV}_{inc}}$ by the directional gyro with ${}^{\mathrm{ROV}}\theta_{\mathrm{MAP}}$ while the heading ${}^{\mathrm{ROV}}\theta_{\mathrm{MAP}}$ can be estimated by Equation (3).

Next, the relative positioning method of the ROV position in the local map coordinate system is described. Here, the ROV position vector ${}^{\mathrm{MAP}}\boldsymbol{P}_{\mathrm{ROV}}$ in the local map coordinate system is calculated by Equation (4) using the estimated heading and the positional vector of the positioning reference point.

$$
\begin{aligned}
\begin{pmatrix} {}^{\mathrm{MAP}}\boldsymbol{P}_{\mathrm{ROV}} \\ 1 \end{pmatrix} &= \begin{pmatrix} \boldsymbol{R}_3\left({}^{\mathrm{MAP}}\theta_{\mathrm{ROV}}\right) & {}^{\mathrm{MAP}}\boldsymbol{P}_{\mathrm{MAP}_{Q_1}} \\ \boldsymbol{O}^T & 1 \end{pmatrix} \begin{pmatrix} -{}^{\mathrm{ROV}}\boldsymbol{P}_{\mathrm{RES}_{P_1}} \\ 1 \end{pmatrix}\\
{}^{\mathrm{MAP}}\boldsymbol{P}_{\mathrm{ROV}} &= \boldsymbol{R}_3\left({}^{\mathrm{MAP}}\theta_{\mathrm{ROV}}\right)\left(-{}^{\mathrm{ROV}}\boldsymbol{P}_{\mathrm{RES}_{P_1}}\right) + {}^{\mathrm{MAP}}\boldsymbol{P}_{\mathrm{MAP}_{Q_1}}
\end{aligned}
\tag{4}
$$

If the number of matched piles is less than one, the heading estimation is switched to the gyro-base. If there are no matched piles, the positional estimation is allowable to be switched to inertial navigation and so on.

Finally, using the positional vectors and heading of the ROV estimated, the positional vectors of piles on the map database in the ROV coordinate system is updated by Equation (5). As a result, the new detected piles and the new map database can be collated even in the next positioning step, and positioning can be continued.

$$^{\mathrm{ROV}}\boldsymbol{P}_{\mathrm{MAP}_k} = \boldsymbol{R}_3(^{\mathrm{ROV}}\theta_{\mathrm{MAP}})(^{\mathrm{MAP}}\boldsymbol{P}_{\mathrm{MAP}_k} - ^{\mathrm{MAP}}\boldsymbol{P}_{\mathrm{ROV}}) \quad (5)$$

3.2.2 Transform to the World Coordinate System

Positional vector of the origin of the local map coordinate system $^{\mathrm{MAP}}\boldsymbol{P}_{\mathrm{MAP}} \equiv \boldsymbol{O}$ is $^{\mathrm{W}}\boldsymbol{P}_{\mathrm{MAP}}$ in world coordinate system, and the inclination of the local map coordinate system with respect to the world coordinate system is direction of face line of the wharf $^{\mathrm{W}}\theta_{\mathrm{MAP}}$. Transformation to world coordinate system of $^{\mathrm{MAP}}\boldsymbol{P}_{\mathrm{ROV}}$ estimated by Equation (4) is represented by rotation trough $^{\mathrm{W}}\theta_{\mathrm{MAP}}$ about third axis, multiplying by meter-lat/long transformation matrix $\boldsymbol{L}$, and parallel translation $^{\mathrm{W}}\boldsymbol{P}_{\mathrm{MAP}}$ [1].

The equation for conversion the positional vector of the ROV $^{\mathrm{MAP}}\boldsymbol{P}_{\mathrm{ROV}}$ in the local map coordinate system to world coordinate system is shown in Equation (6).

$$\begin{pmatrix} ^{\mathrm{W}}\boldsymbol{P}_{\mathrm{ROV}} \\ 1 \end{pmatrix} = \begin{pmatrix} \boldsymbol{L} & \boldsymbol{O} \\ \boldsymbol{O}^T & 1 \end{pmatrix} \begin{pmatrix} \boldsymbol{R}_3(^{\mathrm{W}}\theta_{\mathrm{MAP}}) & ^{\mathrm{W}}\boldsymbol{P}_{\mathrm{MAP}} \\ \boldsymbol{O}^T & 1 \end{pmatrix} \begin{pmatrix} \boldsymbol{R}_1(\pi) \cdot ^{\mathrm{MAP}}\boldsymbol{P}_{\mathrm{ROV}} \\ 1 \end{pmatrix} \quad (6)$$
$$^{\mathrm{W}}\boldsymbol{P}_{\mathrm{ROV}} = \boldsymbol{L} \cdot \boldsymbol{R}_3(^{\mathrm{W}}\theta_{\mathrm{MAP}})(\boldsymbol{R}_1(\pi) \cdot ^{\mathrm{MAP}}\boldsymbol{P}_{\mathrm{ROV}}) + ^{\mathrm{W}}\boldsymbol{P}_{\mathrm{MAP}}$$

According to the Chronological Scientific Tables (NAOJ), the length $\Delta l_{\mathrm{LAT}}[\mathrm{m/deg}]$ corresponding to a latitude of 1deg depending on the geographical latitude φ and the length $\Delta l_{\mathrm{LON}}[\mathrm{m/deg}]$ corresponding to a longitude of 1deg are approximately expressed by the Equation (7).

Therefore, the meter-lat/long transformation matrix $\boldsymbol{L}$ around geographical latitude φ and in the vicinity of $^{\mathrm{W}}\boldsymbol{P}_{\mathrm{MAP}}$ is given by Equation (8). If GRS 80 is applied as an earth ellipsoid model, the equatorial radius a is 6 378 137m, and the ellipticity f is 1/298.257 222 101. Moreover, the eccentricity of the earth ellipsoid e is $\sqrt{f(2-f)}$, and e^2 is an approximate value of 0.006 694 380 022 900 788.

$$\Delta l_{\mathrm{LAT}} \approx {}^{\pi}/_{180} \cdot {}^{a(1-e^2)}/_{(1-e^2\sin^2\varphi)^{3/2}}$$
$$\Delta l_{\mathrm{LON}} \approx {}^{\pi}/_{180} \cdot {}^{a\cos\varphi}/_{\sqrt{1-e^2\sin^2\varphi}} \quad (7)$$

$$\boldsymbol{L} = \begin{pmatrix} 1/\Delta l_{\mathrm{LAT}} & 0 & 0 \\ 0 & 1/\Delta l_{\mathrm{LON}} & 0 \\ 0 & 0 & 1 \end{pmatrix} \quad (8)$$

3.2.3 Correspondence between Shooting Position Information and Obtained Pictures

Two methods are prepared regarding the correspondence between the obtained pictures and the shooting-attribute information such as shooting position. One is directly attaching to the picture data on real-time and another one is recording in a log file synchronized with the shooting time.

The first method is to convert the latitude and longitude position information in world coordinate system calculated by Equation (6) into NMEA0183-compliant packet information and pass it directly to the camera at the same time as shooting. The shooting date and time, shooting direction, shooting position, and so on are directly written in the Exif GPS IFD tag in the picture data, then it is possible integrally to manage and to utilize the obtained pictures in conjunction with shooting position on a map-linked photo viewer or GIS application.

The second method is to prepare a log file synchronized with the shooting, and record the shooting date and time, shooting direction, shooting position, and so on at the same time of shooting in the file. Here, in addition to the latitude and longitude position information in world coordinate system recorded of the first method, the position information in the local map coordinate system with higher resolution calculated by Equation (4) is also recorded. it is possible to utilize highly accurate position information on the local map coordinate system, and it makes easy to secondary use of obtained pictures using shooting position such as making development view using the obtained pictures.

3.3 Avoidance Direction and Autonomous Collision Avoidance Function

Collision avoidance direction is presented on the operation screen in order to support remote control of the ROV. First, the distance L_{LRF_θ} from the ROV to the first reflection points all-around direction observed by two LRFs are obtained. Next, as shown in Figure 4, an alert circle (broken line) with radius R_{margin} is set around the ROV, the weight w_θ in each direction is calculated by Equation (9) according to the magnitude relationship of L_{LRF_θ} and R_{margin}.

As a result, the avoidance direction vector $^{\mathrm{ROV}}\boldsymbol{A}_{\mathrm{LRF}}$ in the ROV coordinate system is calculated by the Equation (9) according to multiply the unit vector $\boldsymbol{e}_\theta$ of each direction by the weight w_θ and taking the sum [1].

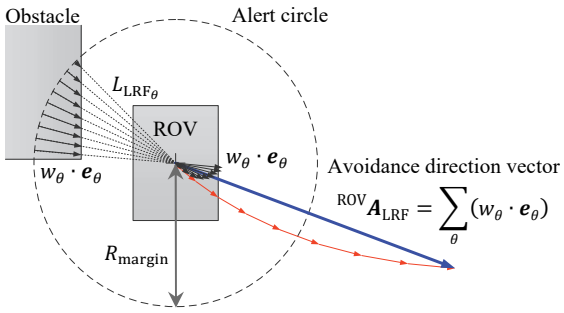

Figure 4. Calculation of collision avoidance direction based on the LRFs

$$
{}^{\mathrm{ROV}}\boldsymbol{A}_{\mathrm{LRF}} = \sum_{\theta}(w_{\theta} \cdot \boldsymbol{e}_{\theta})
$$
$$
\text{where,}\quad w_{\theta} = \begin{cases} -\frac{R_{\mathrm{margin}} - L_{\mathrm{LRF}_{\theta}}}{R_{\mathrm{margin}}} & \left(\text{if } L_{\mathrm{LRF}_{\theta}} \le R_{\mathrm{margin}}\right) \\ 0 & \left(\text{if } L_{\mathrm{LRF}_{\theta}} > R_{\mathrm{margin}}\right) \end{cases} \tag{9}
$$

Here, since the collision avoidance direction is indicated by ${}^{\mathrm{ROV}}\boldsymbol{A}_{\mathrm{LRF}}$, the collision avoidance behaviour vector ${}^{\mathrm{ROV}}\boldsymbol{B}_{\mathrm{LRF}}$ is multiplied by the gain G, and expressed by Equation (10).

$$
{}^{\mathrm{ROV}}\boldsymbol{B}_{\mathrm{LRF}} = G \cdot {}^{\mathrm{ROV}}\boldsymbol{A}_{\mathrm{LRF}} \tag{10}
$$

In addition, the ROV always receives the normalized navigation vector ${}^{\mathrm{ROV}}\boldsymbol{B}_{\mathrm{JOY}}$ by the joystick operation. Therefore, the total navigation vector ${}^{\mathrm{ROV}}\boldsymbol{B}_{\mathrm{TOTAL}}$ of the ROV is expressed by Equation (11) with saturation condition according that the collision avoidance behaviour vector ${}^{\mathrm{ROV}}\boldsymbol{B}_{\mathrm{LRF}}$ is added to the navigation vector ${}^{\mathrm{ROV}}\boldsymbol{B}_{\mathrm{JOY}}$ [2].

$$
{}^{\mathrm{ROV}}\boldsymbol{B}_{\mathrm{TOTAL}} = \begin{cases} {}^{\mathrm{ROV}}\boldsymbol{B}_{\mathrm{JOY}} + {}^{\mathrm{ROV}}\boldsymbol{B}_{\mathrm{LRF}} & \left(\text{if } \left|{}^{\mathrm{ROV}}\boldsymbol{B}_{\mathrm{JOY}} + {}^{\mathrm{ROV}}\boldsymbol{B}_{\mathrm{LRF}}\right| \le 1\right) \\ \frac{{}^{\mathrm{ROV}}\boldsymbol{B}_{\mathrm{JOY}} + {}^{\mathrm{ROV}}\boldsymbol{B}_{\mathrm{LRF}}}{\left|{}^{\mathrm{ROV}}\boldsymbol{B}_{\mathrm{JOY}} + {}^{\mathrm{ROV}}\boldsymbol{B}_{\mathrm{LRF}}\right|} & \left(\text{if } \left|{}^{\mathrm{ROV}}\boldsymbol{B}_{\mathrm{JOY}} + {}^{\mathrm{ROV}}\boldsymbol{B}_{\mathrm{LRF}}\right| > 1\right) \end{cases} \tag{11}
$$

However, the upper limit of the collision avoidance behaviour vector ${}^{\mathrm{ROV}}\boldsymbol{B}_{\mathrm{LRF}}$ is set to 50% of the total navigation vector in order to avoid out of control while collision avoidance (Equation 12).

$$
{}^{\mathrm{ROV}}\boldsymbol{B}_{\mathrm{LRF}} = \begin{cases} G \cdot {}^{\mathrm{ROV}}\boldsymbol{A}_{\mathrm{LRF}} & \left(\text{if } \left|G \cdot {}^{\mathrm{ROV}}\boldsymbol{A}_{\mathrm{LRF}}\right| \le 0.5\right) \\ 0.5 \cdot \frac{{}^{\mathrm{ROV}}\boldsymbol{A}_{\mathrm{LRF}}}{\left|{}^{\mathrm{ROV}}\boldsymbol{A}_{\mathrm{LRF}}\right|} & \left(\text{if } \left|G \cdot {}^{\mathrm{ROV}}\boldsymbol{A}_{\mathrm{LRF}}\right| > 0.5\right) \end{cases} \tag{12}
$$

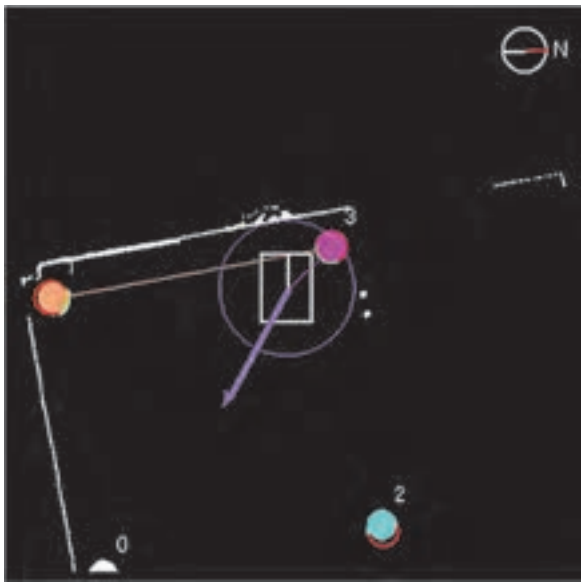

Figure 5. Autonomous collision avoidance behaviour of the ROV

The autonomous collision avoidance behaviour of the ROV is shown in Figure 5. In this figure, the collision avoidance direction has been calculated in response to penetration of the proximate pink pile into the alert-circle-area, and the ROV avoids collision with the pile autonomously.

3.4 Presentation of Shooting History

The picture displayed in the upper part of the in-situ operation application in Figure 3 is the navigation window that displays the ROV on the map database of the piles layout. The operator grasps the current position of the ROV from the information on this window and operates the ROV along the planned inspection route.
The blue line rectangular surrounding the ROV indicates the shooting area of the inspection camera, and the shooting history is presented by leaving the filled shooting area as footprints. In the figure, the filled area in light gray is the captured area. With this function, it is possible to easily distinguish the captured area and the uncaptured area on the underside of the pier superstructure in real time, and it is possible to prevent shooting omissions.

Here, in case of angle of view θ, φ[deg] (horizontal, vertical), shooting distance D[mm], focal length F[mm], sensor size W_s, H_s[mm] (horizontal, vertical), the filled-in area W, H[mm] (horizontal, vertical) as the shooting history in one shooting is expressed multiplying the shooting area of the camera by the safety factor R by Equation (13) [3].

$$
W = 2D \cdot R\tan\theta/2\,,\quad H = 2D \cdot R\tan\varphi/2
$$
$$
\text{where,}\quad \tan\theta/2 = 0.5W_s/F\,,\quad \tan\varphi/2 = 0.5H_s/F \tag{13}
$$

An example of the presentation of the shooting history in field experiment to verify the effect is shown in Figure 6. On the other hand, Figure 7 shows a 3-D model of the pier superstructure constructed by SfM-MVS software from the obtained pictures corresponding to the shooting history.

Both pictures are perspective view looking down the pier superstructure vertically. Comparing shooting history in Figure 6 and the 3-D model in Figure 7, each uncaptured area is the same.

3.5 Effectiveness of Introducing the Developed Technologies

Authors have conducted several field tests for the verification of the developed technologies to date. The proposed method using the technologies is secure and safety because there are no inspectors on the sea.

The proposed method performed well in every test although obtained information were increased. And, one of results showed more than fourfold efficiency on site work to the conventional method by inspectors [4].

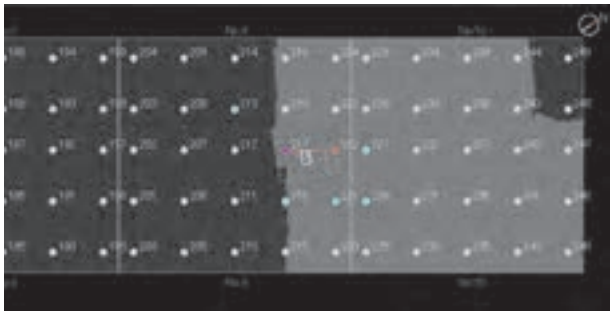

Figure 6. Foot-print of the shooting history

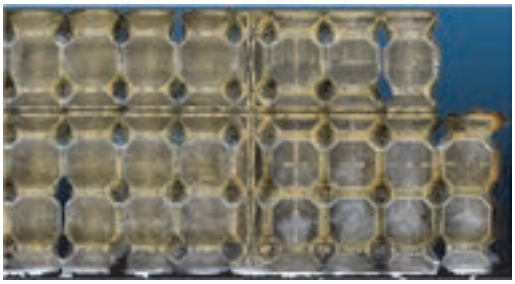

Figure 7. 3-D model concrete pier superstructure constructed by SfM-MVS photogrammetry

4 Inspection and Diagnosis Support System

An inspection and diagnosis support system was also developed for supporting the work to make inspection reports because of obtaining an enormous inspection picture by introduction of the ROV to field work [4][5].

First, 3-D model of the underside of the pier superstructure is composite from obtained pictures using commercially SfM-MVS (Structure from Motion-Multi View Stereo) software. The SfM-MVS technology is a general-purpose technology recently applied to drone photogrammetry and shape measurement of structures.

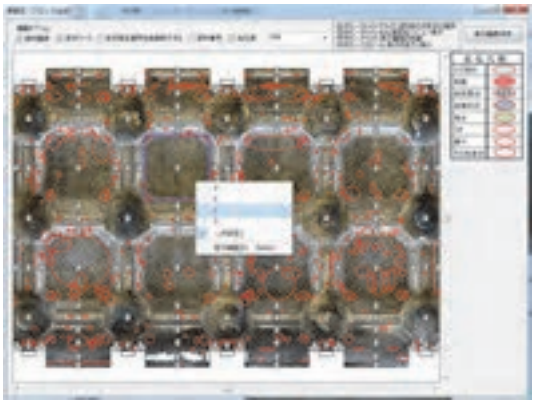

Figure 8. 2-D development view and candidates of suspected deterioration on the support system

2-D development view for each member is automatically created from 3-D model by the inspection and diagnosis support system, and the location that have the possibility of deterioration are automatically detected from the development view in Figure 8. The user distinguishes the position and deterioration type from the detected objects, and classifies the deterioration of the target member as grades a, b, c or d. The inspection report is automatically created based on the distinguished deterioration.

5 Conclusions

This paper reported the ROV for visual inspection of concrete pier superstructure, work support functions for ROV operation, and the inspection and diagnosis support system to save the related work. These are considered to have largely reached a practical level technically

These results promise a certain level of contribution to the improvement of safety and efficiency of the work. Development of linking tool with BIM/CIM is current in progress in order to further improve convenience of them.

Abstract –

In the UK, the railing sector has a large number of ageing masonry bridges that need to be examined every year. The traditional inspection regime consists of visual observation with manually recording the defect information observed on the structure. Previous studies have shown that this method of inspection is not reliable, time-consuming, depends on the inspector's judgment and result in further costs to the inspection process. Thus, there is a need to revolutionise the current inspection regime and improve the efficiency and reliability of the acquired data.

The development of digital surveying technology such as terrestrial laser scanning (TLS) and progressions in innovative software techniques will support the production of accurate representation of any asset, this automation, which results in achieving a tangible survey of a physical asset in a digital environment. In this paper, a strategic approach for an effective solution to automating the traditional process of surveying and processing point cloud data is presented, with further automation of implementing an automated bridge generation approach to large and complex cloud data sets. The presented digital method will generate a digital asset from the point cloud, and this will support surveyors and engineers to identify defects through various digital means. The presented approach has been tested on real-life projects which have demonstrated time-saving workflow on generating digital assets. This research will demonstrate the effective automation of point cloud to producing a physical asset of a structure with the ability to produce BIM model.

Bridge automation; Inspection; Masonry bridge; Terrestrial scanning; Point clouds; Scan to BIM

1 Introduction

In the UK, infrastructure management is facing significant challenges due to ageing assets and increasing demand. In the railway sector, it is estimated that there are approximately 29000 bridges, 22000 retaining walls, 21000 culverts, 200 miles of coastal defence and 600 tunnels, which require regular examination. The current visual examination process involves deploying a large workforce onto unsafe sites to inspect and report upon the status of each bridge on the network. There is increasing demand to replace the current cumbersome process (resource-intensive, unsafe conditions, sub-optimal process) with a faster, safer, digitally-enabled process using digital operators for mostly off-site inspection, automatic defects detection supported by an automated process, such as machine learning.

Due to the ageing nature of the assets, the original design information is often not readily available. The immediate challenge of implementing the digital process is to reconstruct the 3D BIM model from the captured data on-site. This paper aims to address this challenge by proposing a practical solution to rapid reconstruct the 3D BIM model from the point cloud data captured by reality capture technology. A real-life project is presented to demonstrate the effectiveness of the solution.

2 Literature review

2.1 Reality capture technology

Reality capture technology for recording the state of the existing structure has been a focus of many studies [1, 2]. Several technologies have been used for digital surveying such as terrestrial laser scanning (TLS), Terrestrial video and photogrammetry technology, and Unmanned Aerial Vehicle (UAV). The precision of these technologies is varied, which make some of them better than others on different surveying scenarios. For example,

UAV is useful in post-disaster assessment, such as post-earthquake evaluation [3], tornado and hurricanes damage assessment [4], that could give a general damage identification of a structure as a whole [5].

TLS can provide detailed information about the structure with higher accuracy than photogrammetry and UAVs [6]. Zeibak-Shini et al. [6] claimed that the TLS was applicable for damage assessment on building element with better quality than the UAV scanning. In Spain, different digital surveying technologies were used to document the as-is state of heritage masonry arch bridge, static and mobile TLS integrated with a digital camera were able to provide high accuracy 3d digital model [7]. In the US, a study used pre- and post-event approach for damage assessment of buildings after a tornado, both aerial and TLS surveying technology were used to document the state of each building before and after the event to evaluate the damage caused to buildings [8]. In the same study, they have also estimated wind speed and path direction of the tornado using the same digital data.

TLS, terrestrial video, photogrammetry, and UAV can generate point clouds model of a scene, and other low-cost approaches have also been studied to generate the similar dataset such as digital photogrammetry technique called Structure-from-Motion (SfM) [9], Multi-View Stereopsis (MVS) [10], and the combination of both [11]. Even though the above techniques are able to reconstruct the surveyed structure in a 3D environment, none of them can automatically produce and recognise the structure at the component level that is required for a BIM model.

2.2 Scan to BIM – 3D reconstruction of BIM model

Scan to BIM is also known as Point cloud to BIM, the process aims to use point cloud data to generate BIM model [12]. Typically, the point cloud data is obtained by TLS, and the data is transferred to BIM tools such as Revit, Bentley, Graphisoft, to reconstruct a BIM model. The problem of reconstruction of the as-as infrastructure/building assets is not a new area of research [1, 2]. Currently, the scan to BIM process remains largely a manual process which is time-consuming and error-prone [3]. In recent years, researchers around the world have been investigating ways to automate the process, including automatic identification of objects from the geometric features [13].

Roberts et al. [14] developed a technique to digitally capture a physical space from various points using the data to create an intelligent 3D model. The process provides a vital starting point for design teams that use BIM to iterate their designs and then manage, coordinate, and share all of the project information.

In buildings, the reconstruction of interiors and exteriors using the laser scanner was the case of many studies [4-6]. Although many algorithms presented for model reconstruction, most of them emphasise on model creation for visualisation rather than the accuracy of the geometries. Furthermore, the algorithms do not recognise the identity of components such as floors, walls, and ceilings [7]. Macher et al. [3] presented a semi-automatic approach, and segmentation was performed, so that point clouds corresponding to grounds, ceilings, and walls can be established. The output of building components can then be integrated into BIM software using IFC format. In the outdoor environment, Bassier et al. [8] used random forests classifier to automatically identify structural elements such as floors, ceilings, roofs, walls, and beams.

In the infrastructure management sector, several algorithms for 3D data processing and modelling have been developed to achieve surveying goals [9]. One of the significant studies was presented by Sacks et al. [10], they developed a 3D engine to create a geometric model of the assets associated with the point cloud model. The engine was based on surface primitive extraction algorithm, component detection, and classification algorithm for detection and classification. A set of training data was also presented to establish the relationships between surface primitives and the integrated component. However, the BIM reconstruction process is still at its infancy in geometrical creation, particularly for non-standard components with complex geometry.

3 Bridge Scan to BIM approach

In recent years, many algorithms have been developed to extract planar patches from point data or to recognise and identify the components of a structure such as walls, ceilings, and floors [15]. However, very few studies have successfully demonstrated the practicality of rapid reconstructing bridges from point cloud data in a large scale. In this paper, the authors propose a component library based approach especially developed for masonry railway bridges.

The result of the approach is a rich BIM model generation tool that is capable of producing Autodesk Revit BIM model with all the required information about each component constituent of a bridge structure. Furthermore, the proposed system follows the end-user requirements for condition assessment of railway bridge structure to ensure the resulting BIM model is semantically rich and suitable for condition assessment.

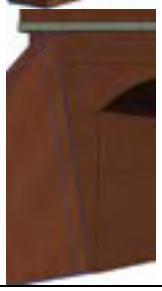
In this paper, three key aspects have been considered during the development of the system.

1. From a practical point of view, it is essential to have both data from the survey and BIM in the same development environment, not only for BIM model

creation but also for component check and validation.
2. Clear definition of the relationships between the elements [16], i.e. bridge elementsneed to be connected in a logical format.
3. The output BIM model must comply with the international standard such as IFC schema.

The railway bridges have a wide variety of components in their geometrical shape, parameters, and position. For example, each bridge component from the same type could have different geometries, parameters, and positions within the overall structure, see Table 1.

Table 1. Different type of wing wall and connection to abutment

Image	Point cloud	BIM
		
		


During the development, the authors recognise the relationships exists between the components in terms of the geometries, parameters and composition. As a result, a unique bridge component library is proposed to include all components and structural elements for bridges in order to reconstruct a bridge from point cloud data. A typical bridge can consist of several major components, such as Deck (DK), End Support (ES), and Intermediate supports (IS). Each major component is formed by several elements, such as Abutment, Wing wall, etc.

The bridge components and elements in the library are modelled based on the following protocols a) a logic of component reconstruction sequence, b) a number of required parameters for flexible geometries c) and relationships between components and elements. Figure 1 provides a high-level overview of the approach, which breaks the BIM reconstruction process into four stages.

In the first stage, a bridge component library is developed, and the bridge components and elements are categorised based on bridge condition marking index (BCMI) guideline. The BCMI helps develop a robust and flexible bridge component from a geometrical perspective that can be used in most bridges with a similar structure. The component library can be developed in standard BIM tools such as Autodesk Revit.

The second stage is to identify the component from the point cloud scene. It will examine if there is a new element, feature with the element, that is missing and/or not included in the library. This step is essential to maintain the library and keep it up to date with all components.

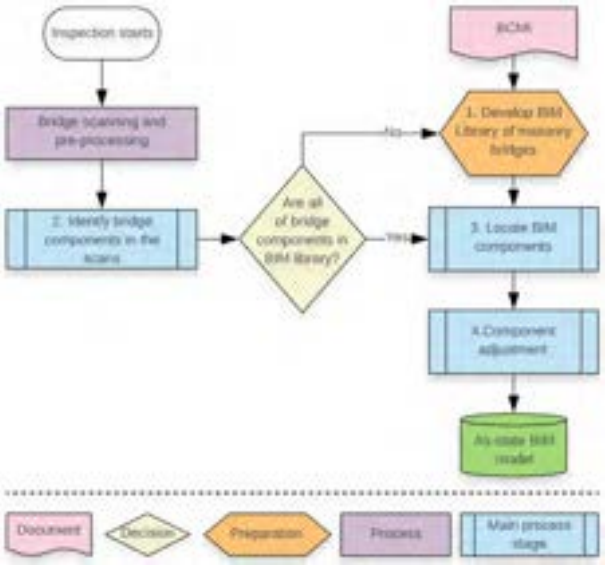


Figure 1. system overview

The third stage is to establish the position and orientation of individual components and elements of the bridge. The scanning provides a point cloud scene registered within a local coordinate system. The point cloud is then used to identify the spatial location of each bridge component. Moreover, the component's connection to other components in the whole structure can also be established based on the relationship rules in the library.

In the fourth stage, the bridge components are being reconstructed from elements in the library based on the information for previous stages. The parametric nature of each component and element gives the flexibility to adjust the geometries of the components based on the point cloud data. The algorithm will extract the required parameters of the individual components from the point cloud data. For the actual implementation, a set of algorithms is developed to connect all stages and interact with point cloud data and the component library.

The proposed approach has been tested on thirty railway bridges in the UK. In the following section, a brief description of the implementation on a single-span arch bridge is presented.

4 Implementation

The single-span arch bridge consists of three major components, Deck (DK), End Support (ES), and Intermediate supports (IS). Figure 2 shows the structural system of the single-span masonry arch bridge. Major and minor elements, names, and codes are explained in Table 2.

The process of data acquisition, BIM reconstruction, and the validation of the produced model are explained in the following sections.

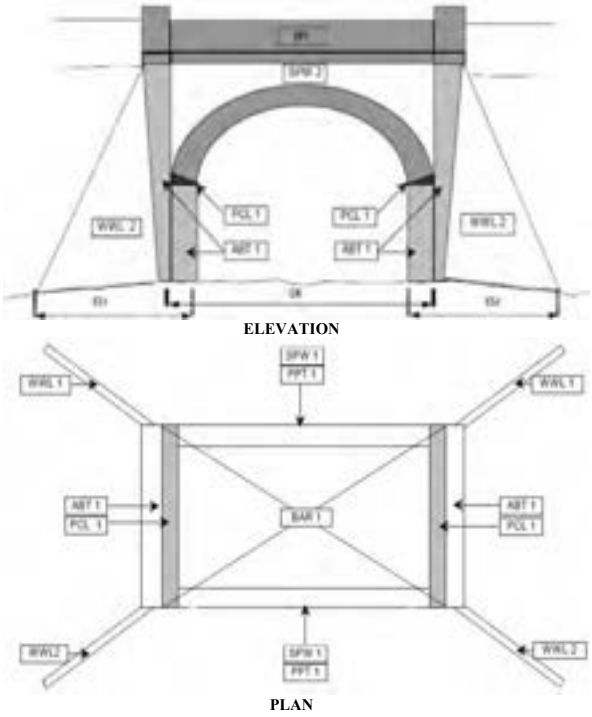

Figure 2. Single-span masonry arch bridge drawing

Table 2 elements in the single-span masonry arch bridge

Elements	Code
Abutment	ABT
Wing wall	WWL
Barrel arch	BAR
Spandrel wall	SPW
Parapet	PPT
Padstone	PCL

4.1 Data acquisition

For the single-span masonry arch bridge as shown in Figure 3, TLS is used for data acquisition. The site condition, weather condition, and other environmental conditions such as site access, traffic situation, vegetation, flooding, etc, are assessed before the scan. The scanning set-points are also planned in order to cover the entire structure.

Figure 3. Single-span masonry arch bridge

On-site, the survey team sets up a ground control point (GCP) for the project. A Global Navigation Satellite System (GNSS) is used to record the GCP in the Ordnance Survey National Grid (OSGB) reference system, and the resulting coordinates will be used in the processing of TLS data sets. The TLS scan is performed at every pre-planned set-point to capture 3D point cloud. The individual scans are then registered to each other using automated software to produce a dense point cloud model of the bridge.

4.2 BIM Reconstruction

In the proposed system, the BIM reconstruction algorithm process the point cloud data and generate a BIM model almost automatically. Moreover, the proposed system does not require a clean point cloud model (noise points such as people, trees in the scene, are not removed). However, a clean model can save processing time and produce better results. In the single-span masonry arch bridge, the scan by TLS has around 440million points (Figure 4).

Figure 4. The point cloud model of the bridge

The resulting 3D BIM model as shown in Figure 5 is a digital representation of the bridge which is formed by the components and the corresponding structural elements of a masonry arch bridge listed in Table 2.

The algorithm is able to identify the structural elements from the bridge point cloud scene. It assembles

bridge components of the elements associated with the point cloud of the structure from the component library. It also fetches the required parameters of each component to finetune the BIM component geometry to fit the point cloud.

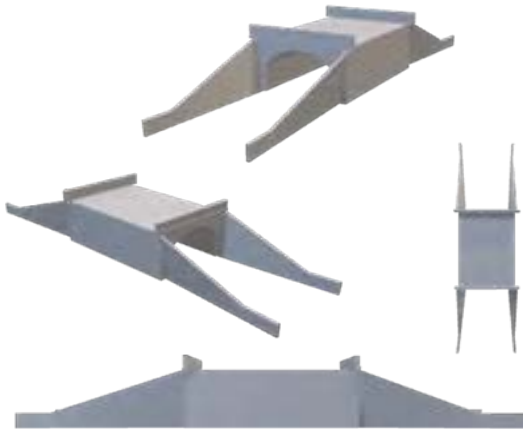

Figure 5. BIM model of the single-span arch bridge.

The algorithm would also position the bridge components following the density of the point cloud data and the relationships between components as shown in Figure 6

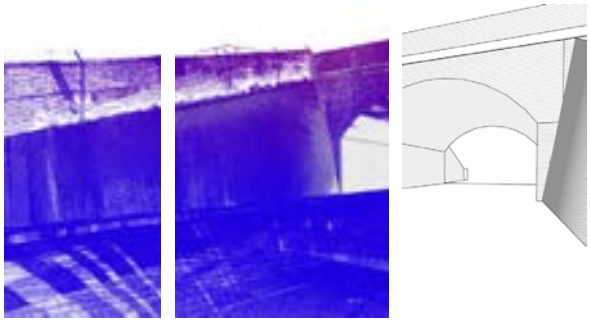

Figure 6. bridge reconstruction

4.3 Validation process

The output BIM model is in Autodesk Revit format that can be exported in IFC. The BIM model is validated in Verity, a construction verification software. Verity would check the point cloud against each bridge component. The visual verification reports show if the structural components are generated correctly within the required 50mm tolerance.

Figure 8 shows the BIM model of a Wing Wall (WWL) that is compared to the surveyed point cloud data under 50 mm tolerance. The colours in the model represent the distance of the points to the BIM component; green shows the perfect match while red is out of tolerance.

Figure 7 shows the results of bridge spandrel (SPW) to 50 mm tolerance. Although the SPW component passed the verification process, the result shows the point cloud does not fully match the BIM components. This could be because the BIM component is not flexible enough to fit the geometry of the bridge, or the point cloud model has too many noises that affect the verification process or both.

As previously mentioned, the system was validated with thirty bridges. Majority of the BIM models could meet the tolerance requirement. On occasion, the component would not line up with point cloud perfectly, and further adjustments are made to improve the accuracy of the bridge model.

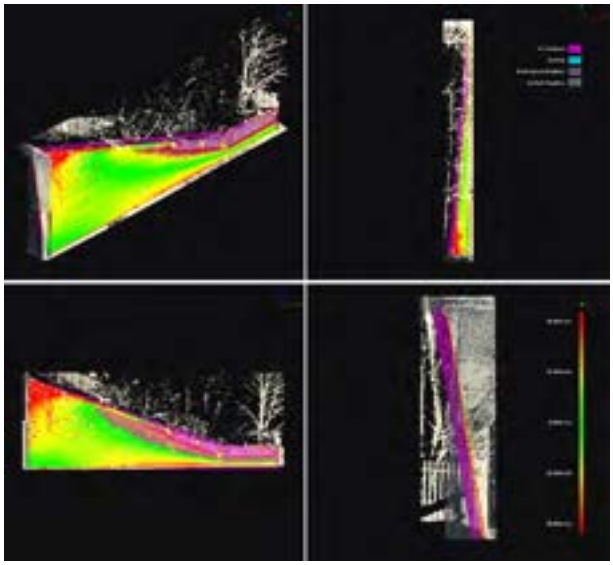

Figure 7. Verification results of the WWL

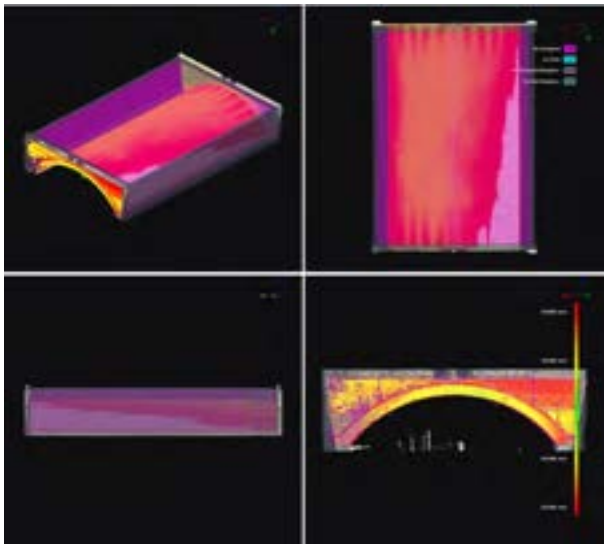

Figure 8. Verification results of SPW

5 Conclusion

Reality capture technology is a promising solution for bridge condition assessment. However, the data acquired from scanning tools can not be directly used to establish a digital information system. Furthermore, the conventional process of creating a BIM model from point cloud data is a time-consuming manual process.

Due to the increasing demand for digitising UK infrastructure, there is a need to develop a workflow to rapid scan the asset and generate a BIM model for condition assessment. This paper proposed a new approach to automate the reconstruction of a BIM model of railway bridge from point cloud data, which can also be applied to other physical assets. The approach is demonstrated on an industry project of thirty bridges of different types, shapes, and spans.

The process includes capturing the masonry structure using TLS and producing a point cloud representation of the bridge and further generating a 3D BIM model. The output result of each bridge component is validated against the point cloud under 50 mm tolerance. The new process has reduced the traditional modelling times from days/weeks to hours for the thirty bridges. The project also identified several advantages and limitations of the proposed approach.

Advantages

- The system can process a complex structure of masonry bridges.
- The digital representation is sufficiently accurate for condition assessment.
- The algorithms work well with an uncleaned point cloud data and are still able to to generate an accurate BIM model.
- The system is very efficient compared to the manual process. (average 15min processing time as opposed to hours in the manual process).

Limitations

- In some cases, it might require manual adjustment of the output in order to achieve 50 mm tolerance level.
- Further development of the library is required when dealing with a new type of bridge.
- The additional parameters of the components/element might be needed to accommodate a certain type of bridge.

Overall, this paper presented a new component library based scan to BIM approach for bridges. It has been tested on a real-life project with a significant number of bridges. Although the current library is limited to railway bridges, it is possible in the future to expand into other infrastructure assets, such as tunnels, culverts and retaining walls.

Abstract –

Surface flatness is an essential indicator for quality assessment of concrete surfaces in the construction industry. Terrestrial laser scanning (TLS) has been popularly applied for surface flatness inspection due to its speed and accuracy. However, scanning area far away from the TLS usually suffers from inaccurate surface flatness measurement and physical barriers such as interior walls are likely to cause occlusion for the surface flatness inspection. To address these limitations, this study proposes a mirror-aided technique for surface flatness inspection. There are two concepts proposed from the mirror-aided technique. First, the mirror-aided approach can address the low accuracy of surface flatness inspection caused by long scanning range and high incident angle, which enlarge the scanning area and increase the surface flatness inspection efficiency. Second, the mirror-aided approach can measure the flatness of the concrete surfaces occluded by barriers based on the mirror reflection principle with one single scan, resulting in efficient surface flatness inspection. To validate the proposed two concepts, a series of tests on laboratory-scale specimens are conducted. The results show that the proposed method provide accurate surface flatness estimation results with an accuracy of more than 85% for the scanning area far away from the TLS and concrete surfaces with occlusion problem, demonstrating the great potential for the application of mirror-aided surface flatness inspection in the construction industry.

Keywords –

Surface flatness; quality inspection; terrestrial laser scanner (TLS); mirror-aided laser scanning

1 Introduction

Surface flatness is an essential checklist for dimensional quality inspection of construction elements and construction floors after manufacturing and construction in the construction industry [1,2,3]. This is because concrete surfaces which have unacceptable deviation from specific tolerance can seriously effect both aesthetic and functional performance of target structures [3,4,5]. Furthermore, the serious non-flatness concrete surfaces are likely to influence subsequent construction and cause poor connection between adjacent elements, resulting in deteriorated structural problem in long term [3,6]. Therefore, it is necessary to implement surface flatness inspection after production to evaluate the flatness quality of the target structure. Currently, surface flatness of concrete surfaces is commonly inspected manually using straightedges in the construction industry [10]. As for straightedge approach, inspectors use a long straightedge to assess surface flatness based on certain measurement patterns, such as grid, to define the gap between the surface and straightedge [1,10]. However, the existing flatness assessment methods have limitations in terms of time consumption, labor intensity and low measurement accuracy.

3D laser scanning has been widely used as a promising data acquisition technology for the purpose of surface flatness inspection of concrete surfaces [11-14]. This is because 3D laser scanning could provide accurate and dense 3D scan points efficiently for surface flatness inspection [15,16]. However, scanning area far away from the TLS usually has large scanning distance and high incident angle, which decrease the accuracy of the surface flatness inspection. Furthermore, construction components are likely to cause occlusion of the floor, which limits the scanning area of the floor. To address these limitations, this study aims to 1) propose a mirror-aided technique for surface flatness inspection to address the low accuracy of the scanning area far away from the TLS and occlusion problems caused by barriers 2) validate the applicability of the mirror-aided flatness inspection technique. The organization of the paper is as follow. The two concepts of the proposed mirror-aided techniques are described in Section 2, followed by validation tests and experiment results in Section 3 and Section 4. Finally, this paper

ends with a brief summary and suggestions for further work in Section 5.

2 Overall concept of mirror-aided approach for surface flatness inspection using laser scanning

Figure 1 shows the overall concepts of mirror-aided approach. Figure 1(a) illustrates the concept of the mirror-aided technique to increase the accuracy of the scanning area far away from the TLS. Here, the scanning area far away from the TLS has large scanning distance and high incident angle (θ). Therefore, the accuracy of the surface flatness inspection for the scanning area far away from the TLS is low, which limits the scanning area of the floor. As for the mirror-aided approach, the flat mirror is located at the backward of the target area far away from the TLS with a certain angle to the ground. The laser beam emitted from the TLS is first reflected by the mirror and then reaches on the scanning area, resulting in a lower incident angle (β). In this way, the mirror-aided approach can increase accuracy of surface flatness inspection caused by large scanning distance and high incident angle, which enlarge the scanning area and increase the surface flatness inspection efficiency. Also, there are rectangular patches attached on the surfaces of flat mirrors to obtain scan points falling onto the patches. Based on the mirror reflection principle [11], the scan points of actual surface obtained from the mirror will be located on the virtual surface. Also, note that the virtual surface and actual surface on the floor are symmetric with respect to the mirror. Figure 1(b) illustrates the concept of the mirror-aided technique to address the occlusion problems caused by barriers. The structural components such as the interior wall are likely to cause occlusion of the floor, which limits the scanning area of the TLS. Therefore, it requires multiple scans to perform the data collection, which deteriorates the surface flatness inspection efficiency. To address the limitation, the mirror is applied to adjust the direction of the laser beam, enabling the scanning of the occlusion area of the floor. In this way, the mirror-aided approach can measure the flatness of the floors based on mirror reflection principle with one single scan, resulting in efficient surface flatness inspection.

3 Materials and test setup

In order validate the two concepts of the mirror aided approach for surface flatness inspection, two experiments named as 'Experiment I' and 'Experiment II' of laboratory-tests were conducted on two specimens. The specific objectives of 'Experiment I' and 'Experiment II' are : 1) to validate that the mirror-aided approach can increase surface flatness inspection accuracy of the area with large scanning distance and high incident angle, 2) to validate the mirror-aided approach can address the occlusion problem caused by construction components for surface flatness inspection, respectively. Figure 2 shows the two specimens named as 'Specimen I' and 'Specimen II' for the validation experiments. The two specimens were manufactured by a ZRAPID iSLA880 3D printer [17] with the material of photopolymer resin. Table 1 shows the dimensions and F_F numbers of the specimens. Specimen I was manufactured with a size of 400 mm (length) × 400 mm (width)× 10-23 mm (height) and has an F_F number of 10.28. Specimen II, which is flatter than the Specimen I, was sized at 400 mm × 400 mm× 20-38 mm and has an F_F number of 21.23. Note that the size of the mirrors is 1000 mm (length) × 1000 mm (height). In this study, a phase-shift TLS, FARO M70 [18], with an accuracy of ±3 mm at 20 m, was used to acquire scan points of the specimen.

Table 1. Dimensions and F_F numbers of the specimens

Items	Size (length × width × height)	F_F number
Specimen I	400 mm×400 mm×10-23 mm	10.28
Specimen II	400 mm×400 mm×20-38 mm	21.23

(a) (b)

Figure 2. Test specimens for the validation experiments: (a) Specimen I and (b) Specimen II

3.1 Experiment I

3.1.1 Experiment set-up

Figure 3 shows the experimental configuration of Experiment I. The height distance of the TLS was set to 1.5 m and scanning distance was adjusted from 2.5 m to 12.5 m with an interval of 2.5 m. Besides, the mirror was rotated based on the bottom line with an angle of 75° to the ground and there was a gap of 0.35 m between the mirror bottom line and the specimen. On the other hand, two rectangular patches of 100 mm × 100 mm in size were attached to the upper-side region of the mirrors. In addition, three different angular resolutions of 0.036°, 0.072°, and 0.144° were used to investigate the effect of angular resolution. Note that the estimation error of F_F number is defined as the difference between the estimated F_F number of the proposed technique and the designed F_F number of the specimen. Also, note that scan points of the surface which are directly falling on the specimen are called 'actual scan points' and the scan points obtained on the virtual surface through the mirror are called 'virtual scan points' hereafter.

Figure 3. Test configuration of experiment I

3.1.2 Data processing

There are four procedures for the proposed mirror-aided surface flatness inspection technique after data acquisition, which are (1) data pre-processing, (2) virtual scan points transformation, (3) coordinate transformation and (4) surface flatness estimation. First, background noise is removed to extract the scan points corresponding to the specimen and the rectangular patch. Next, using the estimated mirror plane estimated from the scan points of the rectangular patch, the virtual scan points of the specimen surface are transformed to the position of actual scan points. Finally, surface flatness is estimated based on F_F number method [10]. Figure 4 shows the determination of F_F number of a test surface. The detailed procedure of determining the F_F number of a test surface according to ASTM E 1155 (ASTM 2008) [10] is illustrated as the following 5 steps.

Step 1: Determination of the sample measurement lines on the test surface. The orientations of the lines should all be parallel, perpendicular or 45° to the longest boundary. In addition, equal number of lines should be placed in two perpendicular directions. Furthermore, the lengths of lines should not be smaller than 3,300 mm and the distance between two parallel lines should not be smaller than 1,200 mm. Step 2: Subdivision of the sample measurement lines. Each sample measurement is divided into 300 mm long intervals and the points marking the ends of these intervals are named 'sample reading points'. Step 3: Measurement of the elevations of the sample reading points (or the elevation difference between all adjacent sample reading points). For sample measurement line j, denote all sample reading points along it as P_0 and P_1, and P_2 and P_3, ... P_{i-1} and P_i, etc. Then, the evaluations between the corresponding reading points are designated as h_0 and h_1, and h_2 and h_3, ... h_{i-1} and h_i accordingly. Step 4: Calculate the F_F number of each sample measurement line. For sample measurement line j, calculate the profile curvatures, q_i, between all sample reading points separated by 600 mm as $h_i - 2h_{i-1} + h_{i-2}$, where i = 2, 3, 4 … n. Subsequently, the F_F number of sample measurement line j, denoted as F_j, is estimated by Eq. (1).

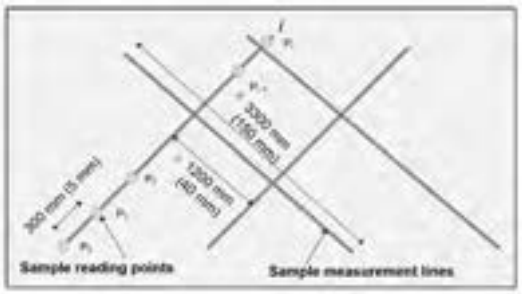

Figure 4. Determination of the F_F number of a test surface

$$F_j = \frac{115.8454}{3S_{qi} + |q_i|} \quad (1)$$

where S_{qi} and $|q_i|$ denote the standard deviation and the absolute value of the mean of all $(n-1)$ q_i values, respectively. Step 5: Calculate the F_F number of the test surface by combining all of the F_F numbers of individual sample measurement lines within the test surface. Considering the limitation of the size of the test specimen, the length of measurement lines and the distance between two parallel measurement lines in this study are selected as 150 mm and 40 mm respectively. In addition, the intervals which separate the sampling reading points is set as 5 mm and the profile curvatures, q_i, is calculated between all sample reading points separated by 10 mm. Since the F_F number is calculated based on the collected scan points, the elevation of each sample reading point will be obtained with the nearest laser scan point. Then, in order to improve the reliability of the results, F_F number is calculated as the average value of the results that is calculated iteratively in 1000 times. For each time, the number of the sample measurement lines and the relative locations between each measurement line are unchanged. As for the distances from the sample measurement lines to the surface boundaries, these values vary in every iteration and is determined by a random number.

3.2 Experiment II

3.2.1 Experiment set-up

In order to validate the concept 2, the height distance of the TLS was set to 2.5 m and scanning distance from the TLS to the mirror and the specimen were 2 m and 1.5 m respectively. Figure 5 shows the test configuration of Experiment II. Besides, barriers were located between the TLS and specimen to make the specimen invisible from the TLS. In addition, a mirror with the size of 1000 mm × 1000 mm was located behind the specimen with a gap of 0.2 m. Here, the center point of the mirror is the pivot point of the rotation and the mirror was aided by a goniometer to achieve rotation in the horizontal and vertical direction. In this experiment, the vertical mirror rotation angle and horizontal mirror radiation angle were set as 20° and 30° respectively. On the other hand, two rectangular patches of 100 mm × 100 mm in size were attached to the upper-side region of the mirrors for mirror plane estimation. In addition, three different angular resolutions of 0.036°, 0.072°, and 0.144° were used to investigate the effect of angular resolution.

Figure 5. Test configuration of Experiment II

3.2.2 Data processing

The data processing process is similar to the experiment I and the only difference is that noise removal. In experiment II, there is no need to extract the virtual scan points of specimen because it cannot be scanned from the TLS.

4 Result and discussion

4.1 Experiment I result and discussion

Table 2 shows the estimation errors of F_F number under varying angular resolutions with different scanning distances. There are three distinctive observations from the results.

First, the estimation errors of F_F number from the scan points are decreased as the scan density increases. Note that the data density is presented as the number of scan points captured each square centimetre. Here, the estimation errors of F_F number under different scan densities from virtual can points are taken as an example to illustrate the effects of scan density on estimation errors. As the scan density increases from 0.3 pts/ cm^2 to 87.7 pts/ cm^2, the estimation error in percentage is decreased from 318.8% to 3.9%. It is also observed that the F_F number cannot be estimated when the scan density is less than 0.2 / cm^2 since the measurement lines are not able to be sampled in sparse scan points for F_F number estimation. In addition, it is also noticed that scan density which excess 5.5 pts /cm^2 are likely to result in accurate F_F number estimation, resulting in error in percentage of less than 20%. However, the actual scan points directly acquired from the TLS usually has low scan density caused by the large scanning distance and high incident angle, which cause low estimation accuracy for surface flatness inspection.

Second, the mirror-aided method can achieve the improvement of 81.5% in accuracy for surface flatness inspection compared to actual scan points under scanning distance of 10 m, addressing the low accuracy of surface flatness inspection caused by large scanning distance and high incident angle. This is because the proposed mirror-aided approach can adjust the incident

Table 2. Estimation errors for F_F number under varying angular resolutions with different scanning distances

Object	Scanning distance (incident angle)	Estimation error of F_F number for Specimen I in percentage (Data density: pts/cm^2)			Estimation error of F_F number for Specimen II in percentage (Data density: pts/cm^2)		
		Angular resolution			Angular resolution		
		0.036°	0.072°	0.144°	0.036°	0.072°	0.144°

	12.5m (86°)	210.3% (0.7)	- (0. 2)	- (<0. 1)	155.6% (0.6)	-(0.2)	- (<0. 1)

angle of laser beam and address the low-density scan points caused by the long scanning range and high incident angle. Due to the long scanning range and high incident angle, the actual scan points which are directly acquired from the specimen are not able to provide accurate results (with error in percentage of less than 20%) when the scanning distance is larger than 5 m. However, the scan density of virtual scan points are around 2 to 4 times that of actual scan points in the same circumstance. Therefore, the mirror-aided approach can acquire accurate result with the scanning distance of 10 m, which enlarge scanning area and increase the efficiency for surface flatness inspection.

Third, Specimen II achieves more accurate F_F number estimation results than Specimen I in most cases, indicating that the mirror-aided approach is more robust for flatness inspection of flatter surfaces. This phenomenon is caused by that the Specimen I with non-flatter surface as shown in Figure 2 is more likely to suffer from the effect of the high incident angle compared to Specimen II with relative flatter surface. Hence, the proposed mirror-aided approach can be effectively applied for floor surface flatness inspection since the concrete floor normally has relative flatter surface.

In summary, the mirror-aided approach can adjust the incident angle of laser beam to address the low measurement caused by the large scanning distance and high incident angle. Therefore, the mirror-aided approach is able to acquire accurate F_F number estimation for surface flatness inspection within a large scanning distance, which enlarge scanning area and increase data collection efficiency.

4.2 Experiment II result and discussion

Table 3 shows the mirror-aided F_F number estimation errors under varying angular resolutions for specimens with occlusion problem. The average errors for Specimen I and Specimen II in percentage are 22.4% and 11.6% respectively, which indicates the applicability of the proposed mirror-aided method for concept 1. This is because that the mirror-aided method adjusts the laser beam direction, enabling the scanning of the specimen occluded by barriers. Moreover, Specimen II achieves more accurate F_F number estimations than Specimen I in most cases since flatter surface of Specimen II is more robust to incident angle

Table 3. Mirror-aided F_F number estimation errors under varying angular resolutions with different scanning distances with occlusion

Object	F_F number estimation error of Specimen I (mm)				F_F number estimation error of Specimen II (mm)			
	Angular resolution				Angular resolution			
	0.036°	0.072°	0.144°	Ave.	0.036°	0.072°	0.144°	Ave.
Discrepancy	1.10	2.84	3.97	2.30	2.21	2.51	2.69	2.47
Discrepancy in percentage	10.7%	27.6%	38.6%	22.4%	10.4%	11.8%	12.6%	11.6%

influence compared to non-flatter surface of Specimen I.

5 Conclusion

This study presents a mirror-aided technique for surface flatness inspection to address low accuracy of the scanning area far from TLS and occlusion problems caused by barriers. First, the mirror-aided approach can increase the low accuracy of surface flatness inspection caused by large scanning distance and high incident angle, which enlarge the scanning area and increase the surface flatness inspection efficiency. The validation results showed that the mirror aided approach can improve the surface flatness inspection accuracy in 81.5%, which address the low accuracy caused by large scanning distance and high incident angle. Second, the mirror-aided approach can measure the flatness of the floors occluded by structural components based on mirror reflection principle with one single scan, resulting in efficient surface flatness inspection. Based on the proposed two concepts, the validation experiments are conducted on two laboratory-scale specimens. From the validation results, the proposed mirror-aided approach achieves an accuracy of more than 85% for Experiment II, indicating the applicability of the proposed mirror-aided approach to address occlusion problems.

However, there are limitations which are left for further study in the near future. First, the test specimens used in this study are lab-scale, so further study is necessary in order to investigate the applicability of the proposed technique to large-scale or full-scale elements. Second, the large-scale mirrors are fragile and take large space which may not be available for extremely large-scale environment.

Abstract –

In typical heavy industrial construction projects, scaffolding can account for 30% to 40% of the total direct man-hours. However, most industrial contractors estimate scaffolding man power based on a certain percentage of the direct work, which leads to cost increase and schedule delay due to inaccurate estimation. In order to aid industrial companies to plan and allocate the resources for scaffolding activities before construction, this paper proposes a methodology which combines the classification tree and multiple linear regression to estimate scaffolding manhours based on available project features. The evaluation matrix involves R Squared value (R^2), Adjusted R Squared value (Adj. R^2), mean absolute error (MAE), root mean squared error (RMSE), and relative absolute error (RAE). The proposed methodology has been tested on the historical scaffolding data in a heavy industrial project and the results showed its effectiveness.

Scaffolding Man-hours; Linear regression; Classification tree; Heavy Industrial Constructions

1 Introduction

Occupational safety and health services [1] defines scaffolding as any structure (suspended structure) which is built for temporary purposes, used for the support and/or protection of the construction workers by providing easy access to work areas horizontally and vertically, and also helps in material transferring. Due to these functions, heavy industrial construction projects usually involve various types and a large amount of scaffoldings to feed the need for different disciplines (e.g., civil, mechanical, and electrical), leading to increased project costs. In the construction site, the scaffolding should be installed, modified and/or dismantled in accordance with the requirements of various disciplines on their demand times in order to prevent project schedule delays. Due to the demand-based scaffolding operation, the construction domain has difficulty to plan scaffolding operation in the early phases of the project.

In practice, planning of scaffolding activities is completely subjective and differs from company to company [2]. The scaffolding tends to be planned and operated as an ad hoc way which leading to schedule delays and cost overrun due to the inefficient utilization of resources. As an effort to develop a scientific and practical planning method for the scaffolding activities, the previous research [2] claims that most construction companies regard scaffolding as a part of indirect expense and calculated as a percentage of the total man-hours of direct work . In this respect, previous study [3] has identified that scaffolding works accounts for up to 30%-40% of the total direct man-hours in the heavy industrial project.

Scaffolding has potential for significant productivity improvement with respect to project cost reduction in construction, especially industrial construction. However, planning and estimating of scaffolding works have received little attention in academia and practice. In its infancy, research on scaffolding mainly focused on structural performance [4]. With safety gaining prominence in scaffolding research, the factors contributing to scaffolding collapse have been studied more recently [5]. In terms of planning of scaffolding works as a temporary structure on-site, there are several research efforts that have investigated the application of artificial intelligence (AI) algorithms (e.g., fuzzy logic and genetic algorithm) and geometries of 3D models for temporary structure or facility planning [8]. However, these studies have not fully directed their efforts to developing methods or systems to improve efficiency of planning and estimating of scaffolding activities for productivity improvement based on the project time progress.

Thus, this paper proposes an integrated method that

combines the classification tree with the multiple linear regression model in order to estimate the scaffolding man-hours efficiently and accurately in the heavy industrial construction projects. The proposed methodology mainly consists of five steps: (*i*) collecting data from construction site through cloud-based computer systems; (*ii*) identifying and cleaning potential outliers from the dataset; (*iii*) selecting and/or transforming the most important independent variables which affect the scaffolding man-hours through statistical diagnosis, (*iv*) developing classification tree based on selected text variables in the dataset, and at each tree node, the multiple linear regression performed to obtain a predictive model for man-hour estimation, and (*v*) evaluating the performance using the tenfold repeated cross-validation.

The proposed methodology has been implemented in Python 3.7 environment. It was tested with the historical scaffolding data in a heavy industrial project in Alberta, Canada, provided by an industrial collaborator.

2 Scaffolding Related Research

Based on the investigation of the previous studies done by authors in planning the scaffolding-related resources in construction domain, previous research has mainly focused on structural performance and safety management. Peng et al. [4] introduced a scaffolding design system in terms of the performance of steel and bamboo scaffolding. Yue et al. [5] studied the effect of wind load on scaffolding in order to promote safety in the design of integral-lift scaffolds. Based on optimization of the scaffolding schedule, which can help in coordinated safety management and control efforts, Hou et al. [6] introduced an operational framework by integrating mathematical models with virtual simulation to optimize scaffolding erections. According to the introduction of advanced technologies, Kim et al. [7] have actively integrated building information modelling (BIM), image processing or wireless sensors with optimization algorithms, to not only identify and mitigate the safety risks but also plan the scaffolding schedules to eliminate potential hazards. Furthermore, Cho et al. [10] have used machine learning algorithms (support vector machine) to assess real-time safety and unsafety status of the scaffolds based on different conditions of scaffolds (safe, overturning, overloading or uneven settlement), which adopts actual strain data of scaffolding members obtained by wireless sensors.

Construction Owners Association of Alberta (COAA) reports that scaffolding plan must provide the estimated scaffolding types, location, duration and quantity requirements including materials and labours [11]. Based on the result of planning and estimating the scaffolding activities, previous studies [12] have suggested that the effective management of the scaffolding in construction projects can improve productivity by: (i) preventing the delays of crews due to absence of scaffolding materials or even man-power; and (ii) understanding the resource requirements to avoid work space conflicts. However, in practice, industrial company plans and estimates the scaffold activities subjectively, which can be up to 40% of total direct man power of an industrial project, based on the regulations of company and engineer's experience which may cause excessive use of man-power, schedule delays and resource shortage.

As scaffolds and their supporting structures being a temporary work platform, there are several research efforts to investigate the applications of artificial intelligence (AI) algorithms and geometries of 3D models for temporary structure or facility planning [9]. However, these studies have not discovered the field of improving efficiency and accuracy of planning and estimating scaffolding man powers. Therefore, several studies [2-3] made an effort to analyse the factors affecting industrial scaffolding estimation based on historical data provided by a construction company. A simulation tool and linear regression models have been developed to predict a range of man-hour values for only scaffold erection on site in their works. However, since the lack of available scaffolding data, the analysis merely regarding scaffolding erection is insufficient. The authors also suggested that further analysis is required with more historical data from other industrial projects and other optimization algorithms in order to generalize a general methodology for estimation and planning of scaffolding works. As a recent study, Moon et al. [13] have investigated the effect on productivity of resource configurations measured during scaffolding operation as part of the construction of an actual liquefied natural gas (LNG) plant. Hou et al. [14] have proposed a feasible multi-object discrete firefly algorithm for optimizing scaffolding project resources and scheduling. However, this model needs to not only be improved in terms of accuracy for scheduling the scaffolding resources, but also be made generically applicable to other projects by incorporating various types of scaffolding constraint. In addition, these previous studies have had difficulty for further analysis or better models to plan and/or schedule the scaffolding activities due to the insufficient scaffolding data since it has not been attention and tends to be ignored in practice. As a result, the development of scientific and systematic methods is still required in the planning and estimating of scaffolding activities due to the lack of accuracy, efficiency, and applicability in the existing systems for various types of construction projects, especially heavy industrial projects.

3 Research Methodology

In order to predict the required man-hours for scaffolds accurately in the early planning phase of the project, this paper proposes an integrated method that combines the classification tree with the multiple linear regression model. As shown in Figure 1, there are in total five steps in the proposed methodology, which are data collection, data cleaning, input data determination, development of classification tree structure, and the final model evaluation with all the outputs from the previous steps.

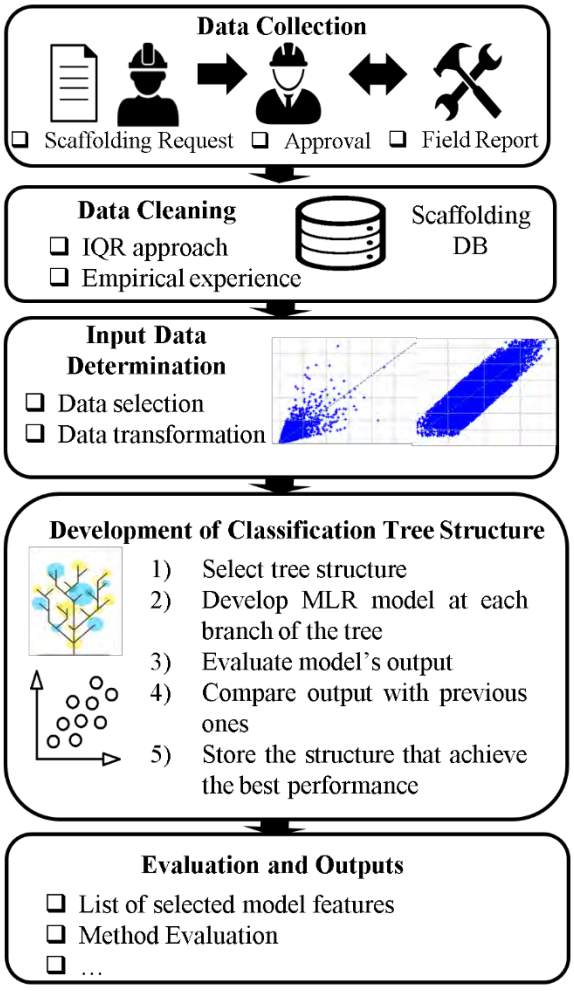

Figure 1. Flowchart of proposed methodology

3.1 Data Collection

As mentioned in Figure 1, the data collection process can be simplified as: scaffolding requests generated for approval along with detailed scope of work, and once the requests are approved and completed, the actual man-hours and work details are recorded. Individual scaffold component details are documented, and the weights summed up for each request by date. The information that can be tracked in the scaffolding activities may vary, but by nature, the key ones are work classification (i.e. erection, modification, and dismantle), scaffolding type (i.e. platform deck, tower, barricade, etc.), actual man-hours, total scaffolding weights. Meanwhile, other project related data that maybe likely to affect the manhour prediction should be extracted from other sources and consolidated for analysis, such as the average temperature during each scaffolding task, the elevation of the scaffold built according to the ground level, and the average aluminum percentage of the scaffolding.

3.2 Data Cleaning

The objective of data cleaning is to remove the outliers in the collected dataset. Outliers are extreme observations in the dataset that are not consistent with the trend of correlation in the data. In data collection process, the outliers may result from errors in data entry. There are generally, two ways of filtering outliers: (i) using statistical approaches to identify outliers mathematically regardless of the nature of data; and (ii) using user experience-based approaches to identify outliers based on users' logics. Often, the statistical approaches take less efforts than the user experience-based approaches due to the experience-based approach do not have a certain criterion but based on understanding, experience and trail-and-error tests. In this paper, an integrated data cleaning process has been adopted using both statistical and experience-based methods.

At first, the interquartile range (IQR), one of the statistical approaches, is used to identify the outliers. IQR is a measure of the location of middle 50% data in the dataset, and it is calculated by subtracting the first quartile (Q1) from the third quartile of the dataset (Q3). Potential outliers are defined as observations that fall below Q1 – 1.5* IQR or above Q3 + 1.5 * IQR. Moreover, under the guidance of the scaffolding experts, the following experience-based rules should be applied to further filter out the outliers: (*i*) value of man-hours is null or less than 5 hours; (*ii*) value of scaffolding weights is null or less than 20 lbs; and (*iii*) productivity (i.e. weight per man hour) is less than 6 lbs/hr, or greater than 125 lbs/hr. These experience-based rules may vary in different project scenario. However, the core concept is to remove data observations that are not physically feasible in scaffolding work, normally reflected by manhours, weight of scaffolding, and scaffolding weight divided by manhours (productivity).

3.3 Input Data Determination

In order to ensure the effectiveness of results from multiple linear regression model, there are five

assumptions need to be fulfilled before the analysis [15]. The assumptions are (*i*) the relationship between dependent variables and independent variable should be approximately linear; (*ii*) the error term ε has zero mean; (*iii*) the error term ε has constant variance σ2; (*iv*) the independent variables are uncorrelated; and (*v*) the errors are normally distributed. Among these assumptions, the linearity between the dependent variables and independent variable and the independence among the independent variables are of the utmost importance. The zero mean of error term can be fulfilled by involving the intercept term in the regression equation and the normally distributed error generally is not a must-have check. The following model feature selection section and model feature transformation section are responsible for check independence and linearity among the dataset, separately.

3.3.1 Model Feature Selection

The model feature selection is one of the most important part in the field of machine learning since (i) the irrelevant input features can induce greater computational cost; (ii) the irrelevant input features may lead to overfitting, which in turn leads to poor results on the validation datasets. Feature selection methods can also adapt the dataset to better suit the selected machine learning algorithm, given that different algorithm may have various requirement for the features. In terms of multiple linear regression, a reliable set of features contains independent variables that are highly correlated to a dependent variable (i.e., scaffolding manhour), also called as a predicted variable, but uncorrelated with each other.

The condition that some of the independent variables are highly correlated is called collinearity [16]. Collinearity can lead to imprecise coefficient estimates during the development of the predictive model since it inflates the standard errors of the coefficients of collinear variables. In this respect, this paper uses correlation matrix which supports users to identify the collinearity problem. The correlation matrix for all the independent variables should be developed at each classification tree node. The Spearman method [17] has been adopted here to perform the correlation analysis since (*i*) it is a non-parametric procedure in which the observations are replaced by their ranks in the calculation of the correlation coefficient so that it can deal with data with outliers; (*ii*) it does not carry any assumptions about the distribution of the data (e.g. Pearson method requires both variables to be normally distributed) [18]. In the correlation matrix M, it is easy to identify that which two variables are highly correlated (> 0.5) [19] and which one of them should be removed to avoid collinearity.

While collinearity means the correlation between only two independent variables are high, multicollinearity can exist between one variable and linear combination of more than two variables [16]. As another indicator of model feature selection for linear regression, multicollinearity can cause regression coefficients to change dramatically in response to small changes in the model or the data. Thus, it may cause serious difficulty with the reliability of regression coefficients. In order to detect whether a regression model exists multicollinearity, Variance Inflation Factor (VIF) [20] of each independent variable need to be checked in the model. VIF is a traditional measure to detect the presence of multicollinearity in multi-linear regression model. It shows how much the variance of the estimator is inflated due to the linear relation between the regressors. Typically, a VIF, which is larger than ten, has been used as a rule of thumb to indicate serious multicollinearity.

3.3.2 Model Feature Transformation

Given a selected feature set, the quality of data can be enhanced by feature transformation. It is common that the real-world data may not show strong linearity between independent variables and predicted variable. However, there are several data transformation methods, such as logarithm, square root, reciprocal, cube root and square, can be applied to enhance the linear trend in data. There are also some guidelines for the selection of transformation method, such as if the standard deviation is proportional to the mean, the distribution can be positively skewed and logarithmic transformation can be performed, or if the variance is proportional to the mean, squared root transformation may be preferred etc. [21].

Among various transformation methods, logarithmic transformation is the most popular one. Using natural logs for variables on both sides of the linear regression equation can be called log-log model. Theoretically, any log transformation can be used in the transformation and all of them tend to generate similar results. However, using the natural log can be seen as the convention since the interpretation of the regression coefficients is obvious using the natural log. The coefficient in the natural log-log model represents the estimated percent change in the dependent variable for a percent change in the correspondent independent variable [22] .

3.4 Model Development

The classification tree structure determines the way how the overall dataset can be divided into several groups in which the regression model can be separately developed. The function of the classification tree is to cluster the similar observations together to obtain more accurate regression sub-models instead of messing all

the data together and get only one model. The proper classification may largely alleviate the effort to achieve the required model efficiency and accuracy. To efficiently build the classification tree, the key categorical variables used to split the tree are of the utmost importance. There are several available categorical variables such as work classification, scaffold type and discipline. The repeated tenfold cross-validation can be used to compare the effectiveness of different classification tree structures developed using various combinations of categorical variables.

The classification tree needs to be utilized with multiple linear regression model. After developing the classification tree structure based on selected key categorical variables, multiple linear regression can be implemented at each tree end node, as long as there are sufficient number of records at the tree node. Previous researchers discovered that when the number of observations n >= 15 * k where k represents the number of independent variables, the model parameter estimation tends to achieve a prescribed level of accuracy [23]. On the other hand, if the number of records at certain nodes cannot meet this requirement, the upper level model should be used to complement the miss of model under certain classification category. Normally, the multiple linear regression model at each classification tree node can be denoted as Eq. (1).

$$y = \beta + \sum \alpha_i x_i \quad (1)$$

Where: y is the predicted variable (i.e. scaffolding manhour) for the *ith* record at current classification tree node; β is the intercept value; α_i is the coefficient for independent variable x_i.

3.5 Model evaluation

Repeated tenfold cross validation has been selected to evaluate the regression models. Kim has found that the repeated cross-validation estimator is recommended for general use regardless of the sample size [24]. Moreover, Witten et al. have conducted extensive tests with different machine learning techniques, and the results have shown that, by repeating the tenfold cross validation 10 times, the results can reliably estimate errors [25]. Tenfold cross validation means to split the whole dataset into ten stratified subsets of equal size ten times, and each subset can be used for testing once and the combination of the rest can be used for training. The final error estimates are averages across each of the fold. Repeat the tenfold cross validation ten times and the mean value would be the final validation result. The evaluation matrix has five parameters in all, including R Square (R^2), Adjusted R Square (Adj.R^2), Mean Absolute Error (MAE), Root Mean-Squared Error (RMSE) and Relative Absolute Error (RAE). All the calculation equations can be found in a book [25] .

4 Case study

The proposed methodology has been implemented in the Python 3.7 environment and the case study is based on a heavy industrial project with data provided by a construction company. The scaffolding related data has been collected onsite through cloud-based data systems, as well as company's internal systems (e.g. project control systems, payroll systems, etc). There are in total three categorical variables and twelve numerical variables have been collected. The categorical variables are work classification, scaffolding type, discipline of trade that scaffolding is built/modified for.

The numerical variables are: average temperature, apprenticeship ratio (the ratio of work carried out by apprentices), night-time ratio, overtime ratio, aluminium percentage of the scaffolding, percentage of completed project, scaffolding weight, workable area (available space for building scaffolds), average scaffolding employee time on site, elevation of the scaffolds, major pieces and minor pieces (number of large/small pieces of scaffolding materials). After data consolidation and cleaning, the dataset contains 12,087 valid observations in total. Figure. 2 compares the manhour distribution of the raw dataset and the dataset after data cleaning.

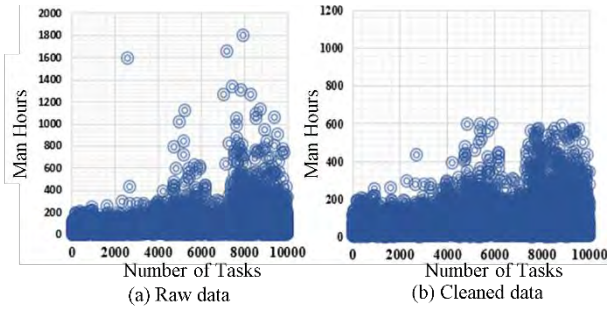

Figure 2. Manhour distribution comparison

After the data collection and data cleaning, the independence in the dataset should be checked. Table 1 illustrates a part of the sample correlation matrix of a classification tree branch (classification: Erection). The independent variables that have much lower correlation with others have been trimmed in the table due to the space limitation; only the most correlated variables were kept: workable area, scaffolding weight, major pieces, and minor pieces. It can be seen that almost all the values in Table 1 are larger than 0.5, which means the four variables are all highly correlated to each other. It should also be noted that all these variables are also highly correlated to the scaffolding manhours which is the predicted variable. According to the previous research, the collinearity can be simply addressed by keeping only one highly correlated independent variable but removing the others [26]. From the industrial view,

these four variables describe the scaffolding work from a similar perspective. To determine which variable is of the most importance, the multi-linear regression models have been developed based on one of these four variables in turn with the rest un-collinear eight variables. The sample results using classification as key variable can be found in Table 2.

Table 1. Sample correlation matrix

	Workable Area	Weight	Major Pieces	Minor Pieces
Workable Area	1.00	0.66	0.63	0.49
Weight	0.66	1.00	0.87	0.62
Major Pieces	0.63	0.87	1.00	0.67
Minor Pieces	0.49	0.62	0.67	1.00
Manhour	0.51	0.60	0.61	0.59

Table 2. Result using different variables

Index	Workable Area	Weight	Major Pieces	Minor Pieces
R^2	0.54	0.73	0.69	0.58
Adj.R^2	0.54	0.73	0.68	0.58
MAE	70.69	51.51	52.18	61.82
RMSE	134.65	107.56	115.32	145.36
RAE	1.30	0.69	0.72	1.01

It can be clearly seen from Table 2 that R^2, Adj.R^2 are the highest while MAE, RMSE, and RAE are the lowest when selecting the scaffolding weight variable. Since the weight variable can give less error and better predicted results, it has been kept in the model feature set but the other three have been excluded to prevent the collinearity.

Moreover, Table 3 shows VIF of all the numerical independent variables in the model at the branch of Erection-Tower as an example. The result shows that there are four variables with VIF factor value larger than 10, which are night-time ratio, project complete percentage, employee time on site, and apprenticeship ratio. Thus, these four variables have been excluded from the analysis to address the multicollinearity problem. Table 4 has been created to detect multicollinearity one more time after the adjustments. It can be seen that the multicollinearity has been solved since all the VIF values are lower than 10 when regress the model using the selected variables.

Table 3. VIF of each numerical variable

VIF Factor	Features
3.61	Temperature
3.52	Aluminum percentage
1.58	Weights
2.69	Elevation meters
1.07	Night-time ratio
28.00	Overtime ratio
70.06	Project complete percentage
223.20	Employee time on site
76.84	Apprenticeship ratio

Table 4. VIF of modified variable

VIF Factor	Features
1.13	Temperature
1.22	Aluminum percentage
2.03	Weights
1.04	Elevation meters
2.04	Night-time ratio

The regression model has been built using the selected five variables which are temperature, aluminum percentage, weight, scaffolding elevation, and night-time ratio. However, some negative manhours are predicted by the model. This phenomenon prompts the discovery of the exact contribution of each explanatory variable. According to the summary of previous work [27], the Standardized Regression Coefficients (SRC) method is suitable to conduct the sensitivity analysis for the linear model. Table 5 shows the result of sensitivity analysis for the classification tree built upon work classification and scaffolding type. It should be noted that the average value of night-time is negative, which indicates that with the increase of night-time working, the required manhours decreases. Thus, the night-time ratio has been removed not only due to its minimum contribution to predict manhours, it is also counter-intuitive to industry experts.

Table 5. Average result of sensitivity analysis

	Temp	Weight	Elevation	Night time	Aluminum percentage
Avg	-0.05	0.83	0.05	-0.02	0.07

Thus, there are four independent variables have been selected at the end. Next, the linearity between the independent variables and predicted variable should be checked. From the sensitivity analysis, it is obvious that in the linear regression model, the scaffolding weight is far more important than other variables. As the most prominent variable, the relationship between weight and manhour has been discovered and some sample scattered figures have been plotted in Figure 3. It can be seen that the dots in the upper left figure are scattered. The original manhour do not show strong linear trend with original scaffold weights. However, after taking the natural logarithm of both manhour and weights, there exists clear linearity between log(weight) and log(manhour). Other data transformation ways have been tried out as well, such as reciprocal transformation (weights versus reciprocal of manhour) shown in the lower left figure, and single logarithmic transformation

which means only transforming one side of variable (log(weight) versus manhour) as shown in the lower right figure. Nevertheless, the log-log model is obviously the best to generate linearity.

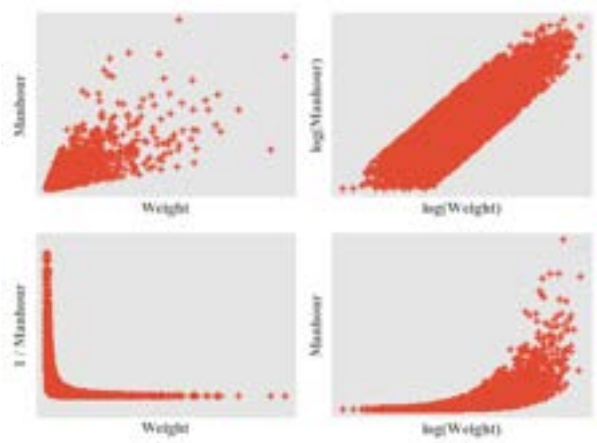

Figure 3. Comparison of data transformation

Furthermore, the log-log model should be applied to all the independent variables instead of only scaffolding weights. It is worth mentioning that since the log-log model can only be applied to positive variables, the temperature variable has been normalized in the range [0°, 10°]. In addition, to deal with the zeros in the dataset, a constant λ has been added to the log-log transformation equation as shown in Eq. (2).

$$\log(y) = \beta + \sum \alpha_i * \log(x_i + \lambda) \quad (2)$$

where λ can be one half of the smallest value in the dataset . In this study, $\lambda = 0.001$ has been adopted.

As for the classification tree structure, the trail-and-error method has been used to determine the best classification method. The repeated tenfold cross-validation results for various classification structures can be found in Table 6. Overall, the work classification works as the best classification tool since it gives the highest Adj. R2, way more than 0.7 which is the criterion to check whether a linear model is a good fit. Also, it produces less error than using other classification methods. After the regression models have been built at each tree node in the classification tree, the correspondent coefficient tables are stored for the future use.

Table 6. Cross-validation results

CT	R^2	Adj.R^2	MAE	RMSE	RAE%
WC	0.81	0.8	38.24	82.53	37.93
DIS	0.78	0.78	48.17	101.93	42.54
ST	0.76	0.76	47.49	87.94	41.09
WC+DIS	0.79	0.79	41.52	94.33	38.84
WC+ST	0.82	0.82	44.5	94.06	36.02
DIS+ST	0.79	0.78	48.04	99.36	40.5

5 Conclusion

As one of the largest temporary works, scaffolding is indispensable, but difficult to manage. Over decades, its requirement has been generally determined based on a percentage factor of the direct work in that project and the expert's opinion. It may result in an ineffective management of scaffolding-related resources and project cost. To address this practical issue, this paper proposes an integrated methodology to predict the required man-hours in the planning stage of the project. There are five main steps in the proposed methodology, which are the data collection, data cleaning, input data determination, development of classification tree structure, and model evaluation.

A case study has been implemented to validate the methodology. From the methodology, four independent variables have been selected at the end. Moreover, it has been found that when use the log-log transformation in the model, the linearity can be built between independent variables and dependent variable. After that, the results show that when using the work classification to build up the classification tree, the performance can be maximized. The best model produces R^2= 0.81, Adj. R^2=0.8, MAE=38.24, RMSE=82.53, and RAE=37.93%.

The current work has been proven to be effective to predict the manhours based on four independent variables which should be available in the early stage of scaffolding construction. However, with the increase of the amount of the available and reliable scaffolding data, the model can be further fine-tuned and trained. Moreover, the non-linear regression such as neural network is still a further research direction and needs to be discovered and compared with the proposed methodology in this research.

Abstract –

Concrete bridges are important infrastructures, which thus need effective rehabilitation to maintain good condition. Bridge rehabilitation projects often have tight schedules, multiple participants and constraints, and scattered project information. Thus, improving information integration in these projects can be critical. This research develops a concrete bridge rehabilitation project management ontology (CBRPMO) to integrate various project information, e.g. information of constraints, tasks, procedures, project participants, and relations between these project entities. The CBRPMO was built based on domain knowledge collected from various documents and was refined in a focus group. The development followed standard procedures. The CBRPMO was also validated in a case study. It turns out the CBRPMO can effectively integrate information and support effective querying, which can save time to manually search for information from scattered sources. The CBRPMO contributes to industry because it expands the boundary and application of ontologies for bridge maintenance by covering the rehabilitation stage.

Keywords –

bridge rehabilitation; project management; semantic web; ontology

1 Introduction

Bridge rehabilitation projects often have a tight schedule and complex tasks with various constraints, e.g. labour, materials, and equipment [1]. Information of these constraints should be timely integrated to assist constraint removal [2]. Moreover, rehabilitation projects involve participants of different backgrounds, who often have isolated databases. Thus, information for managing the project, e.g. constraints and tasks/procedures, are often scattered in project documents or systems [3]. As such, it is essential to improve information integration and exchange in bridge rehabilitation projects so that information can be timely delivered to the right person, e.g. project managers, to support informed decisions.

Ontology is an emerging semantic web technique (SWT), which is built in a standard format while can link heterogeneous information sources. Ontologies have been increasingly applied in construction projects to enhance information integration and sharing [4]. Compared to traditional relational databases, ontologies are more effective to integrate domain-specific and unstructured information, such as constraints related information [5]. Therefore, this study develops the concrete bridge rehabilitation project management ontology (CBRPMO) to integrate information in bridge rehabilitation projects and address challenges of integrating and exchanging information.

2 Related Work

Concrete bridge maintenance includes four stages: inspection, condition evaluation, maintenance decision-making, and rehabilitation. Rehabilitation can include hazard treating, reinforcement, and replacement. Hazard treating fixes damages. Reinforcement increases the structure load-carrying capacity by adding components or materials. Replacement substitutes severely damaged bridge components. In the digital era, many modern information technologies have been applied to collect, analyse, and store bridge data for bridge inspection, monitoring, and decision-making [6, 7].

However, at the rehabilitation stage, studies focus on engineering techniques (e.g. the confinement technique [8], and grouted splice sleeve [9]) and materials (e.g. ultra-high-performance fibre reinforced concrete [10]). Compared to other stages, the rehabilitation stage is also complex and requires extensive information exchange. Rehabilitation projects have a tight schedule, multiple participants, and complex constraints that need to be removed [11]. Constraints are things that prevent work from being smoothly executed (e.g. delay of materials),

and work should not start until all constraints are removed. Constraint removal means required entities of a certain amount and quality are in place on time. The importance of removing constraints is highlighted in other complex projects [12]. Constraint removal relies on identifying constraints based on domain knowledge and sharing constraints related information so that the management attention can be properly directed [11]. However, it can be difficult to access such information in bridge rehabilitation projects because they are often scattered in isolated systems and documents [13]. As such, more efforts are needed to improve information integration in these projects. Bridge management systems (BMSs) and bridge information modelling (BrIM) have been applied for bridge inspection and evaluation and can be used to integrate rehabilitation information as well. However, BMSs are restricted to pre-rehabilitation stages, and they often suffer from the data island problem as they do not adequately consider integration of data of different formats and managed by different parties [14]. Besides, due to features of the industry foundation class (IFC) schema, BrIM tools are good at modelling geometry information rather than semantic information. In this case, SWT-based methods, e.g. ontologies, can be applied.

An ontology is a graphical method for describing domain information and knowledge, which consists of nodes (i.e. classes and instances of classes) and relations (i.e. edges between nodes). Studies of ontologies for information integration focus on building semantic relations between information sources and applying semantic query (e.g. SPARQL) to search for relevant information. Thus, one can not only find contents that match key words textually, but contents semantically related. For instance, a bridge beam can be semantically related to its design drawings. Hence, when searching for the beam, information of the drawing can also be easily explored by navigating the relation between the two ontological instances.

Ontologies can be object or process oriented. The former is based on taxonomies of objects, such as building objects like walls and windows; the latter is based on sequences and constraints of tasks [15]. The object-oriented ontologies are the dominant form, which often stores information that is relatively static, such as material and geometry, defects, quantity and cost, risk, and structure condition from project documents and systems (e.g. BIM and BMS) [16]. Some studies have also built process-oriented ontologies (or as a part of their work) to record information of project progress [15].

However, studies of ontologies in the construction sector focus on vertical buildings and bridge inspection and evaluation. Besides, most ontologies are objects oriented. Therefore, the industry still lacks an ontology especially designed for bridge rehabilitation projects to integrate information specific in such projects, e.g. tasks and procedures, constraints, and participants.

3 Development of the CBRPMO

The ontology development 101 published by the Stanford University was adopted to build the CBRPMO. The document is a general and mature guideline to develop different ontologies and has been applied in several projects in the construction sector[17-19]. The key steps are shown in Figure 1.

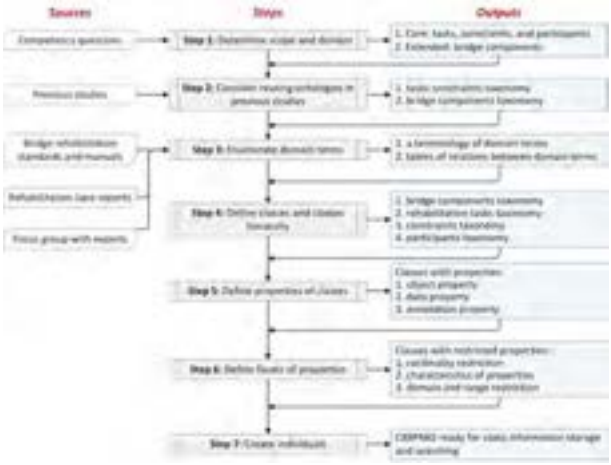

Figure 1. Development process of CBRPMO

3.1 Determine domain and scope

The first step is to define the domain and scope of the ontology. This step can be achieved by answering the following fundamental questions:

Q1: What domain will the CBRPMO cover?

A1: The domain is concrete bridge rehabilitation project management; therefore, the ontological model will cover rehabilitation tasks and procedures, constraints, and project participants.

Q2: For what purpose will the CBRPMO be used?

A2: The CBRPMO aims to improve current project management in bridge rehabilitation projects by integrating project-related information.

Q3: Who will use and maintain the ontology?

A3: The main user is the management team of rehabilitation projects, but other stakeholders, e.g. the bridge owner, can also have access.

Q4: What are the sources for the ontology?

A4: Concrete bridge rehabilitation standards and manuals, case reports, project documents (e.g. work plans and project meeting records), and experts' opinions are the main sources.

Q5: For what types of questions will the CBRPMO provide answers?

A5: The CBRPMO will answers questions that a rehabilitation project manager can ask, e.g. procedures, constraints, detailed activities, precautions of tasks, and methods to address constraints not timely removed.

3.2 Consider reusing existing ontologies
