Preface

The 1st International Symposium on Automation and Construction (ISARC) was held at Carnegie Mellon University in Pittsburgh, Pennsylvania, USA in 1984. Since then, ISARC has been held all over the world every year to exchange information about the development and practical use of construction robot technology among industry experts, academic researchers and individuals with novel ideas for all fields of construction, civil and building engineering, machine automation, robotics applications to construction, information technologies, planning, logistics, etc.

ISARC has been held in Japan four times so far, but it has not been held here since 2006, because the momentum for the development of construction robots declined rapidly with the economic downturn around 2000. We were very pleased to learn that we would be able to hold the 37th ISARC in Japan in 2020 after 14 years thanks to the recent increase of momentum in the development of construction robots.

For the symposium, we had planned and prepared to organize not only research presentations, but also key note lectures, technical exhibitions and technical visits related to construction robots in use on the island of Kyushu, in the western part of Japan. Last December, we started a call for papers, and more than 390 abstracts were received from 33 countries.

Unfortunately, the infectious disease caused by COVID-19, which started at the end of last year, quickly spread throughout the world, and many people are still suffering from its effects. We would like to express our heartfelt sympathy to all the people who are in a severe situation, including those who have lost loved ones and/or have been infected by the disease.

There is still no clear end in sight to COVID-19. For this reason, in May of this year, we decided to hold the symposium online and immediately started the preparations for an online symposium. However, we had neither the experience nor the know-how to organize an online international symposium. Therefore, our original plan was not necessarily a very productive one. Under these circumstances, we received tremendous support from the IAARC Board members and were able to hold the online symposium successfully. We would like to extend our sincere gratitude to them for their kindness and great cooperation.

Although the number of submitted papers decreased, due to changes related to an online symposium, we still received 221 full papers from 23 countries. We believe that this symposium was very fruitful in terms of cross-national technical exchange among all the participants.

Finally, I would like to express our deepest gratitude to the members of the Japanese local committee for all the work they did with us in planning and preparing for this symposium. I believe that the efforts of all the people involved in this symposium will greatly contribute to the further evolution of construction robots.

Kazuyoshi Tateyama
Chair, 37th ISARC
Professor, Ritsumeikan University, Japan

Introduction

This publication is the Proceedings of the 37th International Symposium on Automation and Robotics in Construction (ISARC). The symposium was held online during 27-28 October 2020. The Proceedings include an illustrated review of the program, the names of organizations and persons who contributed to the technical program, and the 221 technical papers from 23 countries authored for this international meeting.

The manuscripts were presented during 57 sessions on 3 tracks, among them: automation and robotics, building information modeling (BIM), inspection and monitoring, artificial intelligence and machine learning, construction management, safety and health, data sensing and analysis, mixed Realities (AR/VR), control technology, education, environmental sensing and modeling, human sensing and monitoring, IT supported system, database, big data, lean, logistics, prefabrication, modularization, leaning/AI/recognition, human-computer interaction, measurement, modeling and management, new application field of construction robots and machines, risk management, robot and interface design, and robot construction.

Please note: All ISARC proceedings since 1984 are available at no cost at http://www.iaarc.org.

We are very grateful for the support of so many. Thank you!

Hyoungkwan KIM

Professor at Yonsei University, Korea

Smart Safety Assurance for Temporary Structures

Temporary structures on construction sites has been the major cause of worker fatalities. According to a Korean statistics report, about 300 people are losing precious lives each year due to accidents involving temporary structures. A new research program was launched this year to develop a smart safety assurance system that recognizes, evaluates, and predicts accident risks that may occur during the installation, dismantling, and operation of temporary structures. It is a part of the smart construction initiative sponsored by the Korean Ministry of Land, Infrastructure, and Transport, and the Korea Agency for Infrastructure Technology Advancement. The program was designed for developing technologies such as deep learning-based hazard identification, augmented reality-based risk warning, and smart mobility for intelligent sensing of construction sites, with a total budget of ₩12.5 billion ($10.5 million) over six years. The program has a clear goal of reducing the number of accidents related to temporary structures by more than 25% through the creation of a new construction culture, safety-related policies, and safety-related industries.

Speaker profile:

Hyoungkwan KIM, Ph.D. is a Professor of the School of Civil and Environmental Engineering at Yonsei University, Korea. His areas of research include construction automation, infrastructure adaptation to climate change, and project finance. He is the principal investigator of a $10.5 million research program titled “Smart Safety Assurance for Temporary Structures,” which is a part of smart construction initiative sponsored by the Korean Ministry of Land, Infrastructure, and Transport, and the Korea Agency for Infrastructure Technology and Advancement. He serves as Vice- President for the International Association for Automation and Robotics in Construction (IAARC), and Associate Editor for Journal of Computing in Civil Engineering, American Society of Civil Engineers (ASCE). He also served as Secretary General for Association for Engineering Education in Southeast Asia and the Pacific (AEESEAP). He has received six excellent teaching awards and an excellent research award from Yonsei University. More information on Prof. Kim can be found at: http://aim.yonsei.ac.kr.

Keynote 2

Naoki SATO

Director of the Space Exploration System Technology Unit, The Japan Aerospace Exploration Agency (JAXA), JAXA Space Exploration Center (JSEC), Japan

International Space Exploration and Japanese Lunar Activities

JAXA is engaged in international collaborations to tackle the challenge of human and robotic exploration missions in and beyond low-Earth orbit (LEO). The current focus is exploration missions to the Moon and Mars, targeting future human activities. His presentation introduced Japan's current exploration activities and JAXA's future plans and studies beyond the Earth orbit with the context of international coordination. Especially for the lunar surface activities, the concept study of the lunar base construction, which JAXA had conducted with a group of construction-related companies across Japan, was introduced along with the technological development.

Speaker profile:

Naoki SATO graduated from the Aeronautics Engineering Department, Kyusyu University in 1986, and gained a master degree of applied engineering of Kyusyu University in 1988. In the same year, he entered the National Space Development Agency of Japan (predecessor of JAXA). From 1990 he had been involved in the International Space Station program for about 16 years. Afterwards, he has been working for the international space exploration program formulation. Since April 2018 he is the current ISECG chair and since July 2018 he was assigned as the Director of the Space Exploration System Technology Unit of JAXA Space Exploration Center (JSEC).

Keynote 3

Yasushi NITTA

Director for Construction Equipment and Safety Planning Office, Policy Bureau, Ministry of Land, Infrastructure, Transport and Tourism, Japan

Initiatives for Robot Introduction in Japanese Public Works

The Japanese society faces various social issues such as frequent occurrences of earthquakes, eruption of volcanoes, floods, landslides, etc., resulting in the deterioration of the infrastructure. Japan also sees a reduction of the working population in the construction industry. In his speech, he introduced initiatives for the social implementation of robots and information and communication technologies in the Japanese construction industry, including the Ministry of Land, Infrastructure, Transport and Tourism (MLIT).

Speaker profile:

After graduating from University of Tsukuba in 1994, Dr. Yasushi NITTA joined the Ministry of Land, Infrastructure, Transport and Tourism (MLIT). There he is widely engaged in policy planning, public works and R&D in the various departments, such as MLIT Headquarters, Regional Development Bureau, National Road Office, National Research Institutes (PWRI, NILIM), Advanced Construction Technology Center (ACTEC). He is especially responsible for the planning and operation of on-site verification projects to promote the introduction of robots to the infrastructure department, development/deployment/budgeting/operation of disaster

countermeasure machines, and nationwide deployment of machine construction (i-Construction) using 3D data. Dr. NITTA is also engaged in establishing technical standards for the purpose, demonstrating ultra-long-distance unmanned construction technology, and flood control as an international emergency relief team.

Abstract –

In recent years, building information modeling (BIM) has been widely used to create animated simulations for engineering demonstrations. On-site engineers often employ animations generated using a BIM system to explain the current project status to their managers, so that the managers can grasp the actual project status. However, the fidelity of the terrain models built using BIM is relatively low, and the modeling process is labor-intensive. These factors negate the advantages of BIM. To overcome these problems, in this study, images of an engineering site are captured using Unmanned Aerial Vehicle and are subsequently used to generate a landscape terrain model of the area surrounding the engineering site by means of image comparison and GPS positioning techniques. The terrain model and the BIM main simulation model are integrated to present the actual site condition. In addition, to further enhance the realism of the integrated model, this study introduces the integrated model into the virtual reality (VR) environment to present the construction site. The manager can check the construction progress of the project easily without having to visit the project site.

To test the feasibility of the proposed method, it is applied to a bridge construction project. The results indicate that the aerial photos captured using Unmanned Aerial Vehicle can be converted into point cloud models and mesh segmentation models. Both types of models can be imported and integrated into BIM software. However, if other renderings (such as Lumion) or VR software (such as Fuzor) are to be used for further animation production, the photos captured using Unmanned Aerial Vehicle can only be converted into mesh segmentation models before importing them for use in subsequent applications.

Keywords –

Building Information Modeling; Unmanned Aerial Vehicle; Virtual Reality, Construction Demonstrations

1 Introduction

Building information models (BIM) have been increasingly adopted to enable construction project presentations through animated simulations. On-site construction projects are usually modeled using BIM with animations to intuitively display the expected final product of a project to managers, allowing managers to understand and manage project progress.

The applications of BIM has also been extended in addition to its common use in animation and four-dimensional simulations[1,2,3]. To achieve satisfactory BIM presentations, using BIM, engineers build a model of the construction site in question and combine it with another model that simulates the surrounding area. However, BIM-simulated terrain models are usually inaccurate, and their construction incurs considerable financial and labor costs, consequently reducing the benefits of BIM displays.

Recently, the rapid advancement of unmanned aerial vehicles (UAV) has enabled the industry and academia in Taiwan to integrate aerial photography with aerial photogrammetry software to create three-dimensional (3D) models[4,5,6]. Numerous studies have proposed route planning suggestions for UAV used in modeling and aerial photography[6]. However, several questions remain unanswered regarding integration between UAV imagery and BIM, including differences between various aerial photogrammetry software programs, UAV 3D modeling procedures, and approaches to integrating UAV 3D models with BIM.

Instead of selecting commercially available UAV photogrammetry software (e.g., Altizure and Contextcapture), this study built models of the project site and its surrounding area simply by using Pix4D and Recap. Subsequently, the constructed terrain model was incorporated into BIM software. The resultant model accurately displayed the actual on-site conditions; different software programs were imported into the model to verify its rendering feasibility.

2 Literature Review

2.1 Display of BIM animation and virtual reality environments

Conventional two dimensional and 3D modeling methods fail to comprehensively display a building. No existing BIM software program can accurately reflect the actual materials or establish a complete 3D scene. Generally, a 3D scene comprises streets, surrounding buildings, cars, pedestrians, trees, and animations. The use of rendering on a virtual scene, which can be realized through a combination of walkthroughs and virtual reality (VR) technologies, creates a realistic scene that offers immersive user experiences [7].

Scholars have incorporated BIM animation into VR in practice; for example, Hu and Wang [8] integrated a tunnel BIM, collision parameters, and remote-control car models with VR to create a third-person VR walkthrough.

2.2 UAV image-based 3D models

UAV photogrammetry 3D models have often been combined with BIM models.Wen et al [4] adopted UAV and augmented reality technologies to construct BIM models. They used a UAV to obtain images of surroundings and established real-time augmented reality markers in a positioning system, after which a BIM model was imported to allow the UAV to instantly combine the BIM with its surrounding area as it flew.

Karachaliou et al [5] preserved cultural heritage buildings by integrating UAV technologies with BIM. Specifically, they obtained indoor data of the target building by integrating a UAV-generated external model with laser scanning and photogrammetry. Next, a BIM was constructed using Autodesk Revit. Through this approach, Karachaliou et al. [5] effectively recorded cultural heritage buildings with complex scales or forms in a museum.

Comparing a conventional model with a UAV imagery-constructed model, Liu [6] discovered that the construction of a conventional environment model involved complex measurement procedures; by contrast, measurements and geographic data can be simultaneously obtained, with the flight route determined, as UAV images were captured. Additionally, UAV can capture images of hazardous regions where human cannot approach and accurately reveal the surrounding terrain.

Researchers of most UAV studies have recognized that UAV-constructed 3D models more accurately present an environment than conventional models do. However, researchers have rarely discussed the overall process of combining UAV imagery with BIM and the subsequent application of rendering software for animation production.

3 Method of integrating BIM, UAV, and VR

This study integrated BIM with UAV and VR technologies to facilitate the presentation and simulation of construction projects; the procedures are presented in Figure 1. UAV images were used to construct 3D models through the separate application of two UAV photogrammetry software programs (i.e., Recap and Pix4D). Subsequently, CloudCompare was used to crop and export a point cloud model with triangle meshes. The exported model was merged with a BIM model, after which Lumion and VR software were run to perform rendering and make animations.

This process is detailed in six subsections, namely “BIM model,” “Aerial 3D model construction using Pix4D,” “Aerial 3D model construction using Recap,” “Point cloud models cropping,” “Integration of aerial 3D models with the BIM,” and “Rendering and animation production.”

3.1 BIM construction

The BIM of a bridge was constructed before being combined with UAV images. This bridge model encompasses basic components including piers, roads, pylons, and steel cables. However, numerous parts of the bridge cannot be established using basic components separately such as pillars, beams, boards, or walls. Therefore, these parts were constructed using grouped components and later integrated into the project.

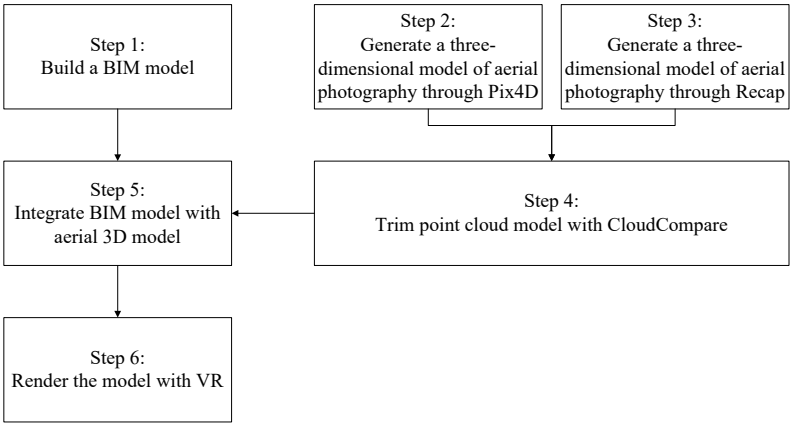

Figure 1. Architecture of integrating of BIM and 3D model

3.2 Aerial 3D model construction using Pix4D

As an aerial photogrammetry software suite, Pix4D can locate UAV-captured images on a coordinate system. After images were imported, this study set the imaging parameters to produce a point cloud model and 3D model.

3.3 Aerial 3D model construction using Recap

Recap is another point cloud processing software program. UAV-captured images were first imported into the software program before a point cloud model was generated using the built-in global positioning system. Furthermore, because Recap is developed by Autodesk, it is more compatible with BIM software than Pix4D is.

3.4 Point cloud model cropping

This study used CloudCompare to crop the 3D models established using Pix4D and Recap. When empty areas are present in the background, CloudCompare allows users to select a few point clouds of the surrounding terrain and fill in these areas through stitching. The software program also hides the area that requires no cropping, making the cropping process easier.

3.5 Integration of aerial 3D models with the BIM

Aerial 3D models must be accurately merged with the BIM model, during which time a point cloud model should be imported into Revit. Currently, only Recap-produced point clouds are compatible with Revit. Because manually aligning the point clouds with the host model does not provide sufficient accuracy, this study redefined the host model position in the Revit project by setting the project base points. This study also relocated the Recap origin to the target position where the point cloud was to be combined the BIM.

The integrated model can be exported to various formats according to different needs. An advantage of combining point cloud data with a host BIM on Revit is that existing BIM software programs can directly import the integrated model into rendering software by using Revit plug-ins. Moreover, these software programs enable simultaneous model revision and rendering as well as the production of animation or a VR display.

3.6 Rendering and animation production

If the integrated model is displayed in a walkthrough on Revit, the fidelity to the terrains and on-site conditions may is inadequate. To improve the fidelity of the terrain model and host BIM, this study displayed the models using Fuzor.

4 Case study

This case study was of a bridge construction project in central Taiwan. In the following subsections, this study describe the construction of a terrain model based on UAV images and its integration with a host model. This study discuss the process by which the fidelity of the integrated model was improved by using rendering software.

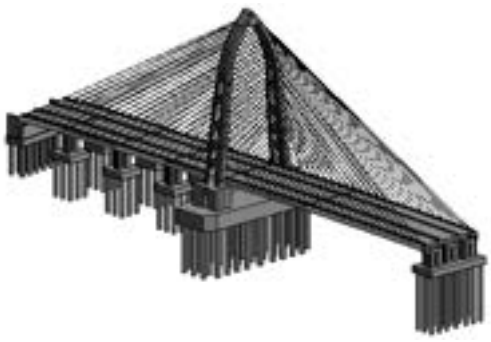

Figure 2. BIM model of case study

4.1 BIM of the bridge

The BIM of a cable-stayed bridge was established. As mentioned, bridges cannot be drawn with basic components used in drawing housing structures, which are composed of pillars, beams, boards, and walls. Therefore, this study divided the bridge into piers, roads, pylons, and cables and built each family components respectively.

4.2 Aerial 3D modeling on Pix4D

On-site images taken by the UAV were imported into Pix4D for 3D modeling in the following four steps:

1. Image importing: The UAV captured on-site orthophotos, oblique photos, and panoramic photos. These photos were then imported into a Pix4D project.
2. Image parameter settings: Image parameters were set after importing was conducted. Because the UAV simultaneously took pictures and recorded their coordinates, the coordinates were already stored in Pix4D in the image importing process. Accordingly, the World Geodetic System 84 (WGS84) was selected in the coordinate system; the coordinate unit was set to m, and the edited coordinate data were directly exported (Figure 3).

Figure 3. Image parameter settings

3. Point cloud modeling: After 3D modeling was completed, the photography methods were set to orthophotography and oblique photography. A point cloud model was then generated, after which two options were available, namely “export the point cloud” and “export the triangle mesh” (Figure 4).

Figure 4. Modeling method settings

4. Exporting the point cloud to CloudCompare: When the terrain in question is vast, the resulted point cloud can be susceptible to the Earth’s curvature and becomes imprecise. To avoid such a problem, repeat Step 3 several times to generate a point cloud and cropped and stitched it using CloudCompare to better reflect the actual terrain.

4.3 Aerial 3D modeling on Recap

On-site images taken by the UAV were imported into Recap for 3D modeling in the following four steps:

1. Photography mode setting: When creating a new project, the user must choose either the “Object” (for general objects) or “Aerial” (for terrains) photography mode for 3D modeling. Because terrain photos were taken by a UAV, “create 3D aerial” was selected to construct a 3D terrain model (Figure 5).

Figure 5. Selecting the Aerial mode

2. Image importing and coordinate settings: To create a 3D terrain model, images were imported (Figure 6);

subsequently, coordinates can be set for the imported images. Notably, our UAV already attached coordinates to images it captured. Consequently, this study only had to choose the coordinate system of the target location (WGS84) when setting coordinates for the project.

3. Point clouds generation: In this step, a point cloud model was constructed. When the model is being exported, .rcp or .rcs formats can be selected to facilitate the subsequent combination with the Revit host model.
4. Point cloud exporting to CloudCompare: Although point cloud clipping and deleting is allowed on Recap, this software focuses on point cloud creation. To obtain an accurate point cloud, this study used CloudCompare to clean up the point cloud, whereby the point cloud model was cropped and modified.

4.4 Point cloud cropping

This study cropped and modified point clouds using CloudCompare to facilitate the subsequent display of an integrated host model. Because the point cloud failed to present vegetation realistically, such parts in the point cloud was cropped out. However, such practice resulted in empty areas in the model (Figure 7); therefore, nearby point clouds were used to perform stitching and fill in these empty areas. When each area is being filled in, at least three base points must be selected, after which the software automatically aligned the clouds with corresponding areas to complete the stitching (Figure 8). The stitching area between the point cloud model and host model was also modified so that other software programs could be used subsequently to more realistically present vegetation.

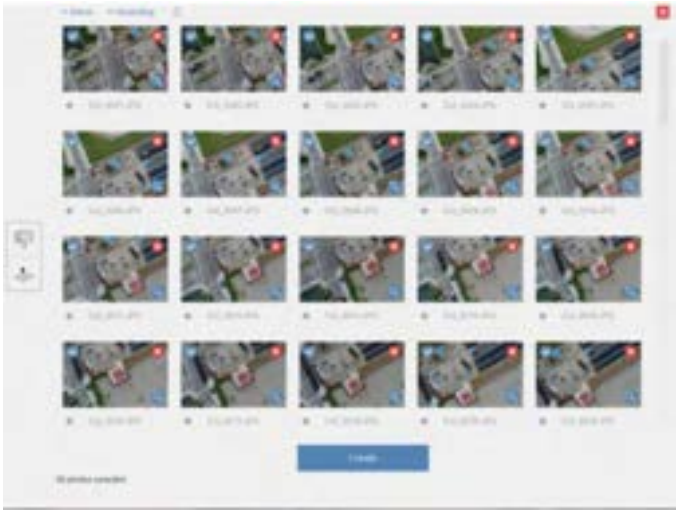

Figure 6. Terrain image importing

Figure 7. Comparison between uncropped and cropped terrain point clouds

Figure 8. Filling up the empty areas

4.5 Integration of the aerial 3D models with the BIM

In this study, the host model of the bridge was built using Autodesk Revit. The aforementioned point cloud 3D model was imported into Revit to merge it with the host model. However, the point cloud exported using Pix4D was incompatible with Revit. Therefore, this study used the origin-updating command in Recap to relocate the origin in the stitching area (Figure 9). By updating the project base points, this study moved the bridge model origin in the stitching area to align the point cloud model origin with the host model origin. When the cloud point was being imported, the option "Origin to Origin" was selected to facilitate the precise combination of the two models, as illustrated in Figure 10.

Figure 9. Updating the origin of the point cloud model

Figure 10. Integration of the point cloud model with the host model

4.6 Rendering and animation production

To further enhance the fidelity of the terrain model and BIM, this study displayed the model using a VR software program termed Fuzor. After the terrain model was merged with the BIM, a plug-in was employed to convert the integrated model for use on Fuzor, whereby the model can be instantly modified and synchronized with Fuzor models. Fuzor were then used to add elements such as trees, cars, and pedestrians in the model. Finally, rendering was implemented and landscape elements were added to create a complete and realistic scene. Subsequently, walkthrough animations or VR environments, which provides immersive experiences,

may be created using Fuzor, allowing users to better understand the project status.

5 Conclusion

This study was of a bridge construction project in central Taiwan. In the following subsections, this study describe the construction of a terrain model based on UAV images and its integration with a host model. This study discuss the process by which the fidelity of the integrated model was improved by using rendering software.

5.1 Comparison of terrain modeling procedures

According to the comparison between terrain modeling procedures in Pix4D and those in Recap, the following advantages and drawbacks were determined.

1. Pix4D terrain modeling
   (1) The triangle mesh is delicate: After generating the point cloud on Pix4D, the user can reduce the size of each triangle by adjusting related parameters. Therefore, the exported triangle mesh is more delicate, contributing to a better visual effect during animation display.
   (2) The point cloud is complete: After the UAV-captured terrain images are imported, the point cloud generated by Pix4D is not affected by overlap rate, allowing researchers to create a point cloud model. By contrast, in Recap, a point cloud model cannot be generated if the overlap rate is low.
2. Recap terrain modeling
   (1) Higher compatibility with BIM software programs: Because Recap was developed by Autodesk, the Recap-derived point cloud is compatible with other Autodesk-developed BIM software programs. By contrast, the Pix4D-constructed point cloud must be converted into a compatible format using Recap before being integrated with a Revit model.
   (2) Ability to redefinition the origin: After creating a point cloud model, Recap can update its origin, allowing the model to be accurately merged with a host BIM. By contrast, Pix4D does not have this origin-updating feature.

5.2 Rendering and animation production

After the terrain model and host BIM are integrated, Lumion and Fuzor may be more suitable options for model rendering and animation display compared with Enscape, which fails to display a terrain model when the model is imported. To use the coordinate alignment function on Lumion, the host BIM and point cloud must be exported to the .fbx format and a triangle mesh, respectively. By contrast, Fuzor can simultaneously display terrain models without changing the file format.

After the fidelity of the terrain and host BIM is improved, the models are ready for animation production and VR environment import. The use of VR technology to present the construction site can provide an immersive experience, enabling users to clearly preview the expected final product and monitor construction progress. The strengths of Fuzor are further demonstrated through its functions of five-dimensional display of construction simulation, conflict detection, and animation production.

Abstract –

Using Building Information Modeling (BIM) technology, a unique virtual model of a project can be created, which will allow all parties involved in the design process of project members (owners, architects, engineers, contractors, sub-contractors and suppliers) to collaborate more precisely and more effectively than using traditional processes. The collaboration of the different parties must be linked by a functional system with the presence of software, the team members constantly refine and adjust their portions according to the project specifications and design modifications to guarantee that the model is as precise. Augmented Reality (AR) in turn can bridge the cognitive gap between pre-sale products and real products. Although the presence of Augmented Reality (AR) and Virtual Reality (VR) is necessary, it is necessary to establish a system that directly connects AR, VR, the company, clients, investors and various construction documents. This VR system will be used in the functions of the pre-sale houses between companies, owners and investors. The project that will be used for this study is a building of five floors and two basement located in the District of Zhonghe in Taiwan. As the result showed, for the presentation of the presale house, the technique of the Event-Driven Process Chain (EPC) diagram is used including the import and export of several files. In addition the diagram system gives customers the opportunity to make changes regarding materials, design and time liner in future construction. These different changes made by the customers and approved by the company will generate consequences for the initial contract drawn up by the company. The software Fuzor to ensure the realization of the VR and AR while maintaining a concordance of the different stages of the diagram. To satisfy the requests of the ownership of, the project price and timing, Navisworks and Revit have also allowed the good management of the project. The EPC diagram will have two alternatives, the first alternative will be proposed by the company according to the demand on the market. Then follow the second alternative, this will be the new proposals suggested by the customers after consulting the proposals of the company using VR and AR. At the end of these various changes by the EPC system the prices of materials, other design, the implication of equipment, labor, materials and subcontractors will be updated according to the proposal of the owner.

Keywords –

Augmented Reality (AR); Virtual Reality (VR); Presale House; Building Information Modeling (BIM); Event-driven Process Chain (EPC) concept.

1. Introduction

In the 1960s, rapid economic development in several Asian countries, including Taiwan, Hong Kong, China, Singapore, South Korea, Indonesia and Malaysia, led to an explosion in demand for housing in several major cities. This growth in housing demand also reflected the economic status of these countries [1]. The solution to this growing demand, a unique and innovative presale housing system was developed, and has been adopted and developed since then. These house pre-sales refer to the contractual sales of housing before the construction of the construction project, i.e. the management companies design a building and start to build or before construction try to make offers to customers for the purchase of their houses. With this system, companies can receive pre-contracts which will allow them to finance future construction. Some customers in order to guarantee a good future for their families will be interested, the pre-sale accommodation can be purchased at a reduced price and they acquire property rights in advance. In addition, home buyers can participate in and oversee the advancement through the VR and AR of the housing project to secure their property rights at the end of the project, and even make proposals during construction [1]. Use to gain customer trust. This requires creating beautiful reception centers and hiring professional real estate sales agents. This

strategy requires a lot of expense, which is a major drawback for companies. Through architectural models, a plan for implementing 3D product perspectives and models coupled with examples of housing, the companies are trying to improve the understanding of investors and customers to stimulate purchase intention. Many customers are dissatisfied after the construction of their infrastructure works, most of these problems are due to the fact that the owner does not really know what his project will look like after construction and the delay in construction. To solve this problem new technique have been developed in this study [2].

2. Presale house presentation

2.1 Research content

The concept of the Event-driven Process Chain (EPC) diagram will be used for the presentation of the presale house.

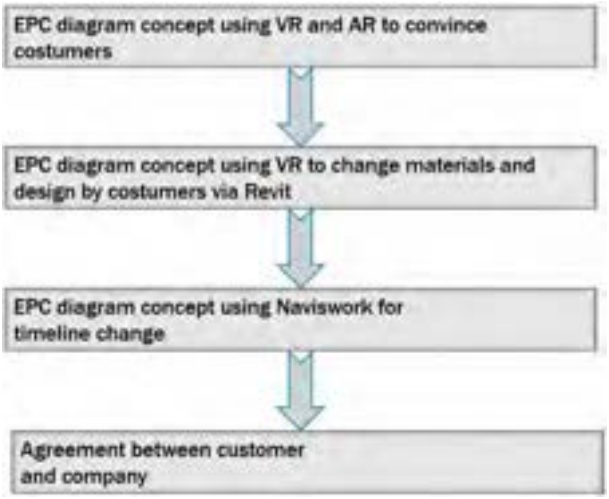

Figure 2.1. Work process

This diagram highlights an intersecting connection between the different parts of the construction. The objective is to convince the owner or investors to buy or place an order before finalizing the construction.

2.2 Diagram of the presale house presentation

In this study for a good presentation and convincing of the presale house, the concept EPC was used. The EPC is a flowchart for business process modeling for product management through multiple partners. EPC can be used to configure company resource planning execution with the aim of structuring all the details in time and in their place, and for business process improvement. Used to control an autonomous workflow instance in work sharing represent in Figure 2.2.

In this study Events are passive elements in event-driven process chains. That event describes under what circumstances a function or a process works or which state a function (Navisworks, Revit, Fuzor) or a process results in. Then the function described below.

Figure 2.2. Event-driven Process Chain

The function of the figures used:

- Event and result event
- Information: output and input documents
- Function
- Supporting system
- Organizational unit type

Figure 2.3 explains the strategies implemented to present the 3D model by the company to the owners. This strategy involves the creation of a 3D animation of the project from the Revit file.

The experimentation is based on a construction project in the district of zhonghe. The project comprises a building of five (5) floors and two bases for habitation. The building will be built in a residential area. The two bases will be used for parking. This experiment will focus on the project information.

In this study the responsibility is to convince the customers or investors to buy or rent the room (building) during or before the construction phase. To convince customers or investors several ideas has been established in which softwires and new technologies will be use.

Owner of the entire building: The whole building belongs to a single structure and all decisions will be specific to these people.

Inspection by Virtual Reality: Step1 owners order to company using Fuzor

In this first step the company uses Fuzor software for a complete presentation of the building to the owners. This presentation concerns the exterior and interior designs. This function will obviously need supporting systems and information (input documents function). This is how the second and the third step, which are respectively construction type to the company, Step2 and Virtual view to the company Step3, will take

place.

In Step 3 the first presentation will be done by VR BOX headset. This involves the use of the Fuzor application on smart phone. First use the Fuzor software to output the construction file in FZM format, then transfer it to the smart phone, then open the file using the Fuzor application. The owner can start to see the virtual view of his future home. The Fuzor 3D view, the company will use the synchronization system from the Revit software to open the project.

This synchronization system is very important because it will facilitate the work when the owner will make a decision regarding a change. After the synchronization the file of the project will be opened on Fuzor.

For the good vision of the project, the environment in which the project will be implemented will be presented to the owner with the presence of his future building. This presentation will be done by Mixed Reality (MR) [4]. The 3D photo model (presented in Figure 2.4 and 2.5) of the construction environment produced by the Bentley contextcapture software which was the subject of the first part of this study.

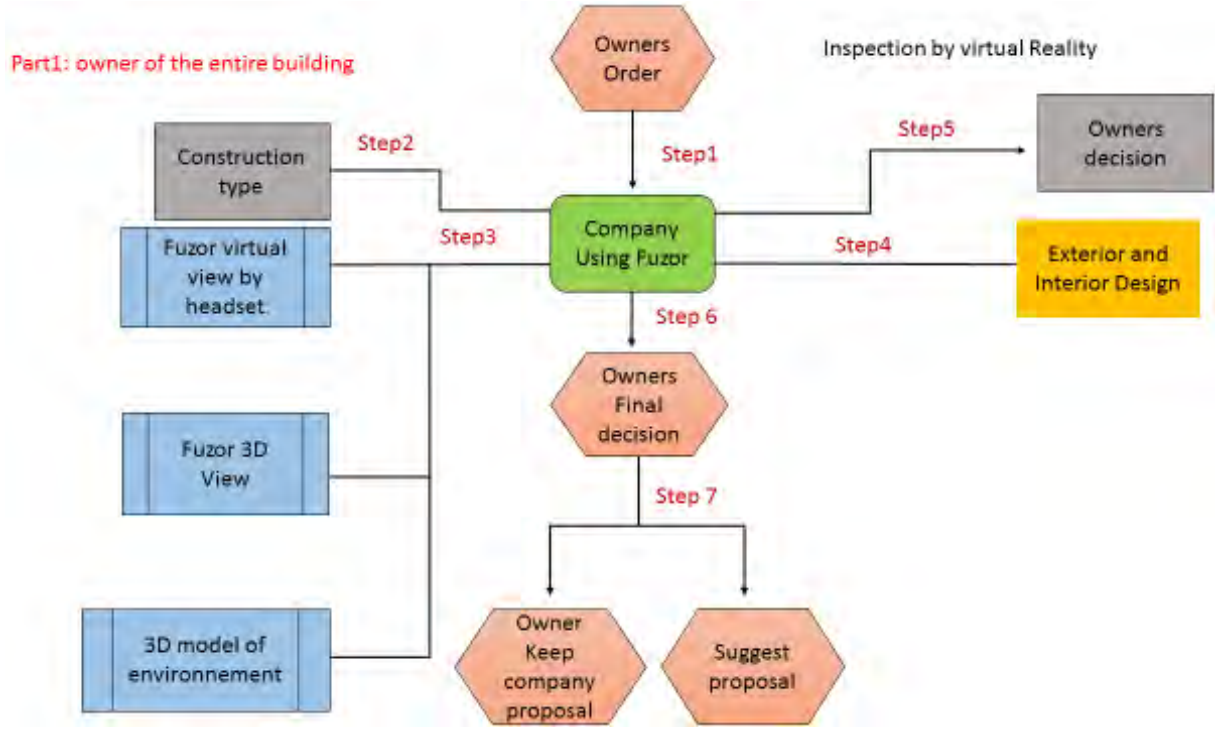

Figure 2.3. Inspection by Virtual Reality

Figure 2.4.3D photo model Augmented Reality1

Figure 2.5.3D photo model Augmented Reality2

For this fact the 3Dmax software will be used, initially the two files will be input in the software 3Dmax namely the format FBX coming from Bentley context capture and the format FBX of the construction coming from Fuzor. In the 3DMax software the 3D model of the construction will be positioned exactly in the space dedicated to the implementation of the project, this is illustrated in Figure 2.6 [5].

MR shows in Figure 2.6 technology allow real and virtual elements to interact with one another and the user to interact with virtual elements like owners viewing their construction in real world. How does MR work? There must be an MR device, either a headset or translucent glasses, in this VR BOX study was used to create the experience [6].

Figure 2.6. Mixed Reality

Using much more processing power than VR, Augmented Reality (AR) and AR technology connects the virtual and real worlds in a single connected experience like combining two visions into one using visual / gesture recognition technology / voice via headset or a pair of motion controllers. In this project, the mixed product was used to introduce the owner to the environment of his new construction. To allow him to understand the situation in which his future building will be presented. Since AR maintains a connection with the real world, it is not considered as a completely immersive experience [7]. In a MR environment, wherever user go and watch when he wear MR technology, the 3D content allow him to meet in space will react in the same way as in the real world under these conditions the owners are assured of see their construction in a real and precise event. In this example study, an object will approach the owner when it changes movement, the object will approach and interact with it [8].

Step 4 will be the subject of the design, i.e. the exterior and interior design. This will be about what types of materials to use.

Step 5 represents an output of the files used in the different software from the information received beforehand for the development of the project.

After submitting the details of the project to the owners, Step 6 will be the owner's decision. The decision of the owner will either keep the proposal of the company or give his own suggestions to change the design, Step 7 shows. If the owner decides to make changes this leads to called Change in Materials and Prices.

3. Change in materials and prices

3.1 The cost of the materials of the structure:

Construction materials are priced by weight or number that of structural steel is normally priced by weight, so it is important to have a clear idea of the structural sections that will be used and the meaning of the lettering of each section to establish an accurate estimate [9].

These structural sections are already chosen according to the construction model established beforehand by the company as shown in Figure 3.1.

Type	Diameter / mm	Pipe cost / $/m	Installation cost / $/m	Total cost / $/m
PVC-1075	75	6,47	12,53	19
PVC-10110	110	11,91	13,5	25,41
PVC-10140	140	18,32	14,34	32,66
PVC-10200	200	30,66	16,11	46,77
PVC-10315	315	60,2	19,74	79,94
PVC-10400	400	95,3	22,64	117,94
HDPE-1075	75	8,85	12,53	21,38
HDPE-10110	110	15,1	13,5	28,6
HDPE-10140	140	20,9	14,34	35,24
HDPE-10200	200	36,69	16,11	52,8
HDPE-10315	315	75,52	19,74	95,26
HDPE-10400	400	119,4	22,64	142,04
HDPE-101000	1000	771,13	57,73	828,86
STEEL75	76	46,74	12,56	59,3
STEEL110	110	53,11	13,27	66,38
STEEL160	160	77,12	14,69	91,81
STEEL200	200	96,51	16,2	112,71
STEEL315	315	139,36	19,84	159,2
STEEL400	400	177,18	23,37	200,55
STEEL1000	1000	405,47	58,71	464,18

Figure 3.1.MEP materials cost

3.2 The cost of the materials of the mechanical, electrical, and plumbing (MEP):

The construction obviously needs a mechanical part in its structuring, the mechanical parts are generally subcontracted to mechanical specialties, which prepare detailed quotes for the plumbing and heating, ventilation and air conditioning (HVAC) systems, this part plumbing promotes comfort in the management of the structure. To accurately estimate plumbing costs, construction contributor must therefore have field experience and a good knowledge of various plumbing systems, materials, labor and equipment, as well as " an understanding of the design and internal and external specifications of the structure. This simply transfers the

preparation of the detailed estimate to another party, but this does not eliminate the need to estimate and analyze the prices indicated by the engineers [11].

Figure 3.2, relates the finalization of the owner decision regarding the change of materials.

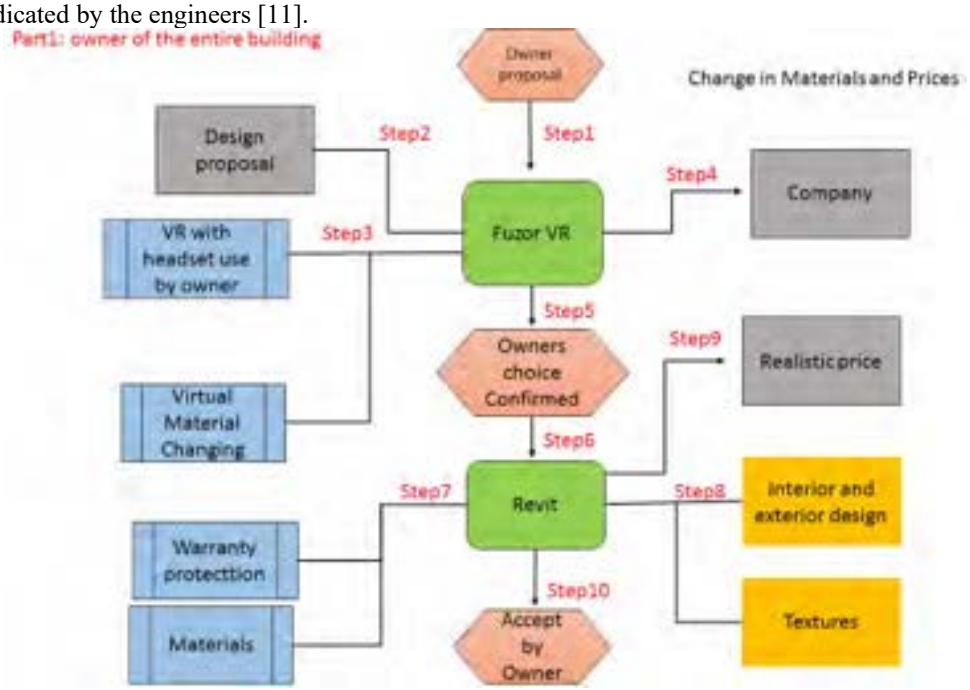

Figure 3.2. Change in Materials and prices

Step 1 explains the changes proposed by the owner. These different changes suggested by the owner will be recorded in project document at Step 2. Fuzor software by VR function will help the owner to make these changes while taking into account the material already submitted by the company.

Step 3 demonstrates the change in the model by the owner. This is done from the VR Box headset or directly on the Fuzor software, and from the already done synchronization above the materials that are changed or created directly translates to the main model of Revit, Figure 3.3 shows a synchronization view between Fuzor and Revit.

Figure 3.3. Synchronization between Fuzor and Revit

In this project the owner has had to change the design exterior first by modifying by itself the shape of the wall. For the modification, the owner prefers to insert a balcony at each floor, illustrate in Figure 3.4.

Figure 3.4. Design change

3.3 Interactive clash management:

The functioning of the interactive clash defines interference and proximity tolerances. To start it, it is necessary to select sections of the building, systems or types of objects to compare, then define the tolerance and execute the conflict check [13]. This procedure will allow Fuzor to list all the conflicts according to defined criteria and lists them in the conflict interface. By clicking on any conflict in the list, accessing this conflict results in highlighting the objects in conflict. After the different changes the clash management system (tolerances 0.83) of Fuzor was used to detect the

presence of indifference in the design. Figure 4.16. Shows that there is no clash problem after changing the facade of the wall by including several balconies, the same result is observed at the change of the exterior texture from yellow to blue. But after changing the size of the wall inside the level 2 chamber, a clash was detected. This was the subject of a bug fix on the Revit software. This error is mentioned in Figure 3.6 in red object [13].

Step 4 will contain data collection after the various modifications. This document contains the price, the size, and the colors of the different materials. This document will be used by the company later to fix the prices and the timeline of execution of the works.

At Step 5, the different changes are finished, and the owner is satisfied with the design of its construction. The company has confirmation from the owner about the texture, the choice of materials and the modeling of the construction.

In Step 6 the changes will be transferred to the Revit software for price validation, material verification and their warranty. This transfer between the two programs is already established by the plugin system in the previous steps.

Step 7 All materials used in the project are chosen according to their quality. These qualities are closely linked to their guarantee, the objective is to present an excellent project in the choice of materials and economically favorable.

In step 8 usually the owners are more focused on the appearance of their home, regarding the exterior and interior design, the texture. These different elements are crucial in the context to convince them. It is to this extent that very special importance was devoted to this part. The interior design can easily be modified if the need arises. The size of furniture, doors, windows etc.… can be altered. Partitions can be moved and rearranged. Making these changes in Revit is very simple and does not require much time either. It is possible to replicate and resize furniture without much effort.

For the realistic price in Step 9, the construction cost estimate is the process of forecasting the cost of construction of a physical structure that is established according to needs and modalities.

4. TimeLine management for presale house presentation

4.1 The setting of the timeline by the company

This diagram (Figure 4.1) presents a flexibility of work between the owner, the company and the different working associates. This is a method which gives the choice to all the participants of the project to freely express for a more balanced management of working time. This diagram is presented in several steps that will often require the desires of the owner.

Step 1: In the first step the company will be the source of manipulation of documents, software and agreements collected at stakeholder level for an adequate balance of the progress of the project.

Step 2, in this part the NWD format to collect at Revit level will import into Navisworks as the diagram specifies.

Step 3, the 3D model of the building space already produced will be used to show the evolution and timing of the building to the owner. This part is a mix of the model produced by Revit and the 3D model produced by Bentley contextcapture. This technique aims to present the owner in what environment will present his new construction. This will also prove the credibility of the planning that will be made later and show the conditions of the realization of the project. Then in the setting of the timeliner organization unit of Step 4 will be a major factor, which are the structure of the building and the MEP. In Step 5, project planning is a crucial element in the relationship between the owner and the company. In Step 6 it will be necessary to transfer to the owner online each step of execution of the project. This will enable him to follow in progress the different phases of the workings. This also aims at pushing the company to respect the deadlines.

In Step 7 after having shown the owner the time of execution of the work he can accept or propose another schedule that suits him. If the owner accepts the schedule of the company the work will take place as such. If the owner suggests another period for the planning this leads to the Timeline B Figure 4.1, which is timelines B.

Timeline B, explains in detail if the owner decides to give a new schedule of the final delivery of the project.

Step1, in this part the owner has decided to change the time of the construction for personal reasons. Consequently, the owner must provide its period of the end of the works. This calendar will be first examined by the company for its feasibility.

In the second Step, the company received the owner's claims, this information was input into the Navisworks software and later produced data.

In order to carry out Step 3 which changes the planning, Step 4 concerning the organization unit (labor, material, equipment, and subcontractor) will be crucial elements. First of all, the different elements that must be influenced by the change of the schedule must be defined.

4.2 A specific part of the building belonging to the owner

Alternative 2: A room or floor level owned by the owner

The inspection of the reality virtual is the same thing as that of the owner for all the building. The parameterize and the use of the files remains the same, in Figure 4.2.

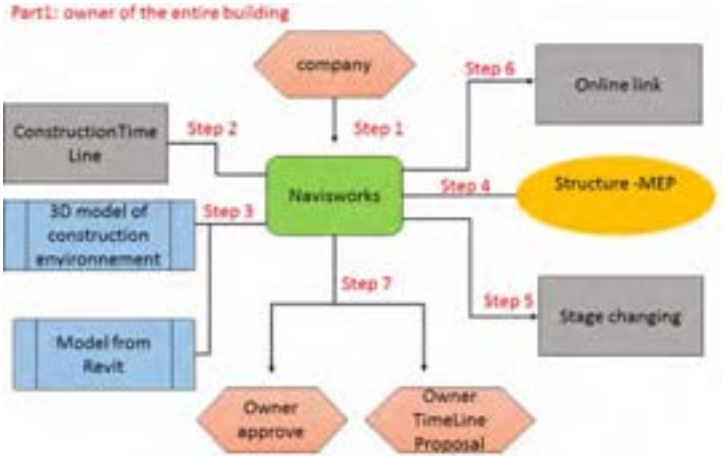

Figure 4.1. Timeline B

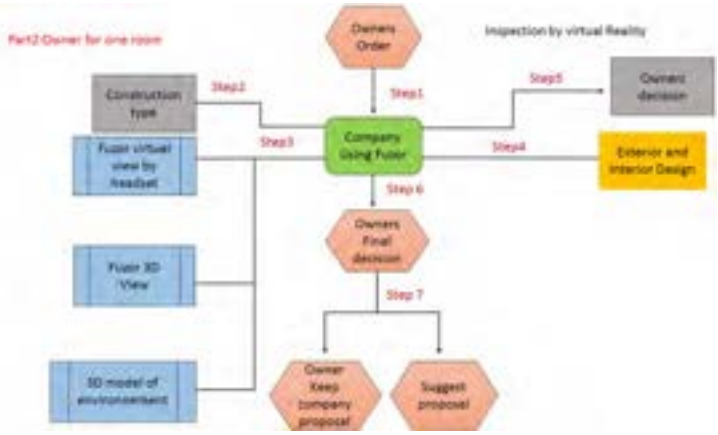

Figure 4.2. Inspection by Virtual Reality

The price and setting of the materials remains the same, except that the setting will not take into account the exterior design, in Figure 4.3. The timeliner of Navisworks will be the same, except that the owner will have no suggestion to make compared to the time of execution.

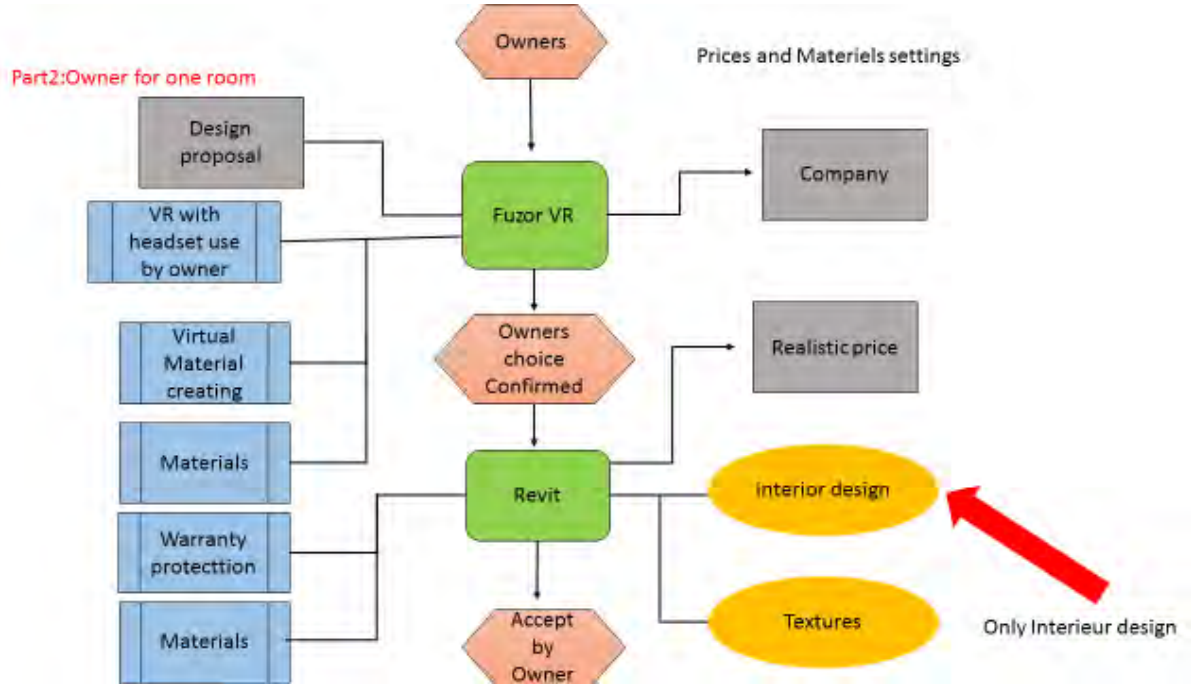

Figure 4.3. Prices and Materials settings

5. Discussion

After having given the owners of the project the choice of design, time and materials, the observation was made in relation to the price because the customer will always want what is comfortable and durable but do not want to invest the necessary money. So to facilitate partnership it was necessary to try to involve the catalogs of the materials. This catalog will be considered as a trust course between the different partners. It should also be emphasized that the use of VR for the presentation of the presale house is a very positive idea for future of owners. They note the perception of their future home and suggestions if possible. Regardless of budget, just about every

developer, realtor, architect, or interior designer can take advantage of VR and AR to showcase a project inside.

VR can show off a project at any stage, from pre-construction to proposed renovations and upgrades. VR with the synchronization system can be customized and quickly updated, complete with interactive components that allow prospective homeowners or builders to change finishes, fabrics, layout ideas, and more. Whether it is the structural part or the MEP, everything is detailed in the report to submit to the owner.

In the analysis of this study of EPC diagram, the observation is that whenever the time of construction has been changed by the owner the load of labor has increased considerably. This means that the company needs to be more lenient in partnering with the subcontractors for efficient execution and on time.

5.1 Conclusion

Traditional way presents many disagreements between costumers and company Owners can make change at the project to solve disagree and delay problems. This study has also allowed to identify some concerns of the owners in the future, about comfort and safety.

In this study the contribution was considerable compared to the previous researches on which the study is focused. The advantage is the technique and the software used allowed efficiency in the study, less time was used compared to the other researches. The major advantage is gaining trust among owners and investors.

5.2 Future work

Future research will be based on the difficulties encountered in the execution of these projects. In addition the new ideas will come from the suggestions given by the different partners for the good execution.

Create a function that allows the owner of a single room or a single level of construction to suggest the construction time.

Using the system of a mobile phone application, project participants can easily view, add a profile to the system and set permissions for what new employees are allowed to do, while following the roadmap of the project. Additionally, tools can be labeled with QR codes to ensure they are easy to find.

Developing a function to adjust parameters such as the number of workers, available equipment and construction materials can be done to show how these changes would affect the cost of the project with a connection of Navisworks and Revit to control the data and the time required for completion.

Virtual Prototyping-Based Path Planning of Unmanned Aerial Vehicles for Building Exterior Inspection

Z.J. Zheng[a], M. Pan[a] and W. Pan[a]

[a] Department of Civil Engineering, The University of Hong Kong, Hong Kong SAR, China
E-mail: zhengzj@connect.hku.hk, panmi@connect.hku.hk, wpan@hku.hk

Abstract –

Proper building maintenance is critical to ensuring the well-being of citizens and sustainable development of the urban environment. For high-rise high-density cities, one challenge to building maintenance concerns the inspection of building exteriors, which has been mostly done manually but is of highly risky, labor-intensive, and error-prone. Unmanned aerial vehicles (UAVs) have the potential to support building exterior inspection in a safe and efficient way. However, the effective application of UAVs for exterior inspection is hindered by path planning problems in high-rise high-density urban areas. Previously developed path planning algorithms are constrained by algorithmic complexity and cannot be implemented in a large three-dimensional space. Besides, path planning assisting tools available in the market that supported by Google Earth Pro can hardly assure high accurate results. In this paper, a new virtual prototyping-based path planning system is developed for UAVs for building exterior inspection in high-rise high-density urban areas. Unreal Engine as a widely-used game engine was applied. The system provides a realistic game world to simulate real-world activities, which enables operators to design UAV paths like playing games. The flight paths and viewpoints can be repeatedly tested in a gaming context until requirements are satisfied. The system integrates expert knowledge through "human in the loop" and realistic information on the virtual environment featured with repeatability. The system thereby greatly alleviates the risks that are induced by physical constraints in the real world when adopting UAV, and thus should significantly improve the effectiveness and efficiency of building exterior inspection.

Keywords –

Unmanned aerial vehicles (UAVs); Path planning; Building exterior inspection; Virtual prototyping; Human in the loop

1 Introduction

The importance of proper maintenance of buildings has been widely recognized to ensure that buildings are function effectively and efficiently for well-being of citizens and sustainable development of the urban environment [1]. For high-rise high-density cities like Hong Kong, one of the most challenging issues with maintenance is the inspection of building exteriors. Visual inspection by professionals is the most common method, but is highly risky, labor-intensive, and error-prone. Tools, such as telescopes and cameras, are applied to help inspectors. Still, they are limited in the distance and inefficiency until the commercialization of Unmanned Aerial Vehicles (UAVs).

UAVs refer to an aircraft that is operated with no pilot on board, also termed as drones or Unmanned Aerial Systems (UASs) [2]. UAVs have great potentials in the construction industry [3]. When paired with video recording and digital cameras, UAVs could provide professionals with an aerial perspective to overcome the inaccessible areas without compromising their safety. UAVs enable various types of surveying services for professionals [2]. Despite the well-demonstrated benefits in reduced labor, cost and risk, there are issues hindering the effective application of UAVs. A critical one is path planning, which is closely related to UAV performance and usually done by drone operators. Due to the flight time limitation, operators could make limited adjustments during operation. It is a sophisticated task to plan paths and viewpoints in a highly accurate manner to avoid collision and invalid data collection, which is even more difficult in high-rise high-density urban contexts like Hong Kong. Especially for tasks such as building exterior inspection (e.g. crack and loose object detection). Moreover, poor path planning could result in distorted images captured from inappropriate viewpoints that further induce false positives [7].

Previously developed path planning methods, such as Dijkstra algorithm [8], A* [9], and D* [10], focus on the optimization of path distance by considering physical constraints in mathematics. These methods well tackle

the distance and obstacle problems, but seldomly address the data effectiveness with the environment in high abstraction. In addition, path planning for UAVs requires the exploration of three-dimensional (3D) space. Many existing algorithms are constrained with its space complexity such as A*, since desktops cannot offer enough memory to store all generated nodes if it needs to explore a large space. Simulation-based methods are preferable to investigate the mechanisms behand path planning for UAVs cost-effectively. Particularly, virtual prototyping offers a favorable platform to animate the real world by using advanced game engines for optimization and visualization. By integrating expert knowledge and experience through "human in the loop" [11], virtual prototyping can be used to handle complex tasks in uncontrollable environments. Nevertheless, there is still lack of knowledge of how to effectively use virtual prototyping for UAV path planning.

Therefore, this paper aims to develop a new virtual prototyping-based path planning system for UAVs, within the context of building exterior inspection in high-rise high-density urban areas. Unreal Engine as a widely-used game engine was applied. Drone operators can simulate flight tasks such as playing games in the simulation system, e.g. controlling the virtual drone to fly in the game environment with virtual cameras providing real-time images and videos. The flight paths and viewpoints can, therefore, be repeatedly tested in a gaming context until requirements are satisfied.

2 Literature Review

2.1 UAV for Exterior Inspection

UAVs originated from the military in 1916 [12], which has not been popularized until UAVs commercialization companies grow up in recent years. Later on, commercial companies, like DJI, made the UAVs commercialized and accessible to the public by providing low-price UAVs that are easy to operate. Owing to the aerial perspective that enables a broad variety of surveying services, UAV has gained considerable interest in the construction industry. One of the important applications is the exterior inspection of buildings. Caballero et al [3] developed a vision-based method to estimate the real motion of an UAV and applied it to the external building inspection. Emelianov [4] inspected the building facades by aerial laser using an UAV for difficult site conditions. Ellenberg [5] detected masonry cracks with visual images captured by an UAV. These applications promote the productivity of building inspection works and greatly reduce the risk of relevant workers. However, there are still some issues that need to be tackled, such as path planning and data effectiveness. Most commercial UAVs have a minimal capacity on flight time, which is usually less than 30 minutes. Path planning is, therefore, critical to not only avoid obstacles but also reduce unnecessary adjustments when operating UAVs [2]. Otherwise, the UAV operator has to abort the task frequently to change batteries, which no doubly decreases the productivity of inspection works.

2.2 Path Planning Methods for UAV

Considerable research has been conducted on the topic of path planning. Many reported methods for path planning are based on mathematics like Dijkstra's algorithm [8], A* [9], D* [10], rapidly-exploring random tree (RRT) [14], bath informed trees (BIT*) [15]. These algorithms can be used to address obstacles and distance problems, which have been successfully applied in game development and robotics for path planning. However, for tasks in building exterior inspection, an essential consideration is imaging effects that are greatly influenced by viewpoints, view angles, and light [2]. Previous path planning algorithms cannot take such constraints into account.

Therefore, in UAV applications in the construction industry for surveying and inspection, path planning tasks are usually conducted manually, which is highly related to operators' experiences. In addition, some operators use the waypoint method assisted by Google Earth Pro, which however has the accuracy issues [16]. The reported root mean square error (RMSE) of its control point is around 24.1m in developed countries and 44.4m in developing countries [16]. Other path planning tools on the market that are developed based on Google Earth Pro service have similar accuracy limitations. For high-rise high-density cities like Hong Kong, accuracy is a critical aspect when adopting UAVs to avoid accidents and improve data effectiveness. There is an urgent need for a user-friendly and accurate path planning tool that can help operators to effectively and efficiently design UAV paths for missions.

2.3 Virtual Prototyping in the Construction Industry

Virtual prototyping refers to the process of constructing and testing a digital mock-up to present, analyze, and test life-cycle aspects [17]. The development of building information modeling (BIM) promotes the application of virtual prototyping in the construction industry, which has been widely reported to increase productivity in design [18], manufacturing [19], construction [20] and maintenance stages [21]. Recently, virtual reality (VR) and augmented reality (AR) supported by powerful game engines are gaining increasing interest in both practice and research in the construction industry. For example, Du et al. [22] developed a real-time synchronization method between

BIM data and VR environment for collaborative decision. Cao et al. [23] adopted VR to study indoor fire evacuation and found out that people under the file emergency condition spent more time in finding their way to exit the building that those under control condition. Shi et al. [24] applied VR for impact assessment of construction workers' fall risk behavior, which demonstrates the effectiveness of using VR in safety studies. Webster et al. [25] developed an AR system for the construction, inspection, and renovation of architectural structures, which improved the construction of performances. Wang et al. [26] integrated AR with BIM to control the onsite construction progress, which demonstrated how AR and BIM can improve the way the information is accessed. With the development of game engines, virtual prototyping has demonstrated its greater potentials for the construction industry.

3 System Architecture

The overall system architecture by using a game engine for UAV path planning for building exterior inspection is proposed in Figure 1, including building environment model structure, game engine structure, device structure and professional structure. In building environment model structure, professional software provides 3D building and environment models, such as 3ds Max, Revit, Rhino 3D, etc. Game engine is the core of the system architecture that consists of a game world and three plugins: a UAV simulator, a model converter, and a path generator. Device structure consists of a remote controller and an UAV. In the human structure, relevant professionals (operators) could assess paths and viewpoints according to their expert knowledge.

The proposed system functions with three stages. Firstly, building environment models will be imported to the game engine by the model converter plugin, which provide the main contents of the game world. Secondly, remote controller will be linked to the game engine by the UAV simulator plugin. The remote controller enables professionals to control a virtual UAV in the game world to simulate the inspection task. The flight paths and viewpoints are repeatedly tested until all requirements are satisfied. Finally, the path generator plugin will generate a path planning file that can be directly used in a real UAV for automated operation.

4 System Development

To develop the system based on the proposed architecture shown in Figure 1, this research is based on the Unreal Engine as it is open source and one of the most popular game engines. The following sub-sections describe the design and development of three major components in the game engine, namely a UAV simulator, a model converter, and a path generator.

4.1 UAV Simulator

UAV simulators are usually designed for testing, operational training and research because of its cost-effectiveness and safety assurance. There are more than 20 types of UAV simulators reported in history [27]. By considering its openness, functions and stability, this research adopted the Microsoft AirSim UAV simulator built on Unreal Engine, shown in Figure 2 [28]. AirSim provides a broad variety of sensor simulations including camera, infrared camera, distance sensor, barometer and so on, which together with Unreal Engine could develop a realistic game world as shown in Figure 3. These sensors can greatly help the operators to make sophisticated mission planning tasks e.g. UAV path planning for building inspection in a cost-effective, safe and robust manner.

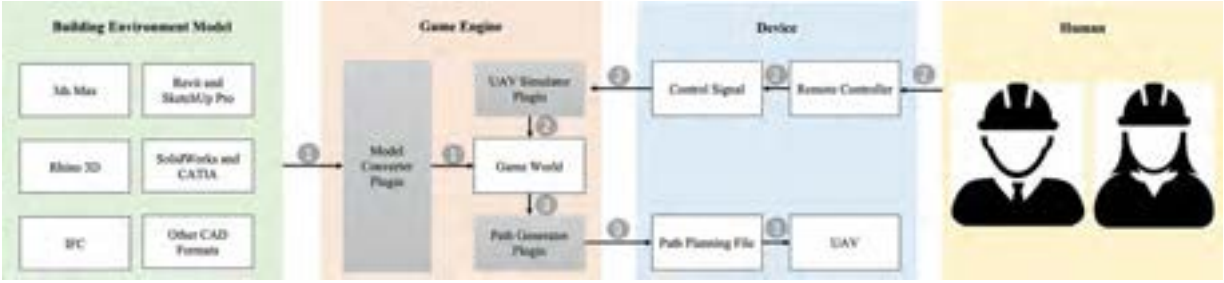

Figure 1. System architecture of the Virtual Prototyping-Based Path Planning for UAV

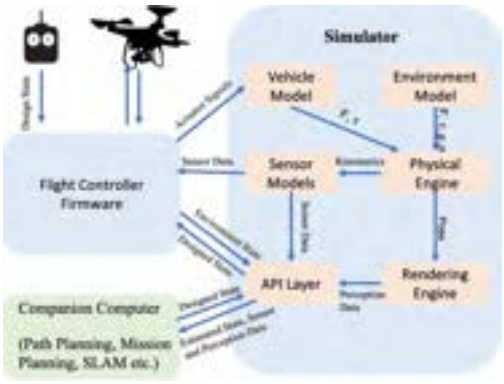

Figure 2. AirSim simulator architecture (reproduced from [28])

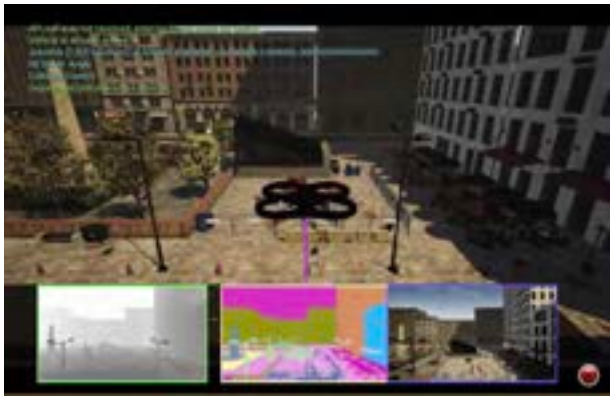

Figure 3. Game world in Unreal Engine

4.2 Model Converter

The model converter enables users to import building and environment models from other professional software. The model converter in the developed system is based on the DataSmith module in Unreal Engine, which supports model importation from a broad variety of professional software (e.g. 3ds Max, Revit and Rhino 3D) [29]. The model converter makes it convenient to build a game world in Unreal Engine based on building and environment models that are commonly available from the design stage of a construction project.

4.3 Path Generator

The path generator plugin records the UAV waypoints, view angles, actions (e.g. take an image or video) and speeds in the game world when professionals are testing paths and viewpoints. After the playing process, the path generator will output a path planning file that can be used in a real UAV, shown in Figure 4. In this research, DJI Matrice 210 V2 RTK (Figure 5) was used, and the path file is generated according to the requirements of DJI products. For example, the North East Down (NED) Coordinate System is applied in the developed path planning system, while geodetic datum is required as input coordinates by DJI products. Thus, the axes conversion [30] is needed during the path file generation, as shown in Figure 4. When the developed system is used for other types of UAVs, the path generator can be easily extended to generate a new path file according to specific requirements by other types of UAVs.

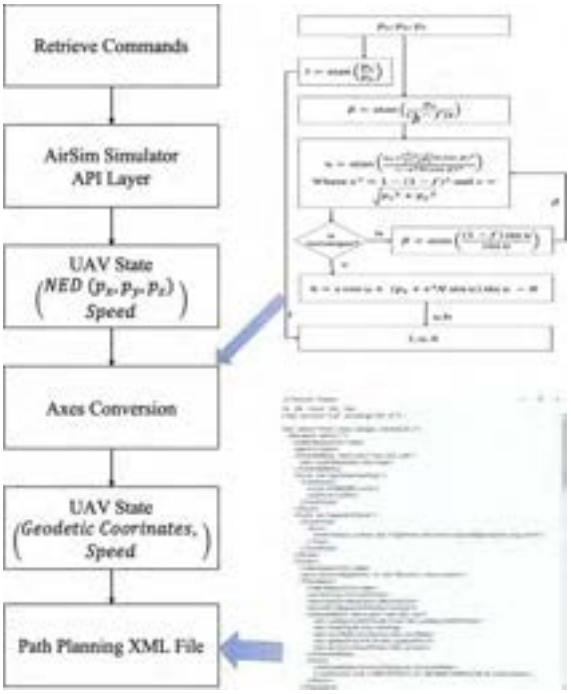

Figure 4. Procedure of path recording and file generation

Figure 5. DJI Matrice 210 V2 RTK used for the study

5 System Demonstration

In this section, demonstration of the developed virtual prototyping-based UAV path planning system was conducted for building exterior inspection, including viewpoint selection and path generation. To illustrate the effectiveness of the developed system, results from virtual prototyping-based method are analyzed and compared with results from using A* method [31] that is the most widely used algorithm for path planning [32].

5.1 Viewpoint Selection

To ensure a virtual camera in the game world can function like a physical camera in the real world, specifications of the virtual camera should be set up like the physical ones, e.g. field of view (FOV), aspect ratio, lens, etc. After that, the virtual camera can be used to test the locations and view angles of viewpoints (Figure 6). When the inspection area is larger than the FOV, more than one viewpoint should be used to cover the whole area, and overlaps could be tested at the same time.

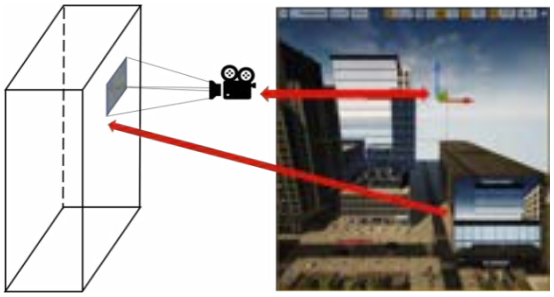

Figure 6. Viewpoint selection

5.2 Path Generation

As the space and the number of viewpoints increases, the challenge of adopting A* method will dramatically increase due to the algorithm complexity [31]. On the contrary, the virtual prototyping-based method is nearly not constrained in such cases. To avoid the problem of out of memory when adopting A* method, the comparative analysis is conducted with a single-viewpoint case. Results are shown in Figure 7, Figure 8 and Table 1.

Figure 7. Path generated by the developed system (shown by green line)

Figure 8. Path generated by A* (shown by red line)

Table 1. Geometry Comparison

Method	A*	Proposed Method
Start Point	(0, 0, 0)	(0, 0, 0)
Middle Points	(-0.9, 0.1, -5.0)	(0, 0, -48.8)
	(1.6, 2.6, -12.5)	(39.6, 0, -48.8)
	(6.6, -2.4, -27.5)	-
	(26.6, -2.4, -27.5)	-
	(41.6, -7.4, 32.5)	-
Viewpoint	(39.6, -22.3, -48.8)	(39.6, -22.3, -48.8)
Distance	88.7	110.7

Notes: local north, east, down (NED) coordinates and international system of units (IS)

In general, the path generated by the proposed visual prototyping-based method (Figure 7) has less twists and turns compared with the path generated by A* method (Figure 8). When implementing A*, the exploration space is discretized into 3D grids. By searching the whole 3D grids, A* method can usually find a shorter path (shown in Table 1) with more twists and turns by linking nodes in the 3D grids, compared with the proposed visual prototyping-based method. If the twists and turns are extremely irregular, UAVs cannot flight as the designed path due to motion constraints [33]. Besides, the path generated by the proposed method (Figure 8) crossed less dangerous areas (e.g. roads) compared with A* method

(Figure 7). The developed system provides a realistic game world for relevant professionals to design a path for UAVs in building exterior inspection like playing games. By implementing "human in the loop", the developed system can easily take more constraints into consideration by integrating expert knowledge and experience.

6 Discussion

Manual visual-based building exterior inspection is usually labor-intensive, time-consuming, error-prone and highly risky. As the low-price commercial UAVs are popularized, professionals start to use UAVs for building exterior inspection works, which brings in benefits including enhanced safety and efficiency. However, in high-rise high-density cities like Hong Kong, the complex flight environments require a more accurate path planning method that can help professionals to design path for their inspection task to avoid accidents (e.g. collision). Previously developed path planning methods like A* [9] well tackle the distance problem but cause too many twists and turns on a path. In addition, these mathematically based path planning methods like A* have a bottleneck on algorithmic complexity when they need to be applied in a large 3D space. The required computing time is too long, or the required memory space is too large [31]. Also, these algorithms seldomly considered the data effectiveness (e.g. image distortion and light effect). Therefore, these path planning algorithms are seldom adopted for inspection tasks in the construction industry.

Virtual prototyping enabled by game engines offers a realistic game word to simulate detailed activities in the real world. The virtual prototyping-based path planning method developed in this paper enables professionals to design UAV paths for their inspection tasks like playing games. The new method not only overcomes the bottleneck of algorithmic complexity of previous algorithms [31], but also takes into consideration more constraints (e.g. dangerous area, images distortion and light effect) by taking the advantage of expert knowledge through "human in the loop". Compared with path planning tools that are supported by Google Earth Pro, the developed system has a higher level of accuracy because the game world is constructed using accurate BIM models.

The developed path planning system involves game engine, UAV and professionals, which can be extended for more general applications in the construction industry. First, game engine can be used for mission planning for robotics. As the development of automation and control technology, adopting robotics has great potentials to improve the productivity in the construction industry [34][35] Robots can be trained, tested and assigned tasks by a game engine. Second, a cyber-physical system for construction management or even smart city management can be built by synchronization between the real and game worlds. Third, human can also be linked to the game world to maximize the power of human/hardware-in-the-loop (HHITL) [36]. For example, a professional can use remote controller to control a robot to conduct a task in a game environment for once, then the robot can learn how to conduct the task in the real world by itself through imitation learning [37].

7 Conclusions

Building exterior inspection using UAVs is widely recognized around the world in recent years, because of a broad variety of benefits including low cost, high safety and efficiency. However, there has been no user-friendly tool that can help professionals with path planning in an accurate and efficient manner. In this paper, a new virtual prototyping-based path planning system is developed for UAVs. It helps professionals to design an accurate path for inspection tasks efficiently. The new method will not only overcome the algorithm complexity problem that exists in many previously developed path planning algorithms, but also provide a higher level of accuracy than the path planning assisting tools available in the market do.

The developed path planning system can be easily extended for other mission planning tasks for robotics in the construction industry. Furthermore, it can also be developed into a cyber-physical system for construction management or even smart city management. These extensions will be explored in future research.

Abstract –

Construction progress monitoring and visualization have recently undergone advanced development. However, the data exchange process between construction offices and jobsites still lacks automation and real-time data records. Furthermore, an information gap between construction offices and jobsite activity persists, and progress inspectors still need to visit jobsites to check progress and assign quality ratings. Therefore, this research proposes a near real-time construction progress monitoring system called (iVR), which integrates 3D scanning, extended reality, and visual programming to visualize interactive onsite inspection and provide numeric data. The iVR system contains four modules: 1) recording jobsite activity through 3D scan (iVR-scan); 2) processing and converting 3D scan data into a 3D model (iVR-preparation); 3) immersive virtual reality inspection in the construction office (iVR-inspect); and 4) visualizing inspection feedback on the construction jobsite using augmented reality (iVR-feedback). In other words, 3D laser scanners first capture an activity point cloud and the iVR-preparation algorithm processes and converts the point cloud into a 3D model that is sent to the construction office's BIM cloud. Then, the proposed VR mode in iVR-inspect enables a quality assurance inspector to trace workflow, compare current project progress with blueprints, measure objects, and add text or design notes to 3D models to improve the site management and decision-making quality. Finally, iVR-feedback sends inspection reports to jobsite workers, who can visualize them in an augmented reality mode integrated with graphical algorithms. An experimental laboratory trial is presented in this paper to validate the concept; the iVR system for progress monitoring successfully generated the required results. The proposed system has the potential to help progress inspectors and workers complete quality and progress assessments and decision making through the development of a productive and practical communication platform. It compares favourably to conventional manual monitoring or data capturing, processing, and storing methods, which have storage, compatibility, and time-efficiency issues. Moreover, iVR minimizes physical interactions between workers and QA inspectors, thus creating healthier construction jobsites that are characterized by minimal human interaction. Finally, the same approach can be applied to more complex construction activities with movable natures.

Kinect Camera; Augmented Reality; Virtual Reality; Building Information Modeling; Progress Monitoring

1 Introduction

Building Information Modelling (BIM) technology, a recent trend in the construction industry, is an exciting solution for achieving automation in construction project progress monitoring. BIM is a rich source of 3D geometry-related information, such as architecture, structure, and MEP; furthermore, it enables knowledge sharing and interoperability over a building's lifecycle [1–3].

Engineers at a construction site find it challenging to manage a complicated BIM model and recognize the necessary attributes in the model [4,5]. Since BIM models are stored on servers or separate computers, they are often not updated synchronously on the jobsite. In other words, the transfer of knowledge from the design office to the engineering office on the construction site is significantly delayed [6]. This delay is crucial in certain projects, such as rapidly tracked projects, where planning and construction occur simultaneously. Slower data exchange results in project slowdown or rework [7]. This implies a need for real-time data exchange between building and planning offices [8]. Therefore, designing a near real-time system for tracking construction projects and closing the distance between jobsite operation and construction offices is necessary.

The aim of this study is to evaluate the degree to

which virtual reality systems can be integrated into and affect state-of-the-art construction progress monitoring workflows. This research demonstrates the degree to which mixed reality equipment and 3D laser scanning embedded in visual programming can solve these problems; furthermore, it assesses the effectiveness of the proposed device and framework. We aim to reduce the distance between the jobsite and the construction office, and establish a framework that can provide near real-time progress tracking and data quality control between the construction office and jobsite activities. Therefore, we developed a near real-time progress monitoring system called iVR that consists of four modules: 1) the iVR-scan module monitors jobsite activity using a Kinect scanner, 2) the iVR-prepare module converts captured point cloud data into a 3D model and sends it to the construction office, 3) the iVR-inspect module utilizes virtual reality to help inspectors check activity quality and write review comments, and 4) the iVR-feedback module utilizes augmented reality to visualize inspectors' review reports on jobsites. The iVR system underwent laboratory testing and produced successful results. This system can aid quality inspectors monitor jobsites from construction offices in near real-time, eliminating the need to visit jobsites. Thus, inspectors can monitor multiple activities over a shorter period compared to conventional quality inspection methods. Furthermore, iVR can contribute to a healthier construction environment by reducing human interaction between construction jobsite workers and quality inspectors in the office.

2 Literature Review

Point cloud has been used in different phases of the construction industry for planning and design; production and development; operation and maintenance; etc. [2]. During the planning and design process, point cloud helps in the reconstruction of 3D site models and existing buildings [2,4]. Suitable data acquisition process and devices for construction work include 3D laser scanning, photogrammetry, videogrammetry, and RGB-D and stereo cameras [3].

The Kinect 3D scanner uses the same technology that a mid-range 3D scanner, projector, or infrared camera might use to measure the depth of, and around, an object [9]. The two cameras of the Kinect enable it to scan almost every item in 3D with good precision. The Kinect cameras have been used in the detection and evaluation of construction sites, product identification, materials and labor [2,10], safety monitoring [11] and reconstruction [8]. Many simultaneous localization and mapping (SLAM) programs have used sparse maps to identify and concentrate on real-time monitoring [7]. Other approaches have been used for point-based reconstruction [5]. Kinect cameras reconstruct surfaces more reliably, based on real-world geometry; thus, they exceed point-based representations [7,8].

Immersive modeling increases the understanding of complex construction processes and facilitates the assessment of project situations at reduced costs and interference levels [12,13]. Furthermore, it enables synchronous cooperation between different stakeholders in planning and design [14,15]. The use of virtual reality during the design process has yielded significant improvements in design, which increase workers' safety during construction [16,17].

Laser scanning data are commonly used for dimensional and surface quality assurance in several civil applications and project quality management [18–20]. We propose a precise and effective laser scanning-based technique to reduce the distance between office and construction worksites by combining Kinect 3D scanning and extended reality for a near real-time dimensional and surface quality control approach.

3 Methodology

The research methodology's design and selection were divided into three steps. First, we analysed the current best practice in construction jobsite progress monitoring and selected the best technologies to achieve its objectives. Second, we developed a progress monitoring system called iVR. Finally, we validated the system with a laboratory test and analysed the results for development (Figure 1).

This research proposes a progress monitoring system, iVR, using extended reality and laser scanning. The proposed system consists of four modules: site model capture using 3D laser scanners (iVR-scan); conversion of point cloud into 3D mesh (iVR-preparation); Quality Assurance (QA) inspection and feedback report generation using VR (iVR-inspection); and visualizing inspection feedback on the jobsite using AR (iVR-feedback) (Figure 2).

Figure 1. Research methodology design and selection

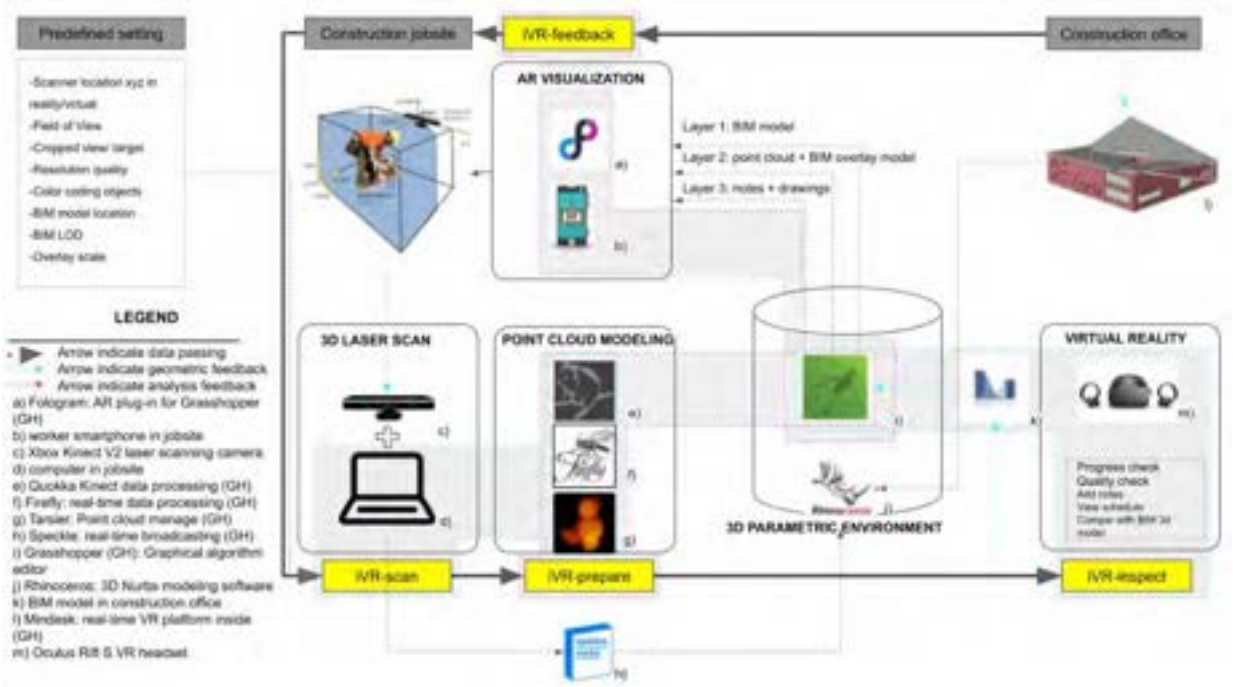

Figure 2. iVR system architecture connection loop between construction jobsite and construction office

3.1 iVR-scan

In this module, a laser scanner installed on the jobsite tracks an operation and sends live scanning data to the building office. This module focuses on the location, path, type of laser scanner, software, and hardware needed to complete this process.

This research used the Kinect V2 [21] [21], offering live scanning, as a 3D laser scanner. (Lidar + photogrammetry = Kinect 3D scan) represents the combination of cameras and sensors for target observation and distance recognition, thus building this research's concept.

The Kinect 3D scanner uses the same technology that is used by a mid-range 3D scanner, camera, or infrared camera to calculate the depth field of, and around, an object. The two "cameras" of the Kinect enable accurate 3D scanning of almost all items.

The scanning process for the target item is as follows: 1) Assign a position for the laser scanner in the BIM area, using the everyday operation optimizer iVR-scan position tool; 2) Set up the laser scanner and direct it toward target objects on the construction site; 3) Connect Kinect V2 to the Grasshopper PC Graphical Algorithm Editor [22,23] in the commercially developed software Rhinoceros [24]. Three point cloud libraries (Quokka [25], Tarsier [26], and Firefly [27]) in Grasshopper manage point cloud data and convert them into point, color, and GPS coordination in order to process the model in real time. Then, the Speckle cloud [28] sends cloud point data from the jobsite to the Grasshopper Rhinoceros in the development office, which gets synchronized and updated per time cycle.

3.2 iVR-preparation

The built algorithm in iVR-preparation processes these data in the construction office as follows, before the inspector gets access to the point cloud data collected from the jobsite: Step 1) Using the Speckle data receiver to receive point cloud data from job PC; Step 2) Building a visual algorithm that coordinates and compares point cloud colours, points, and GPS with the BIM model; Step 3) iVR-crop the selected item from the scanned scene, utilizing colour coding to minimize computational data and the time spent on further measures; Step 4) iVR-preparation uses Alpha shape matching cube mathematical logic [29] and a ball pivoting algorithm [30,31] to convert the point cloud into a 3D mesh object; Step 5) To reduce computational data and time spent, iVR-preparation uses a bounding box to include the produced 3D mesh; Step 6) iVR-preparation contrasts the cloud bounding point box with the BIM model and analyzes the operation's progress.

3.3 iVR-inspect

In this module, 3D mesh is aligned with the BIM model that was developed in iVR-preparation. A progress tracking investigator attaches the virtual reality (VR)

headset to the Rhinoceros area and starts reviewing progress details obtained from the jobsite in VR technology. In general, the iVR-inspection module process is as follows: 1) Aligning the 3D mesh with the BIM model that was developed in iVR-preparation; 2) Linking the VR headset to the virtual reality and set layout design, size, and colors; 3) The controller monitors progress checks, building accuracy, and quality checks; 4) The progress monitoring inspector composes notes, highlights items, and draws illustration types as input; 5) Sending a fresh dataset kit back to the jobsite.

The reason we chose the VR inspection method rather than conventional site visits or BIM versus point cloud screen checking is to give the progress monitoring inspector the capability and power of immersive reality, thereby increasing inspection rate, speed, and accuracy.

Finally, after the progress monitoring inspector completes the progress and quality checks, draws illustrations, and writes comments, iVR-inspection sends multilayer data, including the BIM model, overlay model, comments, drawings, and an accomplishment report to iVR-feedback.

3.4 iVR-inspect

In this module, iVR-feedback uses the Fologram library [32] in Grasshopper Rhinoceros to simulate the inspector's files on the jobsite by utilizing extended reality. The iVR-feedback workflow consists of: 1) A worker's phone is registered with the Fologram tool in the construction office to receive live data; 2) The progress monitoring inspector sends BIM models, comments and sketches, output reviews, and overlay models to a mobile phone on the jobsite via Fologram; 3) A jobsite worker visualizes all the data received via mobile phone in extended reality. Using the parametric models representing the architecture, an immersive holographic instruction set is generated. Fologram synchronizes the geometry created on virtual reality devices through a local Wi-Fi network in a Rhinoceros or Grasshopper file. If a consumer makes improvements to a pattern in Rhinoceros or Grasshopper, those changes will be observed and forwarded to all related extended reality apps, thus allowing users to display digital models in a physical environment and on-scale, while making changes to these models using common, powerful CAD software devices. This tool inspector can also monitor whether a worker uses Fologram to correctly view comments using data from a jobsite; this is a very important benefit of iVR-feedback.

4 Case Study

A laboratory test was designed to simulate a specific activity's quality inspection between the jobsite and the construction office in order to validate the proposed iVR system. All four phases of iVR were introduced in this case study, and the time spent on each phase as well as their accuracy and practicality were reported to facilitate further device growth. The target activity in this research comprised six boxes (20 x 30 x 20 cm) laid in two columns with three boxes on each side of the construction. The target activity was designed in a BIM environment; Styrofoam boxes were used to represent the jobsite (Figure 3) in the laboratory.

The construction site working environment is constantly changing and therefore it is challenging to maintain a constant network between different devices. In the case study one operator runs the iVR-scan that consists of a Kinect V2 camera connected to iVR platform on a portable computer. The computer specifications used in the case study are: (processor: intel core i7 cpu, installed ram 32 gb, graphic card: nvidia GeForce gtx 1060 3gb) which registered 3d point cloud data from target activity in the jobsite. Next, the iVR-prepare cropped the point cloud scene and converted the targeted object into 3D mesh and sent it to the Construction office using Speckle doc cloud synchronizer between two iVR platforms using Wi-Fi internet. After that, the iVR-inspect used VR technology to check quality, insert notes, check progress rate and draw comments and send it to iVR-feedback. In the case study, a smart phone with 4G Wi-Fi was used in iVR-feedback to receive data from the construction office and visualize them in the jobsite. It is essential that both construction offices and iVR-scan are connected to the same wifi host. Finally the worker successfully visualized the inspector report in using AR technology as illustrated in Figure 3.

It takes about 17 minutes to finish one loop of iVR data exchange. It took 23 minutes for the inspector to comment using VR in iVR-inspect and for the worker to provide feedback visualization in iVR-feedback. In total, the laboratory test took about 40 minutes.

First, the laboratory research for the case study began by targeting one pile of boxes for 3D laser scanning, collecting 3D geometry vertices, and documenting the point cloud using Kinect V2 (seconds time). The Qualla library was used to control point cloud resolution to manage the processing and time required for computational data. Next, a cropping box was created containing only selected items (in our case, concrete columns) for the next stage in order to minimize processing time and remove the unwanted items that were scanned from the point cloud, as seen in the iVR-scan module section of Figure 3.

Next, iVR-preparedness monitors point clouds at any interval and updates current point clouds as a loop. In this case study, the interval for updating was set at 17 minutes. As described in the methodology, iVR-preparation used ball pivot algorithms to convert concrete column point

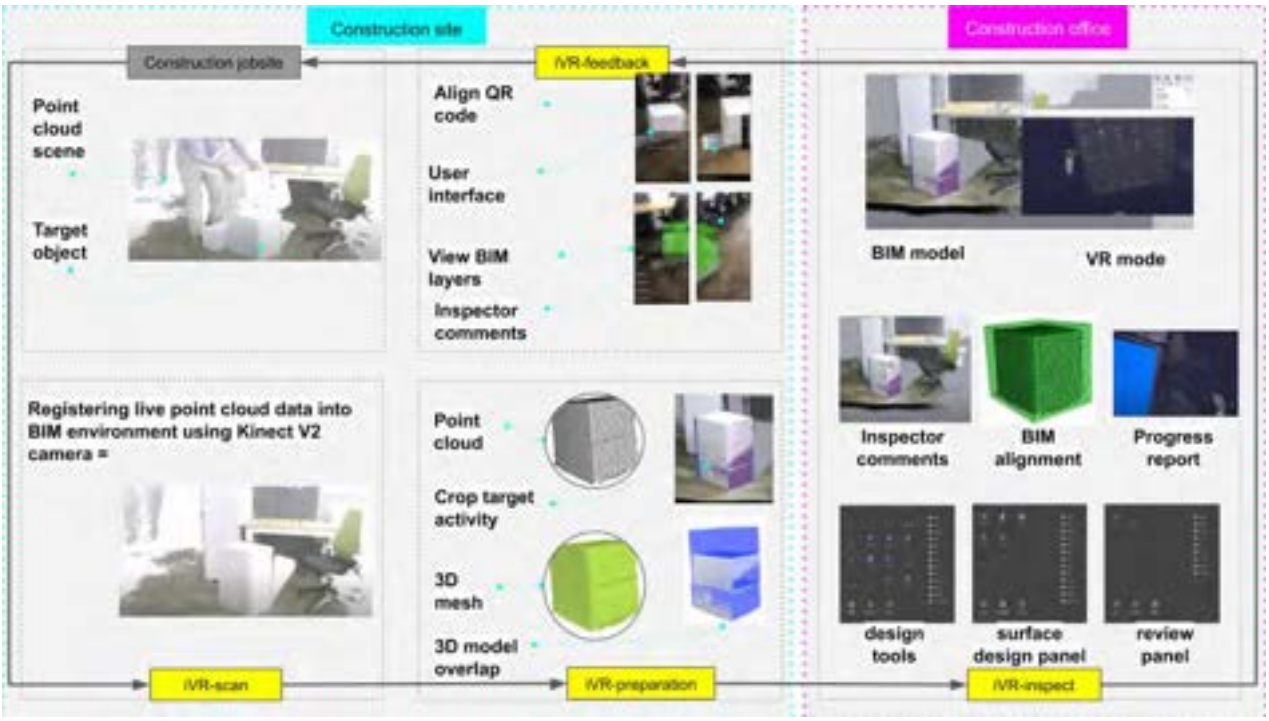

Figure 3. Case study lad test of column monitoring and quality check in near real-time using iVR system

clouds into 3D mesh. Using the Speckle cloud 3D model synchronizing device and overlaying it with the BIM model in the Grasshopper Rhinoceros program as seen in Figure 3, the iVR-preparation module was sent to the development office after the 3D mesh and the point cloud.

After that, progress monitoring inspectors receive point cloud and 3D mesh data in the building office using Grasshopper Rhinoceros and the Speckle data receiver tool. This research used Oculus Rift S [33] [32] to test iVR-inspection. The progress monitoring inspector simulated the 3D model in virtual reality, taking measurements, writing notes, checking development and consistency, taking snapshots of the required information, and producing development reports, as shown in the iVR-inspection module section of Figure 3.

Finally, the iVR-feedback algorithm sends inspectors' progress reports back to the worksite using Fologram's augmented reality platform in Grasshopper Rhinoceros. Workers on the site get progress sheet reports that include

BIM models, feedback, sketches, and accomplishment pace, and overlay models. Notice that external details can often be added to progress reports, including job venue, mission independency, timetable, and building methods. In construction offices, workers' phones and receiver Fologram devices should be connected to the same Wi-Fi network for AR operation. In this case study, iVR-feedback effectively visualized input details on the construction site, allowing workers to check observations from the progress inspector in the overlay model and follow up on the relevant revised information requested by the progress inspector, as seen in the iVR-feedback section of Figure 3.

5 Discussion

The adopted case study to track the concrete columns' progress showed that the new program can accommodate more complex and robust worksite construction. The iVR program successfully captured tracking data, analysed it, produced a progress inspector's report, and returned it to the construction worksite for input. Through iVR-inspect, auditors can harness the power of augmented reality to observe concrete columns from different angles and take samples that are out of the scope of conventional methods. This research argues that using iVR at the progress monitoring stage could improve decision making and result in a better product in a shorter time span and with the lesser human resources. The study also argues that this approach reduces humans' physical contact, which helps maintain social distancing measures to reduce the spread of infectious diseases, such as the COVID-19 pandemic [95]. The innovative methods, algorithms, and technologies developed in this research distinguish it from past research. Hence, this study makes several significant contributions.

First, the 3D laser scanner is directly connected to the

BIM environment in this research. A medium platform is not required, whereas other frameworks developed by researchers need a medium platform to convert scanned data into point cloud or massing geometry.

Second, the iVR system eliminates file format compatibility issues as every hardware and software is connected directly to the Grasshopper Rhinoceros' visual program. Many progress tracking models, on the other hand, involve various scanning tools in a range of formats (xyz, ply, pts, e57, las, and laz) and BIM-type formats (3dm, dwg, obj, ifc, rvt, and nwd); these variations in file format pose consistency concerns and can also trigger data fragmentation or failure due to the need for specific versions or data processing.

Third, data storage in the BIM environment is managed and controlled in iVR. To import or export information, Kinect apps, the VR headset, and Fologram are connected to the BIM environment, which make them extremely light and easy to work with. However, other state-of-the-art data management tracking exists in the scanning business' cloud or on handheld devices, which is inefficient because the customer has to link the processed point cloud data with another data cloud or other BIM applications to track the operation's progress.

In the case study, the accuracy of registered data in the iVR-scan was +- 3 mm compared to the actual measurements. The laser scanned data accuracy depends on various factors including: distance between target object and laser scanner, colour, scale, rotation of the target object, and the lamination of the room. The backside of the target object is not registered by the laser scanner therefore the 3d model of target object misses the backside which is one of the limitations of fixed laser scanners in the jobsite. The point cloud registered in the iVR-scan can is colour coded also which can help iVR-inspect differentiate different objects using associated colour code. The scale factor remained fixed to 1 to 1 throughout the iVR loop to maintain accuracy and data management. There was no data loose during the iVR loop except when iVR-prepare crop the scene point cloud and detach target object from the rest of the point cloud to reduce computation time. The system needs to be tested on a variety of construction activities with different object scales and colour to compare accuracy and efficiency of iVR.

6 Conclusion

Despite critical advancements in 3D scanning and photogrammetry techniques for tracking building progress, traditional quality control and progress testing often entail manual inspection or data analysis, which takes a long time to track and relies on conventional methods. A near real-time project monitoring tool (iVR) has been developed and tested to address this issue. The vital benefits of iVR are summarized, based on the findings, as follows:

(A) The study indicates that the device significantly reduces the information gap between the development office and jobsite; the collection, sharing, and computation of data requires fewer resources and time.

(B) Immersive, interactive, and augmented technologies allow investigators and workers to visualize tasks from perspectives that are unfeasible with traditional approaches; they enable effective interaction and an almost tangible approach to the data by providing investigators and workers with the appropriate means to sketch, report, and add data.

(C) Using iVR, inspectors can monitor several activities in a short period while remaining in the construction office. Furthermore, it can reduce human resources and improve quality and production.

(D) The system can ensure social distancing and minimize human activity among staff and construction officers, which might further mitigate the spread of infectious diseases on building sites during the ongoing COVID-19 pandemic.

To conclude, iVR's potential for progress tracking at the construction level was identified and validated with a laboratory-tested case study. This method will be presented in the future as a tab plug-in to commercial software applications; it will improve the progress tracking inspection process. The methodology's scope in the architectural field is limited to activity geometry, such as construction progress monitoring; however, in the future, it could be expanded to also include progress tracking (photogrammetry + Real 3D scanner), material tracking (GPS, RFID), worker tracking (RFID), and equipment tracking (GPS and distributed sensors). The iVR-scan is currently only applicable to jobsite target activity; however, it can be extended to not only focus on object quality checks, but can also consider human activity, such as human recognition and skeletonizing, to identify human figures and track skeleton images of people moving within the Kinect field of view. In iVR-preparation, generated reports could be integrated with BIM schedule targeted activity reports to give feedback to 4D BIM, facilitating automatic updates and increasing automation in QA inspection.

Data Resources

All of the iVR project's visual program algorithms and datasets are stored in the Mendeley Data repository https://data.mendeley.com/datasets/g2xh9k5yzy/1, and

the results that are presented in this paper can be reproduced by following the readme file instructions or the methodology that this paper explained. Abstract -

Lighting performance simulators play an important role in the architectural design process, as it provides the means to address lighting design issues early within the design stage of a construction project life-cycle. Currently, several lighting performance simulators provide support for glare simulation and analysis; however, they are primarily limited to two-dimensional desktop displays and not capable of simulating glare in real-time. Furthermore, the quantitative data produced from these simulators consist of reports, complex numerical data-sets, two-dimensional graphs, and charts, which creates a divergence between the data produced and the three-dimensional context of the building. As a result, analysis of glare data generally requires specialists such as experienced architects who have an extensive background in interpreting these two-dimensional data-sets. In order to overcome the aforementioned issues, we present VRGlare: an immersive Virtual Reality lighting performance simulator capable of real-time glare simulation and analysis. In addition to semi-realistic lighting renderings, this research proposes four visualisation techniques to represent glare within an immersive three-dimensional context. We also present two multi-sensory approaches designed to re-create the physical discomfort that occurs when experiencing glare. This paper provides an overview of the developed simulator which includes the hardware, software, algorithms, visualisations, and multi-sensory representation of glare discomfort.

Virtual Reality; Lighting Performance Simulation; Immersive Glare Visualisation; Glare Analysis; Building Information Modelling

1 Introduction

Sufficient work-place lighting is an essential requirement for workers who spend multiple hours on a computer per day. Previous studies have demonstrated visual discomfort in the workplace has a negative impact on a worker's overall level of productivity, performance, and overall job satisfaction [1, 2]. The physical symptoms associated with visual discomfort include eye-strain, headaches, fatigue, red, sore, itchy, watering eyes, and lighting sensitivity. Visual discomfort can occur in workplaces due to various factors associated with lighting including uniformity, glare, veiling reflections, shadows, and flicker [3]. As a result, providing architects with the necessary tools to mitigate visual discomfort during their design process is required. With the continuous advancements of Lighting Performance Simulators (LPS) in recent years, LPS has become an increasingly used tool for architects to plan and design their ideal lighting layout. A LPS can be defined as a software system that provides the ability to simulate, analyze, and assess the performance of lighting through realistic simulations, algorithms, and large subsets of data. Currently, several LPS systems provide support for glare simulation and analysis, however, they are primarily limited to two-dimensional desktop displays and not capable of simulating glare in real-time. Furthermore, the quantitative data produced from these simulators consist of reports, complex numerical data-sets, two dimensional graphs, and charts, which creates a divergence between the data produced and the three-dimensional context of the building. These traditional methods of representing glare data were based on the limitation that computers lacked the hardware capability to simulate lighting data in real-time. However, as processing speed and power of computers rapidly advances [4], glare simulators will transition from requiring lengthy calculation processes to real-time simulation of data. As a result, new and improved methods for representing glare will be introduced over-time rendering previous methods obsolete. In order to overcome the aforementioned issues, we present VRGlare: an immersive LPS capable of real-time simulation and visualisation of Glare for lighting design and analysis. The proposed system utilizes Virtual Reality (VR) to improve the spatial awareness, and presence [5] lacking in modern PC-based LPS. A set of five immersive visualisations were developed and presented in this paper to demonstrate the potential of using VR for real-time glare simulation and analysis. Due to the dynamic range of current head-mounted displays (HMDs), it is not possible to experience glare discomfort in VR. Therefore, we present two multi-sensory approaches to achieve recreation of glare discomfort in VR using haptic and audio interfaces.

The specific contributions of this paper are:

- A **real-time Virtual Reality Glare simulator** for immersive glare analysis and design.
- A set of **five visualisation techniques** to represent glare within a real-time immersive environment.
- Two methods for **representing glare discomfort through multi-sensory** approaches.

2 Related Work

Despite the rapid hardware advancements of computers in the last decade, limited investigations have been conducted on real-time simulation of glare data for lighting analysis and design. Moreover, no prior research exists on exploring the use of immersive three-dimensional visualisation techniques to create a direct link between glare data produced and the three-dimensional context of the building. As a result, the related works discussed in this section consists mostly on previous research exploring the integration of immersive displays for lighting performance simulation and analysis. The specific research addressed includes the following areas associated with immersive lighting performance: artificial and natural lighting design, day-lighting analysis, and energy cost and consumption. We also provide a brief overview of the historical research developments for LPS, and describe a modern commercial LPS which supports glare simulation and analysis: DIALux.

2.1 Immersive Lighting Performance tools for Simulation and Analysis

In recent years, researchers have begun exploring the integration of Virtual and Augmented reality (AR) with Building Information Modelling (BIM) for lighting design and analysis. BIM is described as a process where building information related to a project's activities is directly linked with a corresponding three-dimensional virtual CAD model. BIM has the potential to be a valuable tool for improving the accuracy of future lighting simulations as non-geometrical factors such as material can have a considerable impact on lighting performance. One of the earliest works using immersive displays for lighting analysis was achieved by Sheng et al. [6] who built a multi-projector AR table-top visualisation system capable of simulating artificial and natural lighting of buildings. The developed prototype was capable of simulating the effects of day-lighting over a 24 hour day-time cycle. Similarly, Natephra et al. [7] developed a BIM-based lighting design feedback (BLDF) prototype targeted towards immersive visualisation using VR. The motivation for developing BLDF was to address flaws associated with previous LPS tools. The authors noted one of the key improvements of their prototype was the implementation of a built-in system to calculate and provide information relating to lighting energy cost and consumption. The results from a case-study conducted demonstrated BLDF was capable of providing stakeholders with an increased level of satisfaction and understanding for perceiving and optimizing lighting conditions to improve lighting design, and mitigate energy costs for future occupants. The authors discussed one of the future directions of their work is to incorporate support for glare simulation and analysis. More recently, Wong et al. [8] developed an immersive lighting visualisation tool incorporating VR and aspects of BIM. This was achieved by linking lighting simulation data obtained from DIALux with the Unity 3D Game Engine to handle VR visualisation and interaction. The results of this research concluded that the system was capable of producing realistic lighting rendering effects and provided the appropriate feedback for users to make informed lighting decisions. Immersive VR daylighting analysis and simulation tools such as RadVR [9] have also demonstrated VR as an effective medium to improve spatial understanding of tasks, improve navigation, and sun position analysis in comparison to PC oriented LPS tools. Representation of daylighting data using RadVR was achieved through two-dimensional heatmaps which incorporated a three colour gradient palette consisting of blue as the minimum value, yellow as the median, and red as the maximum. Birt et al. [10] performed a comparability study aimed at assessing the advantages and disadvantages of using VR for lighting simulation and analysis compared to AR. The results of this research showed VR was most efficient for lighting visualisation and provided a more realistic reconstruction of the real world, whereas AR improved the manipulability of the system, enhanced creativity, and improved participants confidence of the design.

2.2 Commercial Glare Simulation and Analysis applications

The history of lighting performance simulators dates back as early as 1970s when researchers begun developing algorithms to predict luminance and illuminance levels of natural, and artificial light sources [11]. Due to the limited computational power at this time, data was primarily represented numerically. By the 1990s, computer hardware became advanced enough to allow lighting simulators to produce semi-realistic rendered images of lighting. However, these simulators still primarily relied on representing data through numerical datasets, and two-dimensional images and drawings such as isolines. The 1990s also saw the introduction of Radiance: a LPS capable of simulating glare [12], luminance, and illuminance levels [13]. The lighting engine utilized a backwards ray-tracing approach to produce semi-realistic lighting simulations of CAD models. Among numerical datasets, Radiance also utilized semi-realistic static images to visualise lighting data. These images could be overlayed with different visualisations such as false-colour images or contour lines. Radiance was later open-sourced and is still widely utilized as both a lighting analysis tool and backend lighting engine to several LPS systems. Modern commercial LPS applications such as DIALux[1] provides support for calculation, and analysis of glare, daylighting, and artificial

[1]https://www.dialux.com/en-GB/

lighting analysis, energy consumption, among a variety of other features. The software integrates CAD support allowing users to design buildings directly through their software, or import CAD models and BIMs using the Industry Foundation Class. DIALux utilizes LUMSearch: a catalogue search engine to support the integration of a comprehensive range of lighting fixtures. However, despite the significant computational hardware advancements over-time, lighting visualisations in DIALux still primarily consist of traditional approaches for representing glare. These approaches include isolines, numerical data-sets, two-dimensional graphs and charts, static three-dimensional false-colour images and lighting renderings, and auto-generated reports. Although these traditional methods of representing glare data are still effective, users lack the in-situ awareness of the building which we believe can potentially lead to misinterpretation of data. Furthermore, calculation of glare data requires a lengthy calculation process and isn't capable of real-time. We believe real-time simulation of glare data is necessary to provide a more precise representation of glare data resulting in users making more informed lighting decisions.

3 System Overview

3.1 Hardware

The VR technology used to run VRGlare consisted of a standard HTC Vive[2] setup. We also experimented with the Pimax 5K Plus[3] HMD capable of producing a 170 degree field of view (FOV), and 2560x1440 resolution on each lens. However, due to the significantly higher performance demands of the Pimax we primarily used the Vive. A powerful PC was used to handle the high processing and memory demands of VRGlare. The specifications of the PC consisted of an Nvidia GeForce RTX 2080 Graphics Card with an Intel(R) Core(TM) i7-9700 CPU @ 3.00GHz processor and 16GB RAM. Two standard HTC Vive controllers with 6DOF tracking were used as the input devices.

3.2 Lighting Performance Simulator: VRGlare

In order to develop our own glare visualisation techniques, we designed and built our own custom LPS which we called VRGlare. VRGlare was developed using the Unity 3D game engine, and the software was programmed entirely in C#. The lighting rendering system was based off Unity's High Definition Rendering Pipeline described in Section 3.5.1, and initial lumen calculations were based off Unity 3D's built-in lighting integration. The SteamVR library was incorporated to provide VR support, and the 3D User Interaction Toolkit [14] to provide basic VR interaction. The specific motivation for building our own custom LPS was due to other open-source solutions not providing real-time simulation capability, lacked VR support, or did not provide access to their rendering system to build custom visualisation techniques.

3.3 Glare Calculations

3.3.1 Real-time calculation Algorithm

The following four-step algorithmic approach is utilized in VRGlare to achieve a real-time simulation of glare data.

1. At run-time, all objects within the Virtual Environment (VE) are broken down into smaller submeshes. **(Re-calculated once every 500ms)**
2. Lux is calculated for each submesh by casting a ray from each light source to all submeshes within the light sources range.
3. Retrieve all active submeshes within the user's view frustum.
4. Re-calculate glare for each sub-mesh using the UGR equations shown below.

3.3.2 Unified Glare Rating

The Unified Glare Rating (UGR) [15] illustrated in equation 1 is utilized in our LPS to calculate glare discomfort. The UGR equation is used to determine the likelihood of a luminaire causing glare discomfort to surrounding objects. UGR outputs values generally range from < 10 being imperceptible, to > 28 being uncomfortable (see Table 1).

$$UGR = 8log[0.25/Lb \sum(L^2\omega/p^2)] \quad (1)$$

Where Lb is the background luminance, L is the luminance of the luminous parts of each luminaire in the direction of the observer's eye, ω is the solid angle of the luminous parts of each luminaire at the observer's eye, and p is the Guth position index for each luminaire.

Table 1. This table demonstrates the range of values outputted by the UGR equation and its associated description. The corresponding RGB values used in the heat-map visualisation described in Section 3.5.2 are shown on the right-most column (The RGB colours in the table may differ from the generated colours in the system).

UGR Rating	UGR Description	Heat Map RGB
<10	Imperceptible	0, 34, 255
>10 <15	Just perceptible	0, 255, 255
>15 <18	Perceptible	0, 255, 125
>18 <21	Just acceptable	0, 255, 0
>21 <24	Unacceptable	0.35, 0.72, 0.188
>24 <28	Just uncomfortable	0.7, 0.72, 0.188
>28	Uncomfortable	1, 0, 0.188

3.4 Bench-markings: Performance Analysis

The capability and performance of VRGlare was measured through a series of stress-tests designed to determine how many glare calculations points the system was capable of handling in real-time. The structure of these tests consisted of spawning an increasing amount of light sources, and virtual objects within the users FOV. To maintain a consistent amount of submeshes, we re-used the same object for each trial. The heatmap visualisation later described in Section 3.5.2 was used as the primary glare visualisation technique throughout the tests. The hardware specifications used in these tests are described in Section 3.1, with the exception of the Pimax 5K which was substituted with a standard HTC Vive HMD. The overall results demonstrated VRGlare performed reasonably well (45 FPS) with 5 light sources, and 50 objects (1300 submeshes) within the user's FOV. A full breakdown of the bench-marking results are described in Table 2.

Table 2. Benchmarking results for heatmap visualisation

Objects In FOV	Light Source	Sub-Meshes	Rays Casted	Frames per second
1	1	26	27	90
10	2	260	552	85
10	5	260	1305	50
20	5	520	2605	48
20	10	520	5210	46
50	5	1300	6505	45
50	10	1300	13010	27
75	10	1950	19510	15
100	10	2600	26010	10
100	20	2600	52020	<5

3.5 Glare Visualisation Techniques

In this section we provide an overview of the visualisations and multi-sensory approaches used in VRGlare to represent glare within an immersive three-dimensional environment. The visualisations described consist of a standard semi-realistic lighting rendering, real-time heatmaps, three new visualisations, and two multi-sensory glare discomfort techniques. Each section provides an overview of each technique which includes the design motivations, partial implementation details, advantages, disadvantages, and potential uses.

3.5.1 Semi-realistic Lighting Visualisation

The semi-realistic lighting visualisation is designed to present a standard semi-realistic rendering of the generated lighting, and glare present within the VE. This is achieved through Unity's built-in High Definition Rendering Pipeline (HDRP) which handles the backend rendering calculations. A number of variables such as the intensity, position, and orientation of natural, and artificial light sources within the VE are used to calculate lighting. Additional object parameters such as materials are also considered to generate semi-realistic glare rendering. Furthermore, the HDRP combines semi-realistic shaders, and global illumination algorithms to simulate direct and indirect lighting phenomenons such as glare, shadows, reflectiveness, and light ray bouncing.

Figure 1. This image presents the standard HDRP Lighting Visualisation: which is a realistic representation of Glare within the scene. Lights are set to 800 lumens and a 3 meter range.

The motivation for utilizing the HDRP as our default visualisation is to present a semi-realistic recreation of the expected lighting produced based on a given lighting design. Additional four-dimensional support has been integrated into the system allowing users to simulate the lighting at specific times throughout the day. The combined use of Unity's HDRP with VR also allows users to experience the interior lighting of a building from a first-person perspective. VR locomotion techniques such as teleportation has also been implemented in VRGlare to provide a non-disorienting approach to navigate throughout the building. We believe this visualisation could be particularly useful for architects to gather lighting feedback from client(s) and other stakeholders associated with the development of the building. The disadvantages of using a default lighting visualisation mainly stems from the user's inability to accurately determine whether the intensity of glare present inside the VE is acceptable or not. As a result, we present our implementation of four visualisations, and two multi-sensory approaches to overcome this specific problem. Furthermore, the HDRP utilizes separate algorithms for glare calculation as opposed to the UGR standards described in section 3.3. This results in less-accurate representation of glare depicted in the rendering as opposed to our other propose visualisations which utilize the standardized UGR equations to calculate glare.

Figure 2. This image presents the heatmap Lighting Visualisation: which generates a three-dimensional heatmap to represent the amount of Glare within the scene. Lights are set to 800 lumens and a 4 meter range.

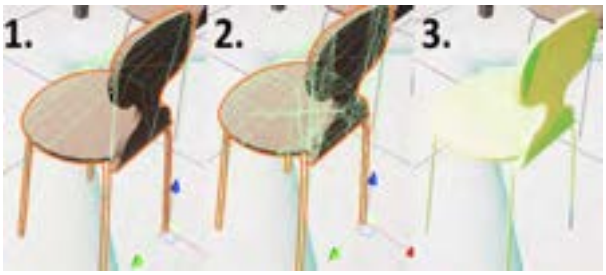

Figure 3. This diagram shows the process of superimposing heatmaps onto virtual objects. *1)* A standard object with a mesh collider is placed into the VE, *2)* The object is sliced into twenty-three submeshes, *3)* Calculations are performed and the generated heatmap is superimposed over the object.

3.5.2 Realtime Heatmap Visualisation

The real-time heatmap visualisation utilizes false-colour images to represent the intensity of glare within the user's FOV. The corresponding RGB colours used in the heatmaps to represent glare intensity follow a four colour gradient palette illustrated in Table 1. At run-time, all objects within the VE are broken down into sub-meshes, these sub-meshes are then used to calculate glare for multiple surface points of an objects. Once these calculations have taken place, the generated heatmaps are superimposed over objects within the VE providing glare feedback to the user (See Figure 3). Unlike previous LPS which require lengthy re-calculation processes whenever a change occurs to the building design, VRGlare is capable of producing calculations in real-time. This means when an object or light source properties are manipulated within the VE, the heatmaps will automatically and simultaneously update in real-time. Prior use of heat-map or false-colour visualisations to represent data on surfaces has been demonstrated as an effective approach to convey feedback due to its high-level of detail, and simplistic readability [16]. Heatmap visualisations provide a simple yet in-depth representation of glare data by revealing the glare intensities for all possible surfaces within the user's FOV using a colour-coded visualisation. The simplistic nature of heatmaps allows interpretation of glare data to be achieved without necessarily requiring an architect or interior designer to analyze data. The trade-off associated with using real-time heatmap visualisations results in users losing the semi-realistic aspects for both the lighting rendering and graphics within the scene. This is due to the visualisation technique superimposing RGB colour-coded heatmaps over the virtual objects thus obstructing the natural material of the objects, and as a result creating an inaccurate representation of how the expected lighting would appear within the building.

Heatmap Visualisation Extension: MirrorViz

MirrorViz is a tool developed as an extension to the real-time heatmap visualisations. The motivation for MirrorViz is that it allows users to overcome the trade-off limitation associated with being unable to experience the realistic-lighting rendering effects when using heatmaps. MirrorViz overcomes this limitation by attaching a 'mirror' to the user's hand which acts as a gateway between the heatmap and semi-realistic lighting rendering effects of the VE.

Figure 4. This image presents MirrorViz: an extension to the heatmap visualisation technique

3.5.3 Bendrays Visualisation

The Bendrays visualisation technique is loosely based off the previously developed interaction technique Bendcast[17]. Bendrays represents glare by casting multiple rays from the user's hand to objects within the user's FOV. The rays bend towards object surfaces that produce a UGR value greater than the glare discomfort threshold set by the user. The casted rays are represented as red bezier curves which bends towards objects based on the angle between the user's hand and the given object. This process provides a natural way of casting multiple rays from the user's hand without obstructing the user's perspective.

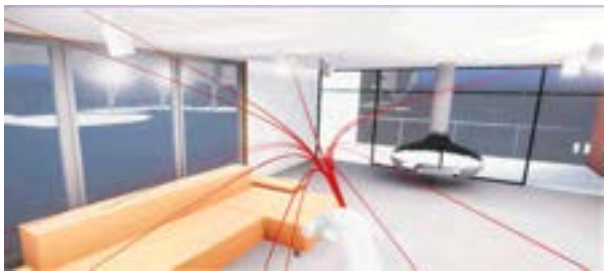

Figure 5. This image presents the Bendrays Lighting Visualisation: (Settings Lights 800 Lumens, 3 meter range in the scene. Rays bend to spots with > 30 UGR

Figure 6. Animated Arrows visualisation. Top image shows the visualisation with a UGR > 24 whereas the bottom image contains a UGR threshold of > 0

The design motivations which led to the development of the Bendrays visualisation stems from addressing the fundamental limitation of heatmaps which results in users being unable to experience the semi-realistic lighting rendering and graphics provided by Unity's HDRP. Due to the high memory usage of the Bendrays algorithm, Bendrays can negatively impact the performance of the real-time simulator when a large number of objects exceeding the glare threshold are present within the user's FOV. Additionally, in this scenario, the large number of rays produced can potentially obstruct the user's perspective and reduce the readability levels of the visualisation. Lastly, based on our informal observations we believe Bendrays is unable to provide the level of detail compared to the heatmap visualisation and as a result interpretation of data is not as intuitive.

3.5.4 Animated Arrows Visualisation

Animated arrows is a volumetric glare visualisation designed to represent glare discomfort through virtual arrow cues. The generated arrows are omitted from a given light source to any light ray hit surfaces within the user's FOV that exceeds the glare threshold set by the user. The trajectory for the animated arrows is achieved by casting rays from the light source to all submeshes within the users FOV. Using this trajectory, the arrow follows the path of the casted ray until it hits the surface of the mesh. Once the animated arrow collides with the mesh, the object's material is momentarily replaced with a generated heatmap. Finally, the animation will reset after a specified amount of time set by the user and repeat the animation cycle over. Additional parameters can be modified by the user such as the speed of the animation, or the amount of arrows produced by modifying the glare threshold. Animated Arrows provides a unique approach to represent glare data as it allows the user to visualise the entire process of a light-ray being cast from the origin light source to the surface it hits. Due to the additional background information provided, we believe this visualisation not only allows users to visualise glare data, but also provides an approach for users to gain a more detailed understanding of the entire process that's causing the glare to occur. As a result, we believe animated arrows can be a particularly useful tool for re-designing artificial light sources to mitigate glare, especially for users who may not have an extensive background in lighting design. Our current implementation of animated arrows utilizes a performance heavy-algorithmic approach. This can specifically becomes an issue if a large amount of objects exceeding the glare threshold are present in the users FOV. The outcome in this scenario would result in the visualisation producing potentially hundreds of animated arrows causing the applications frame rate to drop. Similarly to the Bendrays visualisation, the large amount of arrows produced may result in the visualisation becoming distracting to the users, and partially obstruct the user's FOV resulting in decreased readability levels as depicted by Figure 6. Lastly, based on our informal observations we believe representation of glare data is not as intuitive as the heatmap visualisation. This is primarily due to the user being required to wait for the animation to complete its cycle in order to interpret the glare data from the generated heatmap.

3.6 Multi-sensory Glare Discomfort Representations

Currently, LCD and other related displays do not provide the required dynamic range for reproducing the vi-

sual discomfort phenomena that occurs when a user experiences glare in VR. Therefore, in order to recreate the physical discomfort associated with experiencing glare we propose two multi-sensory approach of representing glare discomfort.

Table 3. Audio and Haptic feedback table

UGR Rating	UGR Description	Mean Pitch Frequency (Sine)	Mean Pitch Frequency (Triangle)	Vibration Freq
<10	Imperceptible	97.8 Hz	151.8 Hz	20 Hz
>10 <15	Just perceptible	127 Hz	224.8 Hz	30 Hz
>15 <18	Perceptible	154.2 Hz	270 Hz	50 Hz
>18 <21	Just acceptable	191.2 Hz	502 Hz	70 Hz
>21 <24	Unacceptable	313.4 Hz	899.2 Hz	100 Hz
>24 <28	Just uncomfortable	494.2 Hz	1152.2 Hz	150 Hz
>28	Uncomfortable	1057 Hz	1794.4 Hz	255 Hz

3.6.1 Audio-based Discomfort Representation

Our first approach utilizes an audio-based interface designed to re-create glare discomfort by stressing the user through audio cues. This is achieved by producing varying pitches of three-dimensional frequencies based on the amount of glare visible within the user's FOV. The algorithm is described as followed: firstly, the UGR calculation is performed to determine the amount of glare associated with each object present in the user's FOV. Next, a three-dimensional audio source is placed at the position of the produced glare sources. Finally, the audio source outputs a three-dimensional sound at a specific frequency based on the amount of glare produced by a given object. The frequencies obtained as illustrated in Table 3 were collected by running a pilot study where participants (n=5) were instructed to change the Hertz frequency to match the description described in the UGR discomfort-scale. The mean pitch was then calculated from the data-set and used to determine the frequencies of the sounds produced by the simulator. Another design motivation for developing this technique was to provide users with an approach to represent discomfort levels of glare in the VE without having to visually the experience the glare. One particular scenario where this technique could be used is to provide 360 degree glare feedback, this would allow a user to gain an understanding of objects producing glare behind or outside the users FOV. The disadvantages with using an audio-based interface to represent glare is primarily associated with the difficulty required to accurately interpret data and locate the origin of a glare source. To resolve this issue, we propose using the audio interface concurrently with a visualisation technique.

3.6.2 Haptic-based Discomfort Representation

In addition to an audio-based glare discomfort technique, we also experimented with an alternative multi-sensory approach which utilizes haptic feedback to convey glare discomfort through vibrations. This is achieved by outputting vibrations ranging in intensity values based on the amount of glare present within the user's FOV. The hardware to achieve this consisted of two HTC Vive Controllers, each capable of producing vibrations ranging between 0-255 Hertz. The motivation for developing this technique was strictly to experiment with alternative multi-sensory approaches to represent glare. Based on our initial informal observations we believe vibrations are not as an effective sensory modality for reproducing the physical discomfort of glare in comparison to an audio-based interface. However, we believe this proof of concept could be potentially used to capture glare discomfort feedback in a less physically distressing manner. The hardware used to output haptic-feedback also plays a key role in how effective the technique will perform. In our case, we used the HTC Vive Controllers which was limited to producing a maximum of 255 Hertz on each hand.

4 Future Directions

The immersive glare-based simulation and visualisations presented in this paper is one aspect of a more compact immersive LPS prototype we built. The future directions of this work aims to conduct a formal user study to evaluate all aspects of our immersive lighting simulator which includes interior/exterior lighting design and simulation, daylight analysis, energy consumption, and cost analysis. We also aim to explore the advantages and disadvantages of using immersive displays and six degrees of freedom input devices compared to a standard PC-mouse desktop setup for lighting analysis, and design. Current implementations of our system is limited to a uni-directional exchange of data between Revit and Unity using the Industry Foundation Class. A future direction could be to develop a workflow that creates a real-time bi-directional exchange of BIM data between Revit and Unity. Finally, using the ZED Mini depth-sensor we aim to incorporate Mixed Reality support into our system. This will allow users to navigate between AR and VR perspectives which has previously been identified as a potentially valuable tool for lighting analysis, and design[10].

5 Conclusion

This paper presented VRGlare: An immersive Lighting Performance Simulator supporting real-time glare simulation and analysis through the integration of Virtual Reality. In summary, we discussed the hardware, algorithms, equations, visualisations, and multi-sensory representations of

glare in respect to the simulator. Five visualisation techniques were presented capable of representing glare and providing feedback to the user in a simplified, and effective manner. We also presented two multi-sensory glare discomfort techniques using an audio and haptic-based interfaces designed to simulate the physical discomfort caused when experiencing glare. Lastly, we discussed the limitations associated with our simulator, future directions, and goals. Our hope is that this work will act as a stepping stone towards the future research and development of using three-dimensional visualisation techniques for real-time lighting performance simulation.

Abstract –

Construction, one of the most information-intensive industries, plays a vital role in the prosperity of nations and is expected to grow to new heights. This significant expansion, along with the increased complexity and sophistication of construction projects and rapid advances in emerging technologies, has fueled construction companies' interest in innovation as a source of competitive advantage. Augmented Reality (AR), a pillar of Industry 4.0, is an emerging technology that is gaining traction in construction. AR can be described as both an information aggregator and a data publishing platform that allows the user to (1) passively view displayed information, (2) actively engage and interact with published content, and (3) collaborate with others in real-time from remote locations. The objective of this paper is to develop an Augmented Reality Fitness Index (ARFI) to assess the suitability and applicability of AR for contractors in the construction industry. The rationale behind the proposed index is to understand the perception of stakeholders regarding the eligibility of AR in the construction industry and to investigate the potential degree of usage of AR throughout the seven phases of the lifecycle of a construction project: conceptual planning, design, pre-construction planning, construction, commissioning, operation and maintenance, and decommissioning. From the literature review, 43 AR use-cases were identified and grouped into the seven phases of a construction project. A survey was then developed to capture contractors' level of familiarity with AR in construction, level of usage of AR in construction, and perceived possible use of each AR use-cases. Next, contractors' perceived relevance of each of the 43 AR use-cases was obtained by surveying a group of subject matter experts. Using the collected data, a mathematical model was developed to compute an ARFI for each phase. The computed ARFI is used as an indication to guide the implementation of AR in construction.

Keywords –

Augmented Reality; Fitness Index; Contractors; Mathematical Model

1 Introduction

Construction, one of the most information-intensive industries, is a major contributor to the prosperity of nations and a sector that is expected to continue to grow [1]. This growth, along with the increased complexity of construction projects and rapid advances in digital technologies, heralds an increased interest by construction companies to innovate and transform their business-as-usual to remain competitive [2]–[5]. One emerging technology that is gaining interest in construction is Augmented Reality (AR). AR, a pillar of the fourth industrial revolution (Industry 4.0), both an information aggregator and a data publishing platform that allows the user to (1) passively view displayed information, (2) actively engage and interact with published content, and (3) collaborate with others in real-time from remote locations [1].

Various research efforts have investigated the potential use and impact of AR on construction projects. Some studies explored AR use-cases in specific phases of the construction project lifecycle, and others developed prototypes to investigate the impact AR on construction projects. While these efforts are critical to understanding the potential of the technology, they don't measure the degree of fitness of AR in construction. Therefore, the objective of this paper is to develop an Augmented Reality Fitness Index (ARFI) to assess the suitability and applicability of AR throughout the construction project lifecycle, using data collected from contractors.

2 Research Methodology

The methodology employed to fulfill the main goal of the research encompasses the following sub-goals. First,

a comprehensive and thorough review of the existing literature is conducted to extract AR use-cases. These AR use-cases are then mapped across the project lifecycle. The lifecycle of a construction project consists of a series of phases, and the literature review showed that there is no single definition for what the phases are. The project phases adopted in this research are those introduced by [6] and are as follows: 1) Conceptual Planning, 2) Design, 3) Pre-Construction Planning, 4) Construction, 5) Commissioning, 6) Operation and Maintenance, and 7) Decommissioning. Once the AR use-cases were identified, a survey was developed and distributed to contractors to collect their perception of AR in construction. The data collected from the survey was then analyzed, and a mathematical model was developed to compute an Augmented Reality Fitness Index for each phase of the construction project lifecycle.

3 Augmented Reality Use-Cases

Research studies by [7]–[35] were reviewed, and 43 AR use-cases were identified and grouped into the seven AR phases, as shown below. *P1* is Conceptual Planning, *P2* is Design, *P3* is Pre-Construction Planning, *P4* is Construction, *P5* is Commissioning, *P6* is Operation and Maintenance, and *P7* is Decommissioning:

P1 Real-time visualization of conceptual projects
P1 Overlaying 4D content into real-world (or physical objects) such as traffic flow, wind flow, etc.
P1 An understanding of how the desired project connects with its surroundings
P2 Overlay of 3D models over 2D plans (i.e. Design [or project] visualization in the office over 2D plans)
P2 Design (Project) visualization at full scale on-site
P2 Virtual tours for clients while on-site or in the office (AR walk-through)
P2 Real-time design change (material selection, design functionalities)
P3 Clash detection
P3 Early identification of design errors
P3 Constructability Reviews during design
P3 Full-scale site logistics (virtually locate equipment, trailers, laydown areas, storage, etc.)
P3 Space Validation and Engineering Constraints Checks (collaboratively locate and operate virtual construction equipment, such as cranes)
P3 Virtual planning and sequencing
P3 Safety orientation (do safety orientation in an augmented virtual environment)
P3 AR-simulation based safety training programs for workers
P4 Visualizing layout and integration of prefab components in the shop
P4 Site layout without physical drawings
P4 4D Simulations on-site (augmented simulated construction operations)
P4 Monitoring the progression of workflow and sequence
P4 Visualization of augmented drawings in the field
P4 On-site inspections
P4 Remote site inspection
P4 Visualization of underground utilities
P4 Visualization of the proposed excavation area
P4 Visualization of the construction systems/work (i.e. MEP, structural, etc.)
P4 Planning the positioning and movement of heavy/irregular objects/equipment
P4 Real-time support of field personnel
P4 On-site safety precautions (site navigation and in-situ safety warning)
P4 Augmented Mock-ups
P4 Construction progress visualization and monitoring
P4 On-site material tracking
P4 Create design alternatives on-site
P4 Visualization of augmented work instructions/manuals/procedures in the field
P4 Real-time visualization, review, and analysis of data associated with a particular worker, equipment, construction system, etc.
P5 On-site inspection/Punchlists
P5 Remote site inspection
P6 Availability of Maintenance information
P6 Locate building systems that need maintenance without destructive demolition or further survey work
P6 Refurbishment visualization
P6 Real-time support of engineers and technicians
P6 Training for maintenance and repair
P7 Remodeling visualization
P7 Evaluation of the new facility/installations over the existing one

4 Data Collection

4.1 Survey

Once the 43 AR use-cases were identified, a survey was developed, tested, and distributed to contractors. The survey was designed to capture the following data:

1. Respondent's level of familiarity of AR in the context of the construction industry measured on the following scale: (0) never heard of it; (1) vaguely heard of the term before; (2) basic understanding; (3) good understanding; and (4) very good understanding.
2. Respondent's level of usage of AR in the context of the construction industry measured on the following scale: (0) have not experienced AR before and not interested in the technology; (1) have not

experienced AR before but interested in the technology; (2) explored/ exploring AR applications; (3) tested/ testing AR applications; and (4) have used AR on at least one construction project.

3. Contractor's approximate average annual revenue in the last three years (measure in U.S. dollars).
4. Respondent's perceived level of usage of each of the 43 AR use cases measured on a five-point Likert scale of (1) very low; (2) low; (3) moderate; (4) high; and (5) very high. Respondents could also select "N/A" (coded as 0) if they don't think an AR use-case will be used.

4.2 Data Characteristics

A total of 46 responses were collected. Survey results showed that 13% of respondents had vaguely heard of AR, 2% had a basic understanding, 14% had a good understanding, and the remaining 17% had a very good understanding of the technology. When asked about their usage of AR in construction, 13% indicated that they had not experienced AR before but are interested, 8% stated that they had explored/are exploring AR applications, 11% mentioned that they had tested/are testing AR application, and the remaining 14% reported that they had used AR on at least one construction project. It should be noted that none of the respondents indicated that they had not heard of AR before or are not interested in the technology, proving that AR is a promising technology in construction.

4.3 Data Analysis

Researchers indicated that the perception of users of a technology is influenced by the users' familiarity and degree of usage of the technology [36], [37]. Therefore, before developing the mathematical model, the relationship between:

1. The respondent's perception of an AR use-case and the respondent's familiarity with AR
2. The respondent's perception of an AR use-case and the respondent's usage of AR

were evaluated using the Kruskal-Wallis H test and Kendall's tau-b. Additionally, the impact of the economic volume of the respondents (i.e. average annual revenue) on the respondent's perception of an AR use-case was also investigated using Kruskal-Wallis H test.

The analysis of these three relationships resulted in significant p-values, providing statistical evidence at the 95% confidence level that the respondent's perceived level of usage of each AR use-case differs across the different levels of familiarity and usage of AR and the economic volume of the company.

5 Augmented Reality Fitness Index (ARFI)

The objective is to develop an Augmented Reality Fitness Index (ARFI) to assess the suitability and applicability of AR in the construction industry using contractors' data. Using the data collected for the survey and the statistical relationships that were identified in the previous sections, this section outlines the steps undertaken to develop the mathematical model.

5.1 Motivation

ARFI is a proposed measure on a normalized scale from 0 to 1 of the usage potential of AR in a particular construction phase and throughout the lifecycle of a construction project. The rationale behind the proposed index is to understand the perception of contractors regarding the eligibility of AR in the construction industry and to investigate the potential degree of usage of AR throughout the seven phases of the lifecycle of a construction project. ARFI in each phase is computed as a weighted average of the usage potential of the technology's identified use-cases in that phase and based the perceived relevance of each use-case.

The usage potential (UP_j) of an AR use-case j is calculated as a weighted average of the perceived possible use of this use-case in its corresponding phase obtained from the survey. However, this variable is subjective by nature and differs among respondents. To reduce the influence of this subjectivity, the perceived possible use of an AR use-case j is, therefore, subsequently weighted based on three variables: familiarity with AR, current usage of AR, and economic volume of the respondent. These three variables are combined into one variable, namely the response weight (w_i), which is used to weigh the perceived possible use of an AR use-case corresponding to respondent i.

Contractors' perceived relevance of an AR use-case j was obtained by surveying a group of subject matter experts on each of the 43 identified use-cases.

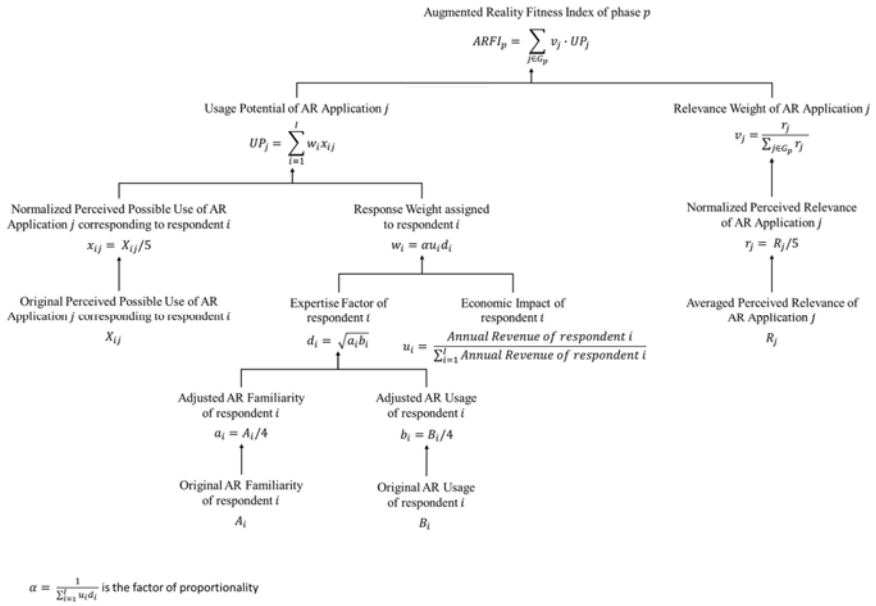

Figure 1. Breakdown of the Augmented Reality Fitness Index Mathematical Model

5.2 Mathematical Formulation

The model computes for each phase p of the lifecycle of a construction project a corresponding Augmented Reality Fitness Index, $ARFI_p$.

$ARFI_p$ is based on the evaluation of the weighted usage potential of a set of AR use-cases in phase p. In the following, J denotes the total number of AR use-cases ($J = 43$), and G_p (with $1 \leq p \leq 7$) denotes the disjoint sets of AR use-cases within a phase p, with:
$G_1 \cup G_2 \cup G_3 \cup G_4 \cup G_5 \cup G_6 \cup G_7 = \{1, 2, 3, \dots, 43\}$,
where:
$G_1 = \{1, 2, 3\}$, $G_2 = \{4, 5, 6, 7\}$, $G_3 = \{8, 9, \dots, 15\}$, $G_4 = \{16, 17, \dots, 33\}$, $G_5 = \{34, 35\}$, $G_6 = \{36, 37, \dots, 41\}$, and $G_7 = \{41, 42\}$ represent the sets of AR use-cases in the Planning Phase, Design Phase, Pre-Construction Phase, Construction Phase, Commissioning Phase, Operation and Maintenance Phase, and Decommissioning Phase, respectively.

The model used to calculate $ARFI_p$ is defined as:

$$ARFI_p = \sum_{j \in G_p} v_j \cdot UP_j \quad (1)$$

where:

- p denotes the number of phases of the lifecycle of a construction project ($1 \leq p \leq 7$),
- UP_j denotes the usage potential of AR use-case j, and
- v_j denotes the relevance weight of AR use-case j, with $v_j \geq 0$ and $\sum_{j \in G_p} v_j = 1$.

The underlying assumption here is that the index $ARFI_p$ solely depends on the AR use-cases in phase p. To compute this index, we need to determine the values of UP_j and v_j.

5.2.1 Usage Potential of AR Use-case *j*

The Usage Potential of AR of use-case j is defined as:

$$UP_j = \sum_{i=1}^{I} w_i x_{ij} \quad (2)$$

where:

- I denotes the number of respondents,
- x_{ij} denotes the normalized perceived possible use of an AR Use-case j corresponding to respondent i. These normalized values are calculated using $x_{ij} = X_{ij}/5$, with X_{ij} being the original perceived impact of a barrier k corresponding to respondent i, where $X_{ij} \in \{0, 1, 2, 3, 4, 5\}$. And,
- w_i is a response weight assigned to respondent i, with $\sum_{i=1}^{I} w_i = 1$.
- w_i is computed based on the following four variables, A_i, B_i, and u_i, where:
- A_i is the AR familiarity of respondent i, with $A_i = \{0, 1, 2, 3, 4\}$,
- B_i is the AR Usage of respondent i, with $B_i = \{0, 1, 2, 3, 4\}$, and
- u_i is the economic impact of respondent i, with

$$u_i = \frac{Annual\ Revenue\ of\ respondent\ i}{\sum_{i=1}^{I} Annual\ Revenue\ of\ respondent\ i}$$

It should be noted that none of the respondents selected 0, and therefore, original values did not need to be adjusted to account for zeroes. Original values were normalized, and as a result, the following variables are defined:

- a_i is the adjusted AR familiarity of respondent i, where $a_i = A_i/4$, so $a_i \in \{0.25, 0.5, 0.75, 1\}$, and
- b_i is the adjusted AR Usage of respondent i, where $b_i = B_i/4$, so $b_i \in \{0.25, 0.5, 0.75, 1\}$.

The variables a_i, and b_i are then combined into a new variable, d_i, which represents the "expertise factor" of respondent i. d_i is calculated as the geometric mean of a_i and b_i, i.e.

$$d_i = \sqrt{a_i b_i}.$$

As shown in Figure 2 the geometric mean (right) gives smaller weights to respondents with lower expertise in comparison to the arithmetic mean (left).

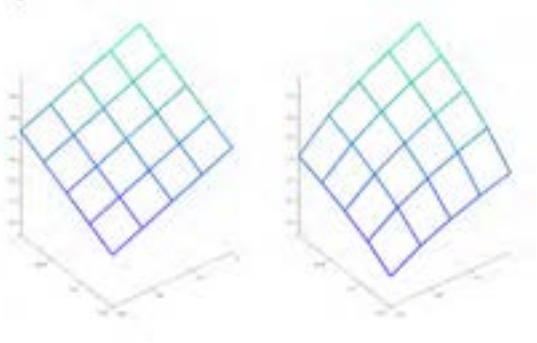

Figure 2. Effect of Using geometric mean on the expertise factor, d_i, for $a_i = 1$

For each respondent i, w_i is then assumed to be proportional to u_i (their economic impact) and d_i (their expertise factor). Therefore:

$$w_i = \alpha u_i\ d_i$$

α is then calculated by:

$$1 = \sum_{i=1}^{I} w_i = \alpha \sum_{i=1}^{I} u_i d_i.$$

Thus,

$$\alpha = \frac{1}{\sum_{i=1}^{I} u_i d_i}$$

and,

$$w_i = \frac{u_i d_i}{\sum_{i=1}^{I} u_i d_i} = \frac{u_i \sqrt{a_i b_i}.}{\sum_{i=1}^{I} u_i \sqrt{a_i b_i}.} \quad (3)$$

5.2.2 Perceived Relevance of AR Use-case *j*

The Usage Potential of an AR use-case j, UP_j, obtained from equation (2) is then weighted using the perceived relevance of that AR use-case j. R_j denotes the perceived relevance of each AR Use-case j obtained by averaging the responses of a group of 10 subject matter experts, where $0 \le R_j \le 5$. These rates were then normalized to r_j, with $0 \le r_j \le 1$. Therefore, for each AR use-case j, $r_j = R_j/5$.

For each AR use-case j, the relevance weight v_j is assumed to be proportional to r_j. Therefore, $v_j = \beta r_j$, and similar to α, β is calculated by:

$$\beta = \frac{1}{\sum_{j \in G_p} r_j}$$

thus,

$$v_J = \frac{r_j}{\sum_{j \in G_p} r_j} \quad (4)$$

Consequently,

$$ARFI_p = \sum_{j \in G_p} \frac{r_j}{\sum_{j \in G_p} r_j} \sum_{i=1}^{I} \frac{u_i \sqrt{a_i b_i}.}{\sum_{i=1}^{I} u_i \sqrt{a_i b_i}.} x_{ij} \quad (5)$$

5.3 Model Validation

The objective of the mathematical model is to reduce the subjectivity of the data by adjusting the answers of the respondents based on their level of familiarity and usage of AR in construction. An important question arises as to how to prove that the methodology employed to develop the model is effective. [38] noted that simulations provide a powerful technique for answering this question. Therefore, a simulation study was designed to evaluate the mathematical model developed and to compare it to competing approaches, i.e. using the arithmetic mean instead of geometric. The objective of the simulation is to prove that the values computed from the model are more representative than the observed raw data collected from the survey.

The Latin-Hypercube Sampling (LHS) experimental design technique in Python was used to run the simulation 1,000 times in a Monte Carlo Fashion.

Four datasets are generated in this simulation: the assumed *true* dataset, the *observed* dataset, the *arithmetic-based modeled* dataset, and the *geometric-based modeled* dataset. The *observed* dataset was generated by adding noise to the *true* dataset, and it represents the data collected from the survey. The *arithmetic-based modeled* dataset was generated by

adjusting the *observed* dataset using the arithmetic mean (i.e. $d_i = \frac{a_i+b_i}{2}$). The *geometric-based modeled* dataset was generated by adjusting the *observed* dataset using the geometric mean (i.e. $d_i = \sqrt{a_i b_i}$).

In order to evaluate the effectiveness of each model, the squared deviations between 1) *observed* and *true* values, 2) *arithmetic-based modeled* and *true* values, and 3) *geometric-based modeled* and *true* values were calculated. Results showed that the deviation between the *geometric-based modeled* and *true* values is statistically significantly less than the other two deviations, justifying the use of the geometric mean.

6 Discussions

ARFI in each phase is computed using equation (5), and the values are displayed in Table 1 and illustrated in Figure 3.

Table 1. $ARFI$ values for each phase

Phase	ARFI
Conceptual Planning	0.743
Design	0.768
Pre-Construction Planning	0.719
Construction	0.709
Commissioning	0.589
Operation and Maintenance	0.701
Decommissioning	0.646

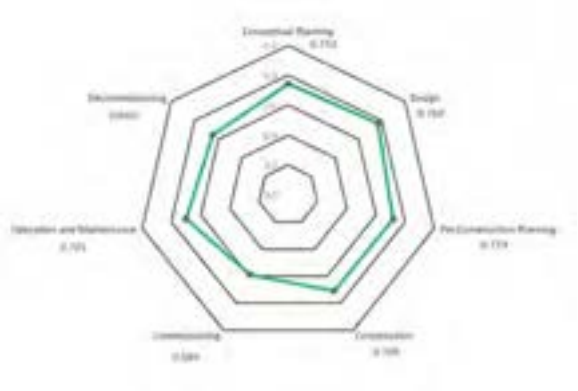

Figure 3. A radar chart of $ARFI$ values throughout the construction project lifecycle

It can be shown from Table 1 and Figure 3 that all ARFI values are greater than 0.5 indicating the potential of AR in construction. According to contractors, AR is perceived as the highest fitness index in Design (0.743), followed by Conceptual Planning (0.743), Pre-Construction Planning (0.719), Construction (0.709), Operation and Maintenance (0.701), Decommissioning (0.646), and finally commissioning (0.589).

These results highlight the importance of integrating AR throughout the entire lifecycle, placing a greater emphasis on early phases. Although the ARFI values were computed from the perspective of contractors, the construction phases – which traditionally is the most relevant phase for contractors – did not have the highest ARFI value. This shows that contractors are aware of the need to integrate AR early in the project for the later project phases to reap the benefits. The results also suggest that the construction industry is shifting the traditional delivery systems as contractors' involvement and engagement in the early phases of the project is increasing.

7 Conclusions

AR is a promising technology in the construction industry. While previous research efforts have investigated specific AR use-cases, this paper investigated the fitness and applicability of AR throughout the seven phases of the construction project lifecycle. Forty-three AR applications were identified from the extant literature and were grouped into the seven phases. Next, a survey was developed to collect contractors' perceptions of the potential of AR in construction, and 46 responses were collected. Data summary showed that all respondents had some level of familiarity with AR in the context of the construction industry, and the majority had previously used the technology to some extent. Statistical analyses showed that the respondent's perception of the potential use of an AR use-cases depends on three variables: 1) the respondent's familiarity with AR, 2) the respondent's usage of AR, and 3) the company's economic volume. A mathematical model, ARFI, was then developed to compute an AR fitness score between 0 and 1 for each phase of the project lifecycle. The calculated ARFI values were all greater than 0.5, indicating that AR can be well integrated into all phases. Additionally, while ARFI was developed using contractors' data, construction did not have the highest ARFI value. Early project phases, namely design, conceptual planning, and pre-construction planning, had an ARFI score slightly higher than construction, indicating contractors' awareness of the potential of AR and increased involvement in early phases. Future work can survey other stakeholders, including Architect/Engineers, subcontractors, facility managers, and owners, and investigate variations of stakeholders' perceptions of the fitness of AR.

Abstract –

Well detailed, informative and accurate work instructions are a necessity to mitigate delays in construction. Today, this is done through a combination of shop drawings, documents, sheets, work pre-planning meetings and onsite verbal work instructions to transfer knowledge and information between all actors. Due to the subjectivity of these methods, many incorrect assumptions and man-made errors originated from miscommunication and misinterpretation can occur. Such issues are tough to identify prior to their occurrence on construction sites, leading to construction delays. Virtual Reality (VR) technology can simulate and visualize assembly processes using Standard Operating Procedure (SOP). The visualization aims to ensure a quality communication with skilled workers and to aid their interpretation of SOPs by reducing assumptions. As a result of a more effective education, it can support the collaboration between actors. Utilization of SOPs for visualization of Work Instructions (WI) and assembly processes are important, because many process WIs on construction sites are repetitive. Modularity can increase the efficiency by supporting instancing and variation creation of construction tasks and products. Interactivity can support the continuously changing status and demands of construction sites.

A method has been iteratively developed to support visualization of modular and interactive SOPs within the context of industrialized house-building (IHB), to increase the quality and consistency of communication at construction sites. Concurrently to development of the method, a prototype using VR technology was developed. Interactive functionalities along with VR technology make it possible to adjust SOP and WI modules to suit the demands and conditions of the construction site, including real-time. As a result, the developed method is responsive and adjustable to conditions such as weather, man-made errors, assembly re-sequencing and re-scheduling. Combining product design, SOPs, WIs and assembly process in early stages of construction has shown to help identify potential issues and aid in planning for cautious measurements. Results show that by using the developed method, skilled workers were able to identify occurring miscommunications, and misinterpretations between them, site managers and foremen as well as ensuring their understanding.

1 Introduction

Usage and distribution of information within offsite manufacturing by having Standard Operating Procedures (SOP) and Work Instructions (WI) have improved the manufacturing workflow in industrialized house-building (IHB). This has however not been well translated to onsite construction, which has been lacking in development efficiency and has become a bottleneck. A well detailed SOP and WI, that are thoroughly and correctly communicated is a necessity to mitigate onsite construction delays.

The difference between the usage of SOP and WI in offsite manufacturing compared to onsite construction has been significant. Standardization reduces the complexity of information flows and its coordination [1]. With adoption of assembly line manufacturing and increased standardization, IHB has optimized offsite manufacturing tasks, resource flow, and repetitive assembly processes for the skilled workers. IHB has invested time and resources to create high quality SOPs and WIs that are thoroughly communicated to the associated skilled workers. This has however not been translated to a construction site in which the flow-oriented workflow meets the project-oriented workflow. Skilled workers on construction sites perform a variety of tasks and often have a limited holistic view of the project. This is due to only performing their allocated tasks and becoming indifferent to assembly sequence, schedule, construction quality and other tasks, leading to the hampering of progress and an increase in waste [2]. Current document-based WIs are time consuming, error

prone, and inconsistent, leading to miscommunications and misinterpretations, which causes delays [3]. With one of the reasons being that many of the skilled workers are contractors, requiring reintroduction to SOPs and WIs of the said project and company, reducing the long-term sustainability benefits that can be acquired from a SOP and WI.

WIs are communicated through a combination of shop drawings, text documents, sheets, and meetings. This means that the recipient of the information, engineers and skilled workers, must interpret the information and create a visual image of the construction, its assembly sequence and its tasks. Due to the risk of misinterpretation, and in turn assembly errors, WIs are communicated to skilled workers mainly through verbal communication [3], resulting in the verbal communication often being a time-consuming and inefficient communication method [4]. Verbal communication of WIs leads to skilled workers having many uncertainties and misinterpretations, including assembly sequence, task instructions, and resource usage [5]. Uncertainty prevents them from recognizing potential problems, communicating potential improvements and simultaneously reduces their motivation [2,5].

The purpose of this study is to iteratively develop a method for the creation of modular interactive visualization of SOPs and WIs within the context of IHB. With the aim of increasing the quality of communication at construction sites, a prototype based on game engine technology was developed and evaluated to reduce man-made errors in construction sites.

2 Research Approach

The study has been conducted with a design science (DS) approach by Hevner [6], to develop the knowledge and understanding of the problems within the field by iteratively building a prototype. Data collection methods were semi-structured interviews, observations, meetings and supplemented by a literature review. The primary activities in DS research are the designing, building and evaluation of prototypes [7]. Prototypes can comprise processes, models, methods, and software. This paper uses DS to describe the development of a software prototype for modular and interactive visualization SOP and WI, and to propose a method based on this process.

To support the development of the method and its evaluation, a study was conducted in multiple IHB construction projects. These projects were selected for the study due to them having new assembly processes for onsite construction, meaning that SOPs and WIs for said assemblies were under development. In an iterative process, the method was designed and built for evaluation of construction sites works in collaboration with site managers and foremen. Using results from the evaluation of the prototype, the method was further developed for upcoming projects. Skilled workers were collaborated with within the later stages of the development, only when a certain maturity had been achieved.

Semi-structured interviews with process development engineers, site managers, foremen and skilled workers were used to identify the information flow within the company, the perception of the prototype, and for comparison of the prototype with text based WIs as well as mapping and development of assembly sequence, SOPs and WIs.

3 Theory

3.1 Standard Operating Procedure & Work Instruction

Standard Operating Procedure (SOP) is a means of documentation that describes the best-known practices within a specific company, often in the form of text-based documents. A company can use SOPs to achieve a reduction in scheduling waste, quality issues and environmental impacts, while simultaneously increasing the safety and consistency of assembly processes [2,8]. SOPs also benefits the company by encouraging the documentation of information resulting in knowledge staying within the company [2,8].

A SOP can include working methods, precautions, task durations, preparatory tasks, step-by-step instructions, resources, etc. [9]. The step-by-step instructions contain a specific start point and a description of each sequenced instruction, where a group of instructions is a WI. A SOP must be user-friendly, easy to understand and must be easily revisable [2].

Work instruction (WI) is an approach to manage the dissemination of information and knowledge within companies [10] and the best practices of work [11]. During its life-cycle, a WI goes through three phases, creation, use and maintenance phase [12]. The creation phase consists of product information, such as 3D models and shop drawings, and resource information such as tools, machinery, skilled workers, and process information that contain step-by-step instruction of the assembly process and construction rulesets [11,12]. Under the use phase, a WI is performed by skilled workers to support the sequenced assembly tasks with guided step-by-step instruction [12].

Process modularity improves the adaptability of a product, its requirements and standardization by simplifying the re-sequencing and addition of new modules to the assembly sequence [13]. It further improves the possibility of parallel assembly, hence reducing lead times [14]. Modular processes are built on

three principles [15]:

- Standardization: Breakdown of a standard process into main sub-processes and instance sub-processes that can be derived and customized from the main sub-processes.
- Re-sequencing: Reordering of sub-processes.
- Postponement: Postponing instance sub-processes to increase flexibility.

3.2 Visualization & Interactivity of Modular SOP

Visualization is an effective method for introducing SOP to construction sites, where it can improve the understanding of construction aims, standards, quality, safety instructions, assembly sequence, schedule, and potentially give an improved holistic view of the construction project [2,16]. With the aim to reduce man-made errors, due to miscommunication and misinterpretation and prior expertize [2], an animated SOP and WI can enhance the holistic view of a project. In comparison to documents and static-pictures, animations are more effective, particularly when combined with realistic graphics and task instructions [17,18]. The improved holistic view and better understanding of construction tasks conducted by other skilled workers can encourage communication, and improve motivation, which can lead to further development of SOP and WI [2,5]. Text based SOP documents are more cognitively demanding, followed by pictures [10], whilst animation could reduce cognitive demand [17]. Visualization might also reduce language gaps, as they simplify communication of important information [8].

WIs require a combination of paper documentations, such as shop drawings and text-based instructions, risking misinterpretations due to subjectivity. Therefore, WIs are instead often delivered via verbal communication to skilled workers by foremen [11]. In a study comparing instructional texts, diagrams and animations for assembly tasks, visualization of WI through animations showed an increase of step-by-step instructions understanding, leading to less man-made errors, increases in efficiency and accuracy of process assembly for the novice users [17].

Best practice changes, design changes and personal changes require revisions and re-education of WI documentations to reflect the changes. These modifications to WI are performed in the maintenance phase [12]. Therefore, effective communication, where information is filtered according to the need of every actor, can improve lead times [17].

4 Development of the method

Real-time visualization of assembly processes with game engine technology can visualize SOPs and WIs. Game engine technology, through Unity, see Figure 1, was used due to its possibility for real-time rendering of realistic environments and models in combination with scripting to create interactivity and modularity as well as for its capability of developing and distributing the prototype to a variety of IT-platforms.

4.1 Development of SOP & WI

Due to the assembly process being a new roof solution within the studied company, no registered SOPs or WIs existed beforehand. Their development started with usage of a detailed 3D-model (with 6565 components) and shop drawings of the roof. In collaboration with process development engineers, site managers and foremen, the assembly process was iteratively mapped, modified and optimized. The mapping led to the possibility of identifying main and repetitive SOPs, WIs, instructions and some foreseeable issues that could occur, mainly due to their limited tolerance values, weather or logistics.

A total of 8 pre-defined main SOP modules were mapped and developed for the roof assembly sequence. These SOPs clarify the WIs required to be performed together with the information needed for a successful onsite construction. Therefore, emphasis on their development, content of information and visualization has been a major focal point. This was conducted through quality control procedures, where the prototype was evaluated by professionals with several roles using different IT-platforms. Every main SOP contains information about its title, a description and a list of sequenced WIs. The main SOPs were utilized to create a total of 25 SOP instances for the roof sequence assembly.

Similar to the described SOP above, a total of 26 pre-defined main WI modules, with 237 instances, were developed for the roof assembly sequence. Every main WI contains information about its title, a description and a sequenced list of step-by-step instructions.

A total of 6102 components have received instructions and animation information. A component (e.g. a single roof truss) contains a 3D model representing its geometrical, positional and rotational data as well as an instruction template. For reusability of information, component information is modularized using instructional templates, with a total of 18 main templates developed for the roof assembly sequence. A template consists of data about instruction, including descriptions, materials, tools, machinery and precautional notes. Each listed instruction has its template parameters gathered, sequenced and sorted in lists available to associated WI. Additionally, the instruction template describes how and

when an animation should occur. This is described using four parameters: task duration, sequence type, adaptive position and adaptive rotation.

Adaptive position and rotation are three-dimensional vector values that indicate how far from the original position and rotation the animation should start.

Sequence type parameter modifies the relation of an instruction with other instructions under the same WI, as in, it makes it possible for the developer to decide when the sequences are animated, from sequence to sequence. The developer can give the user the choice to decide when to start a specific animation by setting its sequence type value in instruction to wait for user input, OnClick, (indicated by a mouse icon, Figure 2). In some cases, it might be preferable to start the next sequenced animation immediately when the previous animation is done instead of requiring user input. The developer can for such cases set the sequence type value in an instruction to wait and be played when the previous animation is done, AfterPrevious, (indicated by a clock icon, Figure 2). For cases where multiple animations should be played simultaneously, such as repetitive screwing of multiple screws, the developer can set the sequence type value in instruction to play the animation when the previous sequence animation starts playing, WithPrevious, (indicated by an arrow icon, Figure 2).

Alternative Sequences (AS) are pre-prepared solutions or modifications to foreseeable changes or issues that can be required to conduct a SOP correctly. From meetings and observations, AS has been identified as a possible interactive functionality where it opens the possibility to develop SOPs and visualize alternative construction solutions that existed but were not included.

AS is integrated with the modularity and interactivity of the method to allow the selection between multiple assembly sequence alternatives. AS modifies the WI sequence within a specific SOP, indicated by the circle icon as seen in Figure 2. Due to AS modifying data within SOPs in real-time, having and caching lists of precaution notices, task durations and resources, which according to theories mentioned before exist in SOP is no longer possible. The information has instead been moved to the individual instructions. With that, SOP now has access to this data through its list of WI, meaning that it dynamically collects data from instructions in accordance with the animation. These dynamically generated lists can later be presented to the user. As it is built on using modular WIs, it is possible for the user to swap modules of WI with other modules.

Sequence details are parameters available within SOPs. The parameter can modify the sequence type and task duration values for all instructions of the SOP. Sequence details were developed to utilize the instances and modularization of SOP by making it possible to use a single SOP in multiple different levels of detail, instead of being required to recreate the SOP or a variety that needs to be modified manually. As an example, in Figure 2, the SOP “Roof Cassette Montage” is using a sequence detail value of Low Detail, while “Roof Cassette & Gable Montage” is using Normal Detail. Both of the SOPs contain instances of the same main WI “Roof Cassette Assembly”, we can however see that their instructions have different sequence types due to their sequence detail.

Sequence details follow rulesets defined by the developer to determine how the sequence type and task duration modifications occur. A ruleset can be based on fixed values but also instructions sequence order, such as first or last sequence. By default, a higher sequence detail value results in fewer simultaneous but more total animations. This corresponds to a more detailed instruction with more steps. Example of a sequence detail ruleset:

- Very High Detail: All Sequence Types to OnClick
- High Detail: WithPrevious to AfterPrevious
- Normal Detail: Preassigned values
- Low Detail: OnClick to AfterPrevious & AfterPrevious to WithPrevious
- Very Low Detail: All Sequence Types to WithPrevious

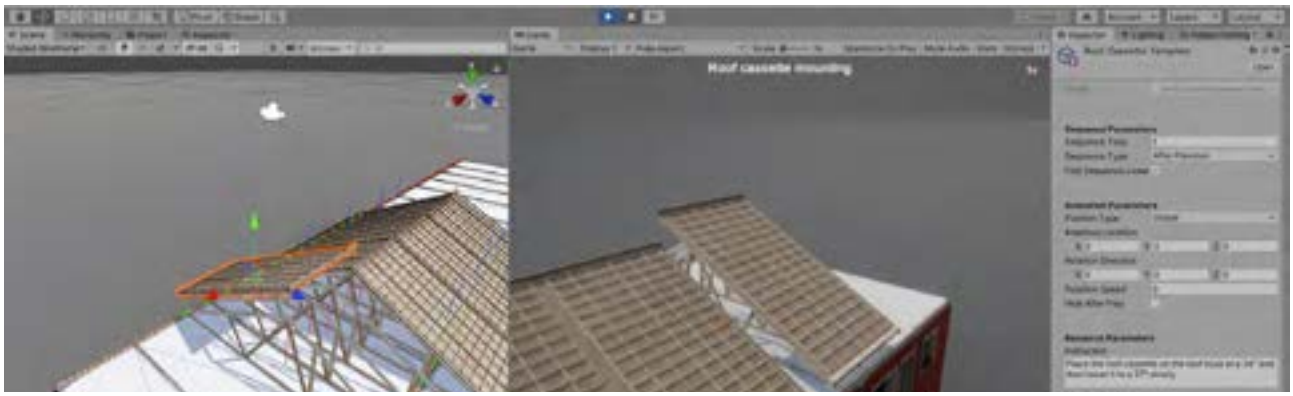

Figure 1. Prototype in Unity. Selected roof cassette (left, Scene tab) is using a Roof Cassette template (right, Inspector tab). Template information is utilized to visualize it (middle, Game tab).

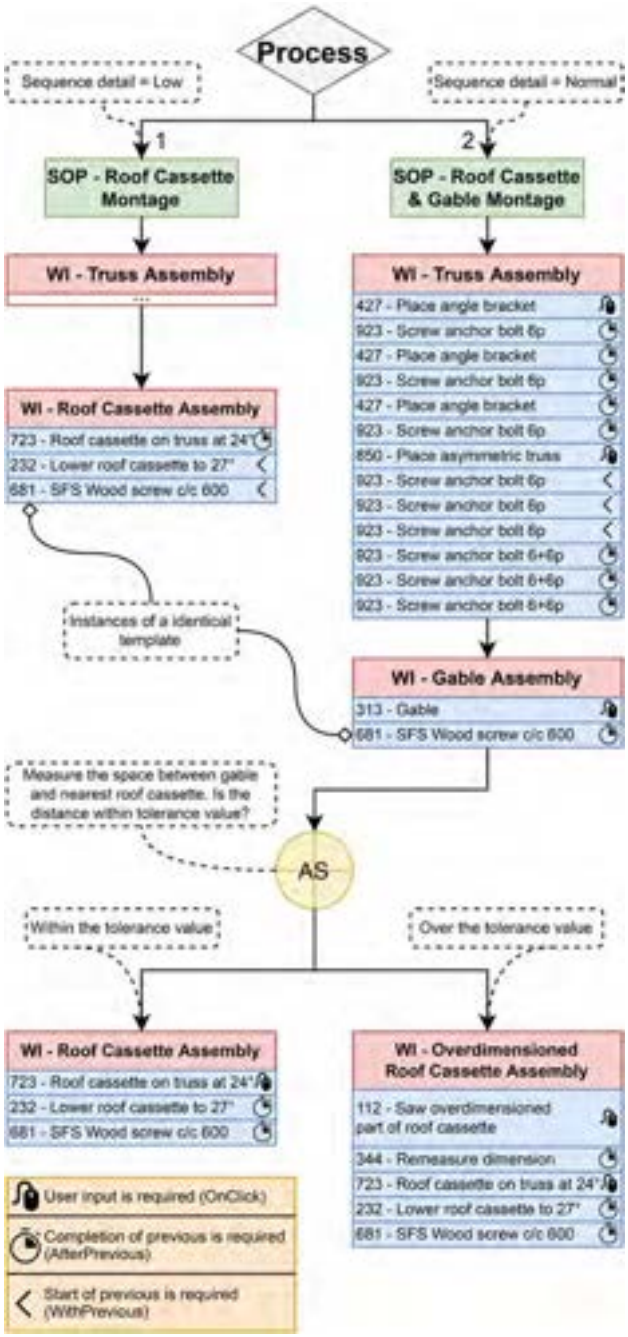

Figure 2. Data model for the developed conceptual model, identifying relations for SOP instances, WI instances, AS and instructional templates. Sequence type and sequence detail effect on instruction templates is also visualized in the diagram.

The use of modularity has been an essential factor for the development of SOPs, WIs and instruction templates. It has aided in the reduction of data redundancy by supporting reuse, updating and maintenance with the prototype. The main SOPs, WIs and instructional templates are developed from scratch. Variants and copies of SOPs as well as WIs are instanced, giving the potential to modify and update the main SOPs and WIs to automatically push the changes to all instances. Examples of main and instanced SOPs include the SOP "Roof Cassette Montage", which is a main SOP, and the SOP "Roof Cassette & Gable Montage", which is a variant from it (where a WI and an AS module are added to it), see Figure 2.

As for instructional templates, the components are using templates to pull data. The SOPs, WIs and template-based instructions are interchangeable, organizable and are decoupled from other SOPs, WIs and templates respectively. Modularization of instruction templates is developed to avoid the need of component instancing and data pushing. For example, 3 components in 2 main WIs are using an identical template "681 – SFS Wood screw c/c 600", as seen in Figure 2. This is desirable because components, in addition to containing identical data, also contain multiple unique data, such as geometrical, positional and rotational data.

4.2 Interactive prototype development

The developed method workflow is divided into 5 phases. First, the initiation phase, see green in Figure 4, where additional data is generated and cached for core functionalities of the prototype. It starts with initializing all components, SOPs, WIs, and instructions. Each SOP that has its sequence detail value changed from normal, gets its instruction sequence type values modified (OnClick, AfterPrevious, WithPrevious). That occurs according to the sequence detail as well as pre-defined rulesets by the developer. To identify animation paths for each component, their original position and rotation data (originalPosition & originalRotation) are cached. Afterwards, through addition with the adaptive values (adaptivePosition & adaptiveRotation), the start position and rotation (startPosition & startRotation) are calculated. Direction of the local axis is considered into the calculation, when the local option is selected. For each instruction not played simultaneously (Sequence Type != WithPrevious), it has its next sequence instruction checked, if any exist, to find out if that instruction needs to be simultaneously played (Sequence Type = WithPrevious). The instruction is added to a list of instructions planned to be animated simultaneously with the original instruction (simultaneousInstructions list), the method loops continuously until either finding no more sequenced instruction or finding a non-simultaneous instruction. The method, lastly in the first phase, disables and hides all component instructions for them to be later enabled and displayed when animated.

The second phase, see orange in Figure 4, focuses on searching for the next sequenced instruction within SOP-WI. A procedure to search for the next sequence starts.

This procedure can be called for multiple reasons, including when the user tries to view the next sequenced instruction. The SOPs, WIs and instructions are sequentially organized. Therefore, using current instructions sequence index + 1 in comparison with the total number of instructions within the WI, it is identified if there are more instructions available to be selected. However, if there are no more instructions available, using current WI sequence index + 1 in comparison with the total number of WI within the SOP identifies if there are more WIs available to be selected. The method selects found WI and selects the first available instruction. Otherwise, if none is found, using the current SOP sequence index + 1 in comparison with the total number of SOPs within the Process identifies if there are more SOPs available to be selected. If the method finds a new SOP, it gets selected together with the first sequenced WI/AS, with also a selection of the first instruction in case of it being a WI. The user is prompted to select one of the available AS options, if the first sequence was instead an AS, Figure 3. When none of the above processes can find a new instruction, the method identifies that no more instructions are available.

For the third phase, see blue in Figure 4, to start, the second phase must find a new instruction. The method utilizes the components' instruction data to animate them accordingly. The method ensures to loop through and animate all components if the instruction has simultaneously planned instructions to be animated (simultaneousInstructions list), else it only animates the selected instructions. The selected instruction is moved to its start position and rotation (startPosition & startRotation) and is made visible to the user. Through linear interpolation, it is possible (with a timer counting the duration of instruction animation as an interpolant) to calculate and animate a moving and rotation pattern for the component. This is a continuous process, until the component reaches its original position and rotation (originalPosition & originalRotation). Using the method in the second phase, the next sequenced instruction is searched. If found, and found instruction is planned to be animated immediately afterwards (Sequence Type = AfterPrevious), the next sequenced instructions animation is started.

Figure 4. AS, user selects a WI from list to modify current SOP. Including step-by-step instructions.

The fourth phase, see yellow in Figure 4, is simultaneously run with the third phase. This phase moves the camera to target the animated components. Using an orbit camera, it is possible, by moving the camera target, to rotate around and view the current instruction. An orbit camera also opens the possibility to zoom in/out (distance parameter). To customize and pre-define the camera viewpoint, two new parameters were added in the prototype to each component of all instructions, rotation (x & y) and distance. Through linear

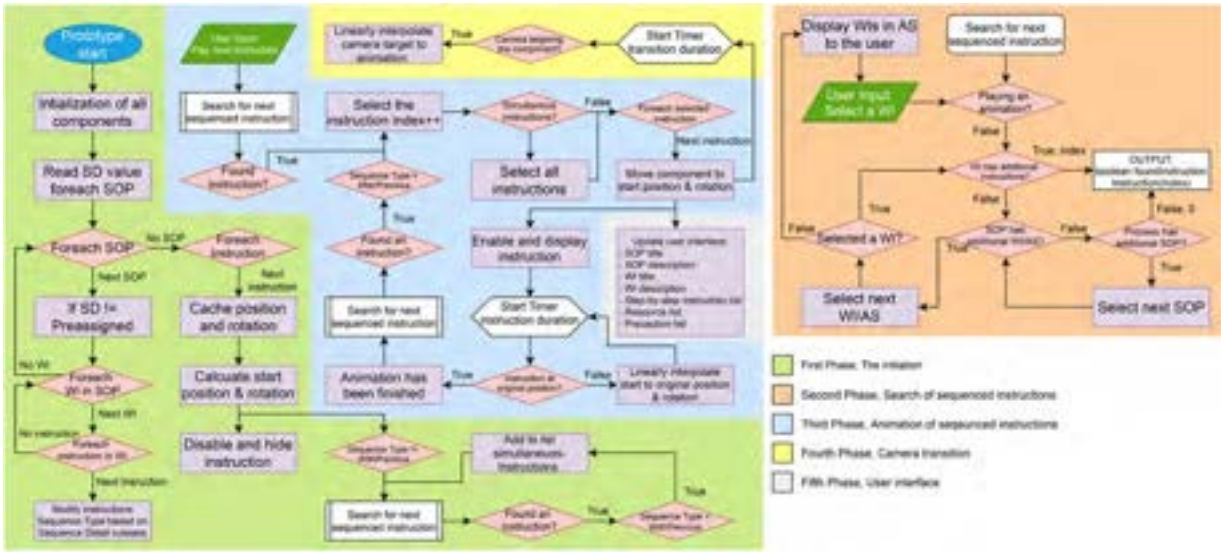

Figure 3. Flowchart of the prototype using the iteratively developed method.

interpolation, in combination with a transition duration timer as the interpolant, the camera glides to its target from its current position to its target position. In addition, linear interpolation occurs even for rotation and distance, ensuring a smooth rotation and modification of the camera's distance to the component's values.

The fifth phase, see gray in Figure 4, runs simultaneously with the second phase. This phase ensures that the user interface is functioning and displaying updated information. The user interface, Figure 5, to not overload the user, only presents the basic information. With additional information being only available when requested by the user. With each newly started animation of a component, its instruction data with description, resources and precautions are added to a list and presented to the user when requested. When a new SOP or WI is selected, the SOP and WI titles as well as descriptions are updated and can be presented to the user. The list is cleared when the selected SOP changes. Combining it all together results in a prototype that can be exported and utilized by a variety of devices for usage in construction sites, see Figure 5.

Figure 5. Prototype running on Android smartphone.

5 Discussion & Conclusion

According to the study, onsite construction at an IHB company has shown to utilize many repetitive processes as well as variants of these processes. Development of a method for the conception and usage of modular SOPs (main & instances), WIs (main & instances) and instructional templates has opened the possibility for reuse of information and experience within multiple construction projects, reducing data redundancy and in turn even decreasing lead times. Reusability of modular AS has encouraged the IHB company to increase their SOP quality by putting more resources into their development and identifying foreseeable issues.

Interactively defining modular SOPs, WIs and instructions has shown the potential to simplify and streamline the assembly sequence process with data within SOPs, etc. The structure of main and instances as well as templates ensured that modifications to mains and templates updated all instances accordingly, aside from unique values within said instances. The interactive modularity has aided the creation of unique variants for mains and templates that later can be utilized in the creation of instances and their connection to components, respectively.

Interactive visualization of modular SOPs, WIs and instructions with user inputs, accurate information and animations have been described by interviewees using the prototype as a usable and useful tool. This, combined with 3D models, potentially gives an improved holistic view of the construction project, assembly process sequence as well as step-by-step instructions that otherwise with many shop drawings and information sources was difficult to obtain. It has assisted the communication between site managers, foremen and skilled workers, resulting in earlier identification of misinterpretations and misassumptions that traditionally instead were identified during the assembly process by foremen. For inexperienced skilled workers and new processes, visualization of the assembly sequence is seen as a massive help in describing and educating how an assembly is correctly performed. Also, ensuring that site managers, foremen and skilled workers have a similar understanding of the construction's assembly processes. Reducing communication deficiencies that can occur due to actors having different backgrounds, experiences or standards is a key to reducing man-made errors. This is supported by theory, as 3D models and good quality instructions could be used for training of new assembly processes as well as for new skilled workers [3]. According to interviewees, inclusion of the developed prototype as a complimentary data source in construction site has shown to bring the typically occurring misinterpretations and misassumptions into the open. With many of them being due to usage of outdated and incorrect versions of the text-based instructions. Prior to usage of the prototype, interviewed skilled workers were certain that their processes were up to the standard set by the company. However, after inclusion of the prototype, they were able to identify multiple processes that are being conducted differently, noting that this is how they used to do it before.

Development of SOPs, WIs and instructions combined with detailed 3D models has been shown in the study to aid project engineers in the identification and mapping process of assembly sequences, their optimization possibilities, sequence errors as well as possible misinterpretations in early stages of the development. Leading to an improved holistic view for process sequence of the construction when the

information is joined together and in turn minimizing possible process errors by improving planning for parameters such as object collisions, zones (reachable & unreachable), avoidance of uncomfortable and risky working conditions. Many of these optimizations and sequence errors are traditionally identified at later stages by foremen and skilled workers, which are often communicated to project engineers. The prototype is expected to increase the construction efficiency by:

- Reducing the required education time of inexperienced skilled workers.
- Reducing misunderstandings and misinterpretations of the standardized processes.
- Visualization of critical sequences, safety instructions, tools and materials.
- Simplifying the conduction of self-control.
- Assisting the daily follow-up of construction job planning.

As a complementary result of the study, improved feedback loops between skilled workers and engineers was observed at early stages using the developed prototype, for assisting in assembly sequence and construction processes.

Acknowledgements

This research study was made in the research project Connected Building Site funded by the Swedish Governmental Agency for Innovation (VINNOVA). Connected Building site is a testbed on digitization of construction with a focus on site planning, production and supply. We thank interviewees as well as construction companies for their incentive and effort.

A Framework for Augmented Reality Assisted Structural Embedment Inspection

Jeffrey Kim[a] and Darren Olsen[a]

[a]McWhorter School of Building Science, Auburn University, United States
E-mail: jeff.kim@auburn.edu, dao0002@auburn.edu

Abstract –

Embedments (embeds) placed in concrete or masonry structures are used extensively in construction to connect the final product of one trade-contractor's work to another and are therefore, a critical coordination facet for most construction projects. A failure in this coordination usually leads to lost productivity. Therefore, the need to productively improve the installation quality is paramount. A between-groups experimental study was designed to measure embed placement accuracy within an experimental space. One group inspected the work with a 2-dimensional set of construction plans while another group carried out the work with the assistance of an augmented reality (AR) inspection tool. An AR headset was used that presented a parametric model as a visual overlay on the walls of the experimental space. In this way, the embed placement accuracy could be inspected. The results indicated that accuracy was weakly significant between the two methods of embed inspection. However, a shortcoming discovered during the research required the precision of the AR tool to be tuned because of an image drift within the AR visualization. This paper analyzes the AR shortcoming, differences in accuracy, proposes reasons for the differences, and addresses the accuracy trade-off in a broader context of the framework.

Keywords –

Augmented Reality; Productivity; Construction Inspections; Embeds

1 Introduction

Construction coordination is a risk that is customarily assigned to the construction manager of a project. While the construction manager is often rewarded commensurate with accepting this risk, there is often a desire for them to develop better ways to manage this risk. Pre and post construction inspections are one way that construction managers have mitigated their risk, but sometimes this process fails. Sometimes, a lack of time becomes the root cause [1] and defects end up costing the project time and money.

In this research, we explore a framework that addresses inspection defects with the understanding of the pivotal role that this process plays in a project's productivity and for its success.

2 Background and Rationale

Concrete and masonry anchors are commonly used for the attachment of other structural members to concrete and masonry. In construction and civil engineering disciplines they are commonly called embedments (embeds). It is best if they can be installed prior to the completion of the concrete or masonry structure [2]. Failure to place embeds prior to the concrete or masonry construction can be problematic for several reasons [3], [4], some of which include:

1. Drilling holes for a post-installation anchor will often hit or compromise the internal steel reinforcing
2. Lost time to re-design and retrofit the structure for a post-installation anchor
3. Added cost of re-design and specialized post-installation anchors

Augmented reality (AR) is a technology that is used to add supplemental information to a real-world view [5]. By adding this meta-information to a person's perception of the real-world view, more insight may be gained by the viewer of what is being observed [6]. AR is quickly finding practicality in the construction industry and some researchers are beginning to refine the ways by which AR can be used for inspection of defects [4]. When inspectors can gain additional insights about what they are observing, they can enhance their work and help to resolve issues prior to construction, when cost and time are less vulnerable to inflationary change [7].

The process of embed placement prior to the construction of concrete and masonry structures is one such situation on a construction project that is

vulnerable to cost and time inflation if they are missed or improperly installed. Therefore, the need for this research was determined based on this observed dilemma and the aim for this research is to use AR technology to assist an inspector in the process of defect detection of embed placement.

3 Methodology

This study was conducted using a between-groups design. One group of randomly selected students were chosen to perform an inspection of installed embeds using 2-dimensional (2D) embed placement drawings. The other group was randomly selected to conduct the same inspection using an AR inspection tool. The following section describes the setting, tools, and procedures that each group was to follow.

3.1 Demographics

A convenience sample was used consisting of postsecondary students in a construction management program in the Southeastern United States. These students were requested to participate in this study at a normally scheduled class time. Students in this CM program, at this point and time in their academic career, have taken plan reading courses, understand building information modeling practices, and several of the students have had some construction-related internships.

3.2 Setting

The study was conducted in a vacant space within the academic building where the students take their classes. This indoor space is approximately 54'-0" long (16.5 m) and 12'-6" wide (3.8 m). The height of the room is 17'-0" (5.2 m) with no finished ceiling – all MEP equipment, conduit, and piping are exposed. On the long side of the room is a 30'-8" x 12'-6" (9.4 m x 3.8 M) window wall, which does not have any window treatments and allows an abundance of outdoor natural light within the space. Refer to Figure 1 for a composite layout of the experiment room.

Figure 1. Rendering of the experiment room

The room in Figure 1 has exposed masonry walls and provided a setting to place mockup embeds on the walls of the space. A parametric model of the room was created in *Autodesk's Revit* and embeds were positioned throughout the room as shown in the closeup rendering of one side of the room (see Figure 2).

Figure 2. Closeup within the parametric model of experiment room showing embed placement

Some embeds were designed to simulate steel angles (colored yellow) and others were designed to simulate flat plates (colored green). Upon completing the parametric model, the embed coordinates were loaded into a total station and the researchers positioned the mockup embeds within the room to match their locations in the parametric model.

3.3 The Embeds

The mockup embeds were fabricated from colored cardboard and matched the color of the embeds in the rendering shown in Figure 2. A *Microsoft* first generation *HoloLens* was used for the AR inspection. The researchers used *HoloLive* and *Visual Live* to upload the model into the HoloLens and for the inspection of the mockup embeds. Figure 3 illustrates the workflow involved in transitioning the parametric model coordinates to the total station that was used to layout the mockup embeds in the experiment room.

Figure 3. Workflow for migrating parametric model information to a total station for embed layout

The researchers preselected that some of the embeds would be placed with identifiable issues. The student-inspectors would have to identify these preselected issues. These issues are summarized below along with the frequency of their use identified in Table 1. The embed issues (listed below) were categorized into three *Issue Categories*.

1. Embed was installed with no issues
2. Embed was installed but has a placement issue
3. Embed was NOT installed

Table 1. Embed configuration

Embed ID	Status	Color	Issue Category
10	Installed	Yellow	1
12 Left	Missing	Yellow	3
12 Right	Installed	Yellow	1
14	Installed	Yellow	1
15	Missing	Yellow	3
16	Missing	Yellow	3
21	Installed	Yellow	1
23	Installed	Yellow	1
A	Installed	Green	1
B	Installed	Green	1
D	Installed	Greed	1
G	Installed	Green	1
P	Missing	Green	3
Q	Installed	Green	1
S	Installed	Green	1
TOTAL 15 Embeds			

Lastly, once the coordinates for each embed was determined, the researchers affixed the mockup embeds to the wall as shown in Figure 4.

Figure 4. Mockup embeds placed in the experiment room (descriptions are shown for clarity but were not included in the experiment room)

3.4 2D Embed Placement Drawings

The parametric model was used to create 2D embed placement drawings. These drawings were printed on 8 ½" x 11" paper without color. The 2D drawings used interior elevations and annotated dimensions to locate the embed within the experiment room. An example of the 2D embed placement drawing is shown in Figure 5.

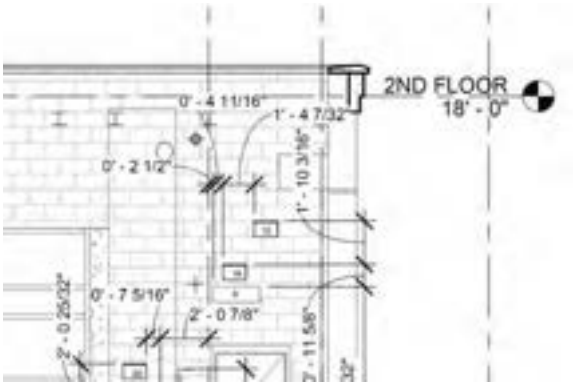

Figure 5. Partial image of 2D embed placement drawings

Students using the 2D placement drawings were to visually compare what they observed on the 2D drawings, matching to what was installed within the experiment room.

3.5 AR Inspection

Students using the HoloLens were to visually observe where they perceived a difference between the image rendered in the HoloLens' overlay of the room to the installed condition within the experiment room. Figure 6 shows what an inspector using the HoloLens would see when inspecting embeds in the experiment room.

Figure 6. Framework of inspecting embeds using AR

The use of the HoloLens in this way allowed for the student inspector to view the correct placement through a model of the room that was superimposed on the visual of the *real-world* experiment room.

3.6 Experiment Procedures

As mentioned, this experiment was designed as a between-groups procedure. The students were randomly selected to conduct an inspection of the experiment room's embed layout using either 2D embed placement drawings or using the HoloLens for inspection.

All students were asked to record their findings on a paper inspection sheet. Because AR does not completely replace the view of the user, the student inspectors were able to report their findings on the paper inspection sheet. Both groups of students used the same type of inspection sheet to record their findings. The inspection sheet contained numbers ranging from 1 to 31 and letters A through Z. With both methods, if the student identified an error, they were asked to record the problem on the inspection sheet with the associated embed identification (number or letter). There were more numbers and letters on the inspection sheet than were embeds placed within the experiment room. This open-endedness was purposefully designed to control for a situation where students may assume that all embeds on the inspection sheet needed to be identified to properly complete the inspection. All inspection sheets were collected and tabulated at the end of the experiment.

4 Data and Results

A total of 46 students participated in the experiment. 25 students used the 2D embed placement drawings to conduct the inspection while 21 students used the AR inspection method.

Table 2 tabulates the error frequency for each of the 15 embeds used in this experiment grouped by inspection method. An error was determined if the student inspector did not accurately identify the installation state of the mockup embeds. While conducting the experiment, some students using the AR inspection reported seeing illusions that obscured the reality of what was installed within the experiment room. The researchers identified these visual anomalies as *mirages* in Table 2. The frequencies identified for the *AR Inspection Errors* is independent of the *AR Mirage Errors*.

Table 2. Embed error frequency for each inspection method

Embed ID	2D Embed Placement Drawings Errors (n=25)	AR Inspection Errors (n=21)	AR Mirage Errors
10	1	1	-
12 Left	-	-	-
12 Right	-	-	-
14	3	4	1
15	24	11	1
16	-	4	1
21	22	1	-
23	-	1	-
26	-	-	1†
A	-	-	-
B	-	-	-
D	-	-	-
G	-	1	1
P	1	5	1
Q	-	1	-
S	-	2	2

† denotes an embed that was identified as a mirage and not a part of the experiment.

The researchers tabulated the errors per embed ID and calculated an accuracy score for each inspection method. The average accuracy for the 2D embed placement drawings was 86.4 out of a possible perfect score of 100. The average accuracy for the AR inspection method (not including the observed mirages) was 90.2 out of a possible perfect score of 100. A Two-Sample T-Test was calculated for the difference between the two averages. Eight outlier results were

excluded to correct for skewness of the data. Assuming a Confidence Interval percentage of 95% (*CI*=95%) then $t_{(38)}$=-2.281802, p=0.0342029 ($p \leq 0.05$), resulting in a weak significance in the difference between the two averages.

5 Discussion

The weak significance resulting from the difference between the average accuracy scores for both methods leads to a conclusion that is somewhat indeterminant. In this section, the impact of the results are discussed along with suggestions for the outcome.

5.1 Visibility

The experiments were conducted during day-light hours. With the room lighting and the allowable natural light in the room, there were no significant shadows or dark areas of the room that could notably affect either method of visual inspection. Despite this fact, the data indicate that identification of embeds "15" and "21" were more successful when the AR method of inspection was used. Embed "15" was accurately reported 4% of the time using the 2D placement drawings and 48% using the AR inspection. Embed "21" was accurately reported 12% of the time using the 2D placement drawings and 95% using the AR inspection. Both embeds were simulated steel angles (yellow) and place in a *side* view when observed from the elevation view of the wall (example embed "15" shown in Figure 7). One embed was missing (embed "15") and the other was installed (embed "21" see Figure 8).

Figure 7. Placement of embed "15" (side view)

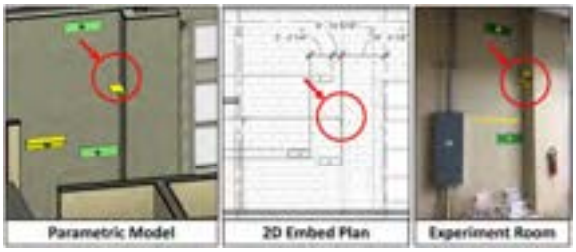

Figure 8. Placement of embed "21" (side view)

The low profile of these embeds on the 2D placement plans made it difficult to verify, especially when the embed was missing, as is the case for embed "15". This condition is a reality for most construction projects. If an inspector takes 2D plans to the field for inspection and only observes what is available to them in an *elevation* view without querying for alternate *detail* views – omissions can occur. With the AR inspection, the original model is available, and an infinite amount of *views* are available to them by simply adjusting their physical position on the construction site – much like an inspector naturally does to inspect installed work at a construction project. Lastly, although the condition was not tested in this study, the embeds tend to be distinguished during the inspection process because a *colored* view was available during the inspection process using the HoloLens. Conversely, the monochromatic view when looking at 2D construction plans does not have this advantage which is why most inspectors tend to highlight their inspection drawings with colored annotations.

5.2 Accuracy

The findings are not strongly significant for the AR inspection method and the data indicate that the 2D embed placement plans were in most cases equally accurate. Aside from the visibility issue discussed for embeds "15" and "21" in the previous subsection, most of the time, the 2D plan inspection method had slightly fewer errors. For instance, embed "16" was a missing embed and was erroneously reported five times with the AR method. It was not erroneously reported using the 2D plan method. Additionally, embed "P" was also a missing embed and erroneously reported once with the 2D plan method and five times with the AR method. Nothing was controlled in the experiment to gather data for these occurrences; however, it is speculated that something within the AR inspection distracts the viewer while performing their inspection. As will be discussed in the next subsection, illusions were noted that caused some misreporting during the inspection process for the AR inspectors.

5.3 Mirages

During the AR inspection, it was anecdotally noted to the researchers that in some cases, the student inspectors could not see the embed or that there appeared to be an embed present, when in fact it was not. The researchers allowed for this condition by having the student inspectors note the aberrations in their inspection reports. As seen in Table 2, this occurred eight times. In two cases, a missing embed was not accurately identified as missing and in the remaining six cases, the embed was present but was missed in the inspection report.

During the experiment, the researcher needed to continually adjust the HoloLens for a condition called "drift" [8]. Drift was identified by the student inspectors as they conducted their inspection and would notice that the image of the model in the HoloLens was not superimposed accurately within the experiment room. In some cases, the difference was slight – enough so that the inspection could continue without stopping the experiment. At other times, the drift was noticeably distracting to the point that a satisfactory reporting could not be made. It is surmised that this condition was responsible for the mirages present during the inspection. This condition is not localized to the HoloLens, it is in fact a common issue within the AR discipline [9].

5.4 Limitations

While the researchers sought to minimize the conditions of the study that could adversely affect the results, upon completion of the experiment some elements became known that should be considered if the study were to be repeated.

5.4.1 Color and Shape

The researchers did not collect data explicitly regarding the shape and color of the embeds used in this experiment. In fact, the color of the embed was not typical to the actual color of an embed installed on a construction project (see Figure 9).

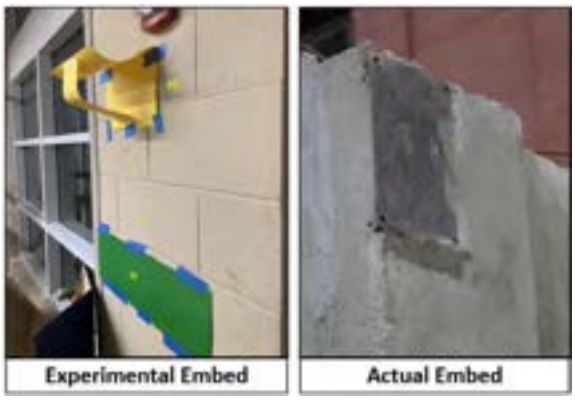

Figure 9. Visual comparison of experimental embed and an actual embed.

The difference between the two images in Figure 9 is obvious. Because this study was designed to establish a framework for future experimentation, it was not necessary to obtain data from actual conditions just yet. In future studies, the color of the surrounding material (concrete, stone, masonry, etc.) may not have enough contrast to make a successful inspection. Therefore, a consideration of the color of the embed and the color of the surrounding materials would be prudent.

5.4.2 Student Work Experience

This study was conducted with a convenience sampling that is not representative of practitioners in the construction industry. While the students that volunteered for this study do have some construction knowledge and skills, they lack experience and advanced visualization skills that more seasoned practitioners may have [6]. Consequently, the results when practitioners are involved in the study may yield different results. Again, future iterations of this study should be conducted with practitioners to obtain more practical results in the accuracy of inspection using the two methods.

5.4.3 Image Drift

Image drift is an issue when working with AR [8], [9]. This study did not collect data for this condition, including its effect on accuracy. However, a more detailed study should be attempted that ascertains the accuracy of the HoloLens when used for inspection, controlling for variables such as lighting (natural and artificial), temperature, reflectivity, and other items that may affect the visual acuity of the inspector.

6 Conclusions and Future Work

This experiment yielded a significance that was weak in terms of accuracy when student inspectors were

trying to identify errors in embed placement. The data however, eluded to some interesting points about using AR as an inspection tool for embed inspections, and quite possibly for other types of inspections as well. In this study, the researchers aimed to create a framework that could be used in ongoing and future studies where AR is used to assist a construction inspector. One key finding that was advantageous when inspectors used the AR method was the visibility of certain elements that were difficult to find on a 2D plan. The drawback with using plans has always been the experience of the person reading and interpreting them [10]. In a time within the construction industry when many seasoned professionals are departing from the workforce [11], either through retirement or disability, their replacements (recent academic graduates) lack the experience to accurately perform these inspections at the same level as their predecessors. This experience gap creates a challenge and an opportunity that the construction industry has always seemed to face. When compared to other non-farming industries, the construction industry's productivity has not made significant improvements [12]. Similarly, the industry's focus on research and development has been paltry – yet may be improving slowly [13]. Therefore, the overarching goal for this research study was to set forth a framework that can improve accuracy, productivity, and fill the ever-widening skills gap in a small part of the construction process.

The researchers acknowledge that the practicality of this tool is *experimental* at the moment, however, through continued field experimentation and with the continual improvement in the hardware and software, there is promise for more advantageous results for the AR method.

Lastly, the researchers would like to express that future developments in this research will include an approach toward having the AR make use of artificial intelligence (AI) for the automatic recognition of embed placement errors. The inspector's attention could be drawn to errors that the AI finds, allowing the inspector to focus more on the serious problems and waste less time on the embeds that meet a certain threshold for accuracy. This process, if perfected, could save a tremendous amount of time for inspectors to perform more worthwhile tasks.

Towards Circular Economy in Architecture by Means of Data-driven Design-to- Robotic-Production

G. Nazzarri [a] and H. Bier [a]

[a] Robotic Building, Faculty of Architecture, University of TU Delft, Netherlands

E-mail: H.H.Bier@tudelft.nl

Abstract –

While the global impact of plastic waste is increasingly concerning, the application of reused materials in the built environment remains little explored. This paper presents research into the reuse of plastic in architecture by means of computational design and robotic fabrication. Design possibilities using reclaimed plastic artefacts were explored by testing their structural stability and robotically modifying them in order to create a pavilion. While the design conceptualization started with the reclaimed material and the analysis of its potential, the digital workflow involved generative and performance- driven design, structural optimization and geometry generation for robotic fabrication.

Robotic fabrication; Circular economy; Reuse; Plastic; Pavilion; Computational design; Waste control; Human-Robot Collaboration

1 Introduction

Applications of Industry 4.0 technologies, such as automation, Internet of Things (IoT), and cyber-physical systems [3] are relatively new in architecture but they have already proven to revolutionize the way architects think and practice.

For instance, Design-to- Robotic-Production (D2RP) approaches developed at TU Delft since 2014 establish a feedback loop between the design and the production of the 1:1 scale building components [1].

This implies that the initial generative design is optimized in order to address functional, structural, environmental, material, etc. requirements and then converted into robotic tool paths to add, remove or transform materials according to requirements.

The challenge is to identify tasks that can be robotized and develop future interaction scenarios between humans and robots. In this paper, work is presented that explores both while taking the challenges of circular economy into account.

2 Circular Economy

Plastics production has increased twentyfold since 1964, reaching 311 million tons in 2014 [4].

Despite the economic crisis, the world plastics request is continuously increasing and it is expected to almost quadruple by 2050. With the increase of the plastic production, the plastic waste increases as well, so much that the ocean is expected to contain by 2050, more plastic waste (by weight) than fish.

Figure 1. The plastic container is tested for structural strength

Currently, this problem is addressed on two levels, firstly the manufacturing of plastic materials from oil is gradually replaced with renewable bio-sourced materials; secondly the recycling or reusing products is considered. When recycling is not the best option because soiled plastics and multi-layered plastic products may not be suitable or difficult i.e. expensive to be recycled, reuse is considered (Fig. 1).

The research presented in this paper explores how by employing D2RP methods and by applying circular economy principles [5], thus reusing objects otherwise designated for the landfill, an approach that can be

applied to various geometries is developed and tested.

The reused objects were searched for in a traditional manner, by going to stores and selecting potentially usable components.

Figure 2. Development of the node from the unrecyclable plastic container using a combination of D2RP and traditional methods

Considering the potential of IoT to connect the D2RP system with materials that are provided with unique identifiers (UIDs) and filter databases for specific plastic materials and products catalogued with respect to their physical and chemical characteristics, it is conceivable that a variety of designs for diverse functions could be easily generated.

2.1 Architectural Structure

From an array of available components, several have been structurally tested and the unrecyclable drill container, which has been chosen to be used in the design, showed a peak close to 80 kg (Figure 1). The test highlighted that the base is the weaker part of the element.

By developing joints (Figure 2) from the drill container that could connect linear frame elements (of Polyvinylchloride or PVC pipes for water supply) with a membrane (of semi-open water repellent fabric) a pavilion has been created (Figure 3).

The vaulted structure has a double-curvature that increases the structural performances. Once inflated, the designed mesh is improved using the Mesh Machine component after which it is tessellated with the Dual Graph component. Joints, PVC pipes, and membrane are then placed resulting in a pavilion that serves as event space.

In order to test structural stability, the mechanical properties of the materials were retrieved from CES Edupack 2018 and used as input for the structural analysis. Furthermore, the structure was analyzed in the Grasshopper plugin Karamba 3D. The latter, being embedded in the parametric design environment of Grasshopper, gives the possibility to combine parametric 3D models with finite element calculations.

Following up the structural analysis, joints, PVC pipes and membrane were further developed and tested. The node was developed by removing and folding parts, so that the folded part of one component fits perfectly into the cut part of another component. The connection is then secured by rivets (Figure 2).

With the robot, the component can be cut at a specific optimum angle in a precise and accurate way. Because of the complexity of the geometry, all the components that form the connections need to be custom cut at a specific angle, thus the use of robotic fabrication will make the process more accurate and faster compared to traditional methods.

The workflow involved several steps such as robotic cutting (drilling holes and material removal), manual folding (with a heat gun), manual gluing of the washers and connecting parts with rivets using pop rivet gun.

While the robotic tool path was integrated into only one path for drilling holes and milling i.e. cutting, which made the process faster and more efficient, the folding of the material of the component itself, the gluing and connecting with rivets remained manual.

Figure 3. Generative design optimized in order to address functional, structural, environmental, material, etc. requirements

The robotization of the folding, gluing, and connecting with rivets would have required additional investigation, which due to time constraints has only been simulated as robot-robot cooperation and envisioned as Human-Robot Collaboration (HRC).

2.2 Human-Robot Collaboration

In order to semi-automate the fabrication of the node, a multi-robot setup has been proposed in combination with an HRC approach. In this context, HRC is defined as work performed simultaneously and co-located by a robot and an operator during production [2].

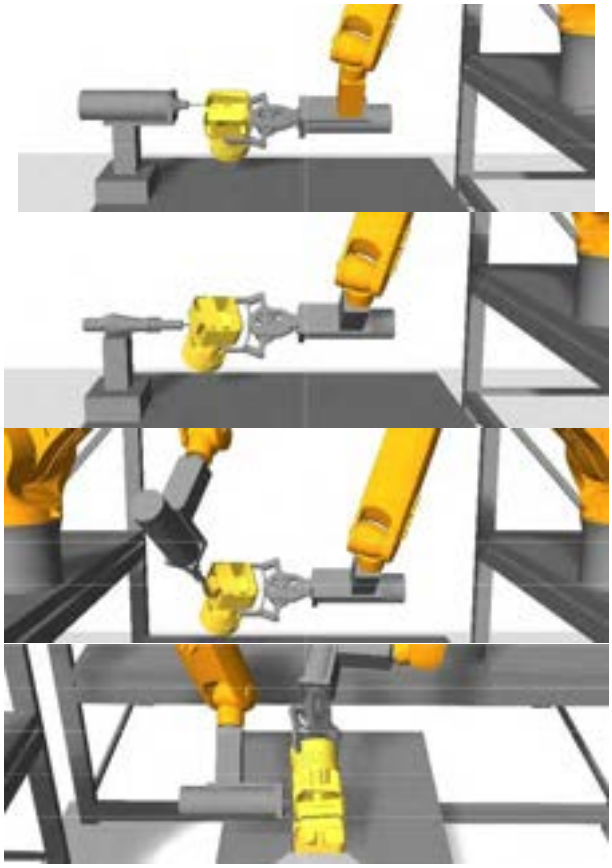

Figure 4. Picking of the first component using the master robot, which is equipped with a gripper, moving then the object around the milling tool and performing the necessary material removal (first image), heating (second image), folding (third image) and placing the rivets (fourth image).

The fabrication sequence of the joints includes two fixed tools, a milling tool and a heat gun, and two moving tools, a gripper and a bolting tool. Hence the component will not be fixed in front of the robot as in the first scenario but it will be moving with it.

The first step of the fabrication sequence will consist in picking up the first component using the master robot, which is equipped with a gripper, moving then the object around the milling tool and performing the necessary material removal (Figure 5).

After that, the object is positioned in front of the heat gun, in order to heat the folding line of the component for one or two minutes, time enough for the plastic to become malleable and for the second robot to come in and easily fold the material using a gripper. The above-mentioned sequence between the two robots is repeated for all the other components.

The last step of the fabrication sequence regards the connection of the objects to each other. The connection will be performed by the second robot, which is equipped with a bolting tool, in collaboration with the master robot, which will hold the component in place.

This proposed HRC approach relies on practical methods facilitating collaborative sawing [7], collaborative polishing [8], etc. It involves limited Artificial Intelligence (AI) that enables the physical collaboration between two robots [7].

This approach is transforming the D2RP process of the joints into a choreography of two cooperating robotic arms alternating their roles along the fabrication process.

In this context, the human may not only orchestrate the sequence of actions implemented by the robots but may help with tasks that could be easier implemented by humans as for instance, inserting the rivets in the holes.

3 Future Steps: Cyber-physical Systems

While the presented research has taken advantage of D2RP and explored the potential of human-robot cooperation, it has not exploited the potential of IoT, which allows selection of materials form a vast variety of materials appropriate for circular economy approaches.

It furthermore, speculated but did not develop and test HRC approaches, which have the potential to make the sequence and safety of human-robot interaction possible.

Figure 5. Simulated and prototyped subtractive D2RP link the virtual and the physical worlds

Both involve tagging and tracing, machine and deep learning in order to establish a cyber-physical system that in time could become an automation ecosystem, wherein architects and constructors collaborate with robots and

customers can purchase online customizable designs using an automated marketing platform that puts the manufacturing plant in action.

The virtual and the physical D2RP&O processes are linked (Fig. 5) and need to take into account the inherent multifaceted nature of building from the early design to the latest building operation phase. Challenges in terms of scale, multi-tool and multi-robot production and operation need to be examined in order to achieve chained processes by linking virtual models (such as Rhino 3D model with Grasshopper plug-ins such as Millipede, Ladybug, etc. for simulating structural and environmental performance) with robotic devices. The aim is to develop/implement chained D2RP&O processes in which robots take specific roles while all (human and non-human) members of the setup including respective (virtual and physical) systems receive feedback at all times.

Abstract –

In 2018, the United States Department of Transportation Federal Highway Administration reported that Americans traverse over 1,000 miles a month on average. Maintenance of pavement marking conditions is crucial to creating a safe driving environment. Traditionally, pavement markings are assessed periodically through manual road inspectors. This method is time consuming and ineffective in capturing the deterioration of the pavement markings throughout their service life. The incorporation of Unmanned Aerial Vehicles (UAVs) and machine learning techniques provide promising ground to detect pavement marking defects. The study proposes a system based on Deep Convolutional Neural Network (DCNN) that can collect, store, and process data to predict pavement marking conditions throughout their service life. The developed pavement marking detection tool has four stages. The Data Collection stage consists of obtaining images using different methods. In the Classification stage, a method for assessing the defects from images is created based on current methods by Departments of Transportation (DOTs) and the Manual on Uniform Traffic Control Devices (MUTCD). The third phase— the Model Development and Data Processing— and the Model Testing phase are to train and test the model using a multi-level classification program and complex algorithms to process the data collected and output a result. The system was implemented, and the preliminary results show that the model can identify and classify the pavement marking defects. The developed system will help transportation authorities identify and forecast future deteriorating rates and intervention timing.

1 Introduction

Road pavement markings are a characteristic of road design that influence drivers' perception of roadway alignment and the ability to maintain safe vehicle positioning [8, 17]. Features such as edge lines, centerline, lane lines, and other pavement markings guide users and provide physical and intuitive barriers that ensure road safety and reduction in traffic congestion [17]. When strategically placed, pavement markings ensure adherence to speed limits [3, 21]. Environmental factors and wear from vehicle contact, as well as misplaced markings, call for the inspection and maintenance of these road markings [21].

The current practices of pavement marking inspection are mainly done manually. Manual inspection techniques such as Visual Nighttime Inspection, Measured Retroreflectivity, Expected Service Life, and Blank Replacement methods are a few of the vision-based techniques employed by DOTs to assess and evaluate pavement marking conditions [9]. Handheld devices, measurements, and Senior Citizen vision characterize these methods. These manual methods allow for high subjectivity and rely on trained inspectors that must go through training to follow the appropriate protocols. These visual assessment techniques require investing time, money, and resources. These processes often require workers to drive in nighttime conditions, evaluate, and record pavement conditions that pose public and individual safety risks.

Experimental studies have found short-term and long-term reductions in speed along hazardous curves by installing and maintaining pavement markings [21, 3]. Drops in speed from 41.3 to 33.9 miles per hour were attributed to pavement markings "designed to make the roadways appear narrower at the beginning of the curves." Other sites saw up to a 50% increase in adherence to advisory speed after the pavement marking installations [3]. Additional pavement markings in 42 sites in advance of roundabouts and termination of high-speed roads saw a 52% reduction in crashes after 2 years. Verbal and symbolic pavement markings consisting of the word "SLOW" and a left curve arrow installed before entering sharp horizontal curves also saw significant reductions in average vehicle speeds [3]. Earlier studies showed crash reductions after the installation of edge lines ranging from 19% to 46% [7, 19]. Despite differences in modern days traffic, vehicle design, and design speeds, more studies continue to report crash reductions as a result of

pavement markings. Particularly, a study across 10 states found crash reductions of 36% after installing edge lines and an average of 21% attributed to pavement markings overall [4, 22].

There are two ways of assigning pavement marking defects: manual and automated. A manual evaluation of pavement markings from photogrammetry data would be highly subjective and time-consuming, thus an automated identification method presents an efficient and reliable alternate [2, 13]. This paper aims to propose an innovative UAV-based Pavement Marking Identifier Tool using a deep learning technique that automatically identifies the pavement marking defects. The tool uses data collected from Google Maps to train and test the model. This stage of the research looks at the applicability and efficiency of the technique.

2 Literature Review

2.1 Overview

An assessment of the effects of pavement markings on road safety reveals the importance of identifying and addressing current defects and missing pavement markings. Efforts are underway to mitigate the risks of missing important pavement markings and those in poor condition. For example, the Michigan Department of Transportation (MDOT) plans to require wrong-way arrows at all target exit ramps [18]. At paired exit/entrance ramps, the left turn into the exit has resulted in several fatal crashes. By installing pavement marking extension lines, vehicles could be guided into the correct ramp. They are considered a low-cost treatment with a benefit-cost ratio of 45.9 and the potential to reduce traffic-related deaths and increase road safety [3, 18]. A study was also conducted to assess whether pavement markings before wrong way entries in two sites were in good condition, or at all present [14]. The study found that both sites lacked pavement markings, such as Wrong-Way Arrows and stopping lines, which are linked to a reduction in fatal crashes. Also, in 2004, the Missouri Department of Transportation began implementing lane departure countermeasures consisting of pavement markings such as edge lines, centerlines, and skip lines, as well as other road features focused on lane departure countermeasures [8]. As a result, from 2005 to 2007, there was a 25 percent reduction in lane departure fatalities. Pavement markings wear out due to constant vehicle contact and weathering and therefore require inspection and maintenance. Given the role they play in road safety and the limited resources some cities struggle to keep pavement markings up to the standards due to limited resources. In addition, prioritizing pavement repair and maintenance in a very efficient way is critical for decision-makers to plan future budget allocation and prioritizing road maintenance.

2.2 Data Acquisition

New technologies of real-time data collection such as drones are an increasingly popular technology in construction and transportation [5, 19]. A recent study developed a framework for using UAVs in transportation, which defined the drone block as (1) flight planning, (2) flight implementation, and (3) data acquisition [15]. This framework was implemented by a later study to capture images of pavement defects [14]. This study outlined the importance of taking weather conditions and flight restrictions into account in the flight planning process. This ensured optimized visuals and adherence to regulations. For flight implementation, flights can be conducted manually or autonomously. For automated surveys, an advanced image processing algorithm is required such as Support Vector Machines (SVM) or Structure from Motion (SfM) [12, 13, 2]. These machine learning algorithms allow UAVs to quickly identify the presence of defects and cracks on the road, although they have yet to be implemented to detect defects in pavement markings. The SfM is an innovative photogrammetry method used to transform photo data sets into 3D models; however, research on its applications for road pavement is limited [13]. The data acquisition consists of captured images by the drones. These images are deemed adequate for analyzing and monitoring the condition of unpaved roads [23] and road pavement distresses [13], but there is very limited research in its applications to pavement markings. Data collection via UAVs also mitigates the risks associated with workers in high traffic zones [14].

2.3 Data Processing and Inferencing

Data processing and analysis is critical in developing an automated defects detection system. Efficient data extraction, noise removal, and storage are necessary components to have a functioning system [15]. Manual evaluations of the drone-captured images based on visual observations are associated with high levels of subjectivity, and low production rates [13]. For example, in a study analyzing the condition of road pavement, different crack types were assigned different ratings to assess and prioritize remedial actions according to the severity and average traffic volume [2]. Due to limited resources and a large area to cover, metric accuracy must be consistent [13]. Therefore, automated identification methods and severity numerical index assignments are considered a fundamental goal in transportation efforts to maintain the assets. Autonomous surveys incorporating machine learning algorithms can process the images automatically to identify the distress type [13]. A study that incorporated a UAV-based system with a machine learning algorithm observed an accuracy in pavement

crack identification of 90.16 [12].

Other studies incorporating the use of multi-level classification and deep machine learning to develop predictive models for addressing pavement defect repairs and maintenance continue to advance [25]. These improvements in machine learning models are pivotal to the development of smart cities and autonomous vehicles. Furthermore, deep convolution neural networks (DCNNs) have been implemented to detect pavement cracks and reduce noise [24]. Using datasets for training and testing models set the basis for a system that can characterize road conditions [25].

Multiple studies have also incorporated a Geographic Information System (GIS) to enable automatic visualization of road conditions and automated pavement management [2, 12, 16, 6, and 20]. This system can be used to position classified images into Google Maps [12] and can cover thousands of miles of roadways as well as smaller volume roads [14]. GIS has spatial analysis capabilities that can integrate the graphical display of pavement condition and the assigned prioritization based on classification to facilitate pavement management operations [6, 20]. Currently, the system cannot predict the rate of deterioration of pavement marking based on its current condition but using a Matlab-GIS-based application, it can rate the condition of road segments [2]. Studies integrating this system for the inspection of pavement markings are very limited.

3 Methodology

The proposed framework for the pavement marking identifier tool is outlined in Fig.1. The framework encompasses four stages: (1) data collection using UAV, (2) data classification, (3) model development and training, and (4) model testing.

3.1 Data Collection

In the proposed framework, the data concerning pavement marking condition is collected using either a UAV or a Light Detection and Ranging (LIDAR) device. In this paper, the authors are using the UAV method given the high number of images that can be collected in a short time. For training and testing the model, two sets of data are required. The authors used Google maps and the Google search engine to collect images that show the defects as highlighted in Table 1.

3.2 Data Classification

The data classification phase consists of developing terminology that informs developed framework users of the pavement marking defects present in a surveying site. These terms, as specified in Table 1, are designed to provide a visual evaluation based on criteria outlined in the MUTCD. Per the standards, all lines must be continuous, and uniform in shape. Class 3, 7, and 8 defects address this standard. Lines must also have clear and sharp square edges, as well as be parallel to each other with discernible space. Class 1, 2, 4, 5 address this. Marking visibility and obstruction are addressed in defect classes 6 and 9.

Based on these standards, the set of defects was developed to inform the user when a pavement marking did not fall within these guidelines, as seen in Table 1. This study categorizes the images by lane feature and the associated defect type. These terms can be modified or expanded to suit the needs of any given road segment or the regulations of a company or department of transportation. The output is the class type.

Class 2	Corner Missing
Class 3	Segment Missing
Class 4	Edge Faded
Class 5	Corner Faded
Class 6	Segment Faded
Class 7	Misalignment
Class 8	Cracking
Class 9	Ghost Marking

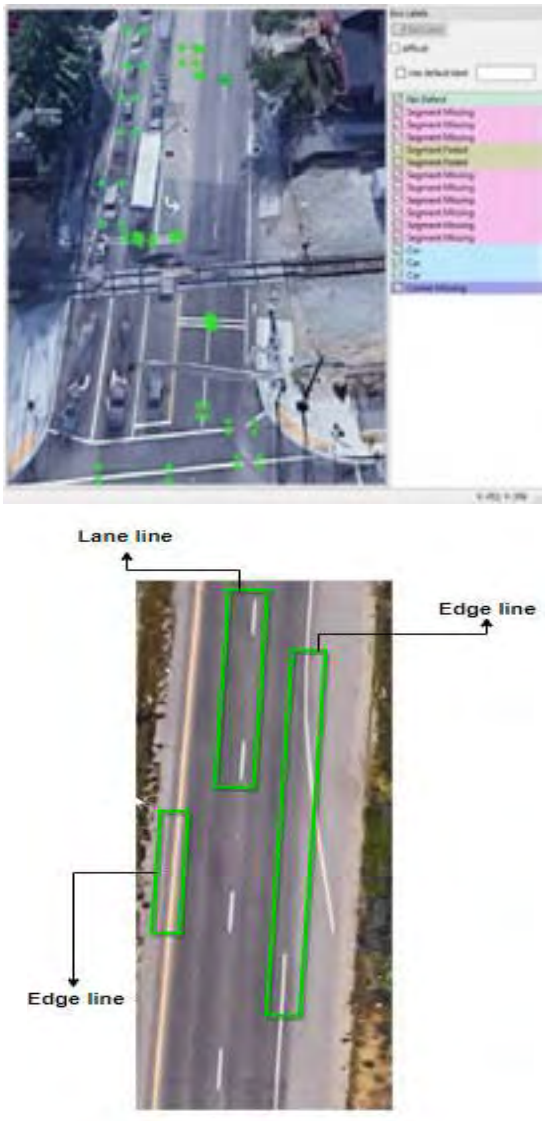

Figure 2. Pavement Marking Annotation and Data Preparation for Model Training

For purposes of this study, lane type identification was added to ensure that the labeling algorithms can differentiate between spacing between dashed center lines and faded sections along a continuous edge line. As seen in Fig. 2 a multilevel classification software was employed in this study in order to annotate the features of the road segment onto the image. This step is essential in developing a reliable and consistent algorithm-based system for future automated classification of roads. The annotations made must be precise and consistent to increase confidence levels. The second round of annotations classifies the markings based on defect types from Table 1. The pavement markings from the training and testing data must be fully categorized to be processed correctly according to MUTCD standards.

3.3 Model Development and Data Processing

3.3.1 Model Development

The model used to detect the objects in the test images was based on a region proposing convolutional neural network (RCNN) written in python. This model initially had the original settings of a pre-trained model called the "faster_rcnn_inception_v2" model from tensor flow's library of packaged models open to anyone for usage and particular implementation. The layers of the neural network were pre-defined for optimal speed and result, and required weights adjusted and optimized for the pavement images.

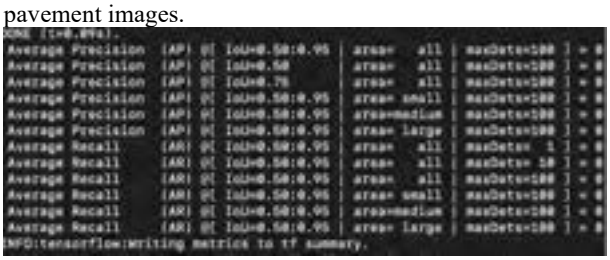

Figure 3. Deep Learning Model Precession Data

3.3.2 Model Training

For this study, this model was trained to identify the specific features of the pavement images. The model was trained using a dataset named pavement marking images (PMI). The model was fed aerial images from Google Maps, which are accessible to all and contain data from roads all over the world. These are updated about every 1-3 years, which renders the satellite-images mostly accurate. Images were captured along the highways of San Luis Obispo County, CA, which were manually inspected and annotated according to the lane type, as seen in Fig. 1, and the defects identified. A multi-level classification program was used in this process.

To train this model, each image's data is passed through the network. Once all the images go through the network, this is considered an epoch. After each epoch,

the weights of the network are changed slightly to yield better predictions on all of the data. 100 training images were collected and annotated and 50 images more were selected for testing.

3.4 Model Testing

The model was only given 80 training images and 20 test images. A snapshot of the model results is shown in Fig. 3. The results of the Validation Data are outlined in the Preliminary Results and Analysis section of this report.

Once all the training and testing images have been processed, the images captured by a UAV, or similar technology, can be automatically processed using complex computer vision algorithms to extract multiple features from the images captured. If these images are annotated consistently and with reduced background noise, the output should be accurate and reliable. The coded data from the collection and classification stage is processed, and its output informs what type of defect, if any, is found along a given road segment.

4 Preliminary Results and Analysis

This study presented preliminary results of the proposed system that automatically predict the pavement marking condition. The proposed deep learning model was trained with a sample of annotated images, and another sample was used for testing purpose. The model was able to predicate road segments with and without pavement marking defects. A group of the defects classified as corner faded and missing were identified with an accuracy of 50% to 80% as shown in Figure 4. Although the model was intended to generate preliminary results using machine learning technique, the results still showed promising trends and levels of confidence for expansion and fine-tuning. The model projected higher accuracy in detecting larger features than small and medium ones. This was expected because larger objects in the image contain more pixels which inform the object detector of what defect it might be, than small and medium-sized features. These results will guide the manual annotation of additional sets of data to enhance the model prediction algorithm. Annotating defects in images, and ensuring less noise within the boundary circling the defects was found to be critical for the model accuracy.

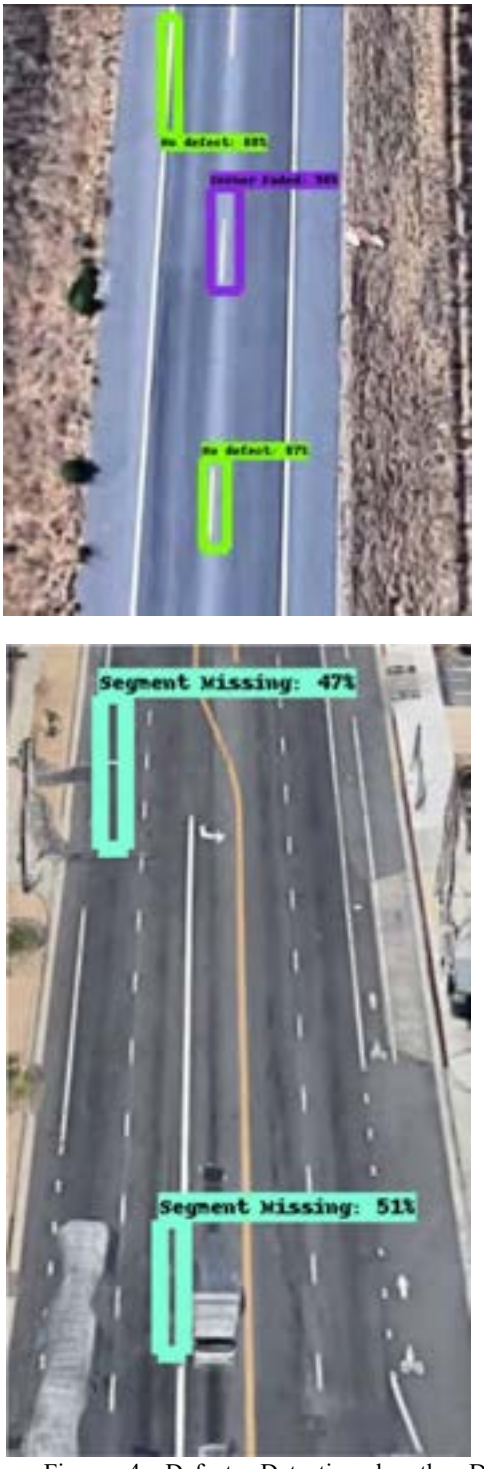

Figure 4. Defects Detection by the Deep Learning Model

Despite the small number of data sets used to train and test the model, the deep learning model was able to

predict road pavement defects with over 50% confidence. In some instances, it predicted the defects with 80% confidence, as shown in Fig. 4. These results also yield increased confidence in identifying pavement markings without defects. This was expected since faded segments vary in levels of marking deterioration and visibility, while pavement markings in good condition are similar in contrast to the pavement in their clean-cut edges. The results of the model were validated manually by comparing the model outcomes with the manually annotated images.

These results inform us of the current condition of pavement markings in the area, as well as which road segments require immediate attention, and which should be monitored. The preliminary state of these results cannot replace traditional methods for pavement marking inspection, but it can still inform road agencies of which road segments output the most defects in an initial site survey using a drone. By expanding the training and testing data, these results could be used to predict the remaining service life of each road segment captured.

Lastly, the results of this pavement marking identifier tool are expected to show an increase in safety, a reduction of labor and equipment-associated costs, a fast identification of defects, and expedited repairs.

5 Conclusion

In this paper, a method for assessing and predicting pavement marking defects using machine learning was presented. Images extracted from a satellite imagery web-mapping service were processed to create a dataset of over 100 annotated images. For image optimization, images compiled were carefully annotated to ensure noise reduction, consistency, and proper labeling. The method employed in this paper used images in PASCAL VOC in a multi-level classification program. For image annotations, tighter rectangles enclosing road features were found to produce results that are more accurate. The preliminary results show higher accuracy and detection for larger segments and most common features. These show potential in an integrated manual identification of pavement marking defects and a python-based image extractor software. Future research will be focused on integrating retroreflectivity analysis and reading into the model to better resemble the standard maintenance protocols used by departments of transportation. This will result in a comprehensive system for assessing, monitoring, and maintaining roads. By implementing this model, drones can automatically detect and classify the pavement marking defect classes. The machine-learning-based methods employed in this research are accessible, cost-effective, and relatively safe to conduct pavement marking assessments and evaluations. With enough data and proper annotation, the model developed can detect marking defects from an aerial view using different camera views. This reduces labor and equipment costs otherwise incurred from manual inspection and reduces the risk of construction-related accidents from placing workers in high-speed roads. The improvement of machine learning models for maintaining pavement markings up to standard is essential for the digital maps integrated into the programming of AV's to detect road surface markers (RSMs). By maintaining roads up to MUTCD standards, AV machine learning can detect the necessary road features to allow for the integration of autonomous vehicles on our roads. Improved roads pave the way for improved cars, transportation systems, and societies.

In the future, this study will be extended to address the relationship between road defects and road pavement marking defects. Many studies suggest that the causes that contribute to pavement defects also contribute to pavement marking defects.

Abstract -

A teleoperated hydraulic excavator is introduced to perform safe and quick restoration work in sites affected by disasters. However, the current efficiency of this system is approximately 40–60%, compared to boarding an actual hydraulic excavator, because of the communication delay. To reduce this delay, we developed a system that can display the predicted position of the excavator attachment to the operator. For predicting the movement of the hydraulic excavator relative to the lever input, it is necessary to consider the dynamic characteristics of the hydraulic excavator. In this study, the dynamic characteristics of the turning motion of the hydraulic excavator were assumed to be the first-order delay with a dead time system, followed by the construction of the turning motion simulator of the hydraulic excavator. Through an experiment in which the bucket tip was stopped toward the target position, the operational time was confirmed to be significantly shortened by displaying the predicted position.

Teleoperated hydraulic excavator; Swinging motion; Interface; Communication delay

1 Introduction

Hydraulic excavators often operate in dangerous locations, such as disaster sites. Recently, teleoperated hydraulic excavators have been introduced and have gradually become mainstream, through which several unmanned construction works have been carried out [1, 2, 3]. However, it is believed to have approximately 40–60% work efficiency compared to an actual machine boarding. Thus, the performance improvement of the teleoperated hydraulic excavator is necessary. Communication delays are one of the factors that reduce work efficiency. Michael et al. [4] investigated the effect of time delay on the surgical performance of teleoperated surgery and confirmed that the accuracy of moving the remote surgery robot decreased as the time delay increased. In the teleoperated system of a hydraulic excavator, Sugawara et al. [5] achieved high picture quality with low image delay and confirmed the operational efficiency improvement through simulation. However, for a teleoperated hydraulic excavator, which is supposed to be utilized in various work sites, secure and stable communication cannot always be guaranteed. Consequently, eliminating communication delay is challenging. Therefore, a technique that can improve work efficiency, even when communication delay exists, is necessary. Richter et al. [6] developed a system to predict a position without time delay to an operator in a teleoperated manipulation robot. When positioning was difficult, the ring was picked up by one arm and placed back after passing it to another arm. By evaluating the operating hours, with and without the proposed system, a significant difference was confirmed. Walker et al. [7] showed that the operation could be facilitated using a virtual aerial robot, which can provide information regarding where and how the robot finally reaches a position. However, to the best of our knowledge, the prediction superposition technique has not been applied to the teleoperated hydraulic excavators yet.

In this study, we propose a teleoperated system for hydraulic excavators that can overlap the predicted position of the arm with the operation input. We focus on the turning motion of the hydraulic excavator and verify the effectiveness of our proposed method through simulation. First, a simulator of a teleoperated hydraulic excavator was generated; then, the overlapping system for the arm predicted position was mounted for the turning operation. Finally, the difference in the work efficiency with and without the existence of the proposed system was experimentally verified.

2 Simlation of overlapping the predicted position of the arm

A simulator was developed to confirm the effectiveness by the overlapping predicted position and by displaying it in the turning operation of a teleoperated hydraulic excavator. A hydraulic excavator was installed in a three-dimensional virtual space using the Unity game engine. A joystick (Logitech Extreme 3D Pro) was used as an operator interface. It was possible to turn the simulated hydraulic excavator by tilting the joystick to the right and left like the operation lever of an actual machine. The transfer function G(s) of the teleoperated system was approximated by the first-order delay with the dead time

system, as shown in Equation 1. Here, the input was the operation quantity, and the output was the turning angular velocity of the hydraulic excavator, where K, T, and L represent the system gain, time constant, and dead time, respectively.

$$G(s) = \frac{K}{1+Ts}e^{-Ls} \quad (1)$$

The communication delay caused by the teleoperated system of the hydraulic excavator is demonstrated in Figure 1. If the communication delay, L_1, is known, the relationship between the operation input and predicted position can be expressed by the following transfer function, $G_{pre}(s)$.

$$G_{pre}(s) = \frac{K}{1+Ts}e^{-(L-L_1)s} \quad (2)$$

Using the transfer function of Equation 2, the predicted angular velocity was derived from the master input, as shown in Figure 2, and displayed as translucent in Figure 3.

Figure 1. Delay occurred in teleoperated excavators

Figure 2. Derivation method of predicted turning speed

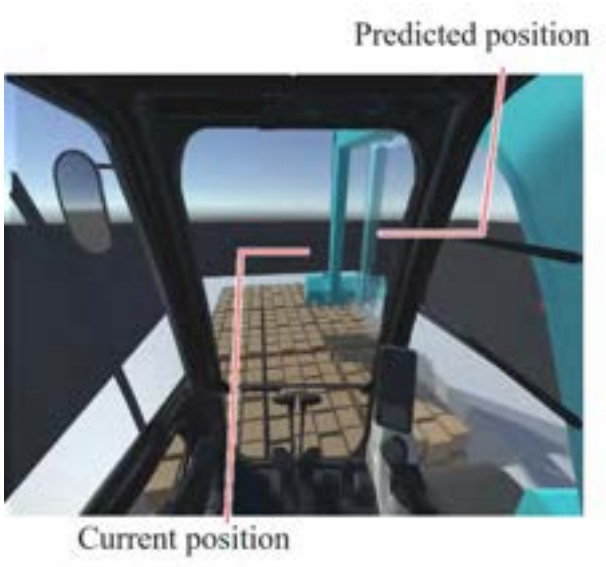

Figure 3. Presentation of predicted position of the attachment in the simulator

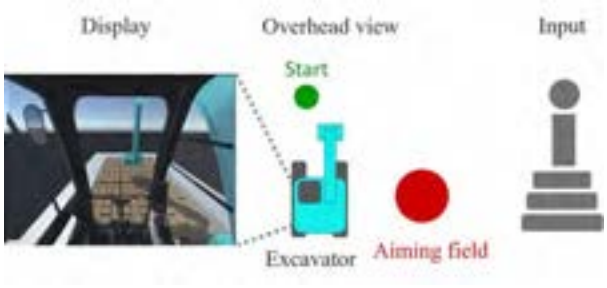

Figure 4. Initial state of the pointing task

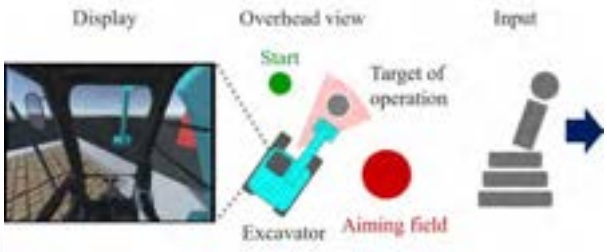

Figure 5. Turning operation state of the pointing task

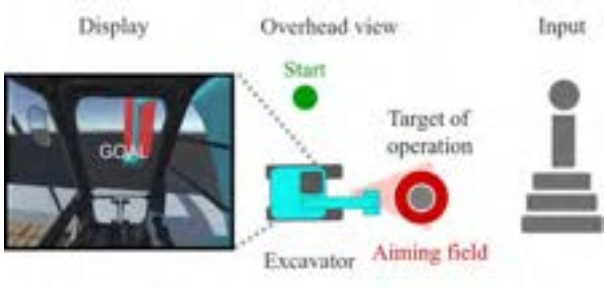

Figure 6. End state of the pointing task

3 Experiment

3.1 Procedure

Using the simulator, a pointing experiment was conducted, in which the bucket tip was turned to the red pole (target position) and stopped. The task started with the state shown in Figure 4 and the subject operated the joystick to turn the hydraulic excavator as shown in Figure 5. Once the target position was reached, the word "GOAL" was displayed on the screen as shown in Figure 6, indicating the completion of a task. The target positions were 30°, 60°, and 90° angles. These were used ten times each for thirty trials forming a task set, and the trial order was randomized. The measured items were the operation time of each task. The subjects performed the above set under the following three conditions.

1. Without dead time and without predicted position display (WOd+WOp)
2. With dead time and without predicted position display (Wd+WOp)
3. With dead time and with predicted position display (Wd+Wp)

Condition 1 assumes the case of operating an actual hydraulic excavator; condition 2 assumes the case of operating a teleoperated hydraulic excavator; condition 3 assumes the case of operating a teleoperated hydraulic excavator by overlapping the predicted position of the arm.

By comparing these three conditions, it was verified how close the working time approaches were in the boarding operation by overlapping the predicted position of the arm in the teleoperated system. Regarding L and T, we set them based on the assumption of an actual machine with a 13-ton excavator, as shown in Table 1, which presents all the relevant parameter values. The communication delay, L_1, was set to 0.26 (s). The subjects were ten healthy persons (Average age 22.7 ± 1.50 years). Before initiating the experiment, the subjects were instructed to finish the task as soon as possible and informed that the target position was on the right side. To eliminate the order effect, the execution order of the above three conditions were randomly made for each subject. Moreover, all subjects performed the test after sufficient practice and agreed to informed consent beforehand based on the Helsinki Declaration.

Table 1. Experiment parameters

	L(s)	T(s)
Acceleration	0.576	1.207
Deceleration	0.422	0.685

3.2 Result

The results of the simulation experiment were shown in Table 2 and Figure 7. For each condition and target position, the average operation time of each subject, as well as that of all subjects, were obtained. Applying the Fisher's LSD test ($\alpha = 0.05$ significant level) revealed that there existed significant differences between Wd + WOp and Wd + Wp at 30° and 90°. Furthermore, a significant difference between the conditions of WOd + WOp and Wd + WOp was confirmed at 30° and 90°. No significant difference was found between the WOd + WOp and Wd + Wp conditions. Detailed statistical results are given in Tables 3, 4, and 5.

Table 2. Result of the experiment

	WOd+WOp	Wd+WOp	Wd+Wp
30°	2.89 ± 0.51	3.93 ± 0.67	3.27 ± 0.67
60°	3.73 ± 0.41	4.17 ± 0.77	3.75 ± 0.59
90°	4.42 ± 0.49	5.69 ± 0.98	4.93 ± 0.63

90°	18	0.16

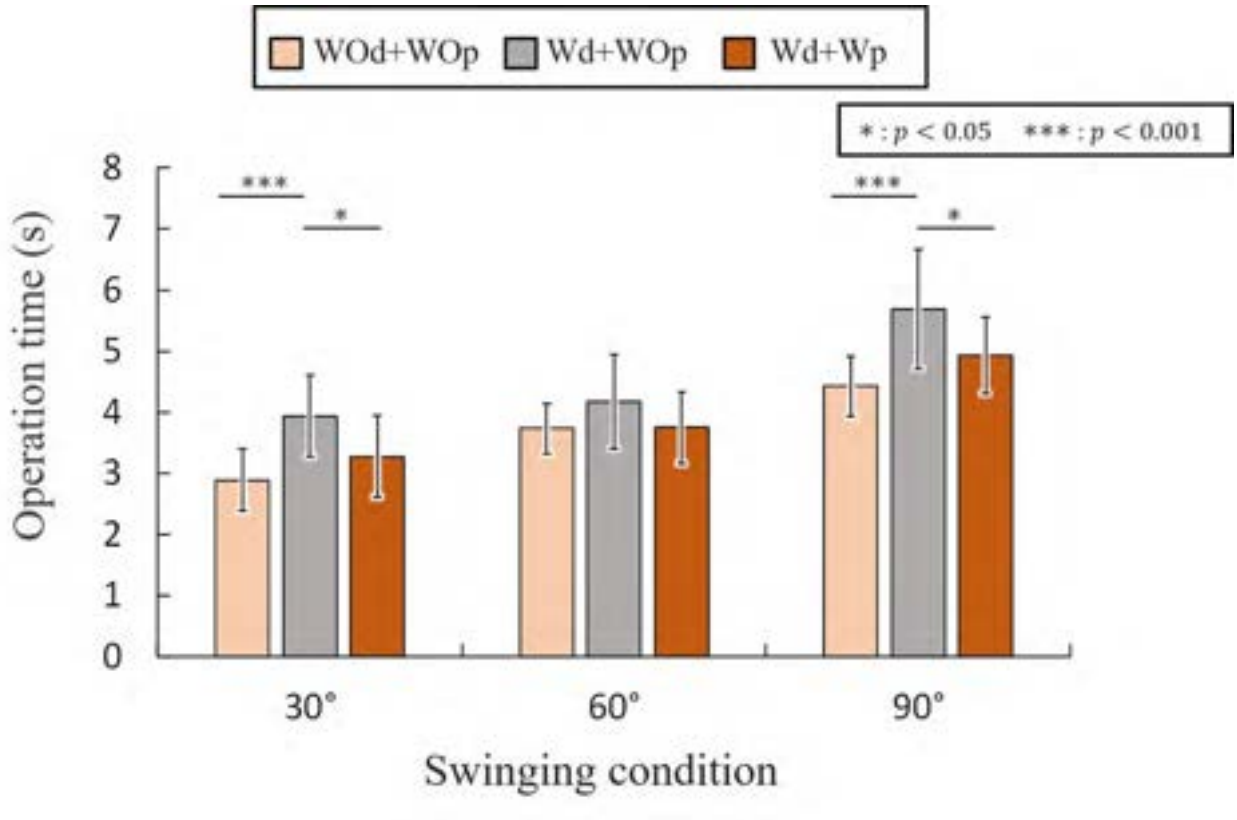

Figure 7. Result of the experiment

3.3 Discussion

This study verified the effectiveness of overlapping the predicted position of the arm in the turning operation using a simulator. The experimental results confirmed that the turning operation time was decreased at 30° and 90° by overlapping the predicted position on Wd + WOp. Moreover, the decreasing tendency of the operation time can be observed even at 60°, although the significance of this tendency could not be confirmed. As seen from Figure 7, it is confirmed that the operation time of Wd + Wp approached that of WOd + WOp. However, some subject commented after the trial that, "The predicted position was always overlapped, and I thought it was in the way.". We think that determining which position should be viewed and which should be operated was challenging when the predicted position overlapped with the current position. Therefore, the work efficiency is thought to be further improved by investigating the display technique of the prediction position, and that it may approach the turning work efficiency of WOd + WOp. Concretely, when the distance between the predicted position and the present position approaches, the predicted position will not be displayed.

4 Conclusion

In this study, the overlapping effects of the predicted position of the arm of the teleoperated hydraulic excavator was verified, during the turning operation, through simulation. The experimental results confirmed that the turning work efficiency, decreased by becoming tele-operational, approached the efficiency of the boarding operation by overlapping the predicted position of the arm. There is the problem of the predicted position on the screen blocking the current arm position. In the future, work efficiency could be further improved by examining the display technique. Furthermore, installing on the actual teleoperated system of the hydraulic excavator is a future investigation topic. With the moment of inertia changes caused by the inclination of the machine body and the weight of the loaded soil, it is necessary to improve the accuracy of the predicted arm position in the actual teleoperated system of the hydraulic excavator.

Abstract

The rotary snow blower vehicle operated for removing accumulated snow on road shoulders must be performed even in the conditions of a poor visibility due to a snowstorm or road markings completely covered by snow. The operators of the vehicle have to pay full attention to avoid contacting road structures and ordinary cars passing just beside the snow removal vehicle. Therefore, we have developed a high-precision snow removal vehicle positioning device using a quasi-zenith satellite and a high-precision expressway map for the first time in Japan. The device can indicate precisely the exact position of the snow blower vehicle on expressways in real time and the operator can drive the vehicle by watching a monitor showing the assistant information provided by the device. The error of the indicated location would be relatively small such as less than a few ten centimeters and several tests have been carried out in a special test field and on the expressway in Hokkaido

Keywords –

Quasi-zenith satellite based driving support system; Snow and ice countermeasure

1. Introduction and background

Since most of the expressways operated by East Nippon Expressway Company (NEXCO East) pass through snowy areas, one of the biggest challenging operational tasks is to ensure smooth and safe traffic even in cold winter.

However, as Japanese future population is in decline, it is anticipated that skilled workers will be aging and it will be difficult to secure the required workers. Since it is expected that snow and ice countermeasures will need to be performed by workers with lesser skills in the future, it is necessary to create an environment that enables such work to be performed more safely and reliably than at present.

In addition, snow and ice countermeasures on expressways involves various types of work and requires skilled operators. The visibility in the environment is particularly bad during snowfall and in snowstorms, and it is difficult for snow and ice work vehicle operators to determine the position of their vehicles on the road at such times, and this labor-intensive work requires the operators to pay close attention to avoid colliding with general vehicles and road structures.

The scarcity of skilled workers in the future is expected to inevitably require this work to be performed by unskilled workers. As such, it is necessary to create an environment where even unskilled operators can perform the work safely and reliably, and this required aiming to provide support for operators by means of driving support technology.

Therefore, we have developed a high-precision snow removal vehicle positioning device using a quasi-zenith satellite and a high-precision expressway map for the first time in Japan. As Wang & Noguchi (2019) reported, the satellite is going to be used in the Japanese agriculture. The device can indicate precisely the exact position of the rotary snow removal vehicle on expressways in real time and the operator can drive the vehicle by watching a monitor showing the assistant information provided by the device. The error of the indicated location would be relatively small such as less than a few ten centimeters and several tests have been carried out in a special test field. In addition one of the tests was conducted on the

expressway in Hokkaido.

In this report, we would like to outline this novel approach to provide a real time exact location on the expressway by comparing a quasi-zenith satellite information with a high-precision map data and some representative test results are going to be explained.

Figure-1. Snow and ice countermeasure work on the expressway (snow blowing work)

Figure-2. Expressway during snowstorm

2. Outline of the developed system

Snow blowing work is performed while running at low speed between the white line of the shoulder and the curb of the shoulder, and the operator of the rotary snow blower vehicle must take care that the vehicle does not run outside the white line on the shoulder into the vehicle lane or collide with guardrails on the shoulder of the road. Using a quasi-zenith satellite positioning device and a high-precision map of the curb, it is possible to continually identify the positional relationship between the rotary snow blower vehicle and the shoulder white line and curb when the vehicle is running out of bounds into the lane or colliding with the guardrails. In this study, we developed a system to warn the operator of a rotary snow blower vehicle when the vehicle was running out of the shoulder area. (Figure-3)

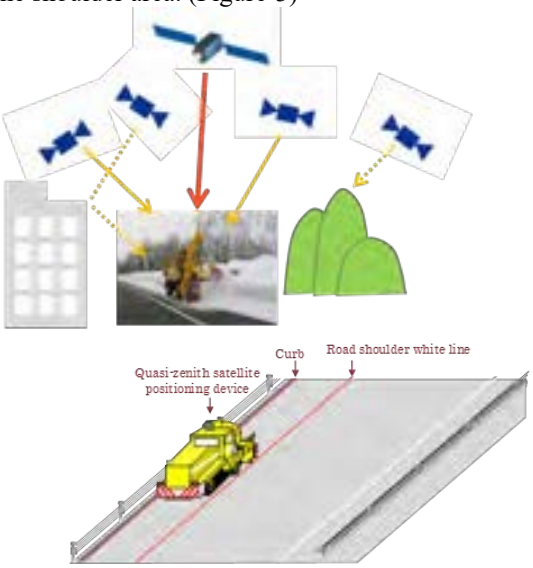

Figure-3. Narrow working range of rotary snow blower vehicle

3. Creation of high-precision maps

3.1 Map creation range

The road features required for snow blower work were created as map information from high-precision three-dimensional point group data by a mobile mapping system (MMS) to create the three-dimensional maps. The target section is 3.0 km (32.4 KP to 35.4 KP) of the outbound lane between the Iwamizawa Interchange and Iwamizawa Service Area on the Hokkaido Expressway. (Figure-4)

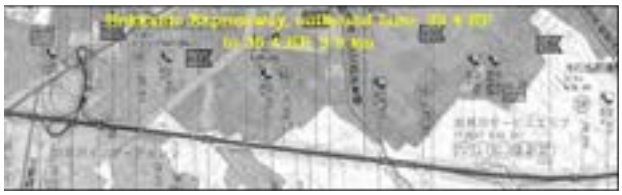

Figure-4. High-precision map creation range

3.2 Mapped road features

The features required for monitoring when the rotary snowblower vehicle runs out of bounds into the vehicle lane and the road features required to avoid colliding with vehicles and blown snow when removing snow are mapped from the high-precision three-dimensional point

group data.(Figure-5)

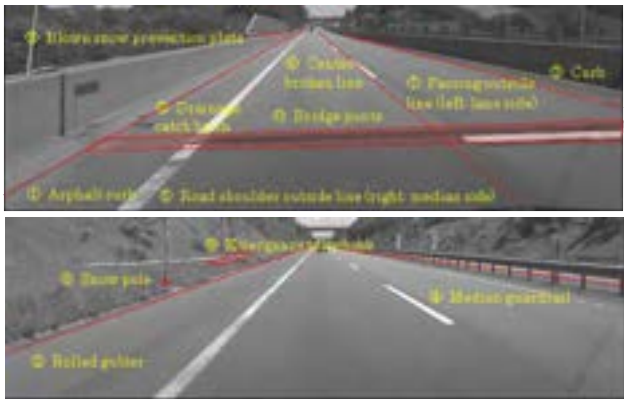

Figure-5 Mapped features

4. Guidance system

4.1 System screen

The system recognizes the running position of the rotary snow blower vehicle from the satellite information and uses the result of collation with the map data to provide guidance for the snow removal work by judging when the vehicle is running out of bounds. The system screen is composed of two screens, a 2D display and a 3D display, and the 3D display screen also displays various types of information about objects requiring caution to make it easier to understand the vehicle's current position and the situation ahead of the vehicle. (Figure-6)

Display description

① 3D display area	Displays an image of the vehicle viewed from behind. Displays the curb ahead and objects requiring caution, and the white lines turn red when the vehicle runs outside the lines on the left or right. The blue line indicates the front position of the vehicle.
② 2D display area	Displays an image of the vehicle looking down on it from directly above. The white lines turn red when the vehicle runs outside the lines on the left or right. There is no display of objects requiring caution.
③ Outside the road shoulder warning information	A warning is displayed when there is an object requiring caution outside the road shoulder 30 m ahead of the vehicle.
④ Road warning information	A warning is displayed when there is an object requiring caution in the road 30 m ahead of the vehicle.
⑤ Running status	When the vehicle is running in the shoulder lane (within the white lines), "OK" is displayed, and when the vehicle runs outside the lane, "OUT" is displayed in red letters. An arrow is displayed indicating the side on which the vehicle ran outside the lane.
⑥ Left clearance (out-of-bounds width)	Displays the clearance to where the left side of the vehicle runs outside its lane. When vehicle is outside its lane, the background turns red and the distance outside the lane is displayed.
⑦ Right clearance (out-of-bounds width)	Displays the clearance to where the right side of the vehicle runs outside its lane. When vehicle is outside its lane, the background turns red and the distance outside the lane is displayed.
⑧ Skew running angle	Displays the skew running angle of the vehicle.
⑨ Road shoulder width	Displays the width of the road shoulder at the point where the running vehicle is located.
⑩ Current time	Displays the current time received from the satellite.
⑪ Reception status display	Displays the reception status and type of position information output from the receiver.
⑫ Sound switching	Switches the warning sound ON and OFF.
⑬ Settings	Switches to the setting screen for vehicle information.

Figure-6. System screen

4.2 System operation when a warning is issued

As shown in Figure-7, in both the 2D and 3D screens, when the vehicle goes out of bounds, the white line on the side the vehicle went out on changes to a red line, “OUT” is displayed in the “Running status” display field, an arrow (⇒) is displayed indicating the side the vehicle went out on, and the amount the vehicle went out of bounds is displayed in meters in red in the "Clearance width (out-of-bounds width)" display field.

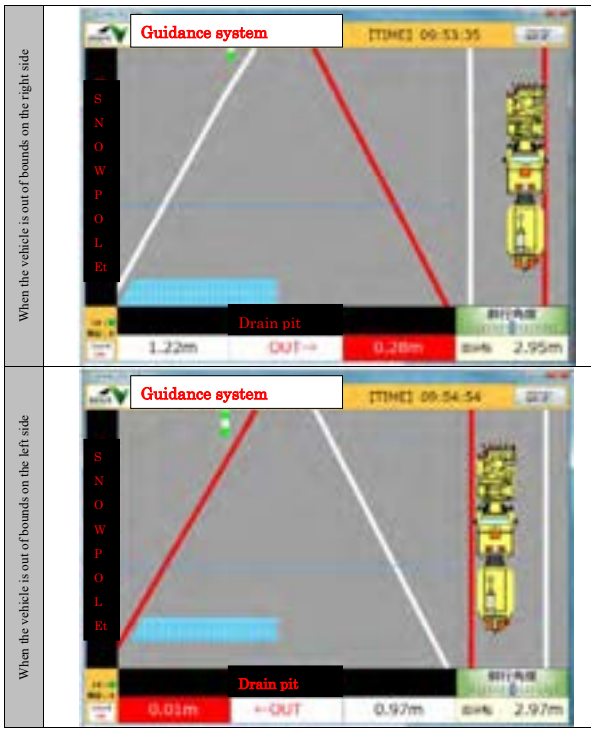

Figure-7. System operation when a warning is issued

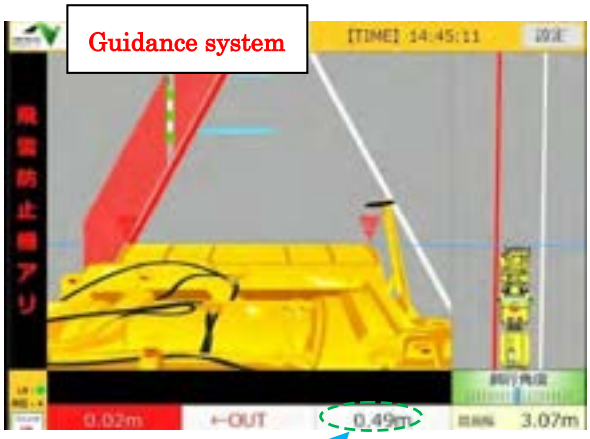
5. Trial test results

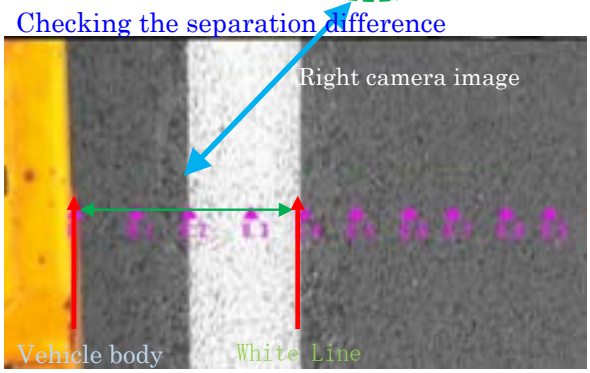
A trial test of the system was performed by running the rotary snow blower vehicle equipped with high-precision positioning equipment and a work guidance system on the shoulder of a road. The test was performed on the shoulder of the outbound lane on a section of the Hokkaido Expressway from the Iwamizawa Interchange to the Iwamizawa Service Area. The trial method involved installing the system equipment and video cameras on a rotary snow blower vehicle in the maintenance yard at the Iwamizawa Interchange, then after moving to the shoulder of the main lane (Iwamizawa Interchange to Iwamizawa Service Area), the rotary snow blower vehicle was run at actual working speed, and system log data and video camera images were recorded.

The method used to verify the trial results was to calculate the error between the system and the actual measurement values from the recorded system log data and each video camera image, and extract and verify the evaluation target section as representative points.

The trial test resulted in an average error value of approx. 0.2 m. By road structure, the error for embankments section was 0.19 m, the error for cuttings section was 0.22 m, and the accuracy of embankments was higher due to the better satellite reception environment. (Figure-8)

The target error of this system is set at 0.2 m, and the above results were almost satisfactory. Therfore, operator would trust the system and could keep the vehicle in an expressway shoulder based on the guidance imformation.





Road structure	System error (m)	
	Average value	Sample
Overall	0.22	171
Embankment	0.19	27
Cutting	0.22	144

Figure-8. Trial test verification method and system errors

6. Conclusion

The developed guidance system could provide resonable results to assit snow blowing operation. We are now under additional testing for improving its further accuracy and plan to use the system practically at the end of 2020.

The system can achieve both providing safer winter expressway for drivers and reducing the burden of the snow blower operatiors, so we are making best effort to complete this project. In additon, we are going to challenge to develop an automonous snow blower based on the quasi-zenith satelite system as the second stage of the project.

Abstract –
Although several previous studies have reviewed 3DCPs, they have been based on few cases and do not include the latest 3DCPs. This study analyzed 139 academic papers and 98 types of three-dimensional concrete printers (3DCPs) developed from 1997 to 2020 through a systematic literature review. A chronological distribution analysis showed that the number of papers and printers suddenly increased after 2012. Most papers (89%) and 3DCPs (86%) were produced from 2012 to 2020. A geographic distribution analysis showed that while Switzerland published more papers than the US, the latter developed more than twice as many 3DCPs than Switzerland. The difference is attributed to who led the development: the industry (US) or academia (Switzerland). Among nozzle-traveling 3DCPs, gantry and cable-suspended platforms were the most common types for some time, but the robotic arm type has spread considerably in the last five years. Since 2013, mobile and collaborative 3DCPs have also increased.

Keywords –
Concrete; 3D Printing; Additive Manufacturing; Technical Specification

1 Introduction

Over the last 30 years, additive manufacturing has been explored to improve construction safety, reduce construction time and production costs, and produce geometrically challenging building elements [1]. In 2012, the number of 3D concrete printers (3DCPs) suddenly increased [2, 3]. Early 3DCPs included contour crafting [4] and D-Shape [5].

Recently, 3DCPs have evolved to support large-scale 3D printing [2, 6]. For example, the Institute for Advanced Architecture of Catalonia [7] developed a family of small-scale mobile robots, each of which can perform a specific task during construction. Keating et al. [8] employed a robotic arm system with a long reach and a terrestrial mobile system as a platform to maximize the building size. Zhang et al. [9] utilized multiple mobile robot printers to collaboratively print a large structure. DediBot [10, 11] adopted an aerial drone-based system to overcome the limitations of conventional 3D printing devices.

Although several studies have comparatively reviewed 3DCPs, none have analyzed their geographic or chronological distributions. This study examined the geographic and chronological distributions of studies and 3DCPs through a systematic literature review of 139 academic papers and 98 types of 3DCPs published from 1997 to 2020. The year 1997 was selected as the starting point because the earliest paper found was published in that year.

The rest of this paper is divided into five sections. Section 2 presents a review of previous studies related to the field and identifies their limitations. Section 3 describes the overall design of the literature search. Section 4 reports the results of the analysis. Section 5 discusses the current status and future directions of the technology. Section 6 summarizes the results and concludes the paper.

2 Previous Studies

Previous studies comparatively reviewing 3DCPs are characterized by two main limitations. First, they have been based on only a few cases. Lim et al. [1] comparatively analyzed only four types of 3DCPs: Pegna [12], contour crafting [13], concrete printing [14], and D-Shape [15]. Ma et al. [16] and Zhang et al. [17] analyzed three types: contour crafting, D-Shape, and concrete printing. Bhardwaj et al. [18] reviewed six 3DCPs, and Paul et al. [19] reviewed 10. Second, diverse 3DCPs have recently been developed, such as multiple mobile printers, aerial drone-based systems, and entrained reinforcement cable systems. These new 3DCPs have not been included in previous analyses, although some studies were published in the past couple of years. Moreover, Chung et al. [20] recognized that new 3DCPs could not be properly categorized using the existing classification system for 3D printers and proposed a new classification

system; however, the classification was based on only 12 relevant papers.

3 Literature Search Method

A systematic literature review (SLR) is a widely used review method in the medical and management fields [21, 22], as well as in the construction field [23, 24]. SLRs aim to minimize bias through exhaustive literature searches related to a specific research question [22, 25, 26].

This study followed the SLR method proposed by Saade et al. [24], Tranfield et al. [22], and Wohlin [26] and used two methods: a keyword-based search and snowballing—a method for finding additional references through the reference lists of identified papers. Figure 1 describes the flowchart of the keyword-based search and snowballing.

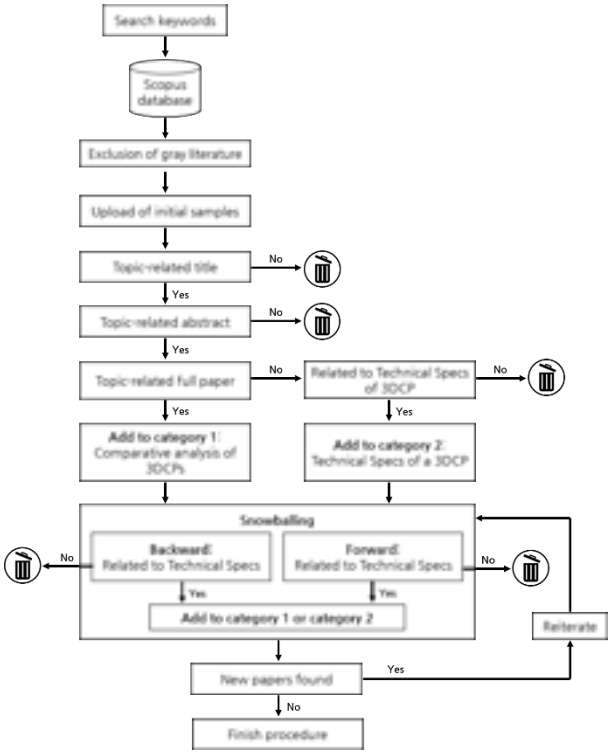

Figure 1. Flowchart of the literature search

The literature search was performed in two steps. The research question on which the search was based was, "What are the geographic and chronological distributions of 3DCPs from their early days to date?" The keyword string [("concrete" AND "3D printing") OR ("additive" AND "manufacturing")] was used to search relevant papers in the Scopus database [27]. To collect as many papers as possible, we intentionally left out specific keywords, such as "classification" or "property," and used generic terms, such as "concrete," "3D printing," "additive," and "manufacturing." Only peer-reviewed journal papers in English were included in the review.

Initially, 433 papers were collected through the keyword search. Irrelevant papers were excluded by reviewing the titles (247 papers), the abstracts (75 papers), and the contents of the full papers (47 papers). The exclusion was performed conservatively. The remaining 64 papers were divided into two categories: a comparative analysis of 3DCPs (29 papers) and a group of studies focusing only on the technical specifications of a 3DCP (35 papers).

Snowballing was then applied. This method is divided into forward and backward snowballing. Forward snowballing identifies studies citing a paper under examination. Backward snowballing identifies studies cited in a paper under examination. Both methods were iterated until no more papers were found. In the first iteration, six papers were added to the first category (comparative analysis), and 51 were added to the second category (technical specifications). A second iteration was then conducted based on these 57 papers, identifying 18 papers, all belonging in the second category. A third iteration returned only one paper, also of the second category. No new papers were found in the fourth iteration, and the process was terminated. In total, the snowballing method identified six papers for the first and 69 papers for the second category. Overall, 139 papers were identified by the two search methods.

4 Results

4.1 Chronological Distribution of Publications

The chronological distribution of the collected papers shown in Figure 2 indicates a growing interest in 3D concrete printing technology. As previously stated, the earliest paper found was published in 1997. Only five papers were published from 1997 to 2004, and 10 papers were published between 2005 and 2012. After 2012, the number of papers suddenly increased, with 89% (124) of the collected papers published from 2013 to 2020. There has been an upsurge in the number of published papers per year (an average of 15.5 papers per year) during the last eight years. This reflects the increasing interest in 3DCPs and 3D printers in general since 2012. One directly related event is U.S. President Barack Obama's speech about 3D printing as the future in February 2013 [28].

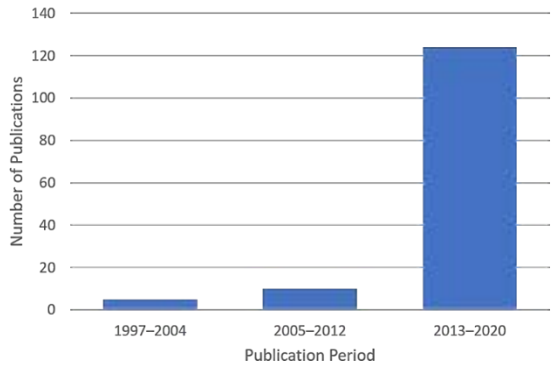

Figure 2. Chronological distribution of publications

4.2 Geographic Distribution of Publications

Figure 3 shows the number of publications per country. The assignment of publications to countries is based on the affiliation of the first author only. As shown in the figure, Switzerland and the US contributed the most publications related to 3DCPs, followed by Germany, France, and the UK.

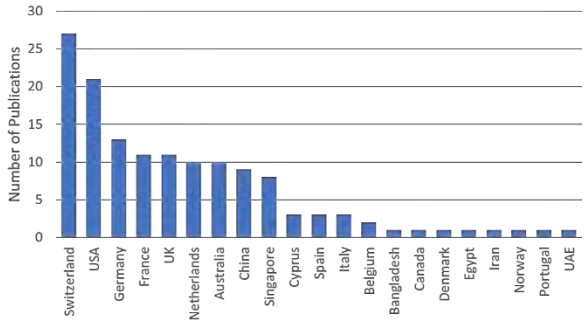

Figure 3. Geographic distribution of publications

4.3 Chronological Distribution of 3DCPs

An analysis of the selected papers identified 98 types of 3DCPs. Figure 4 shows their chronological distribution. Only two were developed from 1997 to 2004, and 12 were proposed between 2005 and 2012. Most (84) 3DCPs were proposed from 2013 to 2020, accounting for 86% of the identified cases. This shows that the number of proposed 3DCPs per year (12.25 per year on average) has substantially increased during the last eight years. This trend is in line with the number of relevant publications and conforms the findings of previous studies [2, 3].

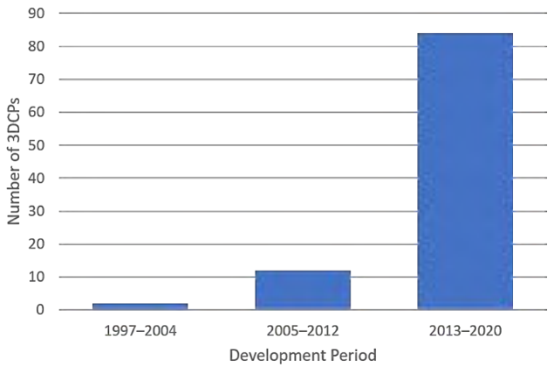

Figure 4. Chronological distribution of 3DCPs

4.4 Geographic Distribution of 3DCPs

Figure 5 shows the number of 3DCPs per country. Many 3DCPs were developed in the US, China, and Germany. An interesting discrepancy can be observed between the number of papers and the number of 3DPCs per country. Although more papers were published in Switzerland than in the US, the number of printers developed in the US was more than double that in Switzerland. This is because many 3DCPs in the US were developed by companies, which tend not to publish their outcomes. In contrast, 3DCPs in Switzerland were developed by research institutions, which are encouraged to publish their work.

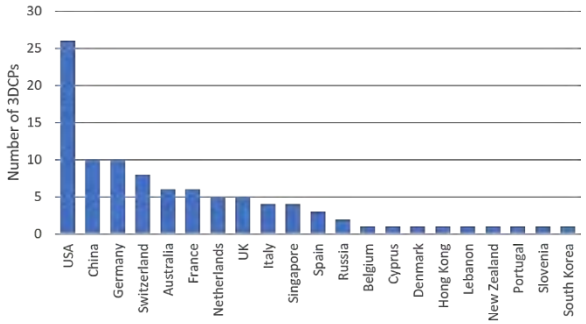

Figure 5. Geographic distribution of 3DCPs

4.5 Distribution of Nozzle-Traveling 3DCPs

To identify chronological trends, 3DCPs were classified based on the classification system proposed by Chung et al. [20]. One of the classification criteria in this system is a type of nozzle-traveling system. Figure 6 shows that the most widely used system has employed a gantry method to move a nozzle since 1997 with some intervals. A cable-suspended platform was the most common system between 2004 and 2010; however, since 2012, the gantry type has become the most

common, and several new types of nozzle-traveling systems, such as the scara, delta, crane, and robotic arm types, have emerged. Especially the number of robotic arm type systems has substantially increased during the last five years. This is because this type can extend the printing range without requiring a massive external framework to support the print nozzle [9]. Considering this tendency, it is possible that the number of robotic arm systems will exceed gantry-based systems in the future.

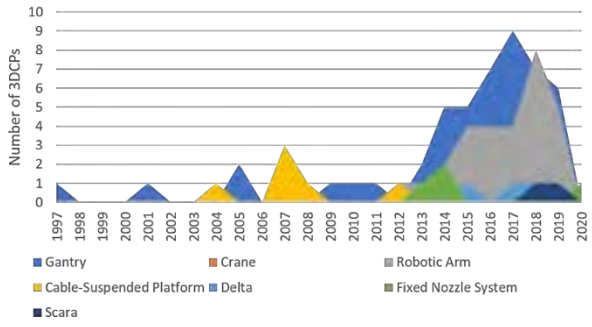

Figure 6. Chronological distribution of nozzle-traveling 3DCPs

4.6 Distribution of Mobile 3DCPs

Another classification criterion is the mobility of the building platform, which means a movable platform equipped with a terrestrial mobile system or an aerial drone-based system. Figure 7 shows that although the fixed system remains the most common system, terrestrial mobile and aerial drone-based systems have printed larger building volumes since 2013. These systems do not require planning or specific infrastructure on the construction site, such as cranes [29, 8]. Given that it enables fully autonomous on-site fabrication, the mobile system can become central to developing 3D concrete printing systems in the future instead of the fixed system. Our analysis also revealed combinations of the nozzle-traveling and mobile platforms: 75% of the terrestrial mobile systems employ robotic arms, and all aerial drones employ fixed nozzles.

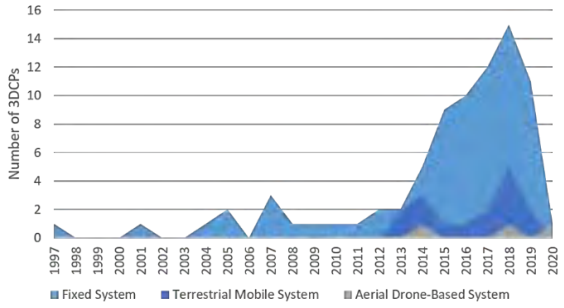

Figure 7. Chronological distribution of mobile 3DCPs

4.7 Distribution of Collaborative 3DCPs

Figure 8 shows the chronological distribution of collaborative robots identified in the 3DCP collection. Eight collaborative 3DCPs have been developed in the last eight years. Although single 3DCPs still represent the most common system, some systems have adopted multiple robots to collaboratively print large-scale structures without increasing the size of the robots. Several researchers have predicted that the collaboration capability of 3DPCs will be a key feature of the technology in the future [2, 8, 9]. Collaborative 3DCPs can be grouped into two types. The first is a collection of different robots designed to perform each task of a series of printing processes. An example is minibuilders composed of three robots [7]. The second type comprises identical robotic 3DCPs simultaneously crowd-printing different parts of a large-scale structure.

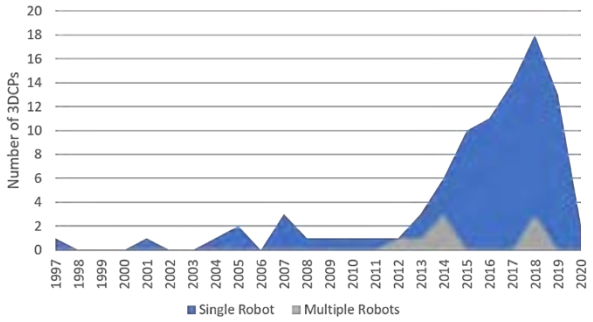

Figure 8. Chronological distribution of collaborative 3DCPs

5 Current Status and Future Directions

This section discusses the current status and future directions of 3DCP technology with regard to nozzle-traveling systems, building platform mobility, and collaborative printing.

Regarding the nozzle-traveling system, the gantry and robotic arm types are currently the most popular. However, most nozzle-traveling systems are designed to print small- or medium-sized structures off site or at fixed locations. To enable 3D-printing of large-scale structures on site in the near future, the development of nozzle-traveling systems on mobile platforms with collaborative printing functionality will be inevitable.

Regarding the mobile platform, although terrestrial mobile and aerial drone-based systems have been developed since 2013, they are still in an early stage. Even if several terrestrial mobile systems were employed on a construction site, they would only be operated on flat concrete slabs. Aerial drone-based systems, on the other hand, are characterized by limited payloads and

unstable printing. If they are to be used in real construction projects, these issues must be addressed.

Regarding collaborative printing, although the number of studies on crowd-printing robots has increased, Nanyang Technological University is the only institution that has implemented the collaborative system—and only in a laboratory environment. To raise collaborative printing to a practical level, more studies on robot localization and nozzle trajectory planning are required.

6 Conclusion

This systematic literature review was conducted to address the limitations of previous studies: few reviewed cases and no reviews of new 3DCPs. The collected 139 papers and 98 types of 3DCPs and the analysis results can be used as a basis for developing a technical specification framework of 3DCPs.

The results show a dramatic increase in the numbers of papers and printers developed after 2012, accounting for an average of 15.5 papers and 12.25 3DCPs per year. Although Switzerland boasts the most publications, the US is home to more printers developed. This is because many manufacturers in Switzerland have been research institutions, which tend to publish their outcomes, whereas many manufacturers in the US have been companies, which do not. The robotic arm type of 3DCP has gained considerable popularity in the last five years, in contrast to the cable-suspended platform. Some types of mobile and collaborative 3DCPs have been adopted since 2013. Given that these types offer greater printing efficiency as relatively new technologies, they can become central to the future development of 3DCP systems.

In the future, we plan to identify the properties of 3DCPs based on a comparative analysis of 35 review papers and 98 types of 3DCPs. We also plan to develop and validate a technical specification framework by conducting surveys or focused group interviews. A technical specification framework can be used as a reference for 3DCP developers and users.

Abstract -

Autonomous road construction offers the possibility to improve the demanding and error-prone process of road compaction. Compaction results and surface coverage are optimized through the coordination of automated tandem rollers. This paper evaluates the impact of different road compaction strategies, ambient influences, and coordination errors on the resulting road. Thereby, suitable compaction parameters for track length, or number of rollers are determined. The concept has been validated in a simulated road construction environment. Additionally, real compaction tests have been performed using autonomous tandem rollers.

Keywords -

Off-road robotics; Behavior-based control; Automated road construction
Topics: (B-1), (B-2)

1 Introduction

Recent construction robotics proceeds towards the complete automation of demanding tasks as high-quality road construction [1, 2, 3, 4]. Thereby, the efficiency, safety, and quality of processes are increased while errors can be reduced. The area of road construction can profit from automation in particular because a fleet of machines has to be coordinated according to time restrictions, and spatial coverage to fulfill clearly defined tasks.

The automation of road work depends on the local construction and communication infrastructure and AI skills of construction robots. The project *Autonomous Mobile Machine Communication for Off-Road Applications* (5G-AMMCOA) funded by the German Federal Ministry of Education and Research (BMBF) targets key topics. The project demonstrators are two pivot-steered BOMAG tandem rollers BW 154 and BW 174 which have been equipped for autonomous operation.

This paper presents a set of improvements to increase the quality and efficiency of a road construction scenario. Furthermore, tests using different roller and road setups are done to conclude a setup for efficient road construction. Sect. 2 presents the state of the art of autonomous street construction. Sect. 3 gives an insight into the road model used for task distribution. Details on the road construction approach are provided in Sect. 4. Details on the robot control approach are stated in Sect. 5 including pivot point selection and multi-field compaction. In Sect. 6 handling of communication errors and task abortion criteria are presented. Finally, simulation and real-world experiments are shown (Sect. 7) followed by a summary and conclusion (Sect. 8).

2 Related Work

Current research aims to improve the quality of road construction processes. Cutting edge technologies as Blockchain and Machine Learning are deployed to improve road construction documentation and monitoring and prevent documentation frauds [5]. Also, road construction efficiency can be improved using the Internet of Things and Industry 4.0 techniques [6]. Additionally, the context-realistic training of construction site personnel as tandem roller operators using Virtual Reality and simulation is of importance to improve the quality [7].

Besides this, research targets the automation of the overall road construction process including the construction machinery as compactors. The automation of tandem rollers and the coordination with a paver was investigated by [3, 8]. Real-time path-planning and data exchange of compactors were investigated in the *SmartSite* project [2]. The follow-up project *Road Construction 4.0* aims to further improve the intelligent control of construction processes [9]. A behavior-based multi-robot coordination approach exploiting 5G-communication was presented in [4]. Additionally, assistance functionality for road construction tooling as automated edge cutting or autonomous collision prevention aid during reverse drive operations has been published in [10].

3 Road Model

The autonomous road construction approach involves a fleet of machines, as tandem rollers, feeders, pavers, and trucks. In the following, the tandem roller automation is targeted. Thereby, the tandem rollers share data with the paver to update a road model and coordinate themselves

accordingly. The road model utilized by the robot control approach is described by [4]. The model considers a spatial description of the individual road segments as lanes, fields, tracks, seams, and edges.

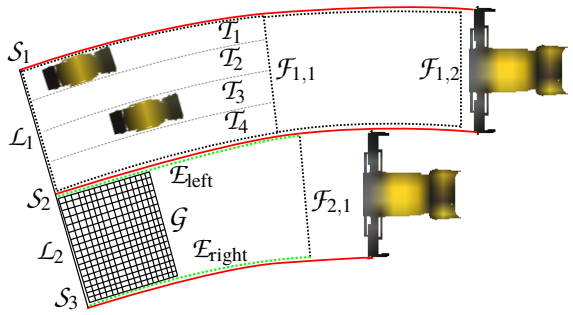

Figure 1. Road model for compaction planning. The road $\mathcal{R}$ has lanes $\mathcal{L}$, seams $\mathcal{S}$, fields $\mathcal{F}$, edges $\mathcal{E}$, grids $\mathcal{G}$, and tracks $\mathcal{T}$ [4, p. 955].

Further, the temperature of the road is considered since sufficient compaction is only possible within a given temperature span and therefore time duration.

The temperature visualization scheme is depicted in Fig. 2a. The road's amount of compaction is estimated through the number of transitions as shown in Fig. 2b. Resulting from current compaction status and temperature, the criticality for ongoing compaction can be determined. The compaction priority visualization can be seen in Fig. 2c. Areas with a low temperature and low compaction amount are visualized orange (high criticality) while hot areas or compacted areas are green (low criticality).

(a) Road temperature model (blue: cold asphalt $\leq$80 °C, pink: hot asphalt $\geq$160 °C).

(c) Compaction priority visualization (green: low priority 0, orange: high priority 1).

Figure 2. Road visualization.

4 Road Construction Approach

The tandem rollers use a distributed, behavior-based control approach [4]. Thereby, several extensions help to improve the compaction result as a more dedicated pivot point selection, multi-field compaction, and the consideration of overtaking maneuvers for a larger group of robots located within the same area.

4.1 Pivot point selection

During road construction, rollers move back and forth between two reversing points: one close to the paver, one further away. The reversing points in a track move forward, as the paver moves forward. The close reversing point will have approximately the same distance to the paver every time, assuming a constant temperature of the delivered material and a continuous material stream. Since the close reversing point is in very hot material, drivers usually make a small curve towards the end of the track. This leaves the wave of material in front of the drum in an angle to the next pass on this position, resulting in a better distribution of the material wave. Otherwise, the next pass could not distribute the material and a permanent wave in the road would be the result. The further reversing points can be chosen on the base of the track length.

Figure 3. Visualization of the reversing points close to the paver from a real world example.

Fig. 3 visualizes the close reversing points in a real world scenario. The building direction is from left to right. One can see how the close reversing points move from right to the left side as the roller changes the track to keep up with the paver. In the middle, there was a temporary paver stillstand due to a lack of material and the roller had

Figure 4. Spatial road visualization with pivot point (blue diamond), support points (track 1), and turn-in point (end point, track 2).

to pass some time resulting in an accumulation of close reversing points. After the stillstand the order in which the roller compacts the tracks change from right to left, to left to right. This is because the curvature of the road has changed and so did the cross slope. The roller always wants to start on the lower side of the road, building a foundation to compact against when moving up.

A lane, a set of support points, is generated to control the autonomous tandem roller. Since abrupt steering maneuvers damage the asphalt surface, sudden steerings have to be avoided. A smooth roller trajectory can be achieved on a track as depicted in Fig. 4. Therefore, a pivot point P_t as a turning point for moving to the next track has to be determined with a minimum distance of d_{min} to the end of the track. The value of d_{min} depends on the track width w_{track} and maximum allowed steering value $c_{\text{track, max}}$. The BW 154 has a drum width of $w_{\text{drum}} = 1.5\,\text{m}$ and a maximum curvature of

$$c_{BW154,\,max} = \frac{\tan\left(22°\right)}{1.35\,\text{m}} = 0.299\frac{1}{\text{m}} \tag{1}$$

In the particular case follows $w_{\text{track}} = 1.3\,\text{m}$ (resulting from the track overlap), and $c_{max} = 0.1\,\frac{1}{\text{m}}$ to prevent sudden steering movements. In contrast to track switching, a turn in maneuver is executed at the front of each track.

4.2 Multi-field optimization

A suggested extension to the compaction process is multi-field optimization. The paver continuously lays out asphalt which can be structured into fields $\mathcal{F}$. For a slower compaction process resulting from a small number of rollers, it may also occur that the tracks $\mathcal{T}_{i+1,j}$ of the field $\mathcal{F}_{i+1}$ already cool down without being compacted accordingly. This results from rollers that are still occupied with the tracks $\mathcal{T}_{i,j}$ of the previous field $\mathcal{F}_i$ (Fig. 5a). Due to the low compaction amount of the field $\mathcal{F}_{i+1}$, a track of $\mathcal{F}_{i+1}$ may have a higher priority as the tracks of $\mathcal{F}_i$.

(a) No multi-field optimization: the front field cools down since the current field is finished first.

(b) Multi-field o ptimization, t he f ront fi eld is in cluded in to the compaction task.

Figure 5. Priority map visualization.

Multi-field o ptimization i s u sed t o a void insufficient compaction. Therefore, previous tracks $\mathcal{T}_{i,j}$ of the field $\mathcal{F}_i$ are included into the current compaction task (Fig. 5b). The compaction of track $\mathcal{T}_{i+1,j}$ also blocks $\mathcal{T}_{i,j}$ since the vehicle needs the track to adjust to the task. Accordingly, track $\mathcal{F}_{i,j}$ is only added to the task if its compaction is not finished yet. Furthermore, it is checked if the task is currently blocked by another roller. By that, it is avoided that the temperature of the unfinished field $\mathcal{F}_i$ drops below the minimum compaction temperature threshold while the rollers are compacting field $\mathcal{F}_{i+1}$. Further, the optimization prevents the adjustment of a task on any unfinished fields. Besides, it is more time-efficient since two tracks are compacted while only adjusting to the task once.

5 Robot Control

The following section proposes further navigation-based robot control add-ons. Such are overtaking maneuvers of other machines in blocked sections and an improved path planning for refueling of water and diesel.

5.1 Overtaking and local trajectory adaptation

An alternative pathway for traveling can be computed as follows (Alg. 1). Considering the field the roller is positioned on it is calculating a path to field $\mathcal{F}_{i-1}$ in front of the targeted field of the next task $\mathcal{F}_i$. Using the information saved in the road model a working begin $\mathcal{F}_w$ is defined. This is the first field of the road which is not finished due to its temperature and compaction value. A field is considered as finished if the temperature is too low or the compaction amount is sufficient. If a roller's position $\mathcal{F}_i$ is behind the working begin ($i < w$) it approaches $\mathcal{F}_w$ by following the points saved in the tracks $\mathcal{T}_{i+1,t-1}$ to $\mathcal{F}_{w-2,t-1}$ where t is the number of tracks.

Algorithm 1: Pseudo code for calculation of avoidance points.

```
if current field id < working begin then
    drive to working begin;
end
if task's field id - current field id > 2 then
    for i = task's field id; i < current field id; i++ do
        add avoidance points of field i to target points;
    end
end
add task points to target points;
```

It is ensured that the rollers are always taking a path in driving direction right on the road by taking the points of the track with the highest ID. The tracks are numbered from left to right and split a field into longitudinal overlapping paths, which are driven by the rollers. This ensures that the driven path is never blocked by a roller driving in the opposite direction.

Next, a path to the task's field has to be determined while not interfering with other rollers currently performing tasks. Usually, the number of rollers compacting a

field at the same time is limited by the number of tracks. Additional rollers can be exploited by compacting fields further ahead. Since rollers are occupying the access route it is not necessarily possible to approach the task directly. Based on the number of fields between the current vehicle position and the target field of the task it can be determined if it is necessary to task evasive actions. If the number of fields between the current vehicle field $\mathcal{F}_i$ and the targeted field of the task $\mathcal{F}_k$ is smaller than two, the task can be approached directly. This is the case since task $\mathcal{T}_{k,j}$ is blocking all neighboring tracks, including the tracks on $\mathcal{F}_{i+1}$ which could be needed to approach the task. If the number of tracks between $\mathcal{F}_i$ and $\mathcal{F}_k$ is larger, other rollers may be occupying the tracks needed to approach the task directly. In this case, an avoidance lane is used which is located on the side of the road. In the case that a roller is required to take the avoidance lane, a request is sent to the paver. The paver is handling the assignment of this avoidance lane in the same way as the handling of the tracks. When performing an evasion maneuver a roller on-field $\mathcal{F}_i$ is aiming for the avoidance points of $\mathcal{F}_{i+1}$ and re-enters the road at $\mathcal{F}_{k-1}$. Afterward, the task can be directly approached.

5.2 Refueling

It is necessary to ensure the water and fuel supply of the rollers to achieve a successful compaction process. For this purpose, it is necessary to periodically send rollers to a refill station. Since the limiting factor of the compaction process is the slow speed of the paver, the refill process should not interrupt the compaction of the road. Typically at most one roller should perform a refill task at a time to secure ongoing compaction.

The refill task is assigned similarly to the standard compaction task. The fill levels of fuel and water of all rollers are monitored at the paver. The paver is creating and assigning the refill tasks based on the fill levels and two thresholds t_{refill} and t_{critical}. A roller is ready to be assigned a refill task in case the fill level is below t_{refill}. The t_{critical} threshold defines the fill level when the roller cannot perform any compaction tasks anymore before refueling. Therefore, each fill level is checked before assigning a new compaction task and refueling is started if at least one roller is fallen short of t_{refill}. Below a specific roller count, only one refill task can be performed at the same time. Accordingly, it is checked if a refill task is currently running. If this is the case, a second refuel task is not assigned and the assignment of the compaction tasks continues. In contrast, if no refill task is running, the roller with the lowest fill level starts refueling. The only case where more than one refill task can be performed similarly is the situation where multiple rollers fall below $t_{critical}$. In this case, the task is assigned independently of the currently running tasks, since the roller is incapable to perform other tasks anymore.

A roller with an assigned refill task follows the previously compacted road up to the road's begin using the points of $\mathcal{T}_{i-1,0}$ to $\mathcal{T}_{0,0}$. $\mathcal{T}_i$ denotes the field where the roller is currently placed on. The overtaking mechanism is used to avoid mutual interference at other field locations that have to be passed. A predefined path is driven which leads to the corresponding refill station after reaching the road's begin. Similarly, after refueling is finished, the roller navigates back to the entry point of the road $\mathcal{F}_w$.

6 Error Handling

A major issue in the communication between rollers and pavers is the handling of message loss and robot control failures. Those problems occur unintended and can consequently not be avoided. Typical situations are a data loss in the communication interface or safety-critical events as construction workers on the road which cause a safety stop of a roller. Therefore such events need to be explicitly regarded by the robot control to prevent a standstill of construction. This includes dynamically adding and removing rollers from the road works.

6.1 Communication failures

Rollers are continuously communicating with the paver and other rollers during the compaction process. Rollers are periodically sending the status of their currently assigned tasks. This is used for calculating new compaction tasks and monitor the state and finished tasks. Additionally, these updates are used as an acknowledgment mechanism to register whether an assignment message is received successfully. Besides, the messages are used to monitor if a roller is still active. If the paver's remote interface does not receive a status update of a roller for a set period t_{active} the roller is set to inactivity. Consequently, it is no longer part of the task assignment process. As soon as the roller is resuming the data transmission, it is reintroduced into the compaction process and can again receive tasks. Thus, t_{active} has to be chosen in a way that rollers can complete their current task before the threshold time is exceeded. A larger threshold is used for refill tasks (around 30 min) since they require a larger time duration due to the potentially large travel distance and the refilling time.

6.2 Task abortion criteria

Task abortion criteria are defined in addition to the communication failures. These should guarantee the revival of the process if an unforeseen event occurs as a roller does a safety stop. Even though the collision of the rollers is prevented by safety systems [11, 12], this does not resolve the problem that a path is not traversable. It is possible to

define upper bounds which should not be exceeded since the time needed to perform a compaction task does not vary considerably. It can be estimated based on the track length and roller's velocity. Therefore, the task is aborted and the roller moves back to the starting point of the task if the execution of a compaction task exceeds this time. Consequently, a new task can be assigned.

7 Experiments

A series of simulated and real-world compaction tests have been performed to evaluate the road construction result. The robot control was implemented using Finroc, a C++/ Java-based framework for intelligent robot control [13]. For simulation, Unreal Engine 4 was used which interacts with the control framework using an interface plugin [14].

Simulated compactions trials were performed on a static test road and the virtual B10 highway, Germany. In a long-term test, a road segment of 800 m with a field width of 7.5 m was compacted. Thereby, the number of rollers and the general road layout data structure were adapted to evaluate the impact on the compaction result (Fig. 6). In a second series, both tandem rollers BW 154 and BW 174 of the 5G-AMMCOA project compacted a road on the ZAK test environment, Germany (Fig. 7). Approximately, 300 m road with a width of 6.5 m have been processed.

Figure 6. Simulated autonomous road compaction tests on the B10 highway using a varying number of rollers and field length.

Figure 7. Autonomous compaction trial on ZAK road using the tandem rollers BW 154 and BW 174.

7.1 Single field compaction

In the first series of experiments, the influence of different numbers of tracks and rollers on the compaction time of a single field is shown. For this, a set of rollers is compacting a static street segment with a length of 25 m. The tests aim to show the advantages of additional rollers on the compaction time of single fields (Table 1). The tests were performed simulating an ambient temperature of 20 °C, and a wind velocity of 5 m/s. To reach the targeted compaction value each track had to be driven two times. Driving a single track on this street approximately takes one minute plus some additional time for the task approach.

Using just one roller, it was not possible to completely compact fields with more than four tracks before the asphalt is cooled down below the stop temperature of 80 °C. Also, it can be seen that a third roller has no impact on the compaction of a field with four tracks since the field overlap limits the space to two rollers at the same time. On larger track numbers, the advantage of additional rollers can be seen on the compaction duration of the field.

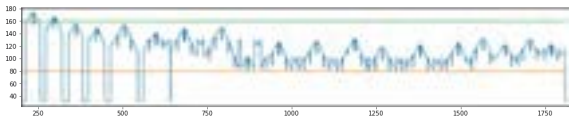
Table 1. Compaction duration for different track parametrization and varing roller counts.

# rollers	# tracks	duration [s]
1	4	630
2	4	360
3	4	360
1	5	–
2	5	540
3	5	350
1	6	–
2	6	600
3	6	420

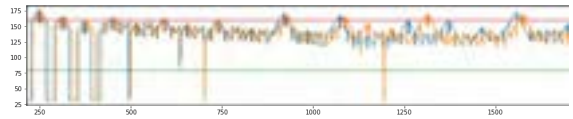
7.2 Simulated B10 compaction

In the simulation, a paver laid out asphalt on the virtual B10 highway. Hereby, each test run was repeated with different test parameters as the number of rollers, compaction field length, and ambient conditions. Each test was running for approximately 30 min creating a road segment of 250 m length. A base course was paved which had a width of 7.5 m resulting in four tracks. The ambient conditions are an initial temperature of 20°C and wind velocity 5 m/s.

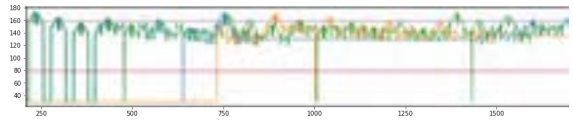
Number of Rollers In the first tests a fixed field length of 25 m is used and the number of rollers is varied. Thereby, it was not possible to sufficiently compact the road using a single roller only since the maximum area the roller can compact in a given time is lower than the area created by the paver. Therefore, after successfully compacting the first fields, the single roller is not able to finish the later fields before cooling off. Using two or three rollers, it



(a) Temperature measurements single roller trajectory over time.



(b) Temperature measurements dual roller compaction over time.



(c) Temperature measurements three roller compaction over time.

Figure 8. Compaction temperature for the tests with one (a), two (b), and three (c) rollers. The top straight line represents the start temperature (160 °C) the bottom line the stop temperature (80 °C).

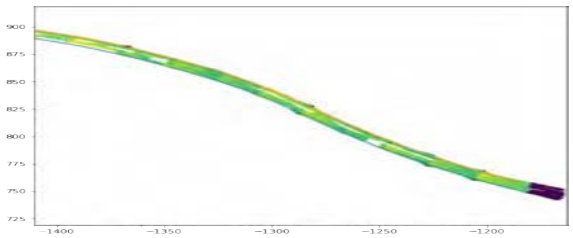
(b) Temperature-trajectory plot dual roller test.



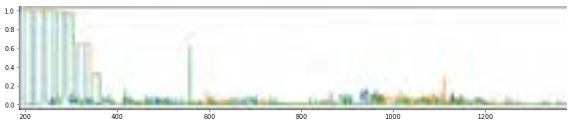
(c) Temperature-trajectory plot three roller test.

Figure 9. Temperature plot according to the roller trajectories. Light green depicts a high temperature (160 °C), purple is below the stop temperature (80 °C).

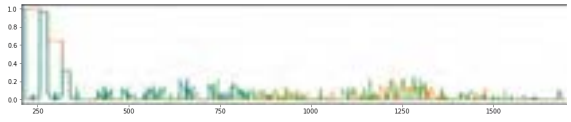
was possible to compact the road within the temperature windows. However, it should be mentioned, that due to the short test duration, no refills had to be performed. Upcoming refill tasks might negatively affect dual roller performance because the scenario changes to a single roller case in-between. Due to this, the deployment of a third roller is recommended in this scenario.

Fig. 8 depicts the surface temperatures measured by the rollers. It can be seen, that in the single roller case, the roller operates most of the time close to the lower compaction threshold temperature of 80 °C. After a while, the roller always compacts tracks which are close to the stop temperature, since they are the most urgent ones. Fig. 9 plots the temperature data against the spatial position of each roller. It can be seen that the overall track temperature is colder (in the visualization more bluish) than in the multi-roller tests. Also, at a later position on the road, only two of four tracks are compacted. In the temperature visualization of multiple roller tests (Fig. 8b-c), it can be seen that the track's temperature is usually close to the start temperature (160 °C). This provides some buffer time for unforeseen delays. Additionally, it can be observed, that in the three roller tests idle times appear in the temperature plot since no task is valid at the moment. In such a situation, the roller has the default behavior to iron a part of the road until a new task becomes available. Temperature data is measured at the kinematic center of the roller. Therefore, some gaps appear in the multi roller spatial plot. This results from the length and width of the roller.

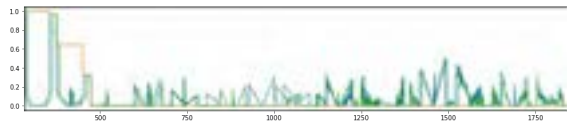
Field length In another trial, the impact of the field length is considered. In addition to the standard field length of 25 m, two additional runs are performed using field lengths of 12.5 m, and 50 m. In general, the desired compaction was achieved in all three road setups.



(a) Compaction criticality for a field length of 12.5 m

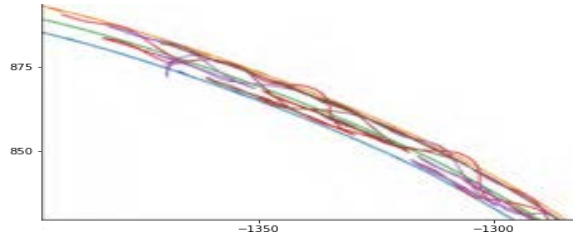


(b) Compaction criticality for a field length of 25.0 m

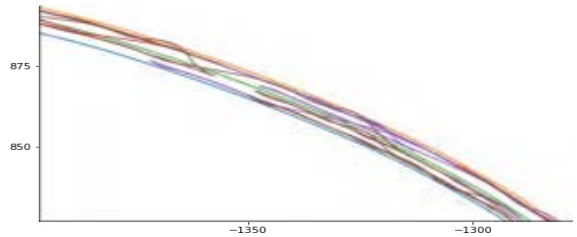


(c) Compaction criticality for a field length of 50.0 m

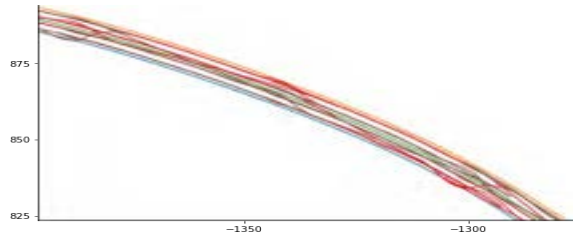
Figure 10. Critically of the for a field length of 12.5 m (a), 25 m (b) and 50 m (c)



(a) Trajectories for a field length 12.5 m



(b) Trajectories for a field length 25.0 m



(c) Trajectories for a field length 50.0 m

Figure 11. Driven trajectories for different field length.

Anyways, the different layouts had various advantages and disadvantages.

In the tests with a short field length, the approach seemed to be much more reactive. The tracks are finished faster and are mostly compacted at high temperatures. This can be seen in the plots of the track criticality value of the road. The critical value is a combination of the temperature and the current compaction, indicating how critical the compaction of a track is at the moment (see Fig. 10). A roller has to wait shorter for a smaller field length to start the compaction than for a larger field length. A major issue is the approach of a task start destination. On one side, the number of task approaches is doubled, since the number of tracks is double. However, the main issue with the task approach is, that the maneuvering needs space in front of the track which should be compacted Fig. 11. The needed space behind the field is larger than the field length of 12.5 m. By that, when approaching a task at field $\mathcal{F}_i$, both the corresponding tracks of $\mathcal{F}_{i-1}$ and $\mathcal{F}_{i-2}$ have to be blocked, while the tests with higher field length only require to block the tracks of $\mathcal{F}_{i-1}$. Driven trajectories are easier to perform using the 50 m fields because less steering are needed Fig. 11. In contrast, the critically of the compacted asphalt is higher in these tests (Fig. 10c) due to the increased time to travel to a track. This is the case due to the larger temperature differences between the start and the end of the field. It also leads to a later beginning of the compaction, since the compaction is started after the average temperature of the track is below the start temperature of 160°C. Finally, another disadvantage is that the number of tracks available for compaction is low and that additional rollers are not exploited. In long term tests a field length of 25 m has achieved the best results.

7.3 Ambient Influences

The time available to compact a field is strongly dependent on the ambient temperature and wind velocity. For simulation, an estimation of the temperature is done. In the real scenario, the temperature is updated using the measurements of the rollers in addition to the model. To show the importance of ambient influences, the available simulated compaction time is shown for different conditions (Table 2).

Table 2. Compaction time based on ambient influences.

temperature [°C]	wind velocity [m/s]	duration [s]
10	5	580
20	5	630
30	5	690
20	10	400
20	20	240

7.4 Real-world ZAK compaction

Finally, tests on the real machine were performed. A single roller was compacting a road consisting of one field (Fig. 12) using the best performing setup from the simulation tests. In general, the roller was able to compact the field as expected and all timing and temperature constrains were fulfilled. However, the accuracy of the trajectories is lower than in simulation and has to be regarded more careful in future. Also, the steering actions are often too large which is not desired when driving on hot asphalt.

Figure 12. Track compaction trajectory of the ZAK test using BW 174 on a single track.

8 Conclusion

This paper presented different extensions to improve the results of autonomous road compaction, regarding the road mode, robot control optimization, and error handling. The impact of different parameters as number of rollers,

field length, and ambient conditions was evaluated within a series of autonomous compaction trials in simulation and real world. The number of required number of rollers and the impact of different field length have been discussed.

Future work aims to consider trucks properties into the compaction planning. So, varying asphalt installation temperatures resulting from transport are included into planning. Also, real-world autonomous compaction tests on hot asphalt are targeted and the impact on sensor quality and the control behavior further examined.

Abstract –

Bridge designs are typically governed by a voluminous set of requirements in various design standards and codes. The requirements are aimed at ensuring the structural safety against different environmental risks experienced by a bridge facility during its service life. The requirements provided in the bridge design standards are generally prescriptive in nature that do not explicitly specify the types of risks addressed in them. As a result, the understanding of the risks hidden in the requirement text is solely associated with the individual designer who often lacks adequate training in interpreting the risks addressed in prescriptive requirements. The conventional practice of manual identification of risks encoded in the prescriptive provisions requires much effort, domain knowledge and may include human errors as well. Little attention has been paid towards automated identification of risks encoded in the prescriptive requirements. The paper presents an ontology-based risk decoding model to decode the risks implied in the prescriptive requirements. The risks included the earthquake, flood, wind, fire, vessel collision, blast loading, temperature and overloading. An ontology for conceptualizing the domain knowledge of the eight risks was first developed. The ontology-based decoding model ranks the risks for a prescriptive requirement by measuring the semantic similarity between the requirement and the risk ontology. The model was tested on the AASTO bridge design specifications and evaluated in terms of Spearman, Kendall tau and Pearson rank correlation test. This study is expected to assist the designers in the improved understanding of risks encoded in prescriptive design standards.

Bridge design;Prescriptive requirements; Design standards; Environmental risks; Natural language processing; Deep learning

1 Introduction

Bridge designs are generally carried out in accordance with a set of requirements specified in the design codes and standards [1]. The primary goal behind these requirements is to ensure the structural stability and durability of the bridge against several environmental risks [2]. The major risks experienced by the bridges are flood, earthquake, wind, fire, etc. In order to execute a safe and reliable design, the precise understanding of the requirements is very crucial [1]. The requirements currently available in the bridges design codes are mostly described in a prescriptive manner where the main intention or the objective behind the requirement is not clearly stated [3]. Accordingly, there is a need for an automated framework which can decode the risks hidden in the text of prescriptive requirements.

The accurate decoding of the risks in the prescriptive requirements is very important to produce a design that can enable the safety of the bridge against all hazards or risks [4]. The prescriptive requirements are typically produced by the code writers with years of experience in the industry and research. In addition, a detailed study of the past failures along with the full-scale testing of the proposed models are also performed while designing the prescriptive requirements [5]. The code writers only present the final criteria for the safest designs without providing any information regarding the types of risks considered while developing that criteria. For instance, the prescriptive requirement *"The maximum girder spacing shall not exceed 10½ ft."* may fulfill the design requirements against overloading, earthquake, and flood but may not fulfil the performance required against the fire risk. Another requirement *"The spacing of intermediate bracing shall not exceed 20 ft."* may achieve the goals of flood, wind, and earthquake risks while the fire, temperature and overloading risks may not be mitigated by implementing this requirement. However, such information of the risks is not provided in the

requirement text. Since many prescriptive requirements have certain limitations in terms of risks, the implementation of the prescriptive requirements without understanding the risks addressed in them may result in the scenarios where a few risks may be go unchecked in the bridge design [6]. Young engineers in the industry mostly lack the experience and knowledge required for understanding the risks encoded in the prescriptive requirements. The blind implementation of the prescriptive requirements by young engineers without understanding the objectives and performance level implied in the requirement may result in an unsafe design. In addition, since the objectives covered in the prescriptive require are not known, it is difficult in international construction industry to establish an equivalence between two different criteria stated in codes of two different countries [7]. Therefore, a risk decoding model is required that can precisely decode the risks encoded in the prescriptive requirements.

The current body of knowledge lacks methods to address the issue of risks hidden in the prescriptive requirements. To fill the gap, this study has attempted to develop an automated ontology-based risk decoding model using the linguistic methods such as vector space models and ontologies. A detailed ontology covering the domain knowledge of the eight risk categories was first developed. The risk categories included earthquake, flood, wind, fire, vessel collision, blast loading, temperature and overloading. Following this, the trained vector space model and ontology were employed to decode and rank the risks encoded in the prescriptive requirements according to the semantic similarity of the requirement text and the risk ontology.

2 Background

2.1 Risks in bridge design codes

The risks involved in the bridge design are controlled and mitigated by the implementation of requirements available in the design codes [1]. The bridge design codes generally include two types of requirements; (1) prescriptive requirements, and (2) performance-based requirements [8]. The prescriptive requirement only states the acceptable solution without indicating the performance level while the performance-based requirements specifies the performance level required without providing any prescription or solution. The prescriptive requirements can further be classified into two categories. The first category is when the quantitative prescription is explicitly stated, for example, *"The maximum girder spacing shall not exceed 10½ ft."*. The second type is when the relevant code or method is specified to be followed in design, for example, *"The deck overhang shall be designed in accordance with Section 13 of the LRFD Specifications."* Since the goals or intention behind the recommendations in prescriptive requirements are not specified, the young designers often assume that the requirements cover all the risks. However, this is not the case for the prescriptive requirement since prescriptive requirements always have certain limitations as well [4]. The implementation of the requirement for a scenario for which is not designed often results in the failure in achieving the required performance. Therefore, the decoding of the risks is very important to ensure that the requirements are applied to the scenarios for which they are actually designed.

2.2 Text processing using ontologies

Ontologies are the knowledge representation methods widely used to present the domain knowledge shared among different systems [9]. Ontologies are employed to provide the background knowledge in a machine-readable format for the development of several automated systems for text classification, word sense disambiguation, etc. [10]. The representation of knowledge in the form of concepts in ontologies enables the reuse of the ontologies for other systems [11]. Concepts are the domain entities which are represented in a hierarchical form in ontologies. The relationships are used to define the type of connections between the different concepts and sub-concepts. Ontologies can also play a key role in text processing. For instance, the ontologies can be used to represent the features of a text document. The extracted features can then be used to classify or rank the labels using a machine learning algorithm [12]. In addition, ontologies can also be used to represent the domain knowledge of class labels. The developed ontologies of the labels can then be used to analyze the documents followed by the assigning of labels or ranks [13].

2.3 Related studies

Several researchers have studied the limitations pf the prescriptive requirements, however, most studies have been focused on the addressing a few specific limitations such as design hinderance while many other limitations such as absence of risk information in prescriptive requirement have not received the equal attention. For instance, [14] studied the limitation of the prescriptive codes in addressing the fire risk. As a solution, the authors stressed upon the improvement of current prescriptive codes, ensuring their proper implementation along with the promoting the fire education. Another study by [15] highlights the limitations of the prescriptive codes in introducing innovative solutions to mitigate problems associated with the climate change. A five-step solution was

provided by the author to control the degradation of environment due to the use of specific materials prescribed in the prescriptive requirements. [16] also addressed the same limitation of hinderance in using alternative methods to improve the project performance in design-bid-build and design-build projects. The study carried out the textual analysis of the performance-based requirements provided in the Swedish design-build contracts.

Prescriptive requirements in the transportation domain also presents the same limitation of disallowing the innovative solutions. Since manufacturers have to follow the prescriptive dimension and weight requirements, they cannot practice new solutions to reduce the road accidents. [17] suggested a performance-based system to address this limitation. The developed regulatory system requires the certification of vehicles as well as operators to meet the approval requirements. [18] highlighted the increase in accidents in Malaysia due to not allowing the new alternative methods in design to prevent the accidents. The author studied the limitations in the prescriptive codes of Malaysia and explored the potential opportunities of improvement by comparing it with the well-established performance-based specifications implemented in Australia. [19] also highlights the limitations of prescriptive requirements in dealing with the complex risks such as blast loading and fire.

Many studies have investigated the limitation of prescriptive requirements in hindering the innovation. However, despite the significant importance, the limitation of prescriptive requirement in specifying the performance level or risk information have not been studied yet. The current study is aimed at developing an automated framework to decode the goals implied in the prescriptive requirements.

3 Methodology

The methodology adopted in this study comprised four major steps illustrated in Figure 1. Firstly, an ontology reflecting the essential semantic knowledge associated with the eight environmental risks was produced. Following this, a vector space model was trained using a domain specific corpus. The third step includes the computation of the semantic similarity scores between the requirement text and the risk categories. After ranking of risks according to the similarity scores, the model was evaluated using different rank correlation coefficients.

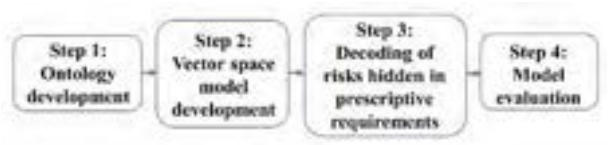

Figure 1. Methodology of the ontology-based risk decoding model

3.1 Step 1: Ontology development

Before development of ontology, the major risks involved in the bridge designs were identified. Upon reading of the relevant published articles, following eight (08) major risks were identified: flood, wind, earthquake, fire, temperature, vessel collision, overloading, and blast loading. A detailed ontology to model all the domain specific knowledge of each of the eight risk categories was developed. The four steps involved in the ontology development are explained below.

1. ***Identification of purpose:*** In the first step, the reason behind the development of ontology was explicitly defined. The ontology developed in this study was aimed to decode the environmental risks hidden in the prescriptive requirements.
2. ***Identification of concepts and sub-concepts:*** The second step involved the identification of all concepts and sub-concepts related to each of the eight risk categories covered in this study. The bridges design codes and published articles were used to identify the concepts and sub-concepts. For instance, 'liquefaction" and 'cyclic loading" is related to earthquake, so these concepts were present under the earthquake category in the risk ontology.
3. ***Identification of relations:*** The third step is aimed at defining the relationships between the concepts and sub-concepts in the ontology.
4. ***Ontology modeling:*** Finally, the concepts and sub-concepts were modeled in the protégé tool to produce the final ontology.

Figure 2 illustrates a partial ontology of a risk category "flood'. The ontology of a risk category mainly shows the essential semantic knowledge associated with the risk category in a hierarchical form. As shown, all the sub-concepts below a particular sub-concept provides additional information regarding the upper concept. The higher concepts are the abstract ones while the lower concepts in the ontology provides detailed knowledge of the upper concepts. Each of the eight risk categories has a different number of sub-concepts below it in the ontology depending on the semantic knowledge required to present the risk category.

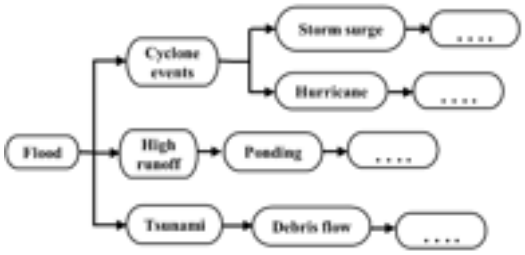

Figure 2. Partial ontology of risk category 'flood'

3.2 Step 2: Vector space model development

Several bridge design codes, standards and the published articles were collected to build a vector space model to learn the semantic meanings of the technical terms used in the design codes. The design codes of ten different state department of transportation (DOT) as well the U.S. DOT was employed to develop the corpus for the training of vector space model. The tables and equations were excluded from the corpus since they are not supported by the natural language processing (NLP) methods. The final corpus used in the training process comprised a total of approximately 1 million words. The domain-specific corpus was pre-processed by implementing the following NLP methods; (1) Lowercasing: The complete corpus was converted into a lowercase format to consider similar meaning words such as "Cracking" and "cracking" as one word. (2) Tokenization: The whole corpus was transformed into a sequence of tokens where a token could be a word, a number or a punctuation. (3) Lemmatization: Lemmatization was performed to convert different grammatical forms of a single word into the root form, for instance, "cracks", "cracked", and "cracking" was converted to the root word "crack".

After pre-processing of the corpus, the wor2vec algorithm was applied to build a vector space model. Both architectures of the word2vec including continuous bag-of-words (CBOW) and hierarchical skip-gram algorithm were applied [20]. Both algorithms have reported comparable performance in the literature [20]. The whole vocabulary in the corpus was presented on a high-dimensional vector space where each unique word holds a unique vector. The distance between the vectors on vector space indicates the semantic similarity between the corresponding words. The training of the vector space model includes the tuning of several parameters such as window size (number of co-occurring words examined in analysing the semantic meaning of a word), vector dimensionality (dimensions of each word vector), frequency threshold (minimum frequency of a word required to include the word in the training process). Different values of the vector dimensionality ranging from 300 to 1200 were tested in this study to determine the optimal value. The window size and frequency threshold considered in all the experiments were 10 and 1 respectively.

3.3 Step 3: Decoding of the risks hidden in prescriptive requirements

The risk decoding approach adopted in this study is the similarity-based. The similarity scores indicating the semantic similarity between the requirement text and the risk ontology were first determined. Based on the similarity scores, the risks encoded in the requirement were ranked in the descending order of relevance. The details of the two steps are provided as follows.

3.3.1 Measurement of the similarity scores

The trained vector space model was employed to compute the similarity score of each term in the requirement and each concept in the ontology. Cosine similarity function was applied for the computation of similarity scores. Cosine similarity computes the angle between the two vectors where a smaller angle shows higher similarity between the corresponding words. The detailed risk ontology and the prescriptive requirement were provided as input to the risk decoding model where the semantic similarity between each word of the requirement and each concept of the ontology were computed using the trained vector space model. After similarities calculation, the similarity values of all terms in a requirement with a specific concept were then summed up to get the total similarity value for the requirement with that specific ontology concept. Since the current study is focused on the decoding of risks which are present at the level 1 of ontology, the similarity scores at the level 1 of ontology are determined by adding the similarity scores of all the concepts below that level 1 concept. Each level 1 concept includes a different number of concepts below it in ontology, therefore, the total similarity values are normalized by the frequency or number of nodes below each level 1 node of ontology. The mean normalized method was applied to compute the total similarity score at the level 1 of ontology. Eq. 1 was used for the computation of mean normalized scores. A total of eight mean normalized scores were obtained where each value corresponds to the total semantic similarity score of the requirement with a specific level 1 concept.

$$mean\ normalized\ score\ = \frac{\sum_{n=1}^{N}(\sum_{t=1}^{T} s_{tc})_k}{N} \quad (1)$$

Where s_{tc} indicates the semantic similarity score of the term *'t'* in the requirement and concept *'c'* in the ontology, *'T'* indicates the total number of terms in a specific requirement, *'N'* indicates the total number of concepts below a level 1 concepts in ontology.

3.3.2 Ranking of the risks

Once the total similarity scores of a requirement with the eight risk factors at level 1 of ontology are calculated, the risk factors are ranked in descending order of relevance. The risk category revealing the highest total mean normalized score was assigned the rank 1 while the remaining categories are ranked from 2 to 8 according to the total similarity scores.

3.4 Step 4: Model evaluation

The risk decoding model was evaluated on a test dataset of 151 prescriptive requirements. The test dataset was manually labeled with the ranks of risks according to the content of the requirement. The performance of the model was evaluated using different rank correlation tests including Spearman, Kendall tau and Pearson rank correlation tests (as shown in Eq. 2-4). The rank correlation value shows the level of agreement between the actual ranks and the predicted ranks. A value of 1 indicates a complete agreement while a value of -1 indicates a complete disagreement between the two sets of ranks.

$$Spearman = r_s = 1 - \frac{6\sum_{i=1}^{n}(x_i - y_i)^2}{n^3 - n} \quad (2)$$

$$Kendall\ tau = r_k = \frac{2}{n(n-1)}(|C| - |D|) \quad (3)$$

$$Pearson = r_p = \frac{n\sum x_i y_i - \sum x_i y_i}{\sqrt{n\sum x_i^2 - (\sum x_i)^2}\ \sqrt{n\sum y_i^2 - (\sum y_i)^2}} \quad (4)$$

where *'x_i'* and *'yi'* are the ranks of a risk category *'i'* in group 1 and 2, 'n' indicates the number of predefined risk categories, *'C'* is set of concordant pairs, and *'D'* is set of discordant pairs.

4 Results and Discussion

This section presents the results of the experiments carried out to evaluate the performance of the risk decoding model. Two different architectures of the word2vec such as CBOW and skip gram algorithm were used to compute the semantic similarities of the requirement terms and the ontology concepts. For each algorithm, four vector space models were developed using a different value for vector dimensionality ranging from 300 to 1200. The window size and minimum threshold value of 15 and 1 respectively were same in all the experiments.

Table 1 presents the results of the risk decoding model using the CBOW algorithm for the similarity computation. The results show that performance of the model was increased with the increment of vector dimensionality until 900. The performance was decreased as the value of vector dimensionality was further increased from 900 to 1200. The highest spearman, Kendall tau and Pearson correlation coefficient of 0.30, 0.23, and 0.29 was achieved with the vector dimensionality of 900 whereas the lowest spearman, Kendall tau and Pearson correlation coefficient of 0.24, 0.19, and 0.23 was achieved with the vector dimensionality of 300.

Table 1. Performance of the ontology-based risk decoding model using CBOW algorithm for similarity computation

Vector dimensionality	Spearman	Kendall tau	Pearson
300	0.24	0.19	0.23
600	0.29	0.22	0.28
900	030	0.23	0.29
1200	0.26	0.20	0.25

Table 2 presents the results of the risk decoding model using the skip gram algorithm for the similarity computation. The same trend as previously seen with the CBOW was observed with the skip gram as well. However, unlike CBOW, the performance of the skip gram model did not change significantly while varying the value of vector dimensionality. A minor increment has been observed till vector dimensionality of 900, however, a decrease in performance was observed for higher values. The skip gram also revealed the highest Spearman, Kendall tau, and Pearson correlation coefficient of 0.64, 0.51, and 0.63 respectively at the vector dimensionality of 900. Among the two word2vec algorithms, the performance exhibited by the skip gram was almost twice better than that achieved by the CBOW algorithm.

Table 2. Performance of the ontology-based risk decoding model using skip gram algorithm for similarity computation

Vector dimensionality	Spearman	Kendall tau	Pearson
300	0.63	0.51	0.62
600	0.62	0.50	0.61
900	0.64	0.51	0.63
1200	0.63	0.51	0.62

4.1 Model performance for different risk categories

The performance of the model in terms of each risk category was further investigated using the best model of skip gram for similarity computation. Figure 3 shows the mean deviation of the predicted ranks from the actual ranks. As shown, the risk categories such as 'temperature' and 'fire' performed the best among the eight categories. For temperature, the mean deviation of 0.23 shows that the model predicts the correct rank for

temperature category most of the times. No risk category exhibited a mean rank deviation of above 2 which proves the adequacy of the model.

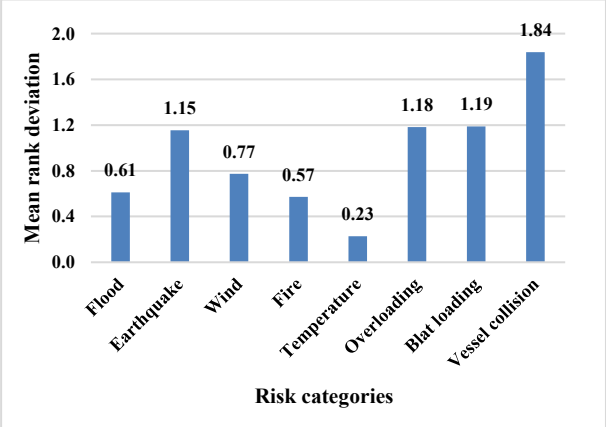

Figure 3. mean deviation of the predicted ranks from actual ranks

5 Conclusion

Bridge design are performed according to the requirements presented in the design codes and standards. However, the requirements are mostly prescriptive in nature where the main objectives or risks addressed in the requirements are not clearly specified. As a result, the designers often face challenges in estimating the limitations and performance level implied in the prescriptive requirements. The study has produced an automated framework using the vector space models and ontologies which can decode the risks encoded in the prescriptive requirements.

An ontology covering the domain specific knowledge associated with the eight risk categories was first developed. In addition, a vector space model was trained on a corpus of approximately 1 million words using the CBOW as well as skip gram algorithm. The model was validated on the unseen prescriptive requirements extracted from the AASHTO bridge design specifications. The experiments revealed that the skip gram algorithm performed better than the CBOW algorithm. The performance exhibited by the skip gram algorithm was double than the performance achieved by the CBOW algorithm. Moreover, the performance was found to be increasing with the increment in the size of word vector dimensions till 900, however, the performance was decreased for higher vector dimensionality values. The overall highest Spearman, Kendall tau, and Pearson correlation coefficient of 0.64, 0.51, and 0.63 respectively was reached by the skip gram model for the similarity computation at the vector dimensionality of 900. Comparing the risk categories, the 'temperature' category performed the best where the model predicted the correct rank in most cases. The model showed the mean rank deviation of 0.23 for the temperature category while the highest mean rank deviation of 1.84 was exhibited by the 'vessel collision' category.

The study has certain limitations in terms of performance. The current model uses the simple mean method to compute the total semantic similarity. In future, the authors will investigate different averaging methods such as weighted average and Bayesian average for the computation of the total similarity scores to examine the improvement in performance. A threshold analysis by setting of a threshold value to exclude the similarity scores of the irrelevant concepts may also improve the performance of the model. In addition, the authors will develop a larger dataset for the training of vector space model to examine if the performance can be improved by using a large dataset.

Abstract –

Unmanned construction work is civil engineering work carried out by remotely operating construction machinery located in a caution zone (a zone whose entry is prohibited or restricted), thus enabling the operator to perform remote work from inside the safe area without any need to enter the caution zone.

This technology came into being as a result of a proposed public offering of technology from each civilian company, which utilized the test field* of January 1994, and also technology verification at the site. From then onward to the present time, new technology was acquired continuously, then it evolved, and spread throughout Japan.

This paper describes the birth of unmanned construction, the development of related technology, and the trend of current technology.

***A system for constructing a life-size building intended for increasing the degree of completeness through technology verification in the field.**

Keywords –

Unmannde Contruction; Remote control; Operation guidance; Wireless communication; Safety monitoring

1 Description of unmanned construction

This unmanned construction technology consists of construction machinery that is operated remotely, and supporting equipment for operating remote operation of this machinery (Figure 1).

Also, it is necessary to arrange the shape of the the civil engineering structure and equipment constructed in the caution zone, and also the quality confirmation method.

A description of each item is set out below.

1.1 History of unmanned construction

Work using remote-operated construction machinery commenced in 1969. In this case, land reclamation was carried out on the Joganji-gawa River in Toyama Prefecture using an amphibious bulldozer (Figure 2). Subsequently, the use of remote operation was extended to land type back hoes, bulldozers and dump trucks.

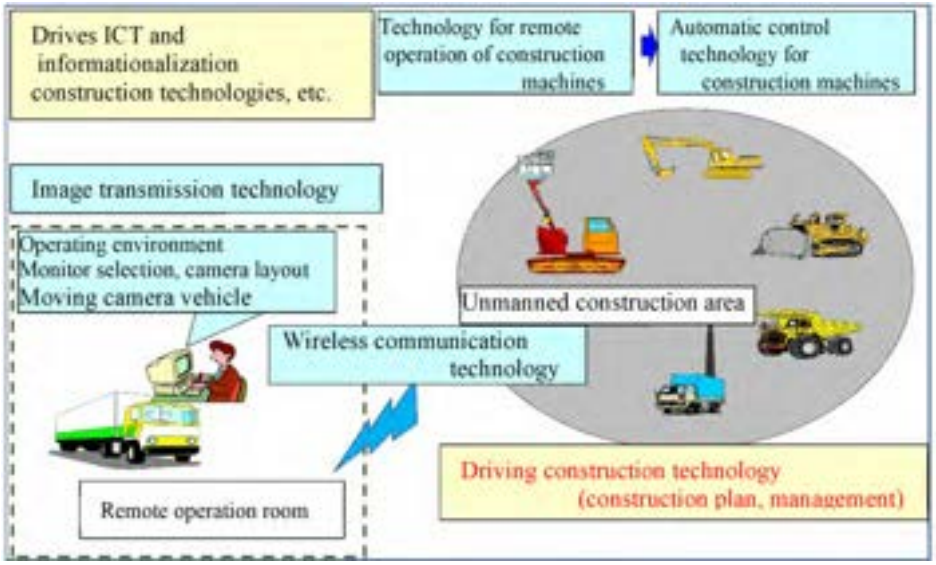

Figure 1. Unmanned Construction Technology

Figure 2. AMPHIBIOUS BULLDOZER

1.2 The birth of unmanned construction

A test field system tests new technology at the jobsite, in order to confirm its integrity.

In the case of the test field at Mt. Unzen-Fugendake, because mudslides occurred due to the increase in volcanic activity, and sand and soil accumulated in sand ponds, it is necessary to urgently remove boulders and also sand and soil. Because it is difficult to carry out construction using manned machinery, topics are assigned such as the acquisition of technology for continuous excavation and removal of soil by unmanned construction (Table1).

Table 1. Technical subject of a test field ［1］

	Contents of a technology	Technological standard
①	Excavatingand carriage accompanied by the smash at the condition and moreover, of a rock that isn't uniform	A pellet smash as much as 2 in diameter - 3 m is possible
②	A temperature in a spot is prepared to the humidity conditions.	It has been possible to operate even the condition as much as 100 ℃ of a temperature, 100 % of the humidity temporarily as a peripheral condition
③	The remote control can do a building machine.	Equal to or more than 100 m of remote control is possible.

In response to this emergency technology, public offering of technology that could be used together with procurable technology were selected, and then grouped together. The base machines consisted of large, remote operation type construction machines (bulldozers, backhoes, dump trucks) grouped together. As the operation support equipment, an ITV camera was used for securing adequate visibility over an operation distance of 100 m. Also, because the operation signals transmitted to and from the construction machines, and the image information obtained from the camera is transmitted wirelessly, wireless relay facilities for preventing instantaneous shutdown of wireless transmission, mobile camera vehicles which compensate for the dead angle of the camera image, remote operation rooms, and other ancillary facilities that are peculiar to unmanned construction were installed (Figure 3).

Figure 3. Relay vehicle＆camera car

At the commencement of construction, work is extremely difficult to carry out, even in the case of excavation work which is considered to be easy work.

Examples include radio interference, power source problems, a breakdown due to impact during construction, and problems concerning contact between construction machines at the in the dead angle of the camera. Upon completion of the test construction it was determined that excavation work could be carried out.

2 Improved technology used at Mt. Unzen-Fugendake

At Mt.Unzen-Fugendake, there is a danger of the lava dome collapsing, even at present. For this reason, a sand arrestation facility was fabricated using unmanned operation, from August 1994 corresponding to the completion of a test construction under the field system, to the present day. Concerning unmanned construction which has been employed in the Unzen region over the past 50 years, it was considered necessary to make technology improvements in communication by using a variety of sand arrestation structures and also the positional relationship between the safety zone and the work location. Also, on the other hand, equipment and other items for performing quality control was installed on trial. These items basically consist of existing useful technology that has been converted into remote technology.

For this reason, “unmanned construction” has been used from August 1994, corresponding to the completion of test construction, to the present day. This technology has been improved according to changes in the situation of the work, such as the object of construction or the operation position. Also, whenever new technology was employed, it was corrected and verified at the jobsite and its effectiveness confirmed.

2.1 Application to a variety of sand arrestation structures

Excavation technology that was confirmed by test construction was developed to the final structure.

2.1.1 Construction of a weir using the RCC method

The RCC (Roller Compacted Concrete) method which enables construction work to be performed by improving earthmoving machines was adopted. To enable this method to be used, vibration rollers, water spraying vehicles, cleaning cars, and sand and soil formwork shaping machines were developed. (Figure 4)

Figure 4. Building of RCC

2.1.2 Building of a steel slit dam

In the construction of a steel open type dam, transportation and installation were carried out, taking into consideration the shape of the steel slit. The dam was fixed by using high-fluidity concrete. Also, conveying of the concrete, conveying of the concrete to be laid, laying of the concrete, and surface-finishing were carried out. (Figure 5).

Figure 5. Building of a steel slit dam

2.2 Operating method

The operating methods are classified as shown in Table 2.

Table 2. operating method

	Watching operation	Monitor operation		
Form of construction work	It operates directly.	Monitor operation	Utilization of a becoming ICT	Utilization of TCP/IP
Overview	Watching operation	It operates while seeing the monitor of a camera.		
		-		Utilization of TCP/IP
Overview of the construction system of becoming of the unmannedness	Independent work of a remote type operation machine	Direct method A remote type construction machinery communicates with an operation place directly. Relay method An operation place and remote type operation machine are done through a relay-aircraft.	Utilization of a becoming ICT GNSS measure uses a technology and guidance equipment.	Utilization of TCP/IP It adopts a wireless LAN to the operation and transmission of the picture information.

2.3 Quality control

In Japan, the control outline was formulated in 2012. Presently, “Compaction control using TS-GNSS” has come into general use. When compaction was carried out in the Unzen zone using unmanned operation, it was used from 1995 as RCC method concrete laying control and also compaction control using a GPS in 1999 (Figure 6, Figure 7).

When an unmanned operation was performed at Mt. Unzen-Fugendake, concrete laying control using a GPS occurred in 1995. In 1999 compaction control took place using an GPS.

In this way, when unmanned operation was performed at Mt. Unzen-Fugendake,new technology was introduced proactively, enabling the performance to be confirmed. As a result, the spread of new technology advanced (Figure 8, Figure 9).

Subsequently as well, efforts were made to promote remote operation of surveying equipment, flat plate loading tests, and core boring machines.

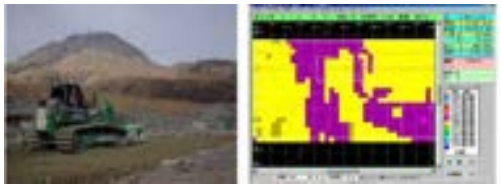

Figure 6. Management of an leveiing

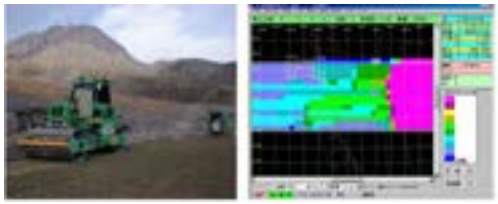

Figure 7. Management of an compaction

Figure 8. Remote control type measure equipment

Figure 9. Measuring machine of a remote control type bearing power of groun

3 Information transmission base of a new technology

Building of becoming of the unmannedness was established by a thing such as it develops Unzen Fugendake as a base in various parts of Japan and that technology feeds back into Unzen Fugendake again with a technology.

Also, we used it at an early stage such as compaction control using GPS to verify its performance.

3.1 Whole country spread of building of becoming of the Unmanned Construction Technology

Building of becoming of the unmannedness of an Unzen area makes it the causing place of a nucleus technology, and that technology is developed in the volcanic disaster / landslide disaster of various parts of Japan (figure 10).Also, also, that disaster occurrence form is done to the improvement adjusted to the characteristic of each place to be different respectively.

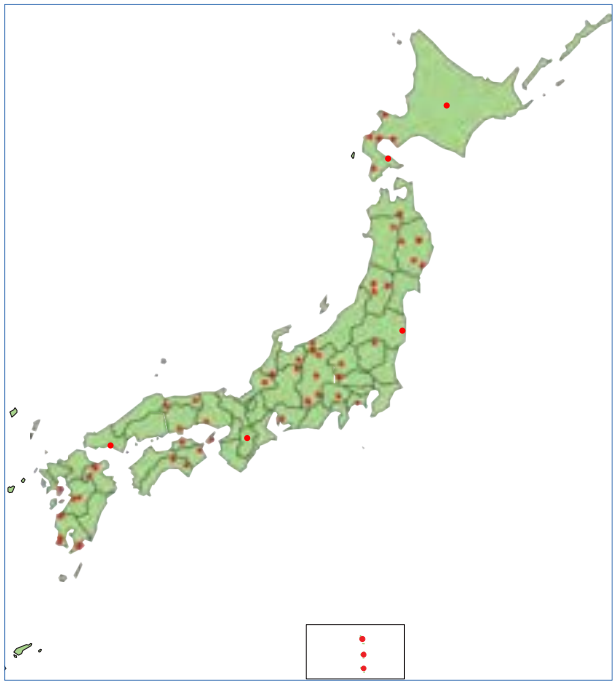

Figure 10. Building of becoming of the unmannedness implemented in Japan

4 Recent situation concerning unmanned operation at Mt. Unzen-Fugendake

Preparation of a sand arrestation on a dry river bed at Mt. Unzen-Fugendake is advancing, and the object of unmanned construction also changes. Very recently, this work consists of reinforcement work for existing sand arrestation facilities. Compared with the previous operations, it can be seen that this work is carried out on a narrow working area. When carrying out unmanned construction in the applicable zone, technology will be updated.

A description of the latest technology is set out below.

4.1 Construction technology

The most up-to-date technology is used. at Mt. Unzen-Fugendake.

4.1.1 Machine control bulldozer

An operation guidance system is provided as standard. Regarding control of the blade of the bulldozer that determines the quality of the concrete compaction, a automatic control system is used.

4.1.2 Compaction using a Excavator

When performing compaction work in confined spaces, a excavator bucket with compaction equipment was used in order to regulate the compaction time (Figure 11) .

Figure 11. Bucket total firming equipment

4.1.3 Surveying by using TS tracking and electronic reference points

In order to increase the accuracy of UAV surveying, it is necessary to use the altitude points (verification points and evaluation points) inside the measurement points. In order to reduce the number of measurement points inside the prohibited zones, the number of elevation points was reduced by measuring the position of the camera mounting on the UAV, by means of an automatic tracking total station. Regarding the evaluation points, a device that measures the self-coordinates by static conveying, of a remotely operated type construction machine was installed on a remote-operated construction machine. (Figure 12).

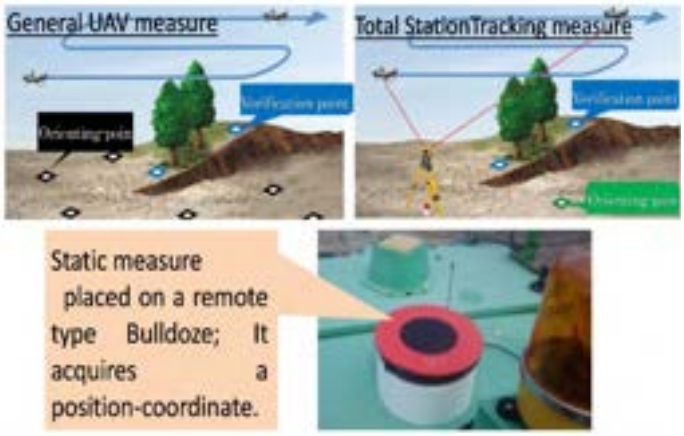

Figure 12. Electronic tacheometer tracking and UAV measure by an electronic reference mark

4.2 Safe watch

When carrying out unmanned construction at Mt. Unzen-Fugendake, it is important to carry out safety monitoring as well. The greatest danger is that of the lava dome collapsing. Consequently, visual monitoring and image monitoring were carried out.

4.2.1 Securing visibility by image clarification processing

Much fog and mist envelope the Mt. Unzen-Fugendake zone, posing an impediment to monitoring. For this reason, image processing was performed to determine whether foggy or misty areas are thin or dense, and also whether the distance is near or far, in order to improve the visibility of misty areas (Figure 13).

Figure 13. Securance of the visibility by processing of becoming of the image clearness

4.2.2 Obtaining an early grasp of an earthquake

There is a danger of the lava dome collapsing due to an earthquake. For this reason, an integrated type quake detection system has been installed in the operation room to permit earthquake monitoring (Figure 14).

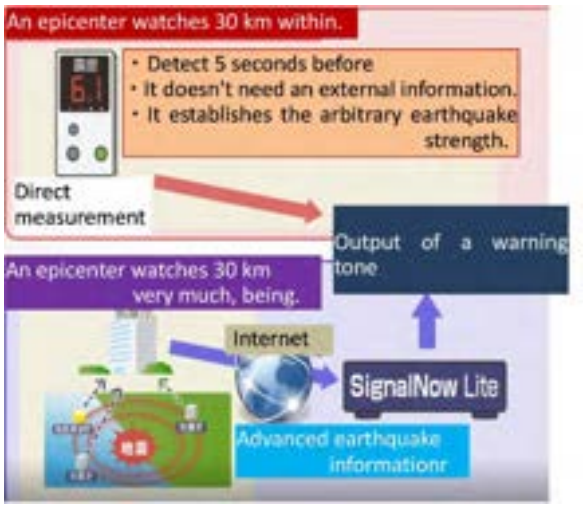

Figure 14. Earthquake watch

5 Conclusion

Even after the eruption of Mt. Unzen-Fugendake, Japan has been fraught with many disasters such as the eruption of Mt. Usu, the Mid-Niigata Prefecture Earthquake, the Iwate-Miyagi Inland Earthquake, and the Great East Japan Earthquake. As a result of the adoption of unmanned constructions, the regions concerned quickly recovered from the disasters.

In this way, unmanned construction enabled quick action to be taken for all disaster regions in Japan. This is because even after the end of the test field system, unmanned operation was performed continuously at Mt. Unzen-Fugendake, and also because efforts were made to realize performance improvement. Also, in recent years, informationalization construction as well is used in advance at Mt. Unzen-Fugendake enabling the performance to be confirmed. It also performs an important role with respect to new technology in the construction zone at Mt. Unzen-Fugendake.

However, at Mt. Unzen-Fugendake, there still exists the danger of an avalanche due to the collapse of the lava dome, and also apprehension concerning the possibility of the disappearance of the unmanned construction jobsite when the scheduled sand arrestation facility is completed.

Japan, from its national land consisting of location, terrain, geology, and also its natural conditions, is considered to be a fragile land from the viewpoint of natural disasters including earthquakes, typhoons, and localized torrential rain. It is also considered that the securing of a providing ground for unmanned construction, which is effective technology for recovery from a disaster, is important for to the future development of civil engineering.

Abstract –

Since March 2020, 5G has been commercialized mainly in urban areas in Japan, and 5G communication infrastructure demonstration tests are actively conducted among various industries such as telecommunications carriers and construction industries.

The authors installed a portable 5G base station close to tunnel portal in "Subcontracting for research and study of technical conditions, etc. for a fifth-generation mobile communication system (Hereafter, 5G). This can handle simultaneous connection requests from various terminals" (Hereafter, 5G demonstration experiment) of the Ministry of Public Management, Home Affairs, Posts and Telecommunications in fiscal 2019, and constructed a high-quality radio wave environment in the tunnel pit, and carried out various experiments to improve working environment such as safety.

This paper describes an experiment in which a long-distance running and lifting work of a construction machine succeeded by remote control, while a high quality radio wave environment was constructed in a tunnel construction site by 5G, and clear multiple images which can surely carry out remote control, and other support information were acquired.

Keywords –

fifth-generation mobile communication system(5G); construction machinery; remote control

1 Summary

Standardization of the next generation mobile communication standard (Hereinafter abbreviated as "5G") is advanced in 3GPP (3rd Generation Partnership Project) which decides the world standard of the mobile communication.

5G can realize high speed and large capacity (eMBB: enhanced Mobile Broadband: up to 10 Gbps or higher), ultra-low delay (URLLC: Ultra-Reliable and Low Latency Communications: One-way transmission delay of 1 ms or less), and multiple simultaneous connections (mMTC: massive machine type communication: 1 million devices/km^2), and is expected to be used not only in conventional communications not only for smartphones but also in various industrial fields [1].

In recent years, there has been a strong movement to improve productivity at construction sites through ICT (information and communication technology) based on the "i-Construction (i-Con)" advocated by the Ministry of Land, Infrastructure, Transport and Tourism. Many IoT and ICT equipment easily used on site, have been introduced and put into operation.

However, even before i-Con was proposed, there was a method using IoT and ICT, which is the focus of this paper, unmanned construction by remote control of construction machinery (Figure 1).

Figure 1. Status of unmanned construction

This method is used at the restoration of natural disasters and in severe places such as radioactive environment, etc., where safety is concerned when person enters and work, and using radio-controlled construction machines communicating by radio and camera images for confirming the construction situation. Therefore, the construction of wireless infrastructure is a very large technical element for this method.

If radio-controlled construction equipment cannot be operated smoothly due to the quality of the wireless infrastructure, or if the quality of camera images for acquisition of construction information is deteriorated, the construction efficiency is affected and construction becomes difficult. Therefore, the present unmanned construction is often carried out in the range of about 150 m in which radio wave surely reaches by utilizing Wi-Fi, etc.

Unauthorized and inexpensive Wi-Fi is said to have a considerable merit, but in reality, there are not many works that can be done within the range of one Wi-Fi communication device.

Even if authorization is necessary, infrastructure which can stably communicate in a wide range will be required in future. Therefore, the experiment was also carried out from the viewpoint of whether the new communication means of 5G can become the communication infrastructure for the remote control of the construction machinery.

Figure 2. Image of remote control

2 Outline of experiment and demonstration site

The Japan islands are divided into the Pacific Ocean side and the Sea of Japan side by chain of mountains. Population tends to be concentrated in lowlands on the sea side and basins in mountains.

Because 70% of the land is mountain and hilly land occupy geomorphologically, the transportation infrastructure between cities in the lowland and basin passes through the mountain.

Since old times, the transportation network has been constructed by cutting down the mountain. In recent years, transportation networks in mountainous areas have been disrupted by disasters caused by abnormal weather.

Losses due to these disasters have social and economic impacts not only on damaged transportation infrastructure facilities but also on the isolation of regions. Therefore, it is highly necessary that the tunnel is newly constructed or improved as a review of the transportation network

The reason we selected "tunnel" is because 1) we thought that tunnels are indispensable infrastructure for modern society as railway transportation infrastructure such as subway and life infrastructure such as water supply and sewerage; and 2) important as social capital in urban areas.

Since the radio wave has the property of reflection and transmission, we thought that it was interesting in the aspect of how much radio wave reaches by repeating reflection and transmission in the tunnel environment.

From such background, this experiment was carried out on a subject of "tunnel", assuming actual possible phenomena, and considering to propose a solution. As shown in Figure 3, it is assumed that a site survey and response are carried out when an inaccessible place occurs in a tunnel. A 5G base station is installed near the entrance (Hereinafter, the pit mouth) of the tunnel, and radio waves are outputted toward the tunnel pit. We decided to carry out remote control of the construction equipment within the range of radio waves.

At present, when such a situation occurs, preliminary investigation and consultation with experts are carried out as much as possible, but there are cases in which eventually carried out by human power. In the future, these cases should be avoided from the viewpoint of worker safety, and they should be dealt with by IoT/ICT or 5G communication technology. This experiment is considered to be a practical use case.

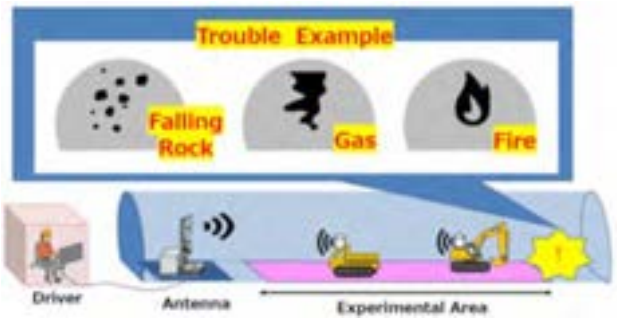

Figure 3. Outline of this experiment

In the experiment, we mainly carried out the following two points.

1. 5G radio wave propagation characteristics (reach distance)
   A 5G radio base station was installed near the tunnel portal to the face, and determined the experimental area by measuring where it reaches in the tunnel.

2. Remote operation of construction machinery The remote control of the construction machine was carried out in the experimental area. (4-ton class crawler carrier and 12ton class hydraulic excavator

2.1 Experimental Location

Project names: Hokkaido Shinkansen Line, Shiribeshi Tunnel (Ochiai)
Owner: Japan Railway Construction, Transport and Technology Agency (JRTT)
Contractor: Taisei, Sato, Tanaka, Horimatsu JV
Construction period: March 26, 2015 - June 24, 2022
Main construction: Tunnel excavation 4,865 m (Standard cross section: 65 m2)

2.2 Use of portable base stations

In conventional mobile communications, in order to deal with data communication traffic of mobile phones such as smart phones, base stations are often installed mainly from urban areas where the number of users is large. On the other hand, in 5G, by utilizing the features of eMBB, URLLC, and mMTC, it is considered that IoT (Internet of Things) will become the mainstream along with smartphone.

However, when it is applied to IoT, not only in urban areas but also in suburban areas where the number of users is relatively small, a large amount of traffic processing will be periodically required. Construction sites are one of such IoT use cases, but constructing new base stations in suburban areas requires more time and cost than constructing in urban areas.

In this experiment, we used a portable 5G base station developed by Softbank Corporation, which can construct a local 5G communication infrastructure (Figure 4). In this base station, not only antennas and radios but also core equipment in the data center can be arranged in the field. Therefore, in the field, the collected data can be processed at high speed and in a complicated manner.

And, if prior adjustment such as license application is completed, 5G communication area can be rapidly developed in a few days, and will be suitable network solution for the development of IoT to the suburb.

Figure 4. Portable 5G facility installed in the tunnel (4.85 Ghz, 120 W).

2.3 Use of on-board remote-controlled robots

For the remote control, we used the construction machine mounted remote control robot (hereinafter referred to as Robot) developed by Kanamoto Co., Ltd. The experiment was carried out by mounting this robot on each of the two construction machines mentioned above.

The robot is a humanoid twin-arm bipedal robot (Figure 5) with the total length of about 1.5 m and the weight of about 20 kg, which can be installed in the operator's seat of a construction machine. (conversion to radio-controlled equipment). By transmitting the image mounted on the construction machine in real time from the driver's viewpoint and transmitting the state of inclination and vibration of the vehicle to the driver's seat bilaterally, the system is capable reproducing the driving remotely feeling close to the real machine.

In addition to such reproducibility, it is highly possible to respond more quickly than the method of procuring radio-controlled construction machinery with limited number of units. For the construction site, there is an economical merit that the construction machinery in the site can be utilized. In this experiment, it was also the first execution to control the Robot by 5G communication in the environment in which the visual observation was not effective at all.

Figure 5. Robot

2.4 Use of Human Body Detection Cameras

There is a report from advanced driver-assistance systems (ADAS) to support the driving operation of the driver of the car that the number of "Rate of contact accidents with people" is decreasing in the cars equipped with "Human body detection system". ADAS is a function to automatically stop a vehicle when a person is detected in a traveling direction by a camera mounted on an automobile, and is an epoch-making technology to improve safety of a driver and a pedestrian.

One of the three major industrial accidents in the construction industry is "construction machinery", and there are many reports of cases in which people and machines come into contact. Taisei Corporation is developing technology to eradicate this disaster.

In this experiment, we plan long distance running by remote control by crawler dump with high rough terrain running performance as an initial action. We also assumed that it was necessary to explore whether there were people left in the tunnel in an emergency. In this experiment, we used a technology that automatically stops construction machinery by sending a stop signal to the construction machinery side when a person enters the movable range of the construction machinery during remote control.

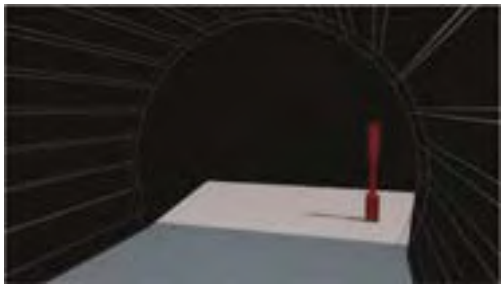
Figure 6. Human body detection camera
(Above: Detected human body)

3 Experiments and Results

Troubles such as “fire”, “toxic gas”, and “rockfall” shown in Figure 3 are supposed in a tunnel pit, which is difficult for a human to approach. For such trouble, the experiment was carried out by the following procedure. (This is an assumption and is not related to the experimental site.)

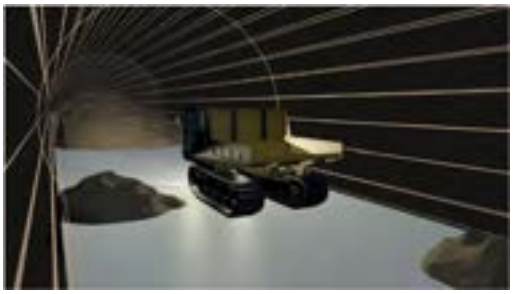
3.1 Experimental Scenarios

1. Portable 5G base station installed near the tunnel portal



2. Investigation by crawler carrier. In addition to cameras, gas detectors and scanners are installed on vehicles.

3. Since the vehicle has high traveling performance, it is possible to search for long distance while avoiding obstacles



4. A loading machine is installed to remove the obstacle

5. Image of Obstacle Removal

6. Removal completed. go further into

3.2 5G Radio Wave Propagation Characteristics (reach distance)

A radio wave measuring vehicle was used to measure the processing speed (UL side throughput) of the 5G radio wave in the tunnel pit for each distance. The results are shown in Figure 7.

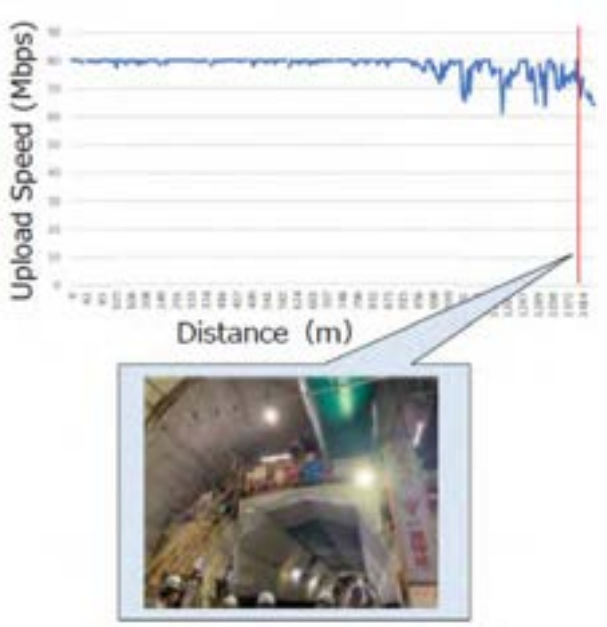


Figure 7. Measured results of the distance reached.

The site had a section including a curve (R = 6,500 m), and it was an environment in which the back side could not be viewed directly, and in addition, it was an environment in which materials and equipment for construction were placed. Therefore, in the preliminary examination, the reach distance of several hundred meters was estimated. However, actually, the radio wave reached far exceeding it. At the 1,400 m point, the "tunnel lining form" which covers most of the tunnel section is located (Therefore, the radio measurement vehicle was

not measured on the face side.), and the processing speed is expected to drop rapidly beyond this point.

3.3 Remote Control of Construction Machinery

Two models shown in Figure 8 and 9 were remotely operated

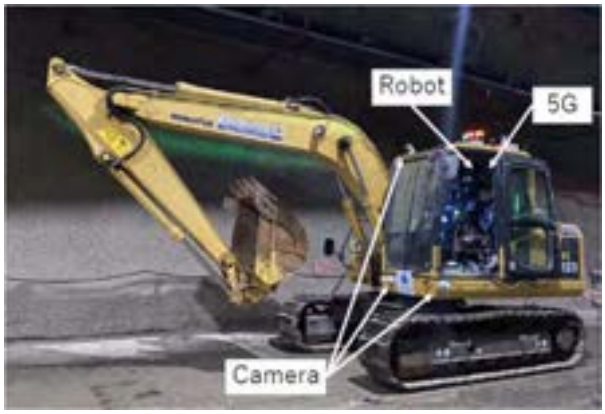

Figure 8. 12ton class hydraulic excavator

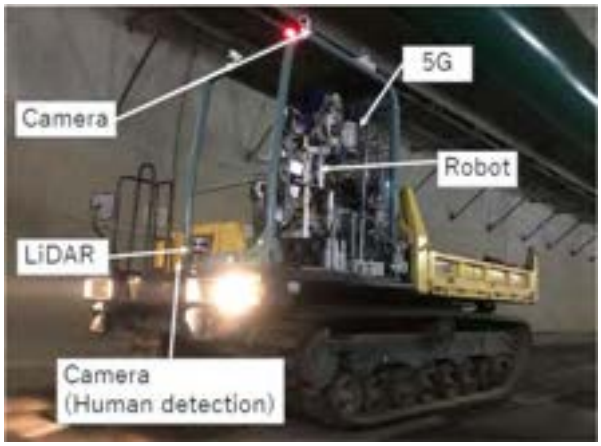

Figure 9. 4ton class crawler career

The remote control which steers while watching the video information is usually carried out by in-vehicle video and bird's-eye view video. However, it is difficult to make a large numbers of birds-eye image acquisition facilities for remote control, because of technical and economic difficulties.

Therefore, in this experiment, by taking advantage of the feature of large-capacity 5G communication, by adding a large amount of sensor information in addition to in-vehicle video as in the past, all remote operation support information was installed in the vehicle, and no birds-eye view video was used (Figure 10).

Figure 10. Remote operation support information

Table 1 lists the remote operation support information for this experiment. Here are two sensors to be noted.

One is the detection of obstacles on the tunnel wall and ahead from the large-capacity point cloud information obtained by sensing with Lidar (Generic 16 Line). The other is the adoption of the human body detection system by AI developed by Taisei Corp.

In both systems, smooth transmission and reception are difficult using conventional Wi-Fi and low-power communication, but 5G communication is possible.

Table 1. List of Remote Operation Support Information.

type	Direction	Units	Capacity (bps)
Vehicle Camera	Up	4	60M
Robot Control	Down	1	40K
Vehicle Vibration	Up	1	40K
Lidar	Up	1	70M
Human detection	Up	1	15M

Each construction machine was able to carry out the following by remote control. Both were successful without birds-eye view (Figure 11).

1. A crawler carrier ran 1,400 m by remote control.

2. 2) Hydraulic shovel: lifted and moved 1ton sandbag by remote control.

Figure 11. experiments

4 Conclusion

The verification of the portable 5G facility was carried out in the tunnel environment this time, following the external environment in fiscal 2018 [2]. From the result, it is considered a communication infrastructure which can be adapted to many construction sites.

In the construction site, the construction is started by improving temporary facilities in accordance with the construction contents. In order to advance the ICT in the construction field, "temporary communication" will be necessary in future, and the possibility that 5G will become highly influential in the selection of the communication radio wave.

The case verified this time is the technology which can be utilized for investigation of tunnel disaster and emergency work even in the present stage, and it is considered to be one of the effective utilization of 5G. We would like to continue our research on the improvement of construction productivity using 5G.

I would like to take this opportunity to thank all of you who are participating in and cooperating with this experiment.

Abstract –

We have developed a remote operation support system for underwater excavators and conducted Sea experiments. Underwater excavators have been operated by divers boarding on them. Their main task is levelling rubble mounds of port structures in Okinawa, Japan. However, in recent years, remote control is required due to the decrease in the number of the divers. Therefore, we have been developing tele-operation support system for underwater excavators. This system integrates three elemental technologies such as "Underwater Information Presentation" that serves as a display interface, "Measurement Method of Mound Shape" and "Attachment for levelling works operated with simple input". So far, we conducted elemental tests of each technology underwater and on land to confirm their usefulness.

In this report, we performed experiments using this system in the sea. First, the elemental test of the attachment was performed by boarding operation of divers. The purpose of the attachment is to perform levelling works without difficult input for position adjustments in order to improve the work efficiency of remote operations. The purpose of the tests is to evaluate the performance of the attachment alone. The measurement items are the varies of mound height and the working time. As the results, the attachment was confirmed to be able to submerge the mound and the operability in the sea is the same as that on land. Next, a remote operation test simulating levelling works was conducted to measure the work accuracy and the work efficiency. As the results, by adding a mechanism to move stones to depressions, this system is demonstrated to level the mound from unevenness of ±30 cm to that of ±10 cm. In addition, it is confirmed that the working times with the system depends on the operators' experiences of tele-operations more than that of boarding operations.

From the above, the proposed system is demonstrated to be useful for levelling works of mounds by tele-operated underwater excavators.

Keywords –

Tele-Operation; Underwater Construction; Port Construction;

1 Introduction

Underwater excavators have been adopting for a long time in port constructions in Okinawa, Japan. They are similar in shapes and mechanisms to those on land. However, their hydraulic systems are powered by electric motors. Therefore, they have cables to supply the electric power for the motors from ships. They have been controlled by divers on their cockpits in the sea.

Their main task is levelling works of rubble mounds underlying port structures. They perform the works by pressing the backs of buckets against the mounds or moving stones to depressions (shown in Figure 1).

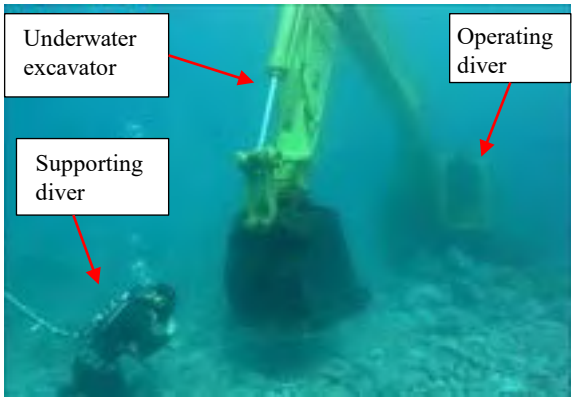

Figure 1. Conventional Levelling work of mound by divers using underwater Excavator

At present, there are two problems. One is that these operations require huge efforts for the safety management. Muddy sea water in construction sites prevents operators from grasping conditions of mounds. Thus, they have to be supported by other divers. The supporting divers change positions of stakes and check unevenness of the mounds. Therefore, they have to stay nearby the vehicles. For this reason, safety checks must be conducted Strictly. Secondary, the work productively is not high due to work suspensions caused by restrictions on dive times or sea conditions. Due to these backgrounds, in order to improve the safety and the efficiently, remote-controlled constructions are required.

Therefore, we have been developing a tele-operating support system for underwater excavators.

2 Tele-operation Support System

An outline of our system is shown in Figure 2.

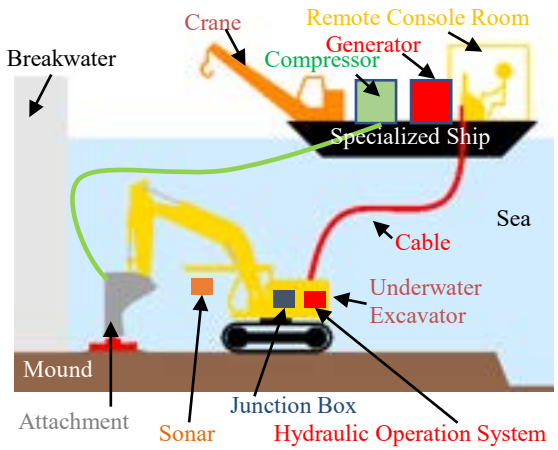

Figure 2. Image of Tele-operation system of underwater excavator

Tele-Operation of underwater excavators is implemented by installing proportional solenoid valves in the pilot hydraulic circuits. Operators use remote consoles on ships, and control the valves by electric signal. Then, the flow rates of the pilot circuits vary and drive the main spool valves. In this way, the flow rates of hydraulic oil are controlled, and operate the hydraulic cylinders.

In addition, we proposed Tele-operation Support System composed of three elemental technologies which are "Underwater information presentation", "Measurement Method of Mound Shape", and "Attachment for levelling works operated with simple input" (shown in Figure 3).

2.1 Underwater Information Presentation

This is an interface that shows work information to remote operators on a ship. It is difficult to visually recognize the position and the orientation of a underwater construction equipment from the ship due to turbidity.

Therefore, the posture of the excavator is calculated with data measured by sensors installed on the vehicle. stroke sensors for cylinders, a gyro sensor, an inclinometer, a geomagnetic compass, a depth gauge, an underwater acoustic positioning device, an encoder etc. are installed (shown in Figure 4).

On the ship, there are a remote console and 3 monitors showing cross-sectional views, bird's-eye views and top views (shown in Figure 5). In addition to them, design information input in advance are also displayed (shown in Figure 6). This allows the operators to work without directly watching the work area in the sea.

So far, an installation test has been performed in actual construction site to verify the robustness of the underwater information presentation alone [1]. In the test, an operating diver ridded on an underwater excavator and performed the conventional levelling work of a mound. The information presentation monitor was installed in the

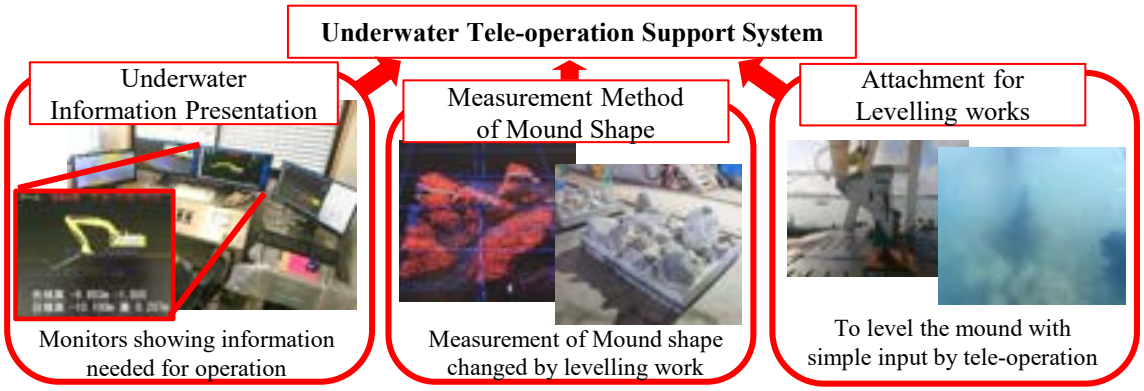

Figure 3. Three elemental technologies for Underwater Tele-operation Support system

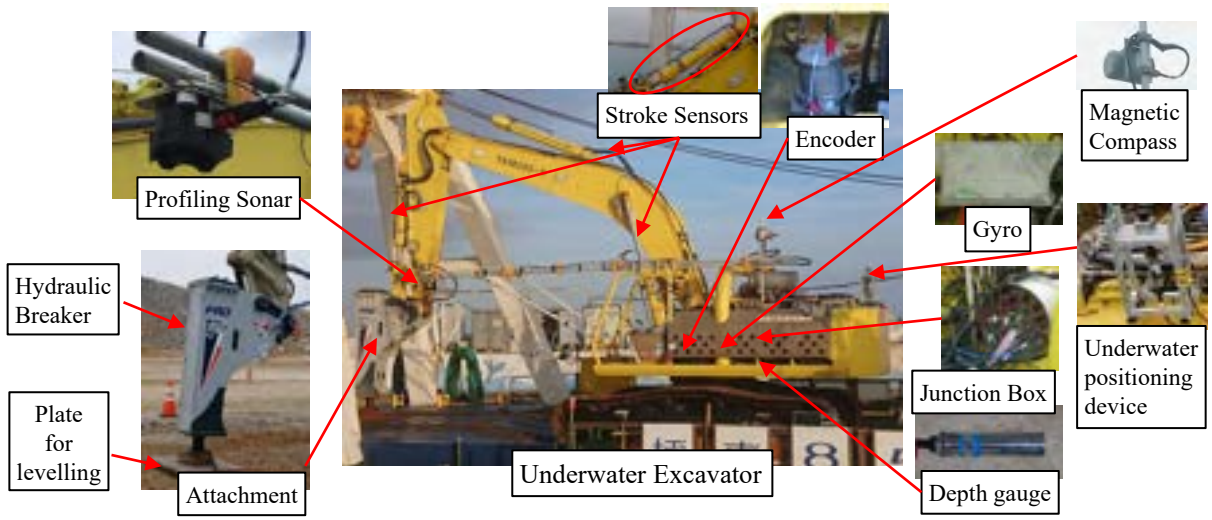

Figure 4. Sensors installed on excavator for underwater information presentation system

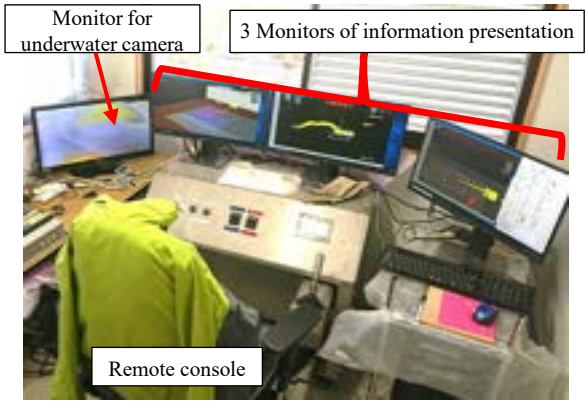

Figure 5. Monitors for underwater information presentation system on remote console room

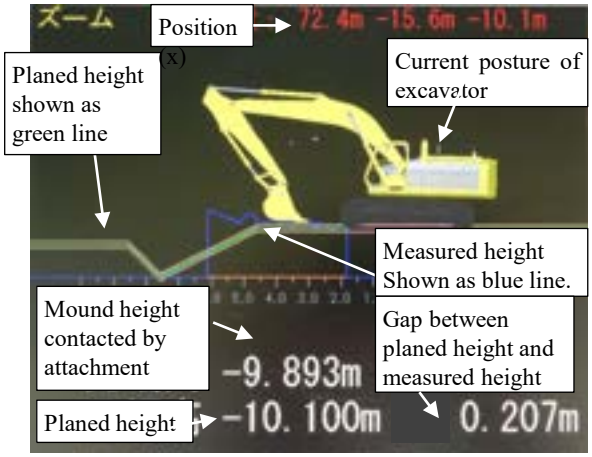

Figure 6. Cross section view of underwater information presentation system in remote console room

cockpit and was used by the diver as a reference for operation. As a result, there was no failure of equipment such as sensors. However, the position measured by the sensor was not correct. The horizontal distance between the ship and the equipment was several meters, but the measured results were often over a hundred meter. This is due to the characteristics of the underwater acoustic positioning system. This system installs a reference station on the ship and a target station on the vehicle. The position is detected by performing triangulation with sound waves between the stations. In this experiment, the sound waves may be blocked by the bubbles from the diver's breathing. Thus, the sound waves may not reach the reference station directly from the target station. At that time, the wave reflected on existing caissons or the seabed may be measured and mistakenly recognized as the direct sound wave. For the reasons, it is considered that the measured values differ from the actual positions. In the experiments conducted in this study, in order to mitigate the effect of bubbles, the installation position of the underwater acoustic positioning system was moved to the rear end of the body.

2.2 Measurement Method of Mound Shape

The height of mounds changes from moment to moment due to the works. Therefore, it is necessary to measure the mound height during the levelling works. We implemented two methods in the system. One is the way using a profiling sonar. Profiling sonars are time-of-flight distance meter using sound waves. Acoustic sensors are less susceptible to turbidity than optical devices such as laser scanners. Therefore, sonars are often used for underwater measurements.

From this measurement, the difference between the mound surface and the target height can be calculated.

The calculation result is shown on the monitors of underwater information presentation and serves as a substitute for the stake. This eliminates the need for the supporting divers to stay in the sea for the staking. This is essential for remote control constructions. In this study, M3 sonar (from Kongsberg Maritime Ltd.) was adopted in consideration of the time required for measurement. The sonar measures the coordinates of 128 points on one cross section up to 40 Hz.

The profiling sonar was installed as shown in Figure 7. The measurements are performed at each time when a certain range end. The sensor was moved with the rotations of the upper part of the excavator to measure the height of the mound surfaces.

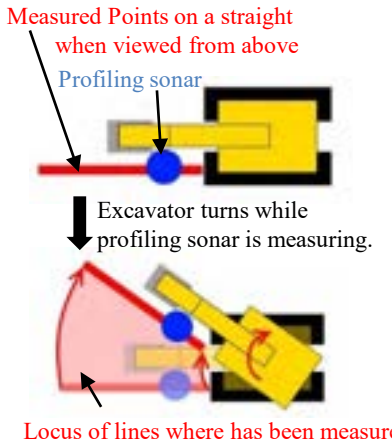

Figure 7. Top view image of position where Profiling sonar installed and the method to measure the height of mound surface

In order to confirm the measurement accuracy, an elemental test was conducted in a water tank [2]. The profiling sonar measured the flat bottom surface of a water tank and mound model in the tank. The mound model was made of rubble stones which are same size as stones of actual rubble mounds in Okinawa, Japan.

As the result, it was apparent that it is possible to recognize the shape of the bottom surface. However, we cannot grasp the contour shape of each stone. This is because the gap between stones could not be measured accurately. In addition, it cannot measure the height under the tip of the arm. Therefore, we cannot judge the completion whether the pressed points get within the acceptable hight. Hence, we examined another way to measure the mound height.

Another method for measuring the height of mounds is to measure by contacting the tip of arms of excavators against mounds. When the attachment is pressed against mounds, the height of the tip calculated by the information presentation system is same as the mound height. It has been shown from the results of previous experiments that this method can measure the mound height with an average error of 31 mm. However, this method can measure only one point in one measurement. Hence, it is not suitable for surface measurement. Therefore, we use the two measurement methods properly depends on the purpose.

2.3 Attachment for levelling work operated with simple input

For the purpose of improving the work efficiency, we examined an attachment that can level mounds without delicate input based on detailed topographic information.

So far, a remote operation test was conducted with a combination of elemental technologies which are "Underwater Information Presentation" and "Measurement Method of Mound Shape". In the test, a stone placed on a flat floor was grasped with a fork grab and moved to a predetermined place. we evaluated the working time depends on the observation method. As a result, it takes 1.8 times longer to perform the work with the profiling sonar, compared with the case of directly visual observation on land. It is considered because the contour of the stone is unclear, and it takes time to perform the operation of positioning for gripping. Therefore, we developed "attachment operated with simple input" for the purpose of improving the work efficiency.

In this system, we proposed a mechanism to attach a plate to the tip of a hydraulic breaker (shown in Figure 4). Not only the static load of the machine, but also the dynamic load of a breaker pushes down protuberances of mounds to perform levelling works. On the other hand, this attachment does not have the ability to raise the lower part than the plan.

An element test was conducted on this device to perform levelling works on a rubble mound installed in the air, to confirm its performance [3]. As a result, it was revealed that the attachment has an ability to level to bring down to the target height from +30cm height.

In addition, we conducted element tests of the proposed attachment in the sea. The purpose of the experiments was to confirm whether the attachment has the ability to level the mound in the sea and the time required for the work. The experiments were carried out at a rubble mound in Hirara Port in Okinawa, Japan. The top surface had a water depth of about 5 m, and unevenness of ±30 cm.

In the experiment, the attachment was equipped on an underwater excavator TKM200-9 (owned by Kyokuto Co., Ltd) whose operating mass is about 20 tons. A diver boarded on and operated it. The diver had experience of controlling underwater excavators in normal tasks. The work was done according to the instructions of an

assistant diver.

The attachment banged the mound for 5 seconds and paused. Then, we measured the mound height. We alternated 5 seconds of beating and measuring for 6 times at the same point. As a result, it was shown that the mound surface could sink 11 cm in 5 seconds and 25 cm in 30 seconds.

In addition, an experiment simulating a continuously work in a range of 2m x 5m was also conducted. In this experiment, we could not recognize the height because we did not stake. Hence, the time for each impact was fixed at 5 seconds. The assisting diver instructed the banging position and the posture of the front part (arm, boom and bucket cylinder). As the result, the working time was the same as the land test if supporting divers guided them. It was confirmed that no deterioration in operability in the sea due to the attachment was observed.

3 Performance test of the remote-control support system in the sea

In order to examine the performance of the remote-control support system, performance tests were conducted in the sea (shown in Figure 8). The experiment was carried out at a caisson mound at Hirara Port. The top is about 8.7m deep. The working areas were 5m x 7m areas on the top of the mound. In the initial state, the top of the mound had unevenness of about ±30cm from the target height. The target of the works is to level unevenness within ±10 cm in the working area.

In the levelling works, the attachment banged a point of the mound until the height gets within the acceptable height. The operator confirmed the completion by watching the cross-sectional view showing the hight of the tip of the attachment contacting with the mound. After that, the attachment was moved to another unlevelled point. The layout is shown in Figure 9. The work procedure is shown in Figure 10.

Figure 8. Captures of sea experiments (left figure; Excavator craned into the sea, right figure; Excavator working without divers on cockpit)

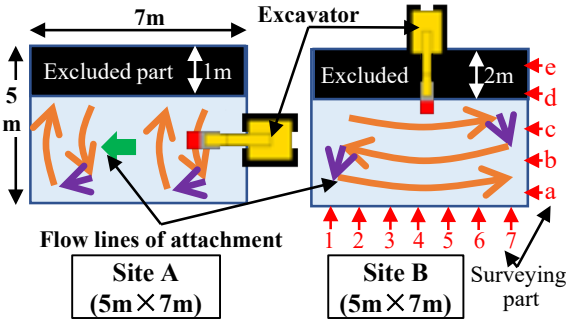

Figure 9. Layout of levelling tests of Site A (left figure) and Site B (right figure)

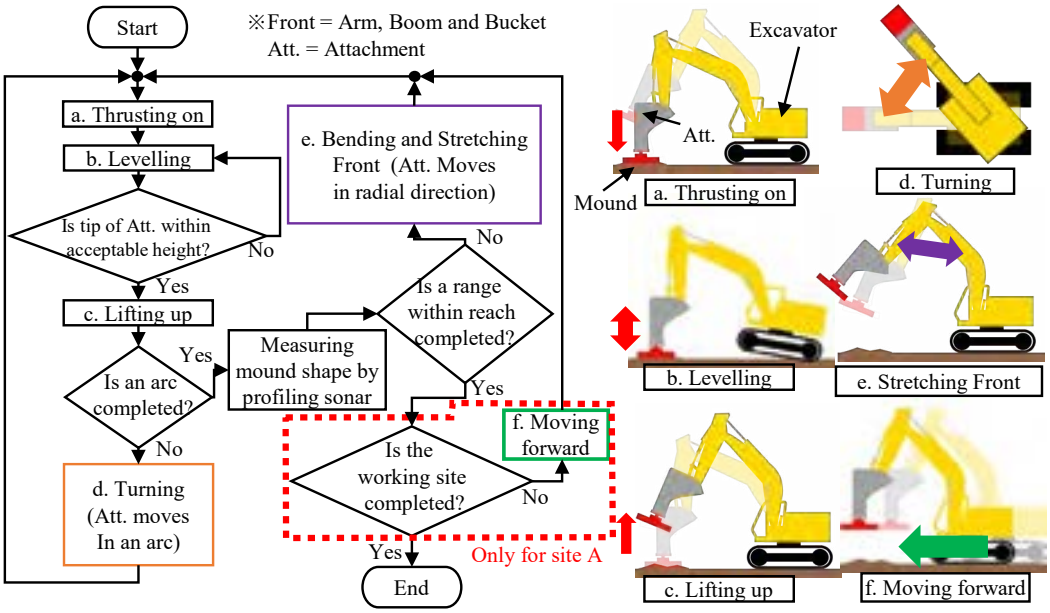

Figure 10. Procedure of levelling tests of mound using tele-operated underwater excavator

The right part of Site A was over 30cm higher than the target height in the initial state. Therefore, it was not possible to make it sink to the target height with the attachment. Therefore, the range was excluded from the evaluation of the work efficiency. On site B, a range in front of the vehicle was excluded from the evaluation. This is because it was out of the working range of the arm.

In Site A, the test is performed by an operator who is an underwater excavator operator and has no remote-control experience. On the other hand, an operator on Site B is not an operator boarding on underwater excavators, but has experiences of remote operations.

3.1 Accuracy of Mound Height

From the results, we assessed the accuracy of the mound height after the works. Before and after the experiment, the mound height was measured by divers using an underwater levelling instrument (shown in Figure 11). Figure 12 and Table 1 show the hight of the Site A after the test. The grey cells in the table are the excluded part. As the results, some points that were higher than the acceptable range remained. The point in yellow circle in Figure 12 is because the initial height was +40 cm from the target. Thus, the attachment could not enough subduct. The part shown in the red circle is because the operator did not bang there due to misunderstanding that it was out of the working range.

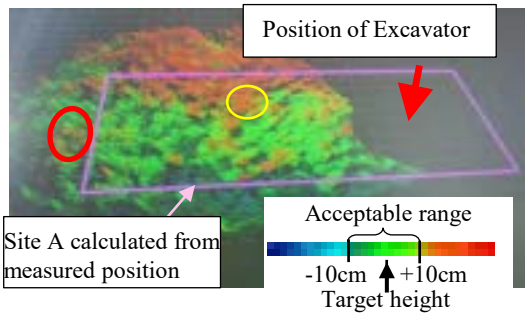

Figure 12. Bird-view of the Site A after experiment shown on monitor of "Underwater Information Presentation"

Table 1. Unevenness from target height surveyed after experiment on Site A

Height [cm]	7	6	5	4	3	2	1
e	23	12	22	21	8	20	25
d	19	10	6	20	5	-2	7
c	14	7	2	-5	-5	6	7
b	2	10	2	4	-3	5	10
a	1	-2	6	-9	9	0	5

The misunderstanding was caused by the measurement error of the horizontal position of the vehicle. That can be dealt with by setting a larger construction range.

In addition, the average height is 0.03m higher than the planed height and the deviation σ was calculated to 0.05m excluding the points in the red and yellow circles. If the mound shape after the work has a normal distribution, 68 % of the mound is within 1σ (-0.02m to +0.08m) in height and 95% of that is within 2σ (-0.07m to +0.13m).

On Site B, 3 survey points were measured -10cm or lower than the planed height. Table 2,3 show the measured height by divers before and after the experiments. Figure 13 shows that measured by the profiling sonar.

The points in black circle in Figure 13 are a missing measurement. The initial height is so low that the sonar cannot measure it hiding behind the rock in front. The points in yellow circles are considered to be the result of striking too much.

Table 2. Unevenness from target height surveyed before experiment on Site B

Height [cm]	7	6	5	4	3	2	1
e	17	30	5	13	28	18	42
d	-6	62	52	32	18	24	22
c	32	31	38	13	38	6	-18
b	-6	35	36	-1	13	33	27
a	-4	24	11	38	21	29	42

Table 3. Unevenness from target height surveyed after experiment on Site B

Height [cm]	7	6	5	4	3	2	1
e	17	34	21	11	30	16	27
d	-11	38	42	29	18	22	5
c	-12	1	-3	6	-1	-10	-17
b	-18	0	0	-2	-15	-5	-1
a	-9	-6	-2	0	-8	2	-2

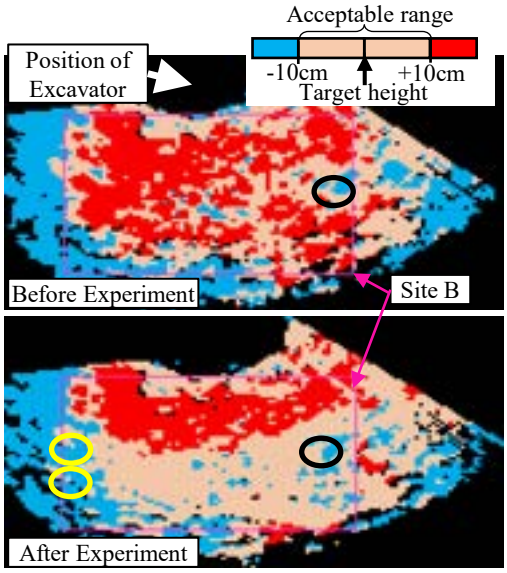

Figure 13. Top view of mound height on Site B measured by profiling sonar before (the upper) and after (the lower) experiment

Since the attachment has only a mechanism that depresses mounds by vibrations, it is necessary to install another function that raises depressions. If the out-of-range points are excluded, the average height is 0.02 m lower than the planed height and the deviation σ is 0.04 m. It means that 95% of the mound is within the range of -0.09 m to +0.05 m in height.

From the results, by taking above measures, underwater excavators with the tele-operation support system seems to have enough performance to level the unevenness of the mounds within ±10 cm from that within ±30 cm.

3.2 Working time

We investigated the work efficiency of the remote operation. The working times in the tests were decomposed into that of each input action. The working time was analysed from the video movie which recorded in the remote-control room on the ship. Figure 14 shows the working times of each items to level one point off.

In the experiment on Site A, the working time was 44 minutes 33 seconds for the work area of about 28 square meters. There are 34 points banged by the attachment, and 0.82 square meters are levelled once.

Site B had the work range of about 21 square meters and had a work time of 20 minutes 39 seconds. The number of banged points is 29, which averages 0.72 square meters.

As the results, the working times of A were longer than that of B in all items. It is considered that the effect of "training for tele-operation" is larger than that of "training of operation of underwater excavators itself". This difference is considered to be due to the fact that the operator engaged in remote operations had empirically predicted and recognized the movement of the equipment with respect to the lever input amount.

In addition, we compared the working time of the boarding-operating work with the supporting diver written in Section2.3. The working times to level depend more strongly on the conditions of the mounds than on the operation method. Therefore, the times of levelling were not taken into account to compare them. Tele-operation support system with highly trained operators was demonstrated to be able to increase the efficiency of the levelling works.

The tele-operating works by operators with great experience of tele-operation is faster than the boarding-operating works in the tests.

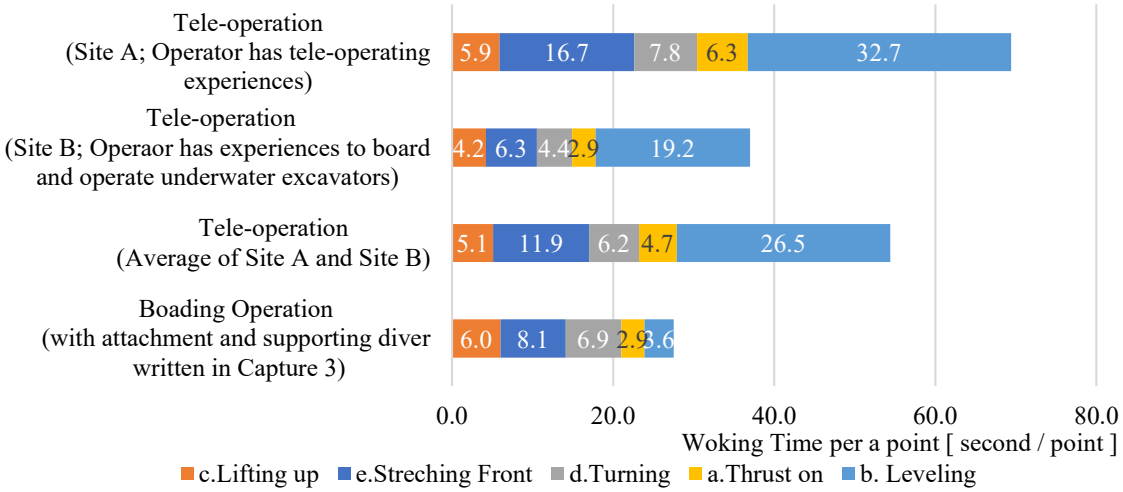

Figure .14 Working times of levelling works using underwater excavator

4 Conclusion

In order to improve the safety and the productivity of underwater constructions, we conducted the study and the sea experiments on remote operation of the underwater excavators.

We proposed a remote operation support system made up of the three elemental technologies. The elemental technologies are ”Underwater Information Presentation,” "Measurement Method of Mound Shape" and "Attachment for levelling works operated with simple input".

In order to assess the performance of the remote-control support system, we conducted the sea experiments simulating the levelling works on the mounds in the sea. The results are shown below.

- The proposed attachment has the ability to level the unevenness of rubble mounds in the sea. The performance to depress mound height was 11 cm in 5 seconds, and 25 cm in 30 seconds.
- Turbidity caused by the attachment is not more terrible than that of conventional works.
- For 28 survey points on Site A, there were 3 points of +10cm or higher than the planed height. Taking measures that set larger work ranges than the target may get rid of the remaining caused by the error of measured position of the vehicle.
- On Site A, the average height was 0.03m higher than the planed height and the deviation σ was calculated to 0.05m without exceptional points.
- For 21 survey points on Site B, there were 3 points of -10 cm or lower than the planed height. It is necessary to add another mechanism to move stones to places whose height are low.
- Excluding exceptional points, the average height after the tests on Site B was 0.02 m lower than the planed height and the deviation σ was 0.04 m.
- Working time was 65 minutes 12 seconds for the total work area of about 49 square meters, which was 45.1 square meters per unit time.
- When the operator with remote-operating experiences performed the simulating task with remote-operating system, the working time is shorter than that performed by the operator with the conventional boarding work. The work efficiency by remote-control is considered to depend on the skill level of the operator.
- By improving the attachment, remote-operated excavators are demonstrated to be able to level unevenness of the top surface of mounds within ±10 cm in the sea.

As the next step, we plan to study and sea experiments on an attachment to move stones into lower place than planed mound.

Abstract –

The wall of the shield tunnel body is made by assembling panels called segments into a ring shape. For the segment transportation in this site, quick, accurate and safe operation is required in each device mainly using a crane. However, in recent years, it is difficult to secure human resources due to the aging of skilled workers, and automation of segment transport equipment has become an urgent issue.

In this paper, we decided to work on automation of a 40t large overhead crane. The focus of this effort was to investigate an automatic gripping device that can handle various types of segments with different shapes, to study the selection and arrangement of sensors that achieve both high-precision positioning and fail-safe functions, and to efficiently use segments in narrow spaces. This is the construction of a management system using a color code for transporting to a computer.

As a result, the number of workers was reduced by automatic operation, and rework due to human error in selecting the carry-in / carry-out segment was eliminated, and productivity was improved through labor savings. In addition, it eliminates damage to the segments due to erroneous operations and contributes to ensuring quality.

1 Introduction

In this work, the main line tunnel is being constructed from the intersection of the Tomei Expressway and the Nogawa River in Okura, Setagaya-ku to Inokashira-dori, Kichijoji, Musashino-shi, as part of the Tokyo Outer Ring Road extending from the Kan-Etsu Expressway to the Tomei Expressway, by the EPB shield tunneling method (Figure 1). This work is characterized by a large section (outer diameter: 16.1 m), long distance (9 km), and high-speed excavation.

The walls of the shield tunnel body are made by assembling panels called segments in a ring shape. At the construction site, segments are carried mainly by using cranes, which requires quick and accurate operation. In recent years, however, the aging of skilled workers has made it difficult to secure human resources, so there is an urgent need to automate the cranes. Therefore, this project worked on the automation of 40t large overhead cranes to be used for carry-in, storage, and carry-out of segments in the segment stockyard. This paper reports on how this project was planned and the actual operation results.

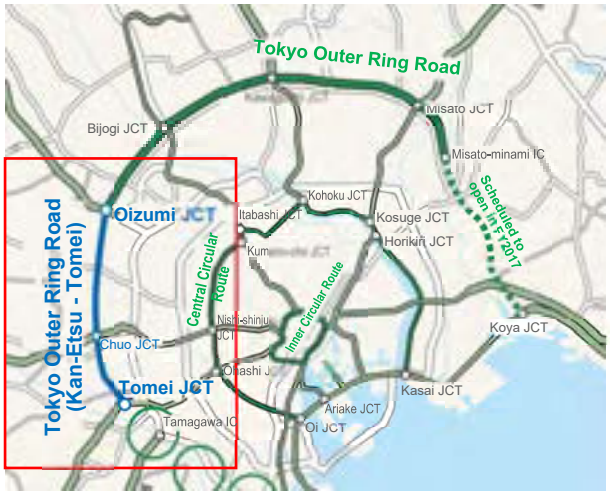

Figure 1. Map of construction location

2 Construction Overview

2.1 Overall Construction Overview

Construction name: Construction Work of the Tokyo Outer Ring Road Main Line Tunnel (Southbound) Tomei Expressway North Route
Orderer: Tokyo Outer Ring Road Construction Office, Kanto Branch, East Nippon Expressway Company Limited

Contractor: Specific Construction Work Joint Venture of Kajima, Maeda, Sumitomo Mitsui, Tekken, and Seibu
Construction area: from Okura, Setagaya-ku, Tokyo to Kichijoji Minami-cho, Musashino-shi, Tokyo
Construction outline

- Section size
  Outer diameter of tunnel: φ15.8 m
  Inner diameter of tunnel: φ14.5 m
  Outer diameter of shield machine: φ16.1 m (largest in Japan)
- Excavation length: 9,155 m
- Construction method: EPB shield tunneling method
- Horizontal alignment: R = 643 m (minimum)
- Earth covering: 38.3 (at the riverbed of Nogawa River) to 55.7 m
- Longitudinal slope: 0.3 to 1.5%
- Cross Passage: 5 locations
- Underground junction: 1 location

2.2 History of Introduction of Automated Overhead Cranes

A multi-shelf automated warehouse is an example of equipment that automatically carries segments in and out. Such warehouses are well-proven and technically established, but if used in construction work that handles large segments such as this project, the following problems arise:

1. The multi-shelf warehouse for large segments requires a large frame structure and consequently large support piles, which increases the construction period and cost.
2. The large frame structure also reduces the advantage of a small footprint of the multi-shelf warehouse.
3. The equipment (a stacker crane) cost is also high (about 2.5 times that of an overhead crane) because it handles heavy loads.

An overhead crane can move freely in three dimensions and function equivalently to a multi-shelf warehouse. Since the overhead crane does not require any special structure, it can shorten the construction period and reduce the cost, and is highly applicable to other similar construction works. Therefore, although it was an unprecedented attempt, this project worked on the automation of overhead cranes as equipment that can automatically carry in and out even large segments instead of a multi-shelf automatic warehouse.

2.3 Segment Overview

In this project the tunnel is constructed by using segments of different materials and widths depending on the purpose and conditions at each location. Over 70,000 segments must be brought in to construct a total of 5,676 rings over the total tunnel length of 9,155 m (Table 1)

Table 1. Segment overview

RC segment		◆ Reinforced concrete structure ◆ Has high rigidity and excellent compression resistance and durability; Used for standard sections across the entire tunnel Number of rings: 4,247 Number of divisions: 13 pcs/ring Weight: Approx. 10 ton/pc
Composite segment		◆ Hybrid structure of steel and concrete ◆ Used in areas where high-rise buildings causing high loads may be constructed Number of rings: 628 Number of divisions: 13 pcs/ring Weight: Approx. 11 ton/pc
Steel segment		◆ Box structure made of steel plates ◆ Used for lateral connecting galleries requiring openings and underground widened sections that need to be cut to be removed Number of rings: 801 Number of divisions: 13 or 14 pcs/ring Weight: Approx. 5 ton/pc

2.4 Overview of Segment Stockyard

Figure 2 and 3 show the workflow from carry-in to carry-out in the segment stockyard.

Segments are transported by trailer, and then picked up, carried in, and stored in the segment stockyard by the overhead cranes. In order to prevent the load from collapsing during transportation, the segments are stacked in only two tiers. In the stockyard, however, segments are stacked in four tiers in principle, and so three rows are used for one ring. In the tunnel, since a precast RC invert is to be installed when assembling segments, it is efficient to also carry in and store RC inverts in the segment stockyard and carry one out together with segments. Therefore, a RC invert storage area is also provided in the segment stockyard. The stockyard as a whole can store segments for 10 rings and RC inverts for eight rings (Figure 4).

Segments stored in the segment stockyard are picked up by the overhead cranes and placed on a temporary receiving pedestal (hereafter, “temporary receiving setter”) to be carried out. The segments placed on the temporary receiving setter are transferred to a transport carriage to be carried into the tunnel. Once the segments are carried out of the segment stockyard, their order cannot be changed in the tunnel. Therefore the segments must be carried out in the order of assembly.

Table 2 shows the mechanical specifications for the overhead crane body. Two overhead cranes are installed in order to shorten the cycle time by alternately carrying in and out segments, eventually enabling high-speed excavation (Figure 5).

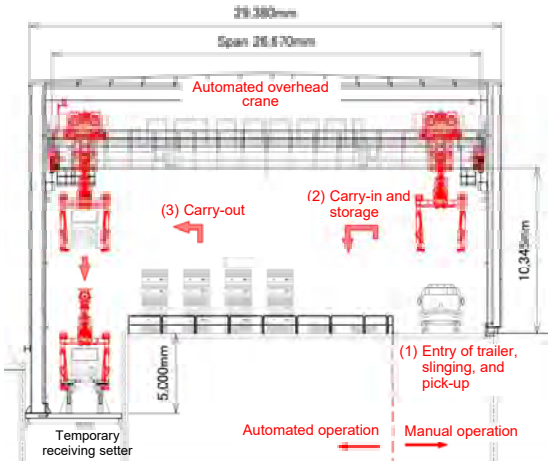

Figure 2. Carry-in/out of segments using overhead cranes

Table 2. Mechanical specifications for overhead crane

Item		Specifications
Rated values	Load	40 t
	Hoisting speed	0.172 m/s
	Traverse speed	0.417 m/s
	Travel speed	0.417 m/s
Wire rope		Type B: IWRC 6 × Fi (29) 8 hooks × 20 mm
Construction	Span	26.67 m
	Crane girder length	27.17 m
	Lifting height	14.25 m
	Crane girder height	10.345 m
Motor	For hoisting	2 × 45 kW
	For traverse motion	2 × 2.2 kW
	For traveling	2 × 5.5 kW
Drum	Hoisting drum	PCD φ540 mm
Sheave	Hoisting sheave	PCD φ558, 400 mm
	Equalizer sheave	PCD φ400 mm

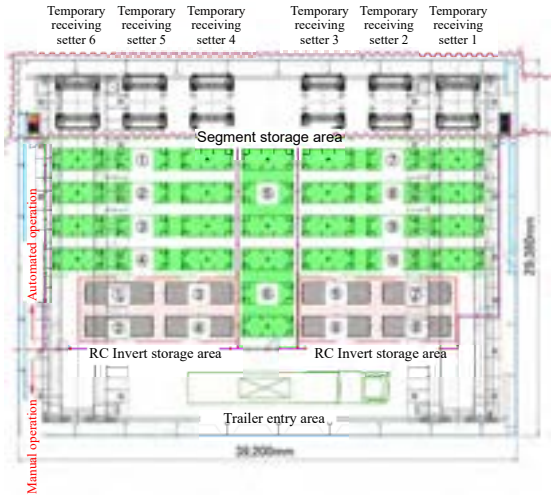

Figure 4. Plan view of segment stockyard

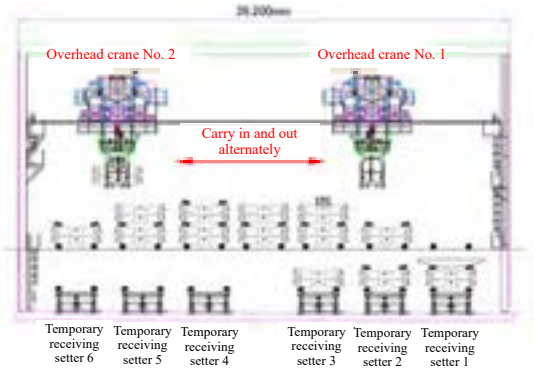

Figure 5. Vertical section of segment stockyard

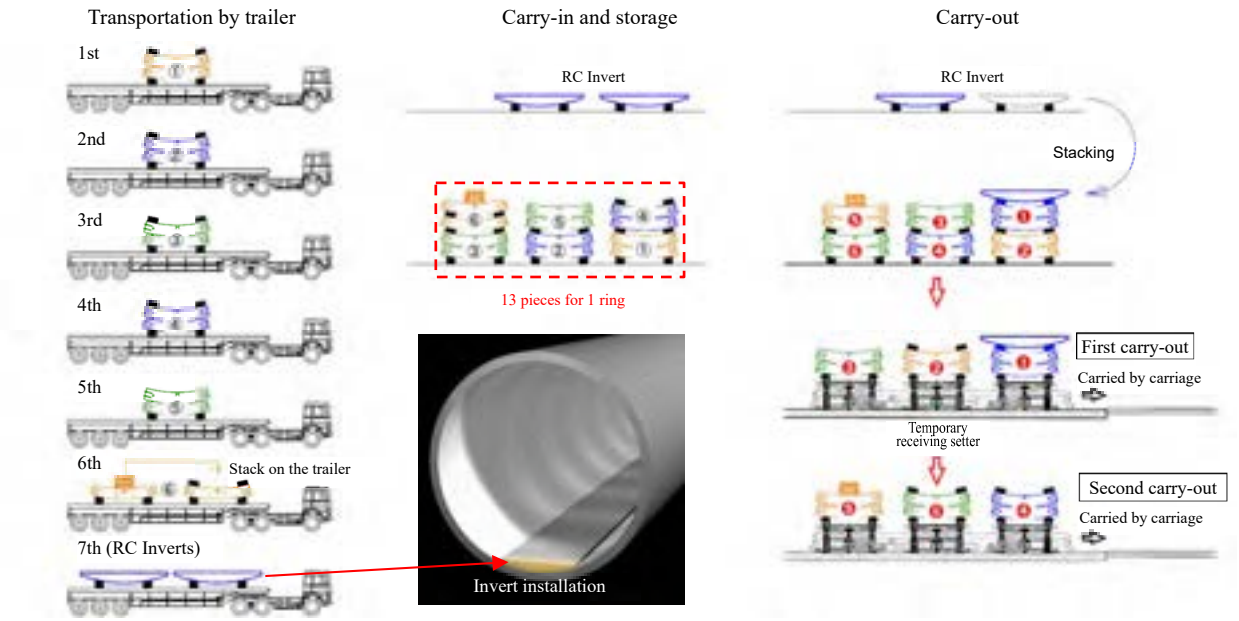

Figure 3. Workflow from carry-in to carry-out in segment stockyard (for one ring)

3 Automated Equipment

3.1 Overview of Automated Cranes

3.1.1 Scope of automation

This time, segments are picked up manually from trailers. This is because there are various shapes of trailers and segments and therefore positioning is difficult, and also the segments brought in by trailers must be checked for damage, requiring human intervention.

After segments are picked up and moved to the storage area, carry-in, inventory management, and carry-out are performed automatically.

3.1.2 System Configuration

Figure 6 shows the system configuration of the automated overhead cranes. The system consists of overhead crane and segment grabs equipped with various sensors and control devices necessary for automation, a management system that issues transport instructions, and a ground control panel that exchanges signals with each piece of equipment.

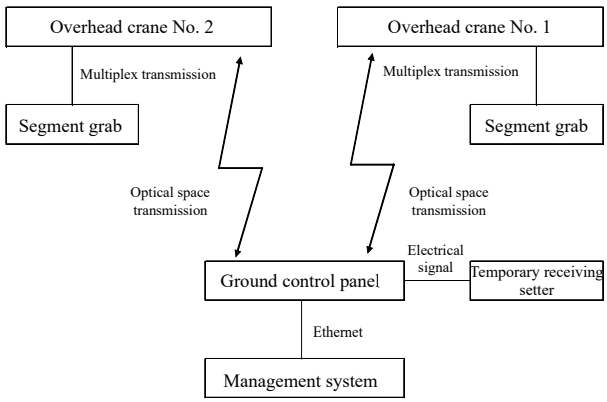

Figure 6. Configuration of automated crane system

3.2 Overhead Crane

3.2.1 Basic Configuration

Table 3 lists the sensors mounted on the overhead crane body for the purpose of automation, and Figure 7 shows the layout.

The position coordinates of the overhead crane were measured by using a laser rangefinder for the travel and traverse directions, and by using an encoder for the hoisting and lowering directions.

Table 3. List of overhead crane sensors

Intended use	Qty.	Model	Intended use of signals	Mounting position and specifications
Hoisting sensor				
Encoder for hoisting position detection	2	MRE-G160SP061FKB (NSD)	For hoisting position detection	Mounted on hoisting drum
Normal upper limit (for origin correction)	2	PSKU-110CO (YE CONTROL)	For correction of hoisting position detection encoder For automated operation control	Weight type
Upper and lower hoisting cam limit switch	2	Supplied with hoist		
Emergency upper limit	2	Supplied with hoist	For master interlock	
Load detector	2	DLS-5033A-1		
Traverse motion sensor				
Laser rangefinder for traverse position detection	1	DL100 (SICK)	For traverse position detection	Mounted on girder With reflector mounted on traverse grab Reflector: 0.5 × 0.5 m
Traverse limit	2	PIKU-110 (YE CONTROL)	Triggers emergency stop when open	
Magnetic proximity switch for traverse position detection	5 (3)	PSMM-R3E1H (YE CONTROL)	For speed monitoring before traverse limit and trailer area detection Triggers emergency stop upon detecting abnormal speed while open	Sensor: Mounted on girder (3 sensors for overhead crane No. 2)
Magnet for magnetic proximity switch for traverse position detection	1	PSMM-M450T (YE CONTROL)	For speed monitoring before traverse limit and trailer area detection Triggers emergency stop upon detecting abnormal speed while open	Magnet: Mounted on traverse grab
Travel sensor				
Laser rangefinder for travel position detection	2	DL100 (SICK)	For travel position detection	Mounted on girder With reflector mounted on soundproof house wall Reflector: 1 × 1 m
Travel limit	1	PIKU-110 (YE CONTROL)	Triggers emergency stop when open	
Magnetic proximity switch for travel position detection	9 (7)	PSMM-R3E1H (YE CONTROL)	For speed monitoring before travel limit Triggers emergency stop upon detecting abnormal speed while open	Sensor: Mounted on travel girder (7 sensors for overhead crane No. 2)
Magnet for magnetic proximity switch for travel position detection	9 (7)	PSMM-M450T (YE CONTROL)	For speed monitoring before travel limit Triggers emergency stop upon detecting abnormal speed while open	Magnet: Mounted on soundproof house wall (7 magnets for overhead crane No. 2)
Others				
Optical space transmission device	1 pair (2 units)	BWF-3EA/B (Hokuyo)	For overhead–ground transmission: 1 pair	Crane-ground transmission
Anti-collision detector	1	TCR-30L3 (Toyo Electric)	For collision prevention between cranes	Mounted on girder With reflector mounted on counterpart crane

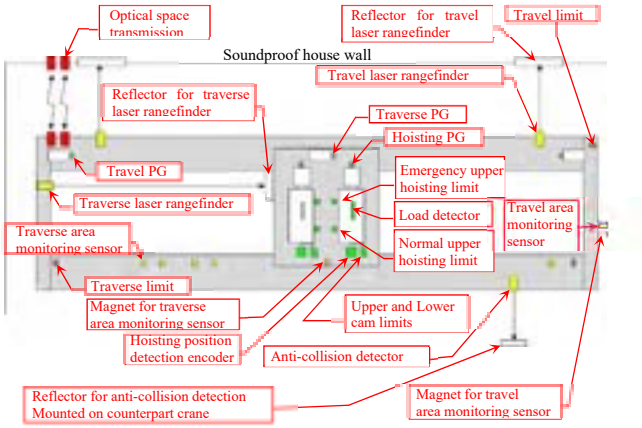

Figure 7. Layout of overhead crane sensors

3.2.2 Positioning Accuracy

The stopping accuracy of the overhead crane must be set to the target value ±50 mm, considering the possibility of interference between the segment to be carried into the tunnel and other equipment. Since high-precision positioning control is required, vector control with PG (pulse generator), which can output stable torque even at low speeds, is used to control the electric motor (Table 4).

Table 4. Specifications for overhead crane motor

Intended use	Qty.	Model	Output (kW)	Control method
Electric hoisting motor	2	For hoist 180Fr	45	Yaskawa Matrix Converter U1000 80 kVA Vector control with PG PG: MSK-510-1024 (1024 pulse/rev)
Electric traverse motor	2	CNVM3-6120-AP-B-21	2.2	Yaskawa Matrix Converter U1000 8 kVA Vector control with PG PG: ERN1330 (1024 pulse/rev)
Electric travel motor	2	CNVM8-6165-AP-B-25	5.5	Yaskawa Matrix Converter U1000 12 kVA Vector control with PG PG: ERN1330 (1024 pulse/rev)

3.2.3 Safety Functions

The following safety functions are provided so that the automated operation of the overhead cranes is stopped if the positions of the cranes cannot be measured accurately due to failure in the laser rangefinder or encoder measuring the positional coordinates of the cranes.

1. Positioning monitoring
   If the deviation between the integrated value of the vector control PG and the value measured by the laser rangefinder, for the travel and traverse directions, or the deviation between the command value from the management system and the value measured by the encoder, for the hoisting and lowering directions, exceeds a certain value during positioning, it is regarded as a position detection error and the overhead crane is stopped.
2. Area monitoring
   The area is monitored by magnetic detection sensors to prevent the overhead cranes from continuing automated operation after deviating from the predetermined area. These sensors are installed near the boundary between the manual and automated operation areas and that between the working areas of the two overhead cranes.Figure 8 shows the area monitoring plan diagram.
   A magnetic detection switch for monitoring deceleration is installed in front of the segment storage area at the end of each area. If the overhead crane is traveling or traversing faster than the rated speed when detected by the sensor, it is judged to be abnormal and the crane is stopped. This ensures that overhead cranes approaching an area boundary are decelerated without fail.
   If the overhead crane continues traveling or traversing even after reaching the segment storage area at the end of each area, the limit magnetic detection switch (or the limit switch for the travel and traverse ends) judges it as an overrun and stops the crane. The limit magnetic detection switch acts as an electric stopper and is set to the position such that the overhead crane stops before hitting against the mechanical stopper.

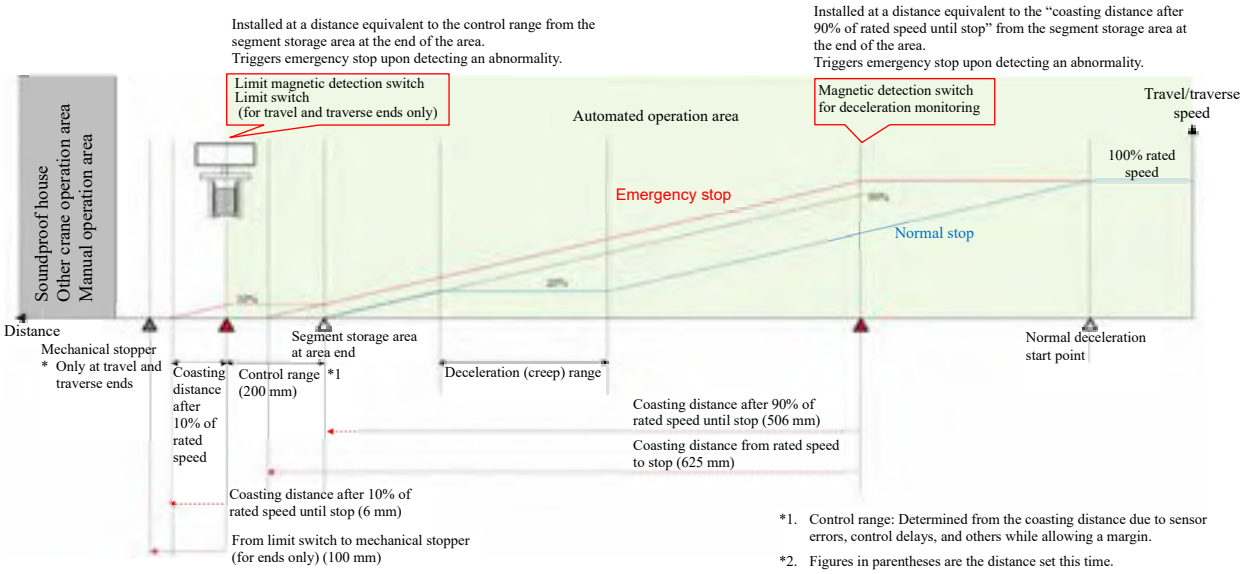

Figure 8. Area monitoring plan diagram

3.3 Segment Grab

Transportation of segments using a crane used to be performed by manually slinging the segments on a sling or the like. This time, a segment grab was newly developed as an automated segment slinging device.

Figure 9 shows the mechanical drawing and Table 5 lists the mechanical specifications for the segment grab. The segment grab is used as a slinging tool by hanging it on the hook of the automated overhead crane. However, the hook would rotate freely if left as it is, so it is pinched with plates to prevent rotation.

In order to align the center of gravity between the segment grab and the segments even for those with different widths, the segments are sandwiched by two arms in the lateral direction and then placed on the grabbing jaws. The grabbing jaws that support segments are fitted with rubber plates, and the arms and the grabbing detection bar that come into contact with the segments are fitted with MC nylon plates (friction reducing plates), in order not to damage the segments during lifting. Photo 1 shows the segment grab grabbing segments.

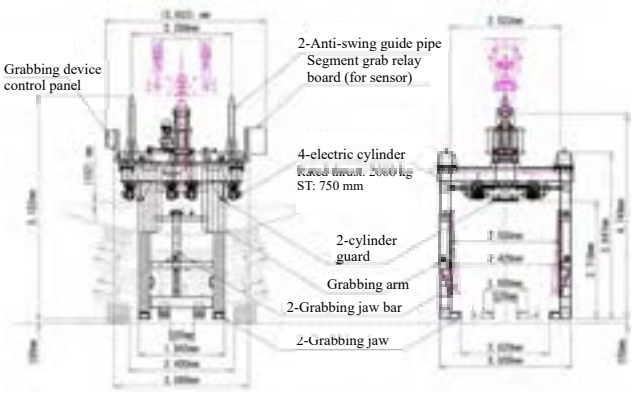

Figure 9. Segment grab drawing

Table 5. Mechanical specifications for segment grab

Item		Specifications
Rated load		33 t
Opening/closing speed		75 mm/sec × 2 (9.0 m/min)
Arm opening		520 to 2,020 mm
Arm length		3,547 mm
Arm width		1,950 mm
Jaw length		240 mm
Own weight		6,800 kg
Electric cylinder	Power supply	3-phase, 400 V, 50 Hz
	Stroke	750 mm
	Motor capacity	2.2 kW × 2 units × 2 arms
	Rated thrust (per piece)	2,000 kgf
	Accessories	Thrust detector Rotary encoder Stroke adjustment LS

In addition, anti-swing guide pipes are installed on the segment grab, which fit into the sheath pipes on the overhead crane when the grab is hoisted to the upper limit, preventing the load from swinging during traverse motion. Although it is necessary to hoist up the grab to the upper limit each time before making traverse motion, this enables high-speed traverse motion and highly accurate positioning.

Table 6 lists the sensors mounted on the segment grab, and Figure 10 shows the layout.

The grabbing sensors detect that the segments are sandwiched by the arms, and the loading sensors detect that the segments are engaged with the jaws. Both types of sensors work together to detect that the segments are securely grabbed.

The pocket collision and bottom collision detection sensors are provided to prevent contact between the segment grab and the segment, RC invert or any obstacle in the event of an abnormality in positioning or an unexpected incident.

The grab opening detectors are provided to detect the cylinder strokes of the left and right arms and are used for positioning correction in the traverse direction (Figure 11). In particular, when picking up segments from a trailer by manual operation, the center cannot be aligned precisely between the segment grab and segments, causing a difference in the strokes of the left and right arms. If the segments are carried in such a state, the center of the segments will deviate from the target position because the positioning is performed using the center of the segment grab as the reference. In order to prevent this, the strokes of the left and right arms are detected when grabbing the segments, and the traverse distance is corrected during positioning by the difference between the strokes.

Photo 1. Segment grab grabbing segments

Table 6. List of segment grab sensors

Name	Qty.	Model	Intended use of signals	Notes
Electric cylinder	4	LPTC2000H7.5V LRIJF-TK (Tsubaki E&M)	For opening/ closing the grab	With thrust detector, rotary encoder, and stroke adjustment LS
Hole detection photoelectric switch	6	PEY-155C (Hokuyo)	For detecting obstacles when opening/closing the grab	Light projector/receiver
Loading detection proximity switch	2	E2E-X3D1 (Omron)	Loading detection	
Grabbing detection proximity switch	2	E2E-X10D1 (Omron)	For grabbing detection	
Bottom collision detection photoelectric switch	16	PZ-G41N (Keyence)	For detecting obstacles under the grab	
Pocket collision detection photoelectric switch	16	PD5-1MC (Hokuyo)	For detecting obstacles when lowering the grab	

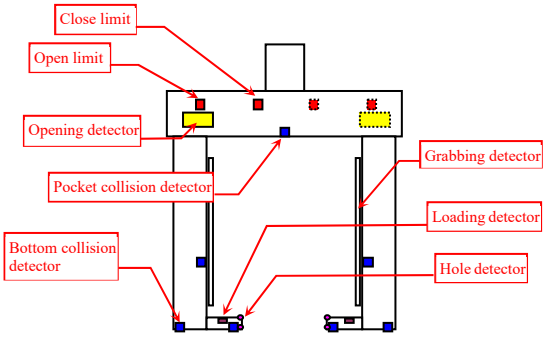

Figure 10. Layout of segment grab sensors

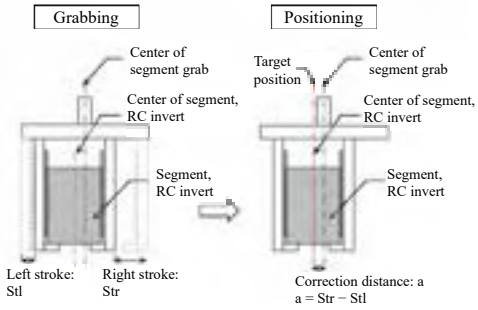

Figure 11. Positioning correction in traverse direction

3.4 Picking Up and Attitude Detection of Segments

It is impossible to position the trailer strictly at right angles to the overhead crane or load segments exactly parallel to the trailer, and consequently, segments are angularly misaligned with the segment grab. As the segment grab is suspended by wires, it rotates to align with the segments upon grabbing the segments, but when the grab is hoisted up to the upper limit, the guide pipes on the grab fit into the anti-swing sheath pipes, so that the angular deviation is corrected (Figure 12).

3.5 Management System

The management system consists of a survey system and an ordering system. The configuration of the management system is shown in Figure 13.

The survey system plans the allocation of future segments based on the survey results of the tunnel alignment and the design alignment plan.

The ordering system orders the factory to ship the segments planned to be allocated by the survey system, and at the same time, specifies the loading order of the segments onto the trailer according to the types of segments, and is also able to check whether the segments are loaded onto the trailer in the specified order at the time of shipment from the factory.

The automated overhead crane automatically determines where to store the segments in the stockyard from the information on the segments brought in by trailers and that on the inventory in the stockyard. In addition, it automatically selects the segments to be carried out according to the allocation plan and transports them from the stockyard to the temporary receiving setter.

The color code shown in Figure 14 was adopted as a marker to identify each segment and RC invert. A color code sticker which identifies the segment type is attached to the side of each segment at the factory, and the color code is read by the camera on a tablet terminal at the site so that the automated overhead crane recognizes the type of the segment brought into the stockyard. Unlike barcodes and QR codes, multiple color codes can be read from a distance at a time, which is ideal for identifying stacked large segments such as those in this case.

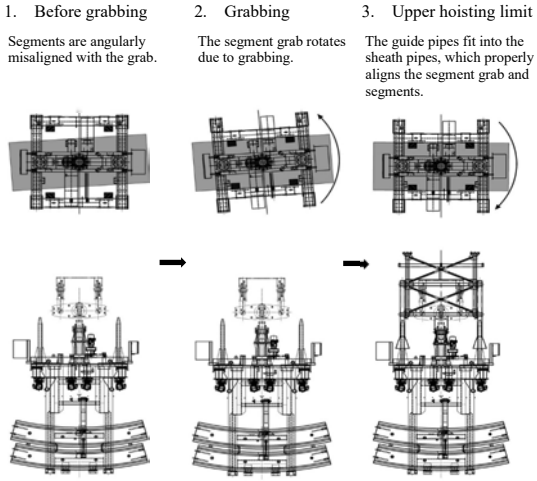

Figure 12. Angular misalignment correction flow for segments

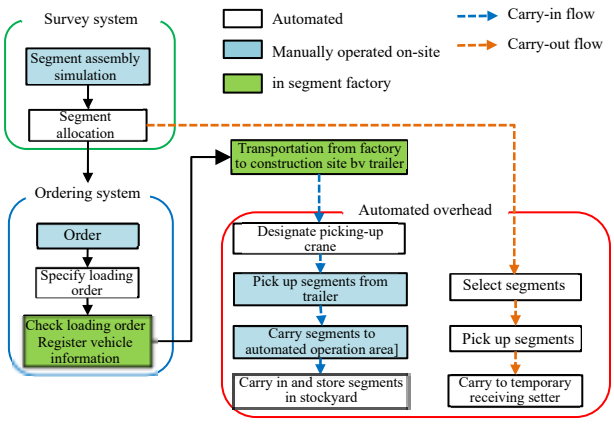

Figure 13. Configuration of management system

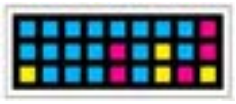

Figure 14. Color code

3.6 Safety Measures

In order to prevent accidents such as people getting caught in the overhead crane during automated operation, fences are installed at the boundary between the automated and manual operation areas. However, to allow people to enter the automated operation area for maintenance, open/close doors are provided at some points of the fences. A lockable open/close detection sensor is also mounted on each door in order to prevent people from accidentally entering the area during automated operation (Figure 15). If any door opens during automated operation, the overhead cranes are stopped. Furthermore, to ensure safety, people entering the automated operation area are obliged to carry the key of the open/close detection sensor with them so that the automated operation of the cranes cannot be restarted until they leave the area.

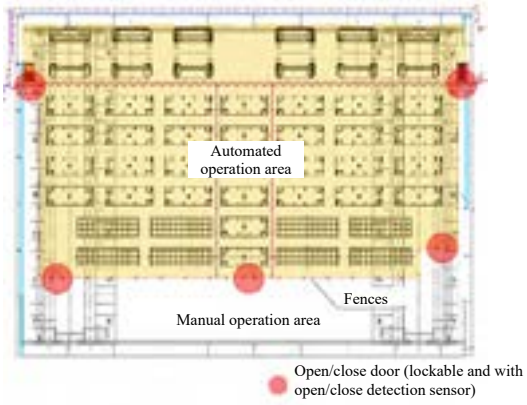

Figure 15. Layout of fences and doors with open/close sensors

4 Actual Operation Results

4.1 Productivity Improvement

4.1.1 Labor saving and reduced dependency on personnel

As a result of the introduction of automated overhead cranes, all the segment stockyard operations were automated except unloading of segments from the trailer, which required only two operators. Before these cranes were introduced, it had been assumed that a total of six operators would be required, two for each of the two overhead cranes and two for the temporary receiving setter. Thus, the use of automated overhead cranes improved productivity by saving labor.

This project significantly improved productivity also by reducing labor hours due to the reduced thinking time required for determining where to store segments and identifying the segments to be carried out, and by reducing the dependency on personnel so that even operators without specialized knowledge or advanced skills can perform the operations.

4.1.2 Reduction of losses due to rework

If a wrong segment is carried into the tunnel, the segment must be replaced, requiring shield excavation to be stopped. This would cause various losses, such as the stand-by hours of excavation operators and cancellation of materials and vehicles. In the case of a large-scale construction work like this, the cost incurred would be enormous.

The segment selection function of the automated overhead crane has been working without requiring any rework until now.

4.2 Quality Assurance

While ensuring a positioning accuracy of ±50 mm, this project achieved automated transportation, and prevented malfunctions by means of various sensors and prevented erroneous operation by humans. The system has not caused any damage, such as cracking and chipping, to segments until now. The project has successfully built equipment that can make a significant contribution to quality assurance.

4.3 Improved Safety

In automated operation, the overhead cranes (machine) and segments and RC inverts (load) are completely separated from humans, eliminating the risk of man-made disasters and contributing to improved safety.

5 Conclusion

This project introduced automated transportation using overhead cranes, which was unprecedented in the carry-in/out of segments for shield construction work. The system improved the on-site productivity and safety, and also contributed to quality assurance. The automated overhead crane we developed can handle segments of different widths and shapes, and is highly applicable to other similar construction works.

We will continue to work on improving the efficiency of construction work on-site in order to address the shortage of human resources due to the declining birthrate and aging population.

Development of an Automated Angle Control System to Improve Safety and Productivity

Abstract –

Currently, the high demands and needs to improve productivity and labor-saving in construction industries leads to many automation and mechanization. This report aims to address the shortage of skilled worker in the future as well as improvement of safety, productivity and quality. Comprehensive collection and utilization of information were carried out and with target to eliminate the over reliance of experience worker in mountain tunneling, "Automated Angle Control System" technology was developed to reduce the overbreak of tunnel during excavation. The concept of this method is to ensure that the productivity of drilling for blasting operation will not be influenced by the worker skills. This system was tested in Shin-Tomei Expressway Takatoriyama west tunnel construction project and results confirmed that the system successfully minimized the overbreak of tunnel during excavation. The authors hope that this report will contribute to the improvement of safety and productivity.

1 Introduction

Over 40 years have elapsed since the introduction of the New Austrian Tunneling Method in Japan; notable advancements have been achieved with respect to the construction methods. However, reliance of experience and instinct of skilled workers still remain because of the heterogeneity and uncertainty of the ground conditions (bedrock) which is the primary material of the tunnel, whereas bridges and framework structures use concrete and other materials of consistent quality and standards.

The recent use of machines and automation to boost productivity, including reduced labor and improved construction methods, is a demand of the times and merits active involvement. In addition, the nature of public construction projects dictates that projects be implemented with greater transparency and objectivity.

Against this background, this paper strives to collect and utilize as much objective information as possible with the aim of achieving construction that does not rely on experience or instinct, resolving the future shortage of skilled laborers, and improving safety, productivity, and quality. To meet these objectives, the authors developed the automated angle control system as a technology for reducing overbreak in mountain tunnels.

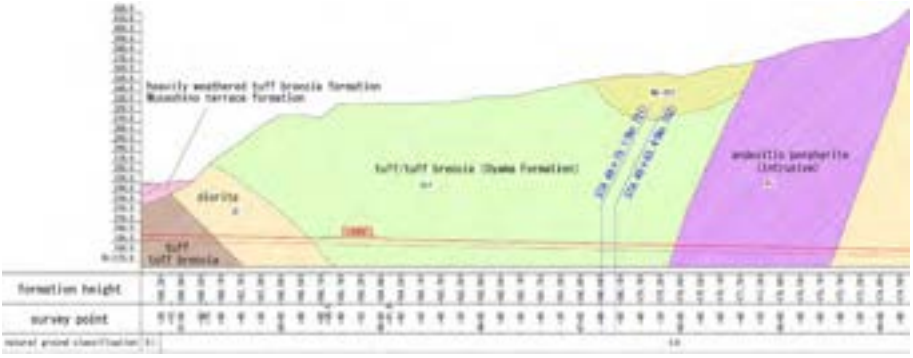

Figure 1. The geological profile and demonstration test area (outbound lane).

The concept of this overbreak reduction technology aims at improved productivity unaffected by skilled labor in explosive drilling and achieves the designed cross-section while allowing accurate formation with minimal overbreak. This reduces the occurrence of mucks as well as shortens time required for mucking and shotcrete. Moreover, it also has the benefit of preventing ground from loosening by smoothing the excavation surface. Additionally, this technology can be used effectively to serve as a safety indicator for preventing accidental flaking of the face as it is possible to understand its ground morphology by using the drilling energy obtained as a byproduct of the drilling work required for explosive drilling.

This paper will report on the results of the demonstration tests conducted in the Mt. Takatoriyama west tunnel construction project.

2 Construction Site Details and Geology of the Demonstration Test Area

Takatoriyama Tunnel is a twin-bore tunnel comprising two highway lanes, which connect the cities of Hadano and Isehara, and has a total length of 3.9 km. Its internal cross-sectional area is 80 m2, and the tunnel extensions on the western side measure 1,573 and 1,609 m for the inbound and outbound lanes, respectively, with downslopes of 2% being observed in both the lanes. The geological profile and demonstration test area are presented in Figure 1. The system trials were initiated in tuff and tuff breccia (Oyama Formation) that are suitable for blasting and proceeded while trying to adjust the system functions. Further, 14-m zones of STA.46+79.1–STA.46+65.4 is designated as demonstration test areas and validated the effectiveness of the system. The demonstration test area is primarily characterized by distributed weathered tuff, with a tunnel face evaluation grade point of 41–44 belonging to CII of the ground classification.

3 Automated Angle Control System

This system is characterized by its ability to reduce overbreak without skilled labor and to prevent face accidents by utilizing drilling energy. Figure 2 gives an overview of the entire automated angle control system.

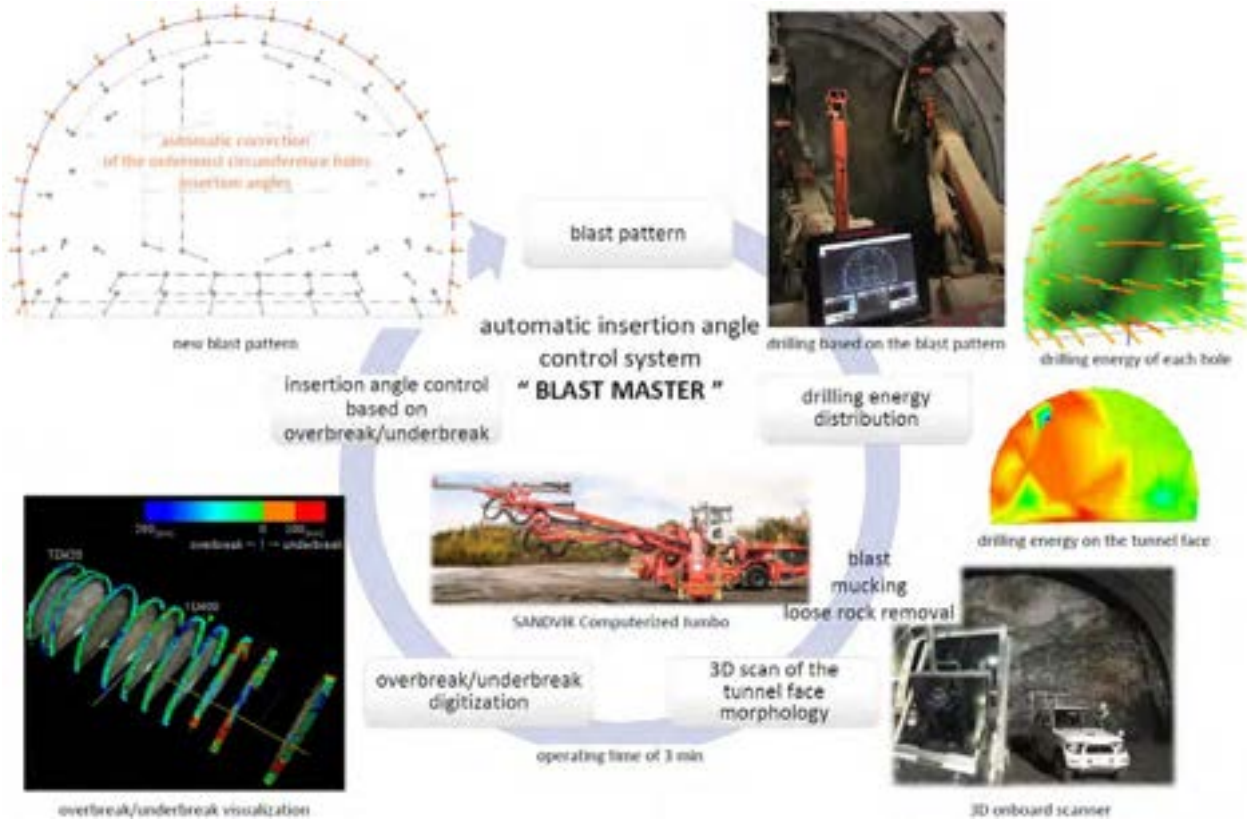

Figure 2. Overview of the automated angle control system.

3.1 Overbreak reduction technology without the need for skilled labor

The authors believe that there are limits for the reduction of overbreak even if a computerized drill jumbo is used to improve the drilling accuracy based on the predefined blast patterns because of the influence of the ground heterogeneity and bedrock fissures. The results supporting this assumption have been obtained from a previous report (1) (2).

Conventionally, the skills of experienced workers are relied on to reduce the overbreak in heterogeneous ground. Our system (Figure 2) solves this issue. The overbreak reduction mechanisms (steps) can be given as follows:

Step I: A blast pattern is created and displayed it on the computerized drill jumbo operating screen (the initial blast pattern is set based on the prior experience and ground strength).

Step II: The jumbo operator accurately performs face drilling based on the generated blast patterns (at this time, the drilling energy is automatically calculated and recorded).

Step III: After charging, blasting, and mucking, scaling will be carried out to ensure the safety of the tunnel face area is confirmed. Subsequently, a three-dimensional (3D) onboard scanner is set in front of the tunnel face, and the face morphology is scanned immediately after the excavation (with a duration of approximately 3 min).

Step IV: The scan result is digitized and examined on the spot to confirm the overbreak/underbreak amounts (underbreaks are eliminated on the spot).

Step V: The corrected drilling angle value is automatically calculated from the predefined correction value derived from the relationship between overbreak amount and drilling angle (the corrected value does not rely on the ground morphology).

Step VI: The corrected value is utilized in the blast patterns of the next cycle, automatically generating the subsequent blast pattern (go to Step II).

3.2 Technology for preventing face accidents by utilizing drilling energy

As indicated in Step II above, face drilling based on the blast patterns also records the drilling energy distribution in the depth direction of the drilling positions as shown in Figure 3. Figure 4 shows the face as seen from the ground.

The drilling energy distribution map shown in Figure 4 is generated by calculating the mean of the drilling energy data obtained 0.5m below the face surface or deeper and projecting the result of each drilled hole onto the face surface. The parts that are relatively shallow from the face surface (less than 0.5 m

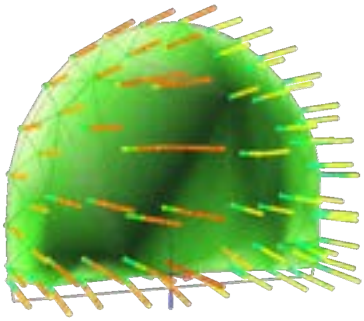

Figure 3. Face drilling in action

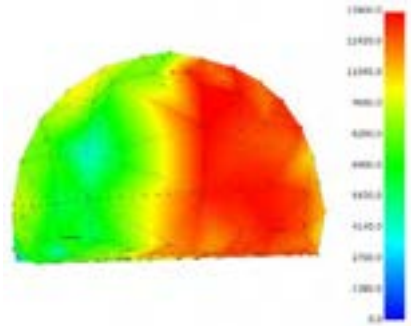

Figure 4. Distribution of drilling energy at completion of drilling

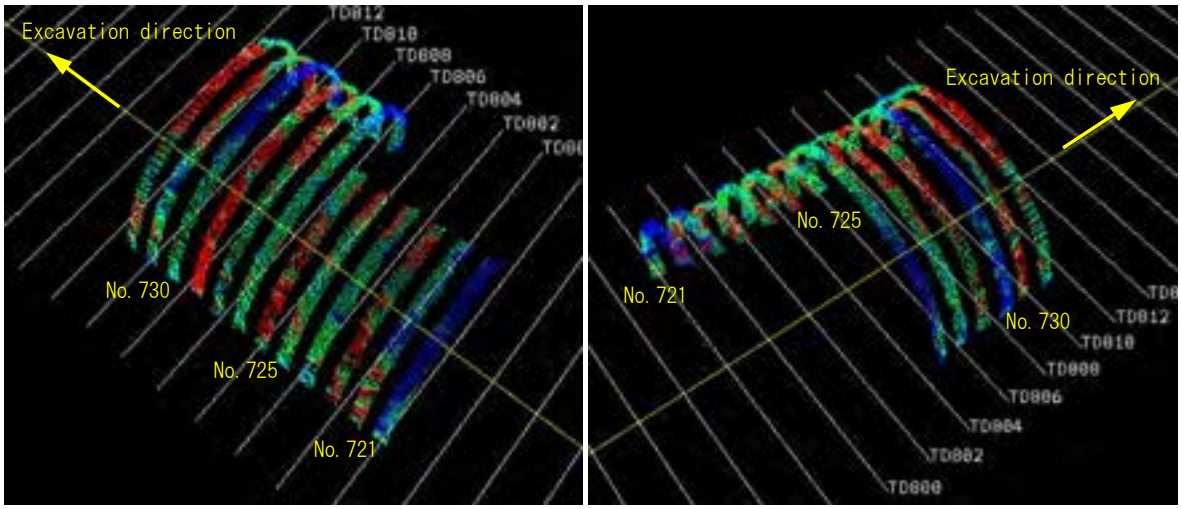
Figure 5. Map streamed to computer jumbo screen

Figure 6. Face monitoring personnel monitors the face



[Left wall] [Right wall]

Figure 7. Measurement results of the 3D scanner used in the demonstration test area

from the surface) are excluded from the evaluation data set because previous blasts and face sprayed concrete can obscure the true ground morphology. Figure 4 is automatically generated at the completion of face drilling.

A face drilling energy distribution map generated such as the one shown in Figure 5 gives an objective indication of the ground morphology distributed along the face, which is referred to as a face safety index in this system, and is used to prevent face accidents.

When the drilling work has been completed, a drilling energy distribution map is generated, after which the face safety index is immediately and automatically streamed to mobile devices such as smartphones and tablets of all tunnel construction personnel, including face monitoring personnel, jumbo operators, and JV personnel. This allows all personnel to continue working with the latest face information. Figure 6 shows the face monitoring personnel observing the face while checking the face safety index.

4 Automatic Drilling Angle Control System Demonstration Test Results

The results from the 3D scanning employed in the demonstration test area are presented in Figure 7. The red and blue colors represent the underbreaks and overbreak, respectively, enabling us to understand the overbreak and underbreak locations. The maximum and mean overbreak based on the obtained scanned data organized in a time series are presented in Figure 8. The following can be stated based on the results obtained from Figures 7 and 8.

No. 721 can be attributed to explosive drilling from the initial blast pattern (set by considering the past experience and ground strength), with all the drilling angles in the outermost circumference drilled at the same angle. The maximum and mean overbreaks were 67.0 and 30.2 cm, respectively, with an increase in the crown area.

Subsequently, the drilling angle of the outermost circumference was individually corrected using the results obtained from the overbreak/underbreaks in No. 721–724. Thus, it can be confirmed that No. 725 showed the lowest number of underbreaks and the overbreak considerably decreased. The maximum and mean overbreaks were 21.0 and 6.6 cm, respectively, with decreases of approximately 69% and 78%, respectively, when compared with the results obtained from the initial blast pattern.

Based on the drilling performance of the entire demonstration test section, it can be assumed that by operating the system several times, it is possible to reduce the effect of excessive overbreak and smooth the excavation surface.

Figure 9 shows the statistical treatment of the relation between the corrected drilling angle of the outermost circumference among all the drilling results in the demonstration test area and the overbreak volume generated from that drilling angle. Despite the lack of sufficient drilling results for obtaining a definitive evaluation, an overbreak value of zero is predicted at a drilling angle of 2°–4°. Therefore, planning with a blast pattern involving drilling angles of 2°–4° is a logical choice for future drilling in a geological terrain similar to that of the Takatoriyama Tunnel (i.e., tuff breccia).

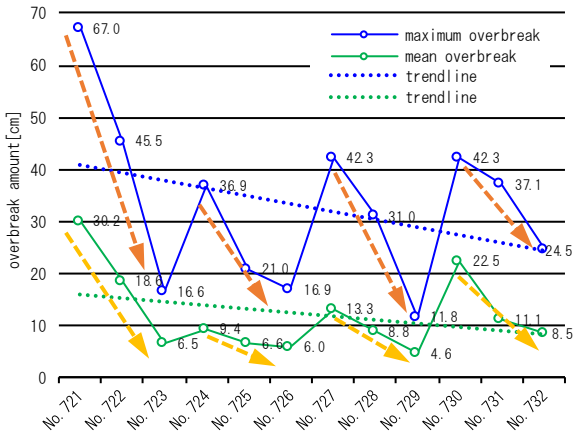


Figure 8. Overbreak reduction effects (tuff/tuff breccia)

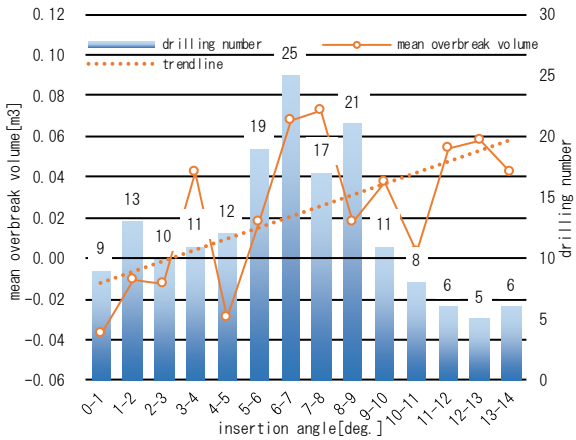

Figure 9. Relation between the drilling angle and overbreak amount (tuff/tuff breccia)

5 Summary

The implementation of the automated drilling angle control system in multiple drilling cycles confirmed a reduction in the maximum and mean overbreak by approximately 69% and 78%, respectively. These values are observed to vary based on the ground conditions (e.g., ground heterogeneity and influence of rock fractures).

Although the effectiveness of overbreak reduction differ based on the ground conditions, this test demonstrate that the system can effectively decrease the overbreak amount without relying on skilled labor forces.

Based on these results, the authors expect to find the most suitable drilling angle and angle correction logic by applying this system to the various ground conditions.

Face drilling energy is used to objectively show the ground conditions distribution in the face, which is regarded as a “Face Safety Index” in this system and used to prevent tunnel face accidents.

While the authors do not consider this index to be an absolute assurance of safety, it has been recognized as a means for offering peace of mind by providing tunnel work personnel, such as face monitoring personnel and workers at the tunnel face, with the most recent ground conditions information that cannot be obtained by visual observation alone, as soon as the drilling work is completed.

Abstract –

Most of the cities road marking inspection is performed manually and considered an ideal candidate for automation because it is a labour-intensive process. We propose a solution based on automated quality assessment tool for road marking to detect and qualify road marking characteristics. Our data inventory and data collection approach work on images collected from a camera mounted on vehicle or drone. We use an automated procedure to choose images suitable for inspection based on road marks conditions. From the selected data we segment the ground and detect three different parameters; road markings conflicts, missing road markings, and road marking reflectivity.

We describe convolutional neural network and image classification algorithms that identifies road marks conflicts, visibility, missing road markings. We also discuss the problem of evaluate the quality of the existing road markings, conserve human and financial resources that is caused by on-site inspections, reduce improper manipulation of road marking (human errors), and prompt jobsite management to focus on promoting fine workmanship of road marking during the execution and train the classifier. We present results from the prototype that shows the detection of the three trained parameters mentioned above. Finally, we show results computed using our method over a subset of a citywide urban and non-urban road network.

Road Marking; Road Detection; Automated Roads Evaluator; Focal Point Detection

1 Introduction

For at least two decades, the development of transportation systems has led to the development of embedded applications allowing to improve the driving comfort and to minimize the risk level of hazardous areas. More specifically, the researches in intelligent and Advance Driving Assistance Systems have provided a great number of devices on many types of automatic vehicle guidance and security systems such as obstacle detection and tracking [1], road visibility measurement [2], pedestrian detection, road departure warn- ing systems. However, one of the first embedded system that was studied is probably the lane detection system. This application is usually based on road marking detection algorithms. [3]. This system is also one of the most important sources of information in order to build a local perception map of an environment surrounding an ego-vehicle. Indeed, this information provides relative vehicle location information to all other perception systems (obstacles, road signs, ...) that need to know the road and lanes attributes. For this reason, the system must be as robust as possible. Moreover, for several year, it appears evident the automation of the driving task is probably a solution in the reduction of the road injuries. But for automated or partially automated driving task, the road marking and lane localization are very important and provide a critical information. This information needs to be really accurate, certain, reliable in order to achieve some manoeuvers like lane changes or generate safe path planing (co-pilot) [4].

The research and the study proposed in this paper are directly dedicated to this important topic of road markings detection and tracking, and lanes estimation for automated and/or partially automated driving applications. Our objective is to provide an assessment of the road surface attributes (road markings attributes, type of road marking, number of lane and characteristic of lanes). This method is based on use of one or several embedded cameras.

Most of the algorithms are basically based on a three-step scheme summarized as follows. First, images are processed in order to extract road marking features. Second, extracted primitives are analyzed in order to extract point distributions corresponding to a road

marking. And finally, in a third step, extracted and validated points are used to extract lane shape. In some previous work [5], the first extraction part has been studied, tested, and evaluated in order to determine the best way to extract road marking primitives. In this paper, a double extraction strategy is proposed to achieve the discrimination of the points for marking points and non-marking points. To guaranty the robustness of our approach, we proposed in addition a performance evaluation protocol for the first road primitive's extraction stage based on the use of the SiVIC platform, which is presented in [6]. This protocol provides an accuracy measurement of the clustering and robustness relatively to a clustering threshold.

In this paper, we present several significant improvements of the original method proposed by S. S. Ieng and D. Gruyer in [7]. The global scheme is the same one, but some enhancements have been done in each part. For instance, the combination strategy of several extractors, the management of the primitives in the detection stage, and the lane and markings estimation in the lane estimation part has been modified. In addition, instead of imposing a very discriminative threshold into the extraction part, we propose the use of the intensity of the extracted point into both the detection and the estimation parts. Lane marking detection, originally based on the study of a histogram containing projected points, is now made by using the same type of histogram but where the projected point is weighted in function of their uncertainty. Moreover, the poly-fitting mechanism has been replaced by a weighted poly-fitting, for the same reason. Higher is the extracted intensity points, more strongly weighted are these points in the estimation process. To robust our approach and avoid false alarms, distribution points which are not satisfying very discriminative criteria for peak clustering are submitted to a robust weighted poly- fitting.

2 Literature Review

2.1 Image Amendment

Because of the point of view impact, it is troublesome and dreary to discover the path of the street just from the first front view. To relieve this issue, we utilize differentiate viewpoint imaging strategies to make an all-encompassing perspective in the city. To do this, we have to figure the homograph network that maps the picture in the essential plane (essential camera pivot) to the vertical virtual camera. This transformation to IPM depends on the alignment boundaries of the network camera, the tallness of the camera over the ground, and the perspective of the camera comparative with ground. This implies the IPM is good with all camera designs in light of the fact that the homograph lattice is evaluated. Take these boundaries as indicated by [19] and change them separately for each shading channel of the picture. On the off chance that the skyline is known, the piece of the picture that contains the sky territory doesn't contain any valuable data identified with the street sign and is evacuated for additional thought.

2.2 Image Improvement

We improve feathered creatures eye picture differentiate by changing over shading esteems utilizing versatile limited complexity histogram evening out (CLAHE). This progression is important to evacuate the difference in the picture brought about by over the top sunlight-based light or. Nonetheless, the improved street picture may in any case experience the ill effects of extreme plan data, which might be unseemly for identifying street signs and may prompt mistaken street mark region proposition. To mitigate this issue, we utilize a snappy two-dimensional channel with portrayed advancements to expel structure data from perception while safeguarding edge data. From that point forward, we propose to use on-board data to improve street marker limits. Such an improvement would improve street marker recuperation results for various lighting conditions and assurance settled street mark zone recommendations at the territory identification stage. Along these lines, a top-notch edge map is separated utilizing the quickest edge locator proposed by Dollar et al. This edge discoverer depends on organized backwoods; it works at 60 fps and is impervious to different light conditions. In spite of the fact that this presents a method of producing material suggestions from edges, this calculation doesn't exhibit the precision of item recommendations good for our specific reason. Therefore, we propose an elective way to deal with recommendations of adjoining territories for recognizing street markings.

2.3 Recognizing Regions

Before we proceed onward to the subtleties of the last period of the field recommendation calculation [10], first depict a portion of the highlights that are helpful for expelling guide zones from the street surface.

1. Street signs are normally light and, in this manner, have a higher incentive than their sides. This expands their permeability and the probability that the driver will really feel them. Likewise, traffic signs are typically geometric and here and there painted in various hues.
2. Traffic signals are typically neighbourhood inside the road with long numbers (which are bigger than the width) to make it obvious to the driver in spite of the fast.
3. Some traffic signs have a lot of signs or text.

For this situation, all their contacts are near one another to guarantee that their mediator will be

equivalent to the street checking. Keeping these properties in mind helps us to develop a robust road marking detection algorithm.

Our zone helps cut the picture of ROI discovery in zones that are acceptable possibility for street signs. Traffic scene symbolism, particularly in urban zones, includes a ton of things, for example, vehicles, individuals, trees, which are not important to us, wiping out most zones where street signs are not noticeable. Improves framework execution. We depend on the distinguishing proof of fascinating territories; street signs are in every case splendid around them since they are intended to look simple. For this reason, we utilize Fixed Additional Areas (MSER) to distinguish territories of intrigue that are street markers for our situation. The MSER is an associated locale, and the pixels in the districts are consistently more splendid or darker than the pixels inside the range. There are compelling calculations for processing MSER. We identify MSER in precise road see pictures. Alongside certain regions of different pieces of the scene, practically all zones with street signs were found. Be that as it may, these phony disclosures don't cause any issues in our calculation as they are detached at a later stage. MSER is steady in splendid and recognizable changes. In the writing, variable similitude of direction is acquired by adding circles to MSER areas, changing over curved districts into roundabout districts, and finding nearby element vectors. For our situation, in any case, rotational shakiness is unfortunate since it causes discovery. Street signs on the contrary roadside.

2.4 Focal Point Detection

We separate a lot of highlight focuses from the districts of intrigue registered as clarified previously. To empower constant calculation without the utilization of GPUs, we utilize the FAST corner locator proposed by Rosten et al [18]. Quick has been accounted for to be around multiple times quicker than the Harris corner locator, and multiple times quicker than SIFT. Repeatability of highlight discovery is accounted for better than, and even under the least favourable conditions practically identical to, the SIFT key focuses indicator. We apply the FAST corner finder on the locales of intrigue recognized on the redressed pictures.

2.5 Highlight Extraction

Every POI is gravitated toward an illustrative descriptor. We figure the histogram of the objective expressive (HOG) for every POI. The descriptor of the HOG comprises of a quality vector with 128 measurements, determined utilizing the "best" approach at picture scales around explicit scales and POIs. Deciding these best scales and bearings is a long count. Given the necessary speed, we draw the HOG work vector with 3 fixed scales and 1 fixed bearing. For each scale, a 128-dimensional trademark is determined for every POI. By taking a gander at the included highlights at various scales, we get the last 384-dimensional element vector for every POI. For every single model picture, the arrival on speculation with traffic signals is gotten from reality on troublesome ground. Following the upgrades, POIs in the ROI named the pictures all things considered. From that point onward, the component vector is utilized for all POIs. All highlights are put away as vector reconciliation model pools and related POIs [20].

2.6 Solid twofold picture

The significant data of primary property on how we can expel street signs [11]. Since the street signs are more brilliant than the territory around them, the top channel utilized in it tends to be utilized to feature territories of intrigue. The top warmth channel has the state of a rectangular progression capacity and channels the closest neighbour. Practically speaking, nonetheless, the top warmth channel produces inadmissible outcomes when seen to some degree because of obscure or outrageous light conditions. Furthermore, the channel is delicate to reaction boundary settings.

2.7 Merging of Regions

The third property gives us bits of knowledge into the reconciliation of recommendations in the region. We can see that some sign-based street markers have numerous associations. While some examination sums up territory recommendations by depicting bunch requirements and others treat every area exclusively, we propose a superior answer for this test. Specifically, we use commotion (DBSCAN) with nearby thickness-based bunching of uses created by Torr et al. Basically, DBSCN is a grouping calculation that makes bunches from high-thickness models dependent on the local range, where searches are performed and the base number of explicit focuses in the group less TS. This calculation accomplishes the base number of focuses by choosing any point in the informational collection and imitating the current group from the current bunch point with the minP ts limitation. At the point when the calculation leaves the focuses to be added to the group, any new point is at long last chosen and the procedure is rehashed. Be that as it may, the calculation becomes flimsy when the limit purposes of neighbouring groups are recognized. The depicted places of business this issue and shows the exhibition of visual execution contentions for information with neighbouring bunches. This makes thickness based grouping a powerful acclimation to accomplish a lot of locales that have a place together and have a place with a similar class. The grouping

calculation is applied to the inside directions of the considerable number of proposals of the street checking zones in the wake of separating the wrong regions. The utilization of thickness-based grouping disposes of the need to consider every locale separately and combine districts utilizing experimentally decided imperatives.

While path identification has been seriously read for a considerable length of time, the recognition of other street signs, (for example, representative and finished) has pulled in little consideration. To tackle the issue of finding street signs, numerous strategies depend on starter data about the area of paths. In any case, path exactness may antagonistically influence the acknowledgment of other street signs. Tao et al. He noticed the requirement for autonomous distinguishing proof of street signs and proposed an elective calculation to recognize and distinguish street signs. This methodology influences the recently applied IPM procedure to manage point of view impacts. From that point forward, numerous ROIs are recovered as MSER.

In this way, the FAST component identifier is utilized to remove the objects of intrigue, and the arranged inclination histogram (HOG) is utilized as a handle to make an example for each class. The layout picture is then contrasted with each picture in the format, and the class mark is doled out by looking at the vectors of the test highlights and each picture in the layout. Despite the fact that the creators report victory, this strategy depends on the precision of an exceptionally quick FAST finder and extricating substantial HOG capacities is computationally costly. On the other hand, [15], Perform low-level preparing to remove ROI from IPM pictures to distinguish target street signs. Recuperated ROIs are breaking down and distinguished dependent on rakish direction and bead size. In spite of the fact that this work has yielded good subjective outcomes, no quantitative appraisal is justified. Moreover, another calculation ought to be liable for recognizing a specific sort of street marker, which brings about lower adaptability. Correspondingly, it tries to expand the unwavering quality of the calculation by separating street markers into text and representative street markers. Text-markers are recognized utilizing the optical character acknowledgment calculation, while character-based markers are distinguished by extricating the HOG highlights ordered utilizing the support vector machine (SVM). In any case, a slight improvement in the proposed calculation doesn't legitimize the need to process street markers independently, prompting computational repetition.

In contrast to physically made assignments, whose exhibition relies upon their planned reason, classifiers have demonstrated their dependability for some PC vision applications dependent on fake neural system extraction (ANN) devices and AI. Various works have endeavoured to utilize neural systems to improve the discovery and recognizable proof of street markers. For instance, [17] the creators propose to utilize the coordinating edge in the IPM picture to discover likely contender to submit to a prepared neural grouping.

This strategy shows great quality against various states of light, climate and street surface. This is the primary method to utilize completely associated neural systems to perceive street signs. Rather than completely associated neural systems, virtual neural systems (CNN) have performed better in characterization results because of their capacity to remove increasingly powerful portrayal highlights. Be that as it may, with current ExxonMobil or VGGNET models, such a profound CNN as a rule requires a great deal of preparing information and is regularly executed on costly GPUs, permitting the vehicle circuit but there is more weight. Following this rationale, Chen and so on. Proposed a calculation that utilizes the Being Object Detector to give proposals to various potential areas with similitudes to the district's images. These up-and-comer territories are additionally grouped by the PCA Network (PCENT). PCN8 is a sort of profound learning system that utilizes PCA channel bank as opposed to confounding layers like CNN. As a rule, PCANet is a lightweight rendition of CNN that is basically basic and has demonstrated to be a compelling technique for picture arrangement. The impediment of the proposed approach is that a fixed number of BNB lines (30 offensive up-and-comers) are drawn per outline, which frequently prompts computational repetition, as the quantity of street signs from the survey perspective never increments. Doesn't reach such huge numbers of locales.

Another disadvantage is that the street markings are not set accurately and regularly the determined bouncing box contains other disconnected articles. Simultaneously as our work, Hyeon et al. We have built up an elective framework for perceiving and perceiving street markings. This technique varies from multiple points of view. Extraction of associated sets is finished utilizing Gaussian diff rather than MSER. Locale put together gathering is accomplished based with respect to curved conditions while depending on thickness-based gathering. Arbitrary woodland is utilized for characterization errands. Rather, utilize further developed AI strategies. Likewise, this paper groups perceived regions into image based or text-based street markings, however the client needs to accomplish more acknowledgment. This technique, then again, treats all street markings similarly and perceives an unmistakable class of all street markings presented. Intrigued per users are urged to think about this synchronous work too. To beat the previously mentioned downsides of the current techniques, we propose a calculation that gives superior on complex datasets. Our commitment comprises of three sections.

We give a framework that dependably recognizes street markings in pictures. Wireframes process a few pictures in equal without expanding the calculation time. This commitment guarantees that street markings are distinguished under various lighting conditions and uses thickness-based bunching to amass street markings. These disposes of the need to process character and text territories independently and utilizes AI procedures to perceive street markings. Notwithstanding PCANet, it proposes a little CNN and gives an iterative answer for improve and keep up the steadiest districts.

2.8 Runtime Template Corresponding

We presently go to the execution coordinating calculation that improves the score. The means recorded in the past areas. Amendment, MSER check, sharp edge location and HOG-explicit computations are performed on each test symbol. The test pictures are uncovered based on POI after indication discovery. In the road see picture, there might be a wide range of traffic signs. What's more, one sort of image can show up in numerous spots in a picture. In this way, each example may have more than one comparing patch in the test picture. Moreover, P.O.I. The identifier doesn't have a redundancy of 100 reiterations, subsequently, a portion of the POI tests found in the test picture don't show up in the example, etc. Accordingly, the test picture for the most part has a similar POI substrate as the POI substrate in the example. There are two stages in our calculation to ascertain this comparability. In the first place, we acquire a positive POI coordinate dependent on their component vector, and second, we improve the outcome utilizing an auxiliary coordinating calculation that coordinates the 2D geometry of the POI in the street sign [3].

3 Research Methodology

Our aim of this research is to develop an automated road marking detector based on multi-deep learning algorithms to detect and qualify the road marking conditions in which is evaluated the best selected road marking that fulfil the future autonomous vehicles needs and requirements, by utilizing deep learning algorithms. Using convolutional neural network and image classification technologies, the proposed prototype system first receives digital images of finished road marking surface and do the images processing and analysing to capture the road marking characteristics.

Those characteristics are then evaluated to determine the quality level of road marking conditions. System will be trained by multi-real cases as well as demonstrated through three real cases to show how it works. In the end, a test comparing the assessment results between the proposed system and expert inspection will be conducted to enhance the accountability and accuracy of the proposed mechanism.

Our system consists of training and testing phases. The input to the training phase is a set of images with ground truth masks and labels of the road markings as shown in Figure 1.

Figure 1. Template Images

We will call these training images as template images henceforth since these are used as templates for the road marking detection.

For each template image, we first perform rectification to compensate the lens and perspective

distortions. Within the regions of interest containing the road markings, a set of points of interest (POI) are detected, for which we use FAST corner detectors [15]. A Histogram of Oriented Gradients (HOG) [16] feature vector is extracted for each POI and the template set is built using the locations and the feature vectors of the POIs extracted from all template images for the particular type of road marking.

During runtime, the same steps are repeated for each frame of the testing video, captured pictures and a set of POIs and their feature vectors are extracted, except that the regions of interest are detected automatically. Subsequently, we find multiple matching candidates for each POI in each template image. Lastly, a convolutional neural network and image classification algorithms are employed to test if a subset of the matched POI pairs forms a road marking the same as the ones in the template images.

3.1 Image Rectifications

The camera we use is mounted on a rooftop rack and focuses to the front of the vehicle. Because of this low perspective, there is a huge point of view contortion with separation. We correct the picture utilizing a reverse point of view change that altogether diminishes this mutilation. Converse viewpoint changes have likewise been utilized widely in past work on street stamping identification [16], [4]. The reverse point of view change is a lattice which just relies upon the camera adjustment, the tallness of the camera over the ground, and the review edge of the camera θ regarding the ground Figure 2. Applying the lattice changes an information picture to a feathered creatures eye see. A case of such a fowl's eye see is appeared in Figure 3. Note that the change boundaries are adjusted beforehand accepting the ground is level, as opposed to aligned in real-time. Subsequently

the paths might be not ideal equal in the winged animals eye see when the vehicle is on slopes or has pitch and move developments. Acquiring the flying creatures eye see permits us to legitimately figure the slope on this picture to get the HOG descriptors. Without the winged creatures eye see, we would have been compelled to utilize an anisotropic angle administrator to represent the point of view twisting.

Figure 2. The setting of Cameras

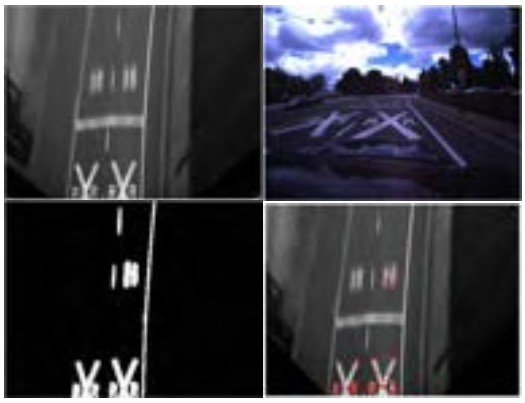

Figure 3. Image Detection multi views

3.2 Region of Interest Detection

Our region of interest (ROI) detector helps prune the image to portions which are good candidates for being road markings. Since a traffic scene image, especially in urban areas, will contain many objects such as vehicles, people, trees etc., which are not of interest to us, removing most of these areas where road signs are not likely to occur improves the efficiency of our system considerably.

We base our recognition of interesting regions on the perception that street signs are consistently more brilliant than their prompt environmental factors since they are intended to be seen without any problem. To this end, we utilize Maximally Stable Extremal Regions (MSERs) [17] to identify locales of intrigue, which are putative street markings for our situation. A MSER is associated district that is extremal as in the pixels inside the locales are consistently more splendid or darker than the pixels on the limit. Proficient calculations for processing MSERs exist. We recognize MSERs on the redressed street scene pictures.

MSERs are steady across brightening and perspective changes. In the writing, perspective invariant coordinating is accomplished by fitting circles to the MSER areas, changing the oval districts to roundabout locales, and extricating nearby component vectors [15]. Be that as it may, for our situation, the subsequent revolution invariance is bothersome as it would prompt discovery of street markings in the contrary roadside too. A model is appeared in Figure 4, where there is a left go sign in the contrary path. Subsequently, we don't change the MSERs into circular districts.

3.3 Runtime template matching

We currently continue to the runtime coordinating calculations that perceive the street markings. The means referenced in the past areas viz. correction, MSER identification, Quick corner discovery, and Hoard descriptor calculation are performed on each test picture. The signs in the testing pictures are then recognized and distinguished dependent on the POIs.

In a street scene picture, there might be numerous diverse street signs. Additionally, a solitary sort of street stamping may show up at different areas in a picture. In this way, every layout may have numerous coordinated fixes in a test picture. Furthermore, since the POI identifier doesn't have 100% repeatability, a portion of the POIs distinguished in the test picture may not be recognized in the layout picture and the other way around. Subsequently, there is generally a subset of POIs in the test picture that coordinate a subset of the POIs in the layout. Our calculation to process this coordinating comprises of two stages. Initially, we find putative coordinating sets of POIs dependent on their element vectors, and second, we refine the outcome through an auxiliary coordinating calculation that coordinates the 2D geometry of the POIs inside the street checking.

4 Dataset

To the best of our knowledge, currently there is no dataset that is designed for evaluating the performance of road marking detection and recognition. Hence, we collected our data using a mounted camera on a rack of a vehicle or drone and facing forwards. The vehicle was driven on urban and non-urban roads in Dubai and Sharjah Emirates, UAE under various road conditions. We manually annotated a subset of the road markings appearing in the captured images. We hope that this extensive dataset will provide a fruitful benchmark for other researchers working on this problem. An example of an annotated template image is shown in Figure 4.

Figure 4. Annotated template

5 Experiments & Findings

We tested our algorithm on the dataset described above. Our algorithm uses OpenMP for parallelization in the feature extraction stage. A value of 1.3 was used for the α threshold from (1), while the value for the β parameter from Section IV-B was set to 0.01.

Figure 5. Detection Segments

Fig. 5 Unqualified Detected Segments left side the wrong road marking and right side the template images

Our system currently depends on two manually selected threshold values, the α parameter of (1) and the β parameter of section IV-B. It is future work to automatically select these parameter values and adapt them online for different test conditions. We currently observe that the values used in our experiments presented above are applicable in a wide range of scenarios including large variations in road marking conditions.

Our system works robustly for complex road markings, but the false positive rate is higher for simpler markings such as forward arrows. Finding a tighter cost function that alleviates this problem is part of future work.

In our experiment, we select several images as the templates, which contain different types of road markings including pedestrians' crosswalks, intersections, and roundabouts. Our algorithm achieves a true positive rate of 90.1% and a false positive rate of 0.9%, indicating that false positive detections occur only very rarely. We found that our algorithm could also detect and recognize road markings clarity in case of sand dunes / snow accumulation.

In our system, we trace and obtain several segments that contains unqualified road markings as shown in figure 5.

Abstract –

An on-site construction progress monitoring and presentation system is herein developed that overlays the virtual building information model (BIM) onto the real-time scene of the construction site using augmented reality (AR). The system utilizes the novel AR technology of simultaneous localization and mapping (SLAM), which is a real-time positioning technology based on visual-inertial odometry and point cloud map construction. Based on the scanned 3D environment point cloud and the adopted plane detection method, the indoor positioning is first initialized by attaching a virtual BIM component, which is set up on the centerline for alignment, to the corresponding real component at the actual site environment. Then, according to the completion surface of the actual object, the parameters of the position offset are kept adjusted at different construction stages, so the model can remain in position with the current scene. In this manner, the 3D BIM will be superimposed and displayed on the real-time view of the site based on the device's understanding of the environment through the recorded point cloud map using SLAM. In addition, the system also provides application modules for monitoring the project progress on-site. The on-site engineer can perform data collection through the designed system by interacting with virtual objects, with visual feedback provided for monitoring progress and evaluating project performance. To monitor the progress of a construction project on-site in real time, a method is proposed to quickly update the SLAM-based indoor positioning for adapting to a changeable construction environment. This compensates for the lack of visualization in the current construction management methods.

Keywords –

Augmented reality; Simultaneous localization and mapping; BIM; Construction progress management

1 Introduction

Augmented reality (AR) has many applications in the field of civil engineering, where the aim is to calculate the user's orientation and position to superimpose virtual objects and information onto the real world through a display device, thereby providing the user with the corresponding 3D model information and spatial details of the project site. The augmented reality positioning mode differs according to the location and use, in addition to variations in the resulting usage restrictions.

In the life cycle of construction projects, as building information modeling (BIM) is gradually maturing and being promoted, the combination of AR and BIM can be used to display increasing amounts of building information. Through visualization technology, the use of traditional 2D drawings has been traded for a more intuitive 3D model, and by combining the model with the actual scene to aid in decision-making, the design, materials, and configuration can be checked whether they are congruent with the designer's concept. If there are issues with the construction, immediate modifications can be made, thereby greatly reducing the errors during design, and reducing the cost and time of retrofitting after construction completion. While some previous studies have attempted to apply AR to the field of architectural engineering [1-3], the applications have been mostly limited to outdoor construction sites or existing construction sites.

Furthermore, in the project life cycle, the construction stage is where most changes occur and is the stage most prone to errors, with immediate corrections being challenging. Once the procedures have errors, the domino effect caused by errors will cause significant

delays and cost increases. Therefore, the accuracy of message transmission of relevant construction operations, flow processes, and information between various construction units appears to be particularly important. A closer look at the construction on-site environment can reveal several characteristics such as a "harsh environment", "many on-site stacking objects and construction equipment", "huge and rapid changing construction environment", "difficulty in equipment setup, update, and maintenance" and "uncertainty in environment situation". As a result, the positioning of an AR system on a construction on-site becomes a major challenge. For many of the technologies used in augmented reality such as GPS, marker indoor positioning, Bluetooth, Wi-Fi, and RFID, the use of some external sensor devices to initialize the AR system is required. Additionally, apart from inadequacies in efficiency and accuracy as well as a higher cost, for the rapid vicissitude of the construction environment, there is a need to set up a device such as a Bluetooth device for positioning, along with installation difficulties and the time-consuming and complex maintenance and updating. In traditional construction management, for progress tracking and checking the construction tasks, there is a need to manually collect data, illustrations, and other information from all construction units, which, can be a quite time-consuming and labor-intensive operation. Presentations through text and data do not provide adequate visualization for the on-site personnel. There is not enough specific intuition. It is not easy to immediately present the work tasks in progress within the local space, and for professionals from different backgrounds, further errors may result in message uploading[4]. Even with the assistance of 3D simulation in BIM, the construction personnel still have to rely on their spatial reasoning and map out the illustrations or 3D models to the physical space, and thus, real-time discussions cannot be made timely on-site, thereby further affecting the time and cost. Meža [5] used AR for the visualization of the preliminary design and the monitoring of the construction on-site, and when compared with other applications, AR was found to effectively and drastically improve the intelligibility of information.

This study attempts to apply an existing AR framework and propose a set of construction management systems based on AR and BIM that are suitable for the construction stage. Through the visual tracking of simultaneous localization and mapping (SLAM) and AR system initialization based on dynamic reference benchmarks in response to the rapid changes and uncertainties of the construction environment, when the construction environment changes drastically, the BIM model is quickly fitted and positioned to improve the updating efficiency. In combination with construction management, interaction with the BIM model is conducted through AR for comparing the pre-planned construction progress with the actual progress on-site as reported by on-site personnel, as well as providing assistance in checking construction tasks. As compared with traditional construction management, visualization technology can be used to enable on-site personnel to view progress more intuitively and accurately, and to look for possible problems or risks in advance.

2 Objective

A "construction progress integrated management system based on augmented reality technology" is herein created with the aim to integrate the ARKit augmented reality framework as developed by Apple Inc., BIM, and construction management concepts, and present them on the site at the construction stage. Apart from the electronic construction management data collection and incorporating progress calculation functions into the system framework, this study proposes a model positioning and fitting system framework that is suitable for an indoor construction site through existing AR tools. The target application is under construction project sites.

For the model positioning and fitting operation flow process, first, due to the unpredictable on-site environment and the characteristics of environmental changes at the construction stage, the on-site configuration cannot be accurately predicted and no fixed object can be used as a positioning reference point. Thus, the pre-setting of a reference point is challenging and it is necessary to set a dynamic reference plane when positioning the BIM model, whereby the plane is used as the basis for initializing the model positioning. This reference plane can be dynamically determined according to the instantaneous configuration of the on-site environment and the offset position can be measured using the setting position in the original model. Then, the visual-inertial odometry (VIO) technology in ARKit is used to perform the positioning and feature point mapping of the AR system initialization in an uncertain space environment, and to create fitting-assisted reference components through existing structures or objects on-site during the mapping process. In this process, the reference components are used as fitting corrections for the 3D model when drifting is generated when a device is moved. Finally, the plane detection technology is used to pre-set the corresponding position of the initial dynamic reference plane in the BIM model onto the actual site. By entering the position parameters in advance, the AR system initialization is completed as the 3D model is fitted onto a relative spatial position. The operation preprocessing flow process for the initialization is shown in Figure 1. Through this process, quick dynamic positioning and fitting of the model can

be achieved. Subsequently, the model repositioning and fitting can be carried out according to the recorded feature point maps in response to the changing construction environment, thereby improving the efficiency of system initialization and achieving a marker-less indoor positioning. The actual operating process is shown in Figure 2.

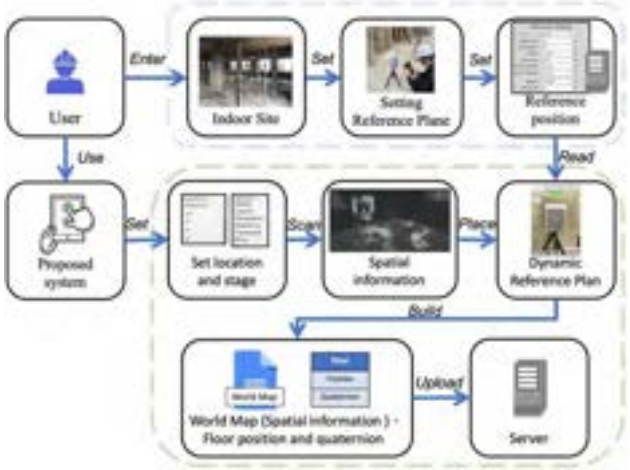

Figure 1. The pre-setting process of the proposed system.

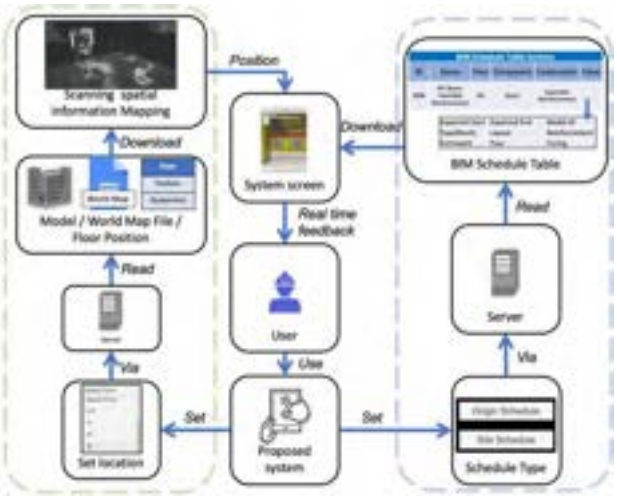

Figure 2. The operating process of the proposed system.

Finally, the BIM model and the construction schedule are integrated to achieve a mechanism for automatic collection of construction task data, daily management operations, information transfer, progress information visualization, and feedback. The mechanism further improves the project AR management framework that is lacking in relevant literature for traditional construction management.

The construction progress integration management system using AR will take the construction of a reinforced concrete (RC) as an example. Main construction operation tasks are divided into lofting, steel bar binding, formwork assembly, grouting, and concrete curing. To verify the proposed system, the positioning is subjected to a verification test on an actual site to monitor whether the BIM models can be efficiently fit to the site and are not affected by the work surface at various construction stages, and whether the system positioning accuracy is sufficient to meet the site requirements. Moreover, through the system display and comparison with the traditional construction management methodology, the proposed system is demonstrated to integrate planning and actual site information, and display this data on an AR device. The progress summary information is displayed using different colors corresponding to construction status, and it is verified that the user can perform queries and comparisons on construction task progress with the use of virtual reality as well as efficiently check construction tasks.

3 System Requirements and Mechanisms

To achieve these objectives, the functional requirements of the system are investigated, with Unity3D and ARKit frameworks used as the system development platforms. These analysis functions include the AR indoor positioning process based on SLAM visual inertia, system pre-position operation test, reference plane design and deployment rules, preprocessing of the BIM model, and the BIM model component information and progress information storage framework. The following subsections focus on introducing the functional analysis and proposed system methodology.

3.1 BIM model preprocessing

To achieve the “construction progress integration management system based on augmented reality technology” as mentioned in the aim of this study, the proposed system needs to establish a BIM model using 2D illustrations. Analyzing the project scale, characteristics, management organization, management method, and work breakdown structure diagram of the RC structure, the scope when operating the system will provide visual feedback to users based on the floor level. To reduce the burdens on the display and storage space of the device, the pre-position processing of the BIM model segments the 3D model into floors, and stores them on the server for users to download. The primary pre-setting process is shown in Figure 3.

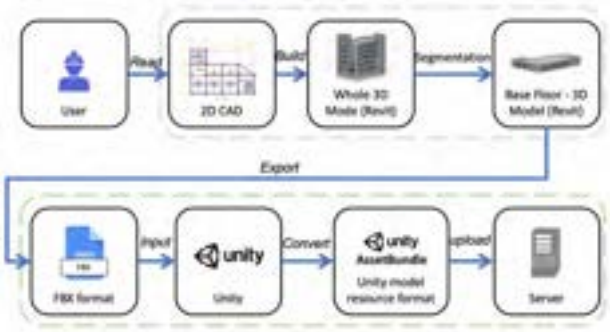

Figure 3. Pre-setting process of the BIM model.

3.2 Augmented reality indoor positioning

The ARKit framework is used as a development tool in iOS. ARKit is a framework based on SLAM combined with an inertial measurement unit (IMU). SLAM refers to a camera device equipped with a lens determining its own position and stance (sensors) by repeatedly observing environmental feature points (e.g., ground surface, walls, columns, etc.) during a movement process, starting from an unknown location in an unknown environment, and then calculating the feature point coordinate data intercepted from the image by its own position and stance to construct the feature point map, thereby achieving the self-positioning and mapping.

3.2.1 ARKit framework

SLAM has mostly resolved the two problems of positioning and mapping. “Positioning” refers to the device location as self-estimated in its environment at that moment, while “mapping” (a.k.a. feature points or a point cloud map) refers to the model of the identified local environment, i.e. the environmental map with incremental feature points as found through continuous movement and repeated observation of environmental features using positioning. The visual SLAM processing procedure is divided into five steps: (1) camera information image sequence acquisition and access, (2) visual-inertial odometry (VIO), (3) calculation optimization of device position and stance, (4) closed-loop detection of repeated observations, and (5) feature point mapping. In the ARKit, stance estimation of the IMU has been added into the second step of SLAM to measure the acceleration and angular velocity of the device, and through Kalman filtering the most accurate position of the device is obtained. Through a combination of the camera and inertial sensor, the estimation errors are lowered to increase the positioning accuracy. In the framework of ARKit, feature points captured by each image will be stored as anchors attributes, indicating that there is an anchor list for tracked positions or objects as detected on the map., If images that are being taken are repeatedly identified, the device location can be repositioned.

3.2.2 Plane detection

As mentioned above, many feature points can be extracted from the camera images to develop a tracking and positioning feature point map. Under this framework, these feature points not only can be used for estimating the device position, any three extracted points can form a plane, and then these triangular planes is subjected to processing through an algorithm and several plane optimizations. Finally, a sufficient number of planes can be used to estimate the real physical plane. Through the estimated plane, model components can be placed at the captured anchor position through interaction with the AR system.

3.2.3 Analysis of feature point mapping

Based on the abovementioned positioning theory of SLAM under the ARKit framework, an analysis is conducted on the construction and operation behavior of the feature point mapping, and the results of a test of using the device movement rate for positioning and mapping, as well as using the measurement mode on the construction site, are presented as shown in Figure 4 and Figure 5.

Figure 4. Actual environment.

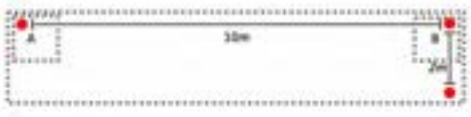

Figure 5. Schematic top-view.

From multiple test results, the movement rate and 3D error with a varying number of intercepted feature points was obtained (Figure 6). Under the same movement range, it can be found that there are more feature points

intercepted at a slower movement rate, and the accuracy in positioning and mapping is also relatively higher. For the variance in errors with the number of feature points found via interception corresponding to the fitted model, it can be found that the errors generated at movement rates less than 0.5 m/s gradually converge to approximately 1% of the overall movement distance. Therefore, when the camera intercepts the feature points, blurring will increase in the camera due to the high-speed movement, which will cause errors in positioning and mapping. At slow movement speeds (approximately 0.5 m/s), the generated errors begin to converge, and the resulting error falls to around 1% of the movement distance. Errors in a very harsh environment can almost be on the order of inches [6].

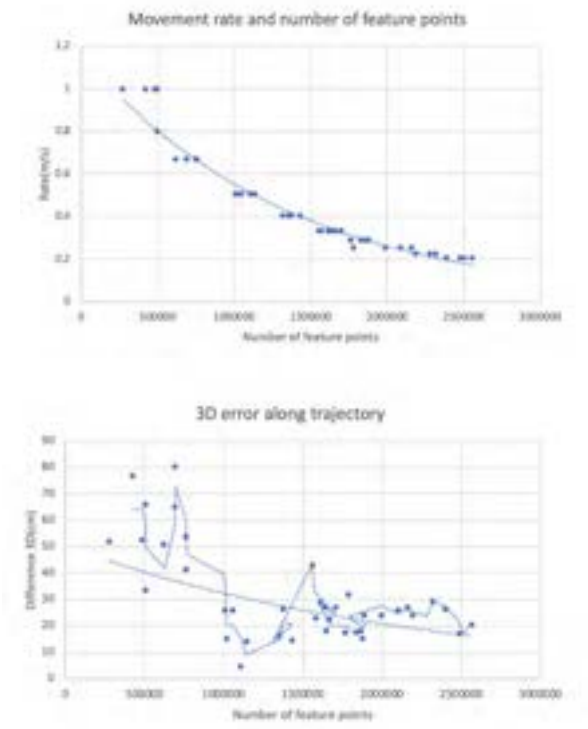

Figure 6. Movement (top) and 3D error (bottom) with number of feature points.

3.3 BIM model fitting mechanism

The model fitting mechanism is mainly to align one of the BIM model components with the corresponding real object for placement, and then to use the relative relationship between a single component of the BIM model and the entire model to fit the entire model on the map of feature points, thereby superimposing the model on the site. However, due to the unpredictable construction environment and characteristics such as environmental changes at the construction stage, the on-site configuration cannot be predicted and no fixed objects on the site can be used as positioning reference points for the feature point map. Therefore, a dynamic reference plane is required as a reference point for position initialization. This reference plane can be dynamically configured according to the configuration of the site environment at the time of initialization. When configuring the reference plane, the positional distance difference $\Delta \boldsymbol{R}$ from the reference plane in the BIM model is measured via centering and leveling operations, as shown in Figure 7. Finally, the offset data is recorded in the database. When fitting the model, the model file is first downloaded from the server according to the selected plane position and stage. Then, the system will first read the coordinate $\boldsymbol{P}$ and angle $\boldsymbol{Q}$ of the previously loaded model. Next, the selected virtual reference plane is aligned and placed on the actual reference plane; during the placement, angles $\boldsymbol{P}'$ and $\boldsymbol{Q}'$ (see Equation (1)) are obtained. Finally, the angle rotations of $\Delta \boldsymbol{Q}$ (see Equation (2)) and the model position movement distance of ΔP for the reference plane offset of $\Delta \boldsymbol{R}$ will be first calculated and then uploaded together to the server as the basis for the model fitting (see Equation (3)).

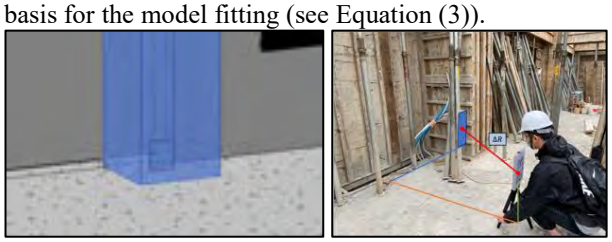

Figure 7. BIM model reference (left) and actual environment (right).

$$Q'\,[x' \quad y' \quad z' \quad w'] = \Delta Q \times Q[x \quad y \quad z \quad w] \tag{1}$$

$$\Delta Q = Q \times Q'^{-1} \tag{2}$$

$$\Delta P = |P - P'| + \Delta R \tag{3}$$

3.4 Integrating BIM model data and progress schedule data

During the construction project, due to the influence of different factors, each in progress construction task can either be ahead of schedule, behind schedule, or on schedule, further affecting the start of relevant subsequent tasks. As a result, the actual construction operations will change from the initial construction plan. Essentially, construction management and control are based on contracts that use the project schedule as a foundation, while for the proposed system, the user continuously updates the actual progress of work tasks on the BIM model via the AR system, as the BIM model components in the system framework are associated with their corresponding work tasks. Given that a user continuously interacts with the model to enter the actual construction progress to dynamically update the schedule,

this dynamic update is based on the successive relationship of construction operation tasks. The overall schedule obtained is thus a real-time prediction of the overall construction length based on actual project progress. Estimations for subsequent tasks can be based on this dynamic scheduling and in the same manner, engineering performance evaluations can be implemented based on planning and actual on-site scheduling; early deployment and improvement can be made on subsequent implementation of the same standard layer using AR feedback for the actual situations that have happened on the site. The operating mechanism of the real-time dynamic update for the construction schedule is shown in Figure 8.

Figure 8. Operating mechanism of the real-time dynamic update for the construction schedule.

4 Application Scenarios

Based on the prototype system developed, four types of application modes that meet the practical requirements are proposed for integrating the virtual and real environments: (1) interface conflict and positional views, (2) component data presentation and task checklist, (3) construction progress presentation and progress comparison, and (4) presentation of affected construction tasks and construction simulation. These modes are applicable for the construction life cycle and acceptance and review stages, with the mode adjustable depending on the degree of detail in the BIM model and operation requirements. It is not necessary that one type of mode can only support operation in one stage. Below is a detailed display and description of these four modes following the characteristic classification of system operations.

4.1 Interface conflict and positional views

The first application mode is used for presentation before the construction of the structure begins. Surrounding a construction site, there are mostly existing buildings or structures such as adjacent houses, slopes, roads, and other structures. The aim of this application mode is to alleviate the ecological impact from the project site and to investigate countermeasures by viewing possible affected location (e.g. surrounding adjacent houses, slopes, channels, and other existing structures) before the construction starts, as well as confirming the construction disturbance range (e.g. construction access roads, earthwork, and material stacking areas, etc.) to determine the project configuration and for moving line planning. For the case study introduced in the present study, it can be clearly seen that there are slopes and existing channels surrounding the future water collecting well, as shown in Figure 9. Through the repetitive detection of the AR, the relative height of the water collecting well with actual possible affected location can be more clearly seen to discover problems in advance. The evaluation via repetitive detections determines whether the original design or construction plan needs to be further adjusted. During construction, this application mode can assist in confirming whether the depth after excavation is sufficient, as shown in Figure 10, and at the construction stage for the structure, this application can also assist in confirming the location of completed components on the site, as shown in Figure 11 for reference.

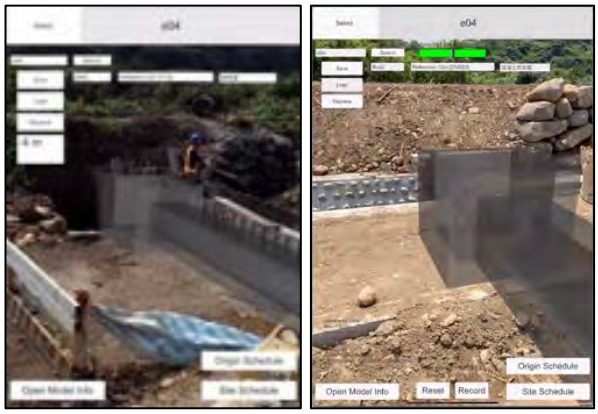

Figure 9. The elevation of the water collecting well and possible a location.

Figure 10. Excavation depth confirmation on the construction site.

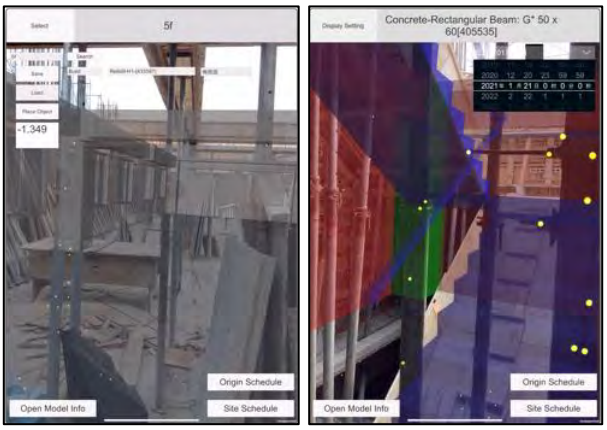

Figure 11. Indoor location assistance for the RC structure construction.

4.2 Component data presentation and checking form

The second mode is to tap and interact with the model after it is superimposed to present relevant information for the selected component. Apart from the attribute parameters and associated construction progress item information, the main presentation content also can have various attached documents according to the component type or usage requirements. Due to the association between components and progress, a user can therefore mark the completion of a system component directly as a unit for a construction task and be provided the construction progress. The information on the progress of components that can be provided to the user based on the ARKit real-time positioning when the system is operating at the construction stage is given below. The application procedure as follows:

1. When a project enters the construction stage, the user enters the location where a task is to be completed and then checks the task when completed to ensure the quality of project work.
2. The user moves toward the component to be checked after the completion of system positioning.
3. Attributes and progress information for the component can be obtained by tapping the component on the device screen.
4. When the quality audit confirms that there are no errors, the task for that component will be marked as complete and updated. At this point of time, following the date of checking, the progress for that will be determined as either ahead, on , or behind schedule. The system will update the dynamic progress schedule for subsequent associated work tasks according to the date of checking, so that the user can estimate future progress, as shown in Figure 12.

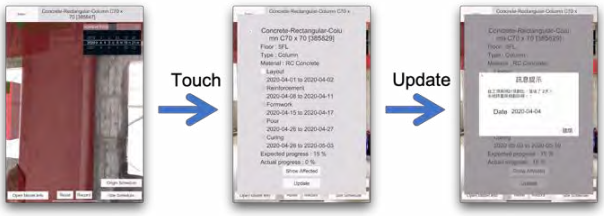

Figure 12. Component information query and task checklist.

4.3 Construction progress presentation and progress comparison

The third mode is to superimpose the actual objects with the virtual objects and view the current construction progress overview based on the schedule, where yellow, green, and red indicate in progress, complete, and delayed, respectively, as shown in Figure 13 (left). Moreover, this mode compares progress with the planning schedule and the actual checking date. It presents whether each work task in the past is ahead of schedule (green), on (yellow), or behind schedule (red), as shown in Figure 13 (right). On site, a user can carry out the presentation and review whether there are conflicts on the moving lines and configurations to adjust the schedule and for early deployment of subsequent work tasks.

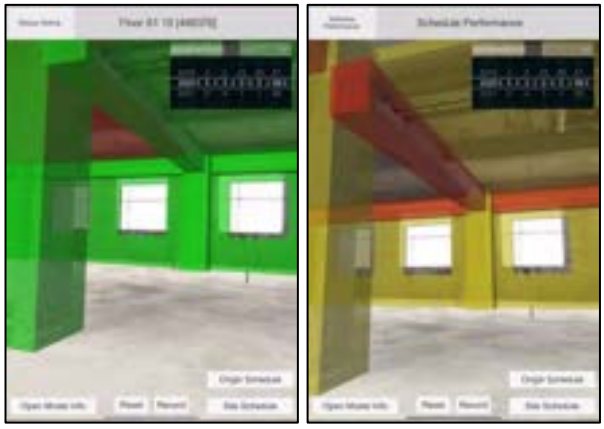

Figure 13. On-site progress presentation (left) and comparison of progress (right).

4.4 Presentation of affected construction tasks and construction simulation

The fourth mode considers the sequence of planned work processes and uses blue as the color for the work task component to be implemented in the future, so that the user can perform construction simulations on site, as shown in Figure 14 (left). Furthermore, following the results of using the previous several modes in sequence,

for the components that are likely to be subsequently affected due to delays in the work process, the components are presented in orange, as shown in Figure 14 (right), giving the user a visual reference beyond than numerical data and text.

Figure 14. A construction simulation (left) and an affected work task (right).

5 Conclusions

This study proposed the "A Construction Progress On-site Monitoring and Presentation System Based on the Integration of Augmented Reality and BIM". The aim was to carry out the positioning of an AR system at a construction site through the ARKit framework based on SLAM for an indoor site at the construction stage, and be able to respond to unknown and rapid changes in the harsh site environment. Under different construction stages, the dynamic reference plane without pre-setting additional sensor devices conducts rapid system positioning initialization. The indoor position is located by visually scanning the site environment characteristics, and then, by downloading the BIM-related information and progress information from the database, a virtual and real integration mode on site allows for viewing the elevation, position, and progress of components. Furthermore, data collection is conducted through user interaction with the AR system, and the collected data is integrated to provide visualized feedback functions, such as a comparison on the difference between planning and on-site actual progress and construction simulations. Adaptability, immediacy, synchronization, and convenience as provided by the proposed system can improve the efficiency of on-site construction personnel in understanding the progress, in planning, and in decision-making. Through the combination of AR and indoor positioning, the proposed BIM information on-site visualization can improve the existing BIM visual model, and can effectively and quickly collect and acquire information, thereby reducing complicated operations and the required time. Through the real-time visual feedback on site, the virtual and actual scenes can be superimposed on a single screen simultaneously, therefore supporting on-site construction monitoring and discussion. The future development of the system will be further integrated with computer vision for automatically identifying the completion rates of all BIM overlaid components in a scene through deep learning based AI.

Abstract –
The efficient construction of large industrial plants (e.g. concrete plants, chemical plants) in high quality requires precise planning and execution of the individual logistics and assembly steps. For this purpose, detailed step-by-step instructions should be prepared that can be clearly interpreted and thus implemented by the staff on site carrying out the work. Especially meaningful and project-specific assembly instructions are very important. In some cases, digital plant models are already being used to visualize the assembly sequences. The individual steps of assembly are animated together with the associated plant elements, staff and other resources. However, the exact assembly sequence has to be specified by a production engineer. This paper presents an approach for semi-automatic generation of step-by-step instructions for assembly in large-scale plant construction. Basic information for the assembly of a plant can already be taken from digital (BIM) models (BIM: Building Information Modeling). They include, e.g., information on components, construction details and connections. Based on this information, specific assembly sequences can be defined as rules for various plant groups. These rules are collected in a central database and provided for further use. An example shows how individual assembly sequences can be generated based on a digital plant model using the rule set. The results can be made available as 4D animations to the involved employees on the construction site. The assembly sequences defined for a project can provide useful support for planning the processes on the construction site (assembly, transport and storage of building elements). A simulation provides the validation of the planning created for this project and therefore also the validation of the defined assembly processes.

1 Introduction

Precisely coordinated individual construction site logistics are of great importance for the efficient and cost-effective handling of large-scale plant construction projects, especially when the transport and storage of very sensitive and large components are involved. Planning includes the selection, design, dimensioning and optimization of processes, material flows and resources. Depending on the complexity of the large plant, many different boundary conditions must be considered in the project-specific planning of site logistics. Therefore, planning is a very error prone and time-consuming process, exacerbated by the fact that it is usually performed manually. Even for the most motivated companies, the effort required for the first draft of a schedule can be so taxing that resources for an improved schedule are not available [1]. The automated planning and control of construction site logistics for such large-scale projects have not been sufficiently supported by digital planning tools so far. Today, planning and control of construction site logistics require extensive project experience. If transport and storage conditions are not properly analyzed and adhered to, not only can installation delays occur, but also damage to sensitive system components. In the worst case, reworking or complete disassembly may be necessary. In order to ensure that components are only delivered when they can be stored as required or directly installed, it is necessary to know the exact sequence of construction in advance.

Digital models have also been used for several years in large-scale plant construction for the planning and prefabrication of plant components. However, the digital models are hardly used on site, e.g. for controlling processes on the construction site. Even though digital building models do exist, only low-detailed assembly sequences, if any, are currently created by hand and given to the workers carrying out the work in the form of a manual, but the sequences are usually only determined

on site. Even if plant components can be visualized on the construction site with the aid of mobile devices, there is currently no IT-supported assistance for compliance with a previously created assembly sequence. Certain information for the exact planning of the construction sequence is already available on the basis of the digital model or can be supplemented by categorizations based on our previous work [2]. However, the existing information is not sufficient for an assembly sequence and has to be systematically supplemented and properly linked.

In our approach, we use geometric attributes and other IFC (Industry Foundation Class) model information in conjunction with a model-specific set of rules to create an assembly sequence that can be transferred into a 4D model by adding the respective performance factor. On this basis, the warehouse logistics, means of transport and shift schedules of the construction workers required for the respective component and assembly tasks can be planned.

2 Related Work

In contrast to industrial production, there are significantly more uncertain factors in construction projects that need to be taken into account during the planning stage and to which a quick and efficient response is required. The basis for the execution of a construction project is the schedule, which is nowadays manually defined by project managers based on their experience and linked to the construction elements. Even the linking of costs and schedules is still done manually today [3]. This is a time-consuming planning process. The project plan is only adjusted in case of interruptions due to due to material shortages caused by delivery delays, lack of storage space or weather conditions [4]. In a global view of construction projects, little attention is given to the logistics on the construction site. Thus, unforeseen events cause delays to the entire project schedule. These delays could be minimized by an iterative re-planning of the project plan based on the current construction status.

In the construction industry, the transition to digital construction planning is mainly taking place with the help of BIM. The BIM methodology allows a seamless transfer of construction project information throughout the entire product life cycle. This is achieved by linking geometry information with other relevant information. With the right BIM management software, this linked data can be used for visualization, checking for compliance with rules, collision detection, assignment of schedules to components (4D), cost estimation (5D) and the generation of construction plans.

As part of our research, we have already developed an approach for linking BIM with logistics information, especially for large-scale plant construction. We created the method of classifying required logistics information for each element and storing it in form of an OWL-formatted ontology (OWL: Web Ontology Language) [2]. A created ontology represents a knowledge model with information for planning and controlling logistical processes on the construction site. The information in this ontology forms the foundation for the generation of assembly sequences in a construction project as used in the methodology presented in this paper. With the help of BIM management software and the extension developed, it is possible to assign any elements to these categories, thus enabling identification for our methodology presented in this work.

In contrast to the collision database shown in this paper, Borrmann and Schraufstetter implemented in their research metric operators of an SQL (Spatial Query Language) with octree and B-Rep approaches to reflect distance relationships between spatial objects [5]. Daum and Borrmann extended this SQL-based approach by a method for its topological and directional predicates which operates directly on the boundary representation [6]. Liu, Lei et al. developed an automatic scheduling approach exclusively for panelized construction in residential buildings [7].

3 Methodology

We developed an approach consisting of two steps to determine an automatic assembly sequence. In a first step, a sequencing of element by element according to the ascending Z-axis is generated. Basically, this procedure is logical for most elements, as the lower edge of an element usually rests on the upper edge of the element below. However, when generating assembly sequences based exclusively on the Z-coordinate of elements, it becomes apparent that logical errors can occur, for example when elements are levitating without being connected to a support structure.

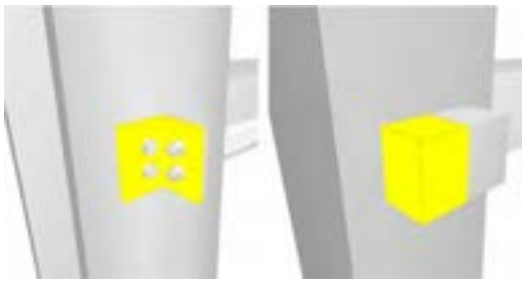

Figure 1. Model elements and corresponding bounding boxes

Therefore, in a second step it is necessary to determine whether all elements located under or next to an element and touching the element in question have already been

built. Although there is the possibility to link elements in construction software, these links are not necessarily created for each element. Thus, we determine such links for any IFC model ourselves. To determine these links between elements, we use the bounding boxes of the elements and define an offset within other elements as shown in Figure 1. We then compare the bounding boxes of each element with those of all other elements and check for overlaps. In the example above (Figure 1), a collision is found between the angle cleats and the database. This is to achieve that in the best case all elements can be automatically assigned to a category with the help of regular expressions. Once this step is completed, the user can display all elements that could not be automatically assigned and thus the user can assign them manually to the categories of ontology. If desired, the manual assignment can be performed globally for the entire model, if elements with similar names are present. The available categories are taken from a direct connection to an *Apache Jena FUSEKI*

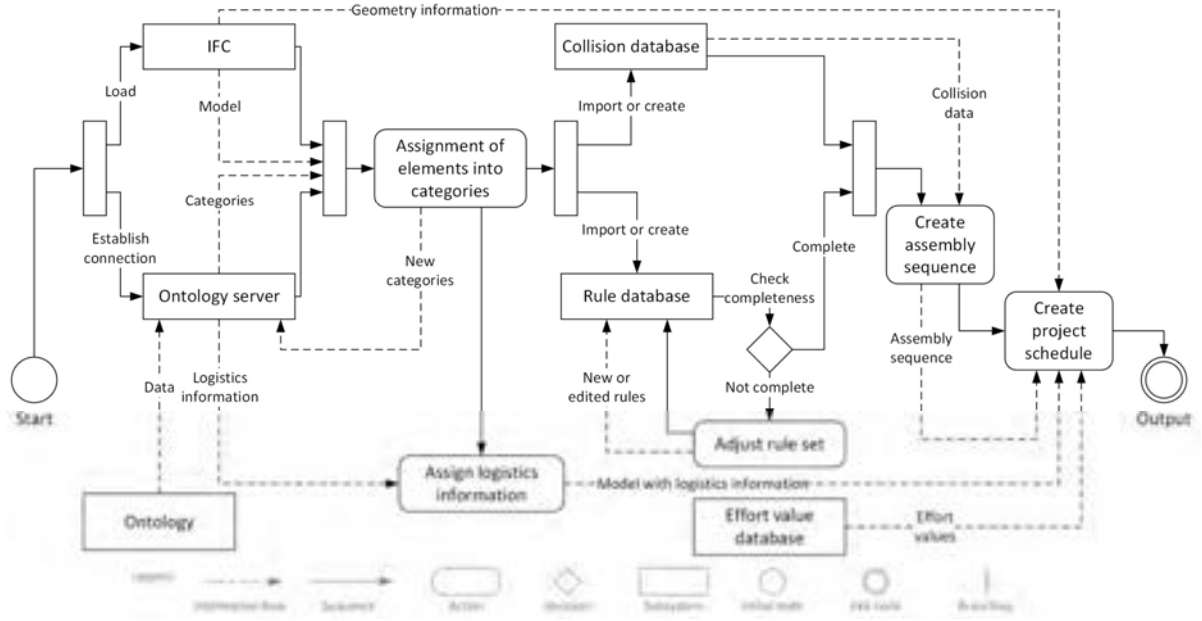

Figure 2. General methodology

column, due to a defined offset which slightly enlarges the bounding boxes, but not between both angle cleats. Using these overlaps, a collision database is created in which all collisions per building element are recorded. This procedure offers a great performance advantage for the actual creation of the construction manual, as the database only needs to be created once for each model and thus in the following steps different rule sets can be applied and tested with little time expenditure. As soon as the rule sets have been defined correctly, i.e. completely, the construction sequence for each element can be determined. In doing so, each foundation is considered separately so that processes can easily be parallelized if necessary.

To be able to assign the construction rules to the individual building elements, these building elements must first be assigned to the ontology categories. We have provided two different methods for this: On the one hand, an automatic assignment can be carried out using regular expressions. These regular expressions must either be stored in the ontology for each category or can be defined in a *JSON* (JavaScript Object Notation) ontology server, where a created ontology is uploaded (see Figure 2). If a required category is not available in the ontology, it can be created directly via the software extension developed by us and transferred to the ontology. After all elements have been assigned to a category, an assembly sequence can be defined using the rule database and collision database. The creation of the rule database and the creation of the assembly sequence is explained in the next chapter. The assembly sequence as well as the logistics information per element can be provided at the output. With the help of a provided effort value database it is also possible to create a schedule for the construction process from the assembly sequence and to validate it together with the geometric information from the 3D model in a simulation study, see chapter 5.

4 Automatically Generated Assembly Sequencing

To specify a construction sequence, a rule database is required in addition to a collision database and components classified in categories of the created

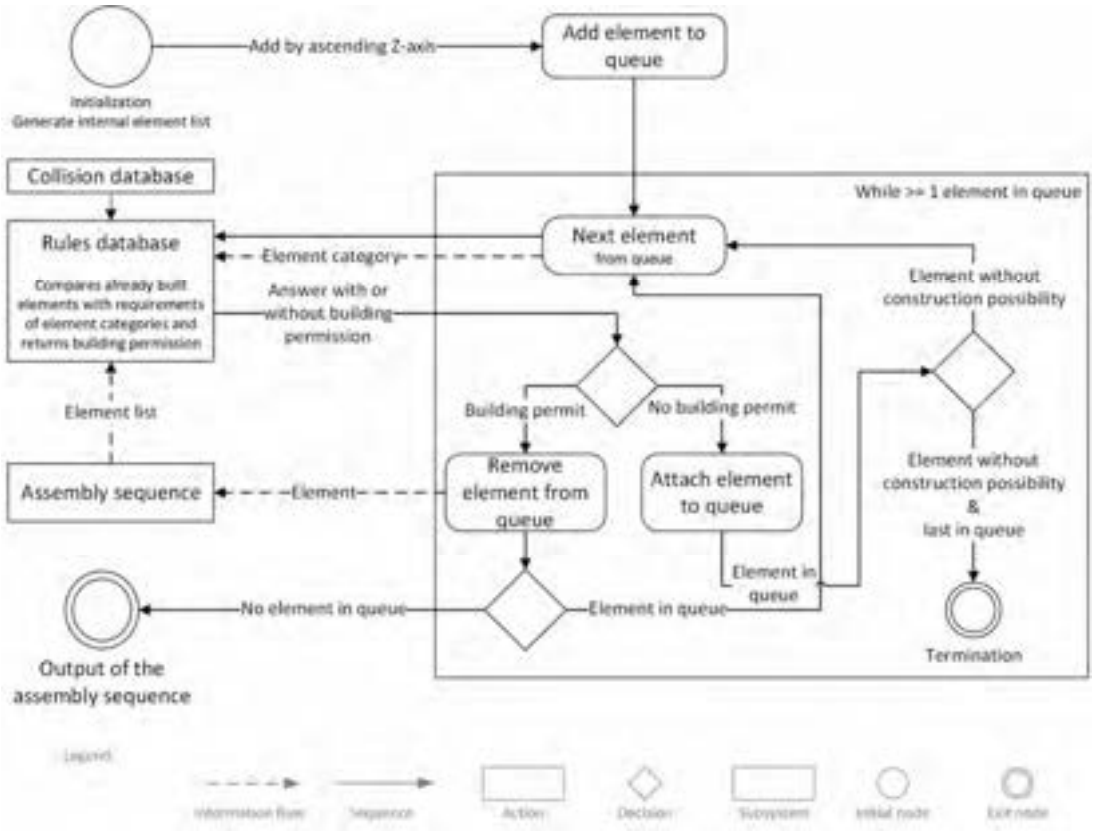

Figure 3. Rule-based assembly sequencing methodology flowchart

ontology. The rule database contains rules for assigning certain numbers of components to other components with AND connections. For each component, different rules can be linked together in the form of OR links. Since this is not a physics simulation, any torques occurring on components are not tolerable and must therefore be prevented by the rule set.

As an example, the rule set for the construction of a beam disregarding joining elements is shown below. The following rules apply to the construction of a beam:

Column(2)
∨
Column(1) ∧ Beam(1)
∨
Beam(2)

Figure 4. Example rules

The beam can therefore be attached either to two columns, one column and one beam, or to two beams as shown in Figure 4. This ensures that there are always two supports for the beam, so that no moments can occur at the supporting structure or the beams themselves and allowable moments in beams [8] and other parts can be neglected. When the rule set is defined, the construction manual can be generated. As shown in Figure 3, we start our rule-based assembly sequencing with the generation of an internal object list. This list contains all building elements which are then added to a queue by their ascending Z-axis. This ensures that the order of the objects is as close as possible to the actual order because we focus on buildings that are generally built from the bottom to the top. For a bridge construction, for example, two-way sorting would be necessary. Now the next element is taken from the queue in a loop and its category is passed to the rule database. The rules database compares already built elements with the requirements of the category of this element and returns a building permission or not. If the element receives a building permission, it will be appended to the building order. In the next step (not shown in the figure), the system always checks directly, independently of the queue, whether neighboring fastening elements (bolts, angle cleats and welds) can be built according to the rule set. If so, all required fastening elements will be immediately attached to the element to be fastened in the construction sequence, followed by the element to be attached. If the element has not received a building permission, it will be reattached to the queue. If there are no further building permissions and it is the last element in the queue, the rule set used will not be sufficient and the generation of the assembly sequence will be aborted. Otherwise, the element is

reattached to the queue so that it can be built later. If the element has received the building permission, it will be added to the building order. The construction sequence also serves the rule database as a basis for the decision. If there are no more objects in the queue, the assembly sequence can be output.

4.1 Case Study 1 – Simple Steel Construction Model

For the validation of our methodology, a simple steel construction model containing 78 elements is used as shown in Figure 5. Despite its low complexity, the design features correspond to an actual steel construction model. The model has two storage areas and simple steel structure on top of a concrete foundation. The steel construction consists of four columns and five beams with two concrete slabs on top, 60 bolt connections (in 30 groups), 16 angle cleats, 16 anchor rods and six steel plates (two of which are already welded to a beam before installation (pre-assembled)).

Figure 5. Overview of the simple model

After completion, this model is exported in IFC format and finally imported into *DESITE MD*. Using the software we developed, the elements of the model are then divided into categories of the ontology according to the methodology [2]. This is achieved using the implemented procedure, which matches elements by their names using regular expressions and automatically categorizes them. The collision database is created with an offset between elements of −0.02 m for the bolts and 0.03 m for all other elements. The collision database is checked against the model to ensure that all elements have collisions and that all elements of the model are considered in the later generated assembly sequence. Afterwards the rules for the assembly manual are defined. These can be quickly and easily adapted by using our rule editor. Once the rule set is defined, it is tested by creating an assembly based on it. To check the correctness of the rules, it has to be possible to create an assembly instruction in the first instance without causing any errors.

In the second step, the correctness of the building sequence is checked by an expert. Special attention is paid to whether the sequence is logical and consistent, for example, that no elements are built until elements that were not previously required have been built and thus no elements are levitating. If problems are found during the check, the rule set will be adjusted and then re-tested. Here, both the linking rules and the prioritization can be modified. To clarify the dependencies between the elements and to identify possible sources of error, the construction plan can be visualized as a Work Breakdown Structure (WBS). Figure 6 shows an example of the construction plan for a beam:

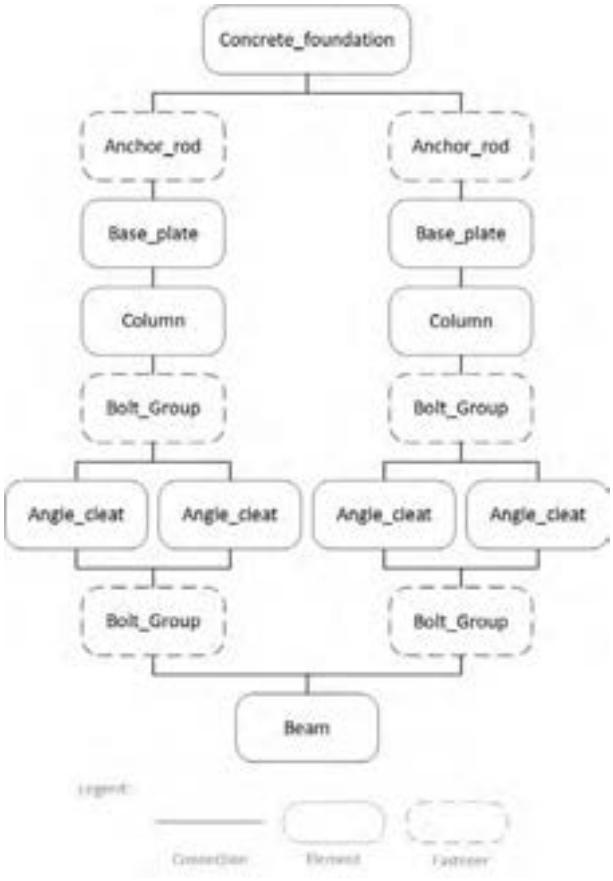

Figure 6. WBS graph of a beam

To build the beam, 15 additional elements are required, with the dashed elements representing connecting elements. Thus, the WBS shows the connection concept and not the construction sequence, since, for example, the final beam is first inserted and then directly bolted to the bolts. The advantage of the WBS illustration is that parallel processes can be identified. In addition, it offers the possibility to develop strategies to compensate for bottlenecks in a WBS branch by first building other branches for which all materials are available.

4.2 Case Study 2 – Complex Model

Once the assembly schedule for *Case Study 1* has been successfully created, we test the developed rule set on a more complex real model. The complex model is a section of a plant construction project of *thyssenkrupp Industrial Solutions* and contains 780 elements. To ensure general compatibility, the model is reduced to a steel construction tower as shown in Figure 7. The model consists of 16 concrete elements, 16 anchor rods, 4 base plates, 4 columns, 8 beams, 14 vertical bracings, 114 plates and 221 miscellaneous elements, connected with 94 bolt assemblies and 216 weld connections. Since the model was engineered in *Trimble Tekla Structures*, it has a completely different terminology. Therefore, the first step is to adjust the regular expressions to assign the categories of the created ontology. The first attempt to create an assembly sequence shows that the previously developed set of rules is not sufficient. A closer examination of the issue reveals that the existing categories of the ontology are also not sufficient.

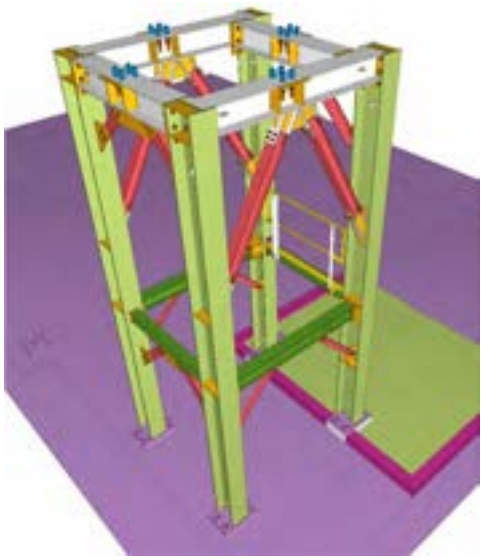

Figure 7. thyssenkrupp steel construction tower

Therefore, different categories are created via the communication link to the ontology server (as shown in Figure 2), especially for the fasteners that were previously assigned to only one category.

Based on this, the rule set is extended and tested using the collision database. After a few iterations the assembly sequence can be correctly created. This comprises 713 individual steps. However, a detailed step-by-step analysis shows that the assembly sequence for the diagonal beams is not logical, because one end of each beam has no direct connection. This problem is solved by recreating the collision database with a lower offset of 0.015 m to prevent the detection of a false number of required building elements in the surrounds.

5 Detailed Validation using Simulation

The detailed validation of the method for creating the assembly sequence is carried out with the help of discrete event simulation. For this purpose, the processes on the construction site are first planned. The generated assembly sequence is an essential prerequisite for a detailed analysis of the construction site assembly and the logistics processes. Using a generated assembly sequence (e.g. the simple model of Case Study 1 with 78 elements), a detailed BIM-based model and related information from the developed ontology, planning of processes on the construction site is carried out. For this purpose, different planning scenarios are defined for the processes on the construction site. In the planning scenarios the construction and logistics activities as well as the planning-relevant properties of the construction elements and materials of the building project are considered. For the creation of the scenarios, the assembly sequences specified by the construction plan and the dates of delivery of building materials are considered in detail. For the representation of scenarios, *Gantt* charts are used in planning. In the *Gantt* diagram, the individual deadlines of the planned processes on the construction site (such as transport, storage, and assembly) and the delivery schedules are coordinated. In addition, information from the ontology (e.g. requirements of building materials for storage and transport on the construction site) and formal descriptions of the processes are used to design the processes.

To enable simulation to validate the automatically generated assembly sequences, the defined processes on the construction site (such as the sequence of assembly, transport and storage) as well as the use of available resources (such as storage areas or transport equipment) need to be modeled. The planned processes, restrictions and resources can then be validated by simulation. For this purpose, material flow simulation models are built in *AnyLogic* based on the supplemented BIM model. Validation scenarios are experimentally examined using the simulation model. The simulation model provides valuable performance data in advance of construction activities and checks the planned equipment of the construction site (material flow and storage technology) and the planned deadlines.

In the following, this simulation-supported procedure is discussed for Case Study 1 – Simple Steel Construction Model (see Figure 8). For the execution of the simulation-supported validation of the construction manual, in addition to the data from the BIM model, the layout and the prepared construction plan (see section 4.1), assumptions are made regarding the dates of delivery of the components, personnel deployment and resources on the construction site. When designing the planning scenarios, it is necessary to know the exact construction sequence and deliveries in advance, because

they are coordinated with each other and thus transports and storage on the construction site need to be planned.

Information on material and resource requirements for each process (e.g. storage conditions for steel beams) from the ontology (see [2]) is used to design transport and storage.

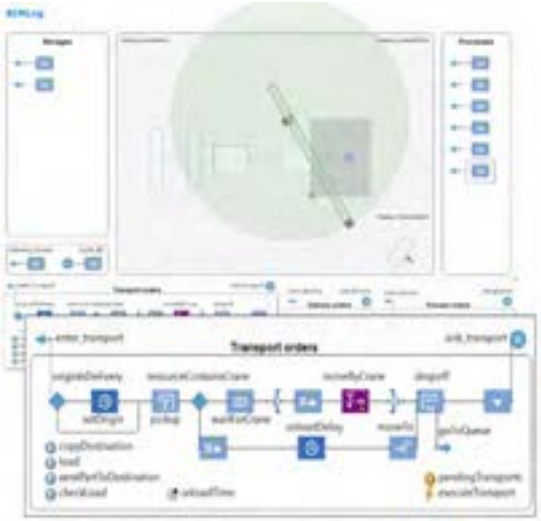

Figure 8. Example simulation model for Case Study 1 – Simple Steel Construction Model

In the simulation model (Figure 8) the layout, the positions of the six assembly locations of the elements, and the project-relevant processes (such as the assembly queues in the *Processes* area and the storages in the *Storages* area) are formalized. The processes sequences (transport by crane, deliveries to the construction site, as well as assembly and pre-assembly) are built in the simulation model (see Figure 8). The modeled processes conform to the generally valid process description at the construction site. They can therefore be extended, adapted and reused for new construction projects or planning scenarios. The relevant process sequences are used in the simulation according to the planning scenario.

The resources planned for the project are one crane, one crane operator, and one worker. The planning data from a defined scenario is implemented in the simulation model as tables, e.g. bill of materials for each construction process, scheduled deliveries to the construction site, scheduled start times of construction processes, transport processes and warehouse processes as well as resources scheduled for the processes. The simulation ensures that the components will only be delivered if they can be stored or installed directly. The simulated process times of the assembly processes are entered into a table during the simulation run, so that the duration of the individual construction processes and the total duration of the project can be estimated. An animation of the processes illustrates the approximate sequence of logistics processes on the construction site.

To evaluate the planning scenario, in addition to the simulated process times, key performance indicators, such as the utilization of resources (in percent) or the utilization of storage areas (in storage units) are calculated over the entire duration of the simulated project. The simulation-based validation provides a consistent and valid logistics model that can also be used to control logistics on the construction site. In case 1, the simulation points out that the crane, the crane operator, and the employee are almost always working at 100% capacity at the beginning of the simulated time (see Figure 9). This indicates that a new scenario with a second crane could lead to a better utilization of resources and personnel. Therefore, this scenario with two cranes is also being tested in a simulation study. The use of two cranes for Case 1 leads to a reduction of the simulated project time. However, this scenario is not regarded to be economical.

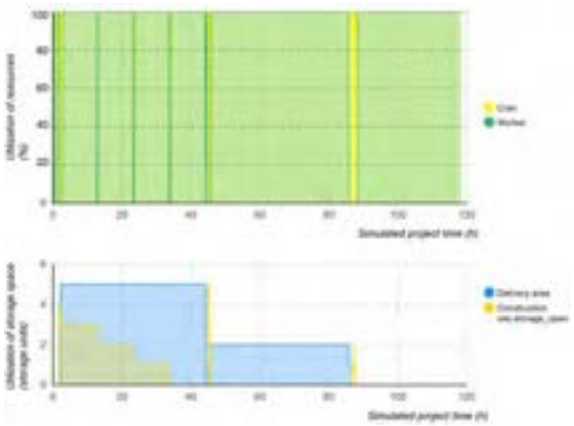

Figure 9. Utilization of resources (%) and utilization of storage space (storage units)

In the first scenario with one crane, the simulation carried out shows the utilization of the storage areas as an example. At the beginning of the construction processes the delivery area is highly utilized and the construction site storage (open storage) only stores a few parts over simulated project time (max. five storage units). Thus, the simulation provides the requirements for dimensioning of storage areas on the construction site (see Figure 9).

6 Conclusion & Outlook

Our approach demonstrates that creating step-by-step instructions for IFC files from any source works very well even at this early stage. The main effort lies in the categorization of the elements. Depending on the source of the IFC file, this can be greatly simplified and thus accelerated by using regular expressions. However, regular expressions can only be used across projects for models in which elements of the same type also have a

similar name. Therefore, it is very important that the models or their elements are always classified in the same way. If a uniform classification is not available, a manual revision based on given guidelines must be carried out. To avoid this problem, interfaces to different modeling tools must be developed. These interfaces could be designed in such a way that they provide more information than the respective IFC export function provides. In addition, this also eliminates the need to create a collision database, since the links between components can usually be determined directly by the design software. This is particularly advantageous for components with a more complex geometry, such as angled pipe connections or reinforcement meshes. Bidirectional communication is also conceivable. With a sufficient number of previous design projects and thus maintenance of the ontology as well as regular expressions it will be possible to generate the design instruction with a single click. In addition to the application for simulation, cost estimation [3] is also possible.

To evaluate our methodology in terms of its practical applicability, we have presented it to seven experts from the industry. The experts are representatives of companies from the fields of plant construction and logistics. They agree that detailed digital construction site logistics planning is of high importance or is becoming increasingly important. The participants in the evaluation survey are convinced that enriching the BIM model with information on construction site logistics will offer their companies advantages in future in the exchange between company departments and project partners. In their opinion, this information should also be available in digital form directly on the construction site. The semi-automatic generation of step-by-step construction instructions is less or not important for two in seven participants in the evaluation survey, while five in seven rate it as important or very important. However, all respondents agree that semi-automatic generation of schedules is very helpful for their companies.

The high potential lies in the iterative construction process and construction logistics planning which is made possible by our methodology. This iterative planning requires that the current state of construction is known accurately at all times. There are already many established possibilities for this today, by means of automated continuous construction progress monitoring [9]. As soon as an interface for communication with the simulation tool has been developed, it is possible to generate the simulation model semi-automatically. In the end, a decision maker will still make the final choice for the preferred scenario. In this way, in case of delays due to bad weather or delayed deliveries, damaged material etc., alternative strategies can be developed in a short time and with little manpower, which ensures an efficient construction process despite the disruption and also minimizes otherwise occurring delays in the best possible way.

7 Acknowledgements

The results presented in this paper originated in the joint research project "*BIMLog* - BIM-Based Logistics Planning and Control in Large-Scale Plant Construction" at the *University of Kassel* and the *Ruhr-Universität Bochum*.

This research project (19720 N) has been carried out within the *Industrial Collective Research* (IGF) and has been funded via the *German Federation of Industrial Research Associations* (AiF) by the *Federal Ministry for Economic Affairs and Energy* (BMWi) on the basis of a decision of the *German Bundestag* and on behalf of *Bundesvereinigung Logistik* (BVL) *e.V.* (German Logistics Association). We would also like to thank *thyssenkrupp Industrial Solutions*, who kindly provided the model for Case 2, and *Doosan Lentjes* for supporting our research activities with data and expert knowledge of large-scale plant construction projects.

Abstract –

The rapid growth on the field of project management and building information modelling (BIM) has led not only to the enhancement of architectural/structural design, construction methodology and operation of facilities but also to the generating of the new and exciting applications such as 4D simulations, project scheduling and controlling. 4D planning and scheduling is one of the BIM uses based on the BIM guidelines. Poor quality of construction works, and ineffective scheduling and planning can be significantly mitigated by adopting BIM in early design processes. In this paper, the advantages, possible risks of 4D-BIM construction scheduling, existing and future challenges of 4D planning in the construction industry are discussed. First presented is the primary concept of 4D-BIM simulation with its possible applications and capabilities in construction planning. After that, weaknesses and strengths of generation of 4D simulation/animation of the conventional and prefabricated construction building projects according to the construction schedule are analyzed. The results show that the integration of BIM model in the construction program is essential and ensures greater control over the construction projects. Also, it can be concluded that the automation in 4D-planning needs to be more considered and optimized by programing and formulating of construction planning and geometric model creation. Finally, this study contributes to the construction/project managers to improve their management performance and efficiency of works, also this investigation contributes to identify research gaps and opportunities for future study.

Building information modelling (BIM); 4D simulation; Project scheduling; Construction projects

1 Introduction

Nowadays, construction building projects are becoming much more difficult and complex. Prevalent problems regarding construction building projects arising from weak and insufficient connection between design and construction phases due to inefficient transferring of information and data have been reported. Building Information Modelling (BIM) is a digital presentation of functional and physical characteristics of a project which is regarded as a potential solution to challenges within the design and construction stages. Therefore, BIM is a good technology not only in the design stage, but also in the construction stage, provided it ensures time saving and working effectiveness throughout the project life cycle. To create a 4D model, BIM as a powerful planning and 3D modelling tool need to be complemented with a specific planning software package. The 4D model of a project can be developed to simulate a graphical sequence of execution tasks and construction operations, therewith providing the stockholder with a visual and virtual understanding of the construction process [1-3]. 4D-BIM has been used by designers, engineers and planners to optimize design, and to analyze the buildability of a project plan and manage resource requirements [3]. 4D planning and scheduling are some of the BIM use based on the BIM guidelines. Poor quality of construction works, and ineffectual construction planning can be significantly diminished by adopting BIM in the early design process [1, 4]. It should be noted that the virtual project planning and progress reporting are the scheduling-related themes of the construction stage and some of the intent of these themes are safety planning, cost reporting, and equipment machine control. The utilization of 4D-BIM modelling in line with analyzing the effectiveness of delays on the project schedule and tracking the actual progress of the project schedule improved the construction performance. The onsite construction performance can be enhanced by linking building information models with schedules so as describe the: 1) material handling and site logistics 2)

virtual building model 3) site production structures 4) environmental management controls and related equipment [5]. A study presented a BIM-based integrated scheduling approach for detailed scheduling under resource constraint to simplify the automatic generation of the optimum construction schedule for building projects by performing in-depth integration of BIM/project models with process simulation and work break down (WBS) information. The proposed scheduling system can produce schedules for panelized construction. This system facilitates on-site assembly work by lessening human error [2]. The contractors' tender team can use 4D-BIM scheduling in developing executable risk mitigation strategies. In addition to that the advancement of efficient risk mitigation strategies are supported by 4D-BIM tool during the procurement phase of an actual construction project. Using the 4D-BIM tool has some challenges due to the dynamic nature of the procurement phase resulting the 4D model was not an invaluable tool for contractors [6]. A study reported the development of a control method and logistics scheduling for site assembly of Engineer-to-Order (ETO) prefabrication building system using 4D BIM as a mechanism for dealing with the uncertainties in the construction project [7]. 4D-BIM contributes to improve the work-space scheduling and the associated frameworks enable the detection of possible site congestions by utilizing workspace specifications, construction schedule and activities. 4D-BIM tool improves safety planning process by analyzing site-specific temporal and spatial information [8]. Another investigation introduced a framework for automatic scheduling of construction project through automatic data extraction by using BIM. The proposed framework creates a schedule which contains construction tasks, duration and the activity's sequences. The model has some limitations which is related to the scalability and complexity. The model is a simple BIMs with limited details so by increasing its complexity the model requires more time to generate the construction schedule, and finally some practical methods need to be applied to determine the interdependency between activities and associated elements to minimize the use of use input and default settings [9]. An innovative BIM-based management workflow has been suggested which integrates digital programing with BIM to implement cost planning and efficient schedule of building fabric maintenance. In this research Weibull Distribution is utilized to specify the main information about the corrective and preventive maintenance for building fabric components. A case study was conducted for checking the validation of the model and the practicability of the proposed workflow. This study not only reduced the knowledge gap between practical maintenance applications and maintenance theory but also linked the maintenance phase with design and construction phases. The investigation asserted that a lot of manual works related to information flow need to be done such as data gathering, entering details and creation of functions and tables [10].

By considering the development of the abovementioned applications and technologies, this study accomplishes a review of the relevant literature with the following objectives: 1) summarizing the capabilities and applications of integrating BIM/4D-BIM in construction projects; and 2) identifying advantages of integrating BIM/4D-BIM in construction projects; and 3) summarizing the potential risks and challenges in integrating BIM/4D-BIM in construction projects 4) analyzing of previous investigations 5) conducting a case study for validation of results. This paper aims to identify research gaps and opportunities for future study by considering the advantages, risks and challenges of using BIM and 4D-BIM planning in construction projects.

2 The Implication of 4D-BIM in the Construction Projects: Capabilities and Applications

2.1 4D-BIM Capabilities

The increasing utilization of 4D modelling in construction projects emphasizes on chances for using these capabilities in recent digital management system incorporating with role reorganization, workflows and practices providing a tool for onsite monitoring and constructability analysis of construction progress. The 4D-BIM can only be developed by the accretion of three main capabilities as follow, 1) capability is the visualization of space and time relationships of construction project activities, 2) analysis of the construction program to evaluate implementations, and 3) reduction of errors via construction schedule validation to improve the integrity of communications and collaborations between the project team. 4D-BIM capabilities can be dived into two categories: 1) construction scheduling, and 2) site scheduling. Some of the prevalent end points in leveraging 4D-BIM capabilities are exemplified to improve scheduling, monitoring and waste management. Rule-checking method is a 4D-BIM platform with a rule engine which provides a capability to determine effective environmental rules to support a rule-checking method. In this method, a time-space detection would automatically recognise environmental hot-spots and enhance monitoring performance [5]. 4D simulation allows for the investigation of different scenarios to optimize the construction process. The arrival of BIM as a first commercial tool has made this discipline noticeably easier, specifically with the capability to use

BIM to streamline the creation of links between activities and the 3D models. 4D modelling provides some planning capabilities and incorporates the CPM logic into the software [11].

2.2 4D-BIM Applications

4D-BIM is used to identify project clashes by applying the outcomes to the case study in order to assess feasibility of the system and practical applications. The application of BIM technology to task scheduling is an appropriate choice for clarification and organization of the execution scheduling [12]. A communication strategy has been proposed between 4D-BIM and Chronographical scheduling application developed on VBA Excel. The use Chronographical 4D planning and its compatible approaches, not only consider the linearity of team's production and the workspaces, but also make the study of links between activities easier. This modelling simplifies the automation of the 4D-BIM and change management process [11]. 4D-BIM is used to investigate and validate necessary details to incorporate a special type of sensor (ultrawide band localization system) and try to diagnose the right amount of details to capture the movement of equipment, work force and material. In this application, semantic data modelling and data mining have been used. This integration provides a flexible and high-performing pattern recognition methods [13]. A BIM base decision-making framework is proposed to minimise construction waste in design phase and to automate waste analysis by planning the process of work to reduce the material wastes for roof sheathing installation for prefabricated buildings. A hybrid algorithm integrating greedy algorithm and particle swarm is used to optimize material cutting plans for minimising sheathing material waste [14].

Integration of 4D-BIM with as-built photographs using time-laps photos was presented for monitoring of construction progress. Visualization is needed to create an automatic monitoring system, and this could be achievable via creating a 4D-BIM modelling from point cloud images and implementing an image classification for detection of progress and as-scheduled model from BIM. Regarding to this matter a framework is proposed to develop a concept archetype of a hybrid system to demonstrate the capability of processing images of construction site and integration of them with the nD-BIM within a game like VR environment. This framework enables stockholders and construction managers to use an advanced decision-making tool while detecting the inconsistencies in and efficient manner [15]. 4D-BIM is used to illustrate the planning phase to communicate, interact and get the final design approval and construction sequence. For improving the communication of construction planning and sequencing, 4D-BIM is developed to link BIM to the project schedule. in addition to that for generating a cash flow 4D-BIM is linked to the costing data [16]. 4D-BIM is presented as a practical tool for determining construction risks in early stages of construction building projects to take proactive measures in the design and scheduling phase to mitigate site hazards and to plan for safety resource allocations [17, 18].

3 Advantages of Integrating BIM/4D-BIM in Construction Projects

Four case studies demonstrate the time and cost savings realized in using and developing a BIM model for the design, preconstruction, project scheduling and construction phases. As mentioned, some noticeable benefits are realized through the applying of BIM technology in construction projects. The time and cost benefits to the owner were important and the unknown costs that were reduced via visualization, coordination, realisation and detection of clashes and conflicts. Some effective negative issues or risks related to the project planning phase can be controlled or mitigated via using BIM technology such as 1) incomplete documents and design 2) numerous uncoordinated consultants 3) field construction ahead of design 4) owner's frequent design/scop changes and constant design development [19]. One of the most crucial benefits regarding to the integration of BIM within prefabrication is the reduction of disagreement in a final model between manufacturers and designers. Second vital advantage is the simplifying the procurement plan as a united BIM system can facilitate design coordination from the beginning of the project. Early detection of long completion time, exploring design limitations for prefabrications, reducing the fabrication cycle time and coordination errors are also listed as the benefits of integrating BIM in prefabrication industry. The reduction in project duration and the increment in mass customisation are the other advantages of integrating BIM into the design and construction stages of a prefabrication building projects [20]. BIM gives unique opportunities to further harness the performance of prefabricated construction. BIM mitigates the risks of programing in prefabricated construction industry [21].

An study showed that only 7 advantages out of 18 advantages are identified and ranked as important with high value as follow: increase efficiency and productivity in pre-construction and main construction process, determine cost and time related to design changes, rectify clashes in design, enhance and maintain synchronized communication, develop integrated construction planning and scheduling, recognise time-based clashes, track and monitor the progress of project during construction. It should be noted that the benefits are significantly depends on BIM implementation which is

driven by some factors the such as personal commitments, mutual trust/respect, early involvement of project team, capability to use BIM technology [22]. 4D environment planning contributes to plan and manage the construction phases including logistics and operations. Also, the 4D-BIM development allows to status, monitor and update the construction progress. 4D-BIM is a practical tool and technology for development of economic and technical documentation such project schedule to be submitted for a construction project bidding. Visualization of work schedule performs a better control and construction management over the different stages of project. Correct distribution of workers, minimising interferences among different construction tasks and preventing unnecessary overlaps into the various construction sectors are the other benefits of using 4D-BIM. 4D modelling increases and modifies the logical-temporal connections between the various tasks which brings a high level of off-site prefabrication and continues improvement of works [23]. Table 1 illustrates a synopsis of 4D-BIM benefits.

Table 1. A summarised list of 4D-BIM advantages

No.	Advantages of 4D-BIM	Sources in Literature
1	Enhancing the project performance	[24, 25]
2	Efficient planning and scheduling	[25, 26]
3	Detailing the project stages	[25, 26]
4	Generating multiple planned scenarios	[25, 27]
5	Being used for project bidding purposes	[25]
6	Enhancing the ability to adapt future plans and network changes	[25, 28]
7	Utilising 4D-BIM in line with VR and mixed reality technologies	[24, 25]
8	Using 4D-BIM in line with 3D point cloud scanning technology	[25, 29]
9	Being a proactive platform for risk detection	[26, 25]
10	Being proactive in directly advising and addressing on solutions for projects issues	[27, 25]

4 Potential Risks of Integrating BIM/4D-BIM in Construction Projects

BIM risks are defined in two categories: contractual and technical. Lack of designation of possession of the BIM data and protection regarding to the copyright laws and other legal issues are known as the first risk. Determining a person to be responsible to enter the BIM data into the model and ensuring its accuracy and consistency is another contractual risk. Cost and schedule are the other dimensions of BIM and the associated contractual and technological responsibilities are becoming an issue. Many contract administrators require subcontractors to present detailed critical path method plans and related work costs prior to start of the construction project. Having an efficient collaboration to share the risks of using BIM between the project participants is one of the most effective way to coupe with these risks [19]. Misunderstanding of BIM as the potential management barrier leads to serious risks such as hindering the remarkable achievement and benefits of BIM in construction industry. Having no mature dispute resolution mechanism increases the risks of BIM implementation. There are some risks related to the costs and training time due to learning curve which justifies the noticeable decrease in staff member's productivity and performance. Some employers are worry about squandering money and time on labor training. In comparison with conventional methodologies and techniques, the use of BIM increases the costs during the design phase which might increase the risk of BIM implementation. BIM impeding profitability in construction building industry is known as a significant risk. Insufficient standard practices and insurance applicable to BIM implementation brings new risks to all project's participants. Lack of a standard form of contract brings uncertainty regarding to the BIM implementation and to dealing with this uncertainty more money and time is needed to be spent [21].

5 Challenges in Integrating BIM/4D-BIM in Construction Projects

The main Adoption and acceptance of the BIM has been much lower than expected due to the main two reasons, managerial and technical. As the technical sake: a well-organized transactional construction process model is needed to omit data interoperability necessities, the requirement need to be identified that the digital design data is computable, and Practical strategies for deliberate exchanges and integration of meaningful information need to be developed between the BIM components. The managerial reason cluster around use and implementation of BIM. Now, there is no an explicit consensus on how to use or implement BIM. As mentioned, a standardise BIM process need to be

established to define guidelines for its implementation. On the other hand, finding an appropriate time to include and engage project's participants into BIM process will be a serious challenge for owners [19]. The changes in business practices to support BIM process is the most significant challenge in the prefabrication. Changing CAD technology to BIM needs more investment in BIM software, also hardware and training are other two challenges in prefabrication. BIM requires comprehensive knowledge of construction processes, methods and extensive resources. As mentioned, legal and collaborative issues are known as barrier of using BIM in construction projects since using BIM contrasts to assign the responsibility to each party and to define liability issues between the parties. In addition, applying BIM in prefabrication building projects increases the complexity of the model of intellectual property rights [20]. Difficulty in reengineering the current existing process and adaptation to the BIM process is a challenge. Lack of adaption of BIM tools to the building codes to meet the requirements is another barrier for BIM implementation. Increase workload for modelling, resistance to alterations, negative orientation towards data sharing and collaborative working, lack of a well-stablished workflow, lack of an efficient interactivity, lack of sufficient external stimulus, lack of doing research on BIM implementation, costs of tools and hiring BIM specialists, vague economic benefits, lack of protective legislation for protecting the IP rights and lack of BIM standards are listed as BIM challenges in construction building projects [21].

Some stakeholders believe that 4D-BIM is used as a business tool for marketing purposes and that most are not interested to develop a 4D-BIM model as opposed to a 2D program during construction projects which are frequently changing. Previous studies emphasised that some 4D-BIM approaches are constrained due to lack of a cooperative environment. The behaviour and culture of those who involved in BIM processes need to be changed to accept this technology. Modifying of culture can be difficult for those who have accomplished their works in the same method may find it challenging to adapt and accept. Project team and client experiences to implement 4D-BIM are further barriers to the associated technology and process. The size of the organization or company, resources availability and risks of each projects might be effective to the adaption of 4D-BIM technology. Insufficient knowledge and technical matters are two barriers for adoption of 4D-BIM in safety management [30].

6 Analysis of previous investigations

All The database of the selected papers includes 100 articles (including the above cited studies) published from 2010-2020. 4D-BIM Construction Planning, BIM scheduling, 4D planning, 4D scheduling, 4D Construction Planning, 4D-BIM Construction and BIM are used as the search criteria and key words for the advanced search through ScienceDirect website. According to the database of selected papers, as analysis has been done to find the most occurring keywords. VOSviewer, a source graph and network analysis software has been used for this analysis [31].

The outcome is shown in Figure. 1, showing the high occurrence of some words such as building information modelling, BIM implementation, 4D model, construction process, visualization, schedule and etc in 2 various clusters. The size of each circle represents its weight. The higher weight of an item resulted in the larger circle and label of the item. It is quite obvious that the red cluster is the representative of the fourth dimension of 4D-BIM and the most related keywords to this study. 4D model which is grouped by schedule related cluster has the strong direct and indirect connection with building information modelling, collaboration, BIM implementation, adoption, productivity, analysis, cost and time from the green cluster.

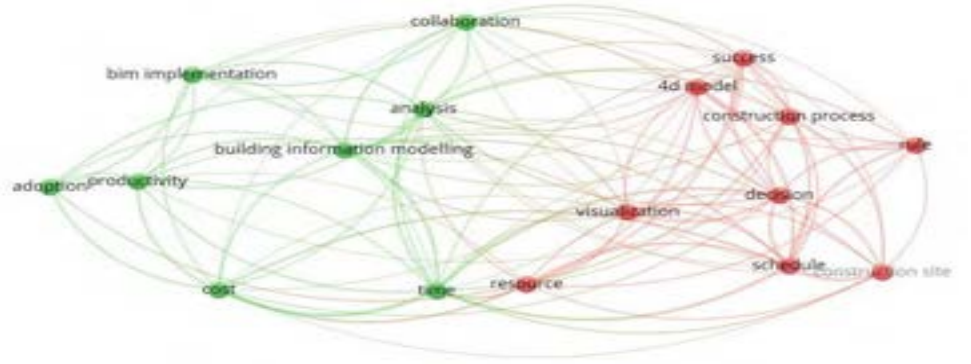

Figure 1. Network representation of keywords re-occurrence in literature

From the above figure, this can be comprehended that 4D modelling as a demanding visualization methodology

is the best solution to visualize the construction process and 2D construction schedule. This would be a practical approach to the successful completion of a construction project, saving time/cost and improving performance of the work, resource management and decision-making process. Automation of construction scheduling as a new approach need more collaboration between different parties to be implemented in construction industry. The adoption of this approach has some benefits like improving the performance of site manufacturing and on-site works, increasing the productivity of works and site safety, and challenges such as BIM implementation and rules as these have been mentioned in literature review.

7 Case Study

The Ovolo Hotel is a 6-storey building including 123-guest room, basement and a ground floor common area. This project is also featured SYNC bathroom pods and prefabricated modules which helped to reduce the construction timeline and fast track the project. Program reduced by up to 30% using fast-track prefabricated system in structure. It should be noted that the prefabricated system design, fabrication and on-site installation always come with BIM modelling. Some advantages, risk and challenges of using prefabricated system integrated BIM are mentioned as follow:

7.1 Advantages of prefabricated system and BIM/4D-BIM in Prefabrication

Time saving is an important advantage of the prefabricated system, for instance, once level 4 is installed and bolted, level 1 can be completely stripped out and the level is ready for fitting out. But in the conventional system fitting out is going to be started about 8 levels below the wet deck. As it is illustrated in Figure 2, you can see that façade is already erected and the fitting out period is reduced by 5 working days in average for each level. The financial advantages of the prefabricated system far outweigh than its drawbacks. It should be noted that the cost of pre-construction works in early stages including design and prefabrication cost is a prefabricated project is significantly higher than pre-works cost in a conventional project, but these costs can be offset in construction stages by proper sequencing and coordinating of off-site and on-site works. Prefabricated system eliminates costs of few trades on site such as façade installation costs which is 60% cheaper than façade installation in a conventional system. Prefabricated system requires less labor on site which means less labor cost in construction period. In terms of safety, the prefabricated system does have some risks both horizontal and vertical. Proper sequencing of loading elements and prefabricated modules on to the job reduces safety-related risks on site. Façade is already installed, and this feature creates full protection. In the prefabricated system there is no form work and back propping, so site is always clean which this increases site safety. As it is mentioned, using the prefabricated modules have noticeable advantages by itself, but by providing an effective sequence of construction/loading and visualizing them construction works can be optimized, and site safety and more time/cost saving can be guaranteed. As the prefabricated system is totally a crane-based system, optimization and visualization of construction sequence and loading plan is highly recommended.

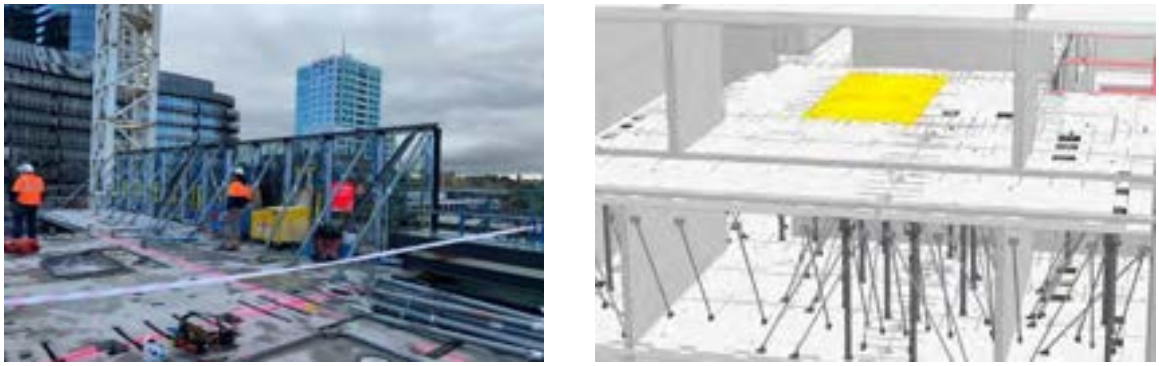

Figure 2. 3D Geometric model of the structure and prefabricated modules

7.2 Challenges/risks of prefabricated system and BIM/4D-BIM in Prefabrication

The main issue in BIM/4D implementation is related to services. Everything related to design such as shop drawings and coordination of shop drawings need to be locked-in early. If all the design related to services is not locked-in on time and early, then technically all penetrations would be wrong due to this fact that all penetrations are casted already in the prefabricated modules. So, any changes need to be captured or any rectifications need to be done early and before pouring

concrete off site. If all related design things are not locked-in enough, all hard works such as over layering, penetrations/service coordination go down to drawings which is required to be checked and reviewed by different groups engaged in a project and this is a very time-consuming process. In a conventional system because everything is in-situ, manipulations and making some changes is possible even in last minutes. But as it mentioned above in the prefabricated system pre-works should be well organized because making changes on site is quite impossible after fabrication of modules. In general, design works in a prefabricated project is more complicated than those in conventional project. To make a prefabricated system perfect, effective and to make key decisions early, less duration should be allocated to the design and material procurement in construction program. For this purpose, in addition to the practical experience, high level of technical knowledge is required in different areas such as creating an effective design (3D model), coordinating of trades off site and planning the construction sequence well enough. Because the prefabricated system method is almost new, labors need to be trained and engineers should teach them the new critical path and sequence of work to change their mind set from conventional to the prefabricated system. In summary, from the above-mentioned challenges and risks in both literature and the case study, it can be concluded that using BIM-4D or in another word visualizing the 3D model contributes a lot in clash detection for early rectifications, optimizes the program of the project from design to construction stages and clarifies construction sequence for engineers, coordinators, managers and labors to streamline the construction process and reduce the associated risks and challenges.

8 Conclusion

The study identified some noticeable advantages, risks and challenges of using BIM/4D-BIM in Construction Projects. The research concludes that the adoption of 4D-BIM in construction industry is highly recommended to improve and facilitate off-site and on-site construction works. Shortening and streamlining the procurement, design, prefabrication and construction duration and process in the project schedule are the significant advantages of 4D-BIM integration in the construction industry. Using BIM/4D-BIM can reduce coordination risks, the fabrication cycle time and risks of programing in construction industry. 4D-BIM enables different project teams to be involved early in design and prefabrication/construction process to detect the existing clashes and design errors. For setting a more realistic target, 4D-BIM contributes to visualize the construction and logistic plan. Some serious risks and barriers are acknowledged such as contractual and technical limitations which lead to legal risks and misunderstanding of BIM/4D-BIM. Implementing BIM/4D-BIM requires enough national and international standard practices, comprehensive practical and technical knowledge in the construction industry. Regarding to technical limitations and practical experiences, the automation of the 4D-BIM is required to optimize and simplify the process for better understanding of clients and subcontractors who are not advanced enough to understand the 4D-BIM concept. By automating the process less time and cost are needed to develop the 4D model and less technical knowledge is needed for model implementation which could lead to more future development and adoption of 4D-BIM.

E-mail: cao@ibi.baug.ethz.ch, hall@ibi.baug.ethz.ch

Abstract –

To support mass customization for industrialized construction, researchers and industry have adopted product configuration strategies. Based on the theory of modularization, pre-defined module libraries can be configured into feasible construction projects. However, the digital representation of configuration knowledge is understudied. Current Building Information Modeling (BIM) product modeling does not enable automatic generation and reasoning of configuration solutions for new products. This study proposes an ontology-based strategy to configure modular buildings. The proposed BIM-to-ontology workflow collects and formalizes configuration constraints. In particular, we elaborate on how those constraints can be modeled within the ontology in a modular building case. The ontology maintains the product hierarchy needed for product assembly. Such ontology development can support the rapid development of new products with customized variations. The paper identifies the limitations of the current product modeling approach. The proposed ontology can act as a foundation for BIM-based product platform development and increase the use of mass customization for industrialized construction.

Keywords –

Product configuration; ontology; BIM; Modular buildings

1 Introduction

Although mass production increases production efficiency and product quality, it lacks design flexibility and customization [1]. Increased design flexibility can be achieved through the configuration of standard components and variant components (i.e. modules) via a platform-based strategy [2]. To support the product configuration, a flexible product model is required [3,4]. It should not only describe the product composition in terms of the assemblies, sub-assemblies and parts, but also satisfy configuration reasoning and inference. However, few scholars uncover how product modeling could support the configuration of industrialized construction, especially modular buildings. For example, software vendors often embed a product structure in configuration applications, i.e. component trees and feature models. The structure has no functionalities to specify how a correct product could be configured from the available parts and assemblies. In many industrialized construction settings, the configuration is done manually based on document-based design handbook. The project practitioners need to familiar with the rules and abide by them. Considering the nature of low digitalization and fragmentation of construction information management, the procedure is difficult to implement. There is significant potential risk of rework and changes during the project.

To fix this problem, the authors propose an ontology-based structure to represent the configuration knowledge for modular buildings. The results facilitate the reuse of the configuration knowledge and lay a foundation for technical platform development. The paper is organized as follows. In the next section, strategies for product modeling in the manufacturing industry and the construction industry are first reviewed. Then, the ontology modeling approach is explained. Built upon that, an ontology-based product modeling is adapted to the modular building settings. In the end, a modular building case is used to illustrate how the configuration semantics could be modeled via ontology.

2 Literature Review

2.1 Product Modeling Strategies

Due to trends of product complexity and global manufacturing, the unified product model is becoming increasingly important throughout the product lifecycle. A unified model that supports the integration and transformation of different model views can improve industrial competitive advantage [5].

In the manufacturing industry, bill-of-material (BOM) is the most widely used approach in modelling a product structure. It uses a tree structure to represent the product hierarchy. However, it is not efficient to enable derivative product modelling with an increasing number of variants

[6]. An alternative approach is the Generic bill-of-material (GBOM). GBOM attempts to fix the variants of the product configuration by inheritance. The parameters of primary generic products are passed through the levels of GBOM and inherited by lower level of generic subassembly products [7]. However, GBOM is only able to model a product with a predefined set of components. It cannot support engineer-to-order variants, which are designed according to special customer requirements.

Two approaches – Adaptive generic product structure (AGPS) and product variant master (PVM) –have been developed to solve limitations of engineered-to-order products by categorizing the base models, reused variants and new components [8] [9]. Two types of syntaxes, including "part-of" and "kind-of" are used to model the structures of aggregation and specialization respectively. Rules are set to restrict the variant selection and property determination. The PVM depicts properties, functions and structure of a product at the engineering view and production view, similar to the engineering bill of material (E-BOM) and manufacturing bill of material (M-BOM).

2.2 Product Modeling for Modular Buildings

Unlike products in the manufacturing industry and projects in traditional site-built construction projects, industrialized construction product platforms combine both product-level information and project-level information [10,11]. The hierarchy between components is more important in industrialized construction systems[10,12], compared with site-built construction.

Several researchers have adapted or proposed product modeling structures for use in industrialized construction. Hvam and Thuesen used Product Variant Master (PVM) to represent a product part view [13]. Ramaji et al proposed a Product Architecture Model (PAM) to capture the product information of modular buildings [14]. Both strategies build upon a hierarchical structure [15,16], where modules are defined at different levels of complexity. First, the overall product architecture uses a hierarchical determination for sub-assemblies and parts. Then, the variations of each assembly and part are decided as a set of interchangeable components, which share similar features and functionalities. Finally, the components and related attributes are categorized based on the level of details. The benefits of the hierarchical structure include ensuring easy connection to the information management systems (e.g. ERP and PLM) [17,18], maintaining consistency with the construction classification system (e.g. Uniclass and Omniclass) [19], and providing customization at different hierarchical levels of products [20].

2.3 Current Product Modeling using BIM

Product modeling in the construction industry is implemented in existing BIM applications. Firstly, the architects have a rough design concept of a certain type of modular construction, such as volumetric modular structures. A general building outline can be created as mass models, including facility layout, building shape and direction, floor plan, etc. Secondly, the conceptual design is developed with architectural modules. The modules are categorized by product hierarchy [21]. For example, these modules can contain standalone units (e.g. smaller room pods), components (e.g. level, floor, wall, ceiling components), and/or subcomponents (e.g. pillars, beams, framing studs). Thirdly, the engineering team receives analytical models to conduct structural and mechanical analysis. The generated component-level BIM is validated and optimized in terms of material use and geometric dimensions. This feedback information is incorporated into the BIM with updated parameters. Finally, a detailed design is conducted by production teams to split the components into subcomponents [22].

Due to BIM's low compatibility with the production systems, the subcomponents are usually modeled within the third-party application, such as HSBCAD. The industry foundation classes (IFC) and a documented information exchange manual (IFD) are used to support the information exchange between model views. Beetz et al. developed ifcOWL and a mechanism to transform IFC specification from EXPRESS to OWL [23], which improves knowledge extraction [24], integration [25] and reasoning [26] from BIM. However, a product hierarchy which reflects the product composition is usually not represented in the exported IFC file.

3 Research Approach

3.1 Ontology Modeling

Ontology is widely applied in many industries for domain knowledge management. Due to its formal representation, ontology facilitates the knowledge capture, reuse and integration [27]. The construction of ontology for product configuration has been studied as early as the 1990s [4]. It is applied to manufacturing products, such as Personal Computers (PC) [28], manufacturing machines [29], and automotive [30]. The formal procedures to build an ontology follow five steps [31]: 1. identifying the purpose and scope of ontology; 2. reviewing existing ontologies, taxonomies, or other sources; 3. Enumerating main classes and build corresponding class hierarchy; 4. constructing an ontology in an ontology editor tool (e.g. Protégé); 5. ontology validation. The construction and validation steps are illustrated via an illustrative example in Section

3.1.1 Define Scope and Purpose

This research looks specifically at floor plan configuration. The proposed ontology is built to represent both the building structure / composition and constraints in a well-defined formal semantics to validate a customized configuration. The information involved in the configuration process includes customer requirements and design regulations. Customer requirements specify the acceptable combinations of spatial modules or variations of compositional building elements in the final floorplan design [15]. The design regulations, such as the horizontal stability, can be encoded to validate the customized floorplans.

The intended users of the ontology are customers without sufficient design knowledge. The ontology is maintained by professionals with the means to develop new spatial modules and building elements for their product platforms.

3.1.2 Reuse Existing Ontologies

Building Information Modeling (BIM) applications contain taxonomies and content libraries, which can be extracted to enable ontology construction. Generally, a BIM project contains system families and loadable families. The former one is embedded in the project template with default structures, while the latter is created independently and loaded into projects. Because most BIM libraries do not contain well-defined components for industrialized construction, design teams for modular construction usually need to create customized ones. The customized BIM modules can be reused in different project settings. In this study, a MEP-integrated volumetric unit is defined as the first level hierarchy under the project. Each unit is modeled as sub-project, which can be further linked to the main project. The main project and linked models are stored separately to facilitate the reuse of linked models. The components of volumetric units, such as walls, floors and ceilings are the second level of product hierarchy, which is modeled in the linked project.

To extract the BIM data of the module as well as their components, Revit API is used in this study. First, the volumetric units can be filtered under the category of "RvtLinks". The "RvtLinks" is a built-in category used to represent linked models in the main project file. Then, the linked document is located. The component granularity is extracted from linked document through the "FilteredElementCollector", which provides access to obtain a collection of elements by category.

3.1.3 Build Class Hierarchy

The extracted BIM data, including BIM families, instances and parameters, should be mapped to the ontology structure. The structure of an ontology is constructed as a tree structure of classes, to represent the hierarchy of the modular buildings. The object properties are used to assert relationships between classes. The attributes of each class are modeled as data properties. The mapping relationships are illustrated as BIM family to Ontology class, BIM instance to Ontology individual, BIM parameter to Ontology data property. In addition, some inexplicit relationships in BIM, such as the hosted relationship between opening families (e.g. windows and doors) and wall families, can be mapped to the object properties. The extracted objects are collected as key-value pairs in the C# dictionary, where the keys are unique "ElementId" used to maintain the one-on-one relationship between BIM and ontology, and the values are attributes of elements. The Python module "Owlready" [32] is used to write the BIM data into the ontology.

The above concepts of an ontology contain the basic taxonomy for a configuration problem. However, they are usually not enough to describe complex semantics. These semantics, including the constraints over the product structure, are useful to reason the correctness of a configured solution. The typical constraints for configuration include composition, compatibility, dependency and cardinality [33]. Composition rules define which components are mandatory or optional in the product architecture. The product architecture can be built as a tree structure. A component can be either a root node, an intermediate node or a leaf node. Once a non-leaf component is selected, the direct child component can be automatically added to the product. Compatibility rules define which components cannot exist simultaneously in the product. If a component with a compatibility rule is selected, the system will exclude certain components from the option lists. Dependency rules define which components must belong together in a product. If a component with a dependency rule is selected, the system will add its mated components to the product. Cardinality rules define the required or limited number of components under certain circumstances. The product structure can only represent the existence of a components. A component with a cardinality rule need to be assigned the quantity occurring in the product and checked against its validity.

4 Implementation

To demonstrate the ontology usage, a multi-story modular residential project from a European construction company is used as an illustrative example. The project consists of prefabricated, highly standardized volumetric units that are combined under a set of restrictions to create apartment buildings. Each module is fully designed for certain functionalities. While the product concept is standardized, the individual configuration can vary from the building profile on the selected site, the layout of the apartment on the floor plan, the material

type of façade, the roof types and the balcony types. The project-specific configuration is supported by a library of 3D models in Autodesk Revit that define all relevant design regulations. The BIM content library can be linked to the proposed ontology following the process mentioned above. Then, the project can be configured with the BIM library and reasoned for correctness. Figure 1 shows the classes and object properties in the configuration model.

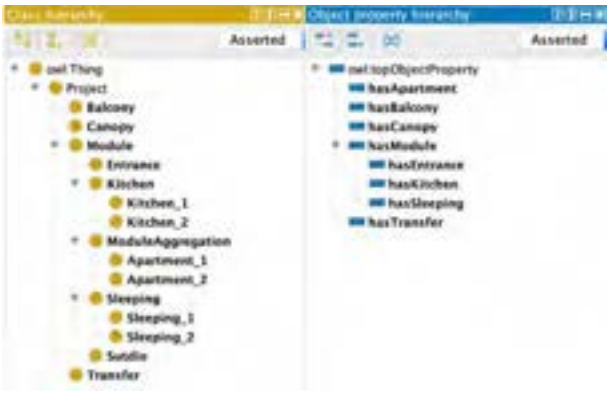

Figure 1. Class hierarchy and object property hierarchy of the modular building

4.1 Composition constraint

"An Apartment_2 is composed of 1) one entrance module; 2) one kitchen module; 3) one sleeping module." The definition of the class "Apartment_2" in Protégé is shown in Figure 2. The "Entrance", "Sleeping", and "Kitchen" are disjointed classes. The "hasEntrance", "hasSleeping" and "hasKitchen" are object properties which map from the apartment class to the corresponding module class. "Exactly" keyword is used to restrict the existence of a certain class.

Figure 2. Composition constraint to define a three-module apartment

4.2 Cardinality constraint

"A two-story modular project is developed for wind loads in terrain type 1, which requires at least five modules in width per floor." The constraint is encoded in SWRL and SQWRL (Semantic Query Enhanced Web Rule Language) as shown in Figure 3. SQWRL support collection operators that provide the grouping and aggregation functionalities. In this scenario, each type of modules, including "Sleeping", "Kitchen" and "Entrance", are grouped and added. Then, the total number of selected modules is compared with the required number of modules based on the design requirements.

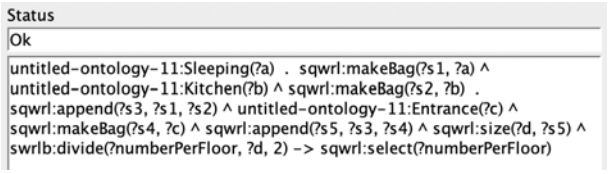

Figure 3. Cardinality constraint to check the required number of spatial modules

4.3 Compatibility constraint

"The Kitchen modules should not be selected to configure a studio apartment". The constraint is defined as a SWRL (Semantic Web Rule Language) as shown in Figure 4 via the SWRLTab of Protégé. The constraint is a conjunction of four positive atoms. The "Project (?x)" and "Kitchen (?m)" represent the instance of project (x) and kitchen (m) respectively, while the "onlyStudio(?x, true)" represents that the project only contains studios. Finally, when the kitchen module (m) is added to the project (x), the "hasModule (?x, ?m)" will be generated automatically. As the consequence of the rule is void, the checker returns an error, representing the event at the left side of arrow cannot occur.

Figure 4. Compatibility constraint to limit the module selection

4.4 Dependency constraint

"If a user specifies an apartment with balcony, the matched canopy will exist in the same configuration." Similar to compatibility constraint, the constraint is defined in the SWRL as shown in Figure 5. For the specified apartment, if a balcony with width equals 1.5 meters is required in the sleeping room. The rule will automatically add the matched canopy and set its width same as the balcony.

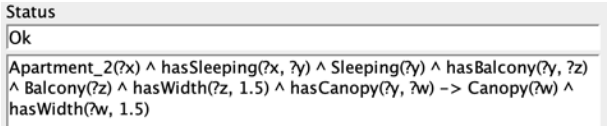

Figure 5. Dependency constraint to select mated

components

5 Discussion

The proposed ontology-based product modeling is a novel approach to represent design information for modular buildings. It is aimed at achieving mass customization by linking customer requirements and design regulations with a predefined module library. The research is built upon the product modularization. With a module library, the various configuration can be achieved. Compared with the PVM and PAM approaches, this ontology-based approach is capable to represent more complex product structures and semantics. Furthermore, the proposed ontology can be well-connected to BIM tools through ifcOWL to avoid reconstruction of taxonomies.

6 Conclusion

Mass customization has been strongly emphasized in the construction industry, especially the industrialized construction. Product configuration is an idea borrowed from the manufacturing industry to achieve mass customization. Similar to the automotive industry, modular buildings can be configured with different categories of modules, such as volumetric units and panels. Compared with the traditional design process, the key benefits of configuration are the fast derivation of product variety to satisfy customer's needs, and the reuse of digital BIM contents to improve design efficiency and product quality. However, the existing product modeling only deals with the categorical classification of product composition, without considering a configurable product structure.

To support the digital representation of configuration knowledge, this research proposes an ontology-based modeling approach. First, it illustrates how configuration tasks can be implemented in a BIM environment via a BIM-to-ontology workflow. Second, the paper focus on how product hierarchical structure and semantical constraints can be modeled in an ontology. A modular building project is used as a case study to explain it in detail. Ultimately, this lays the foundation for the technical configuration platform development.

The research has some limitations. First, the configured product is limited at the floor plan. A wider scope of building products, such as MEP systems, should be included in the configuration process. This might require a better understanding of customer requirements on the building performance. Second, the complex semantics of product configuration has to be manually added into the ontology. Previous scholars have identified that building such large-scale ontology requires domain knowledge, which will take time and considerable resources [34]. Future research direction might be the automatic construction of multi-domain ontology with natural language processing.

On Construction-specific Product Structure Design and Development: the BIM Enhancement Approach

S.Mansoori, H.Haapasalo and J. Härkönen

Industrial Engineering and Management, University of Oulu, Finland
E-mail: Solmaz.Mansoori@oulu.fi, Harri.Haapasalo@oulu.fi, Janne.Harkonen@oulu.fi

Abstract – The construction industry suffers from low productivity, and the Building Information Modelling (BIM) has not been successful in enhancing the productivity and the flow of information throughout highly fragmented construction projects. Hence, this study aims to facilitate consistency in information and addresses the current gaps in BIM by applying the Productization and Product Structure concept. The study follows conceptual research approach and accordingly, previous studies on productization and product structure are reviewed. The Part-Phase-Elements Matrix is proposed as a construction-specific product structure to facilitate consistency in information and enhance BIM.

Keywords– Productization; Product structure; Information Management; BIM; Construction

1 Introduction

Construction industry is highly fragmented and complex and suffers from low productivity improvement [1]. Building Information Modelling (BIM) has shown some promise to assist in improving productivity [2] but remains essentially ineffective despite the potential of enhancing the collaborative way and providing relevant parties with reliable information [3]. Simultaneously, construction projects suffer from different stakeholders and suppliers using a variety of systems [4] resulting in considerable conflicts when operational integration and automation are needed [5]. Loss of relevant information and data corruption are inevitable in such circumstances. Hence, strong needs exist for a unified concept to organize and manage information, including product and process information to facilitate the integration of construction processes.

With increasing moves toward achieving the concurrent construction goal by advanced BIM [6], the construction industry is getting increasingly similar with manufacturing industry. The current situation in construction is quite alike to the experiences by complex manufacturing companies some decades ago [7]. Considerable interests exist for implementing well-established methods from the manufacturing industries to improve BIM implementation [8]. These have common goals with BIM to ensure process fluency and product data integrity among multiple systems.

Various approaches have been proposed for the purpose of improving BIM. The BIM improvement based on Product Lifecycle Management (PLM) [7], [8], adoption of Industry foundation classes (IFC) as a well-known data model standard to deliver the integrated building information [9], implementing situation based management approaches such as Last Planner [10], proposing a central information repository as a multi-disciplinary collaboration platform [11], and modularization via considering the building as a product [10]. Further, Holzer [12] suggest that BIM should be built so that standardized product data can be derived directly from the model to the existing information systems utilized in the industry, rather than transforming BIM into a construction-dedicated PLM. However, the current research is particularly deficient in construction specific information system considerations.

BIM modelling based on a standardized Product Structure (PS) has been argued to be the missing link between BIM approach and the disconnected construction processes to some extent in the literature [12]–[14]. Product structure is a consistent unit representing a physical or conceptual grouping of product components which can be easily identified and replaced [15]. Product structure is the core entity for the transmission of information across the entire life cycle of a production project system [13] that enables platform-based production, and strengthens stakeholder engagement and cooperation from product development to marketing agents [16]. Indeed, the product structure bridges the development and marketing of new products within the concept of Productization [17].

The productization concept was originally borrowed from managerial texts and mainly used in the service or software industries [18]. The concept has evolved over the years, but at a general level, productization is used in the context of creating products or services and covers all the activities required before a product is ready commercially [19]. Productization also refers to

commercial and technical modelling the offer products according to a consistent product structure [20]. Consequently, product structure plays a key role in the Productization process as a structured product information repository and makes products and related data more systematized and manageable. Despite some researchers having addressed the concept of productization in relation to modelling of products and services and the potential of product structure involving acting as a unified concept to ensure consistency of information, the context of construction industry has only been discussed to a certain extent [21]. Further work is necessary to detail the found links and to establish an equivalent central backbone structure to enhance the implementation of BIM.

This study explores the core of productization concept, and the product structure as an eminent solution to facilitate consistency in information, and hence addresses the current gaps in BIM. This is based on the argument that product structure -focused construction modelling is the missing link of the BIM approach and has potential to improve BIM performance. Addressing the gaps in BIM can support the long-term vision of improving the of product data management in the construction industry. The goal is to create a standardized concept for product information and to provide a mechanism for the effective sharing of product data between different phases of the building lifecycle. The intention is to enable flexibility in how many stakeholders can be involved in a specific project.

The above discussion can be outlined along the following research questions (RQs);

1. How does a conceptual product structure look like in a general level?
2. How can the conceptual product structure support BIM Implementation?
3. How can a specific product structure be formed to enable reliable information exchange between different stakeholders in collaboration?

This study is a conceptual research. The research methodology is presented in section 2. The Literature Review on Productization and Product Structure at the general level forms the basis to answer RQ1. Meanwhile, the literature review on construction project specifications and challenges of BIM implementation in conjunction with the conceptual product structure, offers a response to RQ2 and also supports the creation of a construction-specific product structure that responds to RQ3. Discussion and conclusion are presented in sections 4 & 5 respectively.

2 Methodology

The study follows conceptual research approach. The literature on productization and product structure are reviewed first, while seeking for different approaches to interpret concepts at a general level. A construction specific product structure is designed and developed to support BIM implementation. A three-dimensional matrix to is used to combine product structure, building product library as a structured database, and user specifications layers from various construction project phases.

3 Literature Review

3.1 Productization

The term "productization" has been used interchangeably with standardization, systemization, productivisation, industrialization and commercialization. Productization is seen to mean standardization of the elements in the offering [22] and concern all the activities before the product is ready commercially [19]. Productization is also defined as a transformation process from customer specific (low productized) to standard mass market products (high productized) offering [17], [22], in relation to which rationalization is necessary to produce deliverables from individual level tacit abstract knowledge to organization level easier to communicate knowledge [17], [23]. Productization has been seen as a delivery-oriented concept [24], which enables an optimal balance between customization and standardizationas well as the ability to make and to sell [23].

Productization refers to the conversion of custom or incidental products to standard ones [25]. Considering all the above mentioned, productization id a transformational process in which product information and materials are streamlined, systematized and standardized through replicable methods and transparent format. Productization can be seen as a process that transforms inputs into outputs, which is in line with Transformation-Flow-Value theory proposed [26] in which the production in construction is conceptualized in a way that production is one of the major concepts (transformation from inputs to outputs, as a flow to fulfil customer needs and add value). Figure 1 illustrates productization as portrayed by the literature to provide systematics for the discussion. Indeed, productization contributes through systematization and routines to both efficiency and profitability [27], covers aspects relevant to both new product development and marketing by the product-centric view. Literature on product management [14], [17], [28] further splits productization into technological and commercial perspectives. It is also claimed that productization should be split into Inbound and Outbound activities relating to capacity to produce and sell to build a harmonized development process and

avoid duplicating tasks using existing platforms and modules [18]. The outbound productization aims at improving product value for consumers and providing wider product families to satisfy consumer needs. It is believed that productization should cover both abilities to make and sell by finding a balance between standardization and customization [17] .

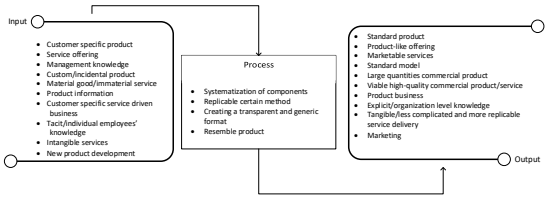

Figure 1. Productization

Evidently, the concept of productization is strongly connected to module-based product development and mass customization (MC). Modularization refers to a product and process structure in which the design elements are divided into modules with well-defined interfaces along a formal architecture [24]. Module based product development is enabler and one of the success factors for MC [29].

MC addresses distinct market requirements and promotes modularization, which can be seen as higher levels of standardization [23]. By increasing the level of productization, the clarity of the offering increases, and becomes more understandable and communicable towards customers [17]. “Successful MC products must be modularized, versatile, and constantly renewed” [29, p. 4]. This is promoted by developing modular product families for the provision of an appropriate variety of products [30] to satisfy customer needs. The concept of productization begins with the core product followed by routines.

3.2 Product Structure

A broad range of definitions for product structure exist in the academic literature [31]. The product structure term is commonly used in various fields under different terms: product architecture [15], configuration model [32], product structure tree [33]and modular product structure [30]. In a general level, product structure is defined as an organized hierarchical classification [34], [35], structural representation [36] and basis for all information of product components (characteristics, technical objects, product functions requirements) [31], [35], [36] and their assembly relationships [15], [31], [37]–[39].

Product structure is a context-dependent explanation of the product’s composition from the elements and the relations between the elements in which all ‘instantiated data’ is managed and stored [40] to realize the product function [41] and form a consistent unit that can be easily identified and replaced [15]. Product structure captures not just the product components’ assembly relationship, but also the data relationship that distinguishes them. “This data materialises as files with revisions and versions" [13, p. 11]. To ensure that product data can be handled well and that the change can be monitored and recorded, the product data should be sorted and managed according to the product structure [39].

Product Data Management (PDM) enriched by unified product structure serves as a central repository of information for process and product history and facilitates integration and data sharing among all business users dealing with products [42]. Several studies have addressed how product structure is the basis for the implementation of product data management (PDM), and fulfils the criteria of generating a manufacturing plan and schedule [39] supports managerial decision-making [39]and collaborative workflow in maintaining all design details up to date [38], so that they are dynamic and reusable.

A generic product structure is a hierarchical structure of either abstract or physical elements [43] which represent the structure of the entire product family and show which modules and part types, or classes are used in the products or a product family [31], [32]. The generic product structure offers information on possible implementations of existing templates in a wide variety of similar products [31]. Opposite of general product structure is a specific or precise product structure in which the information is only limited to a particular product. Specific/precise product structure shows the particular modules and parts, which together form the product [31]. A specific/precise product structure is a set of descriptions of components organized into a part of the hierarchy that is required to create or order the part [44].

Bill of Materials (BOM) is one of the most common product structures which identifies the parent-child relations between product components. BOM is a list of all sub-assemblies, intermediates, parts and materials that form a parent assembly and show the quality of each assembly needed to produce a complete product [45]. The terms product structure and BOM can be used interchangeably in spoken language, however, “The definition of product structure is more comprehensive" [34, p. 54]. At some point during the life of the product development, BOM is regarded as a basic filtered product structure snapshot [35].

BOM itself tends to fall into two main types; Engineering Bill of Material (EBOM) and Manufacturing Bill of Material (MBOM). EBOM is the cornerstone of the “As Designed” Product Structure that describes ‘what’

the product is [46], [47], which is later converted into MBOM. MBOM, refers to 'how' the product is produced and assembled [46] by maintaining manufacturing interactions through the planning of production processes[47]. Also other product structure based BOM categories exist. According to the product structure tree EBOM and MBOM are designed automatically as requested [37]. BOM is the core part of any integration system as a means of communication during product development [48] and it is widely evidenced that the BOM related processes and implementation activities dramatically affect how an organization can run multiple systems like Computer-aided Design (CAD), Product Data Management (PDM), PLM, and (Enterprise Resource Planning) ERP [42].

Product structure can encompass and store various kinds of product information. It is viewed that the product structure description data can be summarized into natural attributes (product and part names, ID, size, material, weight, and origin) and the relevance between the components (father-child relationship between products and parts) [49]. It is also argued that product structure information consisting of product structure decomposition, part ratios and outgoing fractions, help to frame the limits of a system and to model and analyse the subsystems, which can be retrieved from BOM and disassembly BOM [50]. Some academics also suggest an extra node between the product and part nodes and refer to modules [31] or components [37] that can be common or alternative/optional components equipped with configuration rules [43].

3.3 Construction Projects Context

3.3.1 BIM in Construction Project Context

Construction projects have certain properties that complicate their management, to name a few, quite volatile planning environment, evolving production locations, highly fragmented and extremely multidisciplinary non-linear work processes, spatial restrictions, and specific regulations [13]. These properties place difficulties on the construction projects regarding cooperation, accurate exchange of knowledge, and incorporation of various stakeholders.

It is widely acknowledged how the collaboration of numerous multidisciplinary project members through continuous, accurate and real time information sharing, play a vital role in overcoming these difficulties [51]. The ambiguity that surrounds the definition, business value and purpose of BIM impede a common understanding of BIM implementation between stakeholders [52]. Accordingly, the major issue is that "BIM is a powerful but complex technology" [53, p. 321].

The challenges of BIM implementation have been widely discussed in literature. Lack of defined standards and technically integration requirements and management of outcomes as the main barriers to BIM use [2]. BIM implementation faces challenges like the need for a well-design transactional structure and practical strategies for integration and the exchange of information among involved parties, a need for well-developed guidelines, a need for someone to be responsible for the distribution of operational development, cost and to identify a suitable time for the engagement of stakeholders in different segments to exchange the information [3]. Therefore, the challenges to the implementation of BIM with regard to the scope of this study needed to be examined with the capabilities of the construction-specific product structure. In this regard Section 4 presents debate.

3.3.2 Product Structure in Construction Project Context

Product structure concept relating to construction projects follow the general product structure logic in terms of structure and context. A construction project and the related productization mechanism, could be split into capacity to produce (Inbound) and sell (Outbound) activities as proposed by [17]. Harkonen et al. (2018) further modelled the technical product portfolio and commercial product portfolio in the construction project context by simultaneously relating to the development and sales capability activities.

The product structures are generated during the design phase [40], where all necessary stakeholders should be involved to design the product structure according to their requirements [38]. The requirements help to clarify what the product must do, or the qualities of the product. These requirements tend to fall in three categories: functional requirements referring to things the product must do, non-functional requirements referring to qualities the product must have, and constrains referring to context specific limitations that shape the requirements [54]. These requirements must be gathered and categorized according to the customer needs, regional business resources, and context-specific constraints [15]. Nevertheless, product structure might be overloaded with a wide variety of requirements and become difficult to handle should the large number of stakeholders and different domains be considered, meaning all those involved in construction projects. Therefore, also considering the capacity of product structure is vital while attempting to satisfy the various user criteria and the needs of different construction project phases. An unified product structure should be a tradeoff between individual requirements of various stakeholders (differentiation) and keeping standardization and commonality product's components [55].

The next preliminary concept to consider is a

database for potential technical objects that support is among them [2]. General product structure determination proposed by [36] involves arranging functional elements, mapping them to physical components, and defining interface specifications among components, and a technical objects. It is also worth noting that in order to make the database functional, the technical objects library needs to be hierarchically organized in a standard way. Feature templates have been proposed as a database to consist of well-formed, predefined CAD features, attribute aggregations, and constraints enhanced with engineering information and reusable geometric elements [31]. Yet the function models may not have enough structure and integration might be necessary. Accordingly, a construction classification system can be used to provide standardized technical objects, which are coded and organized hierarchically. There are several "construction classification systems" available based on different logics, but the main purpose in all is to classify building artefacts to support reliable information exchange [56]

Comparison between alternative construction classification systems have been investigated, including OmniClass, MasterFormat, UniFormat and Uniclass [57]. The UniFormat classification system is used in this study, as its purpose is to "enhance reporting of design program information, especially for preliminary project descriptions and performance specifications, and provide a basis for systematic filing information for facility management, drawing details, BIM objects, and construction market data" [58, p. 1]. This is in line with objectives of this paper. In this classification system, the building elements are hierarchically grouped into three levels of major group elements, group elements, and individual elements [59]. These three dimensions need to be acknowledged simultaneously to ensure coherent, reliable and structured knowledge to be shared by various stakeholders in the construction project life cycle phases.

A Part Template Matrix has been proposed for a generic product structure, which nicely visualizes dependencies and affiliations between feature templates and product structure [31]. Inspired by that, this study aims to enhance the proposed matrix using standardized and structured database as the source of all applicable individual element level building artefacts.

4 Results and Discussion

4.1 Conceptual Product structure and BIM

The content and structure of the product structure have been discussed in the literature based on hierarchical elements and also on the basis of information within each element. Figure 2 depicts a product structure from the hierarchical elements of the product (Left) and their respective units of information (right). The illustration is inspired by the previous research regrading product structure in general level.

The product part-of hierarchy structure starts with the product family including different products and displays alternate modules and component forms (parts) that could potentially be used in the products, or the product family. Information units correspond to elements of the product structure illustrated in on the right side of figure 2. Information of possible variety of products (Product Data layer) is stored as a generic product structure which includes several different specific products structures (BOM). Next level is the assembly process layer that includes a collection of component descriptions required to build or order a part. In this level, specific EBOM and MBOM describes 'what' the product is and 'how' the product is produced and assembled. Detailed information of the parts is stored within the elements layer to specify the characteristics used for grouping or separating.

The findings indicate that a product structure consist of comprehensive information regarding product and production process with a clear structure of relations between detail information. Meanwhile, information can be tracked and reused from product data, process and elements layer of product structure. The centralized and standardized product structure makes it accessible and easy to follow as a consistent information unit for all the stakeholders involved in the lifecycle of construction projects. In short, a product structure with a well-designed structure can provide a platform for continuous, accurate and real-time information that can be used in collaboration with numerous stakeholders.

Regarding "BIM" implementation, the mentioned gaps in could be well addressed with the potential of the product structure discussed in literature promoting standardization, collaborative exchange of reliable information and integration of multidisciplinary stakeholders. The flow of information about elements and their relationship, production process, specific product and product family will be available via a product structure.

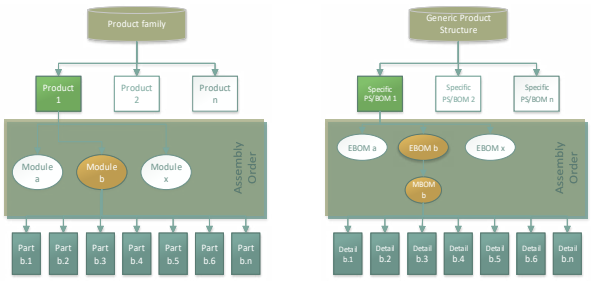

Figure 2. Product Structure from hierarchical elements of the product (Left) and their respective units of information (right).

4.2 Construction Specific Product Structure

The construction projects' specifications are considered to develop a construction specific product structure, since the product structure is a context-specific phenomenon itself that can be interpreted differently through the project life cycle with various disciplines and stakeholders involved in the project.

In this regard, the findings indicate that the product structure could be developed to be used from both technical and commercial standpoints. The conceptually illustrated product structure (Figure 2) was developed to be used for technical and commercial purposes. Involvement of stakeholders and related well-defined requirements within the early stages of construction projects enhance product structure functionality. Hierarchically structured and standard library of building objects further facilitate efficient information exchange among stakeholders.

Accordingly, the product structure is enriched first by the standard construction object library which consist three layer of details including major group elements, group elements, and individual elements. These three levels may well correspond to product structure hierarchy levels of product, modules, and parts. A Matrix based model is used to explain corresponding dimensions and their interactions.

Using a standardized and structured database as the source of all applicable individual element level building artefacts in bottom of product structure will enhance collaborative exchange of reliable information and integration of multidisciplinary stakeholders. This approach provides a basis for systematic flow of information across project and add an appropriate classification of elements.

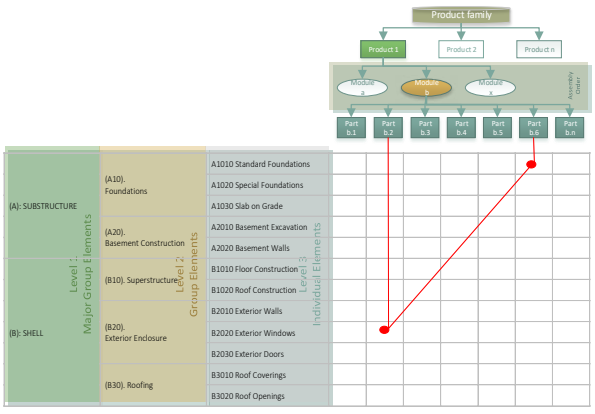

Figure 3. Part-Elements Matrix

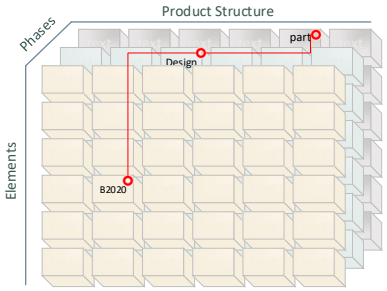

Figure 4. The Part-Phase-Elements Matrix

So far, Part-Elements Matrix is able to integrate PS and library elements. To make the Part-Elements Matrix usable for involved parties acros different stages of the project, third dimension is needed to illustrate the potential inclusion of unlimited users from different disciplines within the construction phases (Figure 4). The addition of user dimension, in other words, allows the collaborative use of the proposed Part-Elements Matrix. The proposed matrix has added new dimensions called Phase Layer. As a result, the 3-dimentional Part-Phase-Elements Matrix has formed demonstrating the relationship between the parts, elements, and users. The Part-Phase-Elements Matrix has Part-Elements Matrix capacities as a basis and allows stakeholder engagement to enhance BIM as well.

The Part-Phase-Elements Matrix shows the relationship between the part and the correlated elements that exist in the object library. In the meantime, the phases layer indicates that the stakeholder involved in the second phase of the project (design) is the corresponding user. In the example given in figure 4, the element no. B2020 related to Part (x) from PS, is used by a user from Design phase. This type of relational information. The proposed Part-Phase-Elements Matrix has the potential to facilitate consistency in information and enhance BIM as a construction-specific product structure.

Abstract -

Individual customer needs and accelerating technological advances in Industry 4.0 are leading to rapid manufacturing changes, thus industrial buildings need to accommodate constantly evolving production processes. The load-bearing structure acts as crucial limiting factor regarding the building's flexibility. As structural performance is highly linked to other design-disciplines, there is a need for integrated computational solutions allowing for performance-oriented structural design and optimization in early-design stage.

In order to address these issues, this paper presents the framework development of an early-stage parametric structural optimization and decision support model for integrated industrial building design. The framework combines architectural, structural, building service equipment and production process planning parameters and evaluates the impact of changing manufacturing conditions on the structural performance, automatically evaluating flexibility metrics to guide the decision-making process towards increased sustainable design. In a case study of ten real industrial construction projects, the interdependencies between discipline-specific data in industrial building design are analysed and collected in a graph data model. The proposed parametric framework is tested on a pilot project from the food production sector. Results validate the efficiency of the framework design and indicate that an optimization of the structural axis grid can save up to 25% of the material demand. A discussion on the results and next steps for further model improvement are presented.

Keywords –

Industrial building design; parametric modeling; performance-based structural design; multi-criteria decision analysis; early design stage; decision support

1 Introduction

Flexibility has become an increasingly important topic in industrial building design. Due to product individualizations, accelerating technological advances in manufacturing planning and shorter production lifecycles industrial buildings strive for highly flexible structures. The load-bearing structure, as the most rigid element with the longest service life in a building, is decisive for the adaptability and transformability of manufacturing systems. Flexible load-bearing structures, which can be implemented by means of wide-span girder systems and different load carrying capacities, can prolong the building's service life without expensive rescheduling measures.

The data and software needed by manufacturing planners differ by the ones from building design and are usually based on special discipline-specific knowledge. Multidisciplinary design teams involve conflicting views of different stakeholders and planning parameters and the prevalent uncertainty associated with multiple discipline-specific models. However, the production owner's demand should be satisfied by cooperating and assessing work of all planning disciplines. Compared with manufacturing services, building components have a much longer lifecycle, though buildings need to supply the interaction between production processes and machines, the building structure and service equipment. Effects of changing production processes on the building structure and consequently on the performance along the whole life cycle of the factory should be simulated and visualized in real time, giving reliable feedback on design-decisions already in early design stage. Therefore, a large quantity of data need to be integrated, although data availability in early design-stage is rare and data exchange between different disciplines rarely exist.

Integrated decision-making systems that provide manufacturing and building criteria is relatively complex, since currently production and building design processes run consecutively, lacking in feedback loops. Additionally, structural considerations usually enter the design process too late and are subservient to

architectural and production goals, leading to suboptimal structures and inflexible floorplans. Thus, environmental and economic aspects such as resource consumption and life-cycle costs could be reduced by collaborative performance-based decision-support systems, optimizing the structural system. However, digital industrial building models do not properly address the interaction between production and building design disciplines, which may later lead to inflexible solutions.

In industrial construction projects, stakeholders are faced with numerous complex design decisions, involving the choice of conflicting variables such as different construction types, production processes or building service equipment (BSE). Multi-criteria decision analysis (MCA) taking into account possible scenarios of production layouts can help to improve the structural performance of production systems. Though, require maximum integration of all stakeholders and a vast amount of data in early design stage. To achieve this integration several architectural, structural and manufacturing aspects and their interrelations need to be considered and new computational strategies developed in order to generate applicable design solutions.

This paper presents ongoing research, conducted within the research project BIMFlexi, which aims to increase the flexibility of industrial buildings towards rapidly changing manufacturing systems in a BIM-based digital platform. This paper explores a novel approach integrating production process planning into performance-based structural design in early design stage of industrial buildings. A framework for a parametric structural design and optimization model in order to allow multi-objective optimization (MOO) with immediate decision support increasing the flexibility of industrial buildings is developed. The parametric model framework is designed to be integrated into the BIM-based digital platform of BIMFlexi in a next step of the research.

In this paper, we first review the state of the art for MCA in industrial building design. We then explore collaborative decision-making problems with focus on structural performance integration (chapter 2). In order to identify relationships between building design and production planning the results of a comprehensive case study, analysing ten real industrial facilities, are summarized in a graph data model. We propose a framework for a parametric structural performance-based design and optimization model that can be used by stakeholders involved in industrial construction projects to support in multi-criteria decision-making in early design stage (chapter 3). The framework is tested on a pilot project and results are discussed (chapter 4). The paper completes with a conclusion and outlook of the next steps. (chapter 5).

2 Literature Review

Research and industry community widely acknowledge the need for flexible and adaptable buildings, contributing to sustainable design choices [1]. Maximizing the flexibility of building structures can minimize costs and time required for rescheduling, but identification of interdependencies among discipline-specific systems bears challenges [2]. Cavalliere et al. [3] develop a BIM-based parametric model for automatic flexibility evaluation for sustainable building design.

Regarding MCA and decision-support systems for production plants, numerous research has been conducted in optimization of manufacturing systems [4-7]. A modular process model taking into account databased interdependencies in factory planning respecting the building is developed by Hawer et al. [8]. Yet, industrial buildings are rarely in research focus [9]. Among the conducted research, several authors proposed models concentrating on industrial building level. Kovacic et al. [10] develop a life-cycle analysis tool for facade-systems of industrial buildings, claiming that decision-making processes require long-term horizons, which, however, still need improvement. Authors in [11] develop an approach for factorial design space exploration supporting in multi-criteria decision-making (MCDM) to study energy performance, environmental impact and cost effectiveness along the life cycle. The author in [12] present a sustainability assessment methodology based on MCDM including factors influencing early design stage of industrial buildings. In [13] a study developed a decision-making model to describe relations between factory buildings, manufacturing equipment, sustainability aspects and the planning process. Other researchers focused on the prediction of the energy efficiency in production facilities [14] or used MCA for space heating system selection in industrial buildings [15]. Methods and models developed for MCA of industrial buildings mostly address energy performance improvement. Less attention is on the structural performance. However, to determine the overall efficiency of industrial buildings a concurrent assessment of the synergy effects of production processes, BSE and the building itself is needed [16].

Current available structural analysis tools are not sufficient for early design stage as their focus is rather on precision than flexibility often lacking in interoperability to other design tools [17]. Few structural analysis methods allow analysis and visualization in a single environment, provide feedback only to the structural engineer himself and do not support an integrated performance improvement [18]. Parametric modeling can support in conceptual design, enabling early integration of engineering-specific knowledge [19] allowing fast variant studies and enabling flexible

exploration of design spaces by varying parameters and their dependencies [20]. Using parametric design tools such as Grasshopper for Rhino [21] or Generative Components [22] provide visual programming environments and allow the integration of structural performance simulations such as Karamba3D [23]. In addition, a number of computational tools supporting MOO are already embedded in traditional parametric modeling software [24], including the generative solver Galapagos [25] for Grasshopper.

Several methods have been used to support integrated design exploration for structural performance with MOO in conceptual stage. Authors in [24] present a case study of a cantilevered stadium roof for early-stage integration of architectural and structural performance in a parametric MOO design tool. In [26] a MOO methodology for structural efficiency and operating energy efficiency focusing on long span building typology is presented. [27] develop a design tool, which parametrically generates and semi-automatically analyzes truss designs with real-time visual structural performance feedback. Mueller and Ochsendorf [18] propose a computational approach in evolutionary design space exploration, combining structural performance and designer preferences. Pan et al. [28] propose a design process for long-span structures composed of a parametric model, a framework of interdisciplinary assessment criteria and MOO with post-processing tools.

The above listed research results are remarkable but focus either on production process modeling or building performance, mostly focusing on energy efficiency. Holistic models receive little attention. Indeed, the focus in early industrial building design should be on the optimization of the load-bearing structure in order to maximize the facilities flexibility, thus prolonging the buildings service life and reduce life-cycle costs.

Hence, this paper deals with the framework development of an early-stage parametric structural optimization and decision support model for integrated industrial building design. It integrates architectural, structural, BSE and production process planning and evaluates the impact of changing manufacturing conditions on the structural performance, automatically evaluating flexibility to guide the decision-making process towards increased sustainable design.

3 Research Methodology

As described in the previous chapter, this paper focuses on the investigation of the interdependencies between building (architecture, structure, BSE) and production (manufacturing program, machine layout and space requirements) data in order to develop a parametric multi-criteria model for structural optimization and decision support. Multi-criteria decision-making requires a vast amount of data in order to come to applicable results. The research is based on a case study to construct a network from direct empirical observations, showing graphical data structure, compactly representing dependencies.

3.1 Use-Case Study

The use-cases under investigation are selected acc. to [29] and are representative for the research objective. Due to different types of production examined – Automotive, Food and Hygiene, Logistic, Metal Processing and Special Products - a diversity is created and not exclusively the needs and objectives of a specific manufacturing sector investigated. The recommendations in [29] are followed with a total number of ten examined use-cases. The purpose of the research is to develop theory, not to test it. The use-cases are selected because the highest density of given information and the best accessibility of data and leading stakeholders was available [30]. Table 1 gives an overview of the examined use-cases.

Table 1. Use-Cases examined

Use-Case	Production Type	Floor Area [m²]	Primary Construction
A	Food	5760	Steel Truss
B	Logistic	5040	Steel Truss
C	Logistic	8064	Timber Girder
D	Metal	16200	Timber Truss
E	Automotive	160704	Steel Truss
F	Metal	2800	Steel Girder
G	Metal	28224	Precast RC Girder
H	Special	1296	Precast RC Girder
I	Metal	6750	Underspanned Timber Girder
J	Special	1992	Steel Truss

3.2 Graph Data Model

We have undertaken a process of creating a graph data model for the representation of interactions between production planning and building design to cover the requirements for the developed parametric model. A graph data structure is naturally defined around graphs, nodes and edges. In the conducted research an attributed graph is used for modeling, describing properties for nodes and edges [31]. The approach consists of two tasks: extracting generic hypothesis-evidence relationships from the case study, concentrating on design variables and parameters and organizing such relationships in a data structure to facilitate quick response using a minimal amount of memory and computational time later on.

The proposed Graph Data Model for integrated industrial building design (GIB) is structured as follows:

- *Nodes:* The design parameters in GIB system include geometric entities (i.e. structural elements), constraints (loads, legal restrictions) or other requirements (i.e. space requirements).
- *Labels:* The nodes are assigned in four labels according to the examined disciplines.
- *Edges:* define the relationship between the nodes
- *Properties:* Nodes or edges maintain a set of attributes (property values) thus allowing storing of relevant data and information.

Figure 1 shows the effective graphic representation of dependencies in integrated industrial building design combining the disciplines of production-, architectural-, structural-, and BSE planning based on the results of the case study. The proposed GIB model is grow- and changeable over time and relationships, nodes, properties and labels can be added or removed. The flexibility and simplicity of the graph data model allows reviewing of the data structure and serves as basis and modeling guide for the parametric script.

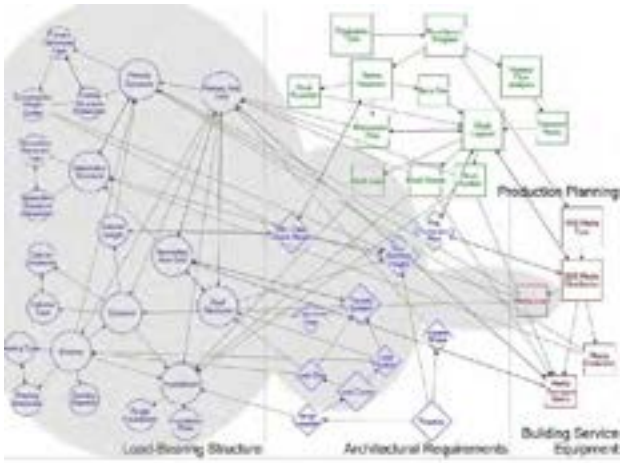

Figure 1. Attributed graph data model for integrated industrial building design (GIB).

Figure 1 additionally highlights the nodes that have already been considered in the status of the parametric framework in grey area. Missing parts, e.g. production- and BSE- entities will be integrated in the next step of the research.

3.3 Model Framework Description

In multi-criteria design analysis, the number of design-options is typically very large and the options not explicitly known. We have developed a framework for a parametric design process in Grasshopper for Rhino [21] in order to find options within the solution space and systemise the appropriate evaluation. Additionally, the Grasshopper components Karamba3D [23] for structural analysis and Galapagos [25] for evolutionary search are used in the parametric design process. Karamba3D allows early-stage structural design, form-finding, and structural optimization. Using a parametric script allows the automatic analysis and optimization of the load-bearing structure in consideration of constraints from other disciplines.

The framework consists of six discrete steps (see Figure 2) that in total comprise the parametric multi-criteria model for structural optimization and decision support:

1. Parameter & Input
2. Geometry & Loads
3. Element Definition
4. Structural Analysis
5. Structural Performance
6. Optimization

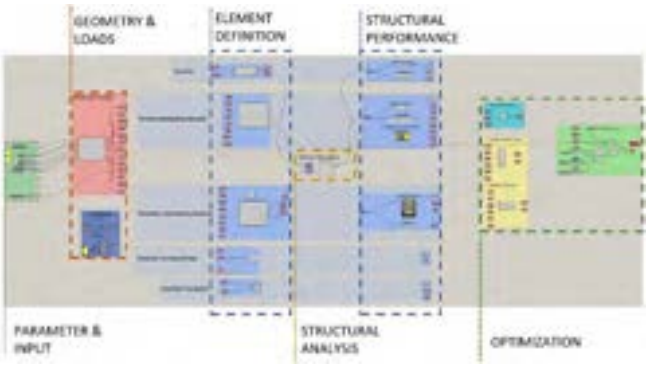

Figure 2. Framework of the parametric grasshopper model containing six steps.

In a first step, the definition of the building's typology takes place by selecting eight design inputs as described in Table 2. The load-bearing element-ranges are defined according to the case-study results.

Table 2. Input variables for the design process

Typology		
	Variable	Range
G1	Prim. Axis Grid (x-axis)	0 – 30m
G2	Prim. Axis Fields	1 – i
G3	Sec. Axis Grid -x	0 – 30m
G4	Sec. Axis Grid -y	1 – j
G5	Hall Headroom	5 - 15m
G6	Max. Building Height	5 - 20m
S1	Primary Structure Type	1-2
S2	Secondary Structure Type	1-2

The design variables for flexible structural industrial building design are defined as the position of the columns representing the axis grid in x- and y- direction, for both the primary and secondary structural system.

Furthermore, an important grid variable represents the z-direction as the free hall headroom inside the building and the outer maximum building height. The primary and secondary structure type can be chosen variable in a range of two pre-defined systems, which are either a truss (Option 1) or girder structure (Option 2).

Following, the base geometry is generated as a wireframe model, according to the definition of the axis grid. Simultaneously, pre-defined loads, obtained from the case study, such as snow load and live loads, dependent from production process and BSE-planning, are applied automatically.

In the third step, the structural elements are generated based on the generated wireframe model. Currently, following structural elements for modeling and calculation are taken in account:

- Primary load-bearing structure
- Secondary load-bearing structure
- Columns
- Bracing system
- Individual foundations
- Concrete foundation plate

After the generation of the structural system with associated elements, the structural analysis is carried out in the fourth step. The pre-dimensioning of the pre-defined elements considering input variables and load-cases takes place. The fitting of the cross-sections is executed with the native cross-section optimizer in Karamba3D.

In the fifth step, the structural performance is carried out. Since as-built structures often differ from idealized finite-element models for structural computation, the elements are re-arranged by considering structural design rules based on gained knowledge during the case study. For further processing, the structural performance is evaluated based on the criteria of utilization and maximum displacement.

The final step contains the calculation of constraints and objectives for design optimization. The optimization step uses Galapagos as an evolutionary algorithm to optimize the design alternative considering the fitness function, as described in the following section.

3.4 Fitness Function and Optimization

In order to allow the optimization of the input variables, the parametric script automatically calculates objectives and constraints of diverse design options. Table 3 shows the set of constraints and objectives considered in the fitness function. The considered constraints are the maximum utilization of the structural elements, the maximum building height and the maximum displacement of the structural system.

The pursued flexibility objectives are the minimization of the structural space requirements in the production hall (F1), the maximization of the free height reserve in the hall (F2), the maximization of the material saving (F3) and the minimization of the structural utilization in order to be able to place additional loads on the system in future without conversion work (F4). The presented objectives are a pre-selection based on a series of interviews with different discipline-specific stakeholders carried out during the case study.

The definition of the flexibility objectives for the fitness-rating is partly based on the method presented in [3], where distance- and percentage-based indicators are presented giving the possibility to determine the flexibility of design alternatives. The distance-based indicator serves for definition of the objective function F2 to maximize the height reserve of the system, whereas the percentage-based indicator is used for the objective functions F1 to minimize the structural space and F4 to minimize the utilization of the structural system. In addition, a reference-value based indicator is defined by putting obtained reference values of the material demand in different production types from the use-case analysis (i.e. average material demand of a structural system) in proportion to the actual material demand of the optimized system. The reference-based indicators serve for the calculation of the objective function F3 to maximize material savings.

Table 3. Constraints and objectives defining the fitness function for flexible industrial building design

Constraints		
	Constraint	Range
C1	Maximum Utilization ≤ 1,0	{0,1}
C2	Building Height ≤ Max. Height	{0,1}
C3	Displacement ≤ Max. Displacement	{0,1}
Objectives		
	Objective	Range
F1	Minimize Structural Space *percentage-based*	{0:1}
F2	Maximize Height Reserve *distance-based*	{0:1}
F3	Maximize Material Saving *reference-value-based*	{0:x}
F4	Minimize Utilization *percentage-based*	{0:1}

During the process, the user is given the possibility to define weighting factors to the different objectives given and these weighting factors are applied to the different objective functions F1 - 4. The weighted objective functions are then gathered in a linear equation describing the function for the fitness rating:

$$Q = \prod Ci * (\sum ajFj) \quad (1)$$

Q *Fitness Rating*
C_i *Constraint [0,1]*

F_j *Fitness indicator*
a_j *Weighting ($\sum a_j=1$)*

4 Results and Discussion

In order to evaluate the accuracy and validity of the proposed framework and the applied fitness function a proof-of concept is performed based on a pilot project. The chosen pilot project is a real production facility from the food and hygiene sector with a total production area of 5.760m² - Use Case A of the Case-Study. The external dimensions of the hall are 48x120m, with a structural axis grid of 12x24m.The building structure was realised as steel truss-system in primary and secondary direction with truss construction heights of 2,4m. The columns consist of pre-cast concrete cross-sections with dimensions of 60x60cm and the bracing system uses end-fixed columns to bear horizontal loads. Figure 3 shows the 3D Visualisation of the Pilot Project and the applied load-areas in Rhino3D, taking into account snow loads and BSE- and production-related loads.

A variant study is carried out in order to obtain and compare analysis and optimization results. The grasshopper script automatically generates and evaluates numerous design options of the pilot project with the goal of optimization of the structural system. After running the analysis and optimization script, the twelve most relevant design options were categorised according to the structural type and examined in detail. Category 1 contains all options with pure truss structures, options of category 2 contain only girder structures and category 3 options represent a set of mixed structures. A balanced objective weighting (each objective 25% importance) has been defined in the proof-of concept.

- PP: Pilot Project – Truss structure
- Cat. 1: Truss structure - primary & secondary
- Cat. 2: Girder structure - primary & secondary
- Cat. 3: Mixed structure

Figure 3. Pilot project model visualisation in Rhino 3D with load distribution.

The optimization results of the best-rated design-option from each category (Cat.1-3) compared to the pilot project (PP) are presented in Table 4.

Table 4. Optimization Results of Proof-of Concept

Options	PP	Cat. 1	Cat. 2	Cat. 3
Variables				
G1 [m]	12	12	12	12
G2 [pc]	4	4	4	4
G3 [m]	24	12	6	12
G4 [pc]	5	10	20	10
G5 [m]	6,35	6,35	6,35	6,35
G6 [m]	9,30	9,30	9,30	9,30
S1 [no.]	1	1	2	1
S2 [no.]	1	1	2	2
Material Demand Results				
steel mass [kg/m²]	45,7	28,7	76,7	89,0
concrete mass [kg/m²]	24,8	25,6	48,9	40,0
Objective Values				
F1	0,94	0,90	0,82	0,90
F2	0,24	0,59	0,59	0,59
F3	1,00	1,27	0,55	0,57
F4	0,91	0,90	0,70	0,76
Fitness Rating				
Q	0,72	0,92	0,67	0,70

Figure 4 presents the best-rated design-option of each category compared to the pilot project in a radar diagram. The objective function of the Material Saving (F3) has a high impact on the performance of the structure.

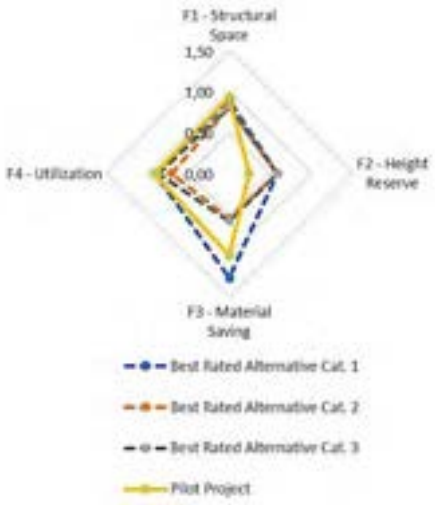

Figure 4. Graphical radar representation of the proof-of concept results.

Table 4 shows that the best rated option with the highest fitness rating is performed by category 1 – the sole truss structure with an axis grid of 12x12m. Highly due to the positive impact of material saving (F3). Results indicate that the Cat. 1 option saves approximately 25% of the structural steel mass compared to the pilot project,

mostly because of the axis grid optimization. Additionally, the structural analysis results in cat.1 increase the utilization of the cross-sections compared to the more conservative cross-section selection in the pilot project. This may also be because during the pilot projects design phase, stakeholders probably may have considered additional design parameters and constraints such as structural reserves, which are not yet represented in the framework of the parametric script.

In category 2, the best-rated option still has a high material demand compared to the pilot project and the positive impact of the Height Reserve (F2), due to girder structures, is not able to compensate this drawback. The bad rating of Material Savings (F3) in category 2 shows that the girder structures are hardly competitive to truss structures due to the high BSE loads.

A mixed structure as analysed in category 3 also has a worse performance compared to the pilot project with a fitness rating of Q=0,70.

In conclusion, results of the variant study show that for the applied load scenario truss structures (Cat.1) are more competitive compared to girder (Cat.2) and mixed (Cat.3) structures. An optimization of the pilot projects performance could be obtained by adjustment of the axis grid in x and y direction.

Regarding the evaluation of the fitness function (Q) and the contained objective functions (F1-4), we observe that the determination of the material saving (F3) has a decisive effect on the performance results (see Figure 4) in comparison to other objectives, considering their narrow value range. Further analysis of the mathematical definition of the objective functions is necessary.

Considering the efficiency of the parametric script, the computational time of approximately 10-15 seconds per option on a standard computational system is improvable but legitimate for a complex structural analysis with parallel optimization.

5 Conclusion

This paper proposed a method to support integrated industrial building design exploration with structural optimization, which is crucial to guarantee the long-term flexibility of factories. In a use-case study, ten real industrial construction projects are analyzed in order to define discipline-specific parameters and their interdependencies in industrial building design. The goal is the development of a computational framework integrating discipline-specific data of production planning, architectural-, structural and BSE design in one holistic model. Parametric modeling combined with structural analysis and optimization algorithms for performance-driven design allows the generation, simulation and optimization of different structural layout options for early decision-making in industrial construction projects.

The developed parametric script considers varying primary and secondary axis grid options with different structural types enabling performance improvement of a building's long-term flexibility. A multi-objective fitness function has been developed rating the flexibility of a building structure and serving as multi-criteria decision support model. A proof of concept on a real pilot project, a food production, was conducted in order to validate the efficiency of the process and show the necessity of extending the parametric framework.

In the next step of the research, the parametric script will be further extended according to the lacking parts of the graph data model, integrating missing production and BSE- data. Furthermore, the mathematical background of the current definition and description of the objectives needs to be further investigated. The mathematical definition of the fitness function and its objectives has to be improved and extended with additional objectives in order to define accurate flexibility statements for all stakeholders. Considering the structural analysis and pre-dimensioning results, an in-depth analysis of the used algorithms in Karamba3D is necessary to cope with utilization fluctuations of the generated structures. The proof of concept will be extended by analysing more case-cases, guaranteeing the robustness of the tool in various production scenarios.

Future work will examine and develop methods to integrate the framework of the parametric model into the BIM-based digital platform by bi-directionally coupling it to BIM, Finite-Element-Method Tools and Virtual Reality software, as aimed in the research project BIMFlexi.

Inspection of Discrepancies in Construction Temporary Safety Structures through Augmented Reality

Hashim R. Bokhari[a], Doyeop Lee[a], Numan Khan[a] and Chansik Park[a*]

[a]Department of Architectural Engineering, Chung-Ang University, Seoul, South Korea
E-mail: hashimbokhari@cau.ac.kr, doyeop@cau.ac.kr, numanpe@gmail.com, cpark@cau.ac.kr

Abstract – Construction safety has been a major area for research for an extensive time as the number of accidents, injuries and deaths has not significantly declined, despite strong implementation of safety laws and major efforts of the construction safety professionals. According to the Ministry of Employment and Labor, Korea (MOEL) [1] from 2012 to 2015 the Construction sector occupied the highest percentage of fatalities among all sectors in Korea. Automation of the inspection process of Temporary Safety Structures on Construction sites (TSSC) can reduce fatalities and injuries on work site. This research proposes a unique approach for the safety inspection of TSSC by using an outdoor marker-less AR system along with Structure from Motion (SfM) to reconstruct the 3DCG (3-Dimensional Computer Generated) models by using photographs from different viewpoints. The system(framework) considers area mobility of the inspector and his long relative distance, along with local feature-based image registration technology to target the location for Augmentation of 3DCG models of TSSC. This system would enhance the inspection, verification, and installation of the TSSC and help in ensuring worksite safety of all individuals involved in the construction development process. In future research, a case study would be conducted to confirm the implementation of this framework and integrate other areas for further development.

1 Introduction

Construction worksite safety is a comparatively high researched area, because of the soaring number of fatalities and injuries during development phase of the projects [1] [2]. Construction caused 20.9% of the workplace related fatalities in the United States from 2003 to 2008 (Bureau of Labor Statistics, 2008) (Census of Fatal Occupational Injuries (CFOI) - Current and Revised Data, 2018) and In South Korea it had the highest percentage of fatalities according to the Ministry of Employment and Labor[4]. The processes involved in construction project development should revolve around the central idea of worksite(occupational)safety, as it directly impacts physical human life safety of the workforce and all other humans beings involved in the construction processes, such as management, trades, and logistics teams. Safety can be ensured in certain scenarios by the proper usage of different types of Temporary Safety Structures such as safety fence, struts, guardrails, scaffoldings, handrails, temporary gates, and others. These Temporary Safety Structures on Construction (TSSC) sites require strict monitoring, detailed concentration of the inspector and need to be setup according to the safety design. This makes the safety inspection process a challenge, as construction sites can cover vast areas and site conditions can be unpredictable.

Currently, in most scenarios, the safety inspection is being conducted manually, wherein the safety inspector visits the worksite and enforces legal safety requirements and best practices. The inspector relies on his observation of the entire safety design, installation & verification processes, and his observation of the Temporary Safety Structures on Construction (TSSC), to ensures safety and provides help in avoiding any discrepancies(errors), which can possibly be a major cause for physical bodily harm (injuries) or even deaths on construction worksites. This method typically involves the usage of 2D drawings and requires detailed attention to temporary safety structures on large construction sites. This inspection method requires constant monitoring, strict and lengthier time span, which makes it predisposed to errors, because of the manual nature of the process. The inspector has limitations as a human being, such as concentration span duration and Vision fatigue, such limitations can lead to reduction in the number of discrepancies (errors) detected which in a large scale construction site can be a major cause of safety lapse. Due to these human limitations despite considerable effort from Construction Safety Professionals for worksite safety, the number of fatalities and injuries has not reduced and continues to be

the highest in construction when compared to other industries.

The advancements of technologies for use in construction, such as Augmented Reality, can help improve construction worksite safety. Augmented Reality (AR) is already being actively used in architecture and urban design fields as it can integrate augmentation with the real-world scenes. Through the help of visualization feature of AR[5], construction safety inspection can be improved both at the design stage (3D design visualization) and later at the safety inspection stage for discrepancy monitoring.

Augmented Reality (AR) provides the users (construction professional) with an interactive experience, where the real-world environment and real-world objects are enhanced by computer-generated perceptual information. This proposed framework AR system would integrate real world scenes with 3D (3-Dimensional Computer Graphics) models, to facilitate the possibility of onsite safety inspection. The AR system is to be set for an outdoor environment, specifically for outdoor safety inspection. This is due to the relatively large distance that exists between the user and the 3D model in outdoor AR systems. Such a system would enable the safety inspector to monitor TSSC with the help geometric registration (location-based monitoring). The reference point is the position of the sensor such as GPS or 3D sensor [6], in contrast to when using a marker based method, where the position of the artificial marker servers as the reference point, which is an example of vision-based methods.

Figure 1. Shows a Safety Inspector monitoring Temporary Safety Structures on Construction site

2 Related Work

2.1 Marker-less AR for Inspection

Generally, the proposed system is to be used for outdoor inspection. If a system is sensor based then, one of the key challenges is to get accurate AR. This requires precise tracking of the geometric registration between the live video stream and 3D reconstructed model image. The reference point for geometric registration is proposed to be positioned near (close) to the user (inspector), hence, the sensing errors that can significantly influence the error of the 3D model registration may be reduced. Whereas, in artificial marker-based methods, it is possible to place any large size markers near the target objects. Moreover, the marker needs to be captured properly, with the right angle, by the AR Camera. This imposes limitations on the mobility range of the user and requires placement of a large sized marker. A Marker-Less AR system would enable the Inspector to monitor the construction site from a distance and enhance his mobility. This mobility factor is the primary reason for the advancement of Marker-less AR (which do not require artificial Markers) Technology for example [7], [8] and [9]. The development of a geometric registration method which corresponds point cloud data to natural features of the real world was developed by Yabuki [10]. This method requires natural feature to be continuously captured by the AR Camera, it also requires special equipment to acquire point cloud data, as the system would use to 3D laser scanner to collect the large amount of data for the point cloud.

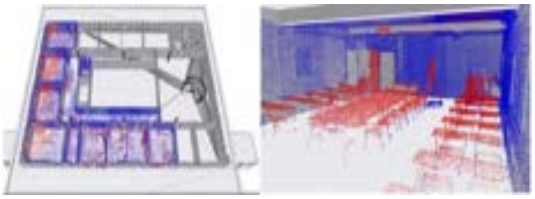

Figure 2. Shows a sample regarding point cloud data & objects segregation for 3D modelling

The 3D Model displayed on the screen uses the equation developed by Zhengyou Zhang [11], where the equation s symbolizes expansion or reduction factor with u and v as the position that draws the object according to the coordinates.

$$s\begin{pmatrix} u \\ v \\ 1 \end{pmatrix} = \begin{pmatrix} f & 0 & c_x \\ 0 & f & c_y \\ 0 & 0 & 1 \end{pmatrix} (R_{3\times3} \quad T_{3\times1}) \begin{pmatrix} X \\ Y \\ Z \\ 1 \end{pmatrix}$$

f denotes the value of the focal length, c_x and c_y determine the coordinates of the center of the image, these values are known as the parameters of the camera where R is rotation matrix and T is the translation matrix of the camera. All these values are known as the external parameters of the camera. The values of X, Y, Z denote the position of the object in the real-world coordinates.

The internal parameter generally remains constant(unchanged), unless camera lens is changed, and can be calculated through camera calibration. Specific to the photograph's viewpoint are the position and posture

data of the camera, for the external parameters. This is the primary reason for the calculation of the external parameters for the AR system. For Marker-based system the calculation takes place via the position of the marker, whereas for marker-less system another calculation method is required. Subsequently, for this study, a novel marker-less based system, along with feature-based image registration technology was used. Additionally, to enhance mobility the system utilizes the sensor-based registration and does not require a marker. The point cloud data used in the system is reconstructed by Structure from Motion (SfM).

2.2 Structure from Motion for 3D modeling

In direct contrast(to Lidar), Structure from Motion(SfM) [12], requires multiple pictures taken from different point of views to create a point cloud data of the TSSC [13]. This a low-cost alternative tool to 3D lasers scanning for creating models [14], it is an emerging method. The system does not utilize any special equipment such as laser scanners.

A major feature of the proposed system is that it does not require any specialized equipment (such as sensors for geomatic-registration between the Augmentations and the real world) as it uses sensor-based registration. Additionally, Artificial Markers are not required (they decrease user mobility and flexibility). Lastly, point cloud data used in this system is reconstructed through SfM and no special equipment such as laser scanners are required. These reconstructed models will be used for 3D model creation.

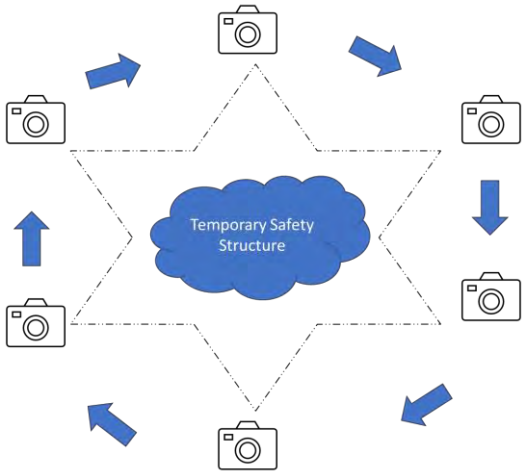

Figure 3. Shows the Image capturing process required for Structure from Motion (SfM)

Figure 4. Shows a sample of different reconstructed models of objects from SfM

This study presents a framework based on a novel marker-less AR system which utilizes local feature-based image registration and Structure from Motion (SfM) technology for discrepancy inspection. The system provides free mobility, reduced limitations, requires less effort and is inexpensive for use in outdoor AR application.

3 Overview of the Proposed System

In this Framework, the proposed system is dived into two sections: Initial-Processing and Core-Processing.

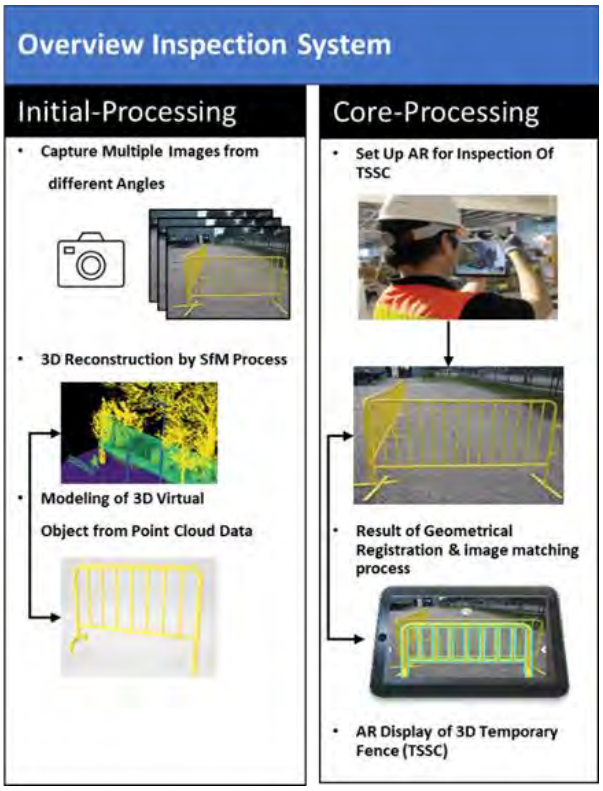

Figure 5. Shows the System Overview

Under the Initial-Process, in the first step, a 3D model of the environment will be reconstructed using the Sfm method, using the pictures taken from multiple viewpoints. The entire data regarding position and orientation of all the viewpoints would be stored in a database. In the second step the coordinates of 3D model generated for augmentation (Safety Fence in this scenario) are to be defined relative to the 3DCG models of the reconstructed environment that was created (reconstructed) using SfM and stored in the database. Finally, the keys point and features from all the pictures used in SfM will be extracted and stored in a separate text file. In addition, the file paths of the all the pictures will be saved in a separate text file.

For the proposed research based framework, the user (inspector) is asked to utilize an advance local feature detector and descriptor known as Speed-Up Robust Features (SURF)[15], as it is based on the improvements from the Scale-Invariant Feature Transform (SIFT) which is used for point detection proposes.

In the Core-Process, Firstly, all the files created in the Initial-Processes step should be imported. Secondly, real time extraction of the features of the live video would be extracted using SURF in real time, the features will then be compared with the features of the stored image in database. Finally, the precise rendering of the 3D virtual objects using position and orientation data of the camera and finding the most similar image in the database will takes place in AR display. For tracking to take place, motion vectors will be calculated by using optical flow. Finally, the calculation of the external parameters would consider internal parameters, Position of points on the screen and the world coordinates of their corresponding points.

To achieve real-time processing, 3 speed enhancement should be applied to processes, firstly, SURF processing, to compare keys features of live video images and all stored images in the database. Secondly, Locality Sensitive Hashing (LSH)[16] algorithm should be applied instead of the full search by linear search algorithms. Finally, a multithreading technique is proposed to be applied for feature extraction during the SURF process. In the Image Registration processing step, the live video images should be trimmed to only process the central area.

3.1 Processes, Software & Libraries

The system design for the proposed project will be implemented using C++ through a combination of multiple open source software applications and libraries. In this context the Initial-Processes will use OpenMVG (Open Multiple View Geometry version 1.6), which is an open source software to conduct Structure from Motion (SfM). Secondly, for 3D modelling Trimble SketchUp (Version 66.1.), which is another opensource software to define the coordinates of the virtual 3D objects.

For Core-Processes OpenCV (Open Source Computer Vision – Version 4.3.0), another opensource library is proposed to be used for live video stream capture and image matching. For Parallel processing

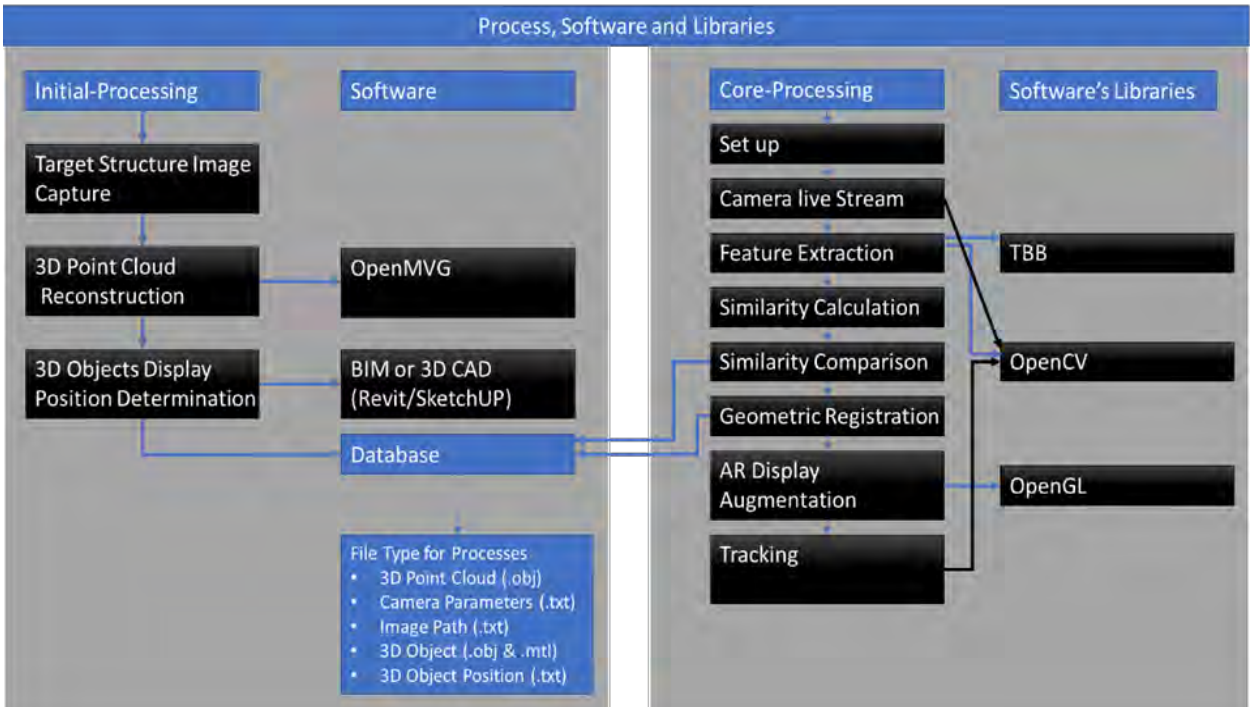

Figure 6. Shows the process, Software and Libraries required for the system

library Threading Building Blocks (2019 Update 8) was used. For Drawing 3D models on the AR display FreeGULT(Version freeglut 3.2.1), it is a toolkit for OpenGL (Open Graphic Library).

4 Designed System Verification Process & Limitations

The 3-step verification process for the proposed system, both the Initial-Processing and Core-Processing need to follow the set 3 steps, for the system to work properly.

Step 1: Location Information and tracking

- Tracking Route of TSSC
- Photography route of SfM
- Registration Position

Step 2: Image Matching

- Live Stream Capture & database Feature Based-Image Matching with SURF

Step 3: Augmented Reality 3D Model Super imposition

- AR Tracking while the User is Walking
- AR Display of Vector Motions
- 3D Model Augmentation

The generated data for each process needs to be saved into the database and will be utilized in the next step until the final step is completed and results are shown.

The proposed system is limited in its geometrical registration to the photography route of the temporary safety facility, this limitation can be overcome by the incorporation of addition photography routes to the TSSC. The 3DCG models face the challenge in tracking due to hand shaking, which can be overcome, by the average of the motion vectors in plural frames can be used when calculating the external parameters, this improvement will require development of new algorithms.

5 Conclusion & Future Research

This research proposes an implementable framework for Inspection of discrepancies in Construction Temporary Safety Structures through Marker-less Augmented Reality, that uses Structure from Motion (SfM) to reconstruct the 3DCG (3-Dimensional Computer Generated) models by using photographs from different viewpoints, along with feature-based image registration technology for construction safety inspection. The system if implemented can enhance the discrepancy monitoring of the Temporary Safety Structures inspection process by providing onsite visual aid of 3DCG models and allow location tracking. The system is limited to photography route and can cover additional routes. In future research, a case study would be conducted to confirm the implementation of the framework, its feasibility as an alternative and further improvements that an enhance the processes, such as blockchain based secure database management system, for the data collection of the system.

Acknowledgement

This work is supported by the Korea Agency for Infrastructure Technology Advancement (KAIA) grant funded by the Ministry of Land, Infrastructure and Transport (Grant 20SMIP-A158708-01).

The researchers would like to thank Mr. Talal Tariq, who is a software developer and Bachelor of Science in Information Technology from the University of Sargodha, Pakistan, for his support during the development of the processes stage for this research project.

E-mail: vpcharlesraj@ricssbe.edu.in, dinesh.mc18n@ricssbe.edu.in

Abstract –

Enhanced visualisation is one of the low hanging fruits of BIM implementation. It helps in improving clarity in communications and fosters collaboration & coordination of construction projects for efficient delivery. 4D BIM combines the proposed sequence of work in a project with the 3D parametric digital model of the facility to be built. 4D BIM is highly beneficial both for managing people and materials. It can revolutionise the way facilities are designed, managed and developed. Significant benefits of 4D BIM have been reported in project planning & programming/scheduling, progress monitoring, conflict prevention & resolution, data security and construction safety. 4D BIM also adds value to business by facilitating marketing and sales.

BIM has been primarily used by design & management consultants and some large contractors in India for design optimisation and construction project management. While 4D BIM has the potential to contribute for the efficient project delivery, there is limited literature on the extent of 4D BIM implementation in India. An attempt has been made to investigate the status of 4D BIM implementation in India and study the perceived benefits, barriers and drivers by key stakeholders in the construction sector using a questionnaire survey among clients and contractors.

The results revealed high levels of awareness of 4D BIM, but the usage is low. Plan for usage in the short term is also found to be low. There is no significant difference in perception between the clients and contractors on benefits, barriers & drivers of 4D BIM. *Visualizing the construction flow, Validating the time schedules by simulations* and *Communicating the construction plan* are found to be the most perceived benefits. *Lack of 4D BIM knowledge within internal workforce, Traditional project delivery methods/contract* and *Lack of 4D BIM expertise in the market* have been reported as the critical barriers. The key drivers of 4D BIM are *Government Mandate for 4D BIM* and *Awareness of 4D BIM benefits and ROI*.

Keywords –

4D BIM; Application & benefits; Barriers & challenges; Indian construction

1 Introduction

Construction is the second largest employer next only to agriculture in India and contributes significantly to its GDP. As part of its goal to become a USD 5 trillion economy by 2024, India plans to spend USD 1.4 trillion on its infrastructure in the next five years. The level of complexity of such projects is very high due to international nature in procurement as well as sophisticated client requirements. Efficient project delivery is key in successful completion of these infrastructure projects. Traditional project delivery systems focussed on the iron triangle of project performance, time, cost and scope [1]. Emerging measures such as quality, occupational health & safety and stakeholder satisfaction demand new ways of doing business. Unfortunately, despite the fact that architects, builders and manufacturers fail every day to deliver on schedule, within budget and effectively meet the needs of their customers, not many of them achieve the desired outcomes [2].

Building Information Modelling (BIM) provides a platform for the stakeholders to work collaboratively under a common data environment for better efficiency and results [1]. Global construction projects are evolving day by day, demand for resources is growing, so there is a rising need for a sustainable process for construction scheduling to complete the projects on time within stipulated budget [2]. Design information 3D model can be used for construction planning, where time is added to the model, which is known as 4D BIM. 4D BIM improves the efficiency by reducing wastes and helps in timely completion of projects within budget by controlling the construction schedule and adds value to customers [3]. Despite the potential, it is reported that 4D BIM is not quite widely used by the construction project stakeholders. Hence, it is proposed to assess the extent of usage and understand the perspectives of key stakeholders on benefits, barriers and drivers of 4D BIM [4].

2 Literature Review

Due to increase in the complexity in projects over time, construction planners are being asked to deal with more responsibility and they play a more critical role in built

environment. Gantt chart was developed by Henry Laurence Gantt in 1910 to schedule, coordinate and track the construction sequence over time. It has become the most used scheduling strategy in conjunction with improved techniques [5]. Later, schedulers understood the importance of critical activities and relations among activities, adopted critical path method (CPM), Program Evaluation and Review Technique (PERT) and many more concepts with the help of scheduling software like Microsoft project, Primavera, AstaProject, etc. to create and update schedules by allocating required resources. Traditional methods and today's scheduling software are not directly linked to design or building model [5].

Complex and large projects have different levels of planning like quarterly, monthly and weekly. Effective communication plays a major role in construction planning and guides the projects by facilitating planning & scheduling of the construction works to complete the projects and meet project objectives that include emerging performance measures [1]. Lack of communication will have immediate consequences like rework, non-uniformity, and misapplication of resources which increases the construction time and cost [6].

2.1 4D BIM

4D BIM allows planners to communicate visually and to schedule activities in time and space by linking of construction plan to the 3D model [7]. 4D BIM provides time-related information that is combined with various components of an information model for a specific item or work area that could include specifics of its design and deployment lead time [5]. The information contained in this model also contains the production rate that can be used to help assess the schedule and configure the activities by considering their position and production rate [8].

2.1.1 Project Planning using 4D BIM

Construction planning involves scheduling and sequencing activities in time and space by taking to account available resources, constraints, and other concerns in the process [5]. Traditional methods such as bar charts and the CPM do not consider the spatial configuration associated with these activities. Scheduling is therefore a complex manual job and often does not fully synchronise with the design and makes it difficult for the project stakeholders to easily understand the plan and its impact on the management of site logistics [9]. 4D planning is an extended and deeper version of conventional planning that develops the construction planning to a higher level of detail to provide greater accuracy and less risk. 4D models are also helpful in speeding up the construction process, thereby reducing mistakes and easily eliminating them [7].

To build 4D BIM model, 4D tools requires 3D model from BIM authoring tool and the construction schedule data from scheduling tool. Both the 3D model and construction schedule data are imported into the 4D tool. Then, the scheduler links the “components from the 3D model to the construction activities from the schedule and forms a time-based 4D BIM model [8].

Simulation provides significant guidance and early detection of mistakes in preparation. Instead of making layout mistakes later in the construction phase and trying to fix on-site issues that can be very costly, errors can already be avoided in the design phase [10]. The information that is obtained from the process will be quite large in the early stages by involving all stakeholders and should be collected in depth as the project progresses. It is important to note that 4D BIM refers to a specific way to link data to a knowledge model. The 4D model can be simulated with 'n' sequence number and can make as many changes as possible, and finally created with appropriate 4D sequence simulation [2].

The expertise of contractors is very critical when designing a 4D model for planning processes. If the model is built during the building's design phase, then the contractor can provide valuable feedback on buildability, estimated cost of construction, and sequencing. Also, 4D process planning simulations serve as a communication tool to identify potential bottlenecks and methods to improve coordination between project teams [11].

2.2 Benefits of 4D BIM

4D BIM offers an enhanced vision for planning, constructing and designing, sustaining or developing uniform information model that includes all the relevant information on the life cycle of the project. 4D modelling plays a major role in coordination between planners and customers during the planning phase. This helps project stakeholders spot issues in the construction phase and keep track of progress [5,6]. 4D BIM application helps to build virtual project and stimulate with different scenarios, which give all the stakeholders a better picture to identify the risks in the project at early stage and mitigate those risks by taking corrective measures.

The following key benefits and applicability of 4D BIM have been reported. Visualizing the construction progress at any time with clear look-ahead presentation [6]; Logistics planning (resources flow with in the construction site) [6,14]; Site layout planning (Reduces field interferences which may occur during the execution process, thereby improving the buildability) [6,15]; Location based planning; Clear understanding of the construction process and Construction methodology studies [6]; Validating the time schedules by simulations; Work progress meeting discussions through video for better understanding [16]; Safety planning (Visual representation of the hazards and the safety plan.) [6,18]; Documentation and claim analysis (Pretty easy to prove

who is responsible for the delay and what potential results are anticipated) [19]; Reduction of risk in the project [6]; Enhanced customer satisfaction [6]; Design investigation with schedule simulations which aid to reduce the amount of rework required [6].

2.3 Barriers to 4D BIM Implementation

Despite of benefits that 4D BIM provides to construction industry, still there are few technical and non-technical barriers which are hindering the widespread diffusion of 4D BIM [5]. The extensive adoption of 4D BIM and BIM has more influence on non-technical barriers than on technical barriers. Construction industry realized the value of BIM to an extent and started using it in design phase but BIM usage in production phase for construction planning is growing at slow rate.

Elghaish & Abrishami [20] and Zou et al. [21] reported *challenges related to developing 4D model (model scope, level of detail, temporary components, decomposition and aggregation)* and *lack of proper execution plans, guidelines and standards to follow* as barriers to 4D BIM implementation. Zou et al. [21] also reported *not worth time investment to learn* and *lack of time for employees to learn* as barriers. *Lack of 4D BIM expertise in the market, lack of standards for 4D BIM, difficulty in understanding 4D BIM methods* and *lengthier process of 4D BIM creation* have been reported by Kassem et al. [22]. Kassem et al. [22] and Ahmed et al. [23] identified the following barriers: *lack of demand from the client side to use 4D BIM, high costs to invest in software, high costs for training, lack of 4D BIM knowledge within internal workforce, employee resistance to change from traditional construction planning practices to 4D BIM, traditional project delivery methods/contract,* and *problems with exchanging data between software/Interoperability*.

2.4 Summary

There is a disconnect between the traditional design & planning methods and contemporary planning & scheduling tools. Construction industry realized the value of BIM to an extent and started using it in design phase but BIM usage in planning & production phases is growing at slow rate. Gledson and Greenwood [6] investigated the benefits and applications of 4D BIM in the context of the United Kingdom. Kassem et al. [22] and Ahmed et al. [23] reported the barriers to 4D BIM implementation in the United Kingdom and Qatar respectively. Although 4D BIM has the potential to contribute for the efficient project delivery, it has been observed that country-specific studies have been reported only for UK [6,22] & Qatar [23] and no study has been reported on the extent of 4D BIM implementation in the Indian context. Hence, there is a need to investigate the status of 4D BIM implementation in India and study the perceived benefits & barriers by various stakeholders in the construction sector. An attempt has been made to investigate the extent of 4D BIM usage, perspectives of key stakeholders on 4D BIM in terms of benefits, barriers and drivers in Indian construction.

3 Research Methodology

Identification of various indicators for benefits, barriers and drivers of 4D BIM is done through literature review. BIM functions are used to assess the applicability and benefits. Indicators used in the study are presented in Table 1.

Questionnaire survey-based quantitative approach is used to study the perspectives of the construction professionals on the applicability, benefits, barriers and drivers of 4D BIM.

3.1 Design of Experiment

Target population for this study are clients and contractors in Indian construction industry. Convenient sampling method is used for the selection of respondents.

A questionnaire survey instrument has been developed and deployed online for the survey. This questionnaire is divided into 6 sections, Section 1 contains cover note and a small video on 4D BIM, Section 2 is used to collect the demographic information of the participant and next four sections have questions on applicability of 4D BIM; 4D BIM's perceived benefits over conventional construction planning approaches; Barriers and challenges of 4D BIM adoption; and drivers/solutions for 4D BIM adoption.

Descriptive statistics is used for data analysis. Relative Importance Index (RII) is used to rank the indicators to understand the relative importance as perceived by the respondents [6,23]. *T-test* is used to check the statistical significance of the perceived differences between clients and contractors, if any. Cronbach Alpha is used for internal consistency and data reliability for analysis [6,23].

4 Data Collection and Analysis

The questionnaire instrument is deployed on Google Forms and the enquiries are sent to over 100 prospective respondents (clients & contractors) through Email, LinkedIn, and over phone. There are 38 valid responses received, which includes 17 contractors and 21 clients after continuous follow-up in a span of 4 weeks. Cronbach Alpha is used to evaluate the internal consistency of the instrument and reliability of the data collected for further analysis. The calculated Cronbach Alpha values are presented in Table 2. It is observed that all the values are greater than 0.7, the threshold for social studies, and the data collected is reliable for further analysis [6,23].

Table 1. BIM functions, Barriers and Drivers

BIM Functions	
F01	Logistics planning
F02	Site layout planning
F03	Communicating the construction plan
F04	Planning the construction sequence
F05	Visualizing the construction flow
F06	Location based planning
F07	Validating the time schedules by simulations
F08	Work progress meeting discussions
F09	Safety planning
F10	Documentation and claim analysis
F11	Risk Management
F12	Design investigation with schedule simulations

Barriers to 4D BIM Implementation	
B01	Lack of demand from the client side to use 4D BIM
B02	High costs to invest in software
B03	High costs for training
B04	Lack of 4D BIM knowledge within internal workforce
B05	Lack of 4D BIM expertise in the market
B06	Not worth time investment to learn
B07	Lack of time for employees to learn
B08	Employee resistance to change
B09	Lack of standards for 4D BIM
B10	Challenges related to developing 4D model
B11	Difficulty in understanding 4D BIM methods
B12	Traditional project delivery methods/contract
B13	The lengthier process of 4D BIM creation
B14	Problems with exchanging data between software

Drivers of 4D BIM	
D01	Developing local standards for 4D BIM
D02	Government Mandate for 4D BIM
D03	Improving software functionality
D04	Good support from software vendors
D05	Awareness of 4D BIM benefits and ROI
D06	Availability of 4D BIM expertise in the market

Table 2. Reliability Statistics

Dimensions	Cronbach's Alpha	N of items
Applicability	0.912	12
Relative benefits	0.934	12
Barriers	0.852	14
Drivers	0.856	6
Overall	**0.888**	**44**

5 Results & Discussion

There were 38 valid responses, which include 17 (45%) from contractors and 21 (55%) from clients. Majority of them are from large organisations (76.3%) and others from medium (7.9%) & small (15.8%) organisations. Respondents belong to top management (34.2%), middle management (50%) and operations (15.8%) level in their respective organisations. Construction work experience of the respondents is presented in Figure 1. It can be observed that 40% of the them have more than 10 years and 26% of the respondents have 5-10 years of work experience.

5.1 Awareness & Use of 4D-BIM

It has been observed that majority (68%) of the respondents are aware of 4D BIM and have not used it and 24% are aware and used. Only a little fraction (8%) have responded that they are unaware of 4D BIM (Figure 2). This shows higher level of 4D BIM awareness and lower levels of usage. It has been attempted to understand the plan of the respondents who are aware but have not used 4D BIM. While some of the respondents indicated that they have plans to use 4D BIM in near future (11% within a year & 31% in 1-3 years), a significant 58% of respondents have plans to use 4D BIM after three years only (Figure 3). This implies anticipated lower adoption of 4D BIM in the short run.

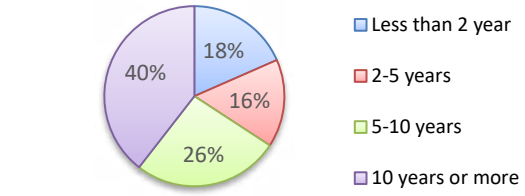

Figure1. Work experience of respondents

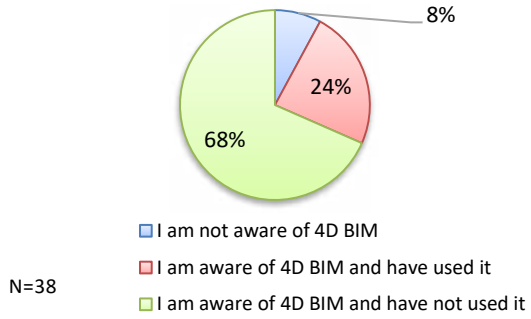

Figure 2. 4D BIM awareness and usage

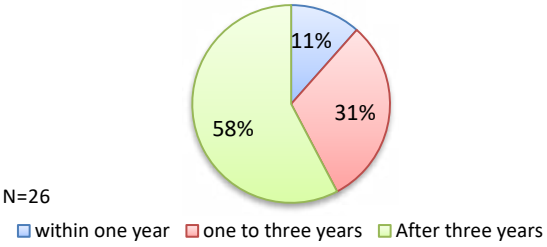

Figure 3. Plan to use 4D BIM

5.2 Applicability of 4D BIM

The participants were asked to provide their opinion on the applicability of 4D BIM by on a five-point Likert scale (Not at all Applicable to Highly Applicable) against various BIM functions as found in Table 1. The frequency distribution of responses as well as RII are presented in Figure 4. It can be noticed from the pattern of responses that the respondents have rated 4D BIM as highly applicable. Among the BIM functions *Visualizing the construction flow (F05), Communicating the construction plan (F03)* and *Validating the time schedules by simulations (F07)* have been found to be the most preferred application of 4D BIM. Even though *Site layout planning (F02)* and *logistic planning (F01)* have been ranked low, they are still very much applicable. In addition, clients have rated *Design investigation with schedule simulations (F12)* very much applicable.

5.3 Relative Benefits of 4D BIM

In response to the question on benefits & usefulness of 4D BIM, the participants rated various BIM functions as found in Table 1 on a five-point Likert scale (Not at all Beneficial to Highly Beneficial). The frequency distribution of responses as well as RII are presented in Figure 5. It can be noticed that the response pattern is similar to the applicability above. *Visualizing the construction flow (F05), Communicating the construction plan (F03)* and *Validating the time schedules by simulations (F07)* have been rated as top benefits of 4D BIM. However, clients perceive that *Design investigation with schedule simulations (F12)* is more beneficial compared to *Communicating the construction plan (F03).* Again, high scores of RII for other indicators reveal the highly beneficial in nature of 4D BIM.

5.4 Barriers to 4D BIM Implementation

The respondents perceive that *Lack of 4D BIM knowledge within internal workforce (B04), Traditional project delivery methods/contract (B12)* and *Lack of 4D BIM expertise in the market (B05)* as the top barriers for the adoption and use of 4D BIM in Indian construction (Figure 6.). This is in response to a question on barriers on a five-point Likert scale of Agreement. *Not worth time investment to learn (B06)* and *Lack of time for employees to learn (B07)* have been rated low as barriers.

5.5 Drivers of 4D BIM

Drivers are key for improved adoption. In response to a question on drivers of 4D BIM on a five-point Likert scale (Very Low to Very High), the respondents rated

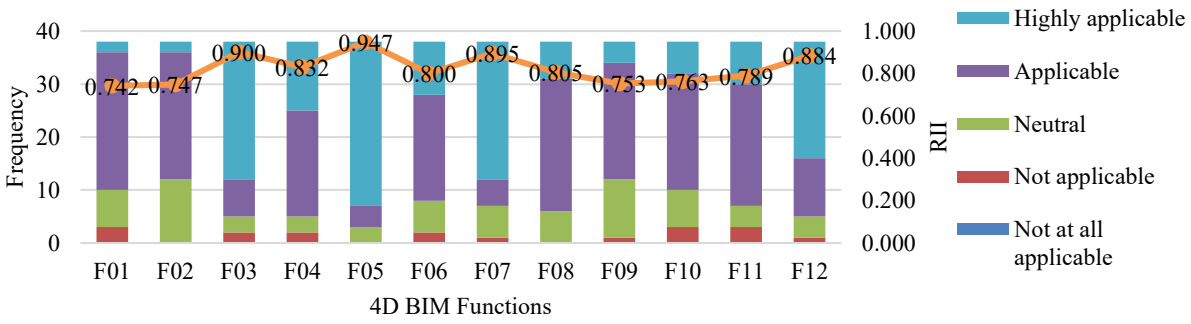

Figure 4. Applicability of 4D BIM

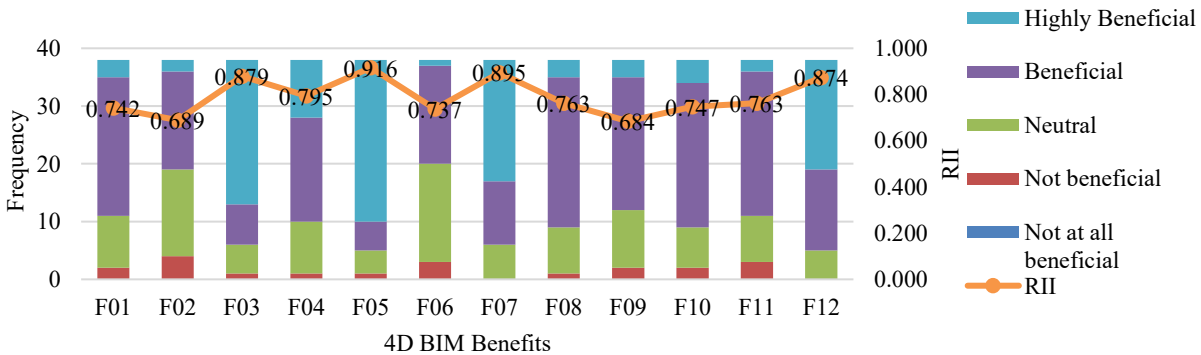

Figure 5. Benefits of 4D BIM

Government Mandate for 4D BIM (D02) as the top driver (Figure 7). Along with D02, *Awareness of 4D BIM benefits and ROI (D05)* and *Availability of 4D BIM expertise in the market* (D06) are also perceived as top drivers for 4D BIM. It can be noticed that *Good support from software vendors (D04)* has been rated lowest.

5.6 Hypothesis Testing

While there has been general agreement among the clients and contractors on their responses with few exceptions, it has been attempted to test this statistically to ensure that this is not by chance. The independent t-test is a statistical test that is used for difference in means [14]. Also, t-test is applicable when there are only two groups to be compared and sample size is very low.

The following hypotheses are tested using t-test for two independent sample assuming equal variance at 5% significance level.

Null hypothesis H0: *There is no significant difference in perceptions of clients and contractors on applicability, benefits, barriers and drivers of 4D BIM in Indian construction.*

Alternate hypothesis H1: *To test the null hypothesis, there is significant difference in the means of Clients and Contractors on applicability, benefits and barriers of 4D BIM functions in construction industry.*

The test results are presented in Table 3. As p-value for all the four variables are greater than 0.05, there is no sufficient evidence to reject H0 and hence H0 is accepted. It implies that the there is no significant difference in perceptions of clients and contractors on applicability, benefits, barriers and drivers of 4D BIM in Indian construction.

Table 3. Results of t-test for null hypothesis

Variables	p-value
Applicability	0.134
Benefits	0.707
Barriers	0.367
Drivers	0.132

However, at indicator level, a statistically significant difference in perception is observed for the barrier, *Lack of time for employees to learn (B07)* between the clients and contractors.

5.7 Discussion

It is indeed an encouraging revelation that there is high level of awareness of 4D BIM in Indian construction. But the challenge is to convert this into adoption and

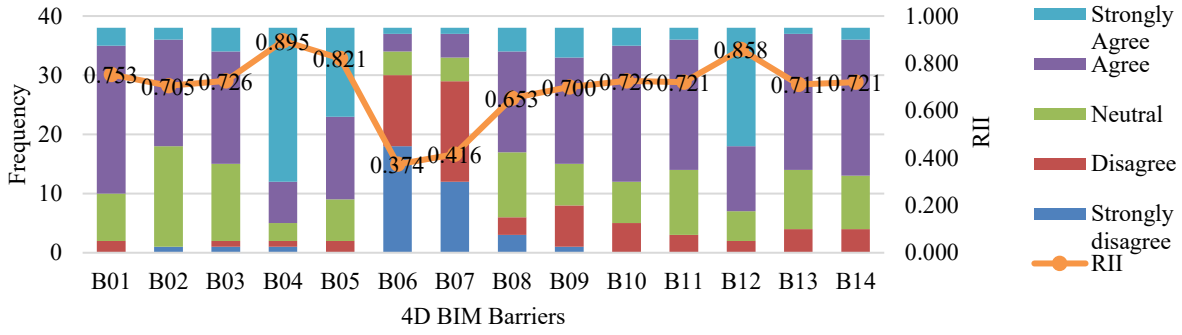

Figure 6. Barriers to 4D BIM implementation

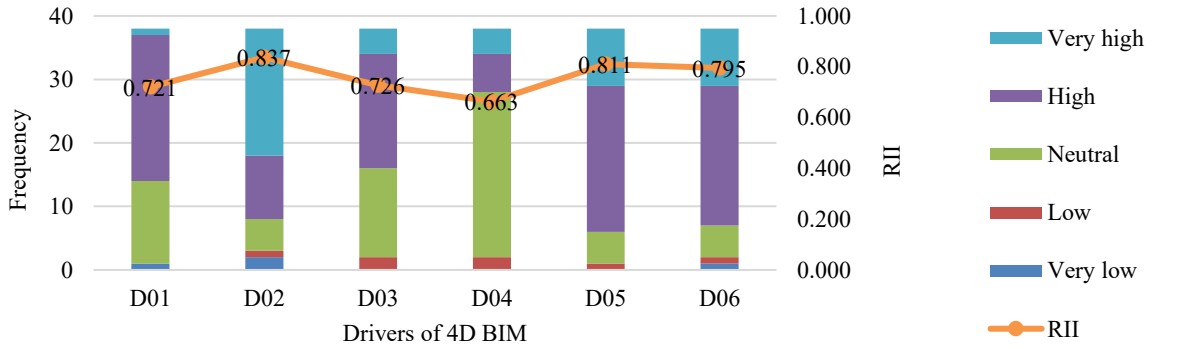

Figure 7. Drivers of 4D BIM

implementation [6]. Despite increased awareness, willingness to use 4D BIM, preferably after three years is not so encouraging. In order to keep up with the global competition as well as to meet the growing demand for infrastructure in India, there is a significant need to embrace 4D BIM sooner than later in Indian construction.

Responses to the application and benefits of 4D BIM *(F05, F03, F07 & F12)* emphasise the need for enhanced visualisation for communication and improved schedule performance. Capacity and capability building through education and training is key to realise these expectations/benefits. This also point towards the digital transformation of construction business in India [2]. Clients focus on *Design investigation with schedule simulations (F12)* over *Communicating the construction plan (F03)* showcases the change in priority of clients to quality designs & timely delivery [24].

It is also important to look at the barriers to 4D BIM adoption. *Lack of 4D BIM knowledge within internal workforce (B04)* calls our attention to training and continuous professional development within the organisations. To overcome the barrier, *Traditional project delivery methods/contract (B12),* innovative procurement methods such as Integrated Project Delivery (IPD) and Smart Contracts with the help of Block Chain can be explored. *Lack of 4D BIM expertise in the market (B05)* demand for educational institutions to relook at the curriculums to ensure that the students graduate with digital skills that are necessary [25]. As *Not worth time investment to learn (B06)* and *Lack of time for employees to learn (B07)* have been rated low as barriers, it seems that the organisations and its employees have mentally prepared to embrace this change.

A closer look at the drivers for the 4D BIM in India reveals that *Government Mandate for 4D BIM (D02)* requires immediate attention. At present, there is no official mandate from the government(s) in India for the use of BIM in construction projects. Other top drivers, *Awareness of 4D BIM benefits and ROI (D05)* demands need for more use cases from India and *Availability of 4D BIM expertise in the market* (D06) points towards education & training for upskilling that shall ensure the supply of talent [24].

It has been observed that the top benefits of 4D BIM identified in India are in line with the UK study [6] except for *logistics planning* (F01) that was rated high in UK. Non-technical barriers such as inefficiency to quantify the tangible benefits and lack of awareness by stakeholders were reported as the critical barriers in UK. In the context of Qatar, in addition to the barriers identified in UK, non-availability of skilled professionals was also found to be critical. In India, use of traditional project delivery methods and lack of demand by clients have been identified as top barriers for 4D BIM adoption in addition to lack of awareness and expertise in 4D BIM.

6 Summary and Conclusions

An attempt has been made to investigate the adoption and implementation of 4D BIM in Indian construction through survey research. The study aimed at assessing the extent of 4D BIM adoption and capture the perceived benefits, barriers and drivers for 4D BIM. The target population for this study was the clients and contractors in Indian construction. One third of the participants responded to the survey and the general pattern in the response revealed that there is high level of awareness on 4D BIM among the clients and contractors in India. Also, most of them plan to use 4D BIM later (after three years) than sooner. It has been found that there is no statistically significant difference between the clients & contractors on their responses.

Visualizing the construction flow (F05), Communicating the construction plan (F03) and *Validating the time schedules by simulations (F07)* have been found to be the top benefits of using 4D BIM. The perceived top barriers for 4D BIM are: *Lack of 4D BIM knowledge within internal workforce (B04), Traditional project delivery methods/contract (B12)* and *Lack of 4D BIM expertise in the market (B05)*. The study also revealed that *Government Mandate for 4D BIM (D02), Awareness of 4D BIM benefits and ROI (D05)* and *Availability of 4D BIM expertise in the market (D06)* are the key drivers for 4D BIM in India. Innovative procurement systems, smart contracts, reinvention of construction education and capacity building & capability development through training can address the changing needs of the clients and contractors for enhanced value creation.

Considering the relatively smaller sample size, the confidence on the conclusions drawn is limited. A wider study among the clients and contractors with increased sample size may reveal greater insight. It is also worth investigating the role of enhanced visualisation for communication in improved schedule performance. Studies on capacity building & capability development would facilitate strategies for supply of necessary talent. Also, the present curriculum in built and natural environment courses may be relooked at to keep up with the demand for digital skills. Policy studies to support government decisions on mandating 4D BIM would be desirable for a roadmap.

An Information Quality Assessment Framework for Developing Building Information Models

L.J. Chen[a] and Justin K.W. Yeoh[a]

[a]Department of Civil and Environmental Engineering, National University of Singapore, Singapore
E-mail: ceecl@nus.edu.sg, justinyeoh@nus.edu.sg

Abstract –

Information Quality Assessment (IQA) is an important, but often overlooked aspect, of the Building Information Modeling (BIM) process. Models with information quality issues, such as incomplete and incorrect information, may cause rework during the design process if detected early. Otherwise errors may propagate downstream, leading to significant cost consequences to stakeholders in the Architecture, Engineering and Construction (AEC) industries. Current approaches of IQA show significant efforts on addressing information completeness issues but are limited when addressing information correctness. Greater understanding of the features of these quality issues is necessary to begin to detect these issues. This paper addresses this problem by proposing an IQA framework that incorporates three identified features: IQ Dimensions, Arity and Data Characteristics. From this framework, 3 classes of algorithms are further defined to detect these features. A validation test was conducted against current modeling guidelines used for BIM quality assurance in both architectural and structural disciplines. The results indicated more than 80% of the rules were able to be categorized using the framework. Guidelines that were not categorized included those that were overly ambiguous, or did not directly involve BIM. The outcome of the paper will enable BIM managers to ensure a fit-for-purpose, quality assured model that can reduce rework, and engender greater trust in the model creation process.

Keywords –

Information Quality Assessment; Features of Quality Issues; Building Information Modeling

1 Introduction

Building Information Modeling (BIM) simulates the construction project in a virtual environment. It provides a platform for collecting building-related information and allows information collaboration between different disciplines [1]. Due to its information-centric characteristics, models with poor information quality may cause significant cost consequences and rework [2][7]. Thus, Information Quality Assessment (IQA) for BIM is essential for stakeholders in the Architecture, Engineering and Construction (AEC) industries to realize the full benefits of BIM.

However, quality assessment is still a crucial and challenging task in BIM project delivery processes. Current ways of auditing for model quality control are manual, and usually involves visual checking of the model [8][9] or comparisons using check lists [6][7]. Such auditing processes tend to be time-consuming and difficult to avoid errors. Other than the tedious process of manually checking the models, there is still a lack of a general framework for defining some information quality criteria such as information correctness or accuracy. This consequently causes ambiguity, and difficulties in identifying model quality issues may arise [3]. Hence, implementing a quality assurance process for BIM requires a significant amount of time and effort from qualified personnel, and despite best efforts, may still lead to errors that may propagate to downstream activities, causing unnecessary rework during design. This then may lead to significant cost consequences to stakeholders. The aforementioned challenges may explain why IQA is often overlooked in the BIM process.

The objective of this paper is to propose an information quality assessment (IQA) framework, by identifying three sets of features related to the IQ dimensions of completeness and correctness, arity, as well as data characteristics. Specific algorithmic approaches can then be identified to detect the model quality issues. Section 3 describes the proposed framework, and section 4 describes the algorithm classes in detail. Validation of the proposed IQA framework is then carried out on a set of BIM modeling guidelines/ quality assurance requirements laid out in the Singapore BIM Guide [7].

2 Literature Review

The information contained within BIM should be

complete and correct to support different BIM use cases such as structural analysis, cost estimation and quantity take off [5]. Therefore, the assessment of BIM information quality is essential to evaluate whether the model is fit-for-purpose. In the following section, a review of the literature will be conducted to show current research efforts on BIM quality assessment.

- **IQ frameworks and quality issues in BIM:** Information Quality (IQ) dimensions help to categorize and identify model quality issues. However, the ambiguity in characterizing IQ dimensions exists in current practice of information quality assessment (IQA) [3]. There is a lack of a general consensus regarding the identification of information quality dimensions as well as an agreed-upon taxonomy of information quality issues. Berard [8] evaluated building design information from 8 quality dimensions: relevance, consistency, correctness, precision, availability, distribution, flexibility and amount of information. Zadeh et al. [9] analyzed facility information quality focusing on information incompleteness and well-formedness. Wang et al. [10] developed a model fitness system to evaluate model quality based on information inconsistency. The differences in IQ dimensions between different studies arise due to the different considerations arising from differing BIM uses. For example, the quality issues such as incorrect placement of model elements and inconsistent naming of attributes are more important during the design collaboration process [10]. On the other hand, during construction management, model information such as scheduling and fabrication type are more important to ensure correct quantities are obtained [11].
- **Information completeness:** Although significant ambiguity exists in current IQA practices, information completeness is one of the most consistently mentioned IQ dimension in the literature [9]. There have been a few of research efforts on checking information quality arising from information completeness. Early studies show that manual checking methods such as using checklists [6][7][12], visual checking [5] and photo-analysis [4] were applied to check for missing information in models. BIM applications such as Solibri Model Checker and iTwo are available to detect missing attributes in building elements. However, a review of previous studies shows that a systematic framework for checking information completeness in BIM has not been discussed widely, and constitutes a research gap to be addressed.
- **Information correctness:** Correct information is vital to fulfil the purposes of building information modeling. It plays a critical role as an IQ dimension in the IQA framework. However, information correctness is a concept with widely varying definitions and meanings. Zadeh et al. [9] discussed information correctness issues as inaccuracy of model attributes specifically for facility management. Berard [8] described correctness as "extent of missing, incorrect outdated design information".

  This inconsistent definition of correctness makes detection and validation of incorrect information in models a difficult problem to solve. Kulusjärvi and Heikki [12] described information correctness checking as "to compare and measure information contained in a BIM against reference information". This reference information can be related documentations, or physical reality [3]. In general, this literature review shows that methods to perform correctness checks are limited to visual checking and use semi-automated ways [9][13].
- **Information Delivery Manual (IDM) and Model View Definition (MVD):** In the study of information systems, the quality of information is a characteristic that should be checked against the information consumers' requirements [14]. Analogously, the aforementioned has been adapted for use in BIM: A good quality model is one with useful information specified by BIM users that is fit-for-purpose. During the BIM development process, model information is typically exchanged downstream for different BIM uses. The current best practice is to specify these exchange requirements in the Information Delivery Manual (IDM). This is a standard methodology for BIM users to specify the information required in BIM for different scenarios [15].

  The current implementation of IDM is to represent information exchange requirements in the format of paper-based documents [16]. Based on the exchange requirements, Model View Definitions (MVDs) would be developed to streamline information specific to the BIM use. However, MVD itself does not guarantee whether the data extracted from model is correct or consistent. Validation still needs to be carried out to check if it conforms to the information constraints or rules specified in exchange requirements [17]. Several research efforts have been made on the development of MVDs from IDM specification [16][18], however the validation of the exchanged information is still an open research question.

3 IQA Framework

The components of the proposed framework for information quality assessment (IQA) of building

Table 1. The proposed framework for information quality assessment

IQ Dimensions	Arity	Data Characteristics	An Example of Quality Issue	Algorithm Classes
Completeness	Element level	Geometry Attributes	Missing and incomplete attributes	class 1
		Non-geometry Attributes	Missing and incomplete attributes	class 1
	Model level	Element	Duplicated elements	class 3a
			Missing elements	class 3b
Correctness	Element level	Geometry Attributes	Length of analytical wire is zero	class 1
		Non-geometry Attributes	Physical-analytical model distance exceeds tolerance	class 2
	Model level	Element	Interference clashes	class 3a
		Relations	Elements are not connected	class 3a
			Mismatch between mapping files in different BIM applications	class 3b

information models (BIM) are as shown in Table 1. The objective of this framework is to categorize quality issues from the perspective of the information requirements of the model. Three features of quality issues are identified: IQ dimensions, Arity and Data Characteristics. Subsequently, specific IQA scenarios may be defined using these three features, and consequently classes of algorithms can be identified to address the quality issue raised. Specific examples of such quality issues are provided in Table 1 as well, where these are common issues faced by experienced structural engineers and BIM managers in actual projects.

- **Information Quality Dimensions:** In the proposed framework, information completeness is defined to mean an element must have complete attributes and values, or a model must contain all relevant elements. In other words, incomplete information refers to missing or incomplete attributes or values in the element or missing elements in the model that should exist according to the design scheme.

  For information correctness, this framework considers elements or models that contain incorrect information such that when they are passed downstream, it affects the performance of the model. For example, a model may contain complete information for structural analysis but if the information is incorrect, then during structural analysis, this may result in incorrect analysis.
- **Arity:** The proposed framework recognizes that quality issues on information completeness and correctness can exist on two levels: on single elements (or a single group of multiple elements) and on a model level. This framework refers to this IQ dimension as its arity. To categorize the arity of these issues clearly, this framework refers to these as Element Level issues and Model Level issues, respectively.

  Information quality on element level focus on the data quality in a single element (or a singular group of elements). This means that some values of the attributes or properties in a specific element in BIM will be checked.

  Model level quality issues refer to issues that exist between multiple elements. In this scenario, the quality auditing task here may involve the checking of the relationship between multiple elements or the existence of several elements in a model.

  One difference between element level and model level issues is the source of information to be checked. In the element level, checking can be done by using information from within a single element, such as the attributes or parameters. While in the model level, checking is performed successfully only when the information from multiple elements

are available and, in some cases, data outside BIM maybe required for checking.

From the viewpoint of quality control, dividing IQ issues into element and model level is an important feature to distinguish the specific IQA scenario. These scenarios are important to identify the appropriate algorithm approach to use.

- **Data Characteristics:** Data characteristics refers to the type of data. From the perspective of data characteristics, this framework considers the following:

1. **Geometry attributes:** properties showing geometry information of physical elements;
2. **Non-geometry attributes:** properties showing non- geometry information of physical elements;
3. **Element:** physical elements in the model;
4. **Relations:** relationships between physical elements;

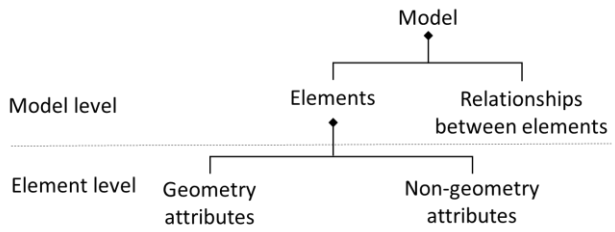

Figure 1. Model Hierarchy

In the model hierarchy shown in Figure 1, "Model" refers to the building information model, and this resides on the highest level. Elements in the model and the relations between these elements are child entities that lie on the second level. Attributes contained within the elements are on the lowest level. Both geometry and non-geometry attributes exist in the element level while existence of the element and the relations between these elements lie on the model level. As IQ issues may arise from different circumstances, issues caused by element attributes can be considered as element level issues and corresponding algorithms can be devised to check this kind of issues.

- **Quality Issues:** In Table 1, examples of common quality issues are listed for different IQA scenarios arising from the structural analysis BIM use. These were identified by experienced engineers and BIM managers in real-world BIM projects. The quality issues mentioned in this framework are categorized according to the features of IQ dimensions, arity and data characteristics. By identifying the features of these quality issues, general approaches for algorithms to detect such quality issues can be developed.

4 Algorithm classification for different IQA scenarios

From the features identified in the framework of Table 1, three classes of algorithms were developed to provide guidance for information quality assessment. Each class of algorithm provides a general approach to detecting the quality issue.

The three classes of algorithms are described in more details below. The description for each algorithm class is also summarized in Table 2, and it is organized by introducing the flowcharts for each algorithm, its features and the IQA scenario it is applied to. Examples are given to illustrate how the assessment can be conducted using the algorithm classes.

- **Class 1 -- Algorithm to check explicit data in a single element:** This class of algorithm can check the explicit data such as values attributes or properties in a single element. Here "explicit data" means the data can be accessed from element directly without any calculations or derivation. It can be applied to check quality issues on information completeness and correctness on element level.

  The procedure of using this algorithm class for checking model information starts from collecting target elements and then examining the specific attributes values for each element. Examples are given here to show how this class of algorithm can be applied to checking model quality issues in two IQA scenarios. When checking information completeness, the algorithm checks whether a specific attribute for an element is missing or the value of the attribute is null. The correctness issues are limit on checking data which are numerical or from string type. When checking correctness issues, it checks whether the value of attributes is within a predefined scope (numerical data) or corresponds with a specific value (string data).
- **Class 2 – Algorithm to check implicit data in a single element:** Checks are based on the implicit data which requires further calculation or derivation from explicit data existing in a single element. This class can be applied to check quality issues on information correctness on the element level.

  The procedure of using class 2 algorithm is very similar to that of algorithm class1, but more complicated with an extra step of calculating the implicit value for the element. Therefore, the function of checking information correctness here is limited to check whether a numerical data is within a predefined scope.

Table 2. Summary of algorithm class

	Algorithm Class 1	Algorithm Class 2	Algorithm Class 3a	Algorithm Class 3b
Description	To check explicit data in a single element	To check implicit data in a single element	To check between multiple elements with native data source within BIM	To check between multiple elements with external data source outside BIM
IQA Scenarios	Information completeness on element level; Information correctness on element level	Information correctness on element level	Information correctness on model level	Information completeness on model level; Information correctness on model level
Flowchart or Conceptual Schema				
- **Class 3a – Algorithm to check between multiple elements with native data sources within BIM:** This class of algorithm checks information involving multiple elements inside BIM. Checks focus on information correctness issues on model level. Since this class of algorithm checks between multiple elements, it is important to specify the relationship and sequence of elements to be checked. Therefore, a concept shown in Figure 2. specify the "primary and secondary" elements to be checked in this scenario.

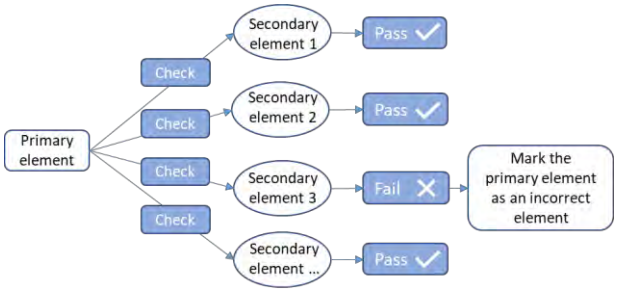

Figure 2. Schematic of checking between primary and secondary elements

The identification of these two element groups depends on what specific quality issues needs to be check. For example, in connection checks, the primary element may be any object which can be connected to other elements. Then the secondary element will be the one close enough to the primary element. During the checking process, primary elements will be collected in the first round. Then in the second round, secondary elements will be collected for each primary element. Checks will be proceeded by obtaining information based on data from the primary element and its secondary elements. Connection checks require the information such as distance between two nodes from different elements. In this case, coordinates of all nodes from both primary and secondary elements will be collected and be used to calculate the distances. The number of checking results depends on the number of secondary elements and if there is at least one result showing two elements did not pass the check. This primary element will be considered as an element with quality issues.

In this algorithm class, checking correctness issues involve the identification of numerical data derived from BIM.

- **Class 3b – Algorithms to check between multiple elements with external data source outside BIM:**
Class 3b requires external data source outside BIM to perform checks. Such algorithms can be applied to check information completeness and correctness on model level. One example can be checking whether there is any missing element in the model. In this case, external data such as 2D CAD drawings may serve as reference information.

Due to the generic nature of procedure, a conceptual schema was given for the instructions of implementation of class 3b algorithms.

5 Validation and discussion

To test the validity of the proposed IQA framework and the algorithm classes derived, the framework was applied to current guidelines for BIM quality assurance. The validation was applied against a set of rules for quality assurance given in Singapore BIM Guide [7]. Both architectural and structural BIM elements were considered in this evaluation. Each rule would be classified according to the specific IQA scenario as well as its corresponding algorithm class. Then the algorithms would be applied to check quality issues against the rules.

A validation set consisting 30 rules from both architectural and structural BIM modeling guidelines was identified and tested on. The applicability rate of the proposed IQA framework to each BIM discipline was calculated (seeing Equation (1)).

$$R_a = \left(1 - \frac{N_u}{N_t}\right) \times 100\% \quad (1)$$

R_a – Applicability rate (%)
N_u – Number of rules categorized to unknown
N_t – Total number of rules tested

The results tabulated in Table 3 indicate more than 80% of rules can be classified through the proposed framework, for both architectural and structural BIM. Results from architectural BIM guidelines show a higher rate of applicability due to greater number of rules on checking spatial information.

Rules categorized as belonging to algorithm class 1 focused on checking existence and correctness of elements attributes such as ID, category, and level information. Compared with the rules in class 1, there were fewer of rules considered to be in class 2 that checks implicit data in elements. The reason can be that quality assurance in this BIM guidelines considers general cases whereas there are no statements on which specific information should be checked. Thus, it would be difficult to decide whether the information to be checked is explicit or implicit. However, in some cases, it was obvious. For example, rules involving checks on distance, areas, and coverage rate etc. were categorized in class 2.

According to the proposed IQA framework, the

Table 3. Validation results

Algorithm Classes	Algorithm Class 1	Algorithm Class 2	Algorithm Class 3a	Algorithm Class3b	Unknown	Applicability Rate, R_a (%)
IQA Scenarios	Information completeness on element level; Information correctness on element level	Information correctness on element level	Information correctness on model level	Information completeness on model level; Information correctness on model level		
Number of architectural BIM rules	6	1	6	2	2	88.2
Number of structural BIM rules	4	0	6	1	2	84.6

quality issues exist not only on element level but also on model level. The validation results demonstrate the current modeling guidelines have many rules for checking information quality on model level. These rules were categorized as class 3a which checks information correctness issues between multiple elements in BIM. Apart from checking data sources within BIM, some rules involving external information source outside BIM were included in class 3b. This indicates checking within single elements on element level is not enough for IQA. Quality issues existing between elements are also important.

Some rules were not able to be classified to any of the IQA scenarios, nor the algorithm classes. One of the reasons is that rule is worded too generally, which may cause ambiguity. For these rules containing general statements, it is not implementable with specific checking methods, nor is it possible to recommend specific instructions. Another reason observed is that some rules have a scope of checking that goes beyond the framework. For example, checking the quality of 2D drawings before exporting to BIM.

6 Conclusion

Good information quality in BIM helps owners in AEC industries realize the full benefits of BIM. Models with poor information quality may cause significant cost consequences. This paper proposed an information quality assessment (IQA) framework to systematically categorize information quality issues existent in BIM. Hence, recommendations for quality control implementation can be formulated. This framework collected quality issues on information completeness and correctness from the perspectives of data arity and data characteristics. Given these features, the quality issues were categorized into IQA scenarios, then corresponding algorithm classes were developed to check said quality issues.

The validation was conducted against current modeling guidelines used for BIM quality assurance in both architectural and structural disciplines. The results indicated more than 80% of rules were able to be categorized using the framework. Further, the rules were shown to fit the IQA scenarios and its corresponding algorithms classes. From the detailed results, it was observed there were fewer rules in class 2 than rules in class 1. This indicated that quality assurance in this set of BIM guidelines consists of general statements on which specific information could not be checked. Thus, it was not possible to determine if the information to be checked was explicit or implicit. It was also observed that there were some rules which were not able to be classified according to any of IQA scenarios. Reasons for this included that rule statement were too general, or

that the content of the rules did not focus on the model or BIM itself, going beyond the scope of this framework.

Thus, the future improvements to the framework should focus on testing more BIM guidelines for quality control to further extend this framework, as well as identifying more classes of algorithms, particularly those identified within class 3b.

In general, the proposed IQA framework is shown to be adequate to guide modeling process, as well as to provide practical guidance for implementation of BIM quality assessment. It enables BIM managers to ensure a fit-for-purpose, quality assured model that can reduce rework, and engender greater trust in the model creation process.

Abstract –

The definition of how agreed information deliveries in building projects are achieved and implemented for different objectives and use cases is always a major topic in project management. This procedure is normally specified in accordance with international standards. However, the absence of checklists, guidelines and recommendations for action leads to vaguely defined content and blurred structure of required documents at each building phase. Based on the aspects above, this paper aims to establish standard employer's information requirements (EIR) and BIM execution planning (BEP) during the life cycle of a project and build an online platform for the execution of semi-automatic checking. For this purpose, the existing EIRs and BEPs would be firstly analyzed and compared with each other as well as with other standards. Practical experience is gathered through expert interviews and workshops and complements the comparative analysis. Subsequently, the resulting requirements for EIR and BEP are presented in checklists and guidelines, which form the basis for the development of a controlling instrument. To develop an online tool, the information requirements and test criteria of this instrument are then derived from a database of process modelling from University of Wuppertal (BUW database). Furthermore, a workshop among experts was organized to collect the necessary functions of the software. Eventually, the online platform should consist of two main functions: generation of EIR files in the form of mvd XML according to various BIM objectives and use cases from the client, and the validation of the EIR by comparing IFC files from a contractor with the MVD files. The results of the checking could be BCF files or a final report as possible symbols for a successful information delivery.

Database of Process Modeling; Exchange Requirements; Information Delivery Manual; Model View Definition; Semi-automatic Checking

1 Introduction

In the construction and real estate industry there is an agreement that the highly efficient and accurate exchange of information along the life cycle of a project should be achieved. To carry out a construction project based on building information modeling (BIM), the client should firstly define the employer's information requirements (EIR). The contractors then describe how the BIM objectives and agreed information delivery are achieved and this is implemented in the BIM execution plan (BEP). This procedure is gradually becoming mandatory in different countries depending on their own specifications. For example, in Britain all projects assigned by government should approach the goal of using complete exchangeable BIM models upon common data environment (CDE) for collaboration from April 2016 [1][2]. However, the specific checklists, guidelines and recommendations for action are still missing, so that the content and structure of the necessary documents are currently not clearly defined.

In this research project, detailed information requirements and data delivery processes in BIM-based construction projects will be structured based on use cases from the database of process modelling from University of Wuppertal (BUW database). For each use case, one or more MVD files will be created based on formulated exchange requirement tables. Furthermore, a controlling instrument based on model view definition (MVD) accomplishing the automatic checking will be developed. Finally, an online platform which provides use cases and MVD templates as well as checking functions will be built and published as open resources.

2 State of the Art

To classify the topic, the preliminary work of the University of Wuppertal in the field of process databases and the current standards for information exchange are important. These areas are explained below.

2.1 University of Wuppertal database of Process Modeling

In recent years, the University of Wuppertal has built up a database for processes in the construction and real estate industry. This database is supported by a visualization based on the Business Process Management Notation. Since 2016, this database has been continuously enriched with information on the technical processes through various research projects. The focus was initially on the continuous flow of information in construction projects, answering the following questions: When (time) who (process owner) processes what (information input), after which (other applicable information), why (process goal), to what (information output)? In the course of the Building Information Modeling method, the question of "how" becomes more and more important, since it is an essential aspect of the intended automated information exchange.

The structure of the database and the flow of information with all other linked information currently consists of five levels that represent different levels of detail of the information. The essential levels for the project "BIM based information delivery controlling" are level three, which contains concrete exchange documents or files and the processes for them, and level five, which shows the concrete information requirements (EIR) for the generation of a document or the execution of a process. The structure is shown in a reduced form in Figure 1.

Figure 1. Structure of the University of Wuppertal database

The aim of the process database, which is continuously being developed, is to create the basis for an electronic transmission of information in the construction industry without media format differences. The information the database contains is based on standard processes in the German construction industry and taking into account the various project participants and areas of responsibility, thus serves as a basis for the structured exchange and verification of information.

2.2 Guidelines of BIM use cases

In the course of structuring data for processing within the BIM method, so-called BIM use cases were developed. These use cases always define a certain framework within the existing business process, which is now implemented differently through data exchange within the BIM method. In this way, all relevant exchange processes are to be successively identified, coordinated and adapted. The use cases will be part of the employer's information requirements (EIR) and thus define the contractual relationship between the client and contractor.

Currently, there is no established structure for the implementation of use cases. Within the framework of the project implementation, DIN EN ISO 29481-1 is used as a guideline, which contains information delivery manual (IDM) for building information models [3]. The basic framework for the connection of the data is shown in Figure 2.

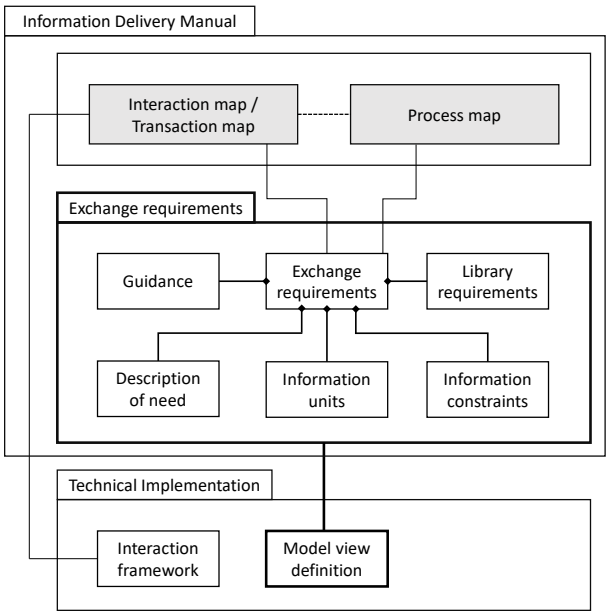

Figure 2. Part of IDM basic framework [3]

This approach is also pursued by the Use Case

Management of Building SMART International [4]. There, building SMART attempts to collect and structure use cases and make them available to the construction and real estate industry. The approach currently differs from that in this research project with the generation of a test file (MVD) being semi-automatic and not having to be carried out manually.

The research team is in close exchange with the use case management of buildingSMART International and the further ISO 29481 development, ensuring that current developments for standardizing the structure of use cases are considered in the project.

2.3 Common Data Environment

The exchange of information within projects is increasingly taking place in common data environments (CDE). CDEs thus serve as a single source of information for the collection, management, exchange and documentation of information, be it graphical information from a model or non-graphical data in various data formats. This shared data environment helps project teams to always have access to all information. To support project workflows, CDE providers offer various modules and functionalities for processing documents and data. In the course of standardization efforts, DIN SPEC 91391 "Common Data Environments (CDE) for BIM projects - Functions and open data exchange between platforms of different vendors" was developed as a first approach. It consists of the two parts "Modules and functions of a common data environment; with digital appendix" [5] and "Open data exchange with common data environments" [6].

The content of DIN SPEC 91391 is the first description of the requirements for manufacturer-independent processing of data within BIM projects. This is important for an implementation of a functioning BIM information delivery controlling in practice, because in this way it can be guaranteed that an open data exchange between different CDE's can be generally valid. A BIM use case is transferred to a CDE use case in a CDE. CDE workflows that support the semi-automatic processing and checking of data are assigned to this CDE use case.

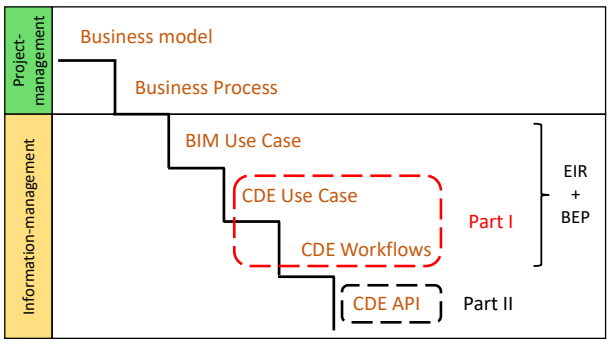

Figure 3. Process detailing from business plan to CDE workflow [5]

According to Figure 3, the areas BIM Use Case, CDE Use Case and CDE Workflow are dealt with in DIN SPEC 91391:1. while the description of the CDE API for the concrete exchange of data is given in DIN SPEC 91391:2. In accordance with DIN SPEC 91391:1, CDE's are divided into three different BIM levels, which represent the different development stages of CDE's. While the common CDE providers currently offer a BIM Level 2 CDE, which in particular provides documents, information containers or nested information containers with metadata, a BIM Level 3 CDE will in future allow direct access to model elements and attributes. The development of a BIM-based information delivery controlling can thus be part of a BIM Level 3 CDE, as it ensures that the information processing requirements of information requests are fulfilled. Accordingly, DIN SPEC 91391 will be considered within the project.

2.4 Information Delivery Manual

In order to describe the concrete information about who delivers what to whom at which point during the life cycle of a project, buildingSMART introduced the information delivery manual (IDM) standard [7]. The IDM plays therefore an important role in specifying the information requirements in tenders, contractors and for guidance in projects [8]. According to ISO 29481-1, the primary IDM components include use case, process map (PM), exchange requirement (ER) and model view definition (MVD). In this case, the user, such as the client, can generate an IDM by defining strategic goals, get machine readable file as MVD, and link IDM to different types of requirements (see Figure 4).

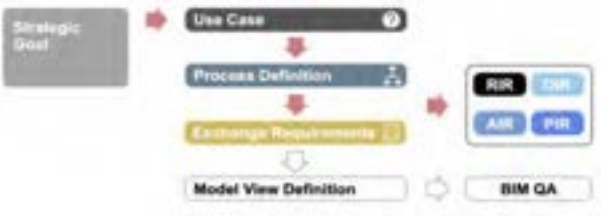

Figure 4. Process of generating IDM and its assignment to various requirements [8]

However, due to the complexity of development process, vague definition for information on exchange as well as lack of physical shared servers and administrator, it is still difficult to implement or share the IDMs under current specifications [1]. To solve these issues, the schema of idmXML is still under development and supposed to be published in ISO 29481-3.

2.5 Model View Definition

When the exchanged information in collaborative work is based on an IFC model, the corresponding partial model in accordance with exchange requirements is able to be expressed as model view definition (MVD) [7]. To allow the quickly mapping of a specific IFC element, the MVD is usually formalized as mvdXML.

The MVD file not only allows the storage of exchange information in a machine-readable format but also enables the checking of IFC files delivered by the contractor. For instance, a MVD checker based on open standard formats for structuring validation rules and BIM collaboration format (BCF) for issue reports was proposed and developed by Zhang, Beetz and Weise [9]. As most of the users are not used to XML format, software suppliers should make more effort in expressing the MVD in a user-friendly way, such as by describing the objective of data exchange [10].

2.6 Linked Data and buildingSMART Data Dictionary

By building a semantic web of data, a machine is able to trace the links between data. Thus, to promote the interoperability of various vocabularies, classification systems, ontologies, etc., the linked data, which origins from semantic web, is introduced in the field of architecture and construction [11].

For international collaboration, the buildingSMART data dictionary (bSDD) was implemented based on the structure from international framework for dictionaries (IFD) and collects tremendous terms and descriptions in multiple languages. It currently contains more than 60,000 concepts and since version 2 X 4 of IFC model serves as a central repository for standard PropertySets (PSet) extensions [12].

The bSDD database is accessable and editable with API. In this project, for example, the GET function by bSDD API is used for extracting all standardized PSets and properties and importing them into University of Wuppertal database, so that the same items would not be created twice. If some attributes or PSets corresponding to specific process in BUW database are created, it is also meaningful to POST the new items into bSDD ensuring that they could be referenced to by other users dealing with similar use case.

3 Concept and methodology

The basic concept of BIM-based information delivery controlling (see Figure 5) consists of three essential steps. Step one consists of a client using an online platform to select BIM use cases to be carried out in the project. The basis for the use cases is the existing BUW database (see section 2.1). The selected BIM Use Cases are provided for the project both as a printed version in the IDM structure and as a digital test file (MVD). In the second step, the contractor will create an IFC model that meets the requirements of the test file. This can be done in any software with IFC export. In the third and last step, the IFC model is checked on the basis of the MVD. During the check, the system checks whether information has been stored within the required fields and whether this information can plausibly describe the required attribute. The check result is returned via a BCF report and a check report.

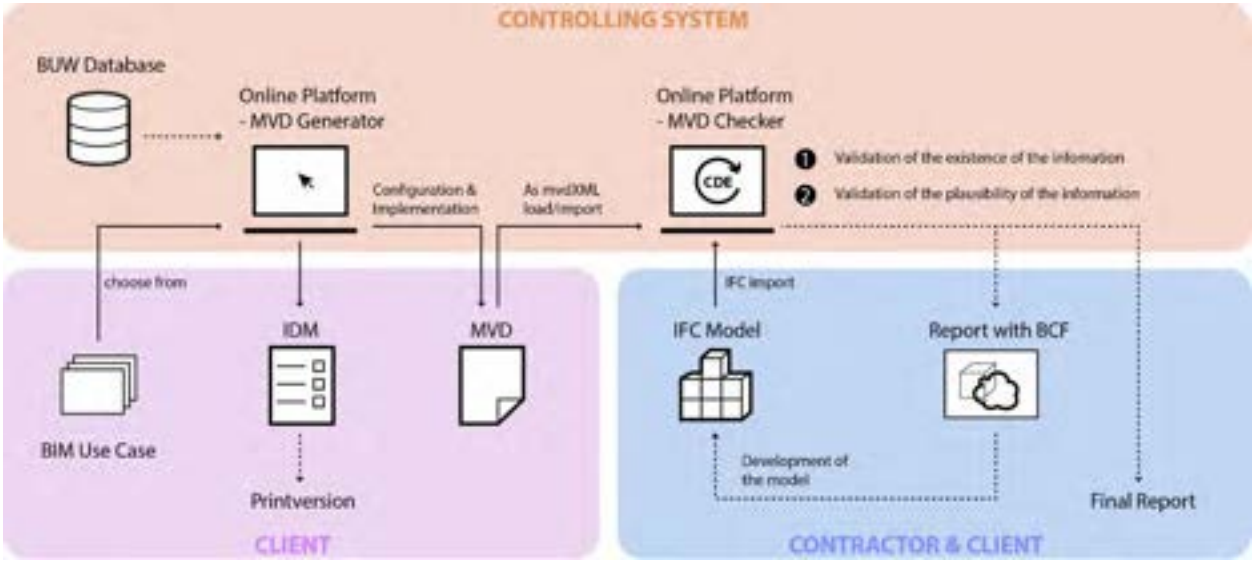

Figure 5. Concept of the BIM Based Information Delivery Controlling System

The Controlling System area is planned as a demonstrator within the project, but will fulfill the requirements for a CDE implementation (see section 2.3).

3.1 Collection of Information

Various methods are used to collect the information required to build BIM use cases. This includes a literature research, a review of existing databases (CAFM Connect, buildingSMART Data Dictionary, Use Case Management bSI) as well as the use cases of clients from BIM pilot projects in practice. In addition, the researched and newly developed use cases were coordinated with partners from industry and local authorities. The development and validation of the information is a continuous process.

3.2 Challenge IFC-connection

Besides the acquisition of information, the biggest challenge is to translate the structured information requirements into the object-based structure according to IFC or to assign the information requirements to the correct objects, generating a functioning inspection file (MVD). This relationship is shown schematically in Figure 6.

The BUW database contains the technical processes that are necessary to fulfill a construction project. The functional processes are mapped to possible objects according to DIN 276 (costs in construction), which in turn are mapped to IFC classes. The complex filtering of possible objects for a process towards a concrete object for a use case is done by building BIM use cases with level 3 processes.

The same structure can be seen in the BIM profiles of CAFM Connect, from which information is taken into account when referencing objects. In addition, the IFC Property Sets (Psets) are imported from the buildingSMART Data Dictionary (bSDD) so that they can also be used when generating the MVD. This ensures that already existing information is processed.

The information requests to be checked are built up by the bSDD both via the processes built up in process levels and via the Psets. The basis for this is a prepared template (see section 4.2). The combination of template and selected processes on process level 3 for the BIM use case leads to the concrete structure of a mvdXML.

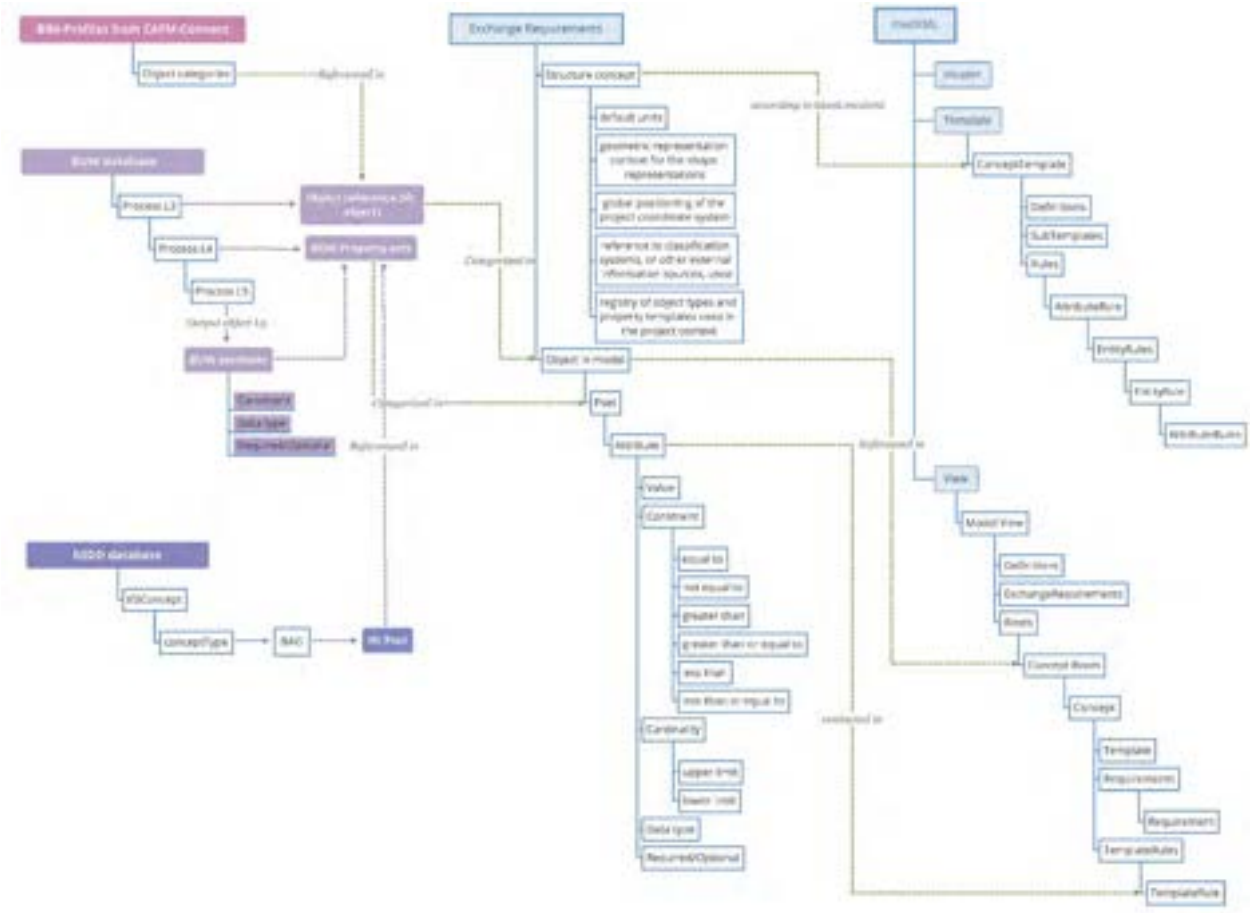

Figure 6. Structure of the data connection for generating mvdXML

4 Implementation

The development of a BIM based information controlling system is carried out in five steps: 1. Establishment of exchange requirements based on specific processes in each use case from BUW database; 2. Generation of MVD files according to exchange requirements; 3. Preparation of IFC model as to be checked file; 4. Examination of IFC file using MVD checker; 5. Building an online platform embedded with all functions. Since the controlling tool is still under test, sample files are taken to explain these implementation procedures in detail.

4.1 Definition and export of exchange requirements

As mentioned in section 2.1, the BUW database contains a tremendous amount of process data, and each use case contains process activity from level 1 to 5, person in charge, relevant object, necessary attributes, etc. Therefore, it is first of all essential to define which items should be contained in exchange requirement table. Because the request of information delivery or file exchange is merely driven by one specific activity at process level 3, only the items at level 3 or its sublevel should be included. To be more specific, process name, person in charge, relevant object, related attributes and property sets are important components in the exchange requirement table. Furthermore, to validate the plausibility of value to the attribute, general conditions should be provided, such as unity, data type, range, cardinality. The exchange requirements are consequently defined by a table or csv file, which forms the basis for generation of MVD (see Figure 6).

4.2 Generation of MVD file

The generation of a computer readable MVDs is based on utilizing predefined mvdXML template files which define the document structure. The template files are filled using exchange requirement information data provided by the BUW database as csv file (Figure 7). This results in standard conformant mvdXML files that can directly be used to validate IFC models.

To be more specific, the process of generating mvdXML itself is carried out in 4 steps: 1. Reading the provided data defined as csv file and extracting all necessary information, such as process name, person in charge, relevant object, IFC object name, property set, attributes and value. 2. Translating the extracted information into structured inputs for the mvdXML template files. 3. Filling the predefined placeholders in the provided template file with translated data. For example, list entries for object references and IFC object names are written into the concept root node. While the entries for property set, property name and all value definition define the constraints in concept nodes. 4. Generating the output files as mvdXML. Multiple mvdXML files are generated for every process name and its associated process owner.

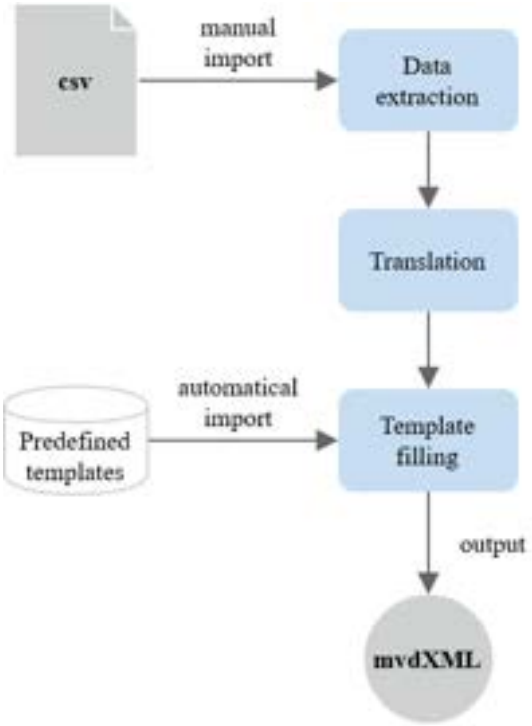

Figure 7. Technical process of generating a mvdXML file

An important aspect of this process is the reduction of effort in generating mvdXML templates by limiting their scope of application on property set definitions. It is possible to get by with a single concept template. However, it is also possible to nest templates in order to allow more complex subdivisions of nodes, as is the case for model view definitions.

Since the generation tool is still in active development, the process has only been applied on the use case ‘facility management’ so far. Further use cases will reveal other possibilities for improvement.

4.3 Preparation of IFC file

The controlling system is developed on the one hand for the client to regulate exchange requirements and to check the IFC file delivered by contractor. On the other hand it also helps the corresponding contractors improve their IFC file before they hand it in to the client. Moreover, to verify the atomization level of this tool, the procedure of importing key attributes in an IFC model should be tested. Hence, it is regarded as an essential part to document the process of preparing the IFC file.

Figure 8. Preview of element "IfcTransportElement-ELEVATOR" with attributes defined by exchange requirements in BIM Vision [13]

Figure 9. Screenshot of result from checking

In this case, the IFC model of a building from the University of Wuppertal is chosen as testing file as a result of its completeness and preciseness. In the very first trial, exclusively one element type (see Figure 8) is used for proof of exchange requirements for facility management. The specific attributes defined in exchange requirements are semi-automatic assigned in Autodesk Revit [14] by importing a shared parameter list.

4.4 Using MVD checker to verify IFC models

The MVD model checker tool is based on the open source software framework bimserver.org [15] . It is a generic tool for verifying IFC model contents for defined exchange requirements using mvdXML [16]. After successful verification, a report is returned as a BCF file, which contains all recognized issues. Consequentially, the MVD model checker has two inputs, the IFC file and mvdXML file and one output, the BCF file.

The controlling tool is still under development, therefore the described validation measures are all based on sample files. These sample files are limited to basic data contents, for example an elevator IFC file and a mvdXML file containing constraints on an IFC transport element. The MVD Model Checker exposes a public REST API which takes the IFC file and mvdXML file as input and returns results as JSON or BCF ZIP formats [17]. After each validation the results are manually examined (see Figure 8). If an unexpected result has been identified, the user can then check the IFC file or mvdXML file and correct errors as appropriate.

To verify the correct behavior of the MVD Model Checker, multiple input files are tested for which the

results can be easily checked manually. That way, for example, a known issue in bimserver.org about IFC inverses has been triggered and was resolved. Boolean string values and complex expressions also have been improved using this method. For the upcoming steps, the difficulty is increased by using more complex IFC and mvdXML files.

4.5 Development of an online platform

Prior to the implementation of this controlling system, a workshop among construction management practitioners was held for coming up necessary functions of the platform and giving those functions priority. Hence, besides the core mechanism of controlling systems which is related to the MVD generator and the MVD model checker, there have been other required functions which were collected in the workshop to be implemented in the platform. The requirements that are rated highest are: automatic choosing of exchange requirement template based on selected use case; test tools are based on open standards and open interface; the application should be possible to reproduce the data records in a way that is understandable to the users, etc.

To realize these functions as well as to combine the MVD generator and checker in one application, a web-based platform is considered to be a suitable tool. The establishment of an online platform will be realized through the following steps: 1. Creating mockups for detailed discussions on user interface design; 2. Using HTML, CSS and JavaScript to build a frontend; 3. Building a backend in Python to drive the MVD model checker and MVD generator. The online platform is still under development and will be published as free resource in the future.

5 Conclusion

The feedback from practice as well as the current topics of the organizations for standardization (ISO, DIN, VDI, buildingSMART) confirm the relevance of the subject in the area of information exchange of the BIM method. In the research project a functioning concept was developed, which is currently in the final phase of implementation, in order to meet the technical and content-related requirements of a semi-automatic BIM-based information supply controlling. The final result of the demonstrator will be provided by the authors via the respective universities and the code will be published.

Development of an Open-source Scan+BIM Platform

Enrique Valero, Dibya D. Mohanty and Frédéric Bosché

School of Engineering, University of Edinburgh, UK

e.valero@ed.ac.uk, d.mohanty@ed.ac.uk, f.bosche@ed.ac.uk

Abstract -

In the last decade, a significant amount of research and development has been conducted at the intersection of Building Information Modelling (BIM) and reality capture data processing, mainly in the two areas often referred to as 'Scan-to-BIM' and 'Scan-vs-BIM'. Interestingly, it appears that all these advances have been made without the availability of any libre, cost-free and ideally open-source software platform that can handle both reality capture data (typically 3D point clouds and images) and Building Information Models. This paper investigates user demands and possible alternative options to develop such a *Scan+BIM* platform to further stimulate research in the field. A set of requirements for such a platform are first identified by means of a questionnaire sent to researchers and industry practitioners. Different software applications, identified from the literature and online, are then assessed against those requirements. A final ranking of these applications is conducted and one suitable solution is identified and suggested for development. The proposed solution combines the OpenInfra Platform, as a BIM and point cloud engine and viewer, and the xBIM Toolkit to provide complementary tools for the BIM engine. This new piece of software is currently under development and the authors intend to make it available to the Construction Informatics community soon.

Reality Capture; Point Clouds; Images; BIM; Engine; Platform; open-source

1 Introduction

The last decade has seen an explosion of research in Construction Informatics. Two fields that have received particular attention are reality capture data processing as well as Building Information Modelling (BIM), the latter being the development of structured data supporting collaborative processes for reliable management of construction projects over their lifecycle [1, 2, 3].

Reality capture technologies have rapidly evolved and are widely used for digital documentation. Digital cameras are now cheap and ubiquitous, and are commonly utilised for the creation of 3D models by means of Structure-from-Motion photogrammetry (PG). Besides, accurate terrestrial laser scanning (TLS) technology is increasingly affordable. Other imaging technologies, such as thermal cameras and ground-penetrating radars, have seen improvements in data quality. And finally, there is an exponential growth in Internet-of-Things (IoT) sensors that can capture various environmental and structural characteristics to be used in the generation of BIM models — and by extension Digital Twins (DTs) — of buildings [4].

These sensors on their own are resulting in a significant increase in data that needs to be curated and processed to extract meaningful information that can support effective design, construction, operation and maintenance of the built environment. The processing of that data along with its structured recording for analysis and efficient retrieval is increasingly considered within a BIM/DT digital framework. While the work conducted here could eventually be extended to a larger set of reality capture data, this paper focuses on 3D (and colour) data acquisition technology, i.e. principally TLS and PG.

Examples of the combined application of TLS/PG and BIM technologies can be found across the lifecycle of built environment assets and can be categorised into three groups [1, 3, 5], discussed in more detail in the following sub-sections: Scan-to-BIM (Section 1.1), Scan-vs-BIM (Section 1.2) and Others (Section 1.3).

1.1 Scan-to-BIM

Scan-to-BIM refers to the process of capturing data of existing built environment assets and producing BIM models representing the *as-is* state of those assets [1, 3, 6, 7, 8]. Although this process has various applications, it is primarily employed for the production of BIM models of existing assets that are then used as a starting point for design of renovation works or for supporting Facilities Management (FM). Scan-to-BIM is an extremely lively field, where academic and private research groups compete in the development of algorithms that automate this process as much as possible (e.g. [9]). While various of the technologies mentioned earlier can be employed in this process, it is notable that the majority of current solutions consider as input laser scanned point clouds [9, 10]. Photogrammetric point clouds and their underlying imagery are also increasingly considered as a valuable input to the scan-to-BIM process [11].

1.2 Scan-vs-BIM

Scan-vs-BIM refers to the process of capturing data of existing built environments and comparing that data against BIM models representing the prior recorded state of those assets [12]. This process has been shown to be of value to progress and quality control during the construction phase of projects, in which case the BIM models are *as-designed* BIM models produced during the design stage [2, 6, 13]. The Scan-vs-BIM process can also be employed to support asset operational monitoring, in which case BIM models are the latest recorded *as-is* BIM models of the assets.

1.3 Others

Other research works also employ reality capture and BIM data, but in different ways. For example, a significant amount of Health & Safety research has been conducted that processes reality capture data (TLS, PG, range cameras, etc.) to detect hazards. In these works, the BIM model of the environment where the sensors are located can be used to provide contextual knowledge to enhance data processing performance [14, 15].

In a different manner, Lovreglio et al. [16] use BIM models and pictures of buildings for the production of Virtual Reality applications to train building occupants in evacuation during earthquakes.

2 Review of Scan Engines, BIM Engines, and Scan+BIM Engines

2.1 Point Cloud Engines

TLS and PG are the two main technologies currently considered in the Architecture, Engineering and Construction (AEC) domain for the acquisition of 3D (i.e. geometric, visual) data of construction assets. For both technologies, the output consists in point clouds containing millions of unconnected 3D points usually enriched with additional data such as: colour, intensity of the received signal, and/or thermal response. Visualisation and navigation of those point clouds are needed for an appropriate understanding and further analysis of the data and processing results.

TLS manufacturers commonly provide users with their own software for data processing and visualisation (e.g. Faro Scene [17], Leica Cyclone [18]). However, these solutions are usually under proprietary (i.e. close-source and non-free) licenses and only allow limited data operations, such as point clouds registration and cleaning. The proliferation of TLS, and therefore the explosion of 3D data processing, have encouraged the development of powerful free and open solutions for 3D data processing and visualisation in the last decade, such as CloudCompare [19] or MeshLab [20].

In the case of photogrammetry, both proprietary software (e.g. RealityCapture [21] and Metashape [22]) and open-source (e.g. Meshroom [23]) are also available for the generation and visualisation of 3D point clouds.

These tools employ well-recognised libraries for handling point clouds, such as PCL [24].

In general, colour information delivered by PG models is more reliable than the colour obtained by TLS devices [25]. However, 3D geometry is less accurate and processes to obtain high resolution point cloud are slower with PG in comparison with TLS.

2.2 BIM Engines

BIM relates to both the creation and the management of structured information on construction projects across the lifecycle of buildings. In BIM processes, visualisation is fundamental for a correct understanding of the asset and its evolution. Therefore, 3D BIM models constitute an ideal visualisation and navigation reference, upon which additional information can be linked, visualise and processed.

A number of BIM engines and viewers have been developed to date, by both academic research teams and leading design software companies, with the purpose of generating, modifying and visualising BIM models. For example, IFC Viewer [26] and the commercialised IFC Engine [27] can load Industry Foundation Classes (IFC) files, visualise the 3D geometry and explore additional non-geometric information through a navigation tree. A more complete solution is delivered by Areddo [28], which is a free but proprietary BIM viewer that can handle IFC files as well as point clouds. Areddo includes additional basic operations like measuring distances and producing cross sections of models. However, this is not an authoring tool, i.e. information cannot be modified. Modification of BIM models, including those stored under the IFC standard, is possible in Autodesk Revit [29], currently the most used tool for the authoring of BIM models. Other related industry proprietary software packages include ArchiCAD [30], and MicroStation [31].

The above solutions, while presenting various levels of capability, are also restrictive because they are proprietary (although some are cost free). Aiming to produce open-source alternatives that could be used, maintained and improved by a community of researchers, alternative solutions for handling and visualising BIM models have been developed in the last decade. This is the case of the xBIM toolkit [32], which includes libraries for the authoring (xBIM Essentials and Geometry) and a Windows Presentation Foundation (xBIM Xplorer) for rendering and visualisation of BIM models based on the IFC open data

schema. Another solution, principally focused on infrastructure, is the OpenInfra Platform [33], which is able to handle BIM models and Geographic Information Systems (GIS) -related data, as well as point clouds (as further discussed below).

A crucial step for the visualisation of the geometry (i.e. 3D models) 'codified' in IFC files is the interpretation of this data and the subsequent generation of renderable models to be shown in a viewer. A variety of libraries have been developed for this purpose in the last decades. Examples of this kind of tools are the open-source ifcOpenShell [34], which is used by the BIM storage and management tool BIMserver [35], or ifcPlusPlus [36] — as well as the xBIM library mentioned above.

2.3 Scan+BIM Engines

Importantly with regard to the focus of this paper, few of the above BIM or point cloud software solutions are able to handle both BIM and point cloud data; and those that do provide various levels of functionalities.

Point clouds can be loaded into Revit, ArchiCAD or Microstation, a feature principally employed to facilitate the production of BIM models of existing structures. In the case of Revit, point clouds need to first be opened with a different piece of software, Autodesk Recap, which exports the data into a unique format readable by Revit. However, the main drawback in all cases is software cost.

As previously mentioned, the cost-free viewer Areddo can be used for visualising both point clouds (in `.pts` format) and BIM models (in `.ifc` format). This tool additionally provides basic functionalities related to visualisation, such as variations in lighting, shadowing effects and navigation; and measuring distances. However, neither point clouds nor 3D models can be modified with Areddo.

Another solution able to deal with point clouds and BIM models is OpenInfra Platform. This modular software, which is still under development, can load BIM models (in `.ifc` format) as well as point clouds (`.e57`).

In summary, it can be observed that, despite the recent explosion in the use of reality capture technologies and BIM methodology for managing buildings over their lifecycle, only a few software packages, mainly proprietary, can handle both reality capture and BIM data, and with limited functionalities in terms of data manipulation (visualisation and authoring for both). Areddo is a visualisation tool that lacks BIM authoring functionalities, and is unable to open standardised formats for point clouds like `.e57`. Besides, like Revit, Areddo is not open-source, which limits the flexibility often required for research.

The research community would be best served by an open-source solution that could handle the two types of data, allowing visualisation and manipulation (i.e. editing/authoring) of both. OpenInfra could be that solution. Although the platform is still under development, it offers great potential since it is both cost-free and open-source and has been conceived as a cluster of interlinked solutions for infrastructure and construction projects, which can be extended with additional tools or features according to the users' needs.

3 User Requirements

The identification of the best way to develop an open-source solution that can effectively handle both types of data first requires that the needs and requirements of its potential final users — i.e. R&D professionals from both academia and construction industry — are brought to light. To this end, an online questionnaire (see Subsection 3.1) has been created and sent to professionals around the world. Results from the questionnaire have then been analysed and the identified requirements are reported in Section 3.2. In Section 4, the existing tools and their functionalities (reviewed earlier) are then juxtaposed to the user requirements to identify the most adequate open-source solution.

3.1 Questionnaire

An online questionnaire was prepared to investigate how R&D professionals, both in industry and academia, work with BIM models and reality capture data. The survey, which can be found in the Annex, enquired about the tools these professionals are currently using, and whether the needs they might have are covered by the software package of their preference.

The questions were divided in three main blocks:

General (Questions 2 - 7): Professional background; experience with reality capture and BIM; their awareness of existing Scan+BIM tools; and their needs and preferences.

BIM functionalities (Questions 8 - 10): Open BIM formats and standards that should be handled by the platform; open mesh geometry formats to be loaded and saved; and the main BIM authoring functionalities (e.g. editing geometric and non-geometric information, changing the topology of the models).

Reality capture functionalities (Questions 11 - 14): 3D and 2D data formats; images and calibration; and functionalities, such as point cloud processing.

A number of questions use a 5-point Likert scale to ask about the criticality of certain functionalities. The scale goes from 1 (not important) to 3 (would be nice) and 5 (critical). For each question the average score is calculated

to help highlight the parameters and requirements which were more relevant to the participants.

The questionnaire was disseminated to academics and construction professionals through specialised mailing lists and social networks (LinkedIn groups and Twitter), reaching more than 35,000 potential users. A total of 31 professionals completed the online questionnaire; 28 of which (90.3%) were academics or researchers and 3 of them (9.7%) worked for construction companies (Question 2). Amongst them, 21 (67.7%) responded to commonly work simultaneously with reality capture data and BIM (Q3).

3.2 Scan+BIM Engine Requirements

3.2.1 General requirements

When asked about their awareness of any 'off-the-shelf' Scan+BIM software platform (Q4), 71% replied negatively. Professionals who gave an affirmative answer to this question (9 out of 31) mentioned Edgewise [37] and Revit [29]. However, only 6 of those 9 people had used those existing solutions.

With respect to their R&D needs (Q5), participants were asked about the size, completeness and format of the datasets handled by such Scan+BIM tool. Table 1 summarises their responses. Note that in this and the following tables, values in bold correspond to those scores higher than the average for the responses to all 7 Likert-type questions, which we refer to as the 'global average'.

As can be seen, participants agreed with the importance of handling open data formats as well as with the development of an open-source tool where other users can contribute. Also, supporting geo-referenced data is appealing to the respondents. However, the score for *handling data from large environments* is below the global average which is $\overline{s} = 3.92$.

Table 1. Question 5: Considering the needs of those responding the questionnaire, "the Scan+BIM software platform should . . . "

Requirement	average	std. dev.
support geo-referenced data	**4.09**	1.14
be able to handle data covering large environments	3.68	1.36
be focused on working with open data formats	**4.55**	0.94
be open-source	**4.14**	1.06

Regarding handling data of different nature (other that point clouds and BIM), 24 participants (>75%) considered that these two sources sufficed (Q6). However, 7 mentioned the advantages of supporting additional data, such as pictures and Geographic Information Systems data.

Finally, from a low level (i.e. software development) perspective, most participants (51%) agreed on the use of the C++ language for the development of the Scan+BIM tool, although some of them (4) mentioned Python as a "versatile and easy to use" alternative (Q7).

3.2.2 BIM functionalities

Regarding the ability of the Scan+BIM platform to handle BIM models, participants were asked about data formats and extra functionalities that they would find of interest for such a tool (Q8). First, when considering the formats and standards proposed in the OpenBIM framework (see Table 2), all respondents essentially agreed about the need to support the `.ifc` format. This is the only standard of the list whose score is higher than the global average $\overline{s} = 3.92$.

Table 2. Question 8: "Regarding the ability of the Scan+BIM platform to handle BIM models, it should support. . . "

Requirement	average	std. dev.
IFC	**4.73**	0.86
IFD	3.45	1.02
MVD	3.35	1.06
BCF	3.38	1.21

In some cases, loading or exporting 3D mesh models could be valuable. Amongst the file formats proposed in Q9, Table 3 shows that `.obj` is the favourite option for those who answered the question.

Table 3. Question 9: "With respect to the ability of handling 3D meshes, the Scan+BIM software platform should support. . . "

Requirement	average	std. dev.
OBJ	**4.24**	1.11
PLY	3.85	1.11
STL	3.75	1.34
VRML	3.5	1.12
COLLADA	3.45	1.36

Finally, the preferred BIM functionalities to be included in the Scan+BIM tool (Q10) are summarised in Table 4. Although most of the proposed features obtained scores above the average, professionals gave priority to the ability of editing the geometry and the topology of BIM objects.

3.2.3 Reality capture functionalities

Following a similar pattern of questions as for the BIM functionalities, the participants were first asked about their

Table 4. Question 10: "Regarding the modification of BIM models, the Scan+BIM software platform should support. . . "

Requirement	average	std. dev.
editing of the geometric information of individual BIM objects (e.g. shape and location)	**4.45**	0.89
editing of the non-geometric information of individual BIM objects	3.77	1.13
editing of the geometric relationships (topology) between BIM objects	**4.23**	1.04
editing of the non-geometric relationships between BIM objects	3.5	1.16
the creation of BIM objects	**3.95**	1.11
the various BIM classifications	**4.23**	1.04

preferred file format for point clouds and pictures (Q11). As illustrated in Table 5, amongst the proposed point cloud file formats, most participants highlighted XYZ, PTS, PTX and E57 as being most important, with values above the global average ($\overline{s}$ = 3.92). Regarding the proposed formats for pictures storage, these obtained lower scores than the alternatives for point clouds, which could reflect the prioritisation of 3D data. Note that pictures can also be stored in `.e57` files.

Table 5. Question 11: "Amongst the following file formats, the Scan+BIM software platform should support. . . "

Requirement	average	std. dev.
E57	**3.95**	0.99
XYZ	**4.38**	0.89
PTS	**4**	1.09
PTX	**4**	1.05
PLY	3.74	0.85
PNG	3.84	0.93
JPEG	3.9	0.89

With respect to point-cloud related functionalities, the participants were asked about the features enumerated in Table 6 (Q12). The preferred option was the ability *to perform some common processing of point clouds*, followed by *adding or editing per point information*.

The last question of those was about the functionalities of the platform for handling pictures and associated features (Q14). Amongst the proposed operations (see Table 7), the most supported functionality was the *support of calibrated images*, the only requirement of this batch with a score above the average.

Table 6. Question 12: "Regarding point-cloud functionalities, the Scan+BIM software platform should support. . . "

Requirement	average	std. dev.
some common processing of point clouds (e.g. cleaning/filtering, segmentation, other)	**4.57**	0.66
adding/editing per-point information (e.g. additional scalar fields)	**4.19**	0.79
the simulation of the acquisition of point clouds (laser scanning)	3.71	0.98

Table 7. Question 14: "With respect to handling pictures and related features, the Scan+BIM software platform should support. . . "

Requirement	average	std. dev.
(externally) calibrated images	**4**	1.04
editing calibration matrices	3.82	0.94
editing images	3.23	1.20
the simulation of the acquisition of images (with or without calibration matrices)	3.45	0.89

4 Comparison of Existing Data Engines and Proposal of a Scan+BIM Solution

After evaluating the results obtained from the proposed questionnaire, the availability of the required functionalities that scored over the global average was assessed amongst current (commercial or free; closed or open-source) software solutions. In the following subsections, the obtained results are discussed for reality capture engines, BIM engines, and Scan+BIM engines. Note that the software packages are compared as 'out-of-the-box' solutions. The use of libraries or application programming interfaces (APIs) to supplement software functionalities is discussed but not considered in the comparison, since those potential solutions have not been implemented yet and, therefore, are not available for the above-mentioned end users.

4.1 Reality Capture Data Engines

A comparison between a number of solutions was performed to analyse how existing reality capture data engines

met the requirements highlighted in the survey result as per questions 11 (Table 5), 12 (Table 6) and 14 (Table 7). As can be seen in Table 8, CloudCompare, MeshLab, Metashape and ReCap meet most of the requirements. In contrast, Reality Capture and Meshroom do not, on their own, fulfil the needs expressed in the questionnaire. All the engines offer *some common point cloud processing* functionalities like cleaning/filtering or segmentation, which is one of the most desirable and basic requirements. However, another highly scored requirement, *adding/editing per-point information*, is only met by CloudCompare and MeshLab. The reality capture engines were also compared based on the general requirements as per question 5 (Table 1). All the engines can work with open data formats and all support geo-referenced data, except Meshroom. However, only CloudCompare, MeshLab and Meshroom are open-source.

In summary, CloudCompare and MeshLab are the solutions which meet most of the desired requirements; and additionally, these are open-source solutions, enabling further development, if needed.

4.2 BIM Engines

Amongst the software solutions presented in Section 2, conventional BIM engines are compared in Table 8, considering the most voted requirements in questions 8 (Table 2), 9 (Table 3) and 10 (Table 4). The evaluated tools handling uniquely BIM objects are the open-source solutions IFC Viewer, xBIM Xplorer and BIMserver. Although the IFC file format is supported by all, the most voted file format for the storage of meshes (i.e `.obj`) is only supported by BIMServer. Additionally, further editing or creation of BIM objects is not in the scope of any of these engines, that basically act as BIM objects viewers only. However, it is worth mentioning that xBIM Xplorer could take advantage of the xBIM toolkit to supplement its functionalities and provide the user with the ability of modifying BIM elements. With respect to the general requirements of question 5 (Table 1), all engines are open-source and allow working with open data format, supporting geo-referenced data.

Commercial solutions such as Revit, Microstation and ArchiCAD, which are provided by renowned international software corporations, all enable, amongst their numerous functionalities, the usage of point clouds. The tree tools are capable of creating and editing BIM object and conduct some basic processing of point clouds. Microstation and Revit can work with most open data formats, whereas ArchiCAD supports limited open data formats. All three solutions are primarily closed, proprietary BIM engines with the capability of loading and visualising point clouds.

Areddo is a freeware and can visualise point clouds and BIM files. However, the range of file formats that can be opened is limited and no operations can be performed on the objects, either point clouds or BIM models.

In contrast, the OpenInfra Platform can manipulate both point clouds and BIM models and is a free open-source solution, which facilitates the addition of new tools and functionalities to the platform. An important advantage of this solution in contrast to all previous ones is its ability to visualise and modify point clouds (as it uses the CloudCompare engine). But, a limitation of OpenInfra is that it offers no native functionality to create and edit BIM objects.

Overall, as shown in Table 8, Revit, Microstation and ArchiCAD meet most of the requirements pointed out in the questionnaire. Although the IFC file format is supported by all engines, the most voted file format for the storage of meshes (i.e. OBJ) is only supported by Microstation. And functionalities related to the creation and editing of BIM objects are only supported by Revit, ArchiCAD and Microstation. Regarding other general requirements, all engines allow working with open data format and support geo-referenced data.

As evident from the comparison above, solutions able to handle BIM models are clearly separable in two different groups: a first group including solutions that cover more requirements, but are closed, proprietary software (ArchiCAD, Microstation, Revit); and a second group with tools that provide comparatively fewer functionalities, but are these are free and open-source which makes them comparatively more flexible to the needs of researchers (IFC Viewer, xBIM Xplorer, BIMserver and OpenInfra). However, in most solutions enumerated in the first group, additional requirements cannot be implemented, since their source code is not available to the general public. In some cases (e.g. Revit), companies provide APIs that can be used for the implementation of supplementary functionalities, but these can be limited and/or complex. On the other hand, amongst the solutions listed in the second group, only OpenInfra can handle both point clouds and BIM objects, but it lacks object editing functionalities.

Therefore, one good solution identified and suggested for development combines OpenInfra, as a BIM and point cloud engine, and the xBIM toolkit that provides supplementary libraries for the BIM engine such as the (semi-)automatic generation of IFC files.

5 Conclusion

This paper presented the first steps on the development of an open-source Scan+BIM platform. First, the authors reviewed a number of existing alternatives that are able to handle point cloud and BIM data, analysing their advantages and disadvantages were highlighted. Considering the main functionalities provided by these solutions, a questionnaire was then sent to potential users of such platform

Table 8. Assessing existing Scan and BIM Engines against the key requirements identified from the questionnaire.

	Reality capture					BIM			Scan+BIM				
Requirement	CloudCompare	MeshLab	RealityCapture	Metashape	Meshroom	IFC Viewer	xBIM Xplorer	BIMServer	ArchiCAD	Microstation	Revit + Recap	Areddo	OpenInfra
IFC	-	-	-	-	-	✓	✓	✓	✓	✓	✓	✓	✓

(externally) calibrated images	×	✓	✓	✓	✓	-	-	-	×	×	✓	×	×
support geo-referenced data	✓	✓	✓	✓	×	✓	✓	✓	✓	✓	✓	×	✓
able to working with open data formats	✓	✓	✓	✓	✓	✓	✓	✓	✓	✓	✓	✓	✓
be open-source	✓	✓	×	×	✓	✓	✓	✓	×	×	×	×	✓

(i.e. academics and construction professionals, principally researchers) to collect their needs and requirements for a Scan+BIM software platform. After analysing the data obtained from the questionnaire, the authors concluded that a combination of available open-source solutions, specifically OpenInfra Platform and xBIM toolkit, would be the starting point for the development of the proposed software platform. The authors are in the process of developing that solution and intend to make it available to the Construction Informatics community soon, for the benefit of the research community in particular.

Annex: Scan+BIM Questionnaire

Question 1: I have read and agree the above information and its privacy policy and consent to the BIMERR Consortium using this information for research purposes.

Question 2: What is your professional profile?

Question 3: Does your research and development (R&D) activity require you to work simultaneously with reality capture data (point clouds and/or 2D pictures) and Building Information Models (i.e. semantically rich 3D models)?

Question 4: Are you aware of any 'off-the-shelf' (or at least easily accessible/implementable) Scan+BIM software platform?

Question 5: When thinking about your R&D needs, to which extent do you agree with the following statements about such a Scan+BIM software platform? [1 (disagree) to 3 (partially agree) to 5 (fully agree)]

- The Scan+BIM software platform should support geo-referenced data.
- The Scan+BIM software platform should be able to handle data covering large environments (e.g. urban and regional scale).
- The Scan+BIM software platform should be focused on working with open data formats.
- The Scan+BIM software platform should be open-source.

Question 6: Should the Scan+BIM software platform handle data of different nature (other than point clouds and BIM)?

Question 7: In which language should the Scan+BIM software platform be developed?

Question 8: To which level the following BIM open data formats should be supported by such a Scan+BIM software platform? [1 (not important) to 3 (would be nice) to 5 (critical)]

• IFC • IFD • MVD • BCF

Question 9: To which level the following other mesh geometry open data formats should be supported by such a Scan+BIM software platform? [1 (not important) to 3 (would be nice) to 5 (critical)]

• OBJ • PLY • STL • VRML • COLLADA

Question 10: To which extent do you agree with the following statements about BIM-related functionalities of such a Scan+BIM software platform? [1 (not important) to 3 (would be nice) to 5 (critical)]

- The Scan+BIM software platform supports editing of the geometric information of individual BIM objects (e.g. shape and location).
- The Scan+BIM software platform supports editing of the non-geometric information of individual BIM objects.
- The Scan+BIM software platform supports editing of the geometric relationships (topology) between BIM objects.
- The Scan+BIM software platform supports editing of the non-geometric relationships between BIM objects.
- The Scan+BIM software platform supports the creation of BIM objects.
- The Scan+BIM software platform supports the various BIM classifications.

Question 11: To which level the following Reality Capture open data formats should be supported by such a Scan+BIM software platform? [1 (not important) to 3 (would be nice) to 5 (critical)]

• E57 • XYZ • PTS • PTX • PLY • PNG • JPG

Question 12: To which extent do you agree with the following statements about point cloud-related functionalities of such a Scan+BIM software platform? [1 (not important) to 3 (would be nice) to 5 (critical)]

- The Scan+BIM software platform supports some common processing of point clouds (e.g. cleaning/filtering, segmentation, other).
- The Scan+BIM software platform supports adding/editing per-point information (e.g. additional scalar fields).
- The Scan+BIM software platform supports the simulation of the acquisition of point clouds (laser scanning).

Question 13: Are there other important, possibly critical point cloud-related functionalities that should be available in such a Scan+BIM software platform?

Question 14: To which extent do you agree with the following statements about 2D image-related functionalities of such a Scan+BIM software platform? [1 (not important) to 3 (would be nice) to 5 (critical)]

- The Scan+BIM software platform supports (externally) calibrated images.
- The Scan+BIM software platform supports editing calibration matrices.
- The Scan+BIM software platform supports editing images.
- The Scan+BIM software platform supports the simulation of the acquisition of images (with or without calibration matrices).

BuiltView: Integrating LiDAR and BIM for Real-Time Quality Control of Construction Projects

R. Abbas[a], F.A. Westling[a], C. Skinner[a], M. Hanus-Smith[a], A. Harris[a] and N. Kirchner[b]

Abstract -

Global spending on rework in the trillion dollar construction industry is estimated at $570bn of direct costs and $440bn of indirect costs. The cost of rework is on the rise, and the main cause is rooted in quality deviations from construction design. Real-time or even near real-time remote progress monitoring and quality control has the potential to prevent a large portion of defects and enables quick detection and handling of errors that often go undetected for too long. Current procedure still relies on human visual inspections that are costly, in terms of time and human resources, and is subject to human error. Moreover, existing tools and services are limited in the size of data they can handle, as LiDAR data can be gigabits in size with hundreds of millions of unstructured points. The technology often fails at being robust to occlusions and other noise elements commonly found on construction sites. More sophisticated algorithms exist to perform different parts of the required analysis; however, they require a high level of expertise to implement and tailor to different use cases. In this paper, we present BuiltView, an automated progressive assurance platform that allows users to validate and document construction activities on a daily basis. BuiltView can significantly r educe r ework b y accurately and efficiently identifying BIM components and detecting discrepancies between the as-designed data and the as-built data, particularly in terms of geometric compliance. BuiltView is a powerful tool that processes billions of LiDAR points in a very efficient manner. Leveraging sophisticated analytical algorithms, BuiltView calculates accurate dimensions and generates comprehensive user-friendly reports to facilitate communication across the business. We show that BuiltView is a valuable tool for automation of quality assurance and quality control, progress tracking and documentation. Using the tool, builders can significantly reduce costly rework, increase productivity and boost transparency between different project stakeholders, thanks to objective, high-accuracy evidence.

Keywords -

LiDAR; BIM; point cloud; progressive assurance; QA/QC; rework; as-built models; project management

1 Introduction

According to McKinsey and Co, most construction projects are expected to run 20% over schedule, and 80% over budget with 25% of profit lost on defects and rework [1]. Moreover, the overall productivity of the construction industry has increased by a mere 1% over the past two decades [2]. The depressed productivity of construction projects is costing the global economy $1.6 trillion each year [3]. For major contractors in the industry, documenting and maintaining a single source of truth is essential for accountability, quality and efficiency of the work. For effective management of construction projects, this data needs to be timely (up to date), detailed and accurate. Autodesk identified frequent information capture of errors, omissions, and defects as the number one key performance indicator (KPI) for construction contractors [4].

Building information modelling (BIM) is widely used in the construction industry to enhance project performance from design to construction and facilities management (FM). Complimenting BIM, point cloud data obtained from LiDAR (Light Detection and Ranging), images, and videos are able to provide accurate and fast records of the 3D geometries of construction-related objects. Point clouds are a set of data points with (X,Y,Z) coordinates along with hardware-dependent additional information, such as reflection intensity, RGB values, and normals. LiDAR, in particular, is able to provide an accurate 3D digital representation of construction site conditions at millimetre level accuracy. The 3D laser scanning market has doubled over the past four years, evaluated now at almost $6bn, and the demand for LiDAR in construction has almost tripled in just four years (approximately 60%) [5]. With recent research showing the efficacy of LiDAR in construction and its capability to reduce rework by 25% [6], there is no doubt that laser scanning is becoming an essential part of the industry.

The value of LiDAR lies in referencing the resultant point clouds to BIM. Despite the fact that there are many existing software and service providers in this space, there is no state-of-the-art framework that can be readily adopted by building design and construction professionals. In this

space, BuiltView presents an innovative and unique solution to the integration of LiDAR with BIM for construction projects. BuiltView is a digital tool that automatically conducts deviation analysis between the as-designed model and point clouds based on as-built conditions.

By automating deviation analysis and progress checking, BuiltView has provided significant value to Laing O'Rourke through reduced rework and improved productivity (as depicted in Figure 2). Laing O'Rourke is an international engineering enterprise, with roots tracing back a century and a half. It excels at delivering large scale projects in building, transport, power, utilities, mining, and infrastructure.

Since inception, Laing O'Rourke has showcased numerous innovative research and development achievements. One recent example is BuiltView, which provides automated reports to improve client and subcontractor relationships. BuiltView is a key enabler of future digital tools such as smart contracts [7] and scan-to-BIM [8]. This paper leverages in-house case studies from past and current projects to assess the value of BuiltView compared with traditional approaches such as survey reports, spot checks, site walks, and eye-balling discrepancies for as-built model creation.

2 BuiltView

In this section, we present the workflow for BuiltView, its key distinguishing features and how it is of value to a multitude of parties of the construction industry, from subcontractors to site engineers to project managers, clients and stakeholders.

2.1 BuiltView: Main Components

BuiltView is a platform that leverages LiDAR and BIM technologies to provide up-to-date information on as-built conditions compared with the as-designed model requirements. BuiltView's value lies in automating quality checking to enable improved productivity and certainty, reduced rework, faster as-built model creation and improved decision making. The main workflow structure is as follows:

1. *Data acquisition*: The data acquisition phase is not limited to any particular hardware and can range from terrestrial laser scanners to drones and handheld mobile devices. The accuracy of the hardware relates directly to the use case it can serve. For instance, photogrammetry cannot yet support millimetre-level floor flatness analysis. Moreover, progress tracking may not require the high accuracy of survey-grade laser scans.

2. *Data Processing*: The data collected is referenced (or geo-referenced) to existing models and analysed in terms of matching objects and geometric compliance.

3. *Quality Assessment*: Quality is assessed through calculated geometric variances between the point clouds and the model, surface deviations and displacement.

4. *Progress Estimation*: Progress is estimated by comparing the amount of work completed with the amount of work planned, while taking into consideration the quality of the work and any rework required on potential defects.

5. *Visualisation*: Customised reports and dashboards are generated to tailor the visualisation of the results to the audience, e.g. project managers will be interested in overall percentages, whereas engineers will be interested in particular activities.

2.2 BuiltView: Key Innovations

There are commercial software packages and algorithms under research and development that aim at detecting and calculating variances between point clouds and models, or between point clouds themselves. With varying features, integrations and pricing models, we have found BuiltView to be the preferred solution in the following areas.

- *Accurate Metrological Algorithms*: BuiltView leverages proprietary deviation analysis algorithms that are capable of detecting objects in point clouds, in the presence of partial occlusions or other noise elements. It is a uniform platform that is independent of the method of capture. The accuracy of the calculated deviations lies solely in the accuracy of the data.

- *Intelligent Referencing and Geo-referencing*: Anyone familiar with point clouds will admit to the difficulties in referencing point clouds to models manually or even using semi-automated tools. The process is theoretically complex and empirically a combination of trial and error. BuiltView leverages intelligent algorithms that can identify different features in point clouds, for example surfaces, corners, beams, and pipes, to better register the point cloud to the model. This is a game changer for use cases where geo-referencing based on survey-grade control points is not possible, for example, in manufacturing facilities (see Section 3).

- *Intelligent Object Categorisation*: The required point cloud quality parameters are highly dependent on the construction-related element classes. For instance, building tolerances of steel beams are not the same as those of pipes or electrical services. BuiltView has built-in intelligence that allows it to produce conformance reports that are specific to every object class.

This saves engineers a tremendous amount of time in translating the results to tangible actions.

- *Robust Data Processing*: While most existing tools and services are limited in the size of data they can handle, BuiltView works with LiDAR data of the order of hundreds of millions of unstructured points with great ease by leveraging proprietary hierarchical data structuring algorithms for efficient processing and storage.

2.3 BuiltView across the Construction Project Life Cycle

Here we present a closer look at the use of BuiltView across a project's life cycle, as illustrated in Figure 1.

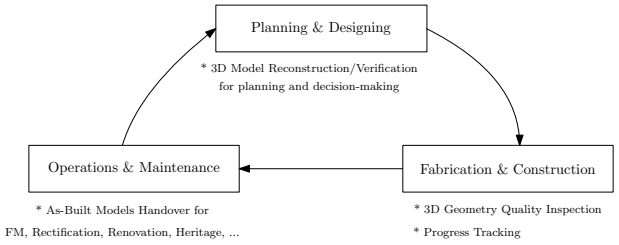

Figure 1. The benefits of BuiltView across the different phases of a construction project

1. *Planning & Design*: This is commonly known in the literature as "Scan-to-BIM", where laser scanning is conducted during the pre-construction phase for site design. This step is crucial for many projects to kick-off the design process with accurate and detailed information. Even when as-built models exist (from previous clients), we find that BuiltView is still invaluable to verify the models quickly, which will serve as a basis for all designs to come. This will be covered in detail in Section 5.
2. *Fabrication & Construction*: BuiltView continues to provide value during the construction phase as a powerful tool to document progress, defects and overall milestones. The nature of the data facilitates communication between different systems (mechanical, electrical, HVAC, etc.) and remote collaboration. The nature of the data, being free of human-error and subjectivity, also facilitates conflict resolution and accountability. This will be covered in Sections 3 and 4.
3. *Operations & Maintenance*: The advantage of laser scanning and the main goal of BuiltView is to close the loop. Laser scanning captures a very high level of detail, and this helps create a permanent as-built record for both owners and facility managers. In the end, this data can help with building operations, renovations, retrofits and future building additions and even demolitions. This will be covered in Section 5.

In the remaining part of this paper, we focus on the three main use cases of BuiltView, namely Quality Assurance and Quality Control (QA/QC), Progress Tracking and Documentation. An overview of the impact BuiltView has had on Laing O'Rourke's projects is depicted in Figure 2.

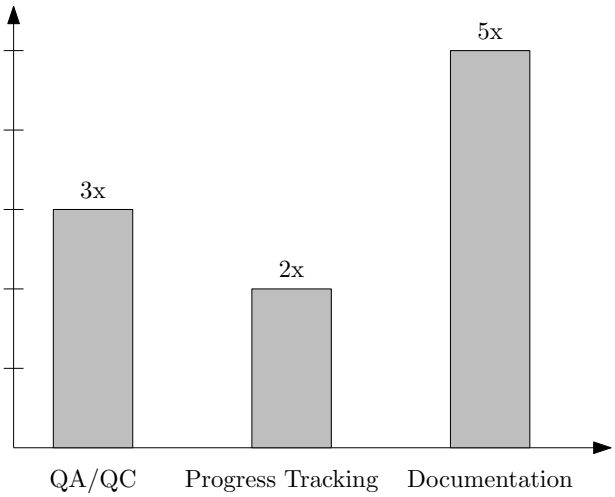

Figure 2. The time savings offered by BuiltView on Laing O'Rourke's past and current projects

3 Quality Assurance and Quality Control

3.1 Traditional QA/QC Workflow

Early identification of defects is critical for quality control because, on average, 6 to 12% of construction cost is wasted due to rework. This is exacerbated when defective components are detected late in the construction process [9]. Traditionally, QA/QC is carried out by periodic site walks and random spot checks that are documented in red-line mark-ups on 2D drawing print-outs. These hard copies are later translated manually in the office into as-built CAD drawings. In other instances, surveyors are sent out to site to check particular areas. The latter is notoriously expensive and is often subject to long turn-around times, leading to delayed detection of defects.

3.2 QA/QC Automation

With BuiltView, LiDAR scans captured with a single site walk can serve a multitude of use cases that can be automatically checked. Laing O'Rourke has successfully

Figure 3. An example of a traditional QA/QC workflow, where deviations are eyeballed in software and measurements are prone to human error.

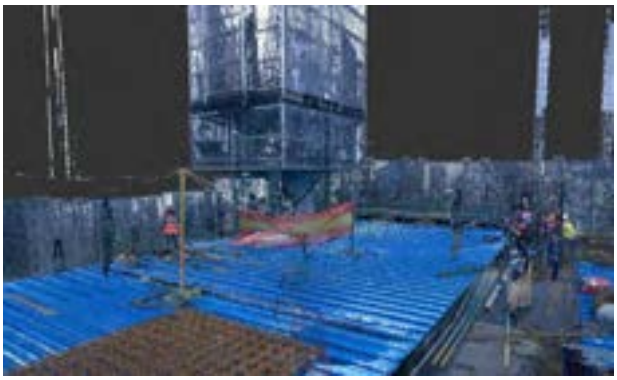

Figure 4. A scan of a 44 level high-rise under construction by Laing O'Rourke.

deployed BuiltView for a number of QA/QC checks listed below.

- *Floor Flatness and Floor Levelness*: BuiltView is capable of replacing manual slab flatness spot checks, based on spirit level and tape measure, with an automated LiDAR-based solution.
- *Reinforcement Steel Bars*: On many projects, BuiltView demonstrated extraordinary capabilities for rebar detection, identification and spacing calculation.
- *Precast Elements*: Precast elements can be checked for quality issues prior to leaving a manufacturing facility - preventing site delays and accelerating rectification.
- *Geometrical Compliance*: Most structural concrete objects - column, beam, wall and slab, and mechanical objects, pipe, duct and cable - can be accurately checked for geometric compliance using BuiltView.

3.3 QA/QC Automation Benefits

- *Floor Flatness and Floor Levelness*: By utilising BuiltView on the 44 level high-rise in North Sydney, Laing O'Rourke mitigated much of the risk associated with the works that followed structural works, for example carpet laying. A scan of the building is shown in Figure 4
- *Reinforcement Steel Bars*: BuiltView demonstrated extraordinary speed and accuracy in counting rebar, computing bar diameter and inter-distances on a large power generation project. The project consisted of 3 million tons of concrete and a total reinforcement weight of 200,000 tons In this environment, assurance checks with minimal labour was highly valued.
- *Precast Elements*: Due to time consuming manual QA processes, it is estimated only 5%-10% of precast units are surveyed in manufacturing facilities prior to delivery. An example of these units is depicted in Figure 6. With BuiltView, this percentage can reach 100% at no additional cost. In practice, BuiltView was used to run automated quality checks on bridge culverts that were scheduled to be installed on a $240 million train bridge project. By detecting defects in a single culvert early in production, BuiltView prevented defects in the remaining 40 precast replicas - preventing rework-related costs and delays.
- *Geometrical Compliance*: By leveraging BuitView as an in-house digital tool for automatically checking geometric compliance (see Figure 5), Laing O'Rourke reduced the turn-around time on as-built validation. Typically, surveyors' reports are based on spot checks of less than 10% of object area. With BuiltView, this percentage can increase to 100% at no additional cost. Moreover, with BuiltView these comprehensive and automated checks allow for a proactive approach to defect identification, allowing for an indirect reduction in total defects and consequent schedule delays.

4 Progress Tracking

4.1 Traditional Progress Tracking Workflow

The process of progress monitoring is traditionally a laborious in construction. Foreman record the work performed on construction sites on a daily and/or weekly basis. Filed reports provide a wide range of data on the available resources, the potential risks, inventories, etc. Nonetheless, these reports cannot capture 3D aspects of the construction work completed and to be completed. They are also prone to human error and aren't frequent

Figure 5. An example of a BuiltView's QA/QC workflow, where deviations are automatically calculated, removing subjectivity in measurements.

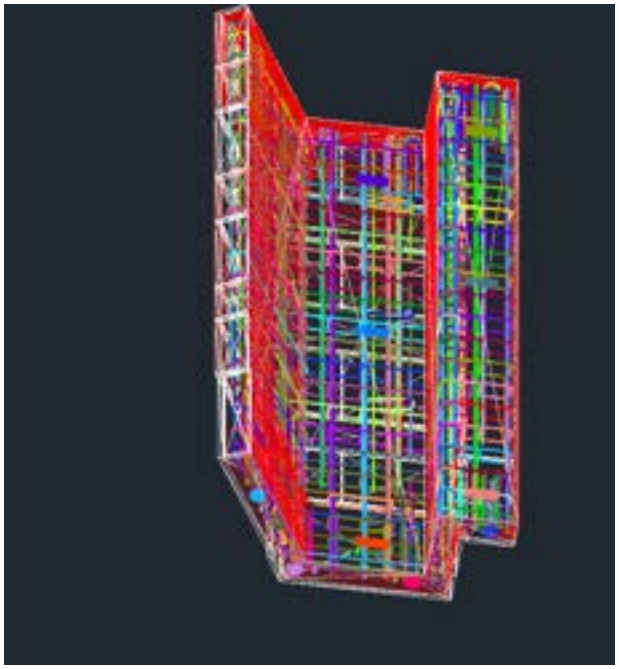

Figure 6. An example of a precast moulds processed by BuiltView for Quality Checks at Laing O'Rourke's manufacturing facility, Explore Industrial Park, UK

enough due to time and cost constraints. This is especially true when multiple site visits are required to collate all data and correct any inaccuracies. Furthermore, significant schedule delays can occur before progress reports can be analyzed and acted upon.

Taking photographs on site is another traditional method of capturing a visual record of on-going progress. Nonetheless, this 2D information is not detailed and comprehensive as 3D geometric data of as-built conditions of construction sites. Consequently, many researcher have directed their work toward generating 3D point clouds from captured photographs, with the aid of photogrammetry and computer vision. The meshes or models generated can be compared with 3D design models and used for automated progress monitoring. However, the capture & analysis process can be laborious.

4.2 Progress Tracking Automation

The traditional process for monitoring progress often prevents corrective actions from taking place in a timely manner, which eventually leads to schedule delays. BuiltView replaces most of these reports (or at least supplements them) with as-built 3D geometric information to minimise delays. By providing reliable progress data of on-site activities, Laing O'Rourke has been able to identify issues that may have caused significant delays. This information is a crucial component of a progress monitoring process as it is timely, detailed, objective, and repeatedly queried at no additional cost. [10].

4.3 Progress Tracking Automation Benefits

BuiltView provides an innovative progress tracking framework that integrates LiDAR and 4D BIM (3D BIM + schedule) [11] as well as 5D BIM (3D BIM + schedule + cost) [12]. Even when BIM is not present in an appropriate format, which is a common aspect of infrastructure and linear projects, BuiltView provides scan to scan comparisons using proprietary point-based algorithm to report temporal changes on projects[13].

Aside from the traditional progress checks of built elements, Laing O'Rourke was successful in tracking earthworks using BuiltView on a 155 km highway upgrade project, one of the largest public infrastructure projects in Australia. By running daily scans and progress checks, the project was capable of accurately detecting schedule delays and make data-based decisions to rectify the issues, boosting overall productivity and mitigating potential budget overruns.

5 BuiltView for Fast, Accurate and Timely Documentation

Data acquisition time for LiDAR in comparison to multiple site walks can be 2-10x faster [14] depending on the hardware used (terrestrial tripods, drones or mobile scanners). As a result, construction professionals are potentially able to document 10x the amount of information [14]. Intuitively, with more high-quality information, data-based decision making becomes easier and more efficient. With BuiltView's high-end processing capabilities, the data size can be reduced by half through de-noising and de-cluttering point clouds and by creating meshes and

Figure 7. An example of point clouds of construction sites, cluttered with equipment and moving personnel.

Figure 8. Multi-Level Buildings can be captured in one day with terrestrial LiDAR scanners, and in under an hour with mobile LiDAR scanners (see Figure 8). Using the correct hardware for the correct use case is a key reason for Laing O'Rourke's success in implementing BuiltView

as-built models. An example of cluttered point clouds is shown in Figure 7.

5.1 As-Built Models for Pre-construction Phase

During the pre-construction phase, the various parties involved in a project collectively define the milestones of the project, based on the expected duration of completion and the available budget. With LiDAR data, heritage buildings were captured with great detail on a number of Australian heritage buildings renewal programs. BuiltView's fast and accurate validation of existing as-built models prior to construction using LiDAR data was invaluable, as it served as the foundation for all works to come. Capturing the intricate architecture of these legacy buildings would have otherwise proven prohibitively slow.

In short, the engineering and risk analysis conducted before starting construction is significantly improved by leveraging accurate as-built data. BuiltView's intelligent system is capable of facilitating the production of as-built models, which clearly improves project performance. In fact, according to recent studies [15], when project definition work is conducted properly, both project schedules and costs are reduced by approximately 20%.

5.2 As-Built Models during Construction Phase

There is a growing requirement for contractors to deliver as-built models during the construction phase or projects, as they progress from one milestone to the next. To streamline this, BuiltView provides a semi-automated workflow for updating the position of BIM components based on point clouds. Compared with manual updates, BuiltView is capable of quickly producing accurate conformance reports that reduce the amount of time designers need to spend eye-balling point clouds to detect variances (see Figure 3. It also reduces the amount of time project engineers have to spend verifying the resulting as-built model from weeks to a few days.

5.3 As-Built Models for Post-construction Phase

It is evident that handover of 3D as-built documentation, whether in the form of a model or a point cloud, is becoming increasingly common in construction contracts. As research and case studies continue to prove the value of objective as-built data, this trend will no doubt continue to grow. As a facilitator of this data, BuiltView is invaluable for closing the loop on learning from one project to the next. We expect opportunities will continue to arise for BuiltView to reduce rework costs, improve productivity and facilitate transparency and accountability within construction. Most recently, following the devastating 2019 Australian Bushfire Season, LiDAR was used to rapidly capture a massive geographic extent for detailed mapping and documentation of the impact of these fires [16]. Laing O'Rourke was appointed by the New South Wales Government of Australia to undertake the first phase of fire recovery clean-up works, and it will leverage BuiltView to rebuild the local community assets with extraordinary performance.

6 Conclusion

In this paper we presented BuiltView, a digital progressive assurance tool that provides construction projects with accurate and timely verification of as-built conditions when compared with design. The tool leverages LiDAR and BIM technologies to provide insights that have been proven useful across multiple project phases and disciplines. Through real-life use cases undertaken at multi-million dollar projects for the international contractor Laing O'Rourke, we showed how BuiltView has been an invaluable asset for reducing rework, boosting productivity, and providing indisputable documentation. By providing an accurate, regular digital representation of

as-built conditions, we believe BuiltView will be a key enabler for digital twins in the near future. Moreover, by providing an accurate, objective measure of construction progress, we forecast that BuiltView will play a key role in enabling the industry-changing efficiencies of smart digital contracts.

Abstract –

The current practice for information sharing with building information modelling (BIM) is a distributed data sharing based on conversions. Conversions are problematic due to data loss, redundancy, and conflicting information. A single data schema used by all applications is a requisite for a conversion-free data collaboration. In the study, a software development kit (SDK) was developed, which implements required features and guarantees compatibility between BIM programs. Three independent applications 3DTrussme, Leonardo, and Viewer were developed using SDK. A cloud service for handling the shared model was implemented. In the experiments, Leonardo was used for modelling walls, 3DTrussme for truss design, and Viewer for model viewing. All three applications were using the same shared model on the cloud.

In the experiments, the information exchange occurred without conversions and all data was saved only once on the cloud database. Without conversions and duplicates less conflicts and redundancies occurred, which lead to better data integrity and integration. Using SDK, there was no technical barrier for applications to join the single shared model ecosystem, but a drawback was that existing BIM programs are not compatible without remarkable changes. The performance was acceptable on the test run, but in real use, the size of the model and the number of applications and users, will be much larger. However, a conversion-free single shared model approach can be a possible trend to the development of the next generation BIM as well as a potential alternative for current data sharing methods using distributed files, conversions, and linked data.

Building Information Modelling; Data Conversion; Cloud Services

1 Introduction

The evolution of the building design has developed from handmade paper drawings to a fully digitalized process using computers. In the 1970s, the first 2D CAD (Computer Aided Design) software came to the market and in the 1980s, first pioneers developed 3D design applications for building design. Acronym BIM (Building Information Modelling) is nowadays commonly used for the digitalized information handling and it was probably Jerry Laiserin who first introduced the term BIM [1,2].

A successful collaboration between all stakeholders requires an efficient and functional sharing of the building information [3]. The amount of the BIM data grows significantly during the design and construction stages of the building project. After the construction stage, new information is still created but not at the same rate. Moreover, the flow of the data substantially breaks off when the construction is completed [4]. A continuous information flow is a necessity for improving the data utilizing within facility management [5].

The prevailing practice for data exchange is distributed data management (DDM) approach based on conversions. In general, an exchange format is used for data transfer. Using an exchange format requires two conversions between two applications, but reduces the total amount of import and export formats each application needs to implement [6]. Direct data exchange between native formats requires only one conversion and is less error prone but, on the other hand, each supported format must be programmed.

A conversion-free data exchange requires the use of only one data format. To fully avoid the problem of overlapping and conflicting information, a single data schema is not enough. Separate models, although in the same format, can still include inconsistent data. With the single shared model approach (SSM) no conversions are needed and all information is saved once, which reduces the data complexity and improves the data integrity and integration. The challenge with the single model is

concurrent changes made by different users. Rules must exist for defining which change is valid, when overlapping modifications happen. Figure 1 illustrates the different exchange methods from the perspective of conversions.

Figure 1.The basic differences for the needed conversions with the different data exchange methods. With application to application, the total number of conversions is the largest, whereas with a single shared model no conversions are made.

2 Development of the single shared building information modelling

For a regular user it is common to mix applications, data models, and storages. However, they have their own functions and objectives from a software technology point of view. When application is running, information is available at the main memory of the computer. When application is closed, the data must be stored to permanent storage which can retain its information even when powered off. The interconnection between the permanent storage and application is the data model. A file or database is read into program's run time memory as a data model, then modified during the application run and saved back to the permanent storage.

2.1 Data model and storage

In today's software technology, the common practice for a data model is an object oriented approach [7]. Each different object is encoded as a software class and a requisite set of classes constitutes the whole data model. The class instance is an object that is created from the definition of the class into the data model. Instances get a globally unique identifier when they are created into the data model and one software class can be instantiated as multiple objects, each having a different unique identifier.

The data on the permanent storage is read to object instances and saved back. For instantiating the correct class to the data model the definition of the class must also be saved on the storage. The class instantiating method can be either static or dynamic. With static binding (called also early binding), code of classes must be available when the program is compiled and built. The drawback of the static binding is that every change or addition of a class requires an updated version of the application. Modern programming languages, like Microsoft C# [8], support dynamic binding (called also late binding), which requires the availability of the class not until the application is started. That is a significant difference and makes changes into data model classes much more flexible. A class addition or change does not require a new version of the application.

In a building data model, classes and instances carry the information as a collection of value-name pairs. The IFC (Industry Foundation Classes) is a standardized object-based data format and model maintained by an international non-profit organization called buildingSMART. With IFC, value-name pairs are called property sets [9]. Term attribute is also commonly used with object-based data models. List of classes and properties are not constant which brings up the challenge of the data compatibility. Standards are common languages which realise the universal and admitted understanding for the content of the building information. But standards change slowly and are not adequate for commercial BIM applications since data content advancement is an endless and all the time running process. Therefore the flexibility and extensibility of the information content are key features for the single shared data model. Supporting standardised data is advisable, but by allowing applications to freely specify additional information content, technical barriers are eliminated from the use of a single data model schema. Both the data model and permanent storage must implement freely extendable data content.

The permanent storage can be a database or a file. A database has a more organised data schema and allows partial data access and sharing with several users. The following three alternatives are technically possible as a database schema for storing the data of classes:

1. Separate table for each class with a separate column for each attribute. This schema has traditionally been used.
2. The vertical database schema also called an entity-attribute-value model (EAV) [10].
3. XML schema, where whole data of the class is packed as XML data.

Juola [11] implemented all the three alternatives using a SQL Server database. With separate table for every class it is almost unfeasible to keep tables and columns up-to-date due class changes. Queries are very complicated with the entity-attribute-value schema. The result was, that the XML schema was best suitable for a building data model having always evolving content.

The number of object instances in a data model can grow huge. Some kind of organising and grouping is needed for maintaining the fluent manageability of the model. Objects can be organised based on their material, structural behaviour, type, name, position, feature, or some other data. As a result, the amount of active objects is decreased making the handling of the model more flexible. IFC supports Model View Definition (MVD and Information Delivery Manual (IDM) standards for defining a data subset [12]. Several studies have been made for extracting IFC partial model based on MVD [13].

Hierarchical organisation is a well-known arrangement method, but that method has very rarely been applied among AEC/FM applications. The hierarchical arrangement naturally enables a model division into partial models and hierarchy is simply constructed by defining a parent object for every object. A partial model is then made up of an object and all its descendants at all sub hierarchy levels. The IFC data model has a static and fixed hierarchy of *Project → Site → Building → BuildingStorey → Space* [9]. According to Singh, Gu and Wang [14] a static hierarchy is inadequate and the ordering should be flexible for fulfilling the requirements of users.

2.2 Data sharing

A data concurrency control is essential for the single shared data model. Simultaneous changes to the same data can be handled by an optimistic or pessimistic method [15]. With an optimistic control, it is assumed that conflicting data changes are rare and can be resolved. The pessimistic control is based on data locking, which fully prevents any concurrent data editing. The validity, reliability, and consistency of the information in the building model is best guaranteed by the pessimistic method. Locking the whole model is not realistic, but only a part of the model can be reserved for one user at one time. The hierarchical model arrangement implements partial models that can be reserved and released. The single data model system and hierarchical arrangement with reserving and releasing partial models together make up a pessimistic data concurrency control system for ensuring the validity, reliability, and consistency of the information in the building model.

With the single shared model, all information must be available for all stakeholders without delays and conversions continuously. In the current internet world that is best achieved with a cloud based system. Using the cloud database only is technically possible, but a synchronised local copy gives next advantages:

- Enables incremental updates reducing the amount and size of data transfers [9]. By keeping a change log, only changed data needs to be synchronized between the cloud and local storage.
- The reserved partial model can be first saved to the local storage before publishing it to the cloud. Unfinished work is then not available for other participants.
- Offline working without a connection to the internet is possible with the local synchronized storage.

The cloud storage cannot be accessed like the local storage. User rights on the server cannot be as extensive as they are on the local computer. It would be a clear risk for the security and data integrity to allow public and direct read-write access to the server storage for all. A cloud service implementing only needed functionality ensures that no data corruption occurs due to a false operation. For a safe and secure access to the cloud storage, next functions need to be implemented on the cloud service:

1. Registration of user.
2. Establishing a new model.
3. Getting a list of models available for user
4. Connecting to a model
5. Load for downloading the whole or partial model from the cloud to the local storage.
6. Reservation of the partial model for editing. Reserved part is locked permitting only reading for other users.
7. Releasing and publishing the reserved partial model to the cloud storage.
8. Get changes due to releases made by other users.
9. Adding a new node to the model hierarchy tree.
10. Removing a node form the model hierarchy tree.
11. Disconnect from the shared model and logout from the cloud service.

2.3 Programming principles of the single shared data model system

A derivation programming technique is a common practice with the coding of classes. With derivation, duplicate code for similar classes is avoided, since a derived class inherits everything as default from the parent. Derived classes can develop the inherited content further as much as needed. The amount of software data model classes that are needed during the whole life-cycle of the building is vast. Thus, the development and maintenance of data classes are not tasks for a single software house. However, for ensuring compatibility, base public classes used by all developers are needed. The derivation of new classes must start from public classes, which must implement the required functionality for forcing the compatibility between all developed applications. Especially reading the permanent storage as a data model into runtime memory of the application and saving it back are operations that must only exist on

public classes. Secondly, classes for geometry must be implemented as public classes so that applications can also view non-public class objects that are defined by other applications.

For uniformity, common understanding and ability to co-operate, the amount of public classes should be as large as possible. Many organisations in various countries are developing various BIM standards for diverse purposes [16] and the public classes can be seen as the standardised part. BuildingSMART International has published a few standards for building information content and data exchange [17]. However, also non-standard classes can be made publicly available.

2.4 Arrangement and execution of the experimentation

For a full scale testing of the single shared model system, a cloud service and applications were developed. Cloud service was running on a Windows Server operating system. The web service was implemented using Windows Communication Foundation (WCF) [8]. Storage system used was a relational database Microsoft SQL Server. For the development of applications a public software development kit (SDK) was created including the next four assemblies:

1. Base public classes (BPC) assembly includes base data model classes from which all application specific classes must be derived.
2. A local storage for client (LSC) assembly offers a synchronised local storage for applications.
3. A model toolkit for the client (MTC) implements functionality for synchronising the local and cloud storage.
4. A web service toolkit for the client (WSTC) is a helper assembly simplifying the use of the web service functions.

Three applications were developed using the public SDK. *3DTrussME* is a 3D modelling and structural analysis software for wooden trusses. It has been the first and main testing application for the single shared model system and has a large application specific class library. *3DTrussME* is owned by a Finnish company, Ristek Oy, and the programming is carried out by another Finnish company, Enterprixe Software Ltd [18]. *3DTrussME* is a commercial application currently used in Finland, Norway and Estonia. *Leonardo* is a 3D design application for concrete structures. The development of *Leonardo* is ongoing and it is not yet available for a practical use. The third application used in testing was *Viewer*, which was only used for viewing the model. Figure 2 shows the general arrangement of the testing environment.

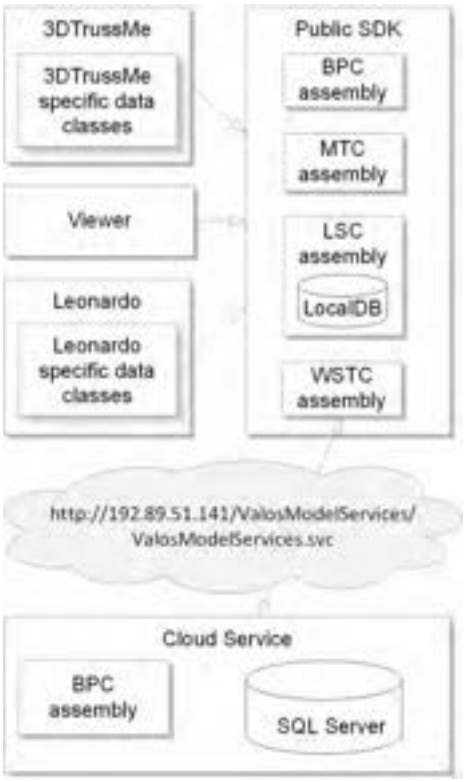

Figure 2. A diagram showing the general arrangement of the testing environment with three applications, public SDK package, and cloud service.

Three users were participating in the test event, one for each application. All three applications were connected to the same shared model on the cloud. *3DTrussME* was used for truss design, *Leonardo* for modelling walls and *Viewer* for viewing the model. The pessimistic concurrency control was in use and partial models were reserved and released. During the test, *Leonardo* data classes were further developed without any compatibility problems for other two applications. The test was executed with steps shown in the next list.

1. Registration of users.
2. A model was established on the cloud database and access to the model for users was granted.
3. User #1 using *3DTrussME* reserved the model, created the base hierarchy and released the model. Fig. 3 shows a screen snapshot after step #3.
4. User #2 using *Leonardo* reserved the *Walls* subtree and started modelling walls. User #1 saw the reservation when getting the latest from the cloud.
5. User #2 finished the modelling of walls, released the node *Walls* and local changes were updated to the cloud model. User #1 updated changes from the cloud and saw the modelled walls. *Leonardo* was using a private wall class, but by using a public wall class instead, walls were available at *3DTrussMe*.

6. User #1 reserved the node *Roof* for truss modelling. User #3 started *Viewer* and saw walls and reservation of the *Roof* node.
7. User #1 noticed that one wall was at wrong position, reserved it, made the correction, and released it.
8. The private data model of Leonardo was further developed by adding new attributes to the wall and by creating a new column class. User #2 started to use the new version of *Leonardo* and updated local model. No compatibility problems or data corruption occurred although *3DTrussMe* used older public wall class and *Leonardo* new changed wall class.
9. User #2 reserved *Walls* and *Columns* node, continued modelling and released nodes.
10. User #1 released Roof node.
11. All users updated their local model and can saw the whole model.
12. All users disconnected from the model and closed applications.

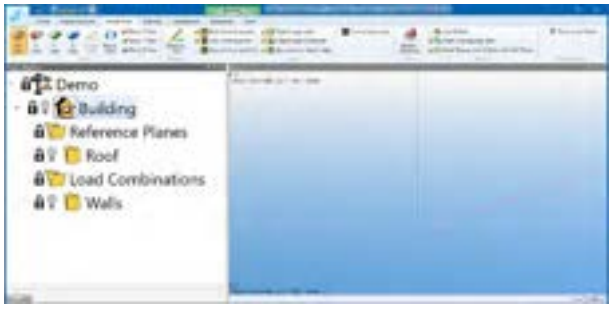

Figure 3. Basic hierarchy after step #3. All nodes are not reserved for changes which is marked as a closed black lock icon in the project explorer tree.

3 Results

As a result of the test execution, a shared model was built up on the cloud. Three applications were using the same shared model on the cloud and all data sharing occurred without conversions and data defects. Figure 4 shows the final model after the execution of the test. The permanent outcome of the executed test was the data stored in the cloud database. Totally five tables were used for data storing:

1. User table for registered users.
2. Model access table for defining the access of users to model.
3. Session table for connected users. With a connection to the model each user gets a session id that identifies the access to one model. Session ids are not permanent and are used instead of credentials after the connection to the model. Session ids are invalidated with disconnect or after defined unused timeout.
4. Event table for the model established, reservation and release events. Events enable the bookkeeping of reserved nodes and incremental updates.
5. Model table for the building model data.

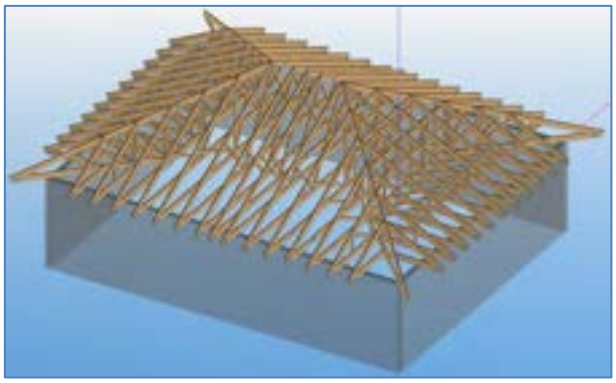

Figure 4. Final model after the execution of the test on *3DTrussME* application.

Just one data format is compulsory for the conversion-free data exchange used. The key points of the specification for a freely expandable data model schema keeping the compatibility backward and forward are as follows:

- The data model schema consists of public part and private application specific portions. All private classes must be derived from public classes.
- Data carriers and all data saving into and reading from the permanent storage are handled by public classes.
- Classes are instantiated using the dynamic binding method.
- Schemas of the data model and permanent storage must enable backward and forward compatibility allowing free changes to the content and number of data classes. This is achieved with a dynamic binding and XML storage format.
- A software development kit (SDK) implements all the key points of this list, and thus, applications developed using SDK automatically realize all key points and are compatible with each other.

Data duplicates are not prevented by using only one data model and storage structure. A single model approach accessed simultaneously by all participants is needed for removing the overlapping information. The following key elements are required for a workable single shared model system:

- The single shared database is placed on the cloud, enabling an equal access for all participants.

- Access control is implemented limiting the entry only for registered and authorized users. Furthermore, access to models per user is controlled.
- All connections to the shared cloud model are performed through a web service that has the required functionality. It is a security risk to allow direct access to the database, which may lead to illegal changes in the database.
- A pessimistic data concurrency control is used.
- An event log keeps track of reservations, releases and data change events enabling the monitoring of the reservation state and incremental updates of the local storage.
- The model arrangement is realized using a hierarchical approach which divides model into numerous and varying size partial models. Those subtrees can be used as units for reservation and for limiting the size of the model that is handled at a time. The hierarchical arrangement is free and the model can be divided as example by design discipline, storey, space or element type using one or combined dimension.
- SDK is used for the development of applications enforcing the compatibility and SDK also eases establishing connections to the single shared model.

4 Conclusions

The presented single data model system is available for all new and old BIM applications. An SDK is free and contains base classes as a start point for the development of application-specific data content. The schema of the data model is version-free allowing changes and additions without breaking the compatibility. In summary, the presented method makes up a conversion-free data exchange solution based on a single extendable data model schema. It is self-explanatory that without conversions all conversion defects will be eliminated. Data duplicates will vanish when a single model schema is extended as a single shared model approach. The data integrity and integration improve when data sharing occurs without conversions and when no overlapping information exists.

To obtain the greatest benefit from the single shared model, software from various disciplines should be available. There is no limit regarding what types of applications can join the ecosystem: the only requirement is to use an SDK. Anyway, many issues can be raised up for the wider industrial use. The incompatibility with the current convention, needed investments and lack of interest hinder the expansion. The reputation and reliability of a new technology is low in the beginning. Rogers [19] divides technology adopters into innovators (2.5%), early adopters (13.5%), early majority (34%), late majority (34%), and laggards (16%). Evidently, the conversion-free single shared model approach needs innovators for the start of the technology expansion.

No commercial single model system for multidisciplinary building information is available. Systems for sharing a model between the same applications have been developed, but none can cross the application boundary. The objective for model sharing with *Tekla*, *Archicad* and *Revit* is to enable multiple people to work simultaneously with the same model. There is no reason to limit the model sharing only between the same applications as long as user and access control prevents conflicting and illegal changes. Indeed, according to Lu, Wu, Chang and Li [21] , there is lack of BIM standards for model integration and management by multidisciplinary teams.

It is a common opinion among the AEC industry and BIM scientists that a single model BIM is an unfeasible solution. According to Day [22], a single building model is only a daydream. On the other hand, Howard and Björk [23] state that a single BIM is the holy grail, but there might not be willingness to achieve it. According to Turk [24], a centralized shared database is impossible but in the future, BIM will approach it. The reasoning for this is mostly not presented by these authors, but model differences between disciplines and the size of model are noted. Because of the rejection of the single BIM model, no research has been conducted of a true single shared model system. Under the umbrella term ‘single BIM’ scientific articles can be found, but they see single BIM as a common repository for distributed data sources. A cloud service or a single address to separate files is only one data delivery tool for distributed information. A true single model system is a shared database that can be accessed simultaneously by several users, and every piece of data is stored only once.

According to Johnson [25], the complexity of design tasks and software evolution raise questions about a single model solution. It is true that tasks performed by engineers and consultants are complex and various. Many kinds of applications are used for design tasks and all software is evolving continuously. However, is that complexity troublesome only for the single shared model approach? The distributed data sharing system uses many data formats and conversions. Is this more complex when compared with the single shared model operating without conversions? Johnson [25] list the next issues for alleviating the skepticism against “One BIM”:

- An open source vendor-neutral elastic data structure.
- Enabling the interoperation of applications from multiple vendors.
- Sharing data in the design ecosystem without explicit import or export.
- Supporting different kind users, tasks, workflows, and stages in the design process.

The presented single shared approach will implement all the above items, but a significant adjustment to current BIM practices and processes must come true.

According to Miettinen and Paavola [2], the benefits of using BIM is often reported by researchers and project participants, but the impact of BIM is difficult to isolate from the success of the entire project. Moreover, increases in the productivity in the construction business have been marginal when compared with other industry sectors [26]. Assuming, that information technology has a notable influence on the improvement of productivity, why has digitalization succeeded in other industry sectors but not in the construction business?

The testing of a software system is not a one-time process. In the test run only three applications and users were involved, but in the reality, many more applications are used with BIM. No technical limit for the number of applications exist, but a growing number of applications and users accessing the same model concurrently can slow down the performance

Microsoft SQL server was used as the cloud storage system and the maximum size of a SQL Server database is 524 272 terabytes [8], which is an incredible amount of information. Before that maximum size limit is reached, other performance issues will probably arise. Client applications do not need to make calls to the cloud service non-stop, but database queries can slow down the cloud service when the database is large. In the test run, there were only three users and one model on the cloud, which naturally cannot show much of the performance for real projects. Microsoft LocalDB was used as a local storage system on the client side. The maximum size of the LocalDB database is 10 GB [8] which is much less than the maximum size of a SQL Server database. Local storage capacity will most obviously be the first bottleneck before any performance problems on the cloud service appear.

An internet service provider (ISP) and independent software vendor (ISV) for web service are needed for offering the cloud service for the single shared model. Figure 5 shows all the major players of the building project. ISVs should not hold a monopoly position in their field of activity. Application development is freely available for all enabling multiple software on the same purpose. Developing the web service can also be done separately by multiple ISVs. There can only exist one public SDK and a private commercial enterprise is not the best ISV for SDK. A public non-profit corporation or alliance would be a better ISV operator for the public SDK.

Allowing all users to change all parts of the model after reservation might not be a desired course of action. As example architects do not usually allow designers from other disciplines to edit architectural plans. By organizing users to groups, more detailed user rights can be implemented. Each group can reserve partial models and control usage rights for other groups. When using both user and group access control the partial model availability can be restricted on many levels.

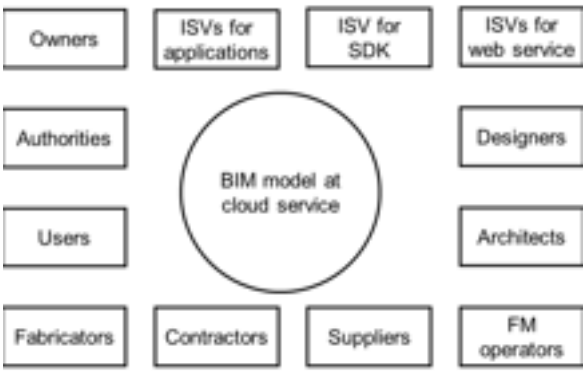

Figure 5. The players around BIM model during the whole life-cycle of the building project.

The main weakness of the single shared model approach is its incompatibility with the currently used data formats. All data classes in current applications must be redone for full compatibility which is likely a threshold for most software houses. Therefore, conversions from existing formats are needed for lowering the obstacle to the presented new single model method; otherwise, it will be isolated without any links to existing systems. Rewriting all IFC classes by starting the derivation from BPC classes could be one solution. After that, importing the IFC files could be done. However, exporting to IFC cannot properly support all the data on a single shared model using a version-free data schema since IFC is not a true open and extendable data format. IFC implements adding new property sets for the objects and the use of IfcProxy for entities that are not defined by IFC [27]. But, this will end up as an outstanding amount of IfcProxies having fully different content if all the native data by all applications is exported. Additionally, updating the schema of the IFC standard will break the compatibility backward and forward, requiring a new version of every application that is using IFC.

Parametric or Non-parametric? Understanding the Inherent Trade-offs between Forms of Object Representation

Abstract –

The need for efficient computing in construction modelling and analysis workflows often requires making tradeoffs between the inherent advantages and disadvantages of different datatypes being generated and managed. This is notably observed in geometry reconstruction (e.g., scan-to-BIM, reverse engineering, etc.), where a tradeoff often occurs between computational efficiency and the choice between increased semantic enrichment or increased representational accuracy (often both cannot be achieved simultaneously). This dichotomy can be generalized as a choice or tradeoff between parametric and non-parametric object representation forms. This paper presents a simple conceptual model for characterizing the datatypes used for representing and defining construction geometry to understand key tradeoffs that exist. First, we survey existing literature across multiple domains to identify and distill key attributes used in characterization according to the terms parametric and non-parametric. Then, we develop and illustrate a conceptual model using an analogy to mathematical expressions vs. discrete digital approximations employed in computer vision (e.g., Gaussian kernel, Hough Transform, and Scale Invariant Feature Transform (SIFT) algorithm). Finally, we outline future research opportunities for improving the state of object representation.

1 Introduction

In construction workflows, the virtual representation of physical objects forms the basis for design, communication of product and process requirements, and as-built verification of constructed works. When objects are represented by a set of simple algebraic primitives such as curves, planes, and polysurfaces, an object is said to have a "parametric" form [1]. In contrast, when objects cannot be accurately represented by such primitives, and rely on implicit algebraic forms (e.g., surface normal histograms) or large, non-semantic data structures (e.g., point clouds and meshes), objects are said to be "non-parametric" [2,3]. Computer-aided design (CAD) and building information modelling (BIM) favor parametric representations [2,4], while workflows used for digitization of as-built objects (using tools such as photogrammetry and laser scanning) favor non-parametric representations [3,5]. Practitioners require specific object representations for different purposes across the construction life-cycle. As a result, across the lifecycle of any given project there can exist a wide range of construction elements, components, assemblies, and conditions exhibiting or being represented by parametric and non-parametric forms. This dichotomy exists due to (1) the nuance of methods employed for object representation, (2) inattention or inability to control dimensional variability during construction, and (3) the diversity of geometric forms and conditions that exist across various systems in the AEC industry.

1.1 Geometric Challenges in AEC Related to Parametric and Non-parametric Forms

The premise that geometry can be characterized by a mix of parametric and non-parametric forms has unique implications in Architecture, Engineering, Construction (AEC) that few studies have investigated in detail, but that continues to create challenges for mediation and resolution efforts. Many geometric and topological challenges can be traced to an inability to mediate effectively between parametric and non-parametric domains, as evidenced in the following examples:

- **Existing conditions characterization.** The challenge in these workflows is the process of fusing parametric and non-parametric data stemming from existing conditions and new components or assemblies. This is evidenced particularly in adaptive building reuse where data used to represent existing conditions is most accurately facilitated through non-parametric data. Parameterization of unstructured data can be performed, but often results in a loss of representational accuracy. Examples of as-built conditions which are difficult to parameterize

include large concrete structures, beam camber, rail track levelness, or curvature of free-formed bespoke architectural features.

- **Updating BIM to reflect the as-built status**. The process of updating BIM during construction is complex and subject to varying degrees of accuracy for geometric representation. When objects deviate outside of allowable tolerance thresholds and cannot be accurately or easily represented using parametric primitives, updating the as-designed BIM becomes time-consuming and error-prone.
- **Abstraction of geometric deviations**. While the comparison of 3D sensed data (e.g., point clouds) with BIM has been relied upon in industry for many uses cases, the challenge that still exists is localization, interpretation, and abstraction of discrepancies. While a 3D point cloud can be overlaid on a 3D model to produce a map of geometric deviations, this analysis by itself does not translate into distinct kinematic (i.e., parametric) deviations or non-kinematic (i.e., non-parametric) deviations. The challenge of sensing and interpreting geometric deviations is especially important in repetitive assembly workflows, such as modular construction, where parametric corrections to assembly geometry configuration (i.e., location, orientation, size of objects, etc.) can have a profound impact on manufacturing efficiency and reduction of rework due to dimensional variability.
- **Mixed-form object assembly planning**. Challenges in object assembly planning arise due to varying levels of object regularity, manufacturing processes and dimensional variability. For instance, the assembly of manufactured products into "stick-built" buildings can be particularly challenging since manufactured products are often characterized as being highly parametric with low dimensional variability, while site interfaces are often non-parametric with a high degree of variability [6]. Another example of mixed-form object assembly planning is the optimal packing of irregularly shaped objects into containers, which occurs in nuclear waste disposal. In this case, irregularly shaped objects exhibit non-parametric representations while regularly shaped objects (containers) exhibit parametric representations [7]. These types of packing scenarios are challenging to derive optimized solutions for.

1.2 Problem Statement and Contribution

In light of the challenges with having a mixture of parametric and non-parametric representations in various AEC workflows, this research provides a better understanding into the trade-offs that exist. In some cases, parametric representations might be preferred, while in other cases non-parametric representations might be necessitated. Current classifications and definitions for parametric vs. non-parametric datatypes are verbose, and as a result of the different requirements for datatypes in AEC, navigating this delineation is challenging.

This contribution of this paper is as follows. First, a review of existing classifications for parametric vs. non-parametric entities is explored from a systems-, geometric schema-, semantic information-, and associative modelling-based standpoint. Then, a simple conceptual model is proposed, which captures the intrinsic trade-offs between these representation forms. A demonstration is used to demonstrate how such a model is efficacious for describing these trade-offs. Finally, the implications of this model are discussed, to provide a better understanding into decision making regarding the handling of geometric data in AEC.

2 Delineating between Parametric and Non-Parametric Entities

2.1 Systems Context

The distinction between parametric and non-parametric systems is verbose and multi-variate. In mathematical modelling of systems, the distinction between parametric models and non-parametric models lies with fixity and immutability of system parameters. Parametric models have fixed non-changing parameters for system characterization, while non-parametric models assume that a fixed set of parameters cannot be used for proper system characterization [8]. This notion also appears in robust parameter design [9] where systems are characterized in terms of controllable design aspects, or parameters, and noise variables which are much more challenging and sometimes not feasible to control.

In some cases, non-parametric systems are viewed as having an infinite number of parameters, and since only a finite number of these parameters are used for modelling these systems, the output can change with the same input [10,11]. It should be noted that a clear association of, and connection between the terms *parametric*, *non-parametric*, *stochastic* and *deterministic* for codifying systems cannot be made. For instance, parametric models can be stochastic if the data being observed fits a known distribution with constant variance, and variables are numerical and continuous [12].

Systems can also comprise both parametric and non-parametric attributes, and thus can be considered semi-parametric. The use of *semi-parametric* for domain classification also appears in the context of regression analysis, where a combination of linear and non-linear regression can be useful for statistical inference [13]. The use of localized variables and global parameters define model components that do not change (i.e., global

parameters of an entire population), and model components that do experience variation (i.e., local variable instances of a sample from a population). In addition to describing system certainty, these classes also describe system scale and provide a distinction between design vs. observational attributes.

In summary, the distinction between parametric and non-parametric systems is multi-variate across domains and is based on several factors including modelling approach, system certainty, design vs observational data, and system scale (Figure 1).

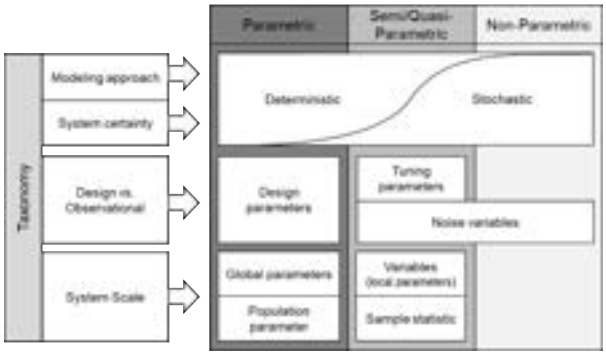

Figure 1. Taxonomy of systems classification in terms of modelling approach, system certainty, design vs. observational data, and system scale.

2.2 Geometric Schema Context

The representation of object geometry using distinct geometric schemas is also verbose and oftentimes unclear. Classification of these schemas are often based on *ambiguity*, *directness*, and *compactness*.

Unambiguous (or complete) representations are used to describe the entirety of a physical object, and underlying primitives or descriptors can be inverted to recreate the exact same object being represented. Unambiguous approaches can be used to provide a one-to-one mapping between objects and their representation [14,15]. Ambiguous representations are often used to distinguish between objects in a very efficient manner [15], even though the descriptors used cannot provide a one-to-one mapping between objects and their representation. Within unambiguous representations, methods can be further classified into implicit and explicit representations. The key difference between these two approaches is the directness for computing objects. Indirect representations use intermediate geometric descriptors such as histograms of normals or curvature to describe objects [1] as compared to explicit methods which directly describe objects using surface (e.g., polysurfaces, meshes), or volumetric (e.g., constructive solid geometry) descriptors [1,5].

A final division between approaches is parametric vs. non-parametric representations. While explicit methods can be either parametric or non-parametric, implicit methods are distinctly not of a parametric form [16]. Parametric representations are more algebraically refined than non-parametric methods, however, they can be more computationally intensive to perform operations on [2]. While this may not be the case for simple primitives such as lines, circles and planes, it is especially true for representing complex geometry, using formats such as polysurfaces, Bezier curves, B-Splines, Non-Uniform Rational Basis Spline (NURBS), and piecewise functions. Non-parametric representations, in contrast, are more computationally efficient, but are more difficult to achieve exact geometric representation. A non-parametric representation can be implicit as in the case of differential properties of a surface of a given location [1], or can also be explicit as in the case of polygonal meshes. The conversion between parametric and non-parametric representations is discussed in [16]. The conversion from parametric to non-parametric is defined as *implicitization* and it is possible to perform for any rational parametric surface of curve. The reverse process, *parameterization*, is not as easy to execute and is not always possible to perform for higher-order descriptors. Parametric representations have become the "quasi-standard" for CAD modelling [2] due to algebraic topology capabilities, while non-parametric representations are preferred in machine vision and as-built modelling systems [5,15] due to computational efficiency.

Despite the existence of classifications for representation schemas such as the one shown in Figure 2, exact definitions and distinctions are at times fuzzy and inconsistent. For instance, some studies state that explicit representations can be either parametric or non-parametric [1,3], while other studies state parametric approaches are always based on implicit methods of describing geometry [17]. This fuzziness stems from the fact that some classifications refer to the datatype itself as the entity being characterized, while other classifications refer to the process taken to derive a datatype as the entity being characterized. In addition, it is difficult to understand clear distinctions between the nature of datatypes with respect to parametric vs. non-parametric attributes. For example, it is well regarded that a representation scheme that allows for modifications of its underlying variables (e.g., control points in NURBS) is parametric. However, the same argument could theoretically be made for meshes (i.e., control vertices can be modified), yet these are clearly defined as being non-parametric schemas. Perhaps there is a theoretical limit to the number of control variables in a representation scheme whereby it starts to become non-parametric. However, no such definitive limit has been (or perhaps can be) defined, which further adds to the existing fuzziness of classification.

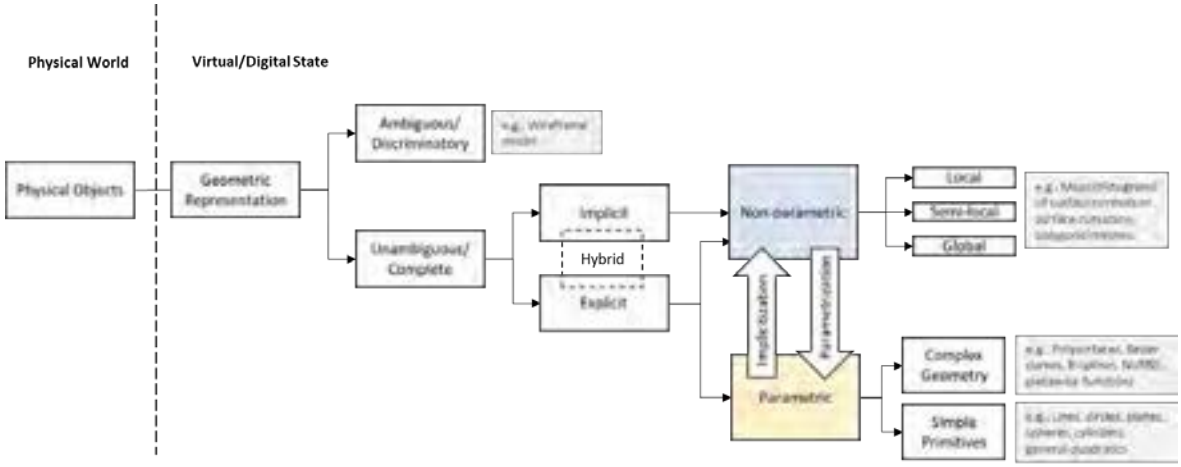

Figure 2. Classification of geometric schemas used to represent physical objects in AEC according to ambiguity, directness, and compactness (adapted from [3] using [1,2,5,14-16]).

2.3 Semantic Information Context

From a building information modelling standpoint, the classification of objects as being parametric extends beyond just representational form and has unique attributes to facilitate use across the entire construction lifecycle. Parametric BIM objects must also include semantic information (parameters) in the form of associated data, rules, topology and material-specific data [4]. Parameters are also used to classify objects into categories, families, types and instances, which is stored as data in the form of text, integers, numbers, area, volume, angles, URLs, or binary data [18]. Across this wide definition of parametric objects in BIM, attributes related specifically to geometry and topology are investigated in this research since they directly affect geometric mediation between objects. Topology describes the spatial relationships between elements that do not change based on changes to geometric parameters of those elements [19]. Topology can relate to the relationship between features of an element (e.g., face to edge), the relationship between elements (e.g., beam to column) or relationship between groups of objects or spaces (e.g., room to room). Topology plays a key role in the way architects and engineers understand the function and expected behavior of building elements. Topology, geometric representation and material properties are distilled into the "semantics" of an object, which can be interpreted as the form, function and behavior of objects and systems of objects [20]. Current modelling practice in construction emphasizes the creation and preservation of semantics by explicitly outlining that building information models must contain parametric intelligence, topological relationships and object attributes [21], otherwise, they are considered no more than 3D geometric models.

2.4 Associative Modelling Context

A fourth context can also be used to describe the delineation of parametric vs. non-parametric entities in AEC. Parametric modelling (or parametric design) involves the use of geometric rules and constraints to embed explicit domain knowledge into BIMs and provides a way for automated design regeneration via an "associative" model [22]. While any CAD modelling system can contain a parametric representation of an object, the following characteristics differentiate parametric modelling systems: users can define custom relationships between features and objects, parameters between objects can be integrated into a system (i.e., a parameter of one object can be used for defining parameters on other objects), parametric definitions are compatible in a system or are otherwise mutually exclusive such that no two parameters create conflicting relationships; geometry should be object or feature-based [22]. This approach to modelling has become very popular in the manufacturing industry and is seen in software such as SolidWorks®. Constraint-based design requires all dimensions of features and parts to be parametrically defined, constrained and related to other features [23], or it is otherwise considered under-constrained, and cannot be realized [24]. While this degree of parametric constraints is not employed in most AEC workflows, the use of associative model does provide a source of additional parametric properties that can be exploited.

2.5 Summary

Exploring a range of contexts reveals a verbose and multi-variate landscape for describing the delineation between parametric and non-parametric entities. Selecting a suitable object representation (whether

parametric or non-parametric) extends beyond just the geometric schema employed, includes semantic information requirements, and might include associative relationships to other objects. In a systems context (2.1), the delineation between parametric and non-parametric is fuzzy (with an intermediate category sometimes being used), and this also translates down to the object level. However, it is clear from the examples of cases where both datatypes exist in AEC, that assessing trade-offs is useful for understanding the inherent benefits and constraints to each datatype. In some cases, parametric object representations are preferred, while in other cases, non-parametric object representations might be required.

3 Proposed Conceptual Model

This research presents a conceptual model to help summarize the key trade-offs between parametric and non-parametric object representations. This model is based on the distinction between analytical expressions and digital approximations that appear in computer vision for pattern and shape recognition processes. As depicted in Figure 3, this model classifies parametric object representations as having many relations between individual datapoints or entities, and are by nature more abstract, while non-parametric object representations have a greater number of unstructured datapoints and are by nature more discrete or approximate.

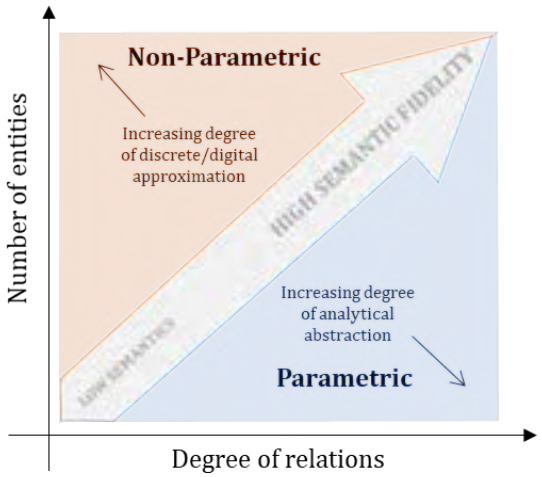

Figure 3. Conceptual model for characterizing the delineation of parametric and non-parametric object representations

3.1 Analogy to Pattern Recognition Techniques

In computer vision, various techniques for pattern recognition can be used to resolutely employ digital approximations of analytical expressions for recognition.

One of the most common methods for shape detection in computer vision is the Hough Transform which detects curves by exploiting the duality between points on a curve and parameters of that curve [25]. It works by first considering the analytical expression of a curve, often in the parametric line form (r, θ), and edge segments of an image given by (x_i, y_i) . The transform is then implemented by discretizing the Hough parameter space over finite intervals of the image, or "accumulator cells". This technique takes an inherently parametric mathematical expression and discretely approximates it in a non-parametric manner to extract and transform information from an image (which itself can also be defined as a non-parametric data source).

Gaussian kernels are another example of discrete approximation used in computer vision to perform an analytical transformation on an image (Figure 4). A more general case of this is convolutional kernels and filters, which transform an expression into a discrete nxn matrix and is convoluted over an image. Discrete approximations such as kernels are efficacious in complex algorithms such as Scale Invariant Feature Transform (SIFT) due to the ability to perform analytical operations in a computationally efficient manner.

In the same way that many pattern recognition techniques transform analytical expressions into discrete approximations, this same analogy can be used to delineate between parametric and non-parametric object representations. On one hand, we can postulate a trend that the more abstract an expression or representation is, the fewer entities are required to relate components together. Conversely however, when these relations are broken and discretized, more discrete values are required to perform a similar level of approximation compared to its analytical counterpart.

Analytical Expression

$$h(u,v) = \frac{1}{2pi\sigma^2} e^{-\frac{u^2+v^2}{\sigma^2}}$$

Discrete Approximation

$$H[u,v] = \frac{1}{273}\begin{bmatrix} 1 & 4 & 7 & 4 & 1 \\ 4 & 16 & 26 & 16 & 4 \\ 7 & 26 & 41 & 26 & 7 \\ 4 & 16 & 26 & 16 & 4 \\ 1 & 4 & 7 & 4 & 1 \end{bmatrix}$$

Figure 4. Analytical Gaussian Expression and its Digital Approximation (i.e., 5x5 Gaussian Kernel)

3.2 Measuring the Degree of Semantic Fidelity

The final component to the proposed model is characterizing the degree of semantic information encapsulated in an object representation. The greater the number of entities and degree of relations between those entities, the greater the semantic fidelity of a representation. In practice, there is a trade-off that occurs between parametric and non-parametric object representations with respect to the degree of semantic encapsulation. This is perhaps most evident when

representing "as-is" objects. While non-parametric object representations are positioned better for obtaining a higher degree of representational accuracy, they cannot be semantically enriched to the same level as parametric object representations. Despite the high level of abstraction in parametric representations and the significant advancements being made to leverage better parametric modelling approaches that maintain representational accuracy of as-is objects, the inability to achieve the same degree of representational accuracy as non-parametric representations restricts its ability to achieve the highest level of semantic fidelity. As such, a notable trade-off occurs between parametric and non-parametric representations with respect to semantics.

4 Demonstrating the Conceptual Model

Previous research has provided information for assessing the trade-offs between geometric schemas (Table 1). Using this breakdown, a simple demonstration can be carried out for the representation of an I-beam element (Figure 5) to show how parametric representations tend to have fewer entities, which are more tightly related. The first digital representation in this figure is a point cloud, which can be obtained by performing sampling reconstruction of existing mathematical descriptions or from reality capture [26]. The other digital representations which are more structured than point clouds are triangular and polygonal (tessellated) meshes. As shown, the point cloud representation has 7296 datapoints (i.e., XYZ points), whereas the triangular mesh contains 1740 datapoints (i.e., triangle vertices), and in the most simplified case, the polygonal mesh structure has 108 datapoints (i.e., polygon vertices). These digital representations are also considered to be non-parametric. As opposed to regular shapes (e.g., rectangular, cylindrical, prismatic, etc.), non-parametric forms cannot be defined parametrically using a shape type and a limited set of parameter values that specifies the object [1]. Figure 5 also depicts two common mathematical representations. Non-Uniform Rational Basis Spline (NURBS) is a common boundary representation, which uses a series of surfaces to completely enclose and represent a given shape. Constructive Solid Geometry (CSG) is a mathematical representation that describes the volume of an object through use of Boolean operations (e.g., addition and subtraction) of simple geometries to create more complex shapes. While CSG has been the preferred method for representing geometry in building information models (BIM) due to its simplistic data structure [1], there are many applications where NURBS are preferred, since it can describe complex geometry more appropriately [21,27]. As shown for the steel beam, the NURBS geometry contains 56 datapoints (i.e., control points), whereas the CSG geometry contains 9 datapoints (3 extrusions built with 3 control points each).

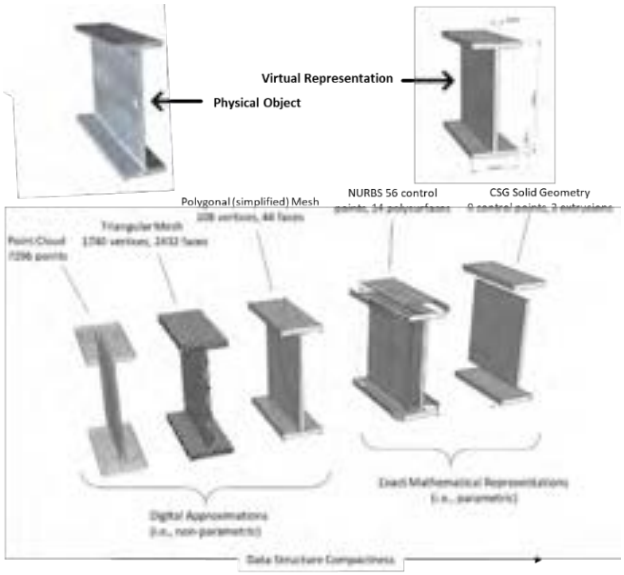

Figure 5. Digital and Mathematical Representations for a Physical Object (Steel Beam Element).

Table 1. Summary of the key trade-offs between geometry representations employed in AEC

Geometry Representation	Geometry Kernel Processing Demand	Continuity	Representational Accuracy (As-is)	Semantic Richness	Exactness for Complex Geometry	Sources
Point clouds	Slow (high computational effort)	Discretized	High	Low	Low	[28]
Mesh	Fast (no interpretation required)	Discretized	Med-High	Low	Med	[28]
BREP	Med (interpretation required)	Exact, continuous	Med	High	High	[17,28]
CSG	Med (interpretation required)	Exact, continuous	Low-Med	High	High	[28]
NURBS	Med (interpretation required)	Exact, continuous	Med-High	High	High	[28]

The general trend for this simple example is that as representation moves from digital to mathematical, it becomes more compact, with fewer entities that are abstractly related. In addition, we can plot each of these geometric descriptors on the conceptual model (Figure 6). One hand the point cloud representation is the most non-parametric with the highest number of entities (which are not related), while the CSG representation is perhaps the most abstract parametric representation. While not directly considered in this example, the Boundary Representation (BRep) geometric schema is another parametric representation which arguably has the highest semantic encapsulation across all geometric schemas. This is because the BRep schema is based on a hierarchical topological structure, with explicit relations between bodies, faces, edges and vertices (refer to [17] for a more detailed breakdown of this schema).

While this example demonstrates how geometric schemas can be characterized using the proposed model, the purpose of the analysis is not to provide a comprehensive (or exhaustive) classification of all possible schemas. However, certain schemas are better suited for more semantic fidelity than others. For instance, given how NURBS and BRep can be discretized by adding additional control points without changing the initial geometry of an object, these representations potentially have the ability to harness the semantic fidelity requirements of a given application as opposed to those of CSG or non-parametric representations.

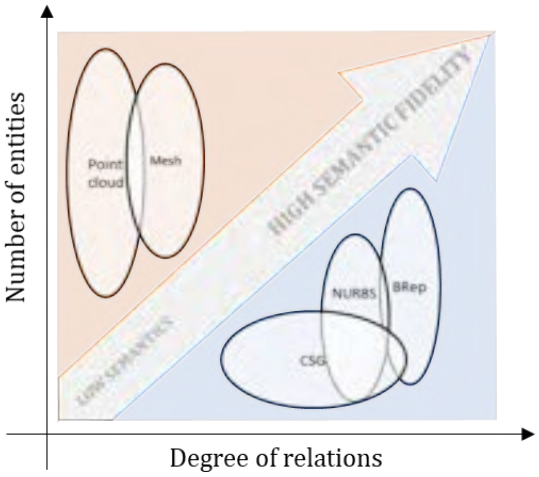

Figure 6. Depicting the Conceptual Model Using Geometric Schemas

5 Conclusions

Within AEC, the choice of object representation form invokes trade-offs with respect to computational efficiency, representational accuracy, and semantic enrichment. Since there remains to be one ubiquitous object representation that can simultaneously meet all of these objectives, the choice of representation will continue to require making trade-offs. Review of existing classifications for object representation reveals that there can be a significant degree of verbosity and ambiguity, further compounding the task of selecting a suitable representation. This paper demonstrates that approaching classification through a parametric vs. non-parametric lens is useful for providing key insight required in selection of a desired object representation. A conceptual model is established by considering two dimensions of an object representation: number of entities used to represent an object and the degree of relations between those entities. These dimensions are fundamental in computer vision for applications such as pattern recognition and shape detection. For instance, the discretization of analytical expressions is a key component to achieving computational efficiency in methods such as the Gaussian kernel, Hough Transform, and Scale Invariant Feature Transform (SIFT) algorithm. In addition to geometric schemas, other attributes can also be described by the proposed model, namely semantic enrichment and associative modelling relationships. These dimensions clearly fit into a parametric vs. non-parametric context within AEC workflows. A functional demonstration using various geometric schemas reveals the trend that parametric representations have a high degree of analytical abstraction, while non-parametric representations have a high degree of digital approximation.

5.1 Future Research Opportunities

In practice, there are numerous workflows which require either parametric or non-parametric representations due to current trade-offs. While this trend is expected to continue, there are opportunities to bridge this gap as evidenced in the following areas of research:

- **'Geometry as a feature'.** Rather than defining objects as an abstraction of geometry, geometry can be viewed as a feature of object. This is already the premise of object-oriented modelling (and is used in IFC, for instance), yet a more concerted focus on this concept can allow for multiple geometric schemas to be used to represent the same object without necessitating the landscape of parametric vs. non-parametric trade-offs.
- **Towards improved geometric schemas.** Current limitations and trade-offs can be addressed by developing new schemas that do not have the limitations of existing schemas. One example is developing a global or 'master' schema that can be modified or updated throughout the lifecycle of AEC projects as required.
- **Developing parametrization methods that preserve fidelity of information.** Rather than converting non-parametric datatypes into a

parametric form at the expense of loss of representational fidelity and semantic information, it is possible to discretize initial parametric forms (e.g., such as NURBS) in such a way that can achieve suitable accuracy while maintaining semantic fidelity.

Abstract -

The Architecture, Engineering and Construction (AEC) industry is still one of the most hazardous industries in the world. Researchers impute this trend to many factors such as the separation between the phases of safety planning and project execution, implicit safety issues and, most of all, the dynamic and complex nature of construction projects. Several studies show that the AEC industry could greatly benefit of latest advances in Information and Communication Technologies (ICTs) to develop tools contributing to safety management.

A digital twin of the construction site, which is automatically instantiated and updated by real-time collected data, can run fast forward simulations in order to pro-actively support activities and forecast dangerous scenarios. In this paper, the twin model of the Digital Construction Capability Centre (DC3) at the Polytechnic University of Marche (UNIVPM) is developed and run as a mock-up, thanks to the adoption of a serious game engine. This mock-up is able to mirror all the relevant features of a job site during the execution of works from a safety-wide perspective. In such a scenario, virtual avatars randomly explore the construction site in order to detect accessible, unprotected and risky workspaces at height, while warning the safety inspector in case additional safety measures are needed.

1 Introduction

Nowadays, the AEC industry represents one of the most hazardous productive sectors [1]. In fact, although it employs only about 7% of the world's work force, yet it is responsible for 30–40% of fatalities. Statistics, which are referred to different countries, demonstrate that the construction safety is a perennial global problem.

In the United States, the census data from the U.S. Bureau of Labor Statistics (BLS) showed that as many as 774 workers died from injuries they suffered on construction sites in 2010, accounting for 16.5% of all industries. The fatality rate accounts for 9.8 per 100000 full-time equivalent workers and is ranked the fourth highest among all industries. Within the two decades of 1990 and 2000, more than 26000 U.S. construction workers died at work [2]. That equates to approximately five construction worker deaths every working day. Out of these fatalities, 40% involved incidents were of the type falls from height. Further investigations showed that inadequate, removed, or inappropriate use of fall protection equipment contributed to more than 30% of those falls [2]. Statistics about other countries, such as China [3], United Kingdom [1] and Germany [4], confirm high percentages of fatal accidents in the construction industry and point out falls from height as one of the most frequent causes. As a result, it is evident that the construction industry is far from the vision of "zero accidents/injuries" espoused by many construction-related companies [1].

The high number of fatalities is generally imputed to several causes, such as the separation between the phases of safety planning and project execution [2, 5], implicit safety issues and, most of all, the dynamic and complex nature of construction projects, which require ever-changing safety needs [5]. Construction safety issues can be properly described as complex sociotechnical system [6], which cannot be tackled simply adopting a best-practice approach defined ex ante. Conversely, the answers to such problems can be described as emergent practices [7].

The AEC industry is often regarded as being hesitant in adopting innovative technologies, due to the inherent difficulties of its unstructured and changing environment [1, 8]. Nevertheless, many research studies [9, 10, 11] demonstrate that the application of the latest advances in ICTs in the safety management field can help to proactively respond to hazardous scenarios and enable the shift from reactive to proactive safety management.

1.1 Rule-checking systems

Some research studies [2, 12] apply commercial systems, such as Tekla® [13] and Solibri™ [14], to execute BIM-based rule-checking analysis for the detection of fall hazards. Rules, once they are translated from human language into a computer-readable format, can be executed supporting labor-intensive safety checking tasks in a little time. In this direction, authors in [15] propose an ontology-based approach for construction safety checking, modelling safety constraints with Semantic Web Rule Language (SWRL). The authors, assuming fall from height as a test case, demonstrate the potential of this methodology for the assessment of fall hazard on the base of hole's acceptance criteria defined by safety regulation. In fact in similar circumstances, i.e. when a dimension has to be

compared with a threshold value, a rule-checking system drives to reliable results.

It must be noted that sometimes safety assessment is contextual, that is it depends from complex geometries and spatial dependencies (e.g. non-perpendicular crane cable that lifts up and swings) or ever-changing site conditions (e.g. temporary structures that aid construction processes and are often not modeled). In cases like these, it is hard to define general rules by means of safety checking constraints which cover all possible scenarios; moreover, information provided by a BIM model can result incomplete, inaccurate or not updated. As a consequence, the correctness of the rule-based safety analysis may be largely affected.

1.2 Real-time tracking systems

In some research studies, prototypes of self-updating BIM models based on sensor data for real-time Health and Safety (H&S) management have been developed. The paper [9] proposes an application which aims to improve environmental safety in construction sites; the BIM model displays the latest data from temperature and humidity sensors and the real-time status of various locations, with a focus on the ones affected by atmospheric hazards. Another research work [10] integrates a rule-checking system and a Real-Time Location System (RTLS) to place dynamic virtual fences and to check whether tracked real fences are properly installed. In the system developed in [11], once risks are assigned to building components, a warning can be sent to tracked workers on site in case they come too close to hazards. A requirement for this approach is that hazards are identified and classified in advance.

1.3 Contribution to research

In this work, the development of a digital twin for H&S management in construction sites to prevent falls from height is reported and tested. This approach can be used to complement BIM-based rule-checking systems, which work well when they come to checking compliance with safety codes, regulations and best practices. But, as already stated in Section 1, construction sites represent a type of complex systems and unexpected emerging hazardous scenarios cannot be anticipated unless a digital twin is put in place.

The research study reported in this paper concerns a methodology to develop a digital twin of construction sites, which makes it possible to find out in real-time hazardous scenarios possibly leading to falls from height. A forward-looking simulation approach, run in real-life conditions and implemented in Unity3D^{TM}, and a real-time monitoring sensor network, to update the status of the ever-changing environment and of involved workers, have been integrated and tested in the Digital Construction Capability Centre (DC3) of the Polytechnic University of Marche (UNIVPM at Ancona, Italy).

This paper is organised as follows: Section 2 introduces digital twins as a candidate solution for the management of complexity. Section 3 provides a description of the developed system architecture, whereas in Section 4 simulation and results are reported. Finally, Section 5 is devoted to conclusions.

2 Management of complexity

2.1 Complex systems

2.1.1 Basic of complex systems

A complex system consists of many elements affected by non-linear interactions [16]. As a consequence, small causes may lead to large consequences, and vice versa; this implies no immediate apparent relationship between causes and effects. Interactions, which cause system changes over time, consist of transference of energy or information, usually have a fairly short range and show recurrency, they being affected by loops. Furthermore, the constant flux of energy ensures the survival of a complex system and its history affects the present behaviour. A complex system is usually open or it is hard to define its borders. The scope of such a system is not an intrinsic characteristic, but is usually determined by the purpose of the description and is often influenced by the position of the observer; this process is called framing. Finally, each element ignores the behaviour of the system as a whole and responds only to information that is locally available. The complexity feature emerges as a result of interactions among constituting elements. The most representative examples of complex systems are the human brain, the behaviour of a flock of birds and economic systems of the modern society [16, 17].

The Cynefin framework (Cynefin in Welsh pronounced kunev-in means the multiple factors), introduced in 1999, is a decision-making conceptual structure which proposes strategies to properly tackle each one of the five domains: "simple", "complicated", "complex", "chaotic" and "disordered" [7]. Whereas cause-and-effect relationships can be detected by everyone in the "simple" domain and by experts in the "complicated" one, the same cannot be said in the "complex" one, where the reason why things happen can be understood only in retrospect, causing unpredictability. In the "complex" domain, the Cynefin suggests to probe and sense eventual emergent instructive patterns to be used as responses.

In this research study, the high-level strategy proposed by the Cynefin framework has been assumed. In practice the digital twin, enabling forward-running simulations, makes it possible to "probe and sense" future scenarios;

emergent safety measures can be suggested and applied in real-time.

2.1.2 Complex systems in H&S management

In the AEC industry, safety issues can be regarded as complex sociotechnical systems [6]. Stakeholders include manufacturers, main contractors and subcontractors, design staff, project and site managers. Moreover, construction sites, which are usually interested by crowds of workers, adjacent buildings and facilities, complex weather phenomena, result in a very dynamic operating environment. In other words, the safety status is an emergent property of a system, whose components are subjected to non-linear interactions that cannot be anticipated [18]. In the research study [6], authors have studied a tower crane safety issues as a systemic problem, assuming the safety risk management framework defined by [19] that was specifically developed with complex sociotechnical systems in mind; as a result, a list of factors affecting tower crane safety has been identified.

2.2 Digital twins

2.2.1 Basics of digital twins

The first definition of the concept, nowadays known as the digital twin, was made in 2002 by Michael Grieves, in the context of an industry presentation concerning Product Life cycle Management (PLM) [20]. A digital twin can be defined as a virtual representation of a physical product or process, used to understand and predict the physical counterpart's performance characteristics throughout the product life cycle [21]. To ensure an accurate modeling over the entire lifetime of a product or of its production, digital twins use data from sensors installed on physical objects to determine the objects' real-time performance, operating conditions and changes over time. Using this data, a digital twin evolves and continuously updates to reflect any change to the physical counterpart, creating a closed-loop of feedback in a virtual environment that enables companies to continuously optimize their products, production, and performance at reasonable costs [21].

The statements "digital model", "digital shadow" and "digital twin" are often used as synonyms, although they differ from each other in the level of data integration between the physical and digital counterparts. A "digital model" is a digital representation of an existing or planned physical object that does not use any form of automated data exchange between the physical object and the digital object. If there further exists an automated one-way data flow between the state of an existing physical object and a digital object, one might refer to such a combination as "digital shadow". If further again, the data flows are fully integrated in both directions, one might refer to it as "digital twin" [20].

2.2.2 Digital twins in the AEC industry

In the near future, digital twins are expected to take a center stage in the AEC industry too, advancing rapidly beyond BIM and enabling asset-centric organizations to converge their technologies into a portal or immersive experiences [22]. The result will be better informed decisions to improve network availability, to enhance workers safety, to ensure regulatory compliance and to reduce environmental impacts. Thanks to the application of Artificial Intelligence (AI) and Machine Learning (ML) methodologies, we envisage immersive digital operations, providing analytics visibility and insights to enhance the effectiveness of operations staff and help them anticipate and head off issues before they arise and react more quickly with confidence [22].

A real commitment in this context was demonstrated by the Centre for Digital Built Britain (CDBB) which published, at the end of the year 2018, the Gemini Principles to guide the National Digital Twin and to shape the information management framework that will enable it [23]. The National Digital Twin itself is not intended as a single, monolithic twin of the entire country's infrastructure. Rather, it will be a federation of many twins, representing assets and systems at different levels of granularity, brought together to generate greater value. A first application was developed implementing three interconnected work packages. The first one provides the BIM model of part of the University of Cambridge. The second one regards the integration of data from various sources to enable effective analytics and drive better decisions. Finally, the third one aims to develop novel applications for facility management that exploit the data captured through the digital twin [23].

3 System architecture

3.1 Technology stack

The digital twin model, proposed in this paper, for real-time H&S management is based on the system architecture composed by the following subsystems (see Figure 1):

- a Ultra-wideband (UWB) sensor network for localization;
- Node-RED™ programming tool;
- ArangoDB database;
- Unity3D™ game engine;

The first subsystem consists of a UWB sensor network. This infrastructure is in charge of tracking what workers and equipment are present in the real world's scenario

Figure 1. System Architecture.

and sending data necessary for updating to the main system. An IoT programming tool, namely Node-RED™, wires together the UWB sensor network and the rest of the system's components. ArangoDB, is a database which stores the complete history of coordinates. The hearth of the developed architecture is the serious gaming platform Unity3D™, which hosts the digital twin's simulation environment and enables forward-running simulations to predict hazardous scenarios. In order to enable the safety manager to remotely supervise safety issues, forward simulations' results can be displayed in real-time to an off-site screen (see Figure 1). Furthermore, as soon as any fall hazard is detected, a warning can be immediately sent to the safety manager. This is made possible by sending a message, via SignalR, to Node-RED™, which can trigger an alarm or a smartphone notification (see Figure 1). In this way, the developed system can support real-time H&S management in order to prevent accidents or fatalities.

For the purpose of this paper, the left part of the system architecture (see the continuous-line of the Service box in Figure 1) has been implemented in the Digital Construction Capability Center (DC3).

3.2 Reality mirroring

Real-time sensing is devoted to the continuous mirroring of the digital twin. According to the system architecture depicted in Figure 1, workers involved in on-field activities can be tracked by means of UWB localization systems. This technology leverages the Time of Flight (ToF) technique, which is a method for measuring the distance between two radio transceivers by multiplying the time of flight of the signal by the speed of light. Thus, knowing the position of fixed UWB anchors and operating a trilateration algorithm, the position of any UWB transceivers (tag) can be determined, even if it is moving.

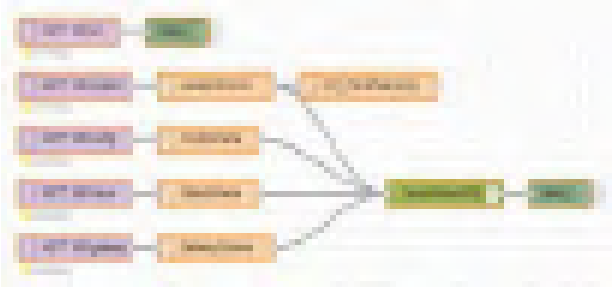

Figure 2. Node-RED flow for storing UWB messages in an ArangoDB collection.

For the purpose of this paper, five anchors were installed in known positions, whereas an UWB tag has been applied to the monitored piece of equipment, that is the ladder, in order to track its position.

In order to wire together hardware devices with the database and again with the Unity3D™ game engine, the flow based graphical programming tool Node-RED™ has been adopted. Node-RED™ is a tool specifically designed for Internet of Things (IoT) applications. In this research, a dedicated Node-RED™ flow wires together the position data coming from the UWB localization system with a database for their storage. The resulting flow built in Node-RED is shown in Figure 2.

During the development of a digital twin, different types of data must be stored and linked together in an emerging way. Therefore, ArangoDB has been selected here, because it is a native multi-model NoSQL open-source database for storing several types of information, including those types typically related to digital twins, such as the complete data history from sensors. Every changes happening in the ArangoDB collection that stores location messages is triggered to the serious gaming engine Unity3D™ by means of the software library SignalR. Hence, sensors data are delivered to the game engine enabling virtual objects' positions to be updated in real-time. As soon as a dangerous scenario is predicted in Unity3D™ by the forward simulations, a real-time notification can be triggered by sending a message to Node-RED™ via SignalR in order to prevent fatal events.

3.3 Implementation of the gaming environment

The use of serious game engines is a promising tool supporting research in real-time control systems, among the others. The first application regarding gaming technology in the area of research was found in the aircraft industry, with the use of Microsoft Flight Simulator for educational purposes [24]. Afterwards, serious game engines had a wide spread for other research purposes such as simulation and analysis, further demonstrating that mere entertainment is not the only feasible, nor the most promising,

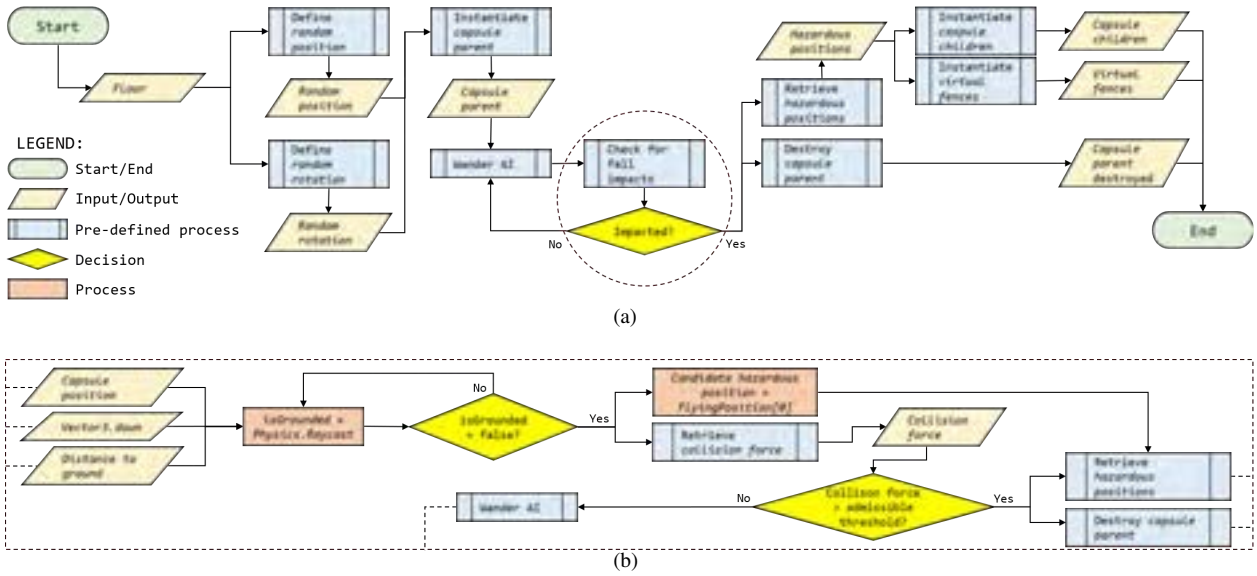

Figure 3. (a) Pseudocode describing the general logic of the digital twin developed in Unity3D^{TM} game engine in order to detect fall hazards; (b) pseudocode describing in details the virtual sensor which checks for fall impacts.

application. The great success of this approach is due to the difficulty of executing real experiments in some fields, especially in H&S management; in fact the need for establishing safe conditions to avoid direct exposure to risks would affect participants behaviour.

In this research study, game technology has been applied to develop the digital twin of a construction site for real-time H&S management. The use of a serious game engine facilitates the modeling of the environment, which includes the physical space, sensors and mechanical physics, and the implementation of simulation. For the purpose of this paper, the gaming platform Unity3D^{TM} has been adopted. The physical space of the digital twin, assumed as case of study, can be directly imported within Unity3D^{TM} as an IFC project with its structure. To this end, an IFC Loader, based on the IFC Engine DLL library [25], has been developed, in order to import topological information, materials properties and all semantic information from the digital model. This tool models the environment using one of the most powerful techniques in solid modelling, that is Boundary Representation (B-Rep). B-Rep represents a solid as a collection of connected surface elements, that is the boundary between solid and non-solid. The digital twin, in order to mimics reality, requires the implementation of human and artificial sensors, known as agents. The sense of sight, for example, must be implemented in digital twins to give humans' avatars the awareness about what is happening around them [26]. In Unity3D^{TM}, this can be done modelling the Field of View (FOV) as a collider by means of a set of quantitative parameters (e.g. FOV angle and elevation angle); a user can see an entity simply if her/his FOV collider intercepts the entity itself. The mechanical physics is a native functionality of game engines; hence, in the game scene every object is affected by gravity and occupies a volume just like in the real world. In details, these properties can be managed by means of the quantitative parameters stored respectively in the rigidbody and collider components of a virtual object. Furthermore, C# advanced programming makes it possible to define, directly in Unity3D^{TM}, a deformation behaviour which acts in response to a rising force applied to an object. To make an example, a ladder could inflect or even break down, if the weight of the overlying avatars is close to or higher than its mechanical strength. To sum up, Unity3D^{TM} hosts the digital twin and can work as a hub that is able to trigger co-simulations related to some specific disciplines and receive back results. In this way, multiple simulators (e.g. fire scenario, plants' functioning, etc.) can be coupled, by means of the models exchange standards (such as Functional Mockup Interface, FMI).

The pseudocode reported in Figure 3(a) describes the general logic at the base of the developed digital twin for real-time identification of fall hazards. At the first instantiation, virtual capsules are generated in a random position and rotation on the surface of a specific floor; instead, at the following instantiations it follows the logic explained below (see the third point in the bullet list). Each of these entities embeds an AI component which allows it to wander and explore the surrounding environment. A virtual sensor, indicated by the red dashed lines in Figure 3(a) and described in details in 3(b), has been implemented in order to evaluate if any possible impact due to a fall can

be harmful and that point must be marked as an hazardous location. To this end, a ray casting algorithm is applied to check if the monitored object is grounded or not; in case of false evidence, which means that the capsule is falling, the first "flying" position is labelled as a candidate hazardous position. The retrieved collision force is then compared with the pain tolerance value of 6 kN, known from literature [27] and regulation [28] about fall-arrest equipment. If the collision force is higher than the admissible threshold, the following events are triggered:

- the point from where the fall has taken place is confirmed as an hazardous position;
- a virtual fence is instantiated in correspondence of the hazardous position as a graphic notification;
- new children capsules are instantiated in the hazardous position with random rotations in order to speed up the exploration of the environment in the nearby;
- the parent capsule is destroyed in order to avoid an overcrowding of capsules.

4 Simulation and results

The system architecture described in Section 3 has been tested in the Digital Construction Capability Centre (DC3), which is a laboratory of the Polytechnic University of Marche in Ancona, Italy. According to the definition of Digital Twin (see Section 2.2.1), the developed digital twin mock-up was meant to replicate the typical environment of the construction site, which continuously changes and evolves. For the purpose of this paper, the works at height scenario has been recreated inside the DC3 laboratory, as well as the evolution of the scene that can be encountered on a construction site.

The top image in Figure 4(a) shows the regular configuration of the DC3 laboratory, in which the floor above the changing room is not accessible since no access path exists; hence, there is no fall hazard affecting that floor area. As shown by the virtual replica of this scenario (see the bottom image in Figure 4(a)), the developed system populates the DC3 digital twin with virtual capsules able to wander on the main floor of the laboratory. It can be noticed that no barrier is suggested by the system and the boundary of the floor on the changing rooms is kept clean.

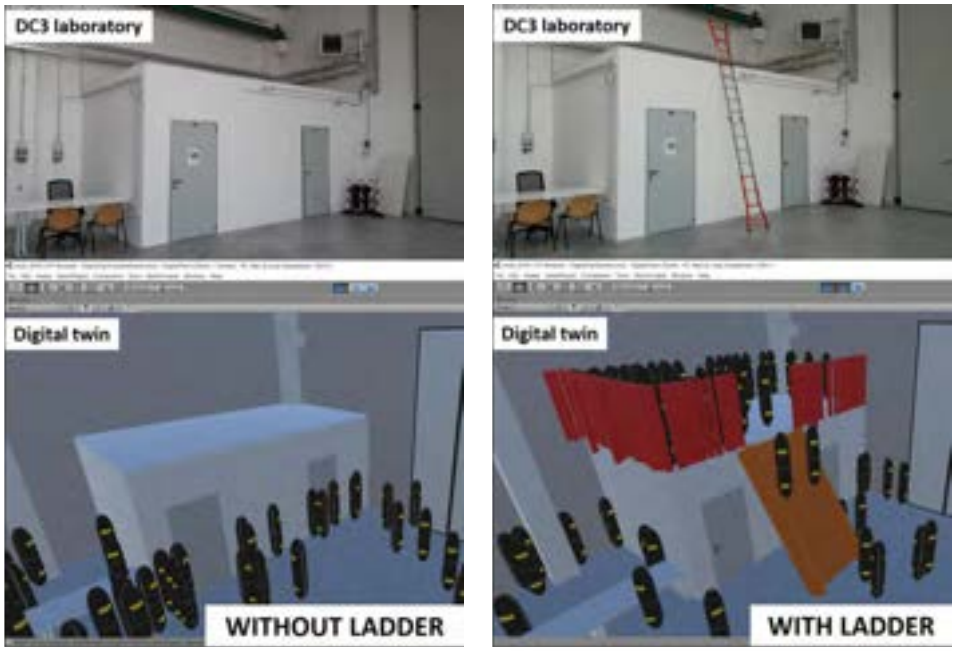
During the execution of the experiment, a real ladder has been placed connecting the laboratory floor and the floor above the changing room, thus allowing workers to reach that area for any reason, e.g. doing works or temporarily laying materials (see the top image in Figure 4(b)). Any human observer would infer that fall hazards have been generated, because workers reaching the higher level may fall down due to the absence of any barriers. Similarly to reality, wandering virtual capsules may reach the floor above the changing room and fall down (see the bottom image in Figure 4(b)). For each fall event occurring in the digital twin, the virtual sensor (described in Section 3.3 and by Figure 3) compares the collision force generated by each impacted capsule with the pain tolerance value of 6 kN, known from literature [27] and regulation [28] about fall-arrest equipment. As a result, if the collision force exceeds the threshold value, the system notifies that falling capsules have experienced harmful impacts and it infers that fall hazards have been introduced. By picking out the positions from which wandering capsules fall down because no fences are installed (see the top image in 4(b)), the virtual replica suggests that barriers must be placed in these areas (see the bottom image in 4(b)).

As a result, according to the logic described in Section 3.3 falling capsules underpin the real-time detection of fall hazards affecting real workers on site. Virtual fences, highlighted in red in the bottom image in Figure 4(b), have been instantiated in those positions from which harmful impacts have taken place. For the purpose of this paper, 300 virtual capsules, moving with a linear speed of 2 m/s, have been instantiated inside the DC3 twin model. Assuming these conditions and using a laptop equipped by an Intel® Core™ i7-8750H CPU 2.20 GHz processor with 16 GB of RAM memory, the digital twin engine takes on average about 2 minutes, after the ladder positioning, to detect all fall hazards affecting the rooms' top floor and place all the related virtual fences (see the bottom image in Figure 4(b)).

It must be noted that, in case a rule-based safety assessment system was implemented (e.g. labelling any surface above a critical height as an hazardous one) it would always suggest that barriers are needed along the perimeter of the higher floor area. In other words, in the simulated scenario the higher level above the rooms (see Figure 4(a)) would be always labelled as hazardous, even in case it is not accessible because the ladder is not present.

5 Conclusion

This paper proposes a system architecture of a digital twin model for H&S management and implements it for real-time identification of fall hazards. A digital twin mock-up of the DC3 laboratory, developed in Unity3D™, mirrors the construction site by means of a UWB localization system and runs looking-ahead simulation in order to detect fall hazards in near real-time. Especially in large construction sites, notifications of safety needs with a delay of a couple of minutes represent a valuable result if compared to the time usually taken by on-site manager to manually detect all fall hazards. Furthermore, off-site managers can benefit from the opportunity, provided by the developed system, of displaying safety alerts and giving suggestions about mitigation measures. The simulation-



(a) (b)

Figure 4. Construction site for works at height recreated in the DC3 laboratory (top images) compared with its mirroring digital twin (bottom images). The floor above the changing room is not accessible (a) until the ladder has been placed (b).

based approach described in this paper can easily be extended to similar scenarios where the strict application of pre-determined rules cannot work due to the dynamic nature of construction sites. On the overall, simulation results demonstrate that the proposed approach can cover the variety of scenarios in which a rule-based checking systems may fail, since safety assessment is contextual or hard to be modelled by means of pre-determined rules.

Abstract –

New innovative and digital approaches, in particular digital methods like Building Information Modeling (BIM), are being used more and more in the Architecture, Engineering and Construction (AEC) Sector. However, most of building operation and maintenance processes still follow conventional processes and are hardly supported by digital databases. Within the widespread field of different infrastructure systems, the railway sector specifically brings a lot of rather old structures and components, which need intense service across their entire lifecycle. Research at Leibniz Universität Hannover explores a fundamental concept for digitally supported maintenance of railway infrastructure to enhance availability, reliability and provide a structured database for the involved stakeholders. Therefore, required methods and processes need to be defined and harmonized for different perspectives like infrastructure operators, monitoring service providers and supervising authorities. Based on digital models, a new approach for a holistic infrastructure management will be introduced and furthermore validated by using a reference project as demonstrator. The paper focuses on the organization, structure and needed level of information within digital models. Further ways of automatization in creation of such models are examined. In conclusion, the risk of damage or breakdown will be reduced and maintenance processes can be initiated on a data-driven basis. By means of this approach, it is possible to change the way from a reactive maintenance processes to efficient repair works in an early stage of damage.

Building Information Modeling; Structural Health Monitoring; shBIM; Digital Maintenance

1 Introduction and Motivation

The German railway and road infrastructure are taking a key role for Germany's economy and public transport, as well as for the European market. Providing a resilient infrastructure is a challenging task with multidimensional complexity [1]. With Germany being in the centre of Europe, six out of nine corridors of the Trans-European Transport Networks (TEN-T) will run across Germany by the estimated completion in 2030. The overall goal is strongly to support the Trans European Internal Market [2]. As shown in Figure 1, Germanys railway network is with more than 33,000 km one of the largest in the European context. This leads on the one hand in high efforts for development and maintenance of the network and its building structures and on the other hand it gives an indication into the complexity of inner-Germanys railway infrastructure.

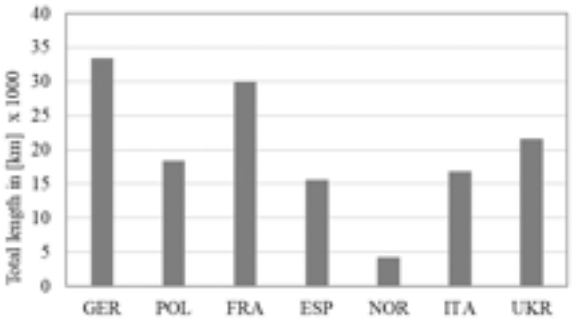

Figure 1. Total length of railway infrastructure in selected European countries, 2016 [3]

With regard to rail, not only the development of new tracks will play an important role in the future. Indeed, retrofitting and especially the maintenance of existing tracks and civil engineering structures like bridges, tunnels or retaining walls will become an enormous challenge for engineering services.

The German railway network operator DB Netz AG is responsible for track maintenance and improvement including civil engineering structures within the infrastructure network in Germany. This covers the responsibilities for the above mentioned 33,000 km tracks, 25,000 bridges and 700 tunnels [4]. The average age of Germany's railway bridges has an age of 73 years with a rising trend.

Bridges are of enormous importance since they are bottlenecks in the infrastructure system. With special regard to railway infrastructure, restrictions or failure in bridge structures have high consequences for the overall track availability and the efficiency of rail-bound traffic. Closed or malfunctioning bridges lead to redirecting trains on non-optimal routes, which leads to a significant loss in the efficiency during operation and high delays.

In order to minimize and prevent the risk of failure, DB Netz carries out a periodic bridge inspection to evaluate the bridge conditions. This binds a high amount of material as well as human resources.

2 Status Quo processes of maintenance

In Germany, the maintenance of civil engineering structures is regulated in a national standard (DIN 1076). Furthermore, there are specific regulations with respect to the infrastructure operator (e. g. Deutsche Bahn, RIL 804 [5]) for Germany's railway network. Due to the later introduced reference project, the aim of the following description of maintenance processes focuses on railway infrastructure in Germany, since the process is highly standardized and regulated by the government.

The established maintenance concepts do not envisage continuous bridge monitoring or condition assessment. The maintenance is usually reactive-oriented and leads to expensive repair works to ensure the system reliability. As can be seen in Figure 2 following the conventional maintenance process results in a periodic assessment of the bridge condition.

The periodic assessment starts with a first obligatory assessment of the bridge structure before start of operation.

The second assessment will be before the end of the warranty period in case of new construction, but in maximum six years after the last assessment. After the end of warranty period the supervision and the assessment will be alternatingly done in a three-year rhythm. The documentation of damages and the information exchange during the process is based on protocols and reports, primarily in paper form or non-object-oriented data bases.

In case of serious damages, solutions for limiting or remedying the damage is approved at a decision conference where all relevant stakeholders are involved. It should be noted, that in all categories the safety of the bridge structure for operation is guaranteed. Otherwise, immediate action would be taken to close the bridge.

Even if small inspections are carried out in the meantime, the periodic condition assessment can lead to a serious lack of information during the inspections. Using Structural Health Monitoring (SHM) in addition to the conventional maintenance process provides a continual assessment in real time (see also Figure 2) [5]. Knowing the real-time-status of the civil engineering structure and evaluating the development in a small-scale, predictive maintenance concepts can be implemented and applied [6]. Appropriate data processing and efficient evaluation mechanisms are required to develop target-orientated treatments.

Data linking between Building Information Modeling (BIM) and Structural Health Monitoring (SHM) to create a holistic data platform with intelligent data organization and data analysis can be a key for a performant status assessment. This new approach is defined as structural health BIM (shBIM) and includes data processing from different sources and different perspectives.

3 Concept shBIM

The key to an innovative digitally supported maintenance approach is a sensor-supported continuous monitoring system, which supports and supplements the traditional manual inspection techniques and leads to a completely new quality of maintenance approaches [7], [8], [9].

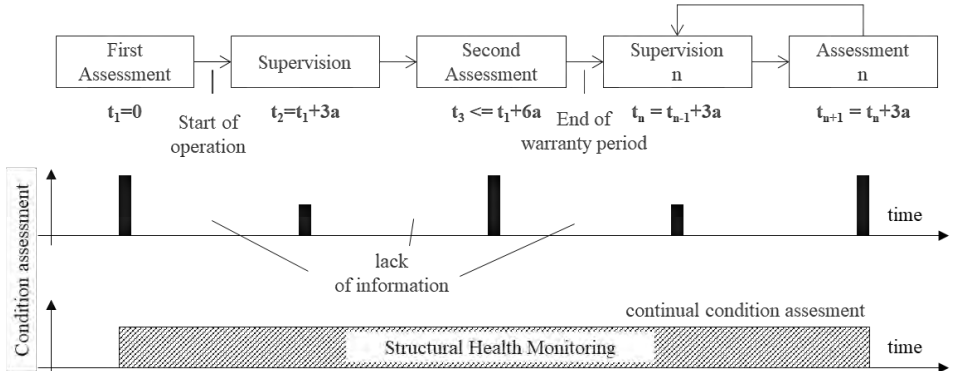

Figure 2. Qualitative degree of condition assessment in the conventional maintenance process (top) compared to a continuous structural health monitoring (bottom)

For this purpose, all information of the inventory, the manual inspection processes as well as from the structure monitoring need to be linked intelligently, edited and provided customized and on demand for the various process stakeholders to enhance the reliability of the rail infrastructure system. The digital method Building Information Modeling provides an ideal conceptual and methodological basis for this collection, linkage and evaluation of multiple data sources and will be extended by the integration of structural health data (monitoring data, inspection data). The overall concept of shBIM is shown in the following Figure 3. The shBIM platform operates as a data hub which is fed by different sources. For generalization, these sources can be defined as three main sources:

First, monitoring data, which includes all data from the SHM systems and dynamic data of the operation phase are linked to an object-oriented building model. The extensive data sets from different monitoring elements like acceleration sensors, strain sensors or temperature sensors will be pre-processed and appropriated for integration in the platform using suitable interfaces (A).

Second, the digital BIM model itself needs to be developed, which includes the information of the infrastructure building and the installed monitoring systems. It contains the object information, geometric information as well as static semantic information and is the central module for the user interface, data visualization and user-oriented data preparation (B).

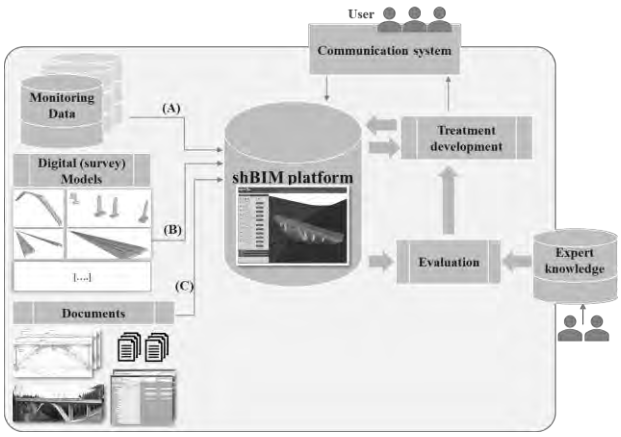

Figure 3. System architecture of the shBIM platform integrating expert knowledge and evaluation processes based on [9]

Third, documents and further data bases, which provide a more detailed description of the construction object, like conventional drawings, photo documentations, reports or maintenance instructions as well as the building documentation of past years, are integrated. They are linked to individual objects or object groups within the shBIM platform (C).

It can be seen that the structuring of the different data sources is strongly dependent on the data sources themselves. Especially for automatization in data analysis and in providing a user-friendly platform, different requirements need to be fulfilled to make evaluations by means of artificial intelligence possible. Merging the information of different sources in an automized way, an evaluation on the health of the examined civil engineering structure can be drawn. The results can be provided for the involved stakeholders to support the maintenance servicing processes. Therefore, also expert know-how can be included in terms of a knowledge-based system. The automated and continuous analysis of the data is used for prediction of probability of occurrence of damage cases as well as for the development of appropriate measures, which are also communicated platform-based. Finally, the information gathered during the service tasks will be recirculated and is used for the assessment of the maintenance measures.

The shBIM approach leads to a comprehensive and user-oriented monitoring data integration. All relevant information is fully integrated into the BIM model and linked to the digital representation objects. To ensure practicability, the question of a convenient level of detail regarding the bridge model needs to be answered. There is a large need for automatization in generating object-oriented models to provide the model as the central data hub to guarantee efficient implementation processes of the existing bridges.

4 Use cases for digital model and needed Information

The use cases for the digital maintenance of bridge structures are diverse. Pursuing different use cases in a digital environment, e.g. manual bridge inspection according to the regulations in RIL 804 [6], supportive monitoring by an SHM system or recalculation to verify the load-bearing capacity of the structure lead to different applications and information densities. However, geometric and semantic requirements of the BIM model need to be formulated for each use case separately.

Important use cases focusing maintenance processes can already be implemented with an abstract information model. An abstract model is defined as a model which consists predominantly of geometric objects without a high demand for geometric detailing, but in accordance to the classification system of Deutsche Bahn. Therefore, the focus is on the semantic description of the objects. It is assumed for use of digital models in maintenance, that the geometry of the components is pushed into the background compared to the specific semantic description [10]. Consequently,

the approach is pursued that abstract geometric objects are sufficient to satisfy the information management in maintenance processes with regard to the introduced structural health monitoring concept. By reducing the geometric detailing, the bridge components can be represented by parameterized objects and thus lead to an enormous time saving in the digital transformation of the documentation of existing bridge buildings. The developed digital models can be integrated as the central data hub for the shBIM platform. Generating the BIM model in an automatized way will reduce errors in manual model creation and enhance efficiency.

- The formulation of the geometric and semantic requirements for each particular use case depends on the internal systems, processes and standardization of the operator. Those are critical input parameters for the automatization process, which will be introduced in the following chapters. The purpose of the abstracted models can be summarized to correspond to the existing standardization of civil engineering structure
- include inventory data for civil engineering structure description
- provide a visual 3D model to improve perception and information management
- allow integration in shBIM-platform for communication and collaboration processes

As already mentioned, this paper focuses on railway infrastructure. However, the developed approach is transferable to any kind of comparable classification system.

5 Concept for parametric modelling

In the following chapter the overall process for an automized abstracted model will be introduced (see Figure 4). In addition, the demonstrated process will be validated on a real reference project within the railway sector in Germany.

5.1 Overall process description

The development of a feasible process for automated model generation is an essential part of the research on digital maintenance of bridge structures. To generate the abstracted models, the approach of parametric modelling with the software Autodesk Revit is used in combination with Dynamo, a visual programming interface. It should be mentioned that the method of visual programming allows an intuitive way of programming, since pre-assembled code blocks are available and can be linked together in a logical way. Instead of having a textual script, the coding follows the logic of the arrangement of the coding blocks (see Figure 5).

Figure 5. Overview of a part of the script to generate abstracted models using visual programming

This software combination enables the implementation of model generation based on defined geometric and semantic parameters. However, the approach is transferable to alternative software solutions that enable export in open data exchange formats.

At the beginning of the process, the use cases for digital maintenance are defined to obtain the relevant semantic information. In dependence on the semantic description, the possible maximum abstraction level of the building elements is defined, which describe the input parameters for automatization in the modeling process. The abstraction is based on company related specifications, which define structuring and also could include derivations for standard cross sections.

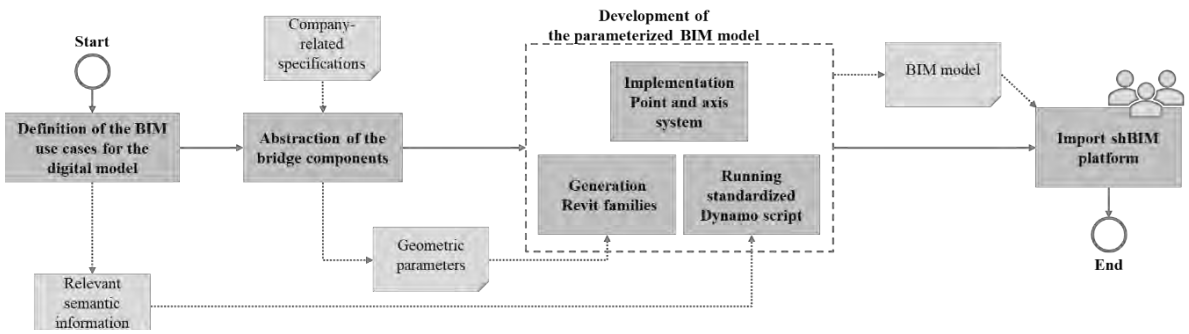

Figure 4. Development process of the abstracted parametrized BIM model

The result of the abstraction is the derivation of geometric input parameters. The development of the parameterized BIM model itself is based on three essential steps. First, the creation of a point-axis-system for the positioning and extrusion of the bridge components need to be set up. The system describes the positioning and the relationships between each abstract component. Components like the abutments can be abstracted as a cube, which follow user-specific input parameters and are placed using a single identification point. Supplementary components like the superstructure, piers and arch are characterized by a start point and an end point, which are represented by the point-axis-system. Between start and end the cross section will be extruded.

The positioning and relationship to other components is realized by the placement of specific points. The arcs are represented in a circle section shaped three-point definition. The extrusion of the rectangle cross section is realized along the curved axis.

Second, the parameterized Revit families based on the identified geometric input parameters from the abstraction process are developed. For cuboid components, the cross section of the element is defined by width and depth. The length of the component is defined due to the length of the corresponding axis.

Third, the creation of a dynamo script that connects the parametric Revit families and the point-axis-system and implements the semantic information from the use cases, has been carried out.

The algorithm goes through the placed families and adds standardized attributes to the components. Then the blank attributes are filled with the values of the specific building. After execution of the script, a geometrically abstracted BIM model is finally generated in an authoring software environment.

An export of the native model to the open standard Industry Foundation Classes (IFC) allows the implementation in the shBIM platform and can be combined with other information such as geodata. This enables the integration of further model data from different disciplines, companies and authoring tools.

In order to be able to practically comprehend the process of geometric abstraction and to demonstrate that a defined information content can be implemented, the development is explained step by step in the following chapter, based on a reference rail infrastructure project.

5.2 Reference project

The *Grubentalbrücke (Railway Bridge Grubental)* is a railway crossing of the "Verkehrsprojekt Deutsche Einheit Nr. 8" (VDE 8), which was completed in 2013. The VDE 8 project is part of an infrastructure program decided by the German government in 1991, to establish the import north-south axis between the cities of Berlin and Munich. The infrastructure is part of the project's subproject 8.1. The Railway Bridge Grubental is one of 24 railway bridges located on the rail route between Nuremberg and Erfurt (see Figure 6), which also interlinks major German cities like Hamburg, Frankfurt and Munich and is of great importance.

The Railway Bridge Grubental is chosen as the reference project since the bridge is characterized by a good data basis and by the existence of an implemented structural health monitoring system. The automated modelling will focus on the geometries of the abutments, piers, superstructure and arch to develop the abstraction process. The implementation of the structural health monitoring components is not part of the automatic process.

Figure 6. Railway Bridge Grubental (left) and the local placement within the high-speed rail network in Germany (right)

5.3 Abstraction of relevant building parts

To start the abstraction process of the Railway Bridge Grubental, two use cases are defined. The exemplary use cases use the semantic information that will be added after the geometric model generation.

Use case A comprises the implementation of a component-specific coding based on the component hierarchy of Deutsche Bahn AG. With the coding it is possible to uniquely identify the individual objects later. This information is model-inherent, directly attached to the component by a corresponding parameter. In addition, almost 450 attributes are taken into account in order to address the maintenance requirements of the existing system with the BIM model. Those parameters can be clustered in different categories. For this use case the cluster results out of the building structure (e.g. abutments, piers, superstructure, etc.), where attributes describe the individual building component in terms of structure, material and environmental conditions. The numerous attributes can be static or be developed dynamically over time. This allows the identification and semantic description of each individual object as

well as the structural health assessment on the level of the component.

Use case B pursues the linking of an as-built drawing in PDF format with the BIM model. Therefore, a unique identification parameter is integrated to the semantic. The linked document can be located on a different location. By mapping the unique object parameter with a document link, a clear allocation is realized.

These use cases have no direct influence on the geometric abstraction, but are intended to show what is possible within linking maintenance information to the model and managing it in the shBIM platform. These use cases present an exemplary method and can be adapted to more detailed considerations.

A geometric abstraction of the Railway Bridge Grubental has been implemented in accordance to the bridge specification regarding the building structure of Deutsche Bahn (see Figure 7). Therefore, it is not important that the exact geometry of the component is created, but their existence is, in order to be identifiable in the classification. The relevant components for the reference project consist of abutments, piers, superstructure and the arch.

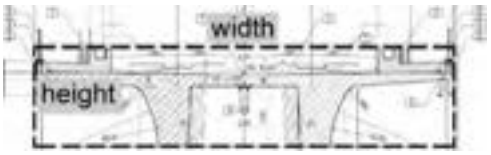

Figure 7. Enveloping rectangle shape to abstract superstructure cross-section

According to the introduced process model, the first step is the description of a point-axis-system for positioning and description of the relationships between the objects (see Figure 8).

A total of 15 points is required to describe the components of the reference railway bridge. For example, the line from point 1 to point 7 is the representation of the superstructure-axis, which is function as extrusion line of the superstructure. The point-axis-system is generated by a standardized dynamo script in accordance to the number and position of the bridge piers. The script acts further as the interface between the developed parameterized Revit families and the point-axis-system. The families are also standardized for cuboid geometries, which have individual compulsion points. The component families are designed in a way that the component is either positioned directly by a pre-defined point in the geometry (abutment) or needs a start and end point to create a corresponding extrusion along the defined axis (piers, superstructure, arch). For the extrusion, an abstracted rectangle cross section as well as the axis itself is parametrized. Focusing on the individual components, they are abstracted in a rectangle shape, so that they take on a simple enveloping shape, here shown using the example of the superstructure.

The superstructure of the reference bridge is a double-webbed slab beam, as continuous beam. The shape is abstracted by stretching a rectangle as a surrounding boundary at the maximum vertical and horizontal shape of the superstructure. The geometric parameters ”height“ and “width“ are created, which define the dimensions of the reduced rectangular cross-section. These parameters are the geometric input for the parameterized Revit families, which can be indicated bridge specific. Using the same method, the other components can also be simplified as cuboid objects, which is the first step to a digital object with a low degree in geometric detailing. The dynamo script has a modular structure and can be supplemented by further components if required or reduced if some components are not needed.

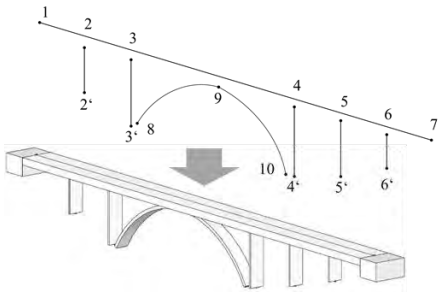

Figure 8. Point and axis system of the abstracted Railway Bridge Grubental and abstract geometric with automated model generation

After the geometry has been created by the script, the semantic information can be added in the next step. For this purpose, an attribute editor forms the end of the algorithm. The attribute editor adds standard attributes from the today’s maintenance system and add the bridge specific values based on a csv-file (use case A). The csv-file is generated as a bridge specific export and is imported as an array to the dynamo procedure afterwards. The last step in accordance to the introduced process is the export of the model for integration to the shBIM platform.

5.4 Evaluation of different Level of Detail

To evaluate the level of detail, a second digital model of the reference railway bridge was modelled in another software tool and has been exported in the open, international standard IFC. This model is characterized by a high level of detail corresponding to the detailed design (see Figure 9). It is used as a reference structure to validate the quality of the abstraction.

Figure 9. Precisely modelled Railway Bridge Grubental on the basis of the detailed design

The validation of the model quality is divided into the criteria of geometric and semantic parameterization and interoperability. During the validation it was checked whether the implemented geometric input parameters like "width_abutment", "height_ superstructure" or "thickness_pier" were generated and transferred correctly.

The model abstraction of the selected bridge components resulted in a reduction of the geometric objects from 4936 of the precise modelling to 9 using the abstract approach. When the two models are overlaid, it becomes clear that the two models differ only in points of geometric detailing of the individual objects and missing equipment components, which are not considered in the abstraction e.g. railings, track, etc. Where in the detailed model the abutments consist out of several components such as swing and chamber walls and the support bench, the abstraction consists of one abutment representation-object. However, bridge specific dimensions such as bridge length, spans, pier heights and the width of the superstructure do not differ from the model based on the detailed design.

The validation of the abstract model with regard to interoperability is of crucial importance. The generated BIM model based on the defined use cases for digital maintenance serves as the data hub in the shBIM platform. Therefore, after integration in the shBIM platform the quality of the abstract BIM model is also validated.

5.5 Integration in shBIM platform

Due to many stakeholders involved in design, construction and operation, this specific platform must guarantee a manufacturer-independent data exchange format, such as the internationally accepted IFC format for open BIM data exchange. The model quality and usability are primarily dependent on the data transfer quality of the interface.

The basis for the development of the shBIM platform is the Common Data Environment (CDE) "Squirrel". To make the abstract model available for maintenance purposes, the last process step is the import of the abstract bridge model into the CDE (see Figure 10) via the open BIM format IFC.

Figure 10. View of the imported BIM model within the CDE-based shBIM platform

On the left side of the user interface, the model structure of the partial model for revisions as well as the partial model management with different functionalities is shown. On the right side, it is possible for each individual user of the CDE to look at the semantics of the bridge elements. Individual elements of the digital bridge model can be selected and therefore their individual properties can be viewed (use case A). Other geometric objects, such as the sensor technology of the SHM system, could also be imported as a separate partial model within the CDE. Specific data, related to the structure or the sensor technology, can be linked to the CDE using a linked data approach (use case B), which means an allocation of each document in the platform to a unique identifier at the building component it belongs to. The overarching objective is to organise and manage all prepared information and processed data within the shBIM concept via the CDE platform. The platform is supposed to support the whole structural health monitoring process of the railway bridge with data and information management throughout the whole life cycle of the railway bridge. Moreover, the shBIM platform will ensure the traceability of edited information and data as well as the documentation of performed maintenance services within the digital BIM model. The access of the shBIM platform is defined via an individual and project-specific authorisation concept.

5.6 Discussion

Deutsche Bahn AG maintains more than 25,000 bridge structures. Detailed 3D modelling for digital maintenance approaches on the basis of the detailed design or even more precisely the actual condition (as built) is economically questionable. The presented approach of abstracted geometric modelling of the bridge using automated generation algorithms shows a method to reduce the effort. It was explained that the semantic information of the digital use cases is in many cases more important for the maintenance processes than the geometric detail depth. In addition, simple

geometric bodies are easier to check during creation and processing. Regarding the interoperability of the models, simple geometry also has advantages. The IFC format has established itself as an international and manufacturer-neutral data exchange format. However, development is ongoing and will continue to be subject to constant changes over the next few years, especially with regard to new infrastructure specifications, which are expected in the next years. Simple geometric shapes guarantee significantly fewer data exchange errors.

Further, the maintenance operator will not be in false expectations due to a reputed exact model. Rather, the stakeholders involved in maintenance are aware that this is an abstraction and that exact geometrical dimensions must be determined, if applicable use cases require a higher level of development. Since bridges along the lifecycle are subjected to modifications, it cannot be assumed, that detailed design from several decades ago and digital models which are based on those, correspond to the status quo. By classifying the bridge types and developing an abstraction standard for each type, an area-wide implementation of automated creation of BIM models for the shBIM platform can be achieved.

Continuous and further detailing of abstract models due to special tasks, such as renewal or repair measures, can be done afterwards.

6 Conclusion and Outlook

In summary the research has shown, that it is possible to highly automate the way of modeling to generate digital models for specific use cases. Abstract models are an adequate option to realize sufficient information management and visualization for various maintenance measures.

However, there is still a lack of description to grasp the manifoldness of bridges and model them in a standardized parametric way. In the next step, the automatization method should be enrolled to a higher number of relevant civil engineering structures from different years of edification and from different structural types to implement specifics in the superstructure and the overall structural system. Open formats can provide a life cycle-oriented, comprehensible and transparent information management in a common data environment, which allows different stakeholders to access. The approach should be exposed for further use cases e.g. the integration of damage assessment and repair measures.

Abstract –

Due to the continuous improvement in data acquisition, storage and evaluation, digital technologies are penetrating ever deeper into the operational business of the construction industry. Modern information and communication systems are at the heart of digital working methods. They encompass the factors - People, Processes and Data -, which are all decisive for successful project management. In the context of digitizing a building project, it is necessary to harmonize these factors. When implementing digitization strategies, the focus is often on finding suitable technical solutions and defining processes. However, the human factor continues to play a decisive role in the construction, as a high degree of coordination between the parties involved in the construction process is necessary in order to produce safe and functional unique buildings. In order to establish the methodology of Building Information Modeling successfully in the construction industry in the long term, it is therefore essential to involve the employees in the developments.

The human factor becomes all the more important in large construction projects, which also involve partners across national borders. The approaches to new methods, as is necessary in the case of BIM, sometimes differ greatly due to cultural differences in the international context and cause problems of understanding, even though certain software applications, for example, work perfectly. In addition, employees often experience personal inhibitions that prevent the consistent use of new methods.

The research project "BIM Game", in which partners from several European countries worked together puts the human factor in the forefront of the BIM methodology and develops new ways of communicating the basic ideas of the method already in the education of students. The project focuses on two main points: Firstly, the linking of students via a Learning Management System, which reflects the work in project rooms of a real construction project and thus promotes collaboration. On the other hand, the use of gamification - the application of game elements as known from computer games, for example - to lower inhibition thresholds and increase motivation to deal with the topic. The aim of the project is to teach future project participants how to collaborate in a digital project, rather than merely addressing technical issues. The students slip into different roles and work collaboratively and digitally on a real scenario. They do not receive feedback through classic evaluation systems such as grades, but through badges and the achievement of levels.

1 Introduction

The digitization of the construction industry is currently being driven forward primarily by the increasingly widespread use of the methodology Building Information Modeling (BIM). When talking about BIM, the acronym does not mean a software application or the mere work on a 3D model [1]. BIM describes "a collaborative working methodology that uses digital models of a building to consistently capture, manage, and transparently communicate information and data relevant to its lifecycle or to hand it over for further processing." [2] The new working methodology thus requires a holistic approach to planning, construction, operation and dismantling. For the successful implementation of the approach, in addition to suitable software solutions, a cultural change in the construction industry is required. Collaboration on a construction project must be thought of in a team-oriented way in

order to reduce interfaces and enable work in a common data environment (CDE). For this purpose, it is advisable to adapt business processes and familiar forms of cooperation [3].

Working with the BIM methodology therefore requires changes in three areas of current mode of operation. First, processes in the company must be adapted to the new methodology. In many cases, it is first necessary to identify and record the processes currently being carried out. Following this, these processes can be digitized and adapted to work with BIM. In a second step, the implementation of the newly designed processes requires the selection of suitable software offers. The most suitable offer for one's own needs must be selected from the large market for BIM software. For this purpose, prior modelling of the processes is helpful, as these can serve as a kind of demand list for the software selection. The third step that should not be underestimated is the people in the project who have to implement the new processes and use the software. Any well-considered steps in the process and software selection can lose their success if the employees are not appropriately involved in the further development. The discussion about BIM currently focuses mostly on software and processes. Important to remember ist that people traditionally shy away from change [4]. Training in BIM is therefore essential for the successful application of BIM.

There are three ways to prepare personnel for working with the BIM methodology [5]:

1. new employees with appropriate knowledge are hired and implement the specific method in the company
2. BIM skills are purchased through cooperation with external partners
3. Ones own employees are trained in the application of the specific method.

The former variant is often difficult to implement in times of a shortage of junior staff. Employees with BIM skills are in demand on the job market and are difficult to find. Apart from the costs, the purchase of external skills brings with it a certain dependency and is usually associated with trust problems. This strategy can provide an introduction to working with BIM, but it must then be possible to continue the implementation independently. The further training of one's own employees involves a certain amount of effort and requires that acceptance hurdles among employees can be overcome [6].

The BIM Game research project addresses the problem of how to prepare employees in the construction industry for working with the BIM methodology using their own resources and trains students as future employees with BIM competencies. The sluggish implementation of the BIM methodology to date also shows that training courses do not meet the demand [7]. Classical training formats can convey the new form of cooperation in theory, but training based on frontal teaching will not be able to convey practice application in detail.

2 Idea of the BIM Game

The idea of the BIM Game is therefore to rethink training in the field of BIM. Instead of classical lectures, the aim is to teach the method in the cooperative collaboration that the BIM methodology demands. The BIM Game research project, led by gip Besancon, is a cooperation of various universities, colleges, training centers and software companies from five European countries (University of Wuppertal, Jade University of Applied Sciences Oldenburg, Lycee du Bois Mouchart France, Universided de Castilla la Mancha, Université de Liège, datacomp, Pôle énergie Franche Comté). The aim of this inter-European cooperation is to find a common understanding of the BIM methodology and to teach the methodology to students, trainees and experienced professionals in a fun, collaborative way using real-life examples and projects. Regarding the preparation of personnel for working with the BIM methodology it addresses the first and third option. Students should acquire the ability to use BIM in a targeted manner in professional practice in order to establish them as sought-after actors and partners in business and society. Through the involvement of experienced experts, people who are already established on the labour market also learn the superordinate or specific use of BIM.

Playful learning is the most intuitive form of learning that people know. Even at a very young age, new skills are learned through play and adaptation to new challenges is tested [8] [9]. Only with increasing age does learning become less and less playful. The fact that adults still like to play is shown, among other things, by the high user numbers of online games across all ages and genders[10]. The BIM Game makes use of this natural play instinct and thus provides a higher motivation to deal with the topic of BIM and increases the participants knowledge about it. The method behind this is called gamification. Gamification stands for the transfer of typical game design elements into non-game contexts [11]. The goal of gamification is to make everyday training situations, which have nothing to do with games, more interesting by enriching game design elements such as a narrative, avatars, levels, points or badges. The goal is to achieve a change in behaviour and an increase in motivation [12].

Beyond the increase of motivation during the training, the project uses gamification to increase learning effects through the activation of long-term memory. “If you

want to explain something to someone else, you must first understand it yourself, e.g. have read or heard it. Whoever tries out or applies something already links the entire course of events with the actual information, which is why the result is anchored more firmly in the brain as if he had only observed the same result in someone else" [13] This effect is achieved by actively absorbing information through multiple cognitive channels (seeing, applying and experiencing) during the game and by incorporating repetition effects of specific thematic areas throughout the total game. This is to be realized by an active and collaborative processing of application-related building scenarios in an environment embedded by computer game elements. This way of gathering information increases the willingness to learn and lowers the barriers to dealing with the complex topics of the holistic BIM work methodology. The goal is to encourage self-study in a playful way.

2.1 Practical implementation of the project

Between 2016 and 2019, 10 events were organised as part of the BIM Game, which introduced students, trainees and experienced professionals to the BIM methodology in the described collaborative, playful way. Each of these events followed a basically identical structure. To ensure practical relevance, the BIM methodology was taught using scenarios from real professional practice. These scenarios were enriched with game design elements to create a collaborative, playful and motivating learning atmosphere. Figure 1 shows the game design elements integrated in each scenario:

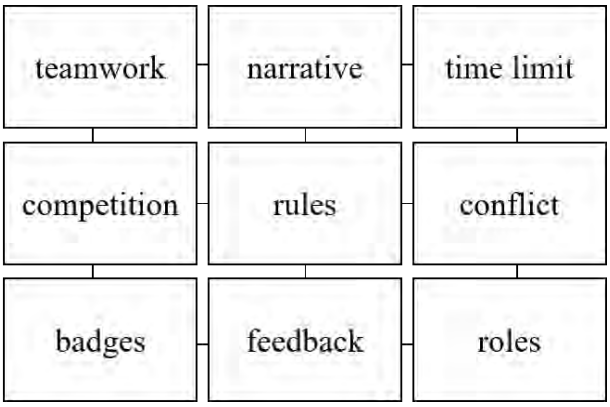

Figure 1. game design elements of scenarios used in the BIM Game

The **narrative** is always based on a scenario of a real construction project. The scenarios correspond to situations from different life cycle phases of a construction project. To classify the scenarios, six life cycle phases from project development to project operation have been defined. This ensures that participants learn that the BIM methodology goes beyond application examples in the planning phase and is relevant for the entire life cycle of a building. The design of the scenarios allowes them to be played through within one day. Depending on the group and event, they can be shortened or extended to half a day or two days by shortening or adding to the task. The content of all scenarios is based on the BIM guidelines ISO 19650. In order to be able to respond individually to the previous knowledge of the different user groups of the BIM Game, each scenario was designed with a unique task and a different focus as well as with different levels of difficulty. All scenarios were developed primarily with the goal of understanding the roles and their tasks in a multinational collaboration in order to strengthen teamwork in an international construction process.

Teamwork is an important part of all scenarios, since BIM projects are never implemented by one person alone, but are always in interdisciplinary teams that have to get along well with each other. Each team member is assigned the **role** of a participant that he or she is not familiar with from the usual project business. An architect, for example, slips into the role of a craftsman, a planning engineer into that of a facility manager. This is intended to create more understanding for the project partners' views of a project. Another aspect of teamwork is **multinational cooperation**. Participants of different nationalities are always mixed so that cooperation with foreign partners, communication in English and the adaptation of different approaches to problems are trained.

Each scenario and each subtask must always be processed within a certain time limit. This simulates the tight schedules of real construction projects and puts the participants under time pressure, which makes cooperation with the project participants indispensable.

For each scenario the participants are given **rules** in the task definition. These can also deliberately contain **conflicts** that need to be resolved within the team and, if necessary, in communication with other participants.

The entire BIM Game and thus also the participation in the individual scenarios is designed as a **competition**. The individual teams compete against each other in the fight for the overall victory. In addition, **badges** are awarded e.g. for the most sustainable project. Winning is always connected with a reward. Extensive **feedback** is given for all teams on the work they have done, which should prepare them for further work with the BIM method.

The central element for the implementation of the scenarios is a digital platform based on common data environments (CDE) from construction projects. The participants process the scenarios completely online

using the platform. They are given the opportunity to communicate via chat functions, files can be stored and exchanged, appointments can be planned and notifications send to others. In order not to prefer a commercial provider of CDE, an open source offer was tailored to the needs of the project. The Learning management system (LMS) nextcloud has been adapted to come close to working in a CDE (see Figure 2).

Figure 2. Extract from the data management area of the platform

The platform serves as a basis and link point for all steps in the scenario processing. The task is provided via nextcloud and all further task parts are organised, processed and completed by the participants via the platform. This set up also made it possible, when organising an event in France, to integrate participants from Spain and Poland who were not on site.

2.2 Example of a scenario

In order to bring closer what exactly a scenario looks like, an example is presented below. In November 2018, 13 students in the field of architecture and civil engineering took part in the described scenario, working in three groups.

In order to bring building product traceability and the application of BIM on the construction site closer, a construction site was simulated in the scenario using Lego bricks. These enabled both a design for a building to be produced and the design to be implemented on the "construction site" within one day. The participants worked through the scenario in the roles of client, BIM manager, architect, engineer, craftsman and supplier. A team of architects and engineers had to develop a design in compliance with budget and sustainability requirements (different stones = different properties). This was implemented "on the construction site". With the help of a BIM viewer, the construction workers could view the design on a tablet and implement it accordingly. Using RFID tags on the individual bricks, the progress of the construction work could be monitored by scanning the tags during installation, then creating an as-built model and tracing the building products in the finished building.

Figure 3. a participant working on the 3D model

The client also acted as a jury in the scenario, evaluating the results and giving feedback to the groups on their solutions (see Figure 4).

Figure 4. client giving feedback to the groups

2.3 Evaluation of events

Selected events were evaluated to continuously improve the scenarios and to check whether the way of teaching the BIM methodology is successful. The evaluation method was based on questionnaires that the participants answered after the scenarios were completed. Over a period of one year and within the framework of four different scenarios, a total of 50 participants were surveyed. The items of the questionnaire were designed as multiple choice questions. Non-symmetrical answer scales were used to avoid an accumulation of neutral answers.

Two aspects were particularly important for the project: Do the participants like the way the method is communicated via collaborative, playful methods and do the participants get a good, lasting impression of the BIM methodology in a short time?

76% of the participants stated that they had gained a good insight into working with the BIM methodology. For the remaining participants, technical problems, e.g.

poor Internet connection, were the main reason why they did not get the desired insight into the methodology. The learning method about collaborative scenarios was positively evaluated by 90% of the participants (see Figure 5).

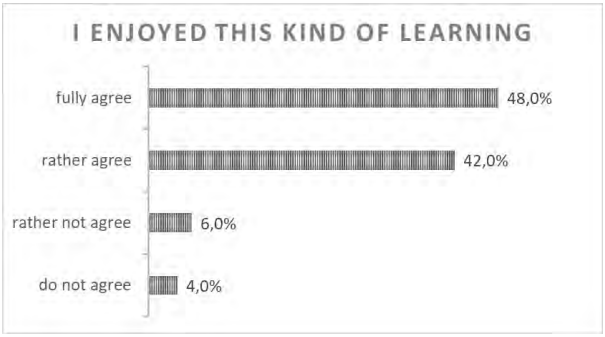

Figure 5. satisfaction of participants with the kind of learning

78% said they had fun and were motivated during the scenario. The idea of competition with other teams motivated 96% of the participants. The gamification method, which has rarely been used in construction training, would be used more frequently by 94% after the BIM game (see Figure 6).

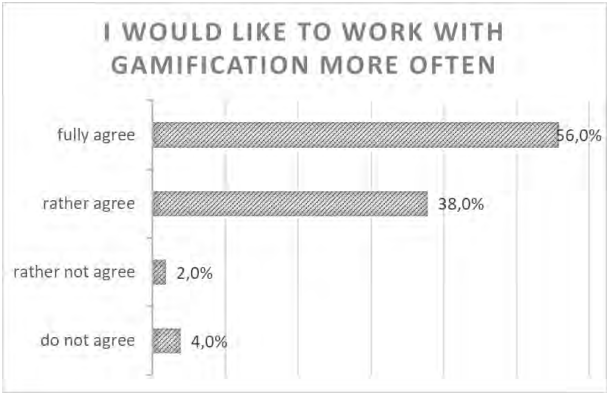

Figure 6. preference of the participants to work with gamification more often

Since it is not only the unique pleasure of teaching that is important for successful application of the BIM methodology, the participants were asked to give their opinion on the durability of what they had learned. More than 70% of the participants stated that they expected the learning content to be more durable than with traditional learning methods. A further 16% rated the durability the same, regardless of the learning methods. The verificaton whether the BIM methodoligy was understood in the context of the scenarios was not done via the questionnaires, but was ensured by presenting the results to the jury.

3 Findings

The study shows that success with the BIM Game has been achieved both in terms of learning the BIM methodoligy and the fun of learning. In comparison to their usual learning settings, the participants were more motivated and felt that they had fun. The playful, collaborative design was also able to help them gain a good insight into working with the BIM methodology and consolidate what they had learned in the long term.

In addition to the positive results of the study, the potential was revealed to make corresponding scenarios more effective in the future. For a digital working method such as BIM, a corresponding equipment of software and hardware is an absolute prerequisite in the learning context. If problems with software or hardware occurred during the events, the positive feedback from the participants decreased. Many training centres and universities have a lot of catching up to do in this area in order to prepare their trainees and students for working life.

Language barriers prevented even more successful results from the participants despite all digitisation. Although collaboration is largely based on technical systems, the simple factor of whether or not participants can talk about complex problems with their counterpart is still an issue that should not be neglected. For a common language on the subject of BIM across national borders, there is also a lack of standardization in the field of BIM. With their understanding of the methodology, each partner works in proprietary systems that inhibit collaborative work. The ISO 19650 standard indeed provides initial guidelines in the direction of standardization, but remains shallow and does not provide enough details to help in the daily work with BIM in the operative business.

4 Conclusion

The study conducted in the context of the BIM Game project shows that alternative learning methods are positively accepted and their application should be further pursued. The implementation of the collaborative working method within the learning phase ensures long-term learning outcomes.

The use of gamification motivates learners to deal with the subject matter more intensely and to get involved with the topic.

5 Suggestions on further research

Within the BIM Game a limited number of game design elements was used. The team was careful in using game design elements to avoid overloading the scenarios.

For future scenarios the use of additional game design elements would be useful, as well as an investigation of how the individual elements work. There has been little research on this so far.

Further information on the project can be found on www.bimgame.eu. The project was co-funded by the Erasmus+ Programme of the European Union.

Abstract –

Digital twin (DT) is commonly known as a virtual model of a physical object, a process or a system. In order to create DT, the emphasis is on building a Cyber-Physical System (CPS), where information collected from physical processes is used for computation to generate a real-time monitoring cyber model. At the same time, changes of the cyber model will either be used for prediction or reflection in the physical system to achieve the control function. With the development of digital and information communication technologies, DT has been applied in various areas such as manufacturing and aerospace industries. However, studies on the application of DT in the building construction sector were limited. Such studies were particularly rare about volumetric modular building which has attracted a burgeoning interest in both academia and practice globally.

This paper aims to contribute a better understanding of integrating the use of DT for Modular Integrated Construction (MiC) by examining the opportunities and challenges. The paper first reviews the state-of-the-art DT applications across various industries, and then focuses on publications about DT applications in the building construction sector through conducting a systematic search of literature using Scopus. After review and analysis of the identified publications, the paper explores the opportunities and challenges of applying DT in MiC. The review results show that DT is often considered with other digital technologies for integration. A conceptual framework is developed for applying DT in module installation in MiC within the context of Hong Kong as a typical case of high-density cities. Promising opportunities with huge benefits are speculated from the application of DT in MiC, including enhanced coordination of logistics and construction management by using DT to monitor on-site progress during the module installation stage. Nevertheless, challenges are also identified, which exist in not only the sensing technology and cyber system, but also the social-political environment supporting innovation and regulation. The developed framework should provide a useful guide to address the challenges and shape future research on DT in MiC.

Keywords –

Digital Twin (DT); Cyber-Physical System (CPS); Modular Integrated Construction (MiC); Smart Construction

1 Introduction

The construction industry is on a pace from being low-tech towards being innovative, in order to address problems and challenges such as low productivity and profitability and skills shortages facing by the industry [1]. Digital twin (DT) as an emerging digital technology has obtained more and more attention across different industries, particularly in the manufacturing industry over the past few years [2], which can also be a possible solution for the construction industry.

It is acknowledged that the concept of DT was firstly introduced in a presentation by Dr Grieves in 2002, which contains four essential elements of the DT: real space, virtual space and dual links for data transmission between real space and virtual space [3]. After that, the name of DT was raised in a roadmap of National Aeronautics and Space Administration (NASA) to describe a virtual digital product of an aircraft's flight system [4] and has been used ever since. DT is defined as a real-time virtual representation of not only a system, but also a process [5] or a physical object [6].

With the development of digital and information communication technologies, DT has been applied in several industries with wide-ranging demonstrated benefits. For example, the use of DT in the aviation industry helps engineers to quickly find out critical weak spots and to predict the future state of the asset [7]. In the manufacturing industry, DT of a physical product enhances collaboration between customers and designers, where communications are faster and more transparent with the function of automatic real time data acquisition [8]. However, studies on the application of

DT in the building construction sector are limited. Such studies of DT are particularly rare about volumetric modular building construction which has attracted a burgeoning interest in both academia and practice globally. Therefore, this paper aims to achieve the following objectives:

1. Review and elicit the state-of-the-art DT applications particularly in the field of building construction sector;
2. Explore the opportunities and challenges to adopt DT in volumetric modular building construction through the analysis of reviewed publications;
3. Develop a conceptual framework for applying DT in Modular Integrated Construction (MiC) in the context of Hong Kong as a typical case; and
4. Identify current gaps and challenges for future research.

Following this introduction, Section 2 explains the background including the state-of-the-art DT applications across various industries, the context of Hong Kong and delimitation of research scope. Section 3 elaborates the methodological approach for the systematic review. Section 4 presents results of the review on the identified publications, and discusses the results from the perspectives of opportunities, challenges and current research limitations. Section 5 proposes a framework of applying DT in MiC considering the scenario of module installation. Section 6 draws conclusions, as well as recommends prospects for future research.

2 Background

2.1 DT applications across industries

Researchers have contributed to the analysis of publications on DT applications across industries. Tao et al. [9] reviewed fifty papers in the manufacturing industry and found prognostics and health management (PHM) as the most popular application area. Enders and Hossbach [10] provided a cross-industry overview of DT applications, and classified ten industrial sectors where DT is applied, including manufacturing, aerospace, energy, automotive, marine, petroleum, agricultural, healthcare, public sector and mining (see Figure 1), where the manufacturing is the most popular industry applying DT. They also found that the applications of DT can be divided into three purposes including simulation, monitoring and control (see Figure 2).

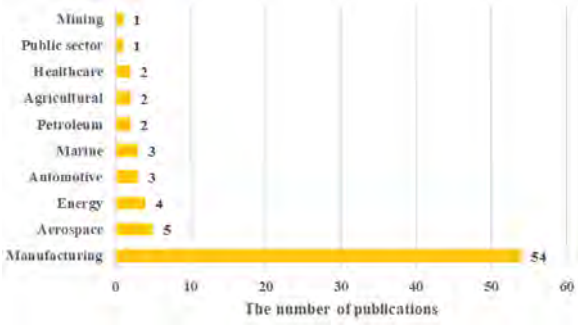

Figure 1. Distribution of relevant publications regarding DT applications across industries identified in the study of Enders and Hossbach [10]

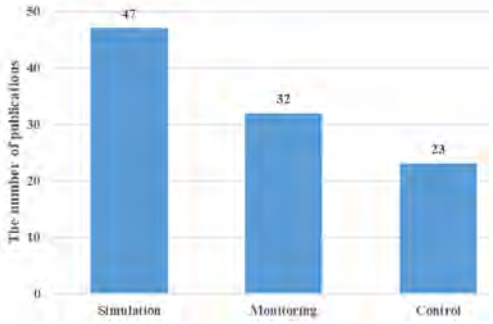

Figure 2. Distribution of relevant publications regarding purposes of DT applications identified in the study of Enders and Hossbach [10]

Even though some studies have been conducted on DT applications in the building sector, most of them focus on post-construction stage so that asset owners can better handle operation and maintenance works. For example, Khajavi et al. [11] established a DT of a building façade in order to collect environmental lighting, ambient temperature and relative humidity, which are used to reduce the overall management and operational cost. Lu et al. [12] developed a DT-enabled anomaly detection system for asset monitoring and validated it in a case study of the heating, ventilation and air-cooling (HVAC) system.

Nevertheless, studies on the application of DT in the building construction sector are limited. The potentials of DT application in MiC are still not clear. Therefore, literature review of relevant publications was carried out in this paper in order to explore opportunities and challenges of DT applications in MiC.

2.2 Hong Kong context

The construction industry in Hong Kong plays an important role in economic growth and social development, which contributed 4.5% of Gross

Domestic Product (GDP) in 2018 [13]. However, the Hong Kong construction industry is facing severe challenges including labour shortage, aging workforce and escalating cost [1]. In order to address these challenges, it was announced in the 2017 and 2018 Policy Address of the Government of the Hong Kong Special Administrative Region (HKSAR) that the Government should lead and promote the adoption of MiC in the construction industry [14, 15].

MiC represents the most advanced level of offsite construction [16], which is first defined by Pan and Hon [17] as "*a game-changing disruptively-innovative approach to transforming fragmented site-based construction of buildings and facilities into integrated value-driven production and assembly of prefinished modules with the opportunity to realise enhanced quality, productivity, safety and sustainability*". MiC is a unique term used in Hong Kong, which belongs to volumetric modular building construction. Compared with conventional construction methods, MiC has distinct characteristics that the majority of on-site works are transferred to a factory for production of modules. In a factory, structural works, architectural works and building service works of modules were completed partially, and then following by transportation of modules to the construction site for installation and assembly. Several MiC pilot projects have been initiated in order to prompt its wide adoption in Hong Kong.

2.3 Delimitation of research scope

In this paper, Hong Kong is selected as a typical case of the high-density city to explore opportunities and develop the conceptual framework for applying DT in MiC. Regarding a building project adopting MiC, the construction lifecycle from offsite production of modules to onsite completion of construction works is the most concerned part, excluding design and operation and maintenance stages. This is because the most significant difference between MiC and conventional construction practices is the change of construction processes. As offsite production of modules in a factory is similar to works in the manufacturing industry, the research scope is limited to onsite works of a MiC project (i.e., module installation and other onsite building works).

3 Methodology

The research approach in this paper for searching and analysing relevant publications and exploring opportunities and challenges of DT applications in MiC, is adopted as proposed by Boje et al. [18]. The overall research methodology process including three steps is provided in Figure 3.

Firstly, publications related to the application of DT in the building construction sector were searched and identified. The search strategy included electronic databases of Scopus. The search terms "digital twin". "building" and "construction" were used to limit the scope. After the initial search, the literatures had to be published in a journal or a conference paper or as a book chapter. Title, keywords, abstract and main contents were then checked to see whether a publication is related to the field of building construction. Secondly, the filtered publications in the first step were reviewed and analysed from the perspectives of time, publication format, topic, consideration of other digital technologies, purpose and potential challenge of DT application in the building construction sector. Thirdly, based on results obtained from the previous two steps, we identified current research gaps, developed a conceptual framework for applying DT in MiC in the context of Hong Kong as a typical case, and explored opportunities and challenges for future research. The original research objectives were considered during each step [19].

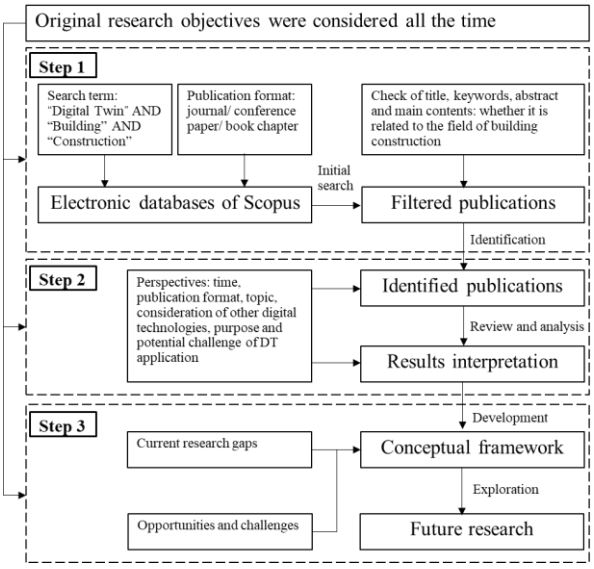

Figure 3. The overall research methodology process in this paper

4 DT applications in the building construction sector

4.1 Review of current practices

The latest search of publications through the electronic databases of Scopus was conducted in June 2020. The selection criteria as elaborated in Section 3 were applied to all papers in the initial search. 46 publications were filtered out for detailed analysis. After title, keywords, abstract and main contents of filtered

publications were checked, there were in total 10 articles identified. All the identified publications are related to the application of DT in the building construction sector. The first related article was published in 2018. The identified publications were evenly split between journal articles and conference papers. Disturbance of publication time and format of the identified publications is provided in Figure 4.

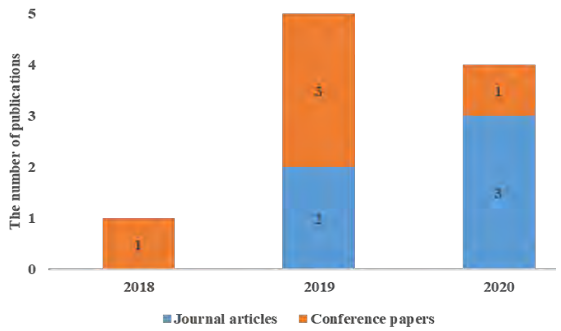

Figure 4. Distribution of publication time and types of the identified publications (as of June 2020)

Three of the identified publications considered the application of DT not only in the construction stage but also in the whole project lifecycle from the planning stage to the operation and maintenance stage [8, 20, 21]. Automated planning and scheduling of works is one of purposes of DT application [18, 22, 23]. Monitoring and assessment of construction performance is achievable with the aid of real-time data capturing from a construction site. One research developed DT of a type of machinery to prevent operation risks [25], while another one developed DT of a type of building material for simulation in order to reduce production time and cost [24]. A summary of different purposes of DT applications in the identified publications is provided in Figure 5.

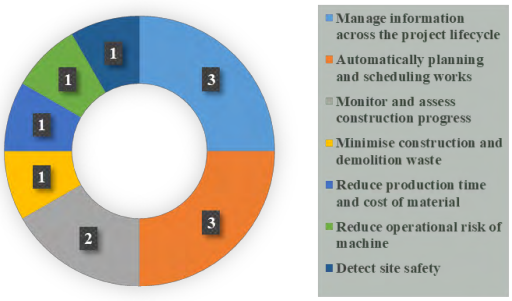

Figure 5. Summary of opportunities of DT applications in the identified publications
Note: numbers in the figure refer to the number of publications

Regarding consideration of other digital technologies, nine publications mentioned about "Building Information Modelling (BIM)", where seven of them considered DT as an evolutional representation of BIM, while the remaining two treated BIM system as a DT [22, 23]. Seven publications [8, 18, 20, 22, 24, 25, 26] included "Internet-of-Things (IoT)" together with sensor in order to collect data from the physical space, but only one of them considered the application of "Wireless Sensor Network (WSN)" for real-time data transmission [25]. Three publications [8, 20, 25] mentioned "cloud platform" when considering storage, analysis, processing and integration of captured data. The concept of "machine learning" was mentioned in three publications [18, 22, 25] so that a self-learning DT can be created. Bevilacqua [20] stated that both Augmented Reality (AR) and Virtual Reality (VR) can benefit from the implementation of DT, as they provide users a more immersed platform to view historical and real-time data. The frequency of other digital technologies, including BIM, IoT/sensor, WSN, cloud platform, machine learning, AR and VR, mentioned in the identified publications is provided in Figure 6.

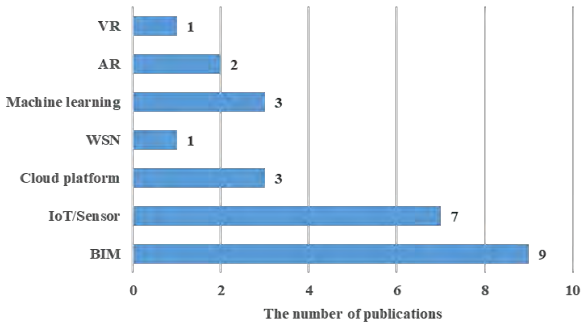

Figure 6. The frequency of other digital technologies mentioned in the identified publications
Notes: VR: Virtual Reality; AR: Augmented Reality; WSN: Wireless Sensor Network; IoT: Internet-of-Things; BIM: Building Information Modelling

Three publications discussed the potential challenges of DT application in the building construction sector [8, 18, 25]. They all mentioned the technology complexity, particularly in the field of sensing technology to gather data on construction site, with the proper consideration of installation and maintenance as well. Development of structuring methods and computing algorithms on the overwhelming amounts of data was also regarded as a common challenge to ensure the high-efficient of data processing. Other potential challenges in terms of the technical level and the social-political level were also

raised as below.

- Lack of sensors with comprehensive capabilities (e.g. integrated measuring distance, temperature, humidity, air quality, etc.) [18];
- Complexity of integration of sensors with different reading frequencies and accuracies (i.e. interoperability) [18];
- Development of reliable and efficient data transmission methods to ensure data connectivity and reduce time delay for further processing [18, 25];
- The existing complex social system [25];
- The dynamic of human interactions with construction activities [25];
- Data privacy (e.g. the sharing of data may need to follow relevant regulations on data privacy) [25]; and
- Data security (e.g. confidential project data needs to be protected during data transmission between real and virtual spaces) [25].

4.2 Opportunities, challenges and limitations

Results of the review on publications related to the application of DT in the building construction sector revealed that relevant researches have been conducted, due to the development of digital and information technologies and demonstration of benefits brought by DT applications across industries. However, only a few researches were conducted in a systematic manner with developed frameworks for DT applications in the building construction sector. Management of information across the whole project lifecycle and automatic planning and scheduling of works are the two most mentioned purposes of applying DT in the building construction sector. The concept of DT was not considered alone, but integrating with at least one existing digital technology. For example, BIM is commonly used as the data model of a building, providing a fundamental basis to develop a DT. Comparatively, DT has extra characteristics of real-time data acquisition through integrating IoT and WSN technologies. Application of DT in the building construction sector has promising benefits such as automated monitoring of site progress and reduced operational risk of machine. However, there are technical and social-political challenges to be addressed including interoperability of various sensors, development of optimised data processing algorithms and data privacy and security issues.

The current research gaps identified from the review are summarised as below for future research.

- The definitions of DT and BIM used in some publications remain identical, which are inaccurate, so a clearer and more uniform definition of DT is needed;
- There is a lack of study on the application of DT in the volumetric modular building construction; and
- There is a lack of empirical evidence to prove benefits of DT application in the building construction sector.

5 A framework of DT application in MiC

In order to apply DT in MiC, the emphasis is on building a Cyber-Physical System (CPS), where information collected from the real space is used for computation to generate a real-time monitoring cyber model. In the meantime, changes of the cyber model will either be used for prediction or reflect in the real space to achieve the control function.

Based on findings in Section 4, a framework of applying DT in MiC is provide in Figure 7. The framework was built in the context of module installation, as it is a unique onsite construction activity compared with conventional construction practices. Interpretation of the framework is provided as below.

1. Firstly, IoT technology is applied on real-time data capturing from labour who is responsible for module installation works, material (i.e. module to be installed) and machinery (i.e. crane) (Sensors supporting wireless transmission of data are required)
2. If BIM containing planning and scheduling of module installation works is available, it will be considered as an input of data source, which is of benefit to enhance logistics coordination
3. WSN or the 5th generation mobile network (5G) is used to ensure transmission and connectivity between the physical space and the cloud platform for storage
4. Computing algorithms are applied for processing data stored in the cloud platform in order to generate real-time DT of module installation process
5. AR, VR and web portal provide construction mangers a user interface to visualize the DT
6. The real-time DT of module installation process has the potentials to provide basic functions including labour safety detection, installation progress monitoring and prediction of required module installation time.
7. The advanced functions may allow construction managers to exert influence on the real space by controlling the DT, through control sensors and a rapid data transmission network. Control sensors include types of buzzing, flashing and vibrating.

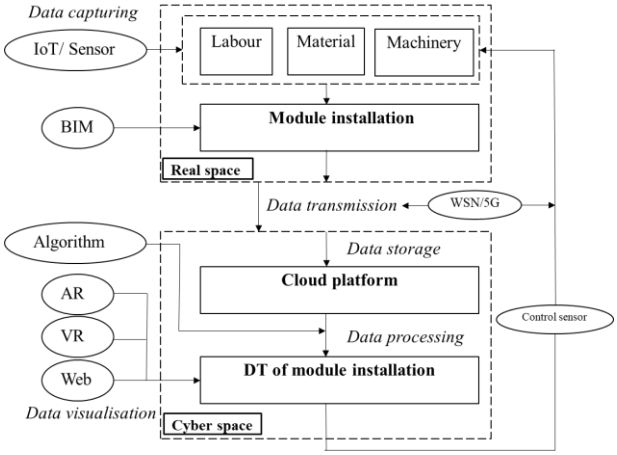

Figure 7. The proposed framework of DT application in module installation of MiC

6 Conclusions

This paper provides an overview of academic publications related to DT applications across industries, particularly in the building industry. The purposes of this paper are to provide a systematic review of application of DT in the building construction sector and to explore opportunities and challenges of applying DT in MiC within the context of Hong Kong as a typical case of high-density cities. Through literature review and analysis of ten publications related to DT applications in the building construction sector, the primary findings are as below.

- Management of information across the whole project lifecycle and automatic planning and scheduling of works are the two most mentioned purposes;
- DT is always integrated with other digital technologies;
- Theoretically, automated monitoring of site progress and reduced operational risk of machine are achievable benefits by adopting of DT; and
- There are technical and social-political challenges to be addressed before adoption of DT.

The framework considering the application of DT in the case of module installation process was proposed based on the findings. Through integrating with other digital technologies in the framework, the DT has potential functions of monitoring, predication and control. In addition to the current generic research gaps for the building construction sector mentioned in Section 5, future research is proposed to explore the following directions about DT applications in MiC:

1. Further literature review and meta-analysis of publications on DT applications in the building construction sector using more electronic databases; and
2. Interviews and focus group discussions with academics and practitioners in the areas of DT and modular building (covering different groups of stakeholders, e.g. client, consultant, contractor) to verify and refine the developed framework.

Integrating Industry 4.0 Associated Technologies into Automated and Traditional Construction

F.R. Correa[a]

[a]Department of Construction, University of Sao Paulo, Brazil
E-mail: fabiano.correa@usp.br

Abstract –

Nowadays, it is ever more common to find mentions in the scientific literature to a "Construction 4.0". Considering, for instance, Offsite Construction, it is clearer how such concept could be realized. Current widespread adoption of BIM helps but is not enough to realize that end, because it is, in general, limited to information being manually created through authoring software, and consumed for different proposes, such as Clash Detection, or 4D Modeling. Construction 4.0 should transcend the limitations of existing only in cyberspace; it should interact directly with the real environment by means of sensors (gathering data), and remote controlled or autonomous machines, employed as part of the production processes, with Machine Learning algorithms handling the transformation of data into information, and actions. The central element of such approach should be a Digital Twin-driven Cyber-Physical System, which when focused on Construction Phase, would be capable to simulate the dynamics of construction processes. In this position article, an evolution of the concept of Computer-Integrated Construction (CIC) is presented as a possibility in representing and guiding developments associated to the incorporation of different technologies from Industry 4.0 to Construction. A framework where such a system could be applied to Off-site or Automated Construction scenario, and to Traditional Construction scenario as well is proposed. In the latter scenario, common in developing countries, which yet has plenty of (and need for) manual labor in the Construction sector, all those technologies are employed not to reduce jobs, but to augment awareness and eventually to turn the tasks safer for the worker.

Keywords –

Digital Twin; Building Information Modeling; Construction 4.0; Cyber-Physical Systems

1 Introduction

Some years ago, few people thought that the subject of a Fourth Industrial Revolution would be relevant to the Construction sector; one of the first researches to look for signs and directions of it on the industry, didn't found anything that helped towards this end [1]. Nowadays, it is ever more common to find mentions in the scientific literature to a "Construction 4.0", i.e., the application of Industry 4.0 associated technologies to the Construction (Figure 1). Yet, it is still not clear how all those technologies, Cyber-Physical Systems, Digital Twins, Industrial Internet or Internet of Things (IoT), to name just a few, will play a role to transform a sector that has been suffering to find its path towards industrialization.

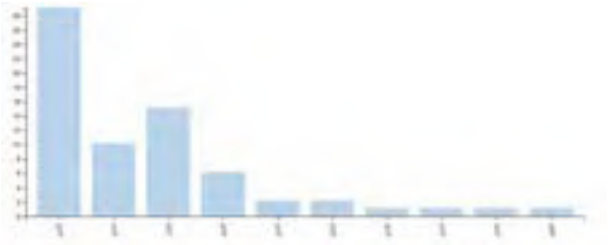

Figure 1. Publications whose subject deals with the concept of Construction 4.0, from Web of Science database.

Both the current importance that Computer-Aided Systems, including PLM (Product Lifecycle Management), has had in Manufacturing Industry [2] and the widespread adoption of its counterpart BIM in the Architecture, Engineering, and Construction (AEC) sector [3], helps but is not enough to realize that end. They are, in general, limited to information being manually created through authoring software, and consumed for different proposes (in case of BIM uses, Clash Detection, or 4D Modeling, for example).

Industry 4.0, as its own name states, is totally focused on manufacturing, i.e., production on a factory,

or more specifically, on a factory with lots of automation that appeared during the Third Industrial Revolution. So, there is this necessity to traverse the cyberspace of digital models of the products towards the control of real machines, or of the entire factory, where happens the production processes.

Such trend aims at reducing time to market, enhance productivity, and achieve mass customization, among other goals. It is the integration of automation in the virtual world, and automation in the real world.

Considering "those aspects of the project that can be designed and managed, i.e., the product (typically a building or plant), the organization that will define, design, construct and operate it, and the process that the organization teams will follow" [4], and the "role of complementarity" that attest to the synergy among Product, Process and Organization [5] ("Manufacturing Technology" being part of the Process), the importance of abstractions or models of those aspects has been increasing. For the goal of a Construction 4.0, it needs a complete virtual or digital representation of the Product, Process and Organization, to be capable to integrate horizontally inside a company, and vertically through the entire supply chain.

Based on a literature review and cross-learning case studies between Manufacturing and Construction Industries [6][7], this position article adopts an evolution of the concept of Computer-Integrated Construction (CIC) as a possibility in representing and guiding developments associated to the incorporation of different technologies from Industry 4.0 to Construction. Industry 4.0, and its inspired Construction 4.0, should be about the integration of virtual and physical, and has in the technology of Digital Twin-driven Cyber-Physical System its most prominent technology.

Although the relevance of such technologies encompasses all the phases in the lifecycle of a building or infrastructure work, due to limited number of pages in that article, the presentation here restricts itself to the Construction Phase. Scenarios where such a framework could be applied to Off-site or Automated Construction in one extreme direction, and on Traditional Construction processes in the other (and the whole spectrum in between), are proposed.

2 Pre-Construction 4.0: Origins of Computer – Integrated Construction (CIC)

Development on Information and Communication Technology (ICT) systems could be traced back to the first hardware that enabled structural calculations, and software that enabled Computer-Aided Drafting systems. It was always done in parallel to innovation in Construction based on new materials, new technology in building systems, and new ways to manage construction processes.

The AEC sector being fragmented as it is, the same happens with its ICT software tools used by different disciplines and professionals. Many researchers were dedicated to the work of integrating the information of those workflows [8]. Construction 4.0 main idea is beyond integration inside virtual world, of the information throughout the lifecycle of the product, the building or infrastructure work: it is the integration of that information with the automation hardware on the shop floor, and the creation of new ways to operate inside an industrialized and automated environment.

There are some similarities between Industry 4.0 paradigm and a popular concept in the 80's, Computer-Integrated Manufacturing (CIM): both incorporate somehow the dynamics of the shop floor computer-based system, towards the goal of automation.

CIM was conceived as an integrated approach to end the 'islands of automation' around Computer-Aided Design (CAD), and Computer-Aided Manufacturing (CAM), and its communication with CNCs machines on the shop floor. The concept took advantage of a digital workflow of information about products and the automated production lines, with machines controlled by computers, and industrial robots: it should integrate and control the machines to produce based on digital information.

The adaptation of that concept to Construction was popular in the 90's, known by the term of Computer Integrated Construction (CIC) [9–11]. It seems that from the researchers inside this theme, there were two approaches:

1. **Focused on the integration between CAD and CAM**: or between design and fabrication – many advanced applications of that era were done without such integration [12]. In the search of that integration in the design phase, it seems also that researchers converged to create object-oriented data schemas and software tools, which in the end became to be known as BIM [13];
2. **Focused on the Digital Fabrication**: whose interest are on Off-site Construction, following assembly on site, and the use of robots and other automated machines – activities of Planning, and Monitoring were done based on digital models.

For the work presented in this article, the latter approach is more relevant. Following that approach leaded to Site Automation [14], Factory Automation System [15], Super Construction Factory [16], or similar approaches, to structure the unstructured onsite environment, so that it would be possible to integrate construction robots without disrupting other workflows around [5].

Such developments by all big Japanese Construction companies, such as Shimizu [17] and Obayashi [18], and replicated by companies of other countries, it should be viewed as a prototype of Construction 4.0, although many of the robots were by then teleoperated. To have a center of operations, and many different digital models, and the assembly of building components itself being done by robots and machines, it had all the elements that comprises the view of the application of Industry 4.0 technologies to Construction.

3 Industry 4.0 Associated Technologies

One way to understand the current drive towards a Construction 4.0 paradigm was presented in the previous section. Today, the maturity of different technologies that could be used in an integrated way allows the development of such future scenario.

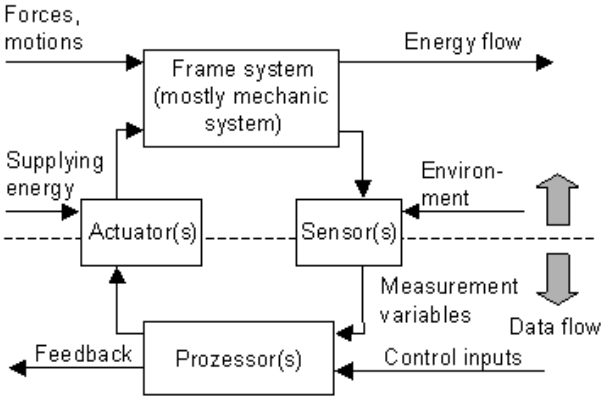

Figure 2. Representation of a mechatronic system [19]

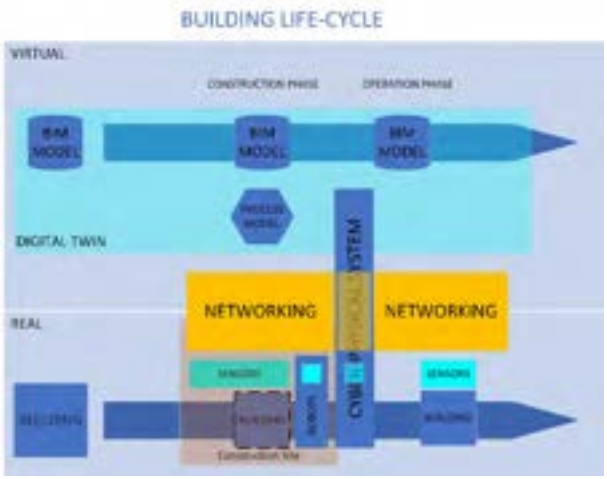

Figure 3. Diagram with the interaction between different Industry 4.0 technologies.

Thinking about construction production as a system, it is interesting to make an analogy with the representation of a mechatronic systems, as shown in Figure 2: 1) Sensor(s); 2) Processor(s); 3) Actuator(s).

Each technology associated to Industry 4.0 paradigm could be viewed as enabling sensing, actuation, and/or processing. The technologies that would be briefly addressed in this section are: Industrial Internet or Internet of Things (IoT), Digital Twins, Machine Learning / Artificial Intelligence Algorithms, and Cyber-Physical System.

Figure 3 illustrate how BIM models changes throughout in the building life cycle in the virtual environment, and its analogous, the physical building is being constructed and operated in the real environment. There is a networking layer that connects both environments, and the sensors that are vital to capture the dynamics of the construction site / shop floor, and the surroundings of robots and of cyber-physical systems, which by its own is driven by digital twins. The hexagon in the figure, bellow the BIM Model in the construction phase, represents the dynamics that are the simulation of the processes, and it enhances the product model, to provide some basis for a digital twin. With it, it is possible to create data and information beyond those produced by the professionals, automatically. In the operation phase, it is only possible to work, if buildings were designed and constructed with embedded sensors, or instrumentalized afterwards, to capture every relevant aspects of its uses.

3.1 Industrial Internet or Internet of Things (IoT)

IoT is about the convergence, where different devices (Things) are capable to communicate one with another over the Internet. They not only communicate; they sense their environment, and they could act over it based on programmed behavior. This “definition” could be stretched to encompass from sensor networks to autonomous systems, and certainly benefit from 5G networks, the existence of Cloud (Edge or Fog) computing nodes, and so on.

It should be the sensing layer, which is essential for whatever scenario of Construction 4.0 that is being proposed. The use of different sensors for tracking people, material, and equipment onsite, and RFID in modular plants could help to leverage the approach to Construction 4.0, producing database for construction processes.

The availability of computational power outside the local where data is collected, and even where it is consumed gives many more possibilities. It is more cost effective.

3.2 Data Analytics: Machine Learning (ML), Artificial Intelligence (AI)

Current successful approach to build complex models is based on data, with Machine Learning (ML) algorithms. It is possible to learn parameters of a parametric model, and to learn the very representation itself.

Machine Learning, or more generally Artificial Intelligence (AI) algorithms could also be used to analyze incoming data, to quantify uncertainty of different scenarios, to propose alternative solutions, and so on.

One necessity with the grow in sensors being used, and data being gathered would be infrastructure to deal with the Big Data Analytics. are analogous to what was presented in the previous sub-section. The differences are the hardware, software and workflow needed to do the same thing in a scalable manner.

3.3 Digital Twins

There is allusions to BIM being the Digital Twin version in the Construction sector, although with different names [20]. Following a PLM approach [2], some works also sees parallel between BIM and PLM. Digital Twins should, in an analogy to object-oriented modeling, provide not only the variables, but also functions pertinent to, and based on those variables. In the case of a building, it should incorporate physics to allow for showing its behavior with software running different simulations [21].

BIM models *per se* should not be considered Digital Twins when the focus of the analysis is the Construction Phase. All uses of BIM models [22] implies taking information from it, quantity takeoff, that generally were inputted by human, and need extra human work to integrate with other databases to achieve the desired result for such utilization – there is no transformation of the data.

So, BIM models, are considered the virtual representation of the Product. In such uses of the model for 4D Planning, 5D cost, it cannot be used *per se* to predict, and it doesn't have dynamic links to account for constant changes in design, planning or construction phases. Those models are created, in general, through human input through authoring software tools, one specific for each discipline, and that need to communicate through interoperable workflows.

Although there isn't general agreement around what BIM is and is not, a process, a 3D digital model of the product with non-geometric and geometric data, or a collection of authoring software tools, here it would follow some VDC practitioners that considers BIM as the digital model, and its uses as part of the VDC practice [4].

Digital Twin should incorporate in its representation functions to transform the initial information and producing result that do not depend only in data, but in inner behavior of the phenomenon modeled.

3.4 Cyber-Physical Systems

The term "Cyber-Physical System" was probably coined by Helen Gill at NSF around 2006 [23]. Figure 4 provides a concept map relating Cyber-Physical Systems to Feedback Systems and Real-Time [24].

Probably an evolution of Distributed Real-Time Embedded Systems (DRE), Cyber-Physical Systems are complex systems, which integrate in its design abstractions of control, system, and software engineering. It is inherently a model-based approach to provide interaction between the physical world and its dynamics, and the cyber or virtual world.

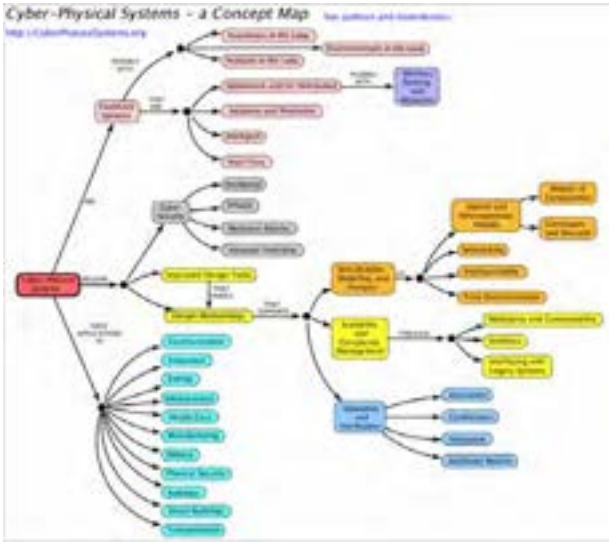

Figure 4. A concept map for Cyber-Physical Systems [24].

It could be driven by Digital Twins or work with other controllers: Additive manufacturing, and construction robots.

4 Construction in the 4.0 era

The challenges in creating a framework, which is valid over the entire spectrum of possibilities of different productions systems in Construction are:

- How to create a Digital Twin of the Manufacturing Technology, or the Virtual Representation of Production Processes;
- How it will behave, its inner dynamics.

It should be a software capable of simulate, at least,

the construction process for each existent building system, allowing predictions in a closed-loop feedback, and possibly in real-time. It will depend on data from sensor networks deployed in production lines for offsite construction (where probably it will be Cyber-Physical System driven by Digital Twins), or on-site, for more traditional production or assembly of modular component.

For the case of the so-called Automated Construction, which we had the Sky-Factories or Site Automation as perfect examples, they already developed such supervisory and control system overseeing the automated processes.

But even for traditional construction in developing countries, that are prone to remain almost that way for the short future, such system could be implemented and used in such a way to give a better understanding to the people making decisions of an uncertainty-bounded possibilities for planning and rescheduling. The technologies adopted should promote the work of people, to make their time more productive, to make their work safer, and make their data-driven decision.

As presented in the previous section, a Digital Twin is the virtual representation of the Production process, when considered only Construction Phase. It represents how raw material and resources such as workers, machines, and so on, are transformed into building components, or the building itself, in such detail that it should be possible to predict the length of time needed to finished each step.

The simulation is the core engine of the proposed framework. Although realistic simulation models of the manufacturing of components in automated lines and considering the human interacting with machines already exist. It could provide scenarios with which to deal during planning, to re-planning during execution.

More challenging is the scenario of simulating traditional construction, in an unstructured environment, with lots of freedom to act. But here it is advocated that with a probabilistic model, constructed over a large collection of data, and individualized to capture each company way of work, could at least provide lower and upper bonds over variables such as cost, amount of human labor needed, alternative plans, risky, and so on.

Example of this approach was set out in [25], and a paper still not published, in which that framework was used over 5-years production data, and results are promising in capturing both the impact of the factory activities, and from panel design in the times in each workstation for wood-framing pre-fabricated homes.

There will be at first, two stages for that approach: 1) gathering data for different construction processes, to build a model or representation based on data [26], instead of expertise from professionals; 2) Application of that model, with real-time data still been gathered, to monitor processes, and to predict future scenarios, and plan in advance for alternative solutions.

Interesting for such approach, is the work that started with Occupancy Grids [27], then evolved to Metric Maps, and algorithms to build such representations at the same time that an autonomous robots navigate knows as SLAM (Simultaneous Localization and Mapping) [28]. Nowadays, SLAM has been used in Construction sector with point-cloud data to produce as-built and as-is BIM models.

It should be possible to decouple complexity on-site by modeling activities individually and allow a simulator for Discrete Event Simulation (DES) like Simphony [29], to add the complexity of interaction, and eventually, movement of resources. In the end, it could constitute a prototype of a library of Construction Processes, based on specific building systems, that could be tailored for each team or construction company, based on historic data of productivity.

5 Scenarios for the Construction 4.0

Two scenarios are being considered, based primarily in the availability of construction work force: 1) Industrialized Scenario, in which there is a lack of construction workers, and the availability of machines and/or construction robots directly responsible to the production process; 2) Traditional Construction Scenario, in which the sector employs a large workforce, but work conditions need to be improved by means of assistive technology.

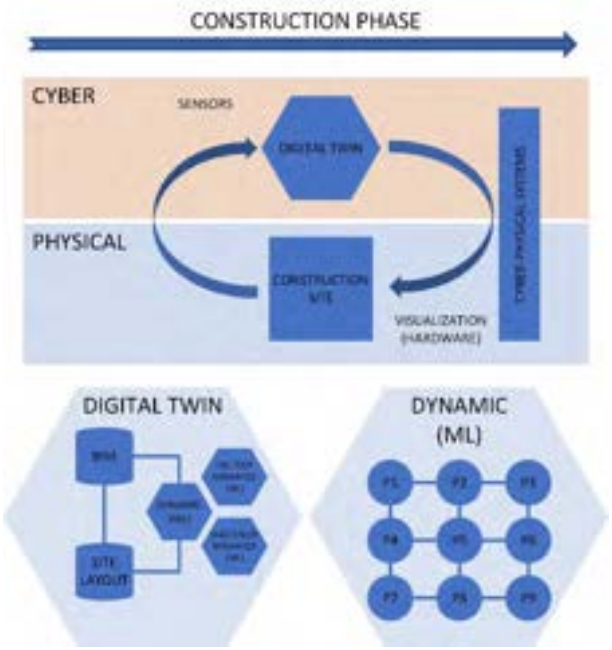

Figure 5. Scenario for Automated Construction.

5.1.1 Industrialized Construction Scenario

Modular, or Off-site Construction in general, could incorporate more straightforwardly Industry 4.0 technologies, although still there is many particularities that should be addressed. There is a large synergy between the different applications, although shop floor in the construction sector, be it for steel-framing, wood-framing, or concrete panels are not very much automated.

Figure 5 represent the industrialized scenario, where there is offsite production, automation in the factory, and eventually construction robots onsite. There are sensors gathering data, monitoring processes, and all data feed in Digital Twin model of the production processes. Those models produce actions to be taken by machines, or equipment which could directly made building components. The bridge between both environments, cyber and physical, is materialized by one or a hierarchical system of Cyber-Physical Systems (CPS), which allows a bidirectional link between BIM model inside the Digital Twin, and the real environment by means of "autonomous" machines.

The more automated the production, the less is the uncertainty, and the final difference between predicted and measured metrics in production. The dynamics would be made of an array, or lattice of production models, with varied dependencies among them, allowing for Machine Learning reasoning.

5.1.2 Traditional Construction Scenario

The main difference between both scenarios is the Cyber-Physical Systems, which are absent in the traditional construction scenario. Moreover, the framework for traditional construction works with human-in-the-loop simulations, as there is not a bidirectional flow of sensor readings and actuation controls between virtual and real environments.

There are countries, mainly developing countries such as Brazil, where there is a real concern regarding substitute Construction workers by robots or machines. Also, workers of the sector receive low wages, and they work in conditions that are potentially dangerous, and hard [30]. For that matter, where there is plenty of (and need for) manual labor in the Construction sector, all those technologies, and the scenario for a Construction 4.0 should be employed to augment and to turn the tasks safer, for the worker.

So, there is an opportunity to change current culture in the sector in those countries, an promote an environment of continuous learning, and to provide better jobs for such individuals by means of using assistive technologies [31][32]. From electric or electronic tools, exoskeletons [33] to facilitate tasks and avoid injuries, tracking systems to manage safety, and so on.

When such approach is deployed integrated with its virtual counterpart to coordinate efforts, to plan and control in a micro-management, it should produce better results.

There are many challenges in this scenario: 1) as it needs more human labor, it increases the number of sensors needed to capture activities on-site – although one could use imaging techniques; 2) the trajectories or the movement of the workforce should allow the identification, at least, of the beginning and the end of each activity in the sequence for the entire production onsite; 3) Those indirect detections could allow the estimation of work complete, and also constitute in historic measurement of productivity; 4) Using Machine Learning algorithms over such databases, it would be possible to incorporate uncertainties in the simulation, and provide worst- and best-scenarios for the planning with human-in-the-loop.

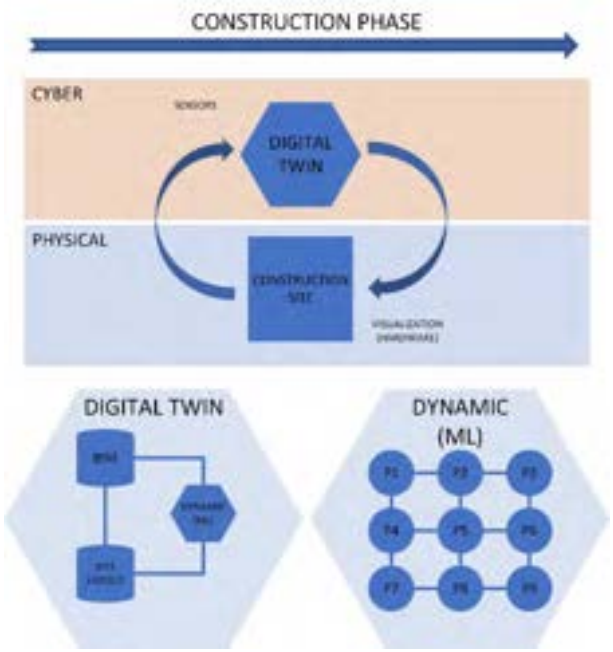

Figure 6. Scenario for Traditional Construction.

It is known that only technology changes would not make a case without addressing how to finance, how to bid public contracts and how to turn it competitive in terms of taxes.

6 Conclusion

In conclusion, a possible Construction 4.0, with two different scenarios that encompasses both Industrialized and Traditional Construction was presented. There should be a large spectrum of applications, in which the assimilation of the different technologies associated to

Industry 4.0 would differ.

As it is based on the digitization process, and its most important piece is the Digital Twin of the Production processes, it is essential that there is a widespread use of sensors to provide real data, and also almost real-time information of the processes, and that planning and control onsite be made in a data-driven approach.

It emphasizes that Construction 4.0 should be a holistic view, to provide a starting point to think about the future of Construction in considering Sustainability, in becoming part of a Circular Economy, and to an approach that considers society and the needs its work force in each different country.

Construction 4.0 won't be relevant without new forms of management and control, that should be proposed to incorporate as a base for a support system a micro-management, with automatic acquisition, and processing of data for the decision-making support system. However, such topic was outside the scope of this article.

Abstract –

Traditionally, when an engineer wants to use Building Information Model (BIM) on-site to support tasks for construction or maintenance, the common approach is to use a tablet or a notebook to run a BIM viewer, thus requiring manual operation for model manipulation. In addition, the BIM presented through the screen and the actual on-site visual are in two separated views, and thus the two are less likely to be synchronized. Augmented Reality (AR) superimposes virtual objects or information that can be interacted with onto real world images or videos. Therefore, this study applied AR to superimpose BIM with an indoor industrial environment for a more immediate and intuitive integration of the physical site and BIM. At present, most applications of combined BIM with AR uses marker or marker-less image recognition to superimpose virtual content using feature points of the marker or object image as an identifier. If the identifier moves outside the device camera view, the virtual content will not appear. With advances in AR, a new AR mode is introduced in this study based on simultaneous localization and mapping (SLAM). Based on this technology, the virtual BIM is placed based on the device's understanding of the environment and then superimposed onto real objects in the scene without any identifiers. A manual method is proposed to align a chosen BIM component to a corresponding real object. Based on the alignment, the system calculates the angle and position to accurately superimpose the BIM on the virtual environment, with these locating characteristics recorded for future use. Since the load and display of an entire BIM model is not necessary and is inefficient in the context of indoor AR applications, the model is divided into room models, and the system only overlays the corresponding room model for a specific room. This is achieved through a combination with the Bluetooth Low Energy (BLE) indoor positioning technology, so that the room in which the user is located can be immediately identified and the corresponding room model can be loaded.

Keywords –

Building Information Model; Augmented Reality; Simultaneous localization and mapping; BLE indoor positioning

1 Introduction

For previous approaches for viewing BIM data, it is generally necessary to use related software, such as Autodesk Revit, Navisworks, Tekla Structures, etc. Moreover, these types of BIM software are traditionally designed for users to operate in an office setting; if it is required to view BIM data during the project maintenance stage, engineering personnel need to configure a lightweight handheld device, such as a tablet or high-end notebook, as a BIM viewing tool. This viewing method results in two problems: (i) BIM software cannot automatically present the model information required by engineering personnel, and (ii) the presented image in the BIM viewing tool and what is visually seen by on-site engineering personnel are two different images, resulting in difficulties in reconciliation.

Recently, Augmented Reality (AR) as a visual technology has risen in prominence. AR can combine the virtual world and the real world on the screen of a specific interactive device. Virtual text, graphics, or 3D models can be superimposed on true images. Based on this technology, the 3D virtual model from BIM can be superimposed onto the image of the project site. There is many applications of Augmented Reality system

development for BIM [1, 2, 3, 4]. For example, during the construction and maintenance stages, an integrated on-site BIM model can be used to present construction progress models at different stages for project management. Additionally, during road maintenance and repair, the state of an underground pipeline can be determined using AR without the need for excavation, thus avoiding losses caused by accidentally excavated pipelines. There also have been broad applications in project operation and maintenance stages, such as in previewing indoor renovations using virtual models or indoor route navigation in large buildings. In essence, AR applications of BIM are typically in indoor environments. Thus, model fitting and accuracy will be a major challenge.

To solve the problem of indoor positioning accuracy, this study uses simultaneous localization and mapping (SLAM) through the combination of visual-inertial SLAM (VI-SLAM) with BIM in AR. SLAM was first proposed in the field of robotics, enabling robots to understand their surroundings during movement, using repeatedly observed feature points to locate their own position (simultaneous localization) and constructing a map based on environmental cognition (mapping). The development process of SLAM also ranges from the earliest sonar and light measurements to the current SLAM based on inertial measurement unit (IMU) and visual measurement technology (VI-SLAM). Recently, an Augmented Reality technology based on VI-SLAM has been developed [5].

This study proposes an overall conceptual framework for a pre-processing system and the user mode. The design of the system concept is conducted according to the abovementioned background and motivation, with the primary application being for the project maintenance stage. To address the effectiveness and localization problems of BIM models for project maintenance when coupled with an on-site inspection, this study introduces AR technology based on SLAM, using its characteristics to optimize the stability and fitness of the AR system as well as for spatial locating via Bluetooth Low Energy (BLE) and acquiring required data through a database. This is so that the cloud data for the room can be loaded immediately to fit the on-site BIM room model.

2 System framework

To effectively meet the abovementioned requirements, a pre-processing (pre-positioning) system is developed before the AR system operation. This pre-processor includes model processing, Internet of Things (IoT) and model data processing, a positioning system, and a model-fitting AR system, with the goal that every building object only needs to be undergo the pre-processing operation once, as well as an AR engineering maintenance system. After completing the pre-processing, the AR system can be used to directly with the model and assist in maintenance operations.

2.1 System pre-positioning operations

This study integrates BLE indoor positioning technology, IoT indoor monitoring technology, and cloud technology as developed previously by our research team, and transplants these technologies to an iOS platform for development. Based on SLAM AR, the Augmented Reality system is redesigned, adding Raspberry Pi into the IoT system for value-added applications to optimize and adjust the BLE positioning mode. The pre-position operation only is required to be performed once, with the expected results obtained without further pre-processing. Before system operation, it is necessary to use Autodesk Revit as a tool to establish the model of a building. This system takes the BIM model of the Second Engineering Building at the National Taiwan University of Science and Technology as an example, with sensors laid out within the required space.

2.2 Model data and sensor data processing

A BIM model has various components such as walls, beams, columns, equipment, etc., and furthermore, every component is configured with numerical data. To import the components contained in a case model into a database, the case statement for itemized components must be exported as a text file. The component data, indoor positioning device and room information, room name, floor number, address, and other related building information are collated into the storage configuration logic of HBase in compliance with the database format used in the laboratory. The component information will be consolidated into an HBase database format through an automated processing program to facilitate future uploading.

For the IoT indoor monitoring data of an on-site room, the perception layer consists of mainly the Arduino microcontroller. Various sensors such as a humidity sensor, water-dripping sensor, and an illuminance sensor are configured with Arduino to collect environmental monitoring data in the space where they are located. The network layer is the XBee communication module, which is connected to the Arduino through the Arduino-XBee Shield to form a ZigBee transmission node with various sensor modules. The Raspberry Pi also needs to be connected to the XBee communication module to form a data-receiving node, transmitting sensor information in the network to the Raspberry Pi through the ZigBee network system. The data is collated and uploaded to HBase via a server-side personal home page (PHP) through a wireless

network, thereby realizing the sensor wireless network transmission framework. The above two data processing flow procedures are shown in Figure 1.

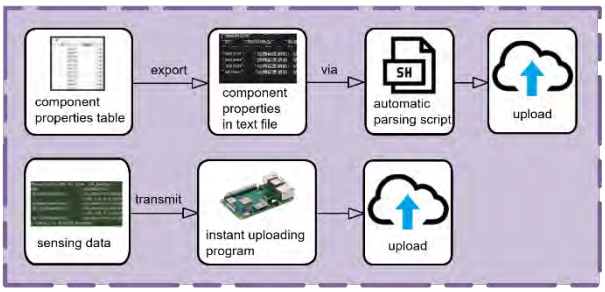

Figure 1. Data processing flow procedures.

2.3 Model processing flow procedure

After a completely established BIM model is exported, problems in material loss are present. If is used directly in the Augmented Reality system, challenges will arise in identifying components. It is necessary to re-render the BIM model material through the 3ds Max material editor and import it into the Unity development platform, so that the identification is correct. An overall BIM model needs to be manually segmented, cutting the model into floor models to be used as floor mini maps of floors. The model is further segmented into room models for the AR system to use for visualization. Finally, the model is converted to a Unity server transfer format through a Unity AssetBundle and uploaded to the server. In future uses, after a user enters the positioned space, the model can be created, deleted, and subjected to other functions during the execution of the AR program through the wireless network, maintaining a stable memory usage in the handheld device. The flow process is shown in Figure 2.

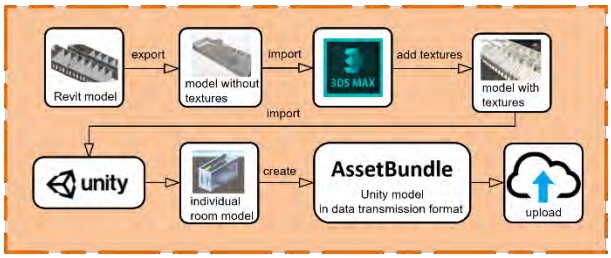

Figure 2. Model segmentation flow process.

2.4 AR pre-processing system

The pre-processing system is used to construct a mapping and record the placement of components. In a fitting operation, when a room to be scanned is entered, the system will first locate the room. After the cloud scanning of spatial points is completed, a selection list of components is produced, and all the components in the room will be listed for the located room. Next, the components to be fit are selected from the list of components. When the model is fit and placed in position visually, the system will calculate the moving distance and rotation angle. When clicking the upload button, the point cloud information file stored in the point cloud map will be uploaded to the server for storage, and the model with the relevant map location information will be stored in the database synchronously. The pre-processing operation procedure is shown in Figure 3.

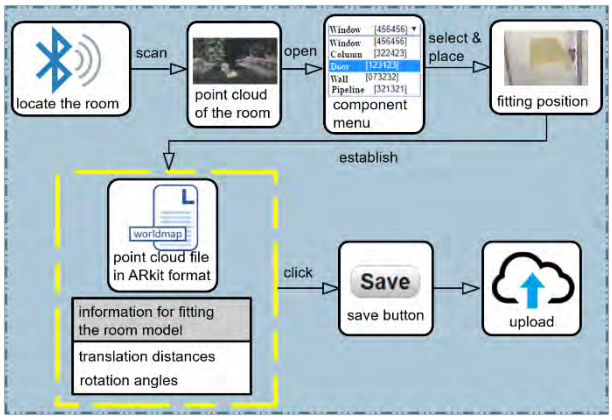

Figure 3. AR pre-processing system operation flowchart.

2.5 AR system operation flow process

The system operation starts mainly after the pre-positioning operations are completed. A user's on-site operation through the proposed system is mainly divided into three parts: indoor positioning, model fitting, and AR presentation. An overall framework of the first two parts is shown in Figure 4.

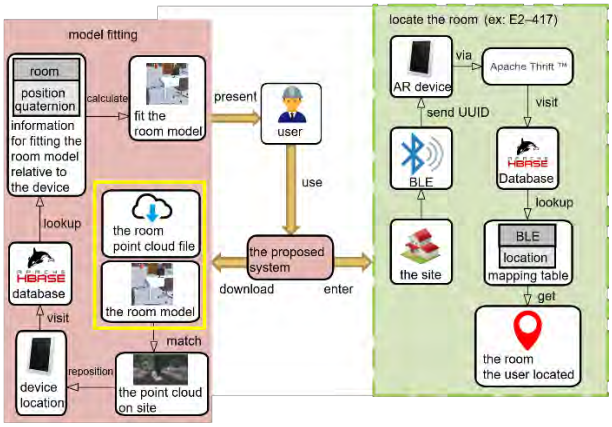

Figure 4. Model fitting flow process (left) and room positioning flow process (right).

In the positioning operation, a user entering the project site can wear a mobile device equipped with the proposed system. The device will receive multiple universally unique identifiers (UUID), with the signal strength transmitted by Beacon devices at each time step. The UUID will be sorted following the received signal strength and ranked from the strongest to the weakest. If the frequency of a Beacon device signal strength per time step is ranked the highest, that UUID will be the UUID of the room. The system will access the Hbase database through functions provided by Apache Thrift, search for the corresponding room position inside the BLE data table, and set it as the system positioning location, as shown in Figure 4 (right).

After a user completes the positioning, the system will download the files corresponding to the room from the server (the point cloud information file that contains the stored point cloud map of the room and the room model file with the pre-position processing). After loading the point cloud information file, the system will compare the feature points in both the point cloud map and the actual environment, and then recalculate the relative position of the device in the point cloud map. Thus, the model will obtain the position and angle of the model relative to the device through the database, and then the room model is fitted to the corresponding position in the point cloud map. The user can see the virtual model overlaid onto the actual environment through the device camera. The flow process is shown in Figure 4 (left).

After the AR model is presented on the system screen interface, users can click on the Revit component model by tapping on the screen. The system will send the Revit ID of the selected components to HBase, search for the corresponding component data parameters, attributes, categories, and other component information via the ID, and transfer the data back to the interface to be viewed by user. From this, if the model is a sensor, the historical data for the sensor can be obtained. Set directly on top of a map, a virtual camera exclusive to the mini map can view the location of the device on the map using an orthographic projection, and thus a mini map navigation mechanism is formed. The complete function flow process is shown in Figure 5.

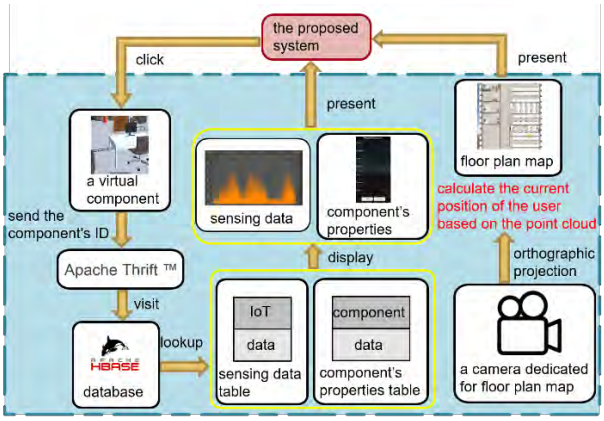

Figure 5. AR presentation flow process.

3 System operation mechanism

The operation mechanism is divided into five sections: BIM model processing method, IoT indoor monitoring sensor group setup, AR preposition processing system mechanism, HBase database configuration, and auxiliary tools.

3.1 BIM model processing method

According to the system requirements, a Revit model of the study site must be first established. Before introducing the BIM model into Unity, the model and component information must first be exported separately. The model must be stored on the HTTP Server in the Unity Asset Bundle format for users to download the model through a wireless network during program execution; component information must be processed before it can be stored in HBase.

Before the Revit model is introduced again into Unity, the model needs to be exported first into a readable format by Unity. The designed system uses the FBX format, while the Revit model is exclusive to the Autodesk software suite. If other software is used for model viewing, the model will not display properly. To resolve this problem, the model must be converted. The designed system uses Autodesk 3D Studio Max (3ds Max) for model conversion.

Considering that the mobile device hardware paired by the user on the project site lacks computational power to process the sizable model and the large-scale rendering of the 3D model, the model is segmented following the room being cut in Revit, as shown in Figure 6.

Figure 6. Schematic diagrams of segmented rooms.

If the attributes of the BIM components are to be imported into the database, processing is necessary. First, the component must have an identifiable code for subsequent component search, and while component itself in Revit is configured with an ID, it is a hidden attribute. At the model establishment stage, the designed system uses the Dynamo extension plug-in to place the attribute members into the ID of each component.

3.2 IoT indoor monitoring sensor group setup

Data transmission of the proposed system uses the Arduino board in combination with sensors, thereby reducing the cost of laying out hardware. The sensor components include an Arduino development board, a number of environmental sensors, the BLE indoor positioning module, and XBee communication module (data transmission). The data processing components include the Raspberry Pi, the XBee communication module (data reception): through the Wi-Fi network module of the Raspberry Pi, the monitoring data received by the XBee module is uploaded to the database storage in the remote server.

3.3 AR pre-processing system mechanism

After entering a room, the positioning of the room can be conducted through this pre-processing system. After confirming the location of the room, the scanning of the point cloud for the 3D space can then be carried out. After the scanning is complete, the point cloud file is uploaded to the server for storage and linked to the database.

Next, it is necessary to record the position of the model in three-dimensional space. First, the user must select the component to be fitted and manually place the component at the true position of the object. Next, the system will calculate the relative position of other remaining components per the position of the manually placed component.

The manual alignment is done through a perpendicular projection from the right center of the screen through a ray. The ray is parallel to the normal vector of the screen plane. If the ray touches the plane of system detection, the right center of the component will be fitted to the position of the system detection ray projection and the model will fit to the parallel plane, as shown in Figure 7.

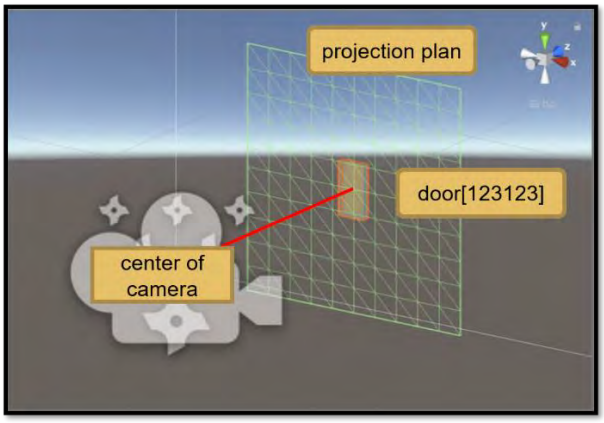

Figure 7. Schematic diagram of the manual model alignment.

After the user performing the pre-positioning enters the room, the system will automatically locate the room where the operator is located, and the room model will be downloaded into the system. After the download is finished, the overall room model will be placed into a point cloud map as a far spot that is invisible to the naked eye. The initial coordinates for this far spot is (10000, 10000, 10000), and for the angle, to avoid the problem of not being able to rotate normally because of gimbal lock, the angle is computed using quaternions with an initial value of (0, 0, 0, 0). When the operator completes the fitting of a single component, the system will calculate record the relative offset of components for the entire room according to the offset of the fitted component. As shown in Figure 8, room model distance before rotating ΔQ is not equivalent to the sub-component distance. After rotating ΔQ, where ΔQ represents relative rotation angle between two components, room model distance is equivalent to the sub-component distance, as shown in Figure 9. The overlaid views in the proposed AR system are shown in Figure 10.

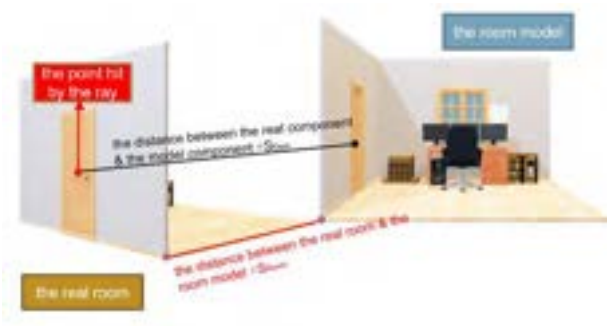

Figure 8. Room model distance before rotating $\Delta \boldsymbol{Q}$ is not equivalent to the sub-component distance.

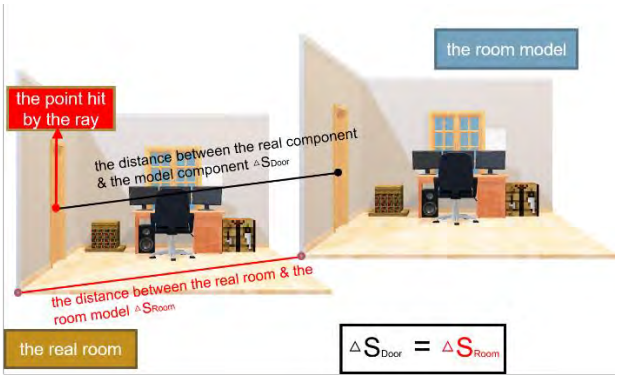

Figure 9. Room model distance after rotating ΔQ is equivalent to the sub-component distance.

Figure 10. The overlaid views in the proposed AR system.

3.4 HBase database configuration

This study assumes that the system application scope is quite large. In practical applications, the dataset may be very large. The designed system adopts Apache HBase, a non-relational database, as a data storage tool, which can allow multiple users to quickly obtain the stored data. The data storage structure is configured according to the system specifications shown in Figure 11.

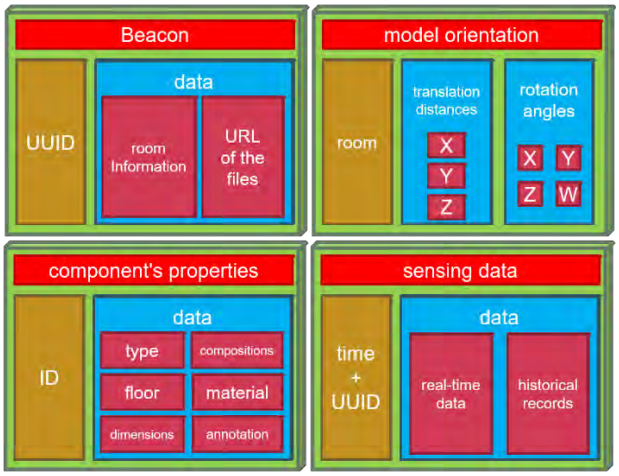

Figure 11. Beacon device data sheet configuration (upper left), model position data sheet configuration (upper right), component information data sheet configuration (lower left), and sensor data sheet configuration (lower right).

3.5 Auxiliary tool mechanism

The AR virtualization for the sensors is similar to presenting the BIM model generally. The sensor models must be first designed and built, as shown in Figure 12. The representative meaning of the models can be intuitively understood by the user.

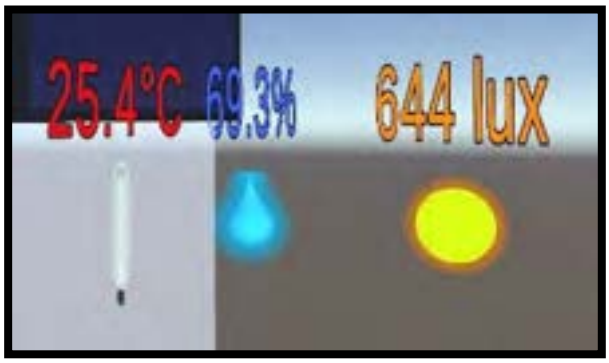

Figure 12. Real-time AR presentation of the sensor measurement data.

When the user taps the model, the system shows the historical data, as shown in Figure 13. To check for abnormal temperatures, the date can be selected. Vertical axis of the chart is the temperature with unit of ℃; horizontal axis is the hours with a range of 0-23.

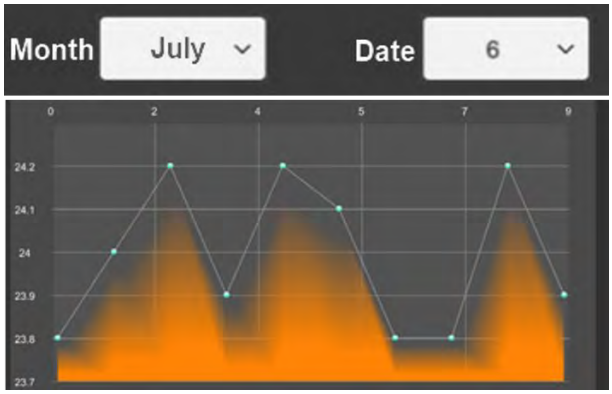

Figure 13. Sensor chart and selection list example.

Users can find a navigation map from the map navigation icon at the lower right of the display. The red sphere is the user's location, which helps the user to understand their current location. After the system locates the room, the system will download the model of the floor from the server and place it on the mini map user interface (UI) layer for viewing. After the room model is completely fitted through the point cloud map, the system will know its relative position between the model and the device. The red sphere is placed on the relative position of the device inside the floor model, and a mini map camera is set directly above the sphere to illuminate the position of the red sphere as an orthographic projection, forming a two-dimensional planar map as shown in Figure 14.

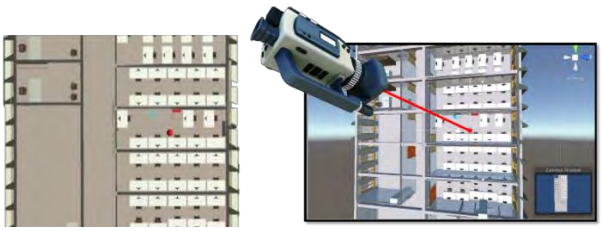

Figure 14. Schematic diagrams of the mini map UI and the orthographic projection mechanism.

4 Verification of system effectiveness

4.1 Effectiveness of program execution

Taking the overall model of the Second Engineering Building as an example, a comparison is conducted on the AR presentations for the unsegmented model and the model placed on the server side after segmentation. The influence of the rendering model on overall system effectiveness is considered, with Xcode Monitor used for monitoring.

iPhone XR is a handheld device with mostly high-end specifications among handheld devices in the current market. The graphics processing has excellent performance in more areas. According to a comparison of the results, the memory usage of the model-processed version is approximately 26.83% of the original model. Using the frame rate to reflect the graphics processing power of the handheld device, the model-processed version reached 205% of the original frame rate, with 60 frames per second (fps) being the current standard of high-resolution TV. Model segmentation is still necessary for the hardware equipment specifications on current handheld devices.

4.2 BLE room positioning verification

For the verifying the indoor positioning of this system, two Beacon devices continuously emitting Bluetooth signals were placed in two adjacent rooms, with the Beacon devices separated by a wooden wall. Enabling the Beacon devices to interact with each other verifies whether the positioned room can be located under the situation where there is mutual interference. Positioning was conducted at the furthest and nearest spots from the Beacon devices in the two rooms and the nearest and furthest positioning results within the same room to calculate the success rate of the positioning. From several tests, an approximate accuracy of 100% accuracy can be obtained.

4.3 Model fitting accuracy

This study conducted a model fitting accuracy test in an office room of the E2 building at Taiwan Tech. The center of a door in the room was taken as the reference point for accuracy measurement. The way to measure fitting accuracy is as follows. Figure 15(a) shows an actual door, with a reference point set at the center of the door. A reference point is also set at the center of the virtual door model. Using the AR pre-processing system for model fitting, shown in Figure 15(b), the reference point has an offset of D1. By comparing the offset of D1 obtained from the observed door at the same actual position, the degree of fitness is calculated in a quantitative approach. The system offsets were measured at two observation points. The first point was at a distance of 109 cm perpendicularly from the reference point of the target component, and the second point was at a distance of 252 cm from the reference point of the target component in the direction of a 60 degrees offset.

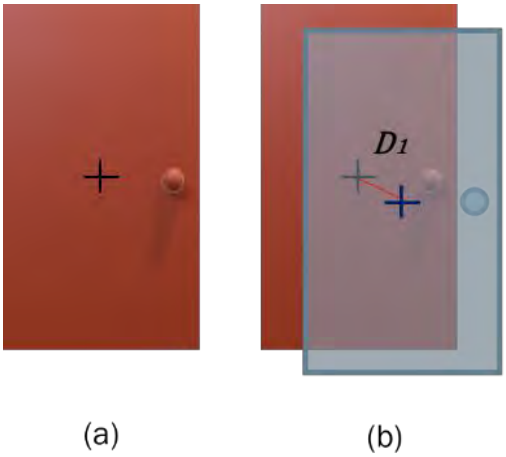

Figure 15. Schematic diagrams of the fitting, with the center of the door taken as the reference points (a) Actual door, (b) fitting of the AR pre-processing system model door.

An average offset can be determined from the statistical results shown in Table 1. The fitting accuracy of the new system can reach errors on the order of millimeters in a single room, with the degree of fitting being more accurate. This degree of errors is acceptable for application at the maintenance stage.

Table 1. Average offset results.

Offset angle	Average offset of x (cm)	Average offset of y (cm)	Normalization of x	Normalization of y
0°	0.0353	0.1623	0.0395%	0.1819%
60°	0.1693	0.2258	0.1898%	0.2531%

5 Conclusions

This study proposes an Augmented Reality system based on SLAM for a marker-less system, and develops a set of AR pre-processing and AR presentation systems to enhance the integration stability of virtual and actual worlds. Moreover, the BIM model and the on-site environment are combined, so that information can be presented to the user on a same interface, information is automatically transmitted to the user, and the complexity of the human-machine interface is reduced, thereby resolving the inconvenience of BIM model on-site operation as mentioned in the study motivation.

Furthermore, in the indoor positioning based on BLE, using a more stable approach than previous research for locating a user's positioned space and loading the room point cloud map and room model based on the positioned room, the subsequent development of AR pre-positioning system and AR presentation system were based on this foundation, thereby reducing system operation complexity. Using rooms to segment the model and point cloud map, pre-storing files in a remote server, and using the database to store the file links and room effectively reduces the system usage space and memory usage during program execution and reduce graphics processing load, thus improving system effectiveness. This framework is taken to propose an augmented reality BIM fitting system that is stable and applicable to a wide range of spaces.

Finally, the designed system uses a Raspberry Pi as the central coordinator. After obtaining all the sensing data, the data is uniformly processed through a regularized program, and then the numerical data is transmitted through the Internet and stored in a database. The integrated application of sensors in augmented reality proactively presents environmental information to the user.

Review of Construction Workspace Definition and Case Studies

K. F. Lai and Y. C. Chan

Department of Civil Engineering, National Taiwan University, Taiwan
E-mail: r08521714@ntu.edu.tw, ychan@ntu.edu.tw

Abstract -

Workspaces in a construction project are considered as critical and limited resources. Since the workspace conflicts cause productivity loss and poor quality, construction researchers have been exploring different workspace definitions and solutions to improve the situations. Construction workspace' function can be classified according to the user's needs and characteristics of activities and can be integrated into 4D BIM simulation. In previous studies, researchers have proposed several different and innovative workspace definition. However, researchers usually only tested their proposed workspace definitions on specific building projects or few particular tasks. It is difficult to tell the effectiveness of the workspace definition when applying to a different construction project or case involving different construction methods. Relevant works of literature regarding construction workspace definitions were collected and discussed in this article to obtain a comprehensive review on this topic. We have applied the proposed definition to the same construction case and also provided an evaluation of their approaches' pros and cons. Then we proposed a criterion of developing proper workspace, so the workspace requirement can be planned based on the project's characteristics and could help the project managers to select the optimum scenario during workspace planning.

Workspace Conflict; Workspace Classification; Conflict Solution; 4D BIM; Conflict Severity

1 Introduction

Various subcontractors have to finish working activities in a space-limited construction site. Each activity requires a certain amount of workspace for workers, equipment areas, etc. Workspace conflicts between activities could result in schedule delays and poor quality. Since there is a rising demand for complicated construction works in the municipal area, the need for a proper construction site layout is crucial to eliminate workspace conflict.

However, it is challenging for the project managers to eliminate the interference caused by workspace conflicts among activities because traditional 2D drawings are not enough to indicate dynamic changes and enough information of equipment's and labors in the construction site.

Therefore, many researchers took efforts to develop techniques such as building information modeling (BIM). The 4D BIM models with schedule management in recent years has been broadly utilized among buildings' life cycle. Researchers also tried to strengthen the techniques of workspace conflict analysis and tried to find better solutions. The studies in the past 20 years covered methods of how to identify the workspace requirement of each activity, how to develop and detect workspace conflict, how to solve the problem before the construction phase starts, and how to simulate dynamic workspace conflict due to dynamic changes.

Since theories of workspace conflict analysis have been evolved for more than 20 years, definitions of workspace has been very different in different studies. While each of these theories of workspace definition can explain some aspects of construction projects, none can successfully be applied to all instances of construction projects. Rather than pursue this further by finding the best definition for all construction projects, we will explore a criterion to select proper definition for workspace conflict analysis by studying and summarizing previous studies from a detailed review covering the different workspace definitions.

2 Literature Review

In this study, we collected previous studies regarding workspace conflict analysis from 2002 to 2018. Table 1 shows a summary of the most important publications in this field and the different factors focusing on by researchers. We will discuss each factor in detail in the following session.

Table 1. Comparison of Previous Workspace Conflict Studies

2.1 Workspace Definitions

Workspace definitions are broadly discussed and classified by researchers. Thabet and Beliveau [1] have classified the space into two groups, one is man and equipment, and the other is materials. These two groups are classified according to whether the size of space will be constant or decreased by time. This classification will help to provide the evaluation of the activity's space demand by the sum of quantities from each factors' physical needs and surroundings' needs.

Akinci, Fischer [2] classified construction activities into three categories based on reference object, orientation, and parameters. The categories included macrolevel, microlevel, and paths. Macrolevel spaces referred to huge-scale, such as storage or prefabrication areas. Microlevel spaces were mostly related to building components, and paths were required for transportation. Guo [3] has classified the spaces based on different four users: labor, equipment, materials, temporary facility. Considering whether the space is available for work or not, the space needed for each user could also be defined by space type as the exterior of the job site, the interior of the job site, inside the structure, and space provided by a temporary structure.

Choi, Lee [4] separated the workspace layout by its function or movability. When by function, it includes direct workspace (object space, working space, and storage space); indirect workspace includes set up space, path space, and unavailable space. When workspace defined by movability, it can be separated into fixed workspaces and flexible workspaces**.** The purpose of classification by function is to stand for total workspace definition without missing; moreover, classification by movability is to supply a resolution of workspace conflict after it has been identified.

To deal with dynamic nature in construction sites, Su and Cai [5] proposed two ways of defining workspace: 1) workspace directly created by users, and 2) workspace created based on geometric shapes such as column, sphere, tetrahedron or hexahedron. The latter is based on the simulation of labor workspace or tower crane workspace and provides users to derive workspace with two functions: offset and rotate.

However, the construction layout may be changed by schedule. Dynamic changes based on time flow in a construction site also need to be considered in the use of workspace[2, 6, 7].

Tommelein and Zouein [6] tried to connect the construction layout plan and project schedule plan, which consider the dynamic changes of location and activities in the construction site. Kassem, Dawood [8] suggested providing the definition based on whether the physical change on the construction site was added or not in 4D BIM model. They also defined the object workspace, which represented building elements, and safety workspace that is tolerance between two workspaces, or the distance which objects may fall from height.

Mirzaei, Nasirzadeh [9] defined the varied nature of activities, considering space should be static when the labor crew occupies a place thoroughly during the whole activity duration. Dynamic workspace, on the other hand, represents that the labor crew will move their space during each time interval.

Table 2 shows the collection of workspace definitions from previous studies.

Table 2. Summary of Workspace Definitions

	Sphere	
	Tetrahedron	
By physical change or not	Main Workspace	[8]
	Support Workspace	
By building elements	Object Workspace	
By safety distance	Safety Workspace	
By position changed of labor crew	Dynamic Workspace	[9]
	Static Workspace	

Since there is a variety of workspaces definition, it is crucial to set a flow chart for construction site layout that is useful for specific needs. In the following paragraphs, we will discuss three workspace characteristics proposed by Akinci, Fischer [2], which are generality, reusability, and comprehensiveness.

Generality means we can apply for various workspace requirement, especially for spaces which are related to building components, such as equipment and crews. However, storage areas for materials are also important that should not be ignored. Since some materials are temporary and are waiting to be installed in buildings, but some materials will be left for owners as a backup in the maintenance stage, it is important to set a clear layout easy to separate temporary and permanent materials.

Reusability means construction activity is repeatable or can be done by the same equipment no matter what locations or sizes they have. Usually, Since the construction methods depend on the location and some specific constraints, there will not 100% the same in each location. For example, if there is a window at 20 floors high rise building, but the space beneath the window is not large enough to locate a crane , then the construction method had to changed based on constraints. However, it is too hard to expect what will happen during construction. So, it will be suitable for site managers to follow the most common construction methods for construction.

Comprehensiveness is about the details when it comes to describing the construction methods. The orientation and the volume (length, width, height) of a required workspace should be seen or modified. Each equipment would have its maximum range of workspace. For example, the crane's range can be calculated by the radius chart.

As we've mentioned, these 3 factors are crucial to represent a construction site. In addition, we still notice that it is hard to define the best layout for the construction site, but we can discuss this problem consider the scale.

The case in Guo's research is a 12-story reinforced concrete, and the case in Akinci's research is about the installation of windows in a wall. Since 12-story reinforced concrete is a huge project, so he first classified by major activities survey, reinforced steel, plumb…etc.), then each major activity requires 4 main categories (labor, equipment, materials and set-up space). However, a small construction site is no needed for such a detailed workspace definition. On the other hand, if the layout classification is too simple, some places could be neglected and may become a potential problem. So, it is much proper to define the scope of a construction site in a simpler way first, then give a more detailed classification if necessary.

2.2 Virtual Spatial Collisions

After the workspace definition is decided, workspace for each activity is created for spatial collisions.

According to a 3D bounding volume, three types of space collision detection algorithm can be used in a 3D model, which are bounding spheres (BS), axis-aligned bounding boxes (AABB), and oriented bounding boxes (OBB). The method of bounding spheres is to detect the collision by detecting the sum of two bounding sphere's radius and also the distance between the center of two spheres [10]. Oriented bounding boxes were introduced by Möller and Haines [11], which created minimum bounding boxes around objects without considering the object's axis, and the existence of another axis identified the collision. Axis-aligned bounding boxes need to determine the minimum and maximum coordinate values of the two bounding boxes, which are parallel to their coordinate axes. Figure 1 illustrates three types of collision detection described above.

	Diagram	Collision Condition
Bounding Sphere		L<R1+R2
Axis-Aligned Bounding Box		L < X1+X2
Oriented Bounding Box		$\|L \cdot v\| < \|b1 \cdot v + b2 \cdot v\|$

Figure 1. Collision conditions

When it comes to the application, axis-aligned bounding boxes (AABB) are used most common on building objects such as beams and columns, most of their shapes are rectangular cuboid. Bounding spheres (BS) methods for workspace conflicts are suitable when there are multiple crane works. But these methods can be combined for specific cases, too. In the installation process of prefabricated steel beams working area, crane work may also affect the installation of the bolt works.

2.3 Moveable Objects

Since the construction site is dynamically changed with schedule, it is critical to detect the resource movement. Previous studies usually assumed that the laborers occupied the whole workspace throughout its duration. However, labors only occupy a part of the needed workspace and change their location all the time. The dynamics of activities should be investigated, and also the patterns of where they start, execute, and end. Few studies have addressed the significance of the activities transition in a required workspace. Mallasi [12] developed 12 execution patterns. Choi, Lee [4] presented the concept of unrealistic workspace problems in Figure 2 which may exist in two activities.

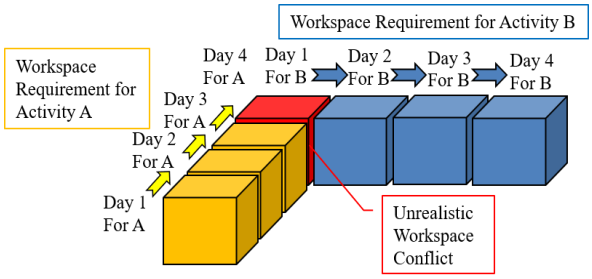

Figure 2. Unrealistic workspace problem modified [4]

The most significant assumption about the construction layout is static. But dynamic changes of the workspace by schedule are also essential when the activities can not be done in a day. If the construction site can be divided into different small spaces, then it will be crucial. This will help when your activity has overlapped other nearby activities' workspace. If both conflict activities can not change each sequence or schedule, then it will be easier to adjust the working sequence and to avoid unrealistic problems.

2.4 Index of Conflict Severity:

The measurements of workspace-conflict need to be qualitative and quantitative.Akinci, Fischen [13] suggested a conflict ratio, which is the ratio between the conflict volume and the required space volume. Guo [3] used the interference space percentage (ISP) and the interference duration percentage (IDP) as two indicators. One is the ratio between the interference space size and the activity's original size, and the other is the ratio between the interference duration and the activity's original duration. Mallasi [12] created a five-criteria quantification index to identify the conflicts. Kassem, Dawood [8] took the congestion severity (CgS %) as the ratio of the sum of the required space and the available space.

The concept of conflict severity can be assessed. However, this indicator cannot quantify the impact of conflicts on project performance. Mirzaei, Nasirzadeh [9] define a new approach to calculate the conflict severity by the labor congestion and conflict space size

Figure 3 shows the different definitions of the conflict severity index.

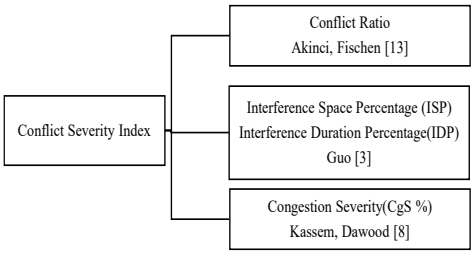

Figure 3. Conflict severity index

In previous studies, several solutions have been derived, but the relationship between the conflict severity and resolution need to be discussed. The goal of conflict severity is to help managers decide the best solution. However, a single number can not reflect the total situation in each study, which may cause the manager hard to decide the best solution. Although in Guo [3] study, ISP and IDP can be calculated and criteria for resolving space conflict are suggested, but there is little discussion on the relationships between these two indicators.

Some studies have suggested congestion as another conflict severity, which is the ratio between the available workspace per person and the minimum workspace required per person.

2.5 Solution For Workspace Conflict

The solution of workspace conflict is crucial since it could help the project managers to raise the working efficiency. Guo [3] not only suggested to change the logical sequence, location, or starting time for conflicting activities to avoid problems but also suggested to recheck the path demand after changing. In a study from Choi, Lee [4], they proposed to change the location of flexible workspace or consider both the schedule plan for critical and non-critical activities. Kassem, Dawood [8]

suggested 2 solutions, first is changing and adjusting the schedule, second is changing and adjusting the physical location and size of workspace.

3 Discussion

The aim of this research was to review previous studies on workspace definitions and conflicts resolutions. Some other factors should be considered and further discussed since there would be some relations between workspace definitions and other factors when conducting conflict analysis.

3.1 4D BIM Applications

Compare to 2D drawing, 4D BIM provides diverse information and visual environment, which can help managers to arrange a proper workspace in the 4D model on a whole scale of the construction site. Most of the previous researches had considered using BIM application programming interface (API) for workspace planning, and this study might help technologists and project managers to follow a criterion for workspace planning by applying BIM API.

3.2 Case studies

Each previous research will choose a case study as their theory's implementation. Now we select the case study in Automated Generation of WorkSpaces Required by Construction Activities by Akinci, Fischer [14], which is about using scissor lift for windows installation.

Figure 4 shows the background of this project. We applied and compared several workspace definitions in the following paragraphs.

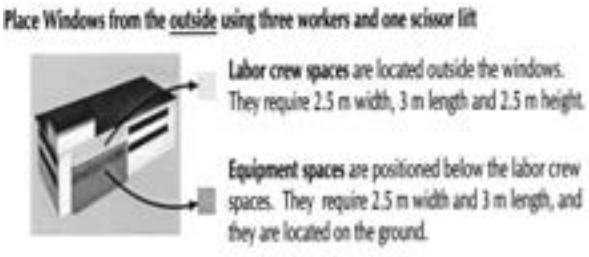

Figure 4. Windows Installation Information [14]

- By scale : This advantage is that we can have a rough range of space sizes for workspace management. Project managers can focus on microlevel spaces, which are the components (windows), equipment(scissor lift), and labors. Its definition seems a little hard and vague to classify whether the items should belong to the macrolevel or microlevel.
- By location: This classification consider whether its the space is exterior or interior of structure/jobsite. However, this does not necessarily needed for a small project since the working and storage area are easy to arrange. It will help if the project's scale is big and the time is long enough so that managers can control all the items in detail.
- By function: The advantage of this definition is that this will help the managers focus more on whether the condition for each workspace is prepared or not to function, rather than to use location or size level as classification.
- By movability: The disadvantage is that this classification may not be so necessary for a small construction project.
- By position changed of labor crew:This can show a dynamic motion for labor workspace by schedule. The feature of this classification is that if the works can not be done in a day, managers can easily understand the work sequence in the schedule. However, if there is no conflict with other activities workspace, then this works sequence seems a little unnecessary.

In this case, we can form up a guideline for planing a proper workspace layout for different kinds of construction sites. Figure 5 shows the workspaces planning into four levels:

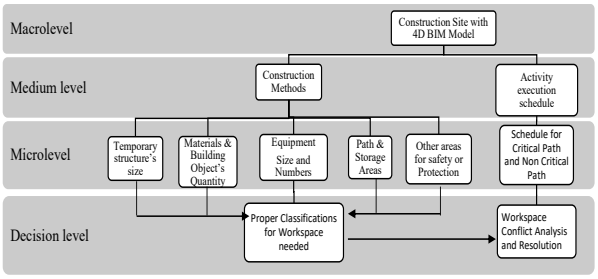

Figure 5. Workspace layout planning flow chart

Macro-level is about choosing types of construction sites, which may be buildings, factories, roads, or other related constructions. The medium level begins to select the construction methods for each activity. Microlevel would let the project manager select necessary and detailed elements to create a proper workspace layout planning in the decision level.

4 Conclusion

This study reviewed the previous research of workspace definitions and conflict resolution. From the literature review, there are different types of workspace

definitions based on several aspects. We also investigate these theories and apply them to a case study. The discussion showed some results that include the pros and cons of whether these factors are necessary for workspace planning. There is no standard answer for classification since each project is unique, a workspace planning flow chart can be helpful to establish a workspace layout with construction methods and quantities of each activities.A proper workspace classification still relies on the degree of understanding among project managers.

However, our study ignores the time-schedule factor, which is a limitation that may somehow affect the result of classification. Future work can focus more on the workspace conflicts of activities in period of time which can discuss a more specific workspace conflict.

Another future research can be further discussed since people can rely more on the development of 4D BIM model. Since BIM model has the function of detecting collision items in design stage, the API developers can improve the function of creating virtual workspace among activities and shows the collisions in the BIM model, and therefore the criterion of workspace layout classification will be more usable for managers to solve the workspace conflict problem.

Abstract –

Construction activities require materials or resources to be arranged while planning the route of how these materials or resources can be transported is not a simple process. Traditionally, subcontractors will arrange a daily meeting and negotiate the desired space on site for the next day's resource transporting. However, many of them only use 2D drawings or aerial images while discussing the routes which lack an accurate calculation on space conflicts. In this paper, an approach combining Building Information Modelling (BIM) and Graph Database (GraphDB) is proposed. With the help from 3D BIM models, the coordinates of resource transporting routes can be first extracted and further analysed by the proposed approach. From the result, the collisions along the planning routes can be detected to assist in making a proper transporting plan. In addition, a web-based platform is developed for validation of this approach. Because the platform is a shared one, each user can arbitrarily plot their desired transporting routes in the model at any time. As long as the actual transporting schedule is known for the corresponding route, the platform can dynamically and instantly inspect whether the desired routes will collide with others. In this way, we can eliminate conflicts prior to the start of those activities and potential delay in the construction process can be reduced.

Building Information Modelling; Construction Conflicts; Construction Management; Separating Axis Theorem; Graph Database

1 Introduction

Construction is a complex process which requires a proper plan prior to its commencement. A proper construction plan can assure the owner of the construction's quality and punctuality while a poor plan can not only cause time overrun but also induce a waste of investment. In an attempt to make a decent plan, several issues should be addressed first, including resource shortage, labour shortage, workspace conflicts, and activity sequence conflicts. With the advent of Building Information Modelling (BIM) and other 3D digitalisation technologies, workspace conflicts and other geometric-related issues can be detected and mitigated. For example, Moon et al. [1] demonstrated that using an algorithm along with the model bounding box concept can assist in determining the adjacency distance between two conflict points. With the information as to where the conflict occurs and the percentage of conflict between two workspaces, the conflicts can be handled and reduced in advance. Similarly, Wu et al. [2] used 4D simulations and colour visualisation techniques on the BIM model to detect space conflict while the required workspace for activity was categorised into five types. In addition, some recent research concerned that the movement of workers could potentially raise workspace conflicts. Therefore, Mirzaei et al. [3] defined 16 execution alternatives for workers' movement patterns and developed a quantification system for calculating the workspace conflict impact level on the project through 4D BIM simulations.

As plenty of research is already concentrating on workspace management, another group of research is focusing on construction materials management. For example, Said and El-Rayes [4] presented an optimised model for making critical decisions on construction logistics while considering both material procurement and material storage on construction sites. Golkhoo and Moselhi [5] proposed a multi-layer perceptron approach to create an optimised material delivery schedule. This schedule enabled contractors to not only procure construction materials with minimum expenditure but also avoid shortage or surplus issues. Although the aforementioned research has helped materials be managed properly on site, little research is concentrating on how the materials can be transported safely from the staging area to the activity execution area in a construction site. Unlike the workspace for each activity which can be defined earlier within the construction plan, material transporting routes are normally assigned by the day before the corresponding activity executes. Furthermore, the transporting routes are not determined

by only one person such as the project manager. Instead, the routes are selected by different subcontractors who are in charge of those activities. In this case, a process is required for enabling users to dynamically assign their routes and automatically detect the route collisions. In addition, a shared platform for multiple users to coordinate their route collision detection is desired.

In this paper, an approach integrating BIM, Separating Axis Theorem (SAT) and Graph Database (GraphDB) is proposed for automatic route collision detection. SAT supports the detection as to whether two objects collide. GraphDB offers an efficient way of storing and extracting the assigned route data and the relationships among activities, materials and routes. BIM serves a visualisation platform and provides data related to the facilities under construction. With the development of a web-based BIM model viewer, all subcontractors are allowed to assign their desired transporting routes by drawing them directly in the BIM model. The viewer will automatically calculate and check whether the newly assigned route collides with the existing routes created by the previous users. In this way, the subcontractors will be able to plan their material transporting routes without requiring that all subcontractors be gathered in the same physical space. As long as they have access to the Internet, they can have discussions about route planning on the proposed platform with automatic route collision detection supported.

2 Methods for Route Conflict Detection

To develop an approach for assessing route conflict, the core algorithm for examining the collisions of objects needs to be proposed first. In this research, SAT is selected to achieve this. On the other hand, how to efficiently and accurately store and extract the route and collision data is another crucial part. Therefore, a graph database is adopted to enhance the efficiency of using the collected data.

2.1 Separating Axis Theorem

SAT is aiming at detecting collisions of two objects by examining if any separating line or plane exists between the objects [6]. The theorem can be applied to both 2D and 3D objects. It says if two 2D objects do not collide with each other, there must be at least one line which can separate the two objects without any intersections (Figure 1). That line is called a separating line. Equivalently, 3D objects can be deemed as not colliding by finding at least one separating plane to separate them from overlapping (Figure 1). As implied, there can be more than one separating line or plane for two separate objects. For example, those dashed lines in 2D object illustration shown in Figure 1 are also separating lines. However, finding all of them is not our intention. Efficiently identifying one existing separating line or plane is sufficient to say that two objects are not colliding. Therefore, SAT allows for a rule-based algorithm to significantly narrow down the necessary lines or planes for checking. The algorithm proposes 4 and 15 equations, respectively, for checking whether the 2D and 3D objects are colliding with each other. Each equation represents an examination of one possible separating line or plane. If any of the equations is fulfilled, that means the corresponding line or plane succeeds in separating the two objects and the two objects are proved to be not colliding. In other words, if all of the equations cannot be fulfilled, the objects are proved to be colliding with each other. This strategy saves us a significant amount of time because only 4 lines or 15 planes need to be checked for every collision examination. There exists numerous possible lines or planes to separate two objects whereas this algorithm allows us to inspect just a few lines or planes to guarantee an accurate result as to whether the two objects are colliding or not. For details about the equations, please refer to the tutorial document by Johnny Huynh [6].

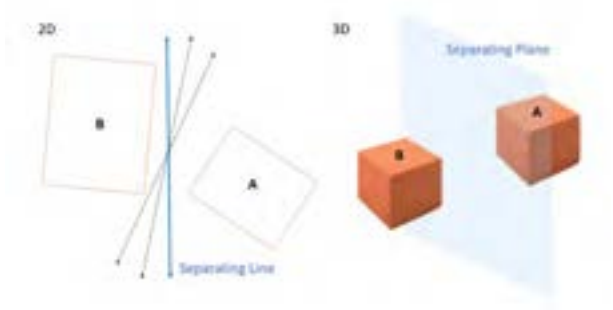

Figure 1. Separating axis theorem illustration

In this research, 3D object collision examination from SAT is applied. A material transporting route is approximately represented by a set of cuboids as shown in Figure 2. In other words, each route can be checked whether they are colliding with other routes simply by examining whether any cuboid in the set of targeting routes is colliding with another route's set of cuboids. For ease of generating a set of cuboids, a central curve of the route should be given first. After that, the curve is further segmented into a list of lines. This is a way of simplifying the curve representation and the point density value can be either specified by the computers automatically or assigned by the users based on their own preference. As the curve is already transformed into a list of segmented lines, determining the width and height of each segment is crucial since the ultimate goal is to transform them into a set of cuboids. Therefore, the width and height of the object using this route can be taken into consideration. For example, assume that the route is assigned for some heavy vehicles to drive through, then the width and

height of the vehicle should be taken into calculation in the collision examination. To achieve this, the segmented lines are horizontally expanded by half of the vehicle width on both sides to represent the total width needed while the vehicle is taking this route. Likewise, the curve is also expanded vertically by the vehicle height to provide the height for the vehicle to pass. In this case, with the segment length already determined in segmenting the curve, a cuboid for every segment can be generated as shown in Figure 2. While each route is transformed into this form of representation, SAT can be applied for checking whether the created routes are colliding with one another.

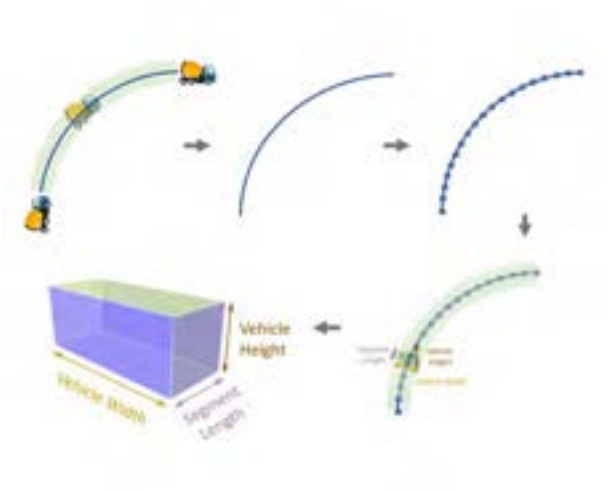

Figure 2. A demonstration of how a route is generated for applying SAT

2.2 Graph Database

Graph database is a database which uses graph as the main structure of storing and querying data [7]. While a graph is generally formed by nodes and edges, it has a greater ability of revealing and explaining complicated relationships among all data. This relatively new concept or technology can be applied to various fields. For example, Sadowski and Rathle [8] proposed using a graph database for finding common patterns from three of the most damaging types of fraud. Cattuto et al. [9] presented a time varying graph database structure for efficiently querying the social network formed with high-resolution records of human activities extracted from mobile devices and sensors. In the field of construction or BIM, Ismail et al. [10] suggested that the 3D IFC models should be automatically transformed into the graph database structure which enables users to manage and analyse the huge amount of building data and complicated relationships. The application of the graph database depends on how to define and manage the nodes and edges.

In this research, three types of nodes are specified, including material, activity and route, which are assigned in green, yellow and blue colour, respectively (Figure 3). Prior to the collision examination, where the route starts and where it ends should be defined first. In this research, it is intended to detect whether a collision may happen while a material is transported from the staging area to the activity area. Therefore, the route's start node is assigned as the staging area and the route's end node is deemed as the activity area likewise. Both nodes encompass the coordinate information of the corresponding area. After the start and end nodes are determined, the route's intermediate nodes are specified by users' drawing of needed transporting routes in the BIM model. As mentioned before, the drawn curve is first interpreted by a list of points and segmented lines. Each point's coordinates are stored in each intermediate node. Furthermore, while the next step is to expand the segmented lines and transform them into a set of segmented cuboids, the information of each cuboid, including width, length, height, can also be stored in the edge (path relationship) between each pair of two adjacent nodes. In this way, each chain in the database can indicate a route for examination and it already contains sufficient information for SAT collision detection including the dimension of each cuboid and its coordinates. Two example chains are illustrated in Figure 3.

After the route data are stored in the database, having them efficiently extracted for SAT examination is another critical part. Taking advantage of the structure of graph database, we can read the cuboid data with just a few lines of code, for example:

```
MATCH (m{name: "<material name>"})-
[rs*]-(a{name: "<activity name>"})
RETURN rs
```

In the above code, m and a are representing the material and activity nodes respectively. Rs* indicates all the relationships along the path from node m to node a. When "return rs" is called at the very end of the code, all the relationships are extracted and returned from the database. In addition, by taking the cuboid coordinates and dimension properties from the relationships (edges), 15 equations can be applied to each pair of cuboids to check whether they are colliding with each other. If any two cuboids are colliding; for example, the two relationships highlighted in pale red in Figure 3 are colliding, then the start nodes of the two relationships will be linked together by an extra relationship called conflict. This relationship is used as an indicator of collision between the two routes to help users identifying all the colliding routes by a few lines of code:

```
MATCH(a1:ACTIVITY)-[:PATH*]-()-
```

```
[rs:CONFLICT]-()-[:PATH*]-
(a2:ACTIVITY) RETURN a1,a2
```

In this graph structure, each pair of colliding routes can be detected. The code mentioned above is basically traversing the graph from one activity node to another and finding paired activities with a conflict relationship as a part of the path. For example in Figure 4, if activity 1 (a1) is able to reach activity 2 (a2) in the graph, the path must contain the conflict relationship because any route chain is independent of others in the very beginning until an extra conflict relationship is established. Therefore, by using this approach, users like subcontractors can make a better material transporting plan by detecting any conflicts in advance.

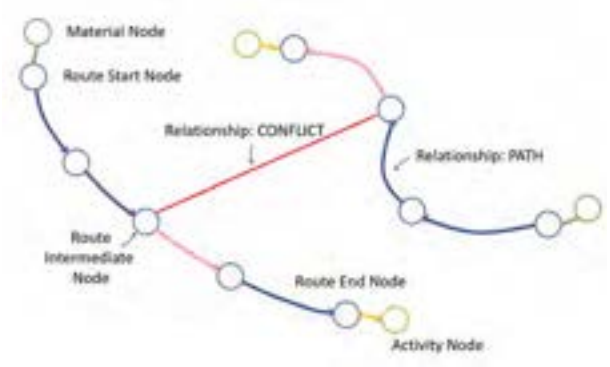

Figure 3. The structure of route data stored in graph database

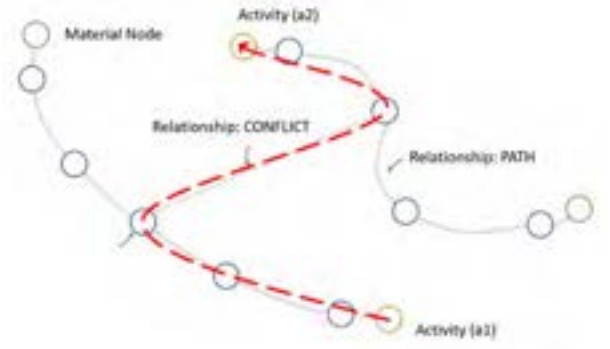

Figure 4. Example for finding colliding routes by traversing the graph

3 Web-based Collaborative Platform

In this research, a web-based collaborative platform is developed for detecting the occurrence of route collisions and making a better material transporting plan. Therefore, a Javascript library called React.js is selected to be the main language for building the whole website. For styling-related works, Bootstrap is adopted by virtue of its convenience. Furthermore, a BIM model viewer should also be provided for reference while users are drawing their material transporting routes. Therefore, a web-based BIM model viewer called Autodesk Forge is employed. The whole viewer is based on another Javascript library called Three.js which is mainly responsible for 3D objects' rendering. For the users' drawn routes, Three.js also helps in displaying them on the 3D models. Regarding backend, Node.js is chosen as the main language handling server-side requests and responses. It is also used for connecting with the graph database management system called Neo4j which assists in creating a database instance and managing the behaviour of the database. The frontend and backend architecture of the platform from the language perspective is shown in Figure 5.

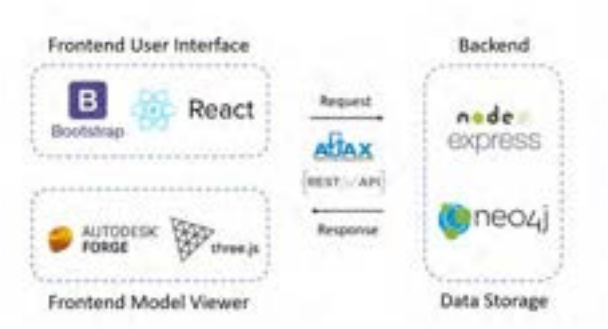

Figure 5. Frontend and backend architecture from the language perspective

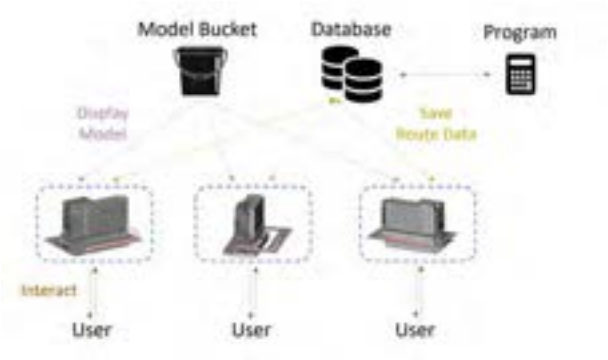

Figure 6. Data flow architecture for the web-based platform

The data flow for the platform (Figure 6) can be split into two parts. The first part concerns 3D BIM models and non-geometric data related to them. For the use of Autodesk Forge, models need to be uploaded to the buckets created in Autodesk server. When models are already in buckets, they can be displayed on any web pages as long as that page contains the configured Forge model viewer. The other part concerns the data related to material, activity and route. As mentioned before, material and activity nodes should be created first with their own coordinates. Those data are stored in the graph database instance as nodes. With that all done, users are

allowed to draw their own material transporting routes and those routes are then transformed into intermediate nodes and links stored in the database. In addition, the moment the route data are stored in the database, the collision examination function written in another javascript program is triggered to check whether there are collisions. If the result is positive, the program automatically creates new conflict relationships between each pair of colliding routes and notifies the frontend Three.js program to display the colliding routes in the 3D model using some conspicuous colours. In this way, users can have clear grasp of which routes are acceptable and which routes need modification.

4 Demonstration

The proposed approach is demonstrated using a prefabricated construction building. In prefabricated construction, most structural components are preliminarily assembled at the manufacturing site. With all processes being completed, the components are further transported to the real construction site for final assembly. Without massive works for on-site grouting, lifting and installing the assembled structures to their designed location can occupy the primary workflow. In this research, the BIM model of the civil engineering research building at National Taiwan University is used. For the purpose of demonstration, the model is filtered and contains only the first floor and the basement. Along the both sides of the building, there are several beams requiring installation for resisting the loading from upper levels. In order to transport the beam from its staging area to the location it was designed, a transporting plan and collision examination should be made first to ensure a smooth process.

The proposed platform is developed to assist in making collision examinations to ensure proper material transporting plans. In the beginning, the platform offers a panel for inputting information including name and execution period of the targeting activity. In addition, the location of the activity should also be assigned by clicking on the 3D model. The program then automatically extracts the coordinates of the clicked point and wraps all the information of the activity into the activity node. Similarly, information such as name and location of a material should be inputted from the platform likewise. Most importantly, relationships between activities and material need to be specified to indicate which material will be used by which activity. With all these prerequisites defined, users can start making the collision examination. By selecting the activity name, the place the activity takes place, the material to be transported and the heavy equipment to use, the system will then be notified about the start point, end point, width and height of the creating route. For easy specification of the equipment, the system has already embedded some crane trucks with its dimension (e.g. HD65 4x2 and HD120 4x2 in Figure 7) for users to select.

From the previous step, the system knows which material and activity the creating route is for. Since the coordinates of the two activities were also defined previously, the start point and destination of the route can be easily displayed in the digital model as the two dark green spheres shown in Figure 8. These actions are for helping users manage the route direction intuitively. After careful consideration, users can draw their own routes as the intermediate points between the start and end green spheres as shown in Figure 8. Once the users finish creating the route and click on the finish button, the data storage process and the collision examination are triggered. If the examination program detects any collision, the colliding routes are displayed with different colours in the BIM model as demonstrated in Figure 9. This collision examination not only detects the geometric overlapping but also takes into account the time period of the routes. Even if the two routes are detected to have geometrical collision, as long as they are not executed at the same time, they would not be considered as having collision by the system. In Figure 9, the system shows that the red and blue routes are colliding on the right side of the building to inform the user to handle the conflict prior to the start of the transporting process.

5 Conclusion

Construction is a complicated process which often involves different kinds of conflicts. In order to mitigate the negative impact the conflicts can make on a project, a construction plan is required for assuring every activity can be smoothly executed. As space conflict is one of the most common conflicts seen in many construction sites, plenty of research has already addressed it. However, research dealing with material transporting conflict is seldom seen although this kind of conflict is still frequently happening and may cause time overrun of a project. In view of this, this research proposes an approach that integrates BIM, SAT and GraphDB for automatically examining potential colliding routes of transporting construction materials. The result from the conflict examination can further assist the managers in modifying some improper material transporting routes. Furthermore, a web-based coordination platform is developed with the proposed approach to help authorised subcontractors view the BIM model and create their own transporting route plans. As long as they input the necessary information regarding the activity, material and equipment in advance, they are allowed to draw their own routes. The system then automatically checks whether a newly created route is colliding with the existing routes previously created by other users. In this way of coordination, subcontractors can make sure their material transporting routes are exempt from having conflicts with others and do not need to plan a meeting in which everyone is usually asked to use 2D drawings for resolving conflicts. This platform offers an accurate and convenient tool to detect the route conflicts and assist in making a better material transporting plan.

Abstract –

The BIM method is perceived as a synonym for the digitalization of the construction industry. The application of this method enables most of all, the consistent and uniform information management and therefore affords a more efficient communication and collaboration environment to all participants in the life cycle of the respective property. Due to the essential role of the building data model within the BIM method, the requirements for modeling at each level must be clarified in detail before modeling. Some companies have internally developed and documented those requirements in their own modeling guidelines. However, small and medium-sized companies often cannot afford the personnel capacity to do likewise.

The development and provision of a standardized guideline for the modeling of building data models by a neutral institution in cooperation with partners from science and economy intends to create a general foundation for the building industry in that manner. The aim of this guideline is to deliver a general framework for the creation of uniform and standardized building models. For this purpose, general regulations, such as the instruction for naming conventions, structure of the project models regarding different planning domains, or more specifically the description of the modeling of individual units, are documented. Within the scope of model elements, the guideline provides the identification in different classification systems as well as the description of the geometric representation along the levels of geometry and a detailed enumeration of the information requirements with the allocation of responsibilities for information delivery and integration for each element. Therefore, the application of this guideline for the modeling of a building data model supplies a clean information management as a basis for a consistent data transfer between different project participants. The application of the BIM Modeling Guideline as part of the exchange information requirements (EIR) is conceivable. Moreover, the provision of this standardized modeling guideline could also serve as a basis for further development within institutions.

Building Information Modeling; Modeling Guideline; Standardization; BIM Model; Level of Geometry; Level of Information

1 State of affairs

A successful and consistent application of the BIM method throughout the entire life cycle of a real estate depends to a large extent on the coordination of the parties involved with regard to the exchange of data and its contents [1]. In addition to the necessary level of detail of the geometric representation and the attributes, this also includes the general organization and structuring of the project as well as the various models to be created. As a result of the prominent role of the building data model when using the BIM method as the lynchpin of information management, it is necessary to create a uniform structure and defined contents for building data models and to set standards for the modeling of building data models in order to create clarity and transparency for all project participants. Such a procedure is usually documented within the framework of a modeling guideline [2].

Research has shown that SMEs in particular do not have the personnel and time capacities to create their own modeling guidelines, whereas many large companies have already started to document their own modeling standards in the form of modeling guidelines, which are continuously updated. The modeling guidelines created in this way are to be regarded as proprietary, as they describe the way of working on the basis of own processes and workflows. Furthermore, the depth of description of modeling guidelines must be considered, since the scope varies in from a pure description of the application of a specific modeling software to a detailed description of the data exchange. The use of external modeling guidelines is therefore not necessarily useful or

feasible. This fact also indicates that there is no company-wide uniform understanding in the German construction industry of the relevant content and the necessary detailing depth of a modeling guideline.

If a company was to develop such a specific modeling guideline, it is still possible that it is not or not sufficiently communicated and coordinated with the project participants. For the successful use of a modeling guideline in a BIM project, it should therefore be agreed upon by all project participants prior to the project start [3].

The development of a standard for the modeling of building data models with the essential specifications and a basis of information requirements on the model element level should serve as a basis for project- and application-specific requirements which should be supplemented if necessary. This basis essentially brings about two changes: On the one hand, not every company would have to think internally about the same or similar BIM goals and the modeling guidelines necessary for implementation. On the other hand, additional work would be reduced by adapting or revising the information structures by project participants when transferring or enriching information. Thus, a standard with regard to the involvement of SMEs and a holistic use of the BIM method over the entire life cycle of a real estate would be advantageous.

2 Development of a standardized BIM Modeling Guideline

Within the scope of the research project "Development of a standardized BIM Modeling Guideline" by the BIM Institute of the University of Wuppertal, the authors, in cooperation with the Technical University of Darmstadt and 17 other partners from the economy, are working on the development of a practical approach to the problems described in Chapter 1. The aim is to create a generally applicable modeling guideline, which defines and describes the basic working methods and specifications as well as the contents and the requirements for the contents of a building information model in a software-neutral way.

The business size of the participating companies in the project vary from large companies to SMEs, which provide planning and construction services at the core of their activities, supplemented by software providers with a focus on BIM content and consulting enterprises. This diversified mix of participating companies allows the identification of a comprehensive cross-section of the current handling of modeling guidelines and modeling in the context of BIM in Germany in general. In addition, the composition of the participating partners enables the consideration of a multitude of perspectives of participants within BIM projects. All companies have already gained experience with the BIM method or are actively implementing it. Figure 1 displays an overview on the respective background of provided modeling guidelines from the project partners.

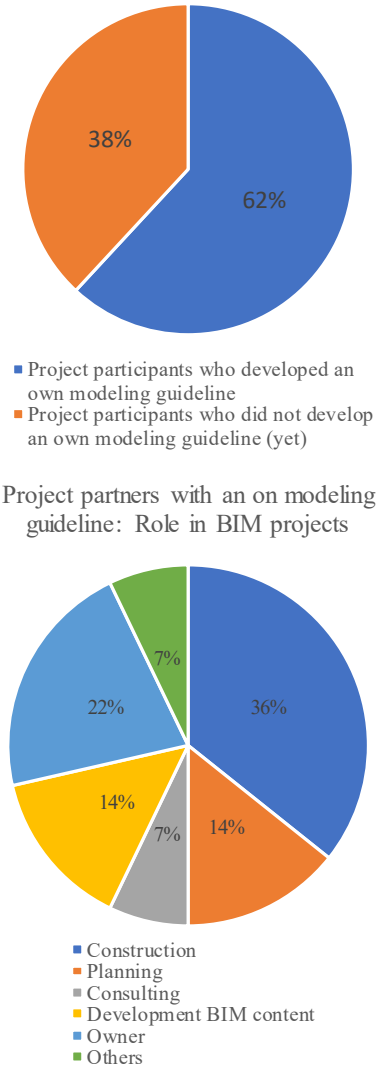

Figure 1. Provided modeling guidelines and their respective background

For the development of the standardized BIM Modeling Guideline, the first step was to analyse the modeling guidelines provided by the project partners, if they have one, and to catalogue content using defined criteria. Some partners, who do not have such a documentation, but implement their own modeling standards, were interviewed for this purpose. The consolidation and analysis of the respective working basis thus provides a view of the best practice currently being lived and implemented within BIM projects and was used as a starting point and working basis for the BIM Modeling Guideline to be created as the project

progressed. The analysis was used to develop an initial definition of the contents and the need for regulation of such a modeling guideline, which was discussed and fixed in an exchange with the project partners: in addition to the description of basic and general principles and specifications for the modeling with the aim of ensuring a clean project and model structure, for example for the coordination of the specialist models of different planning disciplines, content requirements (information requirements) for the building information model to be created are described and additional modeling recommendations are provided. The latter results in a comparison of different working approaches, which can be selected project-specific and according to requirements, for the users, as well as for inexperienced users a simplification of the entry into this complex topic. Considering product neutrality with regard to the use of various modeling applications, the contents are described in such a way that they can always be implemented.

3 Structure of the BIM Modeling Guideline

The BIM Modeling Guideline is divided into a main document and currently into three appendices: the main document of the BIM Modeling Guideline sets a general and descriptive framework around the topic of modeling construction data models using the BIM method. The introductory part of the document describes the motivation and the objectives for the preparation and usage of the document and also clarifies the added value of the application of a (standardized) modeling guideline through cross-institutional standardization of the project and model structure and the model contents. For this purpose, the modeling fundamentals are described with the essential basic principles of model creation, i.e. that the building data model is to be used as the only source for the derivation of plans and documents according to the principle of Single Source of Truth (SSoT), that it is to be modelled according to the actual building process, that the model elements are to be modelled and classified with the appropriate tools and that the data are to be maintained consistently and checked for completeness and correctness before data transfer. In addition to these basic principles, further rules to be considered are listed, such as the handling of model units, schematic representations, labels and regulations, which are particularly necessary for the communication and coordination between non-proprietary authoring systems. These include, naming conventions that must be consistently adhered to for file names, storey definition and the names of model elements and their attributes, or which describe the coordination of the technical implementation of combining different models into one project. Furthermore, the creation of a so-called coordination body is intended to aid bringing together different specialist models to form a central interdisciplinary coordination model, which defines the point of insertion and the reference to the geometric project zero point and serves as the basis for a correct and interdisciplinary quality control. Moreover, modeling specifications on object level for rooms and building elements in general are mentioned, which are especially relevant for a clean geometric mapping and a clean derivation from the geometry, such as that the acidic intersections of the elements or the elements must not be modelled twice. After the description of these modeling definitions follows a list of project-specific aspects to be defined, which have to be agreed upon and documented with all participants before and during the modeling, such as the project structure, the definition of the classification system to be applied or the insertion point.

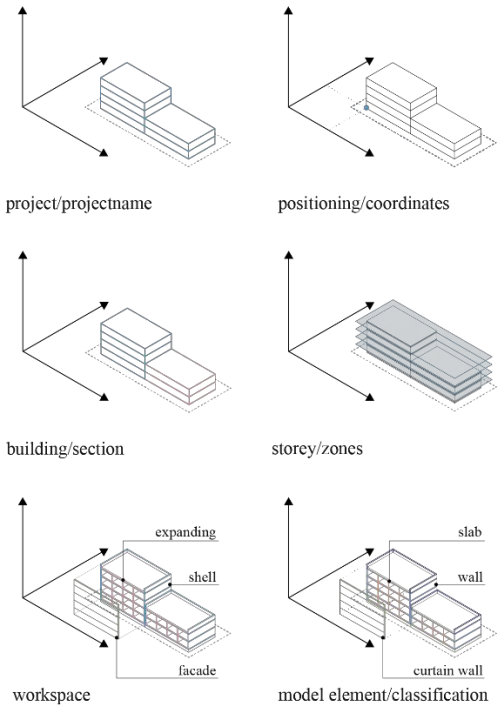

Figure 2. Content of the BIM Modeling Guideline - main document

The main document concludes with some modeling recommendations that have proven themselves in practice, but which are highly dependent on the software and the method (open BIM/closed BIM) and therefore cannot be formulated as a general rule. Topics such as the placement of model elements in the right floors, the extension of vertical and horizontal elements, the handling of multi-layered model elements or baselines are explained and have to be considered.

Appendices 1 and 2 represent user-supporting

documents within the BIM Modeling Guideline: Appendix 1 provides the user with a comprehensive checklist for the definition and documentation of the project organization within a BIM project as an orientation aid. The contents of the main document are divided up and structurally prepared according to the specific topic, so that the project group can implement it quickly and easily.

Appendix 2 takes up the necessary designation system (codification) for models and model elements (beyond the respective classification identifiers) described in the main document and offers detailed suggestions for this. A consistent codification of the model elements as well as of the individual models throughout the entire duration of the project enables, among other things, a simplified and transparent data management [4].

Appendix 3 of the Modeling guideline describes the requirements for the model elements of the architecture, both for the geometric and for the informatic representation. The model elements were catalogued and described in detail depending on the respective workspace: In addition to the respective identifiers of different classification systems (IFC, DIN276, OmniClass, Uniclass) and the graphical representation of the model element, a model element-specific list of the geometric level of detail and the information requirements is provided, depending on the level of detail, Level of Geometry (LoG) or Level of Information (LoI). The geometric level of detail therefore describes the geometric representation of the object to be modelled along the LoG scale from 100 to 500 in keywords, also naming contents that are not to be modelled. The information requirements are described in tabular form along the LoI scale from 100 to 500, considering the designation, the data format and the SI unit. In addition, example values are given for each information requirement. A matrix is used to assign the information requirements to the level of detail. An essential aspect to be considered within the scope of the information requirements is the definition of the information supplying (information generating) and information implementing (information modeling) responsibilities. Considering the project-specific constellations of different participants and different scopes of services, these contents are to be defined in a project-proprietary manner. The modeling guideline and Appendix 3 offer suggestions for the respective spheres of responsibility for each information requirement and model element. The information requirements described in this appendix also represent those information requirements which are to be regarded as fundamental, viz. BIM application-neutral. The consideration of BIM application-specific information requirements is therefore not covered by the current status of the BIM Modeling Guideline.

In the further course of the project, a further document will be prepared which describes the requirements for the model elements of the technical building equipment, whereby the structure and design of this catalogue of requirements will correspond to those of Appendix 3.

4 Benefits

As a result of the development, documentation and provision of the BIM Modeling Guideline, a software-neutral guideline for the modeling of building data models will be made available, which aims to enable and establish transparent information and consistent data management. As a result of the description of project-specific requirements up to the detailed processing of the information requirements for each model element, a working and communication basis is also provided, which can be used or taken as a basis for the tendering and contracting of planning services: both contracting parties start from the same point of understanding and communicate a transparent performance picture along the BIM Modeling Guideline, whereby the understanding of both the expected and the owed performance can be discussed and defined more clearly than ever [5].

Due to its general nature, the BIM Modeling Guideline can also be used for all BIM projects that have chosen object-oriented modeling as the basis for information management, whereby the specification of the authoring software used and the associated processes such as the creation of a model, data transfer or communication may be necessary. The present modeling guideline is therefore particularly suitable as a basis for the development of an institutional modeling guideline for the users or the target groups, which usually use software applications already in use due to their own preferences, existing license agreements or lock-in effects. A one-time adjustment of the BIM Modeling Guideline to the own structures therefore leads to a standardization of all future projects. The shortage of resources of many SMEs for the documentation of their own modeling standards in their own modeling guidelines, as described in Chapter 1, is significantly reduced by the provision of the BIM Modeling Guidelines. This reduced, one-time effort for the adaptation to the own structures is then to be contrasted with the synergy and efficiency effects in future projects.

5 Outlook

In addition to Appendix 4 (Catalogue of Requirements for Model Elements of the Technical Building Equipment) already mentioned in Chapter 2, the BIM Modeling Guideline is to be used and validated in various pilot projects. For this purpose, the authors are in

contact with some of the project participants and other external parties interested in such an implementation. The knowledge und results gained in the course of the practical application enables a determination of the quality, applicability and practicability of the current state of work, which in return allow the derivation of indication and control measures for a revision of the BIM Modeling Guideline. The application in pilot projects promises, beyond the improvement of the quality of the documents, an increased acceptance of these documents, since the BIM Modeling Guideline would thus already be tested in practice in the first stages.

In the further course of the project, the developed modeling guideline is to be transferred to a database in order to make the content more flexibly available. In addition to the provision of the entire modeling guideline (as currently available), the possibility of exporting specific subsets of information requirements via various filters is to be created. By processing the data and integrating these filters, the infrastructure to provide BIM application-specific data packages is created. In this way, it is possible to export exchange requirements per BIM application according to requirements, or conversely, to derive BIM application-specific modeling guidelines. This last step is optional in the context of this project, since the definition of information requirements per BIM application is not part of the project.

Based on the creation of the database and the possibility to output structured data, the aim of the project is to transfer the information into various modeling software. For this purpose, the import requirements for each modeling software are currently being analyzed and the resulting structures are being set up in order to be able to implement such a mapping of the data in the target system. The development of this communication bridge between modeling guidelines (database) and modeling software results in an added value for the user of the BIM Modeling Guideline due to an automated, requirement-oriented mapping of necessary information requirements per model element.

Furthermore, the development of model review rule sets, for example for model checker applications, based on the defined requirements according to the BIM Modeling Guidelines, is to be implemented on the export of the mentioned structured data. The authors are currently analyzing the model import and the systematic structure of the test data and already available model review rules of various applications. As a result of the generation of model review rule sets based on the contents of the BIM Modeling Guideline, the user is enabled to review a model created or received at different points in time of the project (depending on agreed or defined levels of detail) for completeness and/or correctness. The client is thus given the opportunity to track the actual state of work of the planning project participants and to initiate corrective measures if necessary.

6 Notes

As a result of the ongoing project work, updated versions of the modeling guideline including all appendices are developed and made available. When applying the modeling guideline, it is therefore recommended to check that the respective version is up-to-date before using it and to exchange respective documents if necessary. The latest version of the documents can be downloaded free of charge in German language from the authors' homepage.[1]

Abstract -

Digital Fabrication is an emerging systemic innovation in the architecture, engineering and construction sector. However, the design process for digital fabrication lacks an integrated management process or digital collaboration platform. One reason may be a lack of industry stakeholder needs for such processes and platforms. To explore and facilitate such solution in the current practice, more information about the socio-technical industry requirements on such solution and its implementation to support and manage the BIM-based design process of digital fabrication is needed. To fill this gap, this work conducts an industry-needs analysis through content analysis and an online survey of 144 project stakeholders. Based on the results, this work identifies the most needed fabrication-related information, tools and roles at different design stages and the requirements of platform-based management, which include a common virtual environment for collaboration and a common data environment for data management. Moreover, this work shows that fabrication-related information and new roles are required by project stakeholders since the early design stage. The paper concludes by proposing a conceptual management framework for BIM-platform-based integration for design for digital fabrication in construction projects and identifying potential future research directions on the topic.

BIM, platforms, digital fabrication, design process, project management, survey

1 Introduction

Digital fabrication is an emerging systemic innovation in the architecture, engineering and construction (AEC) sector. In this work, digital fabrication refers to the aspects of industrialised construction, off-site fabrication and /or modular construction that connect design and construction with a digital thread using an integrated process that controls machinery during fabrication tasks [1]. Despite many research and demonstration projects [2], the industry is slow in adopting and implementing digital fabrication due to identified barriers such as skeptical attitude towards DFAB from project stakeholders and complexity in managing process and deliverables [3]. Furthermore, digital fabrication changes the requirements of the design process and requires a new framework in which to guide collaboration between designers and fabricators [4].

To facilitate the design process of digital fabrication, scholarship to date has proposed adoption of new management models such as lean design management and new design approaches such as design for manufacture and assembly (DfMA). These efforts have attempted to bring downstream fabrication information into the upstream design process. The objective of these methods is to facilitate process integration in design and construction [5]. However, an integrated management process specific to digital fabrication does not yet exist.

In addition, there are few digital collaboration platforms available to facilitate an integrated design process for digital fabrication. Digital collaboration platforms are cloud-based platforms for multidisciplinary stakeholders to co-create design deliverables in the design process for tendering and construction. Digital fabrication requires a restructured collaboration process that can support new stakeholders' early involvement and break the wall between design and construction for collective knowledge exchange [2]. Digital fabrication should also connect to ongoing AEC digitalisation approaches such as Building Information Modelling (BIM). Both digital fabrication and BIM aim to help to improve various aspects of integration and foster systemic innovation in the current practice [6]. However, both approaches require a change in management of project life-cycle from planning to construction [2, 7]. Furthermore, the adoption of digitalisation is slow compared to many other industries in the current practice [8, 9]. Nevertheless, a BIM-based collaborative design platform that can support collaborative design for digital fabrication in construction does not yet exist [5]. One potential reason for this is that industry requirements for such platforms are not yet identified.

To fill this gap, this work aims to investigate and analyse the industry requirements for BIM-based collaboration platforms and platform-based integrated management for design for digital fabrication. Based on the industry needs

analysis, this work presents a conceptual framework that manages BIM-based collaborative design process of digital fabrication in projects. To do so, the authors first conduct content analysis of literature review to identify and categorise the requirements of such platforms. The identified requirements are composed in a questionnaire for an online survey of industry experts who have experience in the design and/or construction processes of digital fabrication. Based on the survey results, the authors analyse the industry requirements for such platforms and platform-based management for the design process of digital fabrication. The authors then develop a conceptual management framework for platform-based integration in response to the survey results and the industry needs analysis to address the industry requirements.

This work is organised as follows. Section 2 provides a brief overview of digital fabrication and BIM-based collaboration platforms. Section 3 contains a description of the research design and the survey. Section 4 presents the findings of the conducted survey and the industry needs analysis. Subsequently, Section 5 proposes a conceptual framework for platform-based integration and identifies future research. Section 6 concludes with remarks and suggestions for further work.

2 Background

The architecture, engineering and construction (AEC) sector has been fragmented vertically in processes from design to construction, horizontally among project teams, and longitudinally across projects [6]. In particular, the design process is the root cause of many project life-cycle problems, such as quality and cost misalignments and low productivity in construction [10]. Scholars suggest the construction industry has been caught itself in a "mirror trap", where knowledge is trapped tightly with the task dependencies themselves [11]. Thus, the industry resists attempts to innovate. In order to overcome this resistance "disruptive paradigms" are in need [12]. The use of new approaches such as digital fabrication provides the opportunity for integration and systemic innovation that can be key for such a change [13].

In order to bring digital fabrication from theory into practice, scholars suggest digital system-based management approaches can provide better integration [1, 6]. Hall et al. [13] identified digital systems integration as a firm-based "mirror-breaking" approach to adopt digital fabrication. This involves web-based configuration platforms for flexible kits-of-parts to integrate supply chain for design to enable digital production. García de Soto et al. [14] also propose the use of cloud-based platforms and platform-based integration as a project-based approach to implement digital fabrication from design to construction. Such platform-based management requires new roles and new tasks in both design and construction processes. Platform-based integration supports operational and management-related technical requirements for BIM-based collaboration platform. It facilitates the adoption of technologies and intelligent and automated collaboration in design and construction, supply-chain management and systems integration [15]. This includes BIM-based collaboration platforms that allow stakeholders to engage, co-create, communicate, coordinate and collaborate design in a common virtual environment for design modelling in 2D and 3D, design review and project management. Such platform facilitates information exchange and knowledge sharing for design review, progress monitoring and optimisation of cost and constructability, as well as immersive environments for collaboration and the adoption of automation and innovation in design process [7, 16]. BIM-based platforms provide measurable data for progress tracking, risk management, trust-building and benchmark of deliverables for quality control and trade tendering, and supports design integration and integrated management [4, 17].

3 Research Design

To investigate and analyse the industry requirements for BIM-based collaboration platforms and platform-based integrated management for design for digital fabrication, the authors conduct (i) content analysis of literature review, (ii) an online survey with a multiple-choice questionnaire, and (iii) analyses and visualisations of the results.

Firstly, this work involves a content analysis of literature review to identify, condense and categorise the requirements for collaboration platforms in the design process of digital fabrication in construction projects [18]. The authors conduct two rounds of keywords search to screen and review literature published in the past ten years. In the first round of literature search, the keywords used are "digital fabrication", "design process", "collaboration" and "parametric". In another round, the keywords used for literature search are "collaboration", "design process", "platform" and "BIM". Amongst all, the authors filter irrelevant contents to identify the operational and management requirements [15]. The authors group the requirements into five categories, namely technical, technological, organisational, contractual and business-related requirements.

Secondly, based on the content analysis, the authors compose 18 questions in a multiple-choice questionnaire to undertake an anonymous online survey of the industry stakeholders with digital fabrication design and/or construction experience. Each question is composed of seven to twelve multiple choice answers. For most of the questions, participants could choose a minimum one and maximum of three choices. The goal of this survey is to understand the industry needs for collaboration and integration

Table 1. Design stages terminology in this work in reference to the plans of work in Switzerland, U.K., Italy, U.S.A., Japan and Singapore

platform for the design process of digital fabrication in construction.

To assist stakeholders in their survey participation, the authors summarise a comparison of the design stage terminology in existing plans of work in six countries as shown in Table 1. To promote comparative international responses, the definitions are summarised in accordance with the plans of work from Swiss Society of Engineers and Architects (SIA) in Switzerland, the Royal Institute of British Architects (RIBA) in the U.K., Italian (ITA) Procurement Law in Italy, the American Institute of Architects (AIA) in the U.S.A., Tokyo Association of Architectural Firms (TAAF) in Japan and the Building and Construction Authority (BCA) in Singapore, as well as the authors' first-hand work experience in projects in these six countries. The definitions of the design stage terminology might vary project by project, company by company. Thus, Table 1 merely serves as a reference to the terminology for the survey participants.

Thirdly, this work visualises and analyses the results of the industry needs analysis based on the survey [15]. Fourthly, based on the survey results, the authors propose a conceptual management framework for platform-based integration to manage BIM-based design process of digital fabrication in construction projects, and propose future research areas.

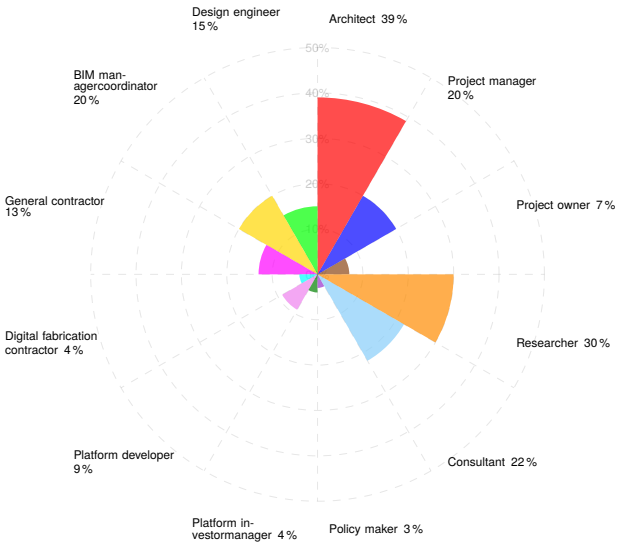

Figure 1. Summary of professions of the online survey participants

4 Findings

Based on the content analysis, the authors elaborated 18 questions in five categories. (1) *Technical requirements* are digital fabrication specific. During the design process, fabrication information and machine code are often required from downstream to upstream decision-making [2]. Moreover, tools such as sensors are used to keep track on the motions of the fabrication machines to ensure consistency between the digital design model and the digital fabrication performance [4]. (2) *Technological requirements* are platforms specific. The authors identify the current trends in cloud-based collaboration platforms for BIM-based design process. Such platform supports multidisciplinary information exchange and constant feedback loops between design and fabrication, and facilitates co-creation and BIM data management for project integration [14, 15, 17]. (3) *Organisational requirements* are digital fabrication design project specific. Implementation of digital fabrication restructures a project's organisation and supply-chain [6, 13]. New roles such as digital fabrication (DFAB) manager and DFAB design coordinator, are evolved in projects. This is similar to the new roles derived due to BIM implementation in projects [7]. While several existing downstream roles such as DFAB programmer are required to participate in the upstream decision-making [14, 19]. (4) *Contractual* and (5) *business-related requirements* are platforms specific. Platform-based integrated management derives new contractual and business strategies to ensure such novel design management approach for process integration, organisational integration and information integration [5, 13, 17]. These two categories are not analysed and presented in this work.

In May 2020, the authors undertook an anonymous online survey of the industry experts who have experience

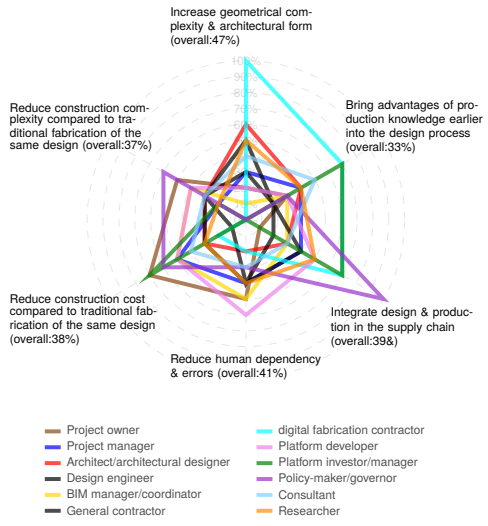

Figure 2. Primary motivations from project stakeholders

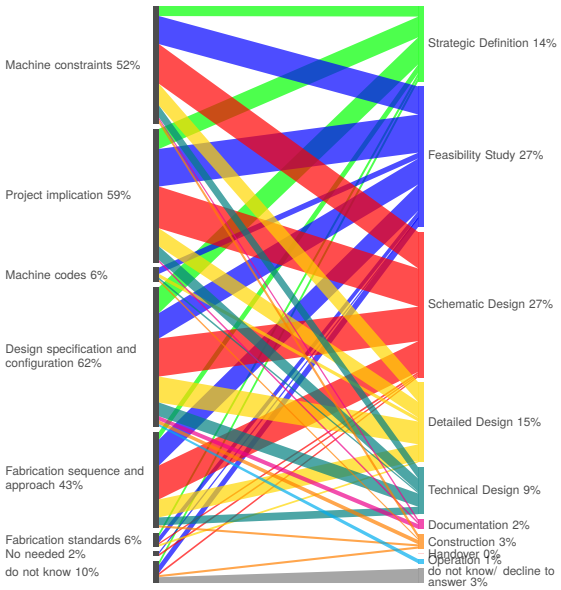

Figure 3. Most needed fabrication-related information at each design stage

Figure 4. Most needed aspects in design modelling for digital fabrication

in digital fabrication in design and/or construction. The survey received 144 responses. Figure 1 shows a summary of the professions of the survey participants. Amongst all, one-third of the participants and one-forth have more than five years of digital fabrication experience in design and in construction respectively.

The following paragraphs describe the fabrication specific *technical requirements* in BIM-based design process of digital fabrication. Figure 2 illustrates in a spider-web diagram the primary motivations of the project stakeholders for design for digital fabrication over traditional construction processes. The overall percentages of each answer are listed. It also shows that the primary motivations of different professions are not the same. The answers exclude the option of construction quality, which is commonly seen as the most popular motivation [1, 2, 3, 5, 14].

Figure 3 differentiates and illustrates in a bipartite-sankey diagram the most needed fabrication-related information at each design stage in the design process of digital fabrication as per the terminology defined in Table 1 is the fabrication-related information first needed. The overall percentages of each most needed information and the overall percentages of each design stage are listed. Figure 3 reveals that various different types of fabrication-related information are in fact needed since the early design stages.

Figures 4, 5 and 6 illustrate the most needed aspects in design modelling, design reviews and design documentation respectively in the design process of digital fabrication in construction projects. Regarding design modelling, Figure 4 shows that the answers are quite evenly distributed among all the multiple choices answers. 4% of the participants provided other answers such as fabrication machines and process constraints are also needed for design modelling to meet fabrication tolerances; interactions between design modelling and fabrication tools such as robotic arms and collaborative mindsets among multidisciplinary stakeholders are also needed in terms of fabrication-related information in design modelling. Regarding design review, the survey results as illustrated in Figure 5 reveal that over half of all the participants expressed their needs in process visualisation and simulation and collaboration in a common virtual environment. 4% of the participants provided other answers such as options such as optimisation, design status scheduling and tracking and information to connect to the factory floor are also needed for design review. Regarding design documentation, Figure 6 shows that the stakeholders needs are also quite evenly distributed amongst all answers. 2% of the participants provided other answers such as configuration

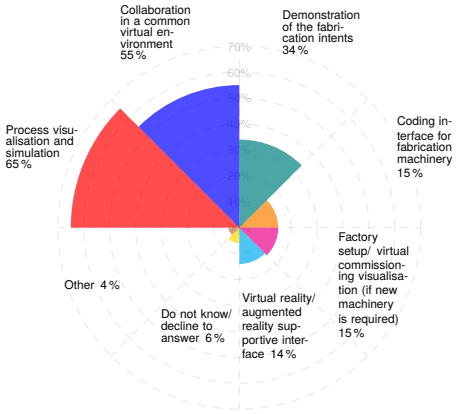

Figure 5. Most needed aspects in design review for digital fabrication

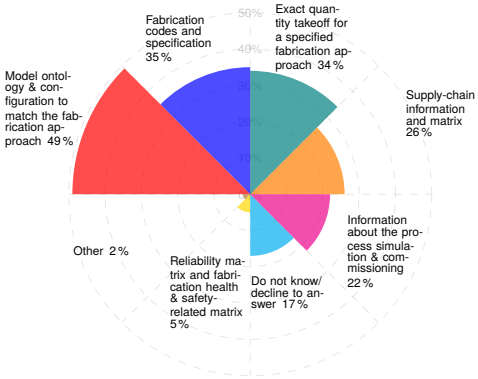

Figure 6. Most needed aspects in design documentation for digital fabrication

management is also needed for design documentation.

Figure 7 illustrates the most needed digital twin strategies for design for digital fabrication. Only 3% of the participants required neither digital twin nor virtual commissioning for design for digital fabrication. 4% of the participants expressed that the digital twin strategies depend on the complexity and delivery models of the projects.

The following paragraphs describe the platforms specific *technological requirements* in BIM-based design process of digital fabrication. Figure 8 illustrates the background information of the platforms and programming languages being used in the current practice. 3% of the participants provided other answers such as solidworks, cadwork and Robot Operating System.

Figure 9 differentiates and illustrates in a bipartite-sankey diagram the most needed ways to support machine code on the collaboration platforms for project stakeholders to edit at each design stage in the design process of digital fabrication as per Table 1. The overall percentages of each most needed ways of support and the overall percentages of each design stage where such support is first needed are listed. 5% of the participants provided other

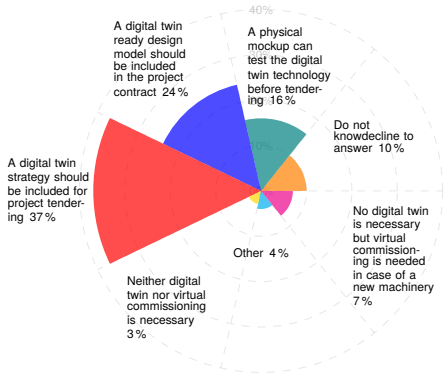

Figure 7. Most needed digital twin strategy for design for digital fabrication

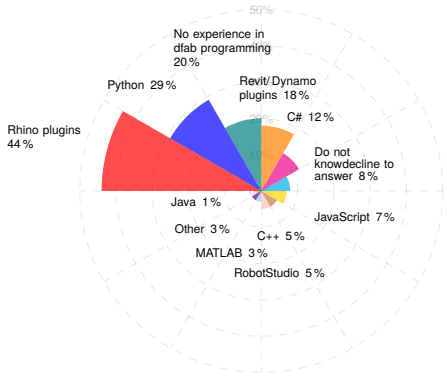

Figure 8. Most used platforms and programming languages for design for digital fabrication in the current practice

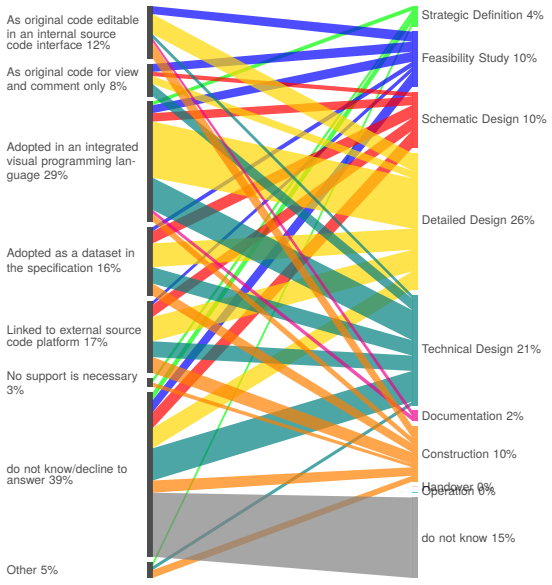

Figure 9. Most needed ways to support machine-code on cloud-based platforms at each design stage

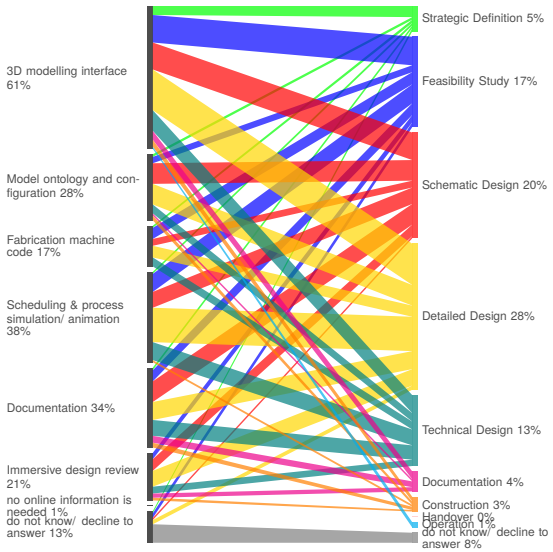

Figure 10. Most needed fabrication information shared on cloud-based platforms at each design stage

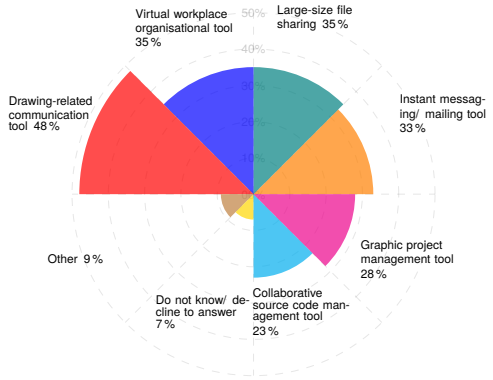

Figure 11. Most needed supporting functions for communication and knowledge sharing on collaboration platforms

answers such as machine code should only be accessible by the fabrication contractor instead of being editable by all project teams on the platforms; another answer is that the ways of support depend on the vary project by project, depending on the project stakeholders' preference. Moreover, only 1% of the participants required no machine-code support on the platforms.

Figure 10 differentiates and illustrates in a bipartite-sankey diagram the most needed digital fabrication information to be shared on cloud-based collaboration platforms at each design stage as per Table 1. The overall percentages of the most needed information to be shared online and the overall percentages of each design stage where such cloud-based sharing is most needed are listed. Only 1% of the participants required no online sharing of digital fabrication. 2% indicated that information sharing on such platforms require a common data environment.

The most needed supporting functions for communication and knowledge sharing on collaboration platforms are illustrated in Figure 11. The answers are quite evenly distributed. The authors especially did not include modelling-related tool because this is by default a must on such platforms. 9% of the participants provided other answers such as issue trackers are needed. They also indicated that the functions require a common data environment for data management.

The following paragraphs describe the digital fabrication design project specific *organisational requirements* in BIM-based design process of digital fabrication. Scholars identified that new roles and new responsibilities are cre-

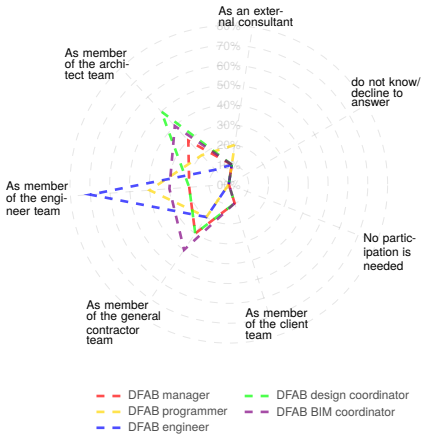

Figure 12. Most needed ways of the new digital fabrication roles' involvements in a multidisciplinary project

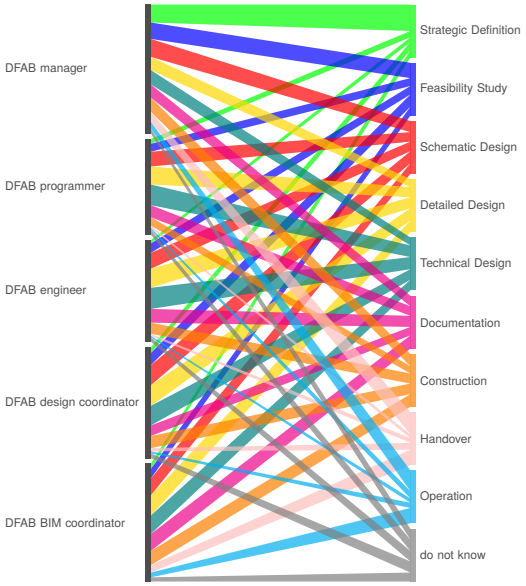

Figure 13. Most needed involvement of the new digital fabrication roles at each design stage in a construction project

Figure 14. A conceptual management framework for platform-based integration in BIM-based design process of digital fabrication in construction projects

ated in particular for digital fabrication projects [19, 14]. The new roles include digital fabrication (DFAB) manager, digital fabrication (DFAB) programmers, digital fabrication (DFAB) engineers, digital fabrication (DFAB) design coordinator and digital fabrication (DFAB) BIM coordinator. Figure 12 illustrates in a spider-web diagram the most needed ways of the five new roles' involvements in projects. In average only 1% of the survey participants required no new roles in projects. The required ways of involvements are different for each role. All in all, the results show that the new roles should be integrated within the existing project team structure.

Figure 13 illustrates in a bipartite-sankey diagram the answers of the question about when the new roles are needed. The percentages of the roles required in each stage are shown in proportion on the left-hand side. It can be seen that new roles for digital fabrication are not isolated to a single design stage but are needed across multiple phases of design and many of the new roles are required to join the project team since early design stages.

5 Discussion and future research

From the industry needs analysis conducted in this work, implementation of digital fabrication significantly impacts the design process with respect to information exchange, workflow and organisational structure in construction projects. The design process of digital fabrication requires new approaches to design management. The industry has specific requirements for the design process of digital fabrication. These requirements enable platform-based integration and integrated project management for design for digital fabrication to integrate process, information and organisation for construction projects [5, 17]. Moreover, such collaboration platforms should connect a BIM-based design process with digital fabrication through a common data environment. This can enable integrated data management and common virtual environments for project stakeholders to visualise, simulate and coordinate design for digital fabrication.

Based on the survey results, the authors propose a conceptual platform-based management framework to manage a BIM-based design process of digital fabrication (see Figure 14). This framework considers four categories of tasks, namely design, digital fabrication (DFAB), BIM and project management. The framework illustrates how tasks of research, planning, preparation, development and provision at each design stage match with the requirements identified in the survey. The proposed deliverables of the tasks are also indicated in red.

The goal of this framework is to assist project managers and stakeholders to manage the BIM-based design process of digital fabrication in construction projects. Furthermore, in order to facilitate BIM-platform-based integration and integrated project management for design for digital fabrication, the authors propose that emerging design management approaches such as Set-Based Design (SBD) and Target Value Design (TVD) could be considered to manage the design process of digital fabrication.

Future research on how to integrate and manage the complexities of design for digital fabrication could include:

1. An in-depth industry needs analysis to investigate how each aspect of the requirements inter-relate and impact on each other;
2. More detailed statistical analysis of the data such as a paired-means test to determine if answers differ by discipline and /or experience level of the participants;
3. An in-depth research on such platform-based management framework for design for digital fabrication;
4. Further investigation and application of lean design management strategies such as SBD and TVD.

6 Conclusion

One potential reason for the slow adoption of digital fabrication in AEC is the lack of a developed management model to integrate project stakeholders. Existing research identifies that BIM-based collaboration platforms and platform-based integration can help to break through the socio-technical barriers and facilitate the implementation of digital fabrication in the design process in projects. To investigate such platforms and their management approaches, this work conducts an industry needs analysis through an online survey of 144 project stakeholders in current practice. The preliminary analysis finds: (i) fabrication-related information such as specification and project implication is needed since early design stage, (ii) collaboration in a common virtual environment and process simulation are needed in the design process, (iii) model ontology to follow the fabrication approach is required in design documentation, preparation for digital twin in digital fabrication is required before tendering, (iv) digital fabrication information is required to be shared and edit among project stakeholders to different extents at different design stages in a common data environment and (v) new roles such as DFAB manager and DFAB BIM coordinators are required since early design stages and continuing throughout the design process. This work further elaborates a conceptual platform-based management framework to manage such complex BIM-based design process of digital fabrication in construction projects.

Abstract –

In a centralized air distribution system, the designed ductwork layout impacts the system performance and the construction time and cost. Engineers face various challenges, including spatial limitations, leading them to use assumption-based design methods to balance their design with construction requirements. As a result of this shortcoming, insufficient design details for construction and improper coordination between designers and trade workers will occur, increasing the project duration and risk for conflicts. As the construction industry shifts towards off-site and fast-paced construction methods, the design processes must comply with construction requirements to ensure a smooth transition from conventional methods to off-site construction. This research provides a scientific and systematic method for design and optimization of the HVAC air distribution system in terms of the ductwork layouts, and sizes and types of ducts to standardize the construction processes for time and cost reduction in the off-site environment. The proposed methodology utilizes Building Information Modeling for coordination of the air distribution system using a 3D database. Furthermore, a trained genetic algorithm processes the data and identifies alternative solutions. As the final step, the algorithm generates the optimal air distribution system in the BIM 3D environment for a visual assessment and detailing. The results are verified based on existing case studies in the Canadian prefabricated, panelized construction company. The potential benefits include 23% savings in duct material, whilst providing an integrated design solution with 32% less conflicts comparing to traditional design methods.

1 Introduction

1.1 Overview

In an HVAC project, the engineer is responsible for determining the required size of the ducts and the capacity of the HVAC equipment. This design process does not consider the detailed layout of the air distribution system for construction. This leads the contractor to use past experience to determine the exact location of supply and return air terminals as well as the routing paths for the installation of floor and wall ducts. In turn, skilled trade workers are then responsible for identifying missing details in the design and resolve the conflicts based on their experience. Lack of coordination between the contractors and designers will cause conflicts during the construction, resulting in increased construction time, cost, and material waste. Uncalculated decisions and assumptions decrease building performance by creating conflicts between the building systems (e.g., plumbing) and/or structural members. This lack of information is a primary barrier to taking the leap between conventional and modular construction. Off-site construction requires extensive planning for the mechanical, electrical, and plumbing (MEP) elements to be installed on the assembly line in parallel with the construction of the panelized walls, floors, and roofs in a closed environment. The design must meet the needs of modular construction to eliminate rework and allow the construction tasks to be synchronized. The duct system must align perfectly with the structural design and other MEP elements to ensure installation is not interrupted by conflicts. If the plumbing system and ductwork overlap, the construction process of the two systems cannot take place in parallel, and there will be idle time for the trade workers.

Furthermore, the traditional experience-based HVAC design and construction do not satisfy the requirements of modular construction, which are standardized designs and sequential tasks aimed at reducing variance in the processing time of tasks on the manufacturing line. In order to address these limitations and industrialize the HVAC system in modular construction, this research integrates modular construction and design requirements when planning the air distribution system layout. This

paper presents an applied approach for designing the air distribution layout, featuring an optimization algorithm that eliminates conflicts and reduces overall cost. The proposed algorithm utilizes BIM data in a tailored GA framework to determine the optimum layout for a given project. The proposed methodology was tested on various housing projects, reducing overall material waste, and eliminating design conflicts for every scenario.

1.2 Background

The MEP systems are complex and variable in terms of design and layout configurations. Improper design and integration at the planning and design stage can negatively influence the entire project. MEP construction can consist of 25%-45% of the total project cost [1]. The HVAC system is generally the most time-consuming and expensive system. One of the most challenging and time-consuming processes during the design of an HVAC system is designing the air distribution layout. The air distribution system is constructed from multi-levels of ductwork, which imposes challenges for the contractors in the decision-making process. The challenges related to the ductwork undertaken in this research are (1) determining the location of the air terminals and (2) selecting the optimum paths for connecting the duct through the floor and wall panels. The location of the air terminals and the duct paths must consider system performance and ease of constructability. During the design and planning stage, the engineer confronts parametric variations, including space occupancy and spatial constraints. The current methods for designing the ductwork focus exclusively on the size of the ducts and the fans, and the layout is not explicitly defined [2].

Space limitations and coordination between different trades are crucial factors affecting the construction time of a proposed design. The architectural design defines most of the spatial constraints and the preliminary limitations in the design and construction of an HVAC project [3]. The constraints of the air distribution system design can vary by the level of significance. They can be directly or indirectly related to system performance, e.g., occupant comfort, construction cost, and life cycle cost (LCC) [4]. Previous research suggests that because ducting system designers are forced to balance constraints and requirements with layout decisions, they often make decisions based on rules of thumb, which can come at a cost to the life cycle of the system [4].

Many HVAC design challenges are optimization problems. Researchers often focus on the most energy-efficient designs and life-cycle costs. According to [4], GA is an effective optimization technique in HVAC applications. However, in the published research projects regarding HVAC optimization, construction challenges, which include a significant portion of the cost, are not considered. The air distribution layout directly influences the construction processes and effects not only the performance of the system but the entire cost and duration of the project. The Air distribution performance index (ADPI) is a standard method for assessing how well the designed air distribution layout performs in terms of the occupant's comfort and the uniform supply of air within the building enclosure [7]. ADPI will assist the designers in the process of selecting the correct diffusers and positioning them in each space. It is a guideline for selecting supply air terminals according to the manufacturer's specifications. The application of the ADPI in the selection of commonly used diffusers for heating and low cooling modes is assessed by [9] and [10], respectively. ADPI is considered a guideline when specifying the location of diffusers prior to construction.

After the locations of the air terminals are identified, the remaining challenge is determining the optimum duct layout that will connect the air terminals to complete the design of the air distribution system layout. 3D tools are proven to be effective in facilitating an integrated design for the layout of the MEP systems. BIM is an industry-standard platform that allows all the project designers, architects, construction managers, and trade workers to seamlessly monitor project progress and exchange information in a 7-D database. BIM integrated design is an effective approach supported by a significant amount of published research. [3, 5, 6]. Utilizing a 3D collaborative database, the designers can compare their plans with the plans of other trades in order to check for interferences and to solve conflicts prior to construction. According to [5], time and cost savings are amongst the multiple benefits of BIM-based coordination as compared to conventional construction methods.

2 Methodology

2.1 Problem Structure

The objective of optimizing an air distribution layout is to generate alternative design solutions to assist the designer in achieving the most efficient performance and cost-effective results. The focus of the proposed framework is on the location of the air terminals and the designed ductwork layout required to create the HVAC system network. There are several requirements to be satisfied to create a high-performance and cost-efficient air distribution system design. (1) The location of the supply and return air terminals must follow ASHRAE guidelines [8]. (2) The duct layout must be easy to install in accordance with the building structure and other plumbing and electrical system configurations. (3) The duct layout must consist of efficient use of duct material

to reduce material waste and construction time.

The scope of this research is to propose a systematic approach for determining the optimal location for the installation of the air terminals and ductwork layout. This research will use BIM for analyzing project information and GA to identify the optimal solution. The final step is to validate the result in a 3D environment. The proposed methodology is illustrated in Figure 1 below.

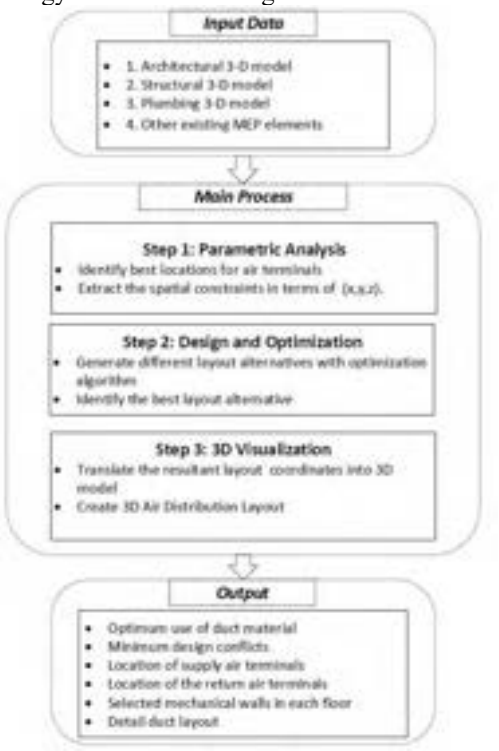

Figure 1. The proposed methodology

In order to apply the proposed methodology, manual input is required from the user, consisting of the project physical model. The 3D architectural model, 3D structural model, other existing MEP elements and a material database must be created in the BIM environment before the implementation of this methodology. The three-step processing modules are created to address the challenges in regards with the design and construction of an air distribution system layout.

The first step in the main process is the parametric analysis. In this module, the architectural boundaries required for the design of the air distribution layout are identified and extracted from the BIM model. Other physical constraints are the location of structural members and MEP elements that co-exist along with the ductwork, which may interfere with the chosen path for the ducts. The spatial constraints from BIM will be used to calculate the suitable locations for installing the supply air terminals based on the ADPI calculations and the relative location for the return air terminals based on ventilation requirements. From the parametric computation module, the extracted parameters are fed into the design and optimization algorithm. This process will assign a single position for each air terminal and asses the routes that are suitable for connecting the air terminals and creating the ductwork layout. The optimization algorithm will then generate different solutions for the layout and verify feasibilities. The layout solution, which is identified as the optimal solution, will satisfy all conditions to the highest degree and will be the resultant design solution.

The result of the design and optimization algorithm is a set of x, y, and z coordinates. The output includes the location of the air terminals and the ductwork layout relative to the chosen floor and wall panels for installation. The final step is to transfer this information back into the BIM model. The final output will be a complete air distribution layout in the BIM environment that is correlated with the project's physical model and is cost-effective. This methodology will assist the designer with the preliminary design of the air distribution network layout. Implementing this framework will automatically generate a duct network layout for any given project with optimized system performance and construction parameters. The proposed design will allow for efficient use of duct material and minimum conflicts with the building structure and MEP systems for improving constructability.

2.2 Parametric Analysis

To factor in all the data required for designing the air distribution system layout, it is crucial to follow a detailed decision-making process throughout the design. This section describes the step-by-step process of the parametric model. Just like a human designer, the proposed algorithm is trained to make decisions at each step. This section will review the process of populating the air terminals, including the supply air outlets and return air inlets, highlighting the design parameters followed by the spatial limitation and constraints.

2.2.1 Floor Mounted Supply Registers

Floor registers with a vertical discharge of supply air are identified as the preferred method of providing heat, especially in the residential houses. For selecting the optimal position of a floor register, the floor area in each space must be considered in accordance with the physical constraints as well as the occupancy requirements. The room perimeter is the ideal location for a floor register with the jet flow direction aiming towards the length of the room. [7]. Each space varies in terms of the architectural layout as well as the occupancy usage. The proposed algorithm identifies the most suitable location for the floor register in each space through a process of elimination. In this subsection, an example of a floor

layout is used to demonstrate the intelligent process of selecting possible locations for supply air floor-mounted registers.

In the initial stage, each space that requires supplied air must be identified (Step 1). In the selection process, the floor space is automatically populated with a series of points (Step 2). Each point represents a possible location for the installation of floor-mounted registers. In this process, each point is eliminated, if it does not meet the design criteria. In Step 3, the points that are adjacent to the walls are eliminated because a clearance distance of 6 inches is required for construction. A floor register should not interfere with the occupancy path. Step 4 removes the points that take away from the living space. Step 5 identifies the points in front of doors and windows and eliminates them accordingly. Step 6 removes the points adjacent to external walls, and finally, Step 7 eliminates the points in each corner, which are constrained by two walls. This process is illustrated in Figure 2 below.

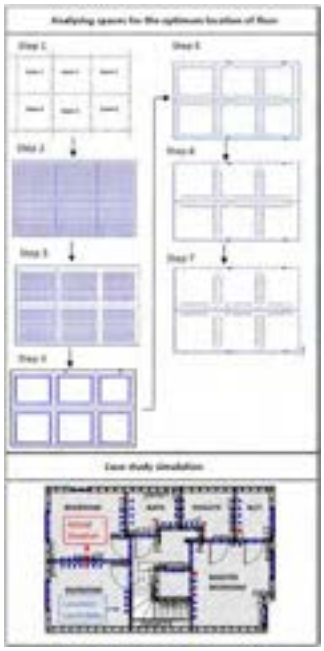

Figure 2. Identifying the best locations for installing floor mounted supply registers.

The algorithm is implemented in Dynamo and verified using the BIM simulation model created in Revit Autodesk. The blue points remaining are a set of locations suitable for the installation of the floor-mounted supply registers. The actual position where the registers are installed by the contractor exists amongst the candidate points in simulation (identified by red points). The similarity of the simulation result and the actual projects confirms the accuracy of the results. However, the final solution must only contain a single point for each space. In order to identify the optimal locations automatically, the optimization algorithm finds alternative routes for connecting the points and creating the air distribution layout. The final layout will be demonstrated in the case study section of this paper.

2.2.2 Ceiling Mounted Supply Diffusers

A ceiling-mounted diffuser is designed to diffuse the airflow in four directions instead of aiming downward. The optimum location to place a ceiling-mounted diffuser is in the middle of a room. However, each space is not perfectly symmetrical, and one side of the room boundary may be closer to the middle than the other. There are different methods for selecting the optimal location for a diffuser in each space; the position of a diffuser always depends on the room geometry, the total number of diffusers, and the required capacity. In this paper, the ADPI will be the primary design method for selecting the position of the diffusers in the designated spaces.

ADPI is a measure that indicates how well the supplied air is mixed with the existing air in the space before ventilation. It is directly related to occupant comfort, designed system performance, and energy efficiency [7]. The location for each diffuser is calculated by finding the isothermal throw distance for the selected outlet type. The throw is the farthest distance a diffuser can project the supplied air before the air stream starts losing velocity. The distance to the closest wall from the diffuser is referred to as the characteristic length. The throw to characteristic length ratio that will result in the maximum ADPI for a selected diffuser will be provided in the manufacturing guide. Table 11-1 of the ASHRAE Handbook Fundamentals Volume 1997 provides the required data for calculating the throw distance of commonly used supply air diffusers [8]. Diffuser manufacturers each have their own specifications for their products. The following equation demonstrates the calculation of the throw distance for a selected diffuser, and according to the result, the optimal position for that diffuser can be determined based on the room boundaries.

$$Maximium\ ADPI = \frac{X_{50}}{L_{Characteristic}} \quad (1)$$

Where:

X_{50} = throw distance with 50 ft/min velocity,
$L_{characteristic}$ = room characteristic length from BIM
Maximum ADPI = from Table 11-1 [8] or manufacturers catalogue

The throw distance provides a relationship between the diffuser's performance and the room boundaries. The throw distance is used to identify suitable locations for installing the supply air diffusers by ensuring that the areal range of diffusion fits inside the space and covers at

least 80% of the area. Each room has a different characteristic length, and the information obtained from BIM will allow the calculation of the diffuser's performance in accordance with the designated spaces. The following region [X_{max}-X_{min}, Y_{max}-Y_{min}] is adequate for installing the diffuser with respect to the throw distance and the room boundaries. Within this region, the characteristic length does not change. Anywhere inside the identified region, the diffuser can be installed while maintaining the areal range of diffusion inside the room boundaries. With this logic, the maximum ADPI remains the same.

Figure 3. Identified boundary suitable for installing a diffuser

Each space has a different required flow rate, which will determine the type and the total number of diffusers required. Based on the selected diffusers and their capacities, the algorithm will determine how many diffusers need to be installed in each space. According to [7], if space requires more than one diffuser, the distance between each diffuser must be 2x the throw distance. The following figure demonstrates each diffuser's specific throw requirement in the simulation model.

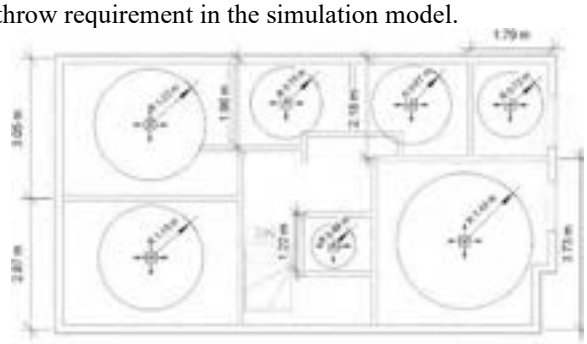

Figure 4. The range of diffusion for each diffuser

The location for each diffuser is identified, and the range of flexibility for the region of installation is determined. Each diffuser can be placed inside a box calculated based on the areal range of diffusion demonstrated in Figure 3. In order to determine the final position, the ductwork layout and accessibility for construction must be considered. The duct layout will create an air distribution network by connecting all the diffusers together. The remaining challenge is to determine the optimal layout for the system, which will be covered in the design and optimization section of this paper.

2.2.3 Return Air and Ventilation

In practice, the return air inlets are positioned as far as possible from the supply air outlets to avoid short-circuiting the conditioned air. Distancing the inlet and outlet air terminals will provide adequate time for the supplied energy to be distributed in the building before it is captured and returned to the central air handling unit. Two modes of ventilation commonly used in residential buildings are demonstrated in this research:

1. Mixing Ventilation
2. Displacement Ventilation

According to [11], mixing ventilation is suitable for heating and cooling applications. To create a network consisting of displacement ventilation, the supply air outlet, and the return air inlets must be installed in the ceilings. Displacement ventilation is a buoyancy-driven, stratified flow with high ventilation effectiveness. Based on the displacement ventilation requirements, the supply system will consist of floor-mounted registers, and the return inlets will be positioned on high walls. This design will allow the supplied air mass to gradually distribute the energy in each space as it rises toward the ceiling and exits through the vents. The figure below demonstrates displacement ventilation in a 3D model.

Figure 5. 3D rendering of a floor register and a side wall return vent in Revit (displacement ventilation)

Based on the mixing ventilation requirements, the supply system will consist of ceiling-mounted diffusers. The return inlets will be positioned relative to the position of the supply air outlets. The return vent must be placed in the farthest location away from all supply diffusers. The path that the supplied air travels must be far enough to allow adequate circulation and mixing of air within the space before the air stream reaches the return inlets and exits the zone.

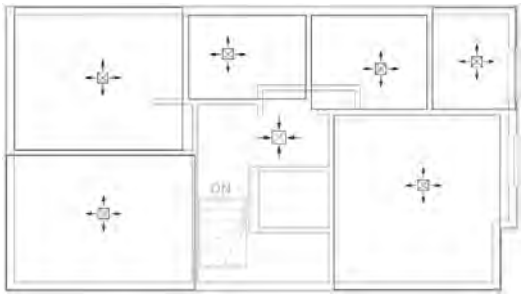

Figure 6. The position of supply and return air terminals for mixing ventilation in Revit

Depending on space flow requirements, the flow in must be equal to the flow out of each zone to provide a net-zero pressure inside the building enclosure. The supplied air must be distributed and cover the entire floor area. Therefore, the total number of supply outlets is more than the return air inlets. The building enclosure must maintain balanced pressure, and all the supplied air must eventually be ventilated. For a residential building, centralizing the return air system within the corridors of the buildings will allow the supply airflow to circulate in each room and gradually travel towards the central corridors prior to ventilation. The return air system will be designed after the supply system is set in place accordingly.

2.2.4 Spatial Constraints

Building construction is an interdisciplinary project that requires extensive planning and correspondence between all trades to ensure timely and cost-effective project delivery. Overlapping MEP elements can lead to congestion, which will increase construction time. For example, the plumbing crew will have to wait for the sheet metal crew to install the ducts and then proceed with the installation of the pipes. With the use of BIM and GA optimization, the proposed solution for the air distribution layout will comply with all spatial constraints of the project without conflicting with any other trades, ultimately reducing the cost and the total construction time.

Building structure dictates the space limitation for installing MEP elements. When the ductwork layout is interfering with structural framing, the workers need to puncture holes in the beams for routing the ducts through the framing. The rough-in work required for fitting the ducts inside the beams will increase construction time and create more construction material waste. Also, the structural integrity may be damaged in the process. Therefore, the designed air distribution system must align with the building structure. The proposed framework integrates the design parameters during the planning stage, using spatial constraints from BIM to automatically assess the number of conflicts in the alternative air distribution layout designs.

2.3 Design and Optimization

2.3.1 Problem Formulation

Once the location for all the air terminals is identified, the remaining challenge is connecting each air terminal to create the final air distribution system layout. The entire system will be constructed from two main parts.

1. Main ducts:
   - The largest duct carrying the highest flow rate from the central air handling unit to each floor
   - The horizontal segment of the main duct is centralized in each floor to reach both sides of the building
   - The vertical segment of the main duct connects each floor and exists in the mechanical walls
2. Branch ducts:
   - Smaller in cross-section
   - Deliver the flow required from the main duct to the diffusers in each space

When considering a duct network, the appropriate route for the main duct carrying the highest flow rate must be considered first. The main duct is often placed along the building corridors or the centreline of the building to have almost equal distance from the furthest air terminals in both directions; this creates a more balanced system in terms of pressure drops due to the friction losses in the duct channel. The branch ducts can be constructed partially from flexible duct material. The branch ducts are required to carry the supply air from the main duct to the location of each air terminal.

The length of the designed system is calculated using a set of coordinates extracted from the project model. These points will be categorized into two groups: endpoints — the location of the air terminals, and the starting points —the connection with the main duct. The distance between the two points will be equal to the length of that duct section. The total length is calculated by the sum of all the branch ducts plus the length of the main duct.

2.3.2 Genetic Algorithm Optimization (GA)

i. Multi-objective Optimization:

The application of GA is used in modern construction problems with multi-objective targets to achieve optimal results that satisfy each parameter requirement. The random generation and nature of this algorithm create a flexible approach to a problem with multiple interacting variables. Each generation will be assessed using a defined fitness function to evaluate the level of satisfaction for each parameter based on a weighted distribution. In this research, GA considers the following objectives:

- Reduction of total duct length
- Space air diffusion (positioning the air outlets in the most effective location in each room)
- Compliance with space availability (routing the ducts through the most accessible spaces for ease of construction and minimum interference with other building components).
- Selection of the most suitable mechanical walls to install vertical duct segments

ii. Fitness Function:

The fitness function is used to evaluate the different solutions generated by the tailored GA algorithm. The defined fitness function measures the total length of the duct system. The solution consisting of the shortest total length, is the most desirable. The two other objectives are the intersection of the ductwork with the structure and MEP elements. The fitness function evaluates the total system interferences for each solution, the system with the least intersection with the structural elements, and MEP congestion is the most favorable choice.

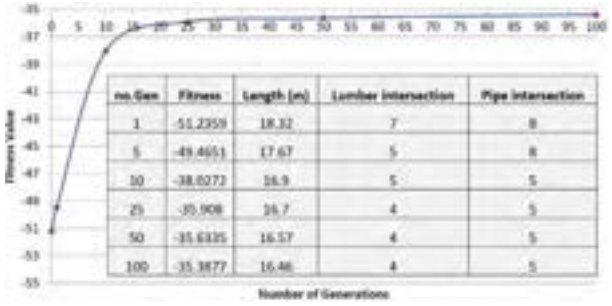
The fitness function is a weighted sum, which means each of the measurable objectives has a different weight on the result. The total length of the system is not as significant as the duct path intersection with the structure; therefore, more weight is assigned to the latter objective. The user can decide which objective is more important and assign the weights accordingly. Each variable is assigned a negative value because the target is reducing these parameters.

$$\text{Fitness Value} = -(W_1)\ \text{Length} + -(W_2)\ \text{MEP Congestion} + -(W_3)\ \text{Structural Interference}$$

iii. Generation vs. Improvement:

The GA starts with generating random solutions and improves the results over each generation. The graph below demonstrates the applied GA on a sample case study with a system of supply air ceiling mounted diffusers. The tabulated results display the total length of the system, the total intersection with the structural members, and the total congestion with MEP members reducing over the evolution process. The result is an air distribution layout solution that satisfies all the conditions as much as possible. Table 1 demonstrates the improvement of the solution over generations. The fitness value is the weighted sum of the total duct length, the number of intersections between the duct and the structural lumbers, and the number of overlapping with the plumbing system.

Table 1. Improvement of the fitness value over the process of evolution (Fitness Value vs Generation)



no.Gen	Fitness	Length (m)	Lumber intersection	Pipe intersection
1	-51.2359	18.32	7	8
5	-49.4651	17.67	5	8
10	-38.0273	16.9	5	5
25	-35.908	16.7	4	5
50	-35.6335	16.57	4	5
100	-35.3877	16.46	4	5

3 Case Study

This section presents a review of the real-world case study where HVAC system construction was identified to be overly time-consuming in panelized construction. The proposed methodology has been implemented, and the highlighted finding validates the given framework. A new and improved design for the air distribution system layout, providing time and cost savings by improving constructability, is proposed in this section. This approach was implemented on four multi-level houses with different layouts. Off-site construction is used for manufacturing these houses. The purpose of off-site construction is to enforce fast-paced construction. During construction the installation of the duct system took a long time due to the following reasons: First, the plumbing and the ductwork were installed in the same planum spaces, which prevented the simultaneous installation of the two trades; and second, the selected ductwork layout required excessive rough-in work, which required many holes to be made in the beams for routing the ductwork.

The following example includes the 3D model of a 3-storey single-family home with an area of 1200 ft^2. Following the framework presented in this paper, the 3D BIM model will be the primary source of data for generating the air distribution system layout. Figure 7 outlines the process for implementing the proposed methodology. This process is applied to four different cases, and the consistent results validate the accuracy of the methodology. Figure 8 demonstrates the three optimization objectives that have improved in comparison with the original design used by the company. The results presented highlight the total savings in terms of the duct length, which is approximately 10 meters (23%). Five intersections with TJI Joists were eliminated, representing a 25% reduction in drill-through holes in the structure. Furthermore, the plumbing and the ductwork did not overlap, thereby eliminating conflicts. Another significant benefit is that the design and drafting time will be reduced because the process of designing the layout and modeling it in a 3D environment is done automatically by applying the proposed algorithm.

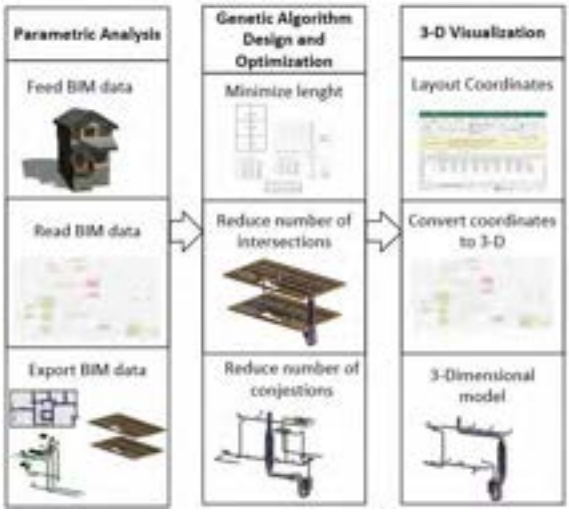


Figure 7. Framework for applying the methodology on the case study

Figure 8. Benefits of the result with comparison

4 Conclusion and Future Work

HVAC systems play a significant role not only in the final performance of the project but also in the initial investment cost and the total construction duration. Assessing alternative solutions during the planning stage will allow the construction process to be applied with more certainty in the outcome, meaning fewer change orders and less waste in the time for the contractors solving conflicts and making assumptions for the missing details. Experienced contractors often produce the best results, but it is proven in this research that this knowledge can be programmed artificially with effective results. The final results include 23% savings in duct material, whilst providing an integrated design solution with 32% less conflicts comparing to traditional design methods. For future work, it is recommended that this framework be applied in compliance with Industry Foundation Classes (IFC). Energy simulation and Computational Fluid Dynamics (CFD) can also be integrated into the process to evaluate the energy efficiency of the results. This framework can be expanded for larger and industrial projects.

Abstract –

Visual facility inspections performed manually are tasks that can be automated. Segmentation of facility image data is one of the automated methods of identifying problems in facilities. However, the machine learning methodology that is mainly used to train the segmentation model requires a large amount of training dataset. Preparing training dataset accompanies laborious manual labeling. To address this issue, we present a new method for generating synthetic data that do not require manual labeling. The method is to create photograph-style images from the BIM images; a generative adversarial network called CycleGAN is used to enable style transfer between the two different domains.

Keywords –

BIM; Cycle-Consistent Adversarial Networks (CycleGAN); Facility Management; Scene Understanding; Synthetic Data

1 Introduction

Facility management aims to effectively operate the facility for a long period of time. Whether the facility is functioning can be understood by comparing the ideal state and the current state. Recent advances in imaging devices have caused image data to be widely used to monitor the current state of facilities. Images show the appearance of the facilities so that people can understand their condition. However, in a large-scale infrastructure, it takes time for a person to check images or videos. Therefore, it is necessary to automatically extract valuable information that provides the current state from the image. Segmentation extracts information such as spatial context [[1], [2]] and structure installation [3] from the image, enabling the identification of the current state of the facility on behalf of the human.

There is a difficulty when carrying out the segmentation. The difficulty is that large-scale training dataset is needed to train machine-learning models for segmentation (such as supervised-learning). Preparing a training dataset involves collecting and annotating multiple images. While image acquisition is effortless, annotating operation requires a lot of time and effort [4]. To deal with this, we propose a novel method for generating synthetic data similar to photograph using Building Information Model (BIM) designed during infrastructure construction.

BIM is the digital twin of the infrastructure, representing geometry, material and time information of the construction entities, in electronic form. Therefore, the images captured from BIM are similar to the photograph, but not completely identical. It is our proposal to create synthetic data that can be used as training data in segmentation models by applying the style of the photograph to the image captured in the BIM. Style transfer between real-world domain and BIM domain is performed using Cycle-consistent adversary networks (CycleGAN[5]). An evaluation of whether the generated virtual data is suitable for scene understanding will be conducted in further research. The framework of the research is shown in Figure 1.

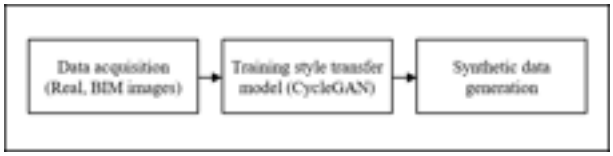

Figure 1. Research framework

2 Related work

In the field of construction, vision-based analysis has been used as an important instrument for understanding the situation. In particular, vision-based analysis using deep learning has recently been actively conducted due to the performance enhancement of computer (CPU and GPU). Among the 2D image-based analysis techniques using deep learning are classification, detection, and segmentation. Among them, segmentation, the technology that classifies the class of each pixel and includes the two preceding methods, are widely used in the latest research in the construction sector. It was used for various construction management purposes including

worker safety enhancement [3], progress monitoring [6], defect identification [[7], [8], [9]], and to update the status of the building [[10], [11]].

The aforementioned deep leaning-based method has limitation that requires a lot of training data to train the model. Preparation for the training dataset includes a labeling task, which is labour-intensive. In an effort to overcome this limitation, the previous studies created databases (ImageNet[12], SUN[13], COCO[14], Cityscape[4]). However, infrastructure facility classes such as HVAC system, plumbing system, structural element and construction materials often do not exist in the mentioned databases. Therefore, it is necessary to create training datasets that can be labelled easily on the desired objects.

To address the above issue, research have been conducted to generate training data using a 3D model [[15], [16]]. In the field of construction, Soltani et al. generated a synthetic image by adding background images and images captured from various angles on the 3D expansion model for visual reconstruction services [17]. Kim et al. took photographs of the concrete mixer trucks with a UAV camera, then created a 3D point cloud with a structure from motion technique, and created 2D synchronous images by projecting the point cloud on the plane [18].

Recently, research has also been conducted to generate synthetic data using BIM, the digital twin of infrastructure. Jong Won Ma et al. generated synthetic point clouds using 3D BIM to train the semantic segmentation model based on deep learning [19]. Although the synthetic point clouds are analogous to real point clouds, the differences in detail and volumetric information of some objects were cited as limitations. It is also difficult to train the model with the 2D synthetic images generated with unprocessed BIM. Inhae Ha et al. showed that differences exist in the feature map of the BIM images and the photographs for the same scene [20]. As such, the gap between real world and BIM is a factor that makes it difficult to use BIM image as training data. In order to reduce this gap, we create synthetic datasets that is transferred with CycleGAN so that the image obtained from BIM has a style similar to photographs.

CycleGAN [5] is a network that transfers images of different domain by learning the two mapping functions. To achieve the objective, the adversarial loss as defined in the Generative Adversarial Networks (GAN [21]) and the cycle consistency loss are used.

3 Methodology

The proposed methodology consists of a step of training CycleGAN and a step of generating synthetic data utilizing the trained network. Details are explained in the following paragraphs.

3.1 Training CycleGAN

CycleGAN [5] is a network that trains mapping function between two different domains. The network include two generators, G_{AB} mapping A to B and G_{BA} mapping B to A and two adversarial discriminators D_A and D_B, which enable mapping between source domain A and target domain B. In the adversarial loss $\mathcal{L}_{GAN}(G_{AB}, D_B, A, B)$, G_{AB} tries to make $G_{AB}(A)$ similar to B, and D_B tries to distinguish B from $G_{AB}(A)$. $\mathcal{L}_{GAN}(G_{BA}, D_A, B, A)$ also works the same. The additional loss due to the possibility that the correct mappings are not achieved with adversarial loss alone is a cycle consistency loss ($\mathcal{L}_{cyc}$). In $\mathcal{L}_{cyc}(G_{AB}, G_{BA})$, $G_{BA}(G_{AB}(A))$ is encouraged to have the same value as A, and $G_{AB}(G_{BA}(B))$ is encouraged to have the same value as B. As a result, the network operates to find G_{AB}^* and G_{BA}^* that satisfy the following expressions:

$$G_{AB}^*, G_{BA}^* = \min_{G_{AB}, G_{BA}} \max_{D_A, D_B} \mathcal{L}(G_{AB}, G_{BA}, D_A, D_B) \quad (1)$$

where,

$$\mathcal{L}(G_{AB}, G_{BA}, D_A, D_B) = \mathcal{L}_{GAN}(G_{AB}, D_B, A, B) + \mathcal{L}_{GAN}(G_{BA}, D_A, B, A) + \lambda \mathcal{L}_{cyc}(G_{AB}, G_{BA}) \quad (2)$$

In this study, real world is the source domain and BIM is the target domain. The structure of CycleGAN is illustrated in Figure 2. The generator G_{AB} receives the real world image (photograph) A_1 as an input and generates $G_{AB}(A_1)$ similar to the BIM image as an output. G_{BA} that receives $G_{AB}(A_1)$ as an input generates $G_{BA}(G_{AB}(A_1))$ similar to the original image A_1. L1-norm between A_1 and $G_{BA}(G_{AB}(A_1))$ is calculated in cycle consistency loss. Conversely, G_{BA} generates $G_{BA}(B_1)$ that is similar to the photograph from BIM image B_1, and the discriminator D_A discriminates whether the input image is from domain A or B.

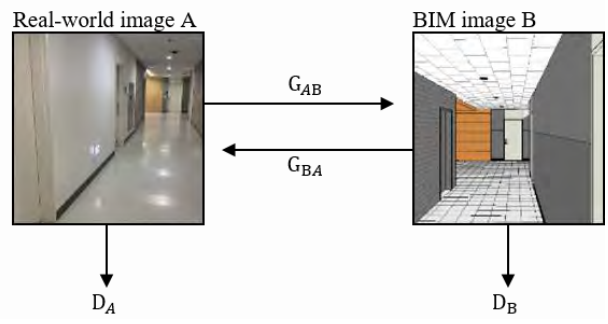

Figure 2. The structure of CycleGAN

3.2 Generating synthetic data

In this study, CycleGAN is set to train for 200 epochs. We used two learning rate settings. One sets the learning

rate to 0.0002 for 200 epochs. The other one sets the same learning rate during the first 100 epochs, and linearly decreases the learning rate from 0.0002 to 0 for the remaining 100 epochs. Then every 40 of the 200 epochs, G_{BA} takes the BIM images as the input and generates the synthetic datasets. Figure 3 shows the process in which synthetic datasets are generated from each generator. We call the generator by concatenating the generator name with the number of epochs and adding the suffix "d" if the learning rate decays.

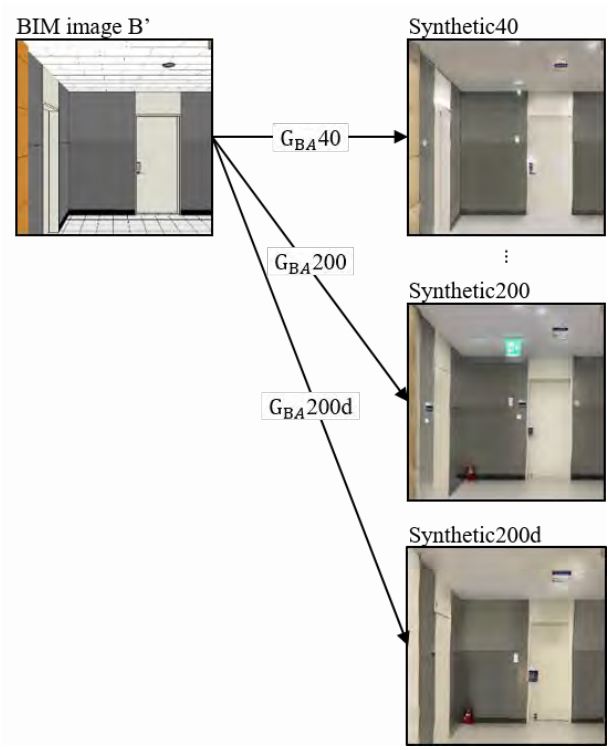

Figure 3. The process of synthetic data generation

4 Experimental Study

4.1 Dataset

The real-world domain training dataset was taken in the corridor of the north wing on the fifth floor of Yonsei University's first engineering building. 550 images were scaled from 3024 × 3024 to 512 × 512 pixels. Another training dataset, BIM domain, was extracted from Yonsei University's first engineering building BIM, which was implemented in Revit software. This BIM is the same as that used in Inhae Ha et al. [20]. 564 images with image size 512 × 512 were obtained by creating 3D views and extracting views as image files. The 3D views were also constructed in the north wing on the fifth floor of BIM.

The dataset, used as an input of generator G_{BA} to generate synthetic datasets, is a set of 100 512 × 512-sized images that do not overlap with training dataset.

4.2 Implementation

CycleGAN was trained with λ of 10 in Equation (2) and a batch size of 1. As mentioned in section 3.2, two settings of the learning rate were used: (1) non-decay setting and (2) decay setting.

4.3 Results and Discussion

This section compares one BIM dataset and eight synthetic datasets. The notation for the synthetic dataset is the same as for the generator. Figure 4 shows the image examples of BIM and synthetic datasets.

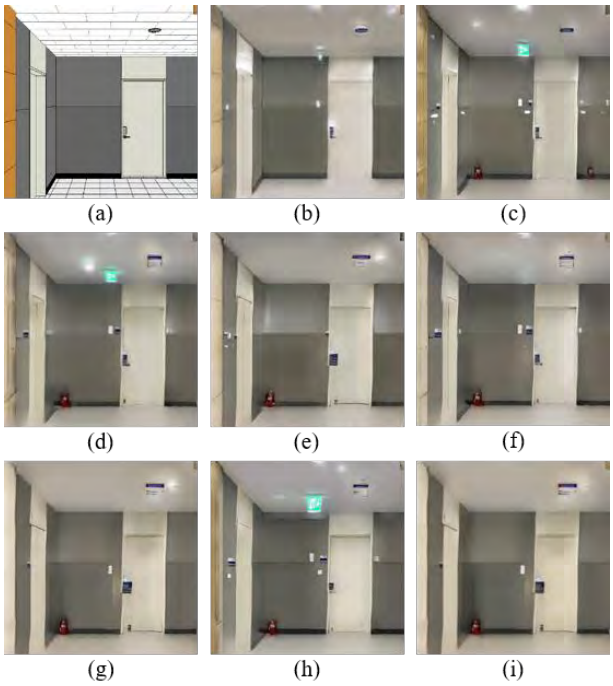

Figure 4. Examples of results from different datasets; (a) BIM, (b) Synthetic40, (c) Synthetic80, (d) Synthetic120, (e) Synthetic120d, (f) Synthetic160, (g) Synthetic160d, (h) Synthetic200, (i) Synthetic200d

As shown in Figure 4(b), synthetic40 looks similar to BIM. The color changed similar to the photograph, and the light shape and part of the exit marking in the BIM were generated. Some noise generated patterns of doorplates that appeared in the photograph. The grid patterns of floor and ceiling in the BIM have not yet disappeared. Synthetic80 shows the disappearance of a number of doorplate patterns in Figure 4(c). The position of the light is similar to the photograph, and the reflection of the light on the walls looks realistic in synthetic80. As shown in Figure 4(h), BIM's floor pattern and repetitive

patterns (especially in wood and brick area) are almost eliminated in synthetic200.

As a result of the style transfer, it was found that the network produced small objects such as the fire extinguisher and exit marker, and caused color changes to produce values similar to those of photograph. In that process, small patterns such as exit marker appeared and disappeared, depending on the number of epochs. It is assumed that the synthetic200 and synthetic200d, the models trained with the 200 epochs, did not converge.

Cosine similarity was used as an indicator of evaluating synthetic datasets. Cosine similarity is a measure of the similarity of two vectors. The cosine similarity was calculated between the photographs having the same scene and generated synthetic datasets. Table 1 shows the average and standard deviation of cosine similarity. All the synthetic datasets have cosine similarity greater than BIM dataset.

Table 1. Average and standard deviation of cosine similarity with same scene real dataset

Dataset	Cosine Similarity Avg.	Cosine Similarity Std.
BIM	.9145	.0220
Synthetic40	.9488	.0198
Synthetic80	.9495	.0193
Synthetic120	.9497	.0204
Synthetic120d	.9479	.0211
Synthetic160	.9492	.0217
Synthetic160d	.9454	.0232
Synthetic200	.9500	.0209
Synthetic200d	.9442	.0237

The synthetic datasets with photograph style and BIM content were created. The datasets, whose label can be easily obtained from BIM, are valuable as the training datasets of the segmentation model. In further research, the segmentation model will be trained with synthetic datasets and the performance of the model will be evaluated to assess whether the datasets are adequate for scene understanding.

5 Conclusion

This study proposed a method for generating synthetic image data that can be used as a training set for scene understanding in the field of facility management. In the proposed method, CycleGAN is used to train a mapping function such that transfer between BIM images and their corresponding real-world images is performed. The generator of the proposed model produces synthetic data similar to real images using the BIM images. Cosine similarity values calculated using corresponding scene-photographs showed that the synthetic data are more realistic than BIM images. The label of synthetic data is the same as that of the corresponding BIM image, so labelled data can be obtained without any annotating works. This method could be highly beneficial for collecting data to train deep learning models in that the models usually require a large amount of data. In the experiment, noise patterns on the synthetic data appeared and disappeared repeatedly as the training of CycleGAN progressed. The noise patterns are expected to adversely affect the training of deep learning models when synthetic data, including the patterns, are used as training data for the models. To tackle this problem, further research should be conducted to improve the stability of training. In a future study, synthetic datasets generated in consideration of the aforementioned problem will be used as training sets for scene understanding.

Abstract –

The article is devoted to the problem of improving the reliability and efficiency of the operation of mechatronic sliding complexes. To solve this problem, a cyber-physical system is proposed that implements the diagnosis and prediction of the technical condition of servo drives. Methods for calculating the current and additional loads on servo drives are proposed. Recommendations are given on changing the lifting mode of the sliding formwork de-pending on the technical condition of the servos.

1 Introduction

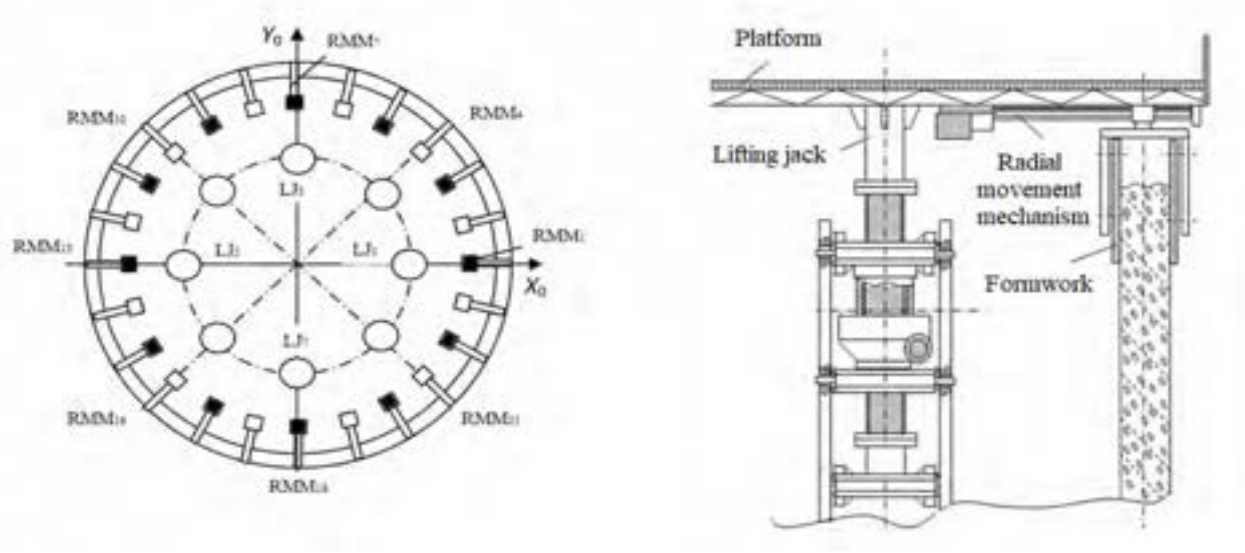
Construction is one of the main actively developing sectors of the national economy of any country. Every year the number of high-rise buildings is growing steadily. Constantly changing requirements for the quality and speed of construction of the building. It leads to the emergence of new construction technologies using robotic and mechatronic systems, allowing high-precision performance and good quality of construction. To solve this problem, it is necessary to ensure the reliable functioning of all the machines and mechanisms of the complex that operate in tight relationship with each other. Analysis of the construction of high-rise buildings technology showed that the main actuating elements of the buildings mechatronic complex are DC or AC servo motors. Their proper work determines the buildings and structures quality. Failure or malfunction of one of the drives can lead to disruption of the entire complex, damage to building materials and to the construction of inadequate quality. Therefore, the urgent task is to ensure the reliable functioning of all the servos included in the mechatronic complex. This problem can be solved by cyber-physical system synthesis that implements monitoring of each servo motors technical condition and optimizing the technological process at the construction site, taking into account the current and predicted state of building robotic and mechatronic complex servo motors.

2 Mechatronic sliding formwork complex structure

The most common method of high-rise buildings and structures is monolithic construction [1]. Technology this method provides a continuous supply and laying of concrete, installation of rebar, formwork hoist, regulation of project sizes and control settings of the building [2]. The modern method of automation of monolithic construction is the use of mechatronic sliding formwork complex (Fig.1), which is a spatial form installed on the perimeter of the structures and moved up by lifting jacks (LJ) [3].

The position of the formwork panels is fixed by Jack frames that accept the loads of the laid concrete. Lifting of the formwork is carried out by Electromechanical lifting jacks based on DC or AC servo motors. Jacks should provide high load capacity, synchronous movement of the formwork, lifting speed regulation and ease of maintenance [4]. It also includes adjustment mechanisms, dynamic properties, design and technological features that determine the structure of control algorithms and the choice of control laws. For example, for structures of conical and hyperbolic shape, these are radial movement mechanisms (RMM), which are located along the radius with a uniform step (Fig.1,a). Their task is to move the formwork panels in the process of lifting it. Changing the position of the boards should be synchronized with the LJ. To do this, the number of RMM mechanisms (m) is chosen as a multiple of the number of LJ (n). This will allow the platform radial beams to be distributed evenly with angular pitch $2\pi/m$ and used for the RMM installation. Important conditions for the quality of construction work are the con-

tinuity of the technological process and maintaining a constant movement speed of the formwork not less than 1 cm/min, as well as the need to strictly horizontal platform. To implement these requirements, it is necessary to ensure consistent operation of all servo motors included in the complex. This problem can be solved by using methods and tools for predictive diagnosis of LJ and RMM servo motor with its operation mode subsequent optimization. For this purpose, it is necessary to provide the technical condition control of all servo motors which are a part of the MSFC, information exchange between drives and decision-making for MSFC operation mode changing.



a) b)

Figure 1. Mechatronic sliding formwork complex (MSFC): a) longitudinal and vertical section of the MSFC; b) the distribution of lifting jacks (LJ) and radial movement mechanisms (RMM) in the plane of the complex platform.

The implementation of this approach involves the integration of computational resources into physical processes using a cyber-physical system. In such a system, sensors, equipment and information systems interact throughout the life cycle of the MFSC and information exchange is carried out using standard Internet protocols. This allows performing self-tuning and MSFC adaptation to changing operating conditions and technical condition of the equipment. Therefore, the development the analysis methods and optimal synthesis of cyber-physical systems for technical condition diagnosis the of MSFC servo motors to improve the operation efficiency and their operational safety ensure is very important.

3 The cyber-physical system structure

The cyber-physical system should implement the collection of diagnostic information, its processing, storage and analysis to determine the current technical conditions, defects development forecasting and the servo failure time determination, MSFC operation mode optimization depending on the its servos technical condition. The cyber-physical system includes the cyber and physical parts (Fig. 2), and the main functions are transferred to the software part. The physical part of the system is represented by the "Hardware" block, which includes MSFC servo-drives functioning in a given technological process. The cyber part is represented by the “Data” and “Internal Software” blocks.

The “Data” block provides diagnostic information from the sensors of the facility, as well as storing the diagnostic results for previous periods of operation of the MSFC in a database used for the technical condition forecasting.

The “Internal software” block analyzes the current and predicted technical condition of all servo drives of the MSFC followed by a decision to change the mode of its operation. The “Internal software” block analyzes the current and predicted technical condition of all MSFC servo drives followed by a decision to change the mode of its operation. In this structure, the technical condition predictive diagnosis is implemented for each servo motor and decision-making is performed for the entire MSFC as a whole.

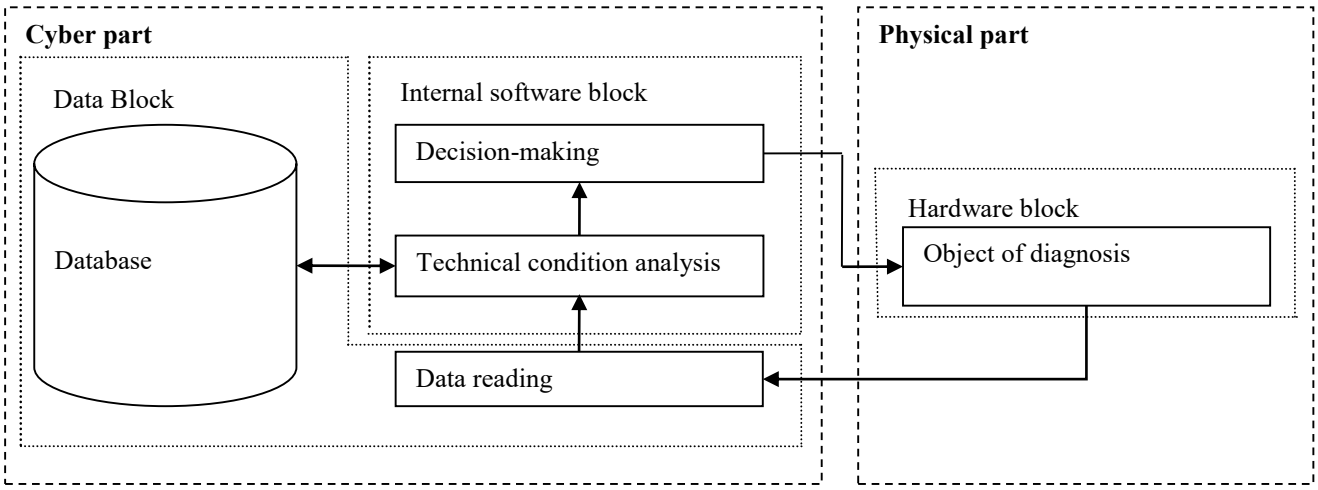


Figure 2. The structure of the information processing in cyber-physical system MSFC predictive diagnosis

Based on this, the architecture of the cyber-physical system has two levels. The main computing function of the system is performed by the lower level associated with the object of diagnosis. At the same time, a higher level of the system will receive information exclusively on the results of diagnostics and prediction of the status of servos and make a decision on reconfiguring the system and changing the operating mode of the mechatronic sliding complex

4 The lower level of the cyber-physical system

4.1 Servo motors diagnosis method

At the lower level of the cyber-physical system, the tasks of determining the current and predicted technical condition of each MSFC servo drive are solved.

For its implementation, it is necessary to develop methods that satisfy the following requirements:

- ability to assess the technical condition in real time;
- minimum composition of measured parameters;
- lack of complex bulky measuring equipment installed on the body of the servo drive, affecting the operation of the MSFC;
- ability to use on a moving object in conditions of high humidity and dustiness of the working environment;
- applicability for AC and DC servo motors;
- ability to automatically analyze the measured parameters in real time;
- ability to record and store diagnostic results on a cloud server and provide the user with an Internet protocol.

Analysis of existing methods and diagnostic tools showed that the only method that satisfies most of the above requirements is the analysis of current consumption. To synthesize a method for analyzing temporary servo signals using wavelet transform, a number of experimental studies have been carried out to diagnose servo motors at different loads. The measured time signals of the servo current were decomposed using a Morlet wavelet in a selected range of scales and a comparative analysis of the results was performed. The results of the analysis of the current signals of the servo drive at various rotational speeds and loading modes made it possible to establish a regularity between the type of wavelet-coefficient graph and the technical state of the servo motors [5]. The established graph types of wavelet coefficients can be classified into three groups: decaying, linear, increasing. Damped oscillations are characteristic of a healthy servo motor, linear - for a faulty unloaded motor, and increasing - for a faulty loaded motor.

To formalize the derived regularity, it is advisable to use the Hilbert transform, which allows for the function of the continuous wavelet transform $\psi_{ab}(t)$, calculated for each characteristic scale to calculate the analytically conjugate function $\hat{\psi}_{ab}(t)$, the mathematical form of which has the following form:

$\hat{\psi}_{ab}(t) = \int_{-\infty}^{\infty} \frac{\psi_{ab}(\tau)}{t-\tau} d\tau = I\left[\psi_{ab}(t)\right]$,

Based on these two functions, an analytical signal is generated.

$$s(t) = \psi_{ab}(t) + j \cdot \hat{\psi}_{ab}(t)$$

from which it is possible to find the instantaneous amplitude (envelope of the signal):

$$A(t) = |s(t)| = \sqrt{{\psi_{ab}}^2(t) + {\hat{\psi}_{ab}}^2(t)}$$

As a result, pairs of points $t(t_1, t_2, \ldots . t_n)$ and ψ_{ab} $(\psi_{ab1}, \psi_{ab2}, \ldots . . \psi_{abn})$ between which there is some dependence $\psi_{ab_i} = f(t_i)$ are obtained.

To search for the analytical dependence, the least squares method was used, according to which the arguments of the function $f(t, c_1, c_2, \ldots c_k)$ must be chosen so that the sum of the squares of the deviations of the measured values

$Y = f(t, c_1, c_2, \ldots c_k)$ minimal

$$S(c_1, c_2, \dots c_k) = \sum_{i=1}^{n} (Y_i - \psi_{ab_i})^2 \to min$$

For a formal description of the envelope obtained as a result of experimental researches, it is advisable to choose a polynomial of degree m, the generalized formula of which has the following form:

$$\psi_{ab}(t) = c_0 + c_1 t + c_2 t^2 + \dots + c_m \mathrm{t}^{\mathrm{m}}$$

The goal of the envelope description being performed is the mathematical formalization of its shape, which allows us to unambiguously describe the process taking place on a given scale. Since the envelope graph has three characteristic features: it is downward, linear, or upward, the change in the amplitude of the wavelet coefficients in time can be unambiguously described using the linear law. Therefore, to formalize the shape of the envelope of the signals, it suffices to choose a polynomial of the first degree.

$$\psi_{ab}(t) = c_1 t + c_0$$

Thus, the problem of approximating the shape of the envelope of the wavelet coefficients can be reduced to obtaining a straight line equation of the type $y = kx + b$, (where $c_1 = k, c_0 = b$), the coefficients of which allow us to describe the main changes in the wavelet coefficients on the selected scale. An analysis of the coefficients k and b of the approximating straight envelope of the wavelet coefficients at characteristic scales showed that a working servo corresponds to a coefficient $k < 0$, and the approximating straight line descends to the abscissa axis, $k \geq 0$ is typical for a faulty state of the servomotor. Coefficient b is always positive, however, with an increase in load on a serviceable drive, coefficient b increases and k decreases.

For a faulty servo motor, an increase in load will lead to an increase in all the parameters of the approximation line. Thus, the sign of the coefficient k of the approximating direct envelope at the characteristic scales of the wavelet coefficients will determine the current state of the servo motor.

4.2 Current servo motor load determination

To determine the current load of the servo motor, it is necessary to calculate the coefficients of the approximating straight envelopes at characteristic scales for a known-good unloaded servo drive ($k_0,\ b_0$) and at maximum load (k_{max}, b_{max}).

The passport data of any servo contains the overload capacity of the servo current K_T, which is calculated by the following formula:

$$K_T = \frac{I_{max}}{I_{nom}}, \text{ then } I_{max} = K_T I_{nom}$$

where I_{max}, I_{nom} - maximum permissible and rated currents of the servo drive.

If the coefficients k_0, b_0 correspond to the rated current, then k_{max}, b_{max} will correspond to the maximum permissible current. Then

$$k_{max} = \frac{k_0 \cdot I_{max}}{I_{nom}} = \frac{k_0 \cdot I_{nom} \cdot K_T}{I_{nom}} = k_0 \cdot K_T;$$
$$b_{max} = \frac{b_0 \cdot I_{max}}{I_{nom}} = \frac{b_0 \cdot I_{nom} \cdot K_T}{I_{nom}} = b_0 \cdot K_T.$$

The coefficients of the approximation straight line k and b of a healthy servo motor are in the following range:

$$k_{max} \leq k \leq k_0 \qquad b_{max} \leq b \leq b_0$$

If the coefficients go beyond the specified limits, it is urgent to stop the operation of the servo drive.

Relative coefficients showing the load on the servo drive can be calculated from the following relationships:

$$\Delta k = \frac{k - k_0}{k_{max} - k_0}; \qquad \Delta b = \frac{b - b_0}{b_{max} - b_0}$$

If $k = k_0$ and $b = b_0$, then $\Delta k = 0, \Delta b = 0$, which indicates the absence of load on the drive. If $k = k_{max}$ and $b = b_{max}$, then $\Delta k = 1$, $\Delta b = 1$, which shows the maximum load on the servo drive. If $k \in [k_0, k_{max}]$, $b \in [b_0, b_{max}]$,, then $\Delta k \in [0,1], \Delta b \in [0,1]$. If $\Delta k < 0$, then the servomotor is faulty and must be turned off. If $\Delta k > 1, \Delta b > 1$ then the load level is higher than the maximum permissible value and it is necessary to change the operating mode of the servo motor.

If both factors are within the specified limits, then you can determine the level of load on the servo motor.

A fuzzy logical model has been developed, the inputs of which are the relative coefficients Δk and Δb, and the output is the level of load on the servo as a percentage of the maximum permissible. To describe such a model, a *Sugeno*-type fuzzy logic inference system with two inputs and one output is used. For each input parameter on the interval [0; 1] the corresponding membership functions are set (Fig. 3). The output parameter *Load* is the corresponding coefficient on the interval [0; 100], showing the percentage of engine load. If this parameter is equal to zero, then the servo drive operates in the nominal mode without load. If it is 100%, then the engine has a maximum load and it is necessary to change its operation mode.

The relationship between the introduced sets is described by the following fuzzy rules:

R_1: *If* k *is* k_0 *and* b *is* b_0, *then* $Load = l_1$;
R_2: *If* k *is* k_{max} *and* b *is* b_{max}, *then* $Load = l_2$;

To convert clear input values to clear output, n is used - the *Takagi – Sugeno* algorithm [6].

The resulting model allows us to determine the degree of loading of the servo motors as a percentage of the maximum permissible value from the analysis of the coefficients of the approximation direct envelope.

This will allow you to choose the operating mode of each specific drive and optimize the operating mode of construction robotic and mechatronic complexes in order to increase their reliability and efficiency.

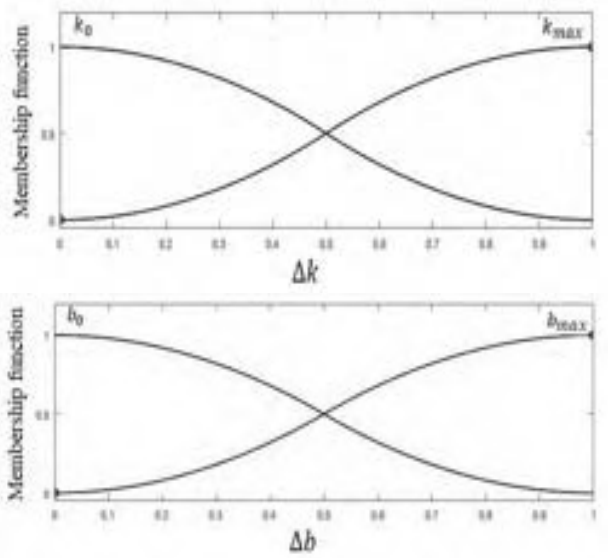

Figure.3. Input data of a fuzzy model for servomotor load determination

4.3 Prediction of technical condition

A method for servo motor technical condition prediction using neural networks is proposed. The forecasting initial data are the trend of the coefficients *k* of the approximating direct envelope of the wavelet coefficients of the current signals at characteristic scales for previous periods of operation, distributed over equal time intervals. The forecasting process includes three levels. At the first level, the values of the coefficients *k* of the approximation direct envelope of the wavelet coefficients for each characteristic wavelet scales are predicted. A direct signal transmission network with three inputs and one output is simulated.

The input vector of the neural network

$$P = [k(t_1),...k(t_{N-3}); k(t_2),...k(t_{N-2}); k(t_3),...k(t_{N-1})]$$

The target vector *H*, the values of the determining parameter are set, which should be obtained at the output

$$H = [k(t_4),...k(t_N)].$$

For a given input *P*, the neural network calculates the output value of the predicted parameter *C*

$$C = [k(t_{N-2});\ k(t_{N-1});\ k(t_N)],$$

corresponding to a given target vector *H*.

To train the neural network, the back propagation algorithm is used.

Similar calculations are performed for each scale of wavelet coefficients. If during the calculation all the coefficients are negative, then the servomotor will remain operational in the next period of operation. If at least one is zero or positive, then in the next period of operation the object will fail.

The forecast at the next levels is an approximation of the values obtained at the previous level. To predict the time of the onset of faults, network outputs are needed that predict the values of the corresponding coefficients of the approximation straight envelope of the wavelet coefficients, apply to the input of the radial basis network. Since the output of the first level consists of values of the coefficients k, negative values of which indicate a working condition, and zero or positive ones indicate a faulty state of the servo, the result of the next level of forecasting can be obtained by maximizing the previous level. The determination of the development coefficients of the motor malfunction K_{MOTOR} ·

$$K_{FAULT_j} = \max(\exp(-(\sum(K_i \cdot IW^{1.1} + b))^2);$$

$$K_{MOTOR} = \max(\exp(-(\sum(K_{FAULT\,i} \cdot IW^{1.2} + b))^2),$$

where $IW^{1.1}$ $IW^{1.2}$ - weights vector of the first (development of a malfunction) and second (forecast of the state of the servo motors) of the approximation steps.

To determine the servo motor failure time, it is necessary to add the predicted values of the coefficients of the approximation direct envelope of the wavelet coefficients in the training set and repeat the entire forecasting process until the coefficient determining the state of the servo motor becomes $K_{MOTOR} \geq 0$. The number of iterations passed will be equal to the number of time intervals *T* during which the servomotor remains operational. The implementation structure of the above method is shown in Fig. 4

The proposed method for forecasting the technical condition will allow short-term and long-term forecasting of defects of each MSFC servo motor. The results will be used for subsequent optimization of the operating mode of MSFC.

The proposed method for forecasting the technical condition will allow short-term and long-term forecasting of defects of each MSFC servo motor. The results will be used for subsequent optimization of the operating mode of MSFC.

5 Cyber-physical system upper level

According to the developed architecture, the upper level collects information about the current state, load and the forecast period of maintaining operability from all MSFC drives and makes a decision on its further operation.

Let be *m* - number of radial movement mechanisms; *n* - is the number of lifting jacks of the MSFC. An important condition for the operation of the system is the identity of the RMM and LJ drives, as well as the uniformity of their loading

If $Load_{RMM}$ and $Load_{LJ}$ corresponding load on each servomotor RMM and LJ, then the total load on all drives of the system will be calculated as follows:

$$\sum Load_{RMM} = m \cdot Load_{RMM};$$
$$\sum Load_{LJ} = n \cdot Load_{LJ}.$$

If the number of simultaneously operating drives RMM as m^*, where $m^* = 1 \ldots . m$ and LJ as n^*, where n^*, then the total load on simultaneously working drives can be determined from the relations

$$\sum Load^*_{RMM} = \frac{m}{m'} \cdot \sum Load_{RMM};$$
$$\sum Load^*_{LJ} = \frac{n}{n'} \cdot \sum Load_{LJ}.$$

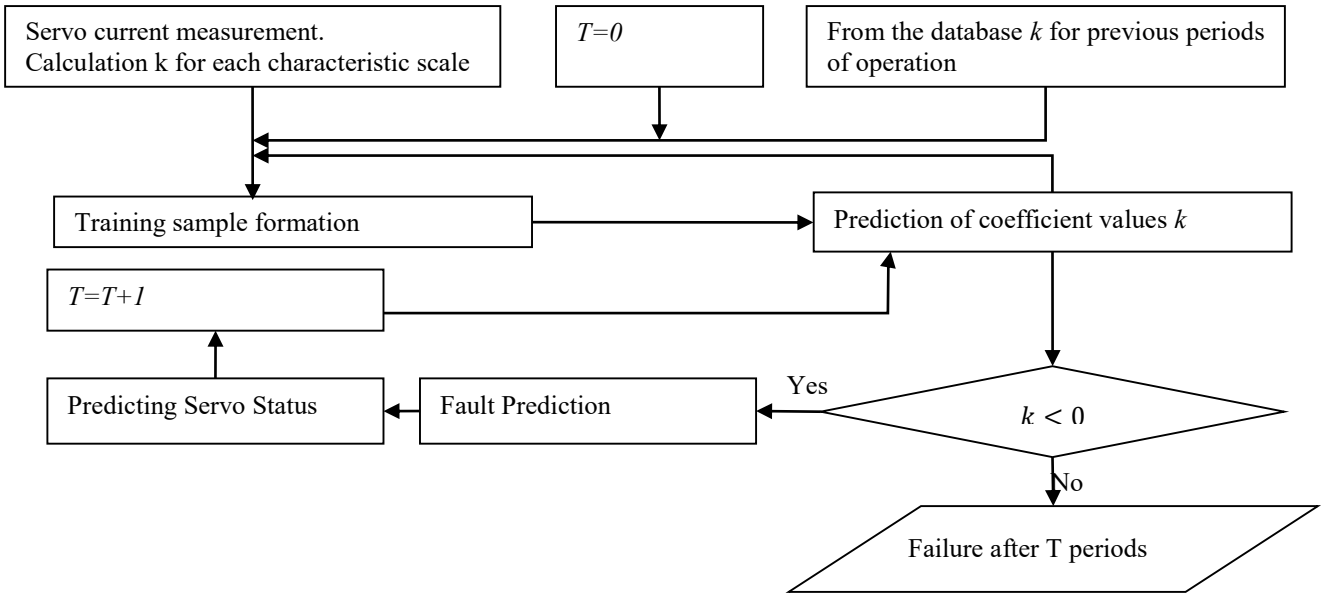

Figure. 4 Structure of the implementation of the method for predicting the technical condition of MSFC servo motors

The additional load on each drive can be found from the ratio

$$\Delta Load_{RMM} = \sum Load^*_{RMM} - Load_{RMM};$$
$$\Delta Load_{LJ} = \sum Load^*_{LJ} - Load_{LJ}.$$

Thus, a ratio is obtained that, knowing the total number of RMM and LJ drives and the number of currently motors operation determines the required load increment for each motor.

The average ($Load$) and average additional ($\Delta Load$) load on the servos of the RMM or LJ group are determined from the relations:

$$Load = \sum Load_{i(j)} / n^*(m^*)$$
$$\Delta Load = \sum \Delta Load_{i(j)} / n^*(m^*),$$

where $Load_i,\ i \in [1, n^*]$; $Load_j,\ j \in [1, m^*]$ - load for each motor RMM and LJ; $\Delta Load_i,\ i \in [1, n^*]$; $\Delta Load_j,\ j \in [1, m^*]$ -additional load for each motor RMM and LJ.

The average predicted period of good operation of the servos group RMM and LJ

$$T_g = \sum T_{i(j)} / n^*(m^*)$$

where $T_i,\ i \in [1, n^*]$; $T_j,\ j \in [1, m^*]$ - the predicted period of good operation of each servo RMM and LJ calculated according to the forecasting model.

The simulated fuzzy logical decision-making system will have three inputs and one output. To convert clear input values into clear output, the *Mamdani* fuzzy logic algorithm is used [7-12]. The fuzzy knowledge base that describes the relationship between the input term sets and the output sets is presented in Table 1. The result of the decision-making model is the value of the decision $D \in [-1, 1]$.

Table 1. The truth table of the fuzzy decision-making model

Current motor load	**Change motor load, %**		
	Less 20	**25**	**More 30**
Forecasted period of service 1 month			
Less 30	+1	+1	-1
50	-1	-1	-1
More 60	-1	-1	-1
Forecasted period of service 3 month			
Less 30	+1	+1	+1
50	+1	+1	0
More 60	-1	-1	-1
Forecasted period of service more 6 month			
Less 30	+1	+1	+1
50	+1	+1	+1
More 60	0	0	0

If $D > 0$, then it is necessary to change the load on serviceable servos of the group by the value $\Delta Load$. If $D=0$, then the operating mode must be left unchanged. If $D<0$, then the condition of the drives of the group is unsatisfactory and it is necessary to stop the process. Based on this model, an intelligent decision-making method has been developed on the operation mode of each of the MSFC servo groups based on the technical condition of its servos, the implementation structure of which is shown in Fig. 5.

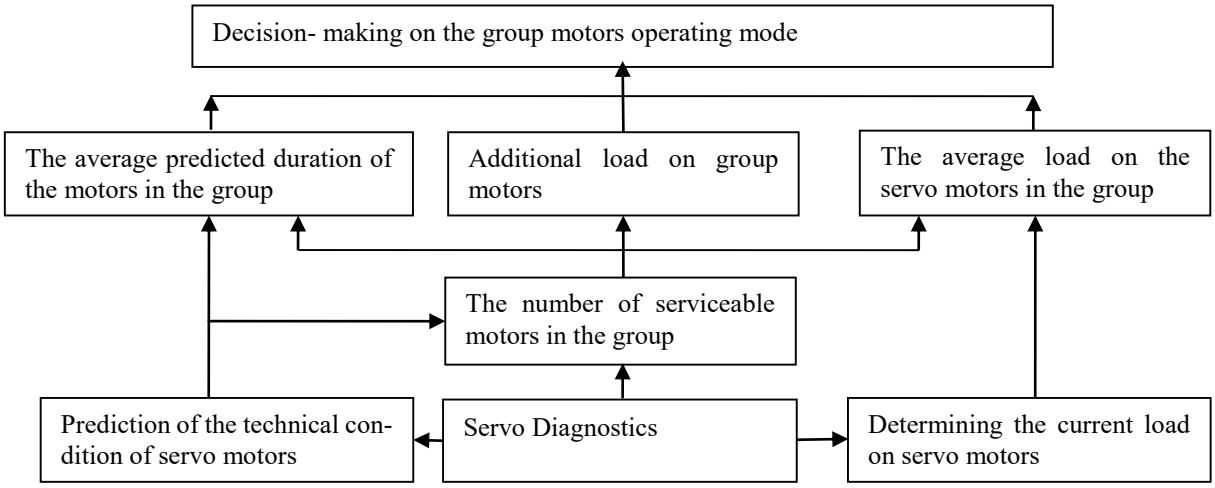

Figure 5. The structure of the implementation of the intellectual decision-making method for managing building mechatronic and robotic complexes according to the results of diagnosing their servos

6 Experimental research

A study of the prediction diagnosis methods of MSFC has been performed. For servo motor KY110AS0415-15B-D2-2000 was carried out according to the measurement of the current signal from January 2008 to January 2015. The obtained records of the supply current signals were processed using the proposed diagnostic method. The coefficients of the approximation straight envelope are found for each scale. According to the data obtained, it is clear that in January 2015 this servo motor was in the boundary state, since the approximation coefficient k for the rolling bearing malfunction is close to 0. According to the record in the equipment maintenance journal, the KY110AS0415 - 15B - D2 - 2000 servo drive failed on 27.02.2015 due to wear of the bearings, which confirms the accuracy of the proposed diagnostic method. According to the values of the coefficients *k* for the period from 2008 to 2012, the values of these coefficients are predicted for 2013-2015. A comparison of the results of diagnosis and forecasting (Fig. 7). It can be seen from this graph that, according to the forecast, the failure of the servo drive occurred earlier than in fact, which will prevent a sudden failure of the equipment. The analysis of the effectiveness and reliability of the proposed methods of predictive diagnosis.

It is established that the use of these methods will increase the coefficient of technical use by 16%. The reliability of the diagnosis is 93%. The accuracy of short-term forecasting is 1.7%, long-term forecasting does not exceed 10%. Prediction accuracy can be increased by increasing the volume of the training sample, as well as adding it to the current values of the diagnostic parameters.

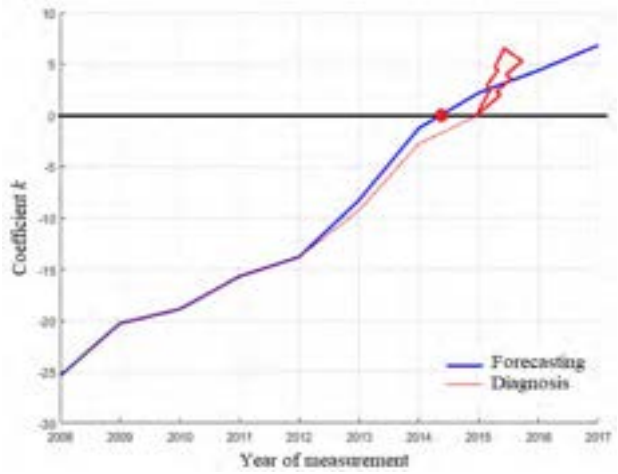

Figure 7. Comparative analysis of the diagnosis and forecasting results

A study of the prediction diagnosis methods of MSFC has been performed. The experimental stand was a fragment of a sliding formwork of four lifting jacks interconnected by formwork panels suspended on crossbars. This stand was put into step-by-step motion at a speed of 1 cm / min. For each scale of wavelet coefficients, the relative coefficients of the approximation straight envelope were calculated, which were substituted into the model for calculating the load. As a result of the calculation, it was found that the average load on the drive is approximately the same and amounts to 29.52% of the maximum, which corresponds to the average statistical load on the formwork drives during operation. The health checks of the models for calculating the load change and the decision on

the control of servo drives were carried out with the KY110AS0415-15B-D2-2010 formwork drive turned off. The objective of the experiment was to calculate the necessary change in the load on the three remaining drives and to study the behavior of the system when working on three servos. To compensate for the failure of one of the drive jacks, it is necessary to increase the load on each of the three remaining drives by 9.84%. As a result of the calculation using a fuzzy decision-making model, it was found that the current load on the group drives can be increased by $\Delta Load = 9{,}84$ %.

For the three switched-on drives, the load on the calculated percentage was increased and the speed of the fragment of the sliding formwork was measured. The results of the study showed that the control system allows for uniform constant movement of formwork panels with a given speed of 1 cm / min with four drives with a load of 29.52% each, and with three motors with a load of 39.36%.

The nature of the movement of the mechanism remains almost unchanged when the load is redistributed within the motors group. This makes it possible to carry out repair work on replacing a faulty drive without stopping the process, reducing complex performance and losing quality of the monolithic structure being constructed.

7 Conclusions

The article presents the structure of the cyber-physical system for predictive diagnosis of the technical condition of MSFC servo motors. This system contains two levels. The first level is connected to the servos and provides their predictive diagnosis. At the second level, decision making and changing the operating mode of the servo drive are implemented. The innovative methods of diagnosing and predicting the technical condition are described. Methods of calculating the current and additional load are presented, as well as a decision-making model on the advisability of changing the load on the servos depending on the current state of operable motors.

Abstract –

In Japan, earthmoving workers are aging rapidly, and more than one million skilled workers will retire at once in the near future. Thus, the mass retirement of these skilled technicians could bring a significant drop in production capabilities throughout the earthmoving industry. To solve this problem, it is expected that automatic construction systems using robotics technology will improve productivity at earthmoving field. To efficiently promote further advancements in earthmoving automation research, it is necessary to systematize the entire earthmoving construction and classify automation levels.

In this paper, we formed a team in collaboration with project owners, civil engineers, engineers of construction machinery manufacturers, and robotics researchers, and others. Then, with them, we attempted to formulate a "automation system diagram for earthmoving work" to systematize the entire earthmoving construction, and "automation levels for earthmoving machinery" to grasp the achievement of current technologies. It is anticipated that these will make it possible to give concrete shape to research aims and plans, and that automation research will proceed as a result.

Keywords –

Earthmoving machine; Automation; system diagram; level

1 Introduction

The aging of workers in Japan's construction industry has been progressing rapidly in recent years. The percentage of construction workers aged 55 years or older, which stood at 24.2% in 1998, rose to 34.1% in 2017. Meanwhile, the percentage of workers aged 29 or younger, which was 21.6% in 1998, fell to 11.0% in 2017 (Figure.1, [1]). Moreover, looking at the number of construction workers by age group in 2015 (Figure.2, [2]), a reverse pyramid is created whereby the number is largest in the elderly group and becomes smaller with each descending age group. This problem is more serious in the earthwork field than in the building field.

From this, it is estimated that at least one million skilled technicians will retire in the near future. The production capabilities of skilled technicians (having at least 15 years of experience) is roughly 1.8 times that of less-skilled technicians (having experience of less than

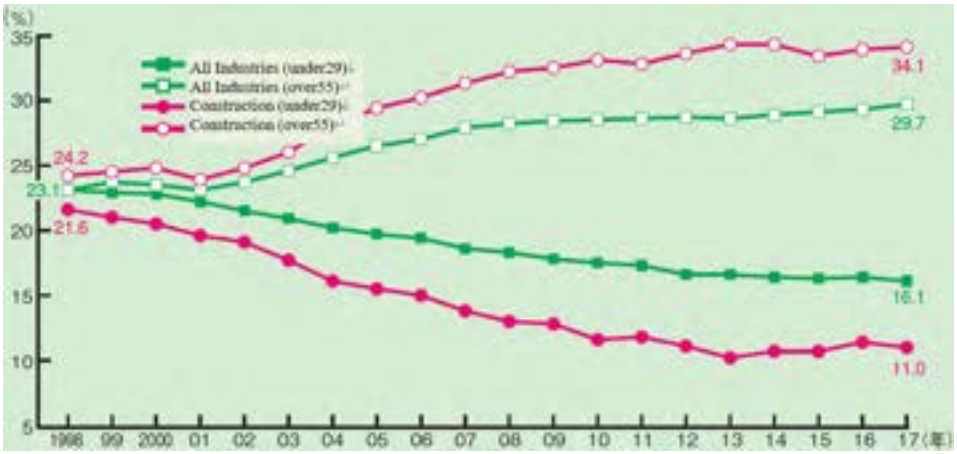

Figure 1. Number of workers [1]

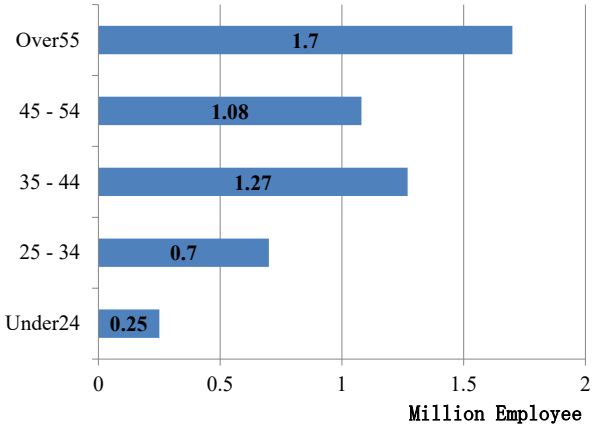

Figure 2. Number of construction workers (2014) [2]

ten years) [3]. Thus, the mass retirement of these skilled technicians could bring a significant drop in production capabilities throughout the earthmoving industry.

It is expected that one way of resolving this problem is to improve productivity by applying robotics technologies in earthmoving work. Specifically, it is anticipated that automating earthmoving work with robotics technologies will raise the production capabilities of less-skilled technicians and achieve manpower savings at earthmoving sites. A number of such automation technologies have already been studied and some are being put to practical use [4] – [11].

However, most of the research conducted so far has been limited to the automation of individual earthmoving machinery, and is far from the automation of the entire earthmoving work.

To efficiently promote further advancements in earthmoving automation research, it is necessary to clarify the research goal to be carried out next by understanding the scope that the current research occupies in the entire earthmoving work and the degree of achievement of the research. For that purpose, it is necessary to systematize the entire earthmoving construction and classify automation levels. There are some examples of these studies in the earthwork field [12] – [14]. However, these are discussed on limited conditions only, and overall examination by many category researchers (for example, owner, contractor, robotics engineer, etc..) is insufficient.

In view of this, we, the authors, formed a team in collaboration with project owners, civil engineers, engineers of construction machinery manufacturers, and robotics researchers, and others. Then, with them, we attempted to formulate (1) a "automation system diagram for earthmoving work" to systematize the entire earthmoving construction, and (2) "automation levels for earthmoving machinery" to grasp the achievement of current technologies. It is anticipated that these will make it possible to give concrete shape to research aims and plans, and that automation research will proceed as a result.

This paper presents one such proposal that we studied toward this end.

2 Study of a vision and an automation system diagram for earthmoving work

Earthmoving work involves various types of work, for example embankment work, cutting work, slope work, and soil improvement. earthmoving sites are comprised of the some types of work that are required there. For example, if a site is for road construction, it will be comprised by embankment work, cutting work, culvert work, and pavement work, etc..

Additionally, types of work are largely divided into components termed "construction," "construction planning," and "inspection." "Construction" is the execution of actual work by earthmoving machinery and people; "construction planning" includes the ordering, arrangement, and scheduling of personnel, machinery, and materials; and "inspection" is the task of inspecting daily operations and final products to determine if they meet specifications.

Furthermore, there are elements that comprise each of the components of "construction," "construction planning," and "inspection." For example, "construction" in embankment work that is part of road construction is mainly comprised of the four operations using various types of earthmoving machinery shown in Table 1. In the case of "construction planning", it is comprising elements include "effective arrangement of machinery, workers, materials, etc." "appropriate ordering" and "coordination of various types of machinery". While in the case of "inspection," it is comprising elements include "measurements of layer thickness, as-built form, density, etc." and "pass/fail judgments."

Figure 3 provides an outline of the study detailed above. It is an "automation system diagram for earthmoving work."

We presented "road construction" and "embankment work" as examples for this diagram. However, it is possible to prepare diagrams for various types of work by changing necessary components and elements.

3 Study of automation levels for earthmoving machines

Next, we conducted our study with the goal of proposing "automation levels for earthmoving machines" necessary to grasp the performance of current technologies.

Here, we studied with the following approach, referring to the previous research [12] – [14].

- "Construction" and "construction planning" are considered to be separate. This is because, as mentioned in the previous chapter, they are separate in the system diagram.
- Remote control is not included as an intermediate step to autonomous. This is because, remote operation is the

same as boarding operation, except that only the operation location is different.

Then, we decided to use the levels for motor vehicles, for which similar automation levels already exist, as a reference.

It should be noted that, in order to simplify our study, we narrowed it to the work of "excavating and loading by hydraulic excavator" in embankment work within road construction.

Table 1. Elements of construction (ex. embankment work)

Operations	Image
Excavation and Loading (Hydraulic Excavator)	Transportation and Dropping (Dump Truck)	
Spreading (bulldozing) (Bulldozer)	
Compaction (Compactor)	

3.1 Study of levels of driving automation for motor vehicles

The Society of Automotive Engineers (SAE) of the United States has issued a standard for levels of driving automation vehicle called SAE J3016 that has become the international mainstream. On this SAE J3016, the level is divided by whether "(1) vehicle motion control," "(2) object and event detection and response (ODER)," and "(3) dynamic driving task fallback (DDT fallback)" is handled by a person (driver) or by a car (system), and whether "(4) operational design domain (ODD = conditions)" is limited or not (Table.2, [15]).

Using these levels as a reference, we first decided to substitute items (1) to (4) above to achieve compatibility with earthmoving machinery.

3.2 Item substitution

(1) "Vehicle motion control" → "earthmoving machine control"

Here, we focus on earthmoving machine control. In the case of a hydraulic excavator used in embankment work, for example, this refers to commanding the excavator to move, excavate, rotate, drop soil, etc.

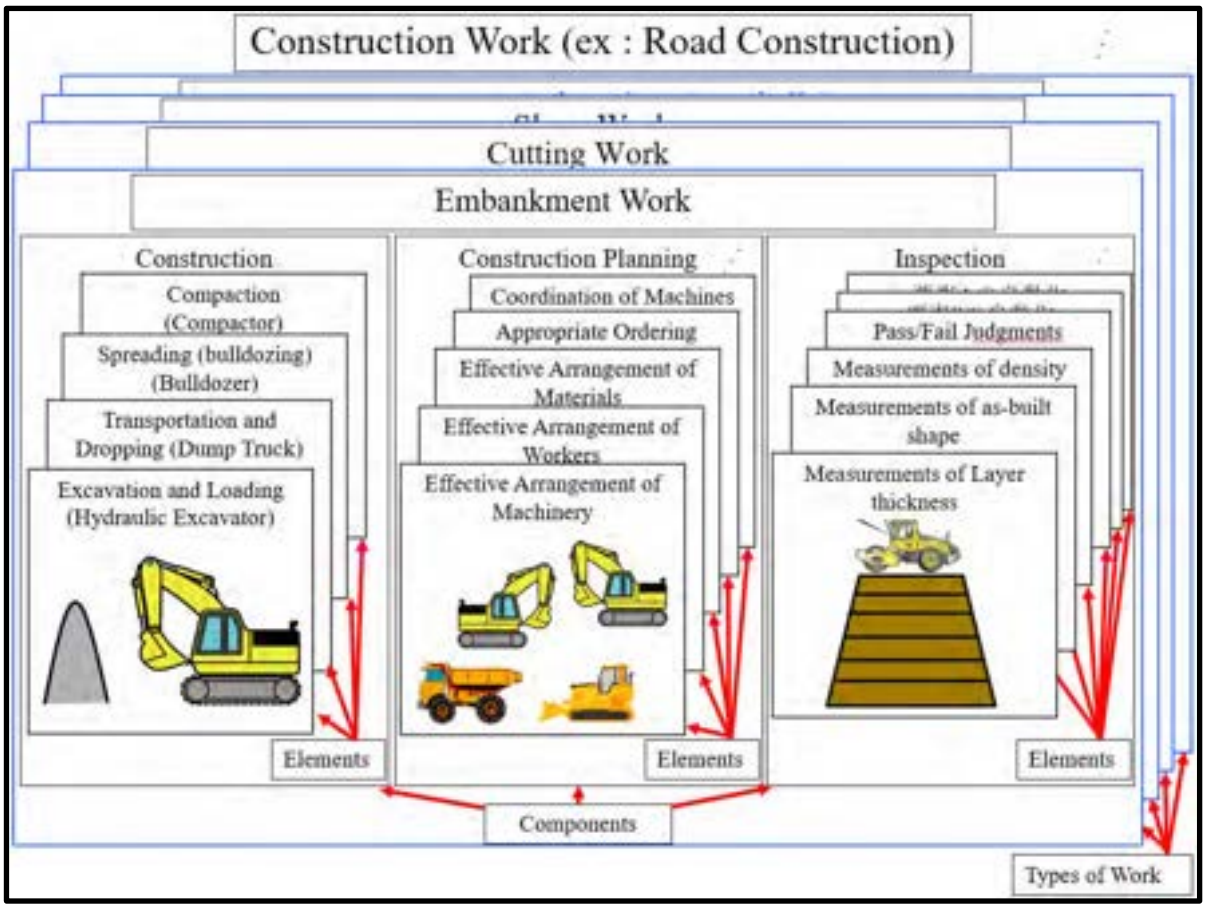

Figure 3. Automation system diagram for earthmoving work

(2) "Object and event detection and response" → "detection and judgment for high-efficiency construction"

This is the conscious (or unconscious) detection of surrounding information and judgment by the operator to improve construction efficiency. For example, in the case of a hydraulic excavator used in embankment work, this refers the detection and decision of optimal machine position, optimal excavation operation, optimal soil drop position, etc., based on conditions around the machine (e.g., locations of other machines, condition of materials).

(3) **"Dynamic driving task fall back" → "Response when autonomous operation is difficult to continue"**

This refers to response to unexpected events that make continuous automated driving difficult. In the case of a hydraulic excavator used in embankment work, for example, such events include obstacles within excavated materials, load spillage from the bucket, obstacles encountered while moving, deviation from course, etc.

(4) **"Operational design domain" → "site condition limitations"**

This refers to whether or not to limit the conditions of the construction site. Examples include topography (e.g., size or slope of worksite, etc.), ground (firmness, surface conditions, etc.), targeted material (type [such as sand or clay], moisture content, etc.), and weather.

Table 2. Levels of Driving Automation [15]

Level	Name	Narrative definition	DDT		DDT fallback	ODD
			Sustained lateral and longitudinal vehicle motion control	OEDR		
Driver performs part or all of the *DDT*						
0	No Driving Automation	The performance by the *driver* of the entire *DDT*, even when enhanced by *active safety systems*	*Driver*	*Driver*	*Driver*	n/a
1	Driver Assistance	The *sustained* and *ODD*-specific execution by a *driving automation system* of either the *lateral* or the *longitudinal vehicle motion control* subtask of the DDT (but not both simultaneously) with the expectation that the *driver* performs the remainder of the *DDT*	*Driver* and *System*	*Driver*	*Driver*	Limited
2	Partial Driving Automation	The *sustained* and *ODD*-specific execution by a *driving automation system* of both the *lateral* and *longitudinal vehicle motion control* subtasks of the *DDT* with the expectation that the *driver* completes the *OEDR* subtask and *supervises* the *driving automation system*	**System**	*Driver*	*Driver*	Limited
ADS ("*System*") performs the entire *DDT* (while engaged)						
3	Conditional Driving Automation	The *sustained* and *ODD*-specific performance by an *ADS* of the entire DDT with the expectation that the *DDT fallback-ready user* is *receptive* to *ADS*-issued *requests to intervene*, as well as to *DDT performance-relevant system failures* in other *vehicle* systems, and will respond appropriately	*System*	**System**	*Fallback-ready user (becomes the driver during fallback)*	Limited
4	High Driving Automation	The *sustained* and *ODD*-specific performance by an *ADS* of the entire *DDT* and *DDT fallback* without any expectation that a *user* will respond to a *request to intervene*	*System*	*System*	**System**	Limited
5	Full Driving Automation	The *sustained* and unconditional (i.e., not *ODD*-specific) performance by an *ADS* of the entire *DDT* and *DDT fallback* without any expectation that a *user* will respond to a *request to intervene*	*System*	*System*	*System*	**Unlimited**

DDT : DYNAMIC DRIVING TASK
ODER : OBJECT AND EVENT DETECTION AND RESPONSE
ODD : OPERATIONAL DESIGN DOMAIN

3.3 Study of automation levels

Table.3 shows the results of our study of automation levels for the work of "excavating and loading by hydraulic excavator" based on the items presented in the previous section are shown.

In this levels, we focused solely on the element of "excavating and loading by hydraulic excavator." However, it is possible to propose automation levels for other element and other machines by changing the details of the work, the specifics of problems, limiting conditions, and other factors.

It should be noted that remote operation is not considered in these levels, as mentioned above. Although the operator will get off the earthmoving machine at one of the levels, we decided not to specify that level. In other words, the operator can engage in either onboard operation or remote operation at levels 1 to 5. SAE J3016 is the same in this regard.

4 Conclusion

In this study, we discussed with many category researchers, project owners, civil engineers, engineers of construction machinery manufacturers, and robotics researchers, and others. And through this study, we successfully proposed draft versions of an "automation system diagram for earthmoving work (Figure 3)" and "automation levels for earthmoving machines (Table 3)." We believe that referencing these outcomes will make it possible for all researchers to understand the scope that the current research occupies in the entire earthmoving work and the degree of achievement of the research. And it will be possible to clarify the research goal to be carried out next.

For example, based on the outcomes of this paper, "Autonomous Hydraulic Excavator", which is researched recently [10][11], are autonomous research only for a "Hydraulic Excavator" element in "construction" component (Figure 3). And it corresponds to "automation level 1 (Table 3)". Thus, as future research and development policies, it is possible to propose an advancing the automation level or an automatization other elements or components (Figure 4). It can be expected that this will effectively promote further advancements in earthmoving automation research.

Additionally, no single correct definitions exist for the diagram and levels mentioned here, and interpretations will vary depending on the viewpoint. It is therefore inappropriate

Table 3. Levels of Automation for Construction Machines

Level	Name / Definition Example：Hydraulic shovel in embankment work 	Construction Machine Control	Detection and Judgment for High-efficiency Construction	Response when Autonomous Operation is Difficult to Continue	Site condition limitations
0	No automation	Human Operator	Human Operator	Human Operator	Limited
1	Automation of individual behavior Automation of locomotion / excavation / turning / releasing (Automation of each operation can be individual) Excavation position, bucket point, release point, each optimal operation, completion judgment, etc. can be instructed by a human operator.	Human Operator and System	Human Operator	Human Operator	Limited
2	Automation of series operation Automation of series operation. Move→Excavate→Turn→Release Excavation position, bucket point, release point, each optimal operation, completion judgment, etc. can be instructed by a human operator.	System	Human Operator	Human Operator	Limited
3	Automation of detection and judgment for high efficiency work The system determines and executes the optimum excavation position, optimum bucket point, optimum release point, optimum operations, completion judgment, etc. for high efficiency construction.	System	System	Human Operator	Limited
4	Trouble shooting Example : Load collapse, sudden obstacle, etc.	System	System	System	Limited
5	Open the limited scenario	System	System	System	Unlimited

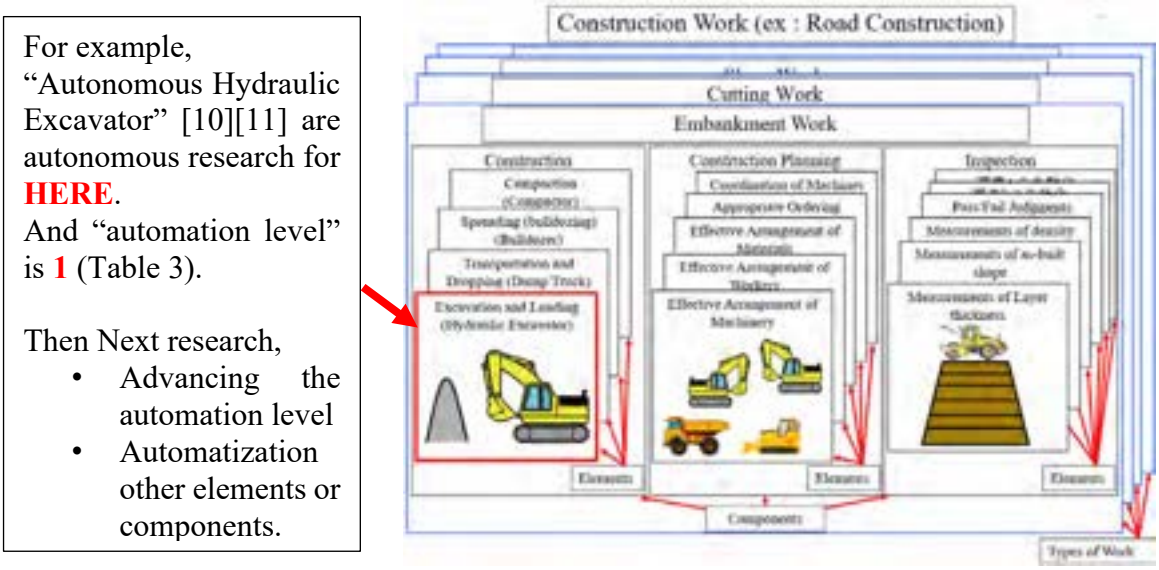

Figure 4. An example of understanding the position and level of current technology and setting the next goal

to immediately view them as universal standards. However, we believe that concretely conceptualizing the performance of current technologies and R&D aims by illustrating proposals and stimulating discussion by presenting studied processes are extremely meaningful endeavors. We would like to see the outcomes described herein be at the forefront of discussions among researchers.

We hope that the outcomes presented in this paper will be of assistance to researchers and engineer who aim to autonomous earthmoving construction.

Abstract -

The McKinsey Global Institute's digitisation index ranks construction amongst the least digitised sectors globally. This translates to a relatively slow rate of labour-productivity growth which, according to McKinsey, costs the global economy US$1.6 trillion per year. One area ripe for improvement is validation of final components on construction sites. This is a critical step in the quality assurance process, but also one that consumes significant resources when performed manually. Digitisation, using reality capture technology, can enable rapid component analysis through automation. However, traditional survey tools, which focus on individual points or fixed locations, tend to provide limited coverage, are difficult to operate and hard to interpret. More recently, developments in Light Detection and Ranging (LiDAR) has enabled rapid digital representation of geometry. The resulting point clouds can then be processed using modern computing techniques, including the proprietary BuiltView platform used here, to perform automatic checks that are faster and more accurate than manual measurement and achieve greater coverage than traditional surveying technologies. As the technology develops to become cheaper and more readily available, potential on-site applications should be fully explored. To improve the understanding of options, applications and productivity benefits, we present case studies performed on active construction sites in which an aspect of the built environment was scanned with LiDAR and the data analysed to estimate value accretion for the builder. In floor flatness analysis and site visualisation we demonstrate results that are prohibitively difficult to perform manually. In LiDAR-based precast scanning and formwork analysis we show promise for detecting defects before they cause delays and costs further down the value chain. We present the context and methodology for each case study, along with the benefits and difficulties encountered with LiDAR use. Finally, we calculate the approximate value added compared with traditional approaches to quantify the relative merit of point cloud data. Findings from our case studies suggest LiDAR has the potential to significantly improve construction productivity, quality of works, documentation and client engagement.

Keywords -

LiDAR; Construction; Productivity; Case studies

1 Introduction

Due to a variety of factors including underinvestment in digitisation and innovation, the construction industry is losing $1.6 trillion globally each year [1]. As project and site complexities increase, the industry can leverage technological advancements to increase productivity through automation and quality improvements. In this study, we focus on one such technology - Light Detection and Ranging, or LiDAR - and investigate its potential for adoption through the BuiltView platform to complete a variety of tasks on active sites. LiDAR, like that shown in Figure 1 is commonly used by surveyors to take accurate measurements of spaces, particularly where traditional manual measurement is prohibitively difficult or slow.

Figure 1. Survey grade tripod LiDAR scanning piles during excavation works.

Here we present case studies of five applications of LiDAR that were conducted to address issues site engineers were facing during a particular phase of construction, with a high-level overview of the technical approach taken in each case.

Our main objective for each case study is to estimate the potential for productivity, financial o r r isk management improvements provided by the LiDAR application.

2 Background

The construction industry is worth roughly US$10 trillion (2017), accounting for roughly 13% of world GDP. According to the McKinsey Global Institute [1], this number could grow by US$1.6 trillion if productivity enhancements, such as digitisation and advanced automation, were more widespread. These productivity improvements can come from a variety of sources, including additive manufacturing [2], increase prefabrication [3], or by automating progress monitoring [4, 5] inspection [6] or as-built modelling [7], to name a few.

One of the major issues facing construction is the cost of rework, defined as "activities in the field that have to be done more than once, or activities which remove work previously installed as part of the project" [8]. A 6-year study of nearly 20,000 rework events across 346 projects concluded that the mean yearly profit reduction was 28%[9]. As much as 52% of total cost growth is due to rework, which also increases schedule overrun by 22%[10, 8]. As such, any preventative methods to reduce rework, for instance by increasing quality checks [11, 12, 13], have the potential to drive considerable productivity improvements.

Technological advancements in laser scanning using Light Detection and Ranging (LiDAR) have enabled several notable high-accuracy inspection processes with the potential for automation, primarily focused on 3D model reconstruction and geometric quality inspection [12]. LiDAR produces an output commonly referred to as a "point cloud", which is a collection of thousands to millions of positions in 3D space representing solid matter and derived from high accuracy distance measurements from the sensor. A lot of work has gone into converting these point clouds into Building Information Models (BIMs) which are more common in the industry and easier to work with. This can take the form of generating as-built models of site [14, 15] or precast units [7], quickly generating models of existing structures for heritage, renovation or integration purposes [16], or updating progress through comparison with 4D BIM [4].

Another common use for point clouds is high-fidelity quality inspection. In some cases, this involves directly measuring particular built elements like railway power lines [6] or concrete rebar positions [13]. Another case is floor flatness measurement, typically performed using manual straightedge methods which can be automated with tripod-based LiDAR or aerial scanning [17]. Laser scanning is capable of great accuracy, with some scanners detecting 1mm flatness defects from 20m away [18].

Recent advances in algorithm development have enabled a trend towards mobile LiDAR, which enables rapid surveying, whether handheld [16, 14], vehicle-mounted [6] or aerial [19, 20]. With handheld LiDAR, for example, a single operator can scan entire floors of buildings in a few minutes using a backpack-sized device. Similar scanning using static (tripod mounted) equipment can take hours. The downside however, is mobile LiDAR lacks the accuracy of static sensors. The need for programmatic stitching, and a proclivity towards cheaper laser scanners, means handheld sensors typically achieve 5-30mm accuracy, depending on the object being scanned [14]. Despite this impediment, mobile LiDAR has several site applications due to its ease of use. For example, colourised mobile LiDAR enables rapid detailed capture of site conditions which can be used for communication or documentation purposes [21].

Our study employed a combination of mobile and static LiDAR, while also varying static LiDAR between high density (1M points per scan) and low density (1K points per scan) capture.

2.1 Sites

This study was undertaken on a number of active construction sites operated by Laing O'Rourke in various stages of development which have different contexts and priorities.

Project 1 was a newly developed Health Precinct consisting of an 8-story building. The building comprised mainly teaching and learning areas including lecture theatres, labs, hospital simulation studios, X-Ray and CT rooms and other work spaces.

Project 2 was a 10 story building composed mainly of engineering laboratories. This was further complicated by revitalisation and integration with an existing engineering building which was still largely operational for classes and research.

Project 3, located in Western Australia's Pilbara region, required replacement of 7 active railway bridges with precast concrete culverts. The project complexities included high desert temperatures over 40°C and short time windows to replace each bridge to ensure the rail line remained operational.

Finally, Project 4 was not a construction site but rather a Design for Manufacture and Assembly (DfMA) facility in London, England, operated by Laing O'Rourke which produces high-volume and bespoke components for sites around the country. For quality assurance purposes, laser scanning is used to validate precast components and formwork. However, technical constraints limit the rate at which such analyses can be performed, so automation can add significant value.

3 Methodology

In this section we provide an overview of our five case studies, the data capture and method used, and processed data visualisations.

Throughout these case studies, we utilise the BuiltView platform for data capture and processing. BuiltView is a software platform developed in house which comprises robust data handling methods and innovative point cloud handling tools. The technical details of this platform are out of scope for this report.

3.1 Precast verification

As described in Section 2.1, Project 3 involved assembling a railway bridge using large precast concrete culverts. Due to the site conditions and time constraints, there was interest in verification of the culverts before attempting assembly. Of particular interest were any twists in the uprights which would affect the fit of adjoining culverts.

To enable the analysis, site engineers scanned two precast culverts using static LiDAR, compiling scans from multiple directions into one point cloud shown in Figure 2. The point clouds were then split into individual culverts and registered to their respective design models by performing optimised alignment using the Iterative Closest Point (ICP) algorithm.

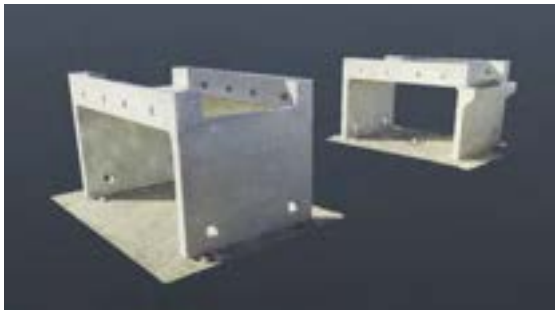

Figure 2. Point cloud scans of precast culverts at Project 3. The culverts are approximately 4m tall.

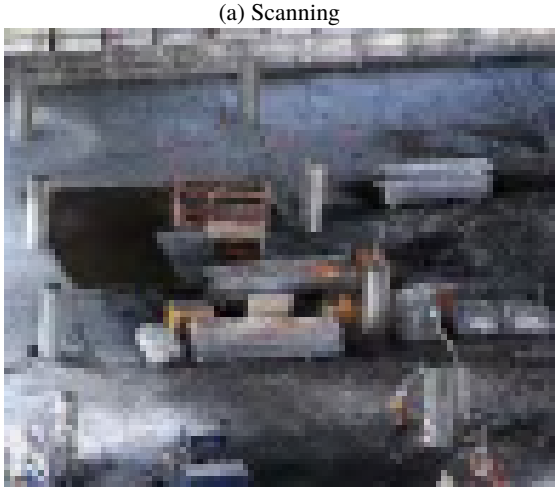
After the scan was aligned with the design model, a pointwise distance metric was computed by finding the distance between each point in the scan and the nearest point on the model. This metric allowed identification of specific points that were significantly deviated from design, in addition to geometric differences like scale and twist. For improved understanding, we displayed this information as a heatmap by projecting the distance metric of each point on a colour scale from blue to red.

3.2 Floor flatness

At Project 1, site engineers requested an analysis of floor flatness on several levels of the building. Due to changeover of subcontractors, a short timeframe was required, as any defects discovered after several weeks would cause program delays. Consequently, manual checking was infeasible, and LiDAR was trialled as a potential solution.

In previous collaborations with Project 1, we found static LiDAR scanning prohibitively slow. This was primarily due to increased processing (registration) time, caused by internal walls that limited the visibility from individual locations. Knowing this, we opted to use a handheld mobile LiDAR for this capture - a Paracosm PX-80, shown in Figure 3 - that enabled rapid scanning of the building.

(a) Scanning



(b) Raw scan output

Figure 3. Capture process and output from Paracosm PX-80 handheld LiDAR scan.

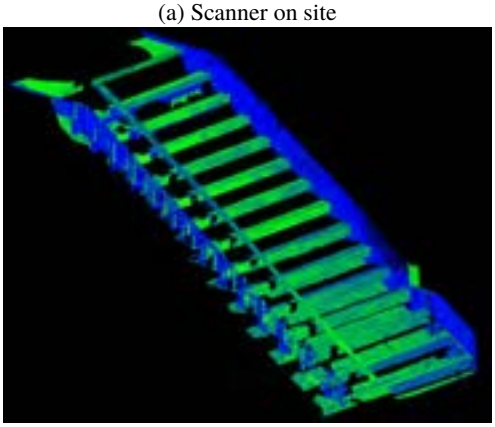
When processing the data, we considered registering the point cloud to the BIM to compare points with their exact location on the ground plane. However, this approach would demonstrate global deviation (the entire slab being slightly too low or high), when the desired insight for flooring compliance was relative deviation. Therefore, we extracted the points representing the ground from the raw point cloud data and computed a best-fit p lane. We then computed the point-to-plane distance from each point to this best fit plane and displayed this data using a heat map

visualisation.

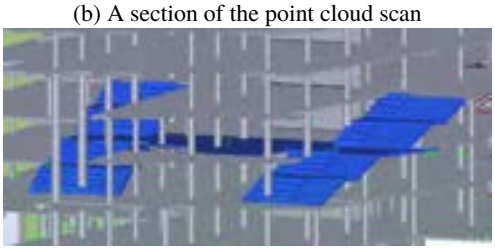
3.3 Formwork

Prevention is always preferable to reparation on site, as rework is costly in both time and money. With this being the case, we investigated the possibility of validating concrete pours at the formwork stage rather than after the pour as in the other case studies. Also taking place on

(a) Scanner on site



(b) A section of the point cloud scan



(c) Building Information Model

Figure 4. Context of staircase formwork at Project 1. Four sensor locations captured using a Leica BLK360 were registered to generate a scan which was then compared to the BIM shown.

Project 1, this case related to a set of multilevel staircases undergoing rework due to an error in the original design. Due to this context, we had an opportunity to scan the formwork of the stairs before the pour, and compare it to a correct BIM as well as an incorrect BIM to investigate preventative analysis.

We scanned the formwork using a Leica BLK360 static LiDAR as shown in Figure 4. Since a static LiDAR was used, occlusion was a significant concern so we scanned the formwork at several positions along the staircase and then registered the scans using common points. We then aligned the completed scan to the BIM, using the inner faces of the formwork to align to the outer faces of the concrete model. This process was repeated for the correct and incorrect model, at which point computing the shortest distance metric allowed us to analyse the formwork scan to determine if it was correctly built.

3.4 Reinforcement scanning

Correct placement of rebar in concrete is critical to the long-term survival of the construction project. Inspecting the size, number and spacing of rebar can be difficult and time-consuming. Enabling easier inspections is of particular interest at Project 4's manufacturing facility, where components are prepared for use on construction sites. Furthermore, there is value and interest in having detailed information about the internal structure of a slab for future works including penetrations and proof of completion to specifications in the case of disputes.

Figure 5. LiDAR scan of rebar at Project 4

By scanning the reinforcement before the concrete is poured, the structure can be inspected digitally using the point cloud and future works can be performed using a 3D map of the internal structure of the component. Rebar is difficult to scan with LiDAR due to the reflective properties of the steel, so the scanner used by Project 4 is a low-density high-accuracy scanner which captures point clouds in the order of thousands of points rather than millions. An example of this scan is shown in Figure 5.

Our primary aims in this case were identifying bars by diameter and detecting relative spacing between bars. To achieve both aims, we perform cylinder fitting on the point clouds. This generates a collection of 3D shapes from which the diameter and spacing can be derived.

3.5 Visualisation and Documentation

Documentation and communication between parties involved can be difficult, particularly between agents in different industries. Project 4 faced challenges in this domain communicating a planning error with the client relating to shared access to a teaching lab which was intended to be used while construction was being undertaken. The issue faced was caused by a design element whose size dictated an overlap into the teaching space which would cause logistical issues, but communicating and proving this using 2D resources proved difficult. By using LiDAR to capture the contested space in 3D, dimensions and clashes could be made more visible and easier to communicate.

Again, we used the Leica BLK360 static LiDAR to create a highly detailed colourised scan of the space. Use of this LiDAR also allowed capture of panoramic photography during scanning which could also be used for visualisation. Due to the cluttered nature of the scene caused by internal walls and furniture, many scans were required to generate a clear and complete scan of the area. All individual scans were then registered together using shared points and vision targets to create a cohesive scan, which was then further registered to the building model to allow the scan and model to be overlaid to demonstrate any clashes.

4 Results

4.1 Precast verification

We validated precast components on Project 3 using nearest-point heatmap analysis, comparing the point cloud scans as built to the design model. An example of the result for this analysis is shown in Figure 6.

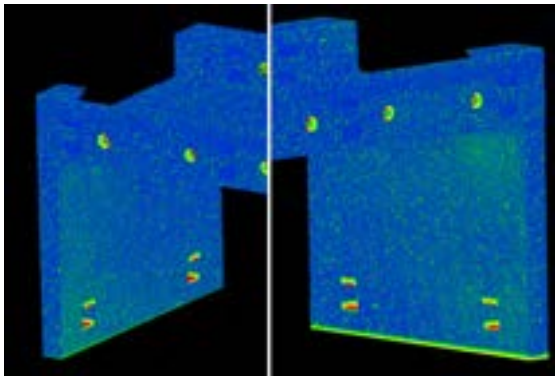


Figure 6. Heatmap analysis of Project 3's precast culverts. Colour scale represents distance from each point to the design model, from blue at 0mm to red at 100mm.

In general, the distances measured are blue, implying little difference between the scan and the model. However, the green gradients towards particular corners of the culvert imply a subtle twist in the uprights which are designed to be planar, which was a very useful insight for the site team as it is a difficult thing to measure manually but could cause gaps between installed culverts which could have flow-on effects. The other features of note were the interfacing holes at the bottom of the uprights. The red points around these reveal that they are not in the correct location, rather they are approximately 11cm out of place vertically.

There is good potential here for process improvements here, specifically in the area of risk mitigation. The LiDAR scan can analyse the entire culvert at once, and potential catch geometrical deformations that a human inspector would not notice. Project 3 required many of these culverts to be cast, so early detection of any issues would prevent inordinate amounts of rework.

4.2 Floor flatness

Our results for floor flatness analysis are similarly presented in heatmap form, though the distances in this case are computed as normal distance to an artificial plane. The results for one floor are shown in Figure 7. Around the starting position of the scan, circular "ridges" in the point cloud can be seen which likely are artefacts caused by the initialisation procedure of the mobile sensor and can be safely ignored. The rest of the scan shows minor variations in the height of the floor, where green points are level with the computed best-fit plane, blue points are lower and red points are higher. The pattern of points shows areas which are of concern, in particular near the edges of the scan where some areas demonstrate a rapid shift from green to red. Besides gradient changes, the other area of interest is local inconsistencies which could cause problems for flooring, and small red and blue areas can be seen in the scan which also merit manual inspection.

Another consideration here is that the operator was able to scan 5 floors in only a few hours, despite significant internal occlusions.

As mentioned, the floor flatness inspection at Project 1 took place before a changeover of subcontractors. Typically, the surveyors used have a turnaround time of approximately 2 weeks, which would delay the identification of faults until after the relevant workforce had vacated the site. These sorts of delays to rectification works can easily cause cost increases of 5 to 10 times, due to the additional logistics of bringing back subcontractors to perform the works. Rapid detection of issues would enable the project to keep the relevant workforce in place and siginificantly reduce the cost of rectification.

4.3 Formwork

Analysis of the Project 1 formwork is a slightly different case, since the object of interest is the concrete

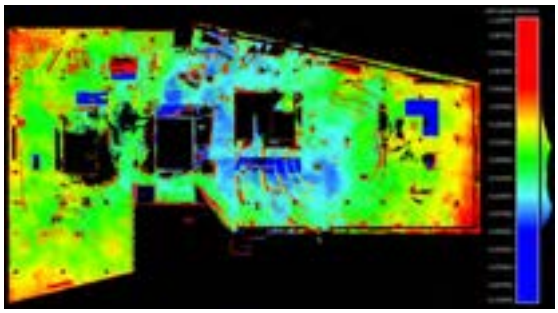

Figure 7. Point-to-plane distance heatmap analysis for the floor slab of a single level of Project 1.

pour which does not yet exist, so the analysis has to be of the shapes surrounding it. As mentioned earlier, we performed a heatmap analysis after aligning the inner faces of the formwork structure with the outer faces of the correct and incorrect building models, then compared the results. This comparison can be seen in Figure 8.

The result for the incorrect model demonstrates some notable characteristics. Several steps are mostly blue and green, representing the part of the scan which has aligned best to the model. However, further along the scan the shortest distances get higher, with significantly more orange and red points visible.

The result for the correct model, however, is far more uniform, with most steps an even blend of blue and green. In this context, the green points represent the sections of formwork which are not close to the final concrete product, while the blue points represent the faces which will directly contact the concrete.

Comparing the two, it is easy to distinguish a correct model from an incorrect model when measured against the as-built formwork, implying the possibility of a method to assess the correctness of formwork prior to the pour and enabling pre-emptive rectification works.

This could potentially reduce costly rework. In particular, this case involved a demolishing and reconstructing a four-story concrete staircase due to design errors. The rework required to complete this took several weeks, increasing both budget and schedule blowout. Through formwork assessment, many situations like this can be avoided.

4.4 Reinforcement scanning

Due to the difficulty in scanning steel rebar and the low-density scanner used, the cylinder fitting must be able to distinguish between individual bars in the point cloud. Figure 9 shows a section of the rebar scan with each point assigned a unique colour according to the cylinder to which it was fit.

The resulting colours demonstrate that the analysis is able to correctly distinguish between the bars using cylinder fitting. The derived cylinders also have specific geometric properties which can be used to analyse the rebar as needed. Firstly, each cylinder has a diameter, which is important during inspection since certain numbers of bars need to be installed to fulfil design specifications. Furthermore, since the cylinders are roughly parallel, the distance between them can be derived, which is another important consideration for as-built verification.

Errors in reinforcement and a lack of asbuilt information can significantly affect project risk, from increased danger during slab penetrations to short- or long-term deterioration of structural components. At Project 4, one engineer with expensive LiDAR equipment is able to inspect 5-10 elements before casting per day on the manufacturing line, which is approximately 10% of the project throughput. By automating the data processing and limiting manual activities to data capture, this productivity can be easily improved by 2 to 5 times, enabling a much higher coverage rate and significantly reducing risk.

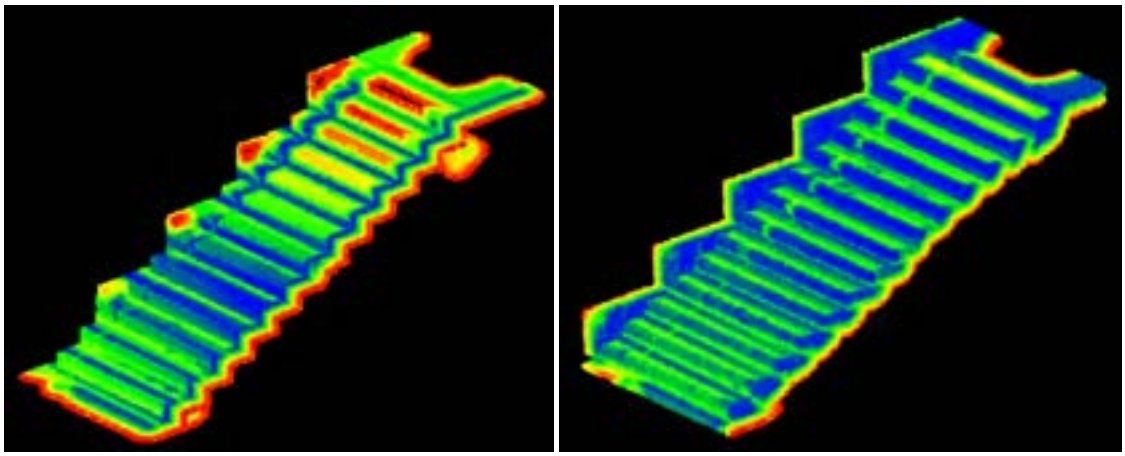
4.5 Visualisation and Documentation

A high-density visualisation of the contested space on Project 2 was completed using colourised LiDAR scans. A snapshot of the results is presented in Figure 10.

The visualisation allowed for better communication with the client since two dimensional plans can be harder to understand for people outside construction, and furthermore the scan is correctly scaled such that the building model can be overlaid to illustrate conflicts. Improvements in communications can have signficant effects on productivity and avoiding rework by ensuring a cohesive understanding of the works to be undertaken. In this case specifically, the improved ability to convey information ensured that the project did not impact, and was not impacted by, client operations in the same space. This avoided damaging relationships with stakeholders as well as preventing rework due to a misunderstanding.

5 Discussion and Future Work

The case studies presented here represented just a few use cases for LiDAR on construction sites. Even with the scanning infrastructure used here, many more applications could be implemented. For example, the floor scans of Project 1 were used for floor flatness analysis, but the data captured also included construction equipment which could be used to infer utilisation, service installations which could update progress, and incomplete elements which could be analysed for impending clashes. The adoption of scanning as a frequent operation in the industry would enable more value-add propositions in this vein, though several considerations are involved.



(a) Incorrect BIM (b) Correct BIM

Figure 8. Heatmaps for the same point cloud compared to two different versions of the BIM. The first version was revised due to stair spacing and the scanned formwork was built to the specifications of the second.

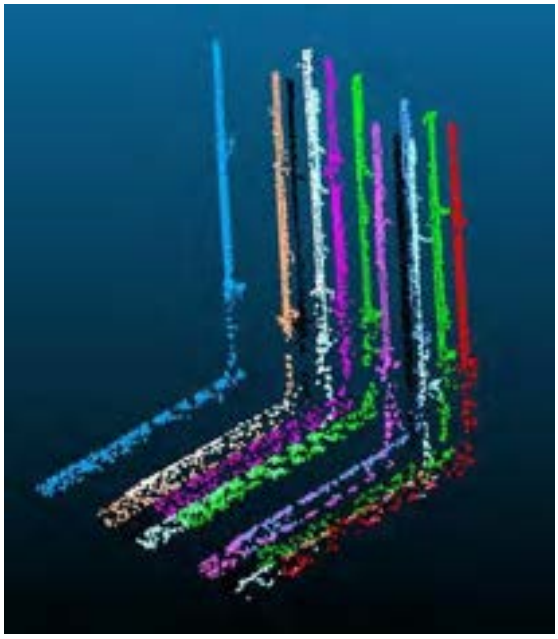


Figure 9. Analysis of rebar using LiDAR scans. Each bar has been identified as separate using cylinder fitting.

Static LiDAR is currently used commonly in surveying but requires significant processing and trained operators. Furthermore, scanning can take a long time when features like internal walls are involved and causing occlusions. The rise of mobile LiDAR enable scanning of large-scale infrastructure projects (using vehicle-mounted scanners), scanning of difficult-to-reach areas (using aerial LiDAR) and rapid scanning for applications requiring frequent updates (using handheld LiDAR). Many handheld sensors are also very simple to use, requiring minimal training or

Figure 10: Snapshot of visualisation of contested space at Project 2

processing time. However, the accuracy of mobile LiDAR is not as good as that of static scanners, due to error introduced by motion. Because of this, the application of the different technologies depends on tolerance requirements and liability. Operations like progress updates, communication and visualisation can easily be performed using mobile scanners, while small-tolerance deviation analysis requires more accurate static ones.

A major advantage of the processes presented here is the potential for significant automation. If sensors can be operated autonomously, as is already the case with certain aerial or robotic scanners[20], certain aspects of processing may also be automated. This can enable high quality inspection and verification works with far less human intervention and allow the industry to operate with more confidence than it currently does with less effort.

There is also a push in the construction industry for greater progressive documentation of the build. Such documentation can be helpful for future works on completed sites, and also reduce difficulties during conflict resolution. LiDAR is a powerful way to capture this data, since the results are relatively simple to collate and analyse and contain high quality measurements of all surfaces. Whereas

traditional point-and-line survey can verify locations of key components, LiDAR measures the entire visible area, so defects or deformations are more likely to be discovered early.

6 Conclusion

In this study we have presented several applications of LiDAR on active construction sites to provide value using relatively simple algorithmic techniques and user-friendly outputs. As the technology develops and becomes more usable and affordable, we hope to see widespread adoption to help the industry close the digitisation and productivity gap which is currently in evidence.

Abstract –

One of the problems in the practical use of 3D printers using cement-based materials is how to withstand the tensile force. In general, cement-based materials can withstand compressive forces. Therefore, reinforced concrete structures are applied as composite structures with steel materials such as reinforcing bars that can withstand tensile force.

In this study, we developed a composite structure, in which the outer part was laminated with mortar exclusively for 3D printers, and the inner part was filled with ultra-high strength fiber-reinforced concrete as a substitute of reinforcing bars. When the test piece was manufactured and its mechanical properties were tested by experiments, it was concluded that the desired strength had been obtained. Then, a large shell-shaped bench, whose outer dimensions comprised a width of 7 m, depth of 5 m, and height of 2.5 m, was manufactured. The design used topology optimization that derived a shape with high structural rationality; the total weight was reduced by approximately 60%. The shape derived by topology optimization would have been difficult to construct with a formwork, and we were able to exploit the advantages of using a 3D printer.

Keywords –

3D Printer; Automation; Laborsaving

1 Introduction

A 3D printer using cement-based materials (hereinafter called "3D printer") ejects special mortar (hereinafter called "3D mortar") from a nozzle attached to a mobile mechanism, such as a robot arm, and laminates the mortar to construct a structure. We have developing a 3D printer, which we refer to as a 3D printer for construction. Since the structures could be constructed automatically without using a formwork, freedom in design and laborsaving ways of construction could be realized.

One of the problems in the practical use of 3D printers is how to withstand the tensile force generated in the structure. In general, cement-based materials can withstand compressive forces. Therefore, reinforced concrete structures are applied as composite structures with steel materials such as reinforcing bars that can withstand tensile force. To solve this problem, the following methods have been devised: a) inserting a steel material such as a reinforcing bar during the 3D printing process [1], b) manufacturing a piece with a hollow using a 3D printer, and inserting a PC steel bar into the hollow to introduce a prestressed force [2], and c) using a cement-based material capable of withstanding the tensile force such as ultra-high strength fiber-reinforced concrete (hereinafter called "UFC") [3].

Therefore, we developed a composite structure in which the outer part was laminated with 3D mortar and the inner part was filled with UFC as a substitute to reinforcing bars. In this study, basic structural experiments were conducted to confirm that an actual structure could be constructed using this composite structure. And, we designed and constructed a large shell-shaped bench with outer dimensions comprised a width of 7 m, depth of 5 m, and height of 2.5 m; this experiment demonstrated the use of the composite structure.

2 Development of Composite Structure

2.1 Composition of Composite Structure

We developed a composite structure by using 3D mortar and UFC. In order to construct the composite structure, first, the outer portion of the structure was laminated with 3D mortar so that the portion that was to be reinforced by a reinforcing bar became hollow. Then, the UFC was placed into the hollow. The filled UFC could withstand the tensile force generated in the structure.

2.2 3D Mortar and UFC

For the 3D mortar, mortar premixed with a hardening accelerator was used, and the hardening speed was adjusted by setting up a retarder. In addition, polyvinyl alcohol (PVA) fiber was mixed to increase the bending strength. It had a compressive strength of 60 N/mm^2 and a bending strength of 3.5 N/mm^2.

UFC [4] is a room-temperature-hardening-type mortar, developed by the Obayashi Corporation that can achieve a compressive strength of 180 N/mm^2, tensile strength of 8.8 N/mm^2, and bending strength of 32.6 N/mm^2. This material has a high tensile strength, bending strength, and tensile toughness; thus it can function as a structure in itself. This slump flow was approximately 600 mm and had a self-filling property. Therefore, the placement work was easy, and the automation and mechanization will be easy as well, compared to the manual arrangement of reinforcing bars.

2.3 Verification of Mechanical Performance

2.3.1 Outline of Experiment

Figure 1 shows the cross section of the test piece. The width and thickness are 500 mm and 120 mm, respectively, and the UFC parts with a width of 50 mm and a thickness of 70 mm, are evenly arranged in five different positions.

Photo 1 shows the manufacturing status of the test piece. First, the 3D mortar was laminated with a 3D printer until the height was 1 m. Next, as shown in Photo 2, the UFC was placed in the hollow. The UFC, which was placed in the hollow, was constructed without being spliced.

A three-point bending test was conducted to confirm the bending properties of the test piece (No. 1) manufactured with the composite structure. For comparison, a bending test was also conducted on a test piece (No. 2), which was not filled with UFC, as shown in the cross-section of Figure 1.

2.3.2 Methods of Loading and Measuring

Photo 3 shows the device loading for the bending test. The left end of the test piece was supported by a pin, the right end was supported by a pin roller, and the distance between the supporting points was 800 mm. In order to maximize the bending moment at the center of the test piece, a hydraulic jack and ball seat were attached to the upper center part of the span, and the load was applied vertically downward. Since the width of the test piece was as large as 500 mm, a vertical load was applied through a beam with a height of 200 mm. The applied force was a monotonic load that was pushed in one direction. The vertical load at the center of the test piece was measured with a load cell. The displacement in the vertical direction at the center of the test piece was

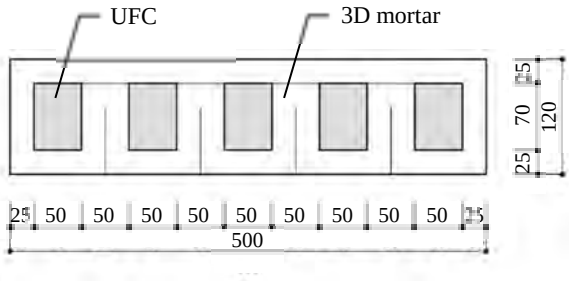

Figure 1. Cross section of the composite structure

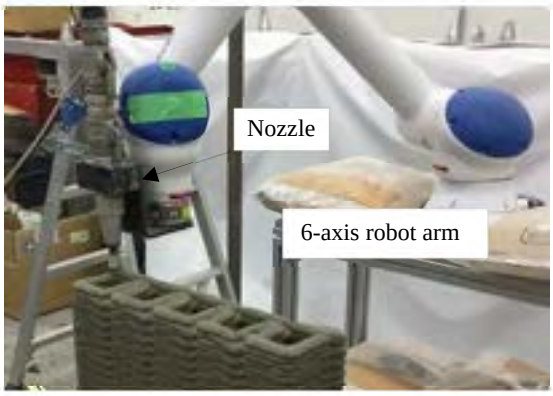

Photo 1. Printing of test piece

Photo 2. Placing UFC

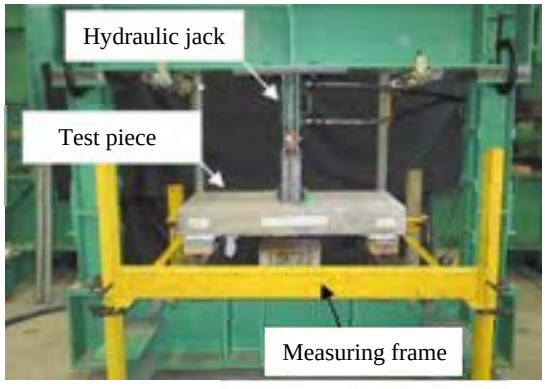

Photo 3. Loading device

measured with a displacement meter, and the downward direction reflected the positive values. The displacement was the average of the values measured at the front and at the back of the test piece.

2.3.3 Result of Experiment

Photos 4 and 5 show the final destruction status. Photo 4 shows the final fracture of No. 1. Photo 5 is an enlarged photograph of the fractured surface of No. 1. In both No. 1 and No. 2, cracks were found near the lower end of the center of the test piece, and finally a fracture surface was formed almost in the center of the test piece. Many steel fibers protruded from the portion of the UFC on the fracture surface of No. 1. It was also confirmed that the hollow was filled with the UFC without any gaps. In both the test pieces, there were no evidences that the mortar at the compression edge had undergone compression failure.

Figure 2 shows the relationship between the vertical load and the center deflection. The maximum load of No. 1 was 47.4 kN. On the other hand, the maximum load of No. 2, which was not filled with the UFC, was 22.5 kN. No. 1 shows a maximum load of more than twice the maximum load of No. 2, because the UFC withstood the tensile force. Moreover, in No. 2, brittle fracture occurred after the maximum load was applied, and the yield strength decreased sharply. However, in No. 1, due to the tensile toughness of the UFC, the yield strength gradually decreased.

From the above, it was found that the developed composite structure improved both the maximum load and the toughness performance, because the UFC was placed in the hollow and could withstand the tensile force.

3 Design of Shell-shaped Bench

3.1 Outline of Design

To verify the practicality of the developed composite structure, the shell-shaped bench, which is shown in Figure. 3, was manufactured. The design included a cantilever shape that produced a large tensile force and incorporated a curved surface that 3D printers were good at.

The outer shape was manufactured by laminating the 3D mortar, but if the entire interior was filled with the UFC, as shown in Figure 4, the weight increased and the structural rationality decreased. Therefore, the internal structure of the shell-shaped bench had a hollow part, as shown in Figure 5, to reduce the weight. Therefore, in order to determine the morphology of the internal structure, we applied topological optimization that gradually removed the stress and derived the optimum morphology by Finite Element Method (FEM) analysis. Figure 6 shows the design flow of the internal structure.

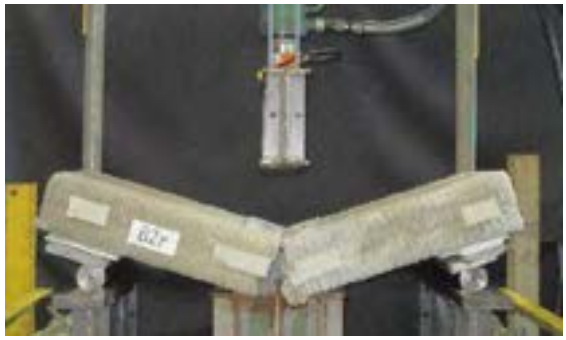

Photo 4. Final fracture (No.1)

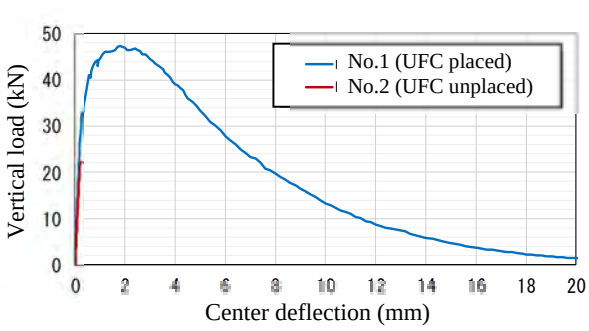
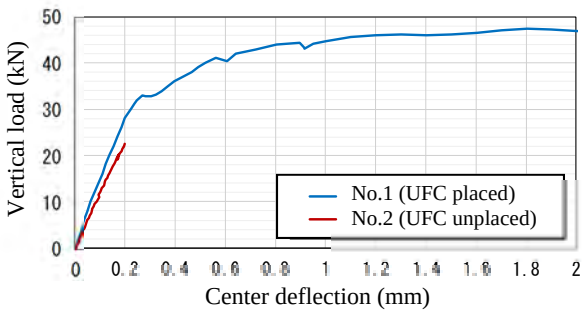
Photo 5. Detail of the fracture surface (No.1)



(1) Entirety



(2) Initial loading

Figure 2. (Relationship between) vertical load and center deflection

Since a 3D printer could manufacture pieces without using the formwork, it was suitable for manufacturing complex shapes that had hollow internal structures derived by topology optimization.

3.2 Topology Optimization

In topology optimization, the ratio of the reduced weight to the initial weight was set as the target value. Then, a form in which the stress was minimized in a range satisfying this target value was derived. The target value for weight reduction was set at 65% of the initial weight. Only the long-term load (self-weight) was used as the load condition in the FEM analysis, and the short-term load (horizontal force) generated during use was not considered. The reason for this is that shell-shaped benches have a cantilever shape and are easily affected by their own weight. As shown in Figure 7, topology optimization was performed by assuming a thin plate with a width of 30 mm in the cross-sectional shape of the center position of each piece obtained by dividing the total bench width of 7 m into 1 m intervals. For fixing the conditions, both the ends of the bottom of each piece were fixed.

Figure 8 shows an example of the result of topology optimization. The result of topology optimization of each piece divided into seven parts was truss-shaped, similar to that shown in Figure 8. The truss-shaped portion derived by topology optimization was made visible as a shell-shaped bench design. Therefore, as a design adjustment, the position of the bundle was adjusted finely so that the positions of the holes could be seen continuously from one end to the other.

3.3 Checking Allowable Stress

Topology optimization does not check whether the stress calculated in the morphology derivation process is within the allowable stress level of the material used. Therefore, the static stress analysis was performed on the design adjusted form, and the allowable stress level was checked. At that time, in addition to the long-term load, the horizontal force (0.2 G) was also considered as a short-term load that was generated during the use. The structural designer manually corrected the cross-sectional shape till the allowable stress level was cleared. Structural experiments have suggested that in the composite structure, 3D mortar and UFC behave as a unit. However, since the mechanism is still unclear, we used a design so that it could be established only for the cross section of the UFC.

3.4 Final Design

Figure 9 shows the final design of the shell-shaped bench. The shell-shaped bench was divided into 12 parts.

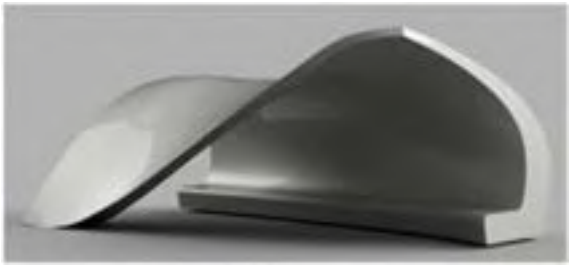


Figure 3. External design of shell-shaped bench

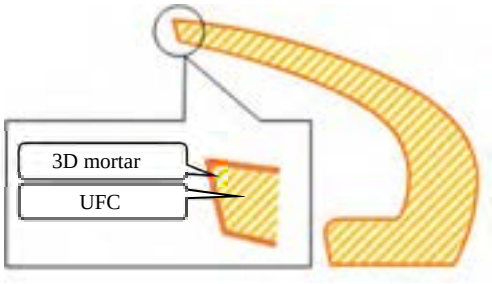

Figure 4. Layout of 3D mortar and UFC (Fully filled)

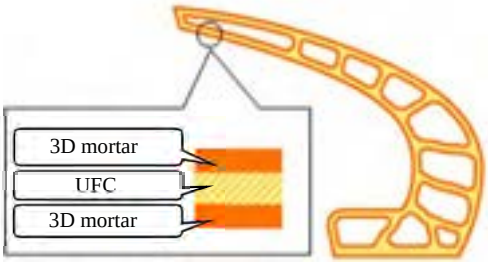

Figure 5. Layout of 3D mortar and UFC (Structurally rational)

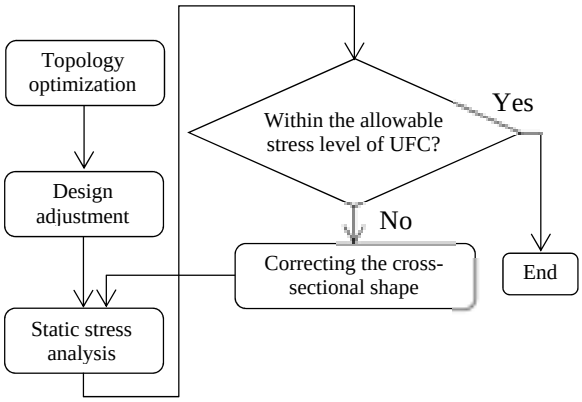

Figure 6. Design flow

The reason for this was that the time required for printing 3D mortar (working time per day) was limited, and transportation and erection after manufacturing became safe and smooth. The divided width of the 12 pieces was 500 mm at both ends and 600 mm at the other parts. Each piece was installed by a crane, with a joint width of 10 mm from the adjacent piece, and then sealed without connecting to the adjacent piece. The final design was approximately 60% lighter than the structure fully filled with the UFC.

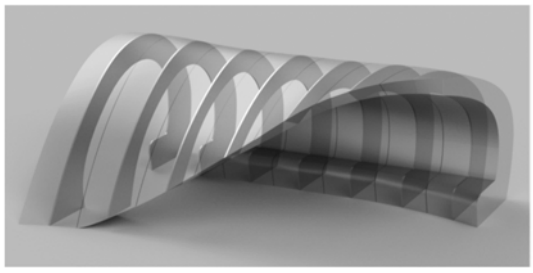

Figure 7. Sections to apply topology optimization

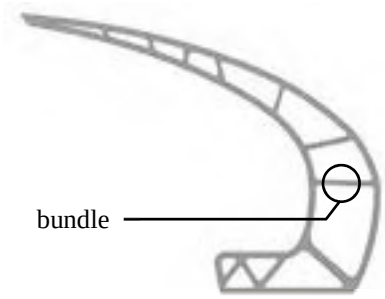

Figure 8. Example of applying topology optimization

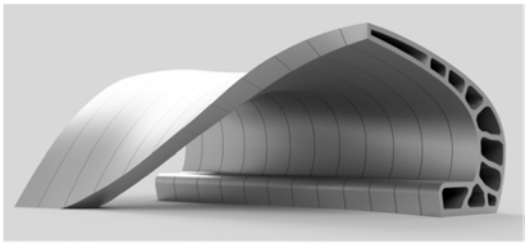

Figure 9. Final design

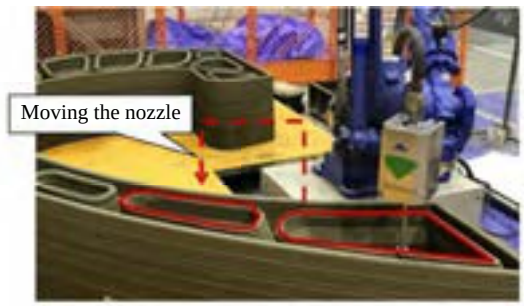

Photo 6. Example of jump in the print path

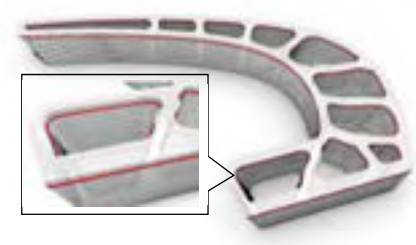

Figure 10. Automatic generation of the print path

4 Development of Elemental Technology for Printing 3D Mortar

4.1 Development of Valve

If the material ejection cannot be stopped in the printing 3D mortar, the print path must be a one-stroke and a non-intersecting path. Since the shell-shaped bench had a hollow, it was necessary to print the outer and the inner peripheries separately. Therefore, as shown in Photo 6, it was necessary to intermittently move the nozzle from the outer periphery to the inner periphery and from the inner periphery to the other inner peripheries. Therefore, we developed a valve that worked with the pump so that the ejection of the mortar could be stopped temporarily.

4.2 Automatic Generation of Print Path

We developed a software that automatically generated print path data from a 3D model. The 3D model was prepared in a format that represented a solid with a triangular mesh called the stereolithography (STL) format. In 3D modeling software, the STL format is a standard output format. Figure 10 shows an example of automatic generation. The 3D model was cut with the laminated thickness of the mortar, and the coordinates of the obtained intersections were classified into "outer periphery" and "inner periphery ". A print path was generated from the classified intersections and converted into a robot language used to control the robot arm.

5 Construction of Shell-shaped Bench

5.1 Outline of Construction

The 3D printer was installed in the building for experiments using concrete. Figure 11 shows the manufacturing process of the shell-shaped bench pieces. Manufacturing is a 5-day process. On the first day, the outer shape of the composite structure was manufactured using a 3D printer. The second day was a curing day and was used for developing the strength of the 3D mortar. The third day was the placement day of the UFC. The

fourth day was also a curing day for developing the strength of the UFC. On the fifth day, the piece was moved from the 3D printer to the installation location.

5.2 State of Construction

5.2.1 Printing 3D Mortar

Photos 7 and 8 show the condition of the printing 3D mortar. The width and thickness of the 3D mortar lamination could be controlled to a designated size by adjusting the ejected amount of the 3D mortar and the moving speed of the nozzle. These were adjusted in advance to obtain a mortar width of 30 mm and a mortar thickness of 5 mm.

The piece was printed, laid down, and was divided into three layers in the direction of the height. The net time required for printing the 3D mortar was approximately 5 h. To lift the piece during construction and connect it to the foundation, a hole with a diameter of 24 mm was drilled, and an insert with an inner diameter of 20 mm was attached before the 3D mortar hardened. After printing the 3D mortar, it was covered with a wet curing mat. Water was sprayed till evening before the day of placing the UFC.

5.2.2 Placing UFC

UFC was placed at once without any jointing, using a concrete bucket with a capacity of 0.3 m^3. Photo 9 shows the UFC condition. The UFC is self-filling. Therefore, the UFC could be placed without any problem even if a 3D printer complicated the shape. In addition, because it has the characteristic of being hardened at room temperature, special curing methods such as heat curing was not required. However, after the placement was completed, a sheet curing was performed, after spraying a surface curing material, in order to prevent the dry shrinkage cracks on the top surface.

5.2.3 Moving Pieces

After the curing day of the UFC, the piece was moved from the 3D printer to the installation location. Lifting was performed under balanced conditions based on the position of the center of gravity calculated from the 3D model of the piece. After moving the piece, the 3D printing yard was cleaned to prepare for the next piece.

5.2.4 Erection and Installation of Pieces

First, the laid-down piece was raised. Gradually the roof side of the piece was lifted with a crane. When the piece was raised, the level was adjusted using the level gauge. Next, the piece was moved to the installation position, as shown in Photo 10. Support was installed to the bottom side of the roof to temporarily receive the piece. Then, the piece was anchored to the foundation with an insert attached to the bottom of the bench seat.

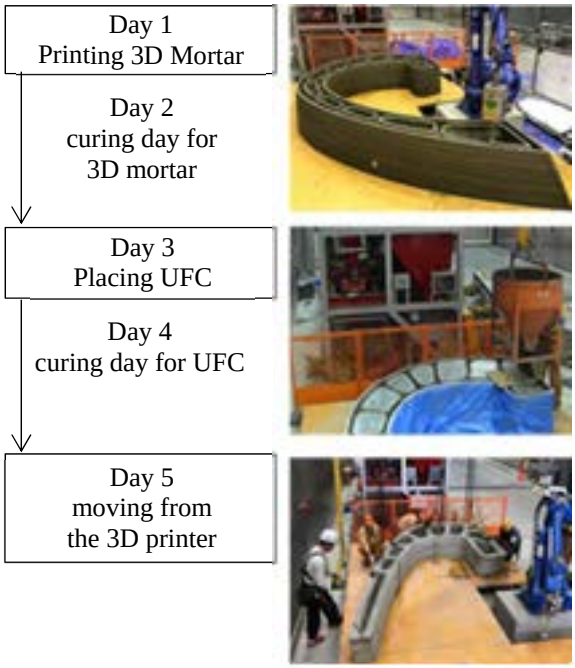

Figure 11. Manufacturing process of shell-shaped bench

Photo 7. Printing of 3D mortar (at the start)

Photo 8. Printing of 3D mortar (at the finish)

This support was removed after the foundation was established.

5.2.5 Finishing Work

A modified silicone sealing material for construction was applied to the joints between the pieces. In order to perform an exposure test on the coating performance on the 3D mortar surface, an aqueous fluororesin-based paint and a weak solvent-type two-component silicone-based paint were applied half by half. Photo 11 shows the completion of the shell-shaped bench.

6 Conclusion

We developed a composite structure in which the outer part was laminated with 3D mortar and the inner part was filled with UFC, as a substitute for reinforcing bars. In this study, basic structural experiments were conducted to confirm that a structure could be actually constructed with this composite structure. In this paper, we have described the design and the construction of a large shell-shaped bench with outer dimensions comprised a width of 7 m, depth of 5 m, and height of 2.5 m, respectively, which were conducted as a demonstration experiment for this composite structure. The findings obtained are as follows:

1. In the developed composite structure, the UFC withstood the tensile force and the maximum load, and toughness performance improved. Using this composite structure, it was possible to manufacture a shell-shaped bench having a complicated shape that generated tensile force.
2. By topology optimization, the overall weight of the shell-shaped bench was reduced by approximately 60%. In addition, the hollow part consisting of curved surfaces, generated by topology optimization, had a shape that was difficult to construct with a formwork, and we were able to exploit the advantages of manufacturing with a 3D printer.
3. Since UFC has a self-filling property, it was possible to place it into a complicated shape manufactured by the 3D printer without any gaps.

Abstract –

Construction robots are devices of increased danger and, under certain conditions, can become a source of injuries to maintenance personnel, as well as lead to the failure of technological equipment. Most of the accidents are associated with the presence of maintenance personnel in the working area during programming, configuration, training, repair and maintenance of robots. The article describes measures to ensure safety during the maintenance of robots and manipulators. The stages of preparing the construction industry for the use of manipulators, robots and robotic complexes are presented. A system of measures for preparing equipment for use and its maintenance during operation is proposed.

Keywords –

Construction Manipulators and Robots; Maintenance of Robotic Systems; Operation; Service; Safety

1 Introduction

Under certain conditions, construction robots can become a source of injuries for maintenance personnel, as well as lead to the failure of technological equipment. The main causes of emergency situations during the operation of robots and robotic complexes are mechanical damage, disruption of the drives, failure of control systems, increased positioning error, programming and tuning errors, exceeding permissible load values, occurrence of super-permissible dynamic modes, loss of the manipulated object, malfunction of safety equipment, violation service personnel operating conditions. Most of the accidents are associated with the presence of maintenance personnel in the working area during programming, tuning, training, repair and maintenance of robots [1-10].

Important in achieving the safe operation of robots and manipulators is their rational installation. Placement of robots and robotic systems (RS) should provide free, convenient and safe access for maintenance personnel to equipment and controls. The layout of the RS should take into account the shape, size and characteristics of the technological equipment, the location of the working areas, the level of automation and the degree of information support. When organizing the RS, it is necessary to have special devices that provide for the safety of staff. Enhancing safety is facilitated by safety enclosures, blocking and signaling devices, as well as the development of an information support system about the state of equipment and the environment. Protection devices must turn off the equipment when a person is in the danger zone of the workspace. The signal can only be taken by an operator who is setting up and maintaining equipment. The safety fence of the working areas of robots should not impede visual control over its work and the associated technological equipment. Safety fence is installed at a distance of at least 0.8 m from the boundaries of the working area of the robot and can be performed not only mechanically, but also on the basis of special devices: contact, power, ultrasonic, capacitive, induction, optical, etc. Automatic and automated lines and sections at enterprises manufacturing construction products should be equipped with emergency shutdown facilities equipment placed along the line with an interval of not more than 4 m.

During the operation of robots in the RS and in conditions of limited space, their working bodies are necessarily equipped with tactile sensors that are triggered by the contact of the working body with an obstacle.

The operation of robots and robotic systems imposes high requirements on the training of staff. Only persons who have undergone special training should be allowed to work on commissioning and operating robots. In addition to safety issues during the training of personnel, the device and features of the work of robots, the

procedure for controlling them, and actions of operators in emergency situations should be considered. Training in practical skills in working with building robots is preferably carried out on special simulators equipped with an automatic training system. Each operator should be given a safety note and instructions for controlling manipulators and robots. The industrial safety service of the construction firm should periodically monitor compliance by personnel with safety requirements, equipment status, and check the serviceability of safety equipment.

It is very important to have a choice of a rational mode of work and rest for staff, as fatigue can become a source of emergency situations caused by wrong actions.

2 Preparation of construction production for the use of manipulators, robots and robotic systems

The installation of robots by the construction projects and plants of the construction industry is preceded by a set of preparatory work, including a number of stages. The economic and social efficiency of robotization depends on the composition, volume, sequence and completeness of the implementation of the complex of works [11-14].

Preparation of building production for the use of manipulators and robots has its own distinctive features, characterized by the specificity of technological processes and the need to use new methodological foundations for their design concept. In addition, the content and scope of preparation of processes at construction sites differs significantly from the preparation of technological processes at construction plants, which are more similar in character to technological processes in mechanical engineering. The process of preparing for the introduction of robots is determined by the character of the re-equipment of production. In the case of capital reconstruction, the construction of new manufacturing divisions and plant floors in the construction industry, the basic technical solutions for process automation should be underprin at the stage of preparation of technical documentation and comprehensively linked to the design and technological features of robotics objects. With the technical re-equipment of individual production lines and plant floors and in the case of robotization of individual operations at existing plants, preparation for the introduction of robotics should begin with an analysis of the process features and the effectiveness of the existing technology, the degree of use of equipment and the identification of tight spots when performing certain operations. A variety of technologies for work on construction sites and technological operations at construction industry plants requires a systematic approach to assessing the volume of implementation of manipulators and robots, choosing the objects of robotization and drawing up a work plan. In preparing the construction industry for the introduction of manipulators, robots and RSs, special attention should be paid to the issues of specialization, typification, unification, conveyorization and improvement of technology. The system of preparation for the robotization of production processes in construction should be based on rational organization, mechanization and automation. When solving robotization issues, it is necessary to achieve the optimal technology option based on the economically feasible choice of equipment, manipulators and robots, devices and tools that provide the necessary level of mechanization and automation of production processes.

In connection with the peculiarities of the introduction of robotics in the construction industry, let us consider in more detail the volume and composition of organizational and technical measures for the preparation of technological processes for the use of manipulators and robots.

At the plants of the construction industry, robotization of technological processes can be carried out both comprehensively on the production line, site, in the workshop, and locally in individual operations. Currently, manipulators and robots are mainly introduced in separate operations with the aim of eliminating tight spots in the process and eliminating monotonous and heavy physical labor. However, due to the large capital costs, this method is ineffective. This greatly inhibits the widespread adoption of robots in the construction industry. It is possible to increase the economic efficiency of using robotics tools only by preparing the conditions for their use in the complex solution of automation and robotization of production lines and plant floors on the basis of improving technology and product design. Therefore, the robotization of technological processes in the construction industry must be carried out on the basis of comprehensive scientifically based plans for technical re-equipment, which provides for a phased transition from the robotics of individual operations to complex automation and robotization of lines and sections. With this approach, individual local control systems of operations are gradually combined into systems for controlling lines, sections, and workshops with simultaneous solutions to the issues of automation and robotization of transport-auxiliary operations. In this regard, the process of introducing robots in the construction industry is preceded by a series of preparation stages associated with the formation of plans for technical re-equipment and reconstruction of production facilities.

In order to prepare a comprehensive production robotics program, which is an integral part of these plans,

the existing production processes (Fig. 1), technologies, equipment, products and transportation relations are

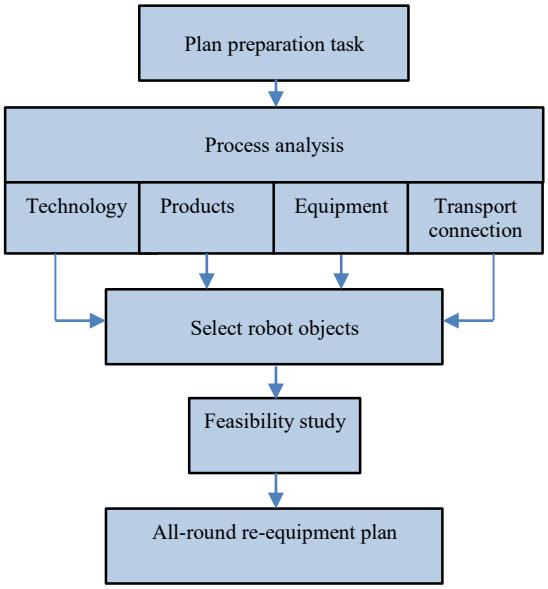

Figure 1. Scheme for a comprehensive plan for the technical re-equipment of production processes in the construction industry

analyzed. Depending on the scope of tasks for the reconstruction of production, it is necessary to analyze the entire production process, as well as its components or individual operations. The analysis reveals all the features of production, unused reserves, bottlenecks, the level of technological and design solutions, the level of mechanization and automation of individual operations, the composition and characteristics of technological equipment, organization methods and means for performing transport and auxiliary operations, transportation and storage of finished products.

As a result of the analysis, ways to improve the production process are developed, recommendations are given for the modernization of technological equipment or its replacement, ways to change the organizational structure and increase the efficiency of the process are outlined, measures are proposed to increase labor productivity, reduce the complexity of operations and employment of workers, improve working conditions.

In the course of a comprehensive assessment of technical, technological, organizational and social factors, proposals are formed for comprehensive mechanization, automation and robotization of production processes. An important stage of this work is the preliminary selection of objects of robotization, the purpose of which is to determine the feasibility of robotization of a particular technological operation. A number of factors are used as evaluation criteria. The use of manipulators and robots in the production process can be aimed at increasing production productivity, improving product quality, improving working conditions for workers, improving labor safety, reducing the complexity of auxiliary and transport operations, ensuring a high degree of equipment load. When introducing robotic means in existing plants, the volumes of redevelopment of production facilities, modernization of installed equipment and additional costs should also be taken into account.

Preliminary selection of robot objects is usually carried out by expert experts. At the stage of preliminary selection, a group of experts determines the significance of factors for a comprehensive assessment of production and, depending on its conditions and the resulting estimates, carries out an adjustment of the composition of factors. Further, each expert gives an assessment of the measure of influence of each factor on the decision in favor of robotization, and an average and relative assessment of the significance of each factor is established. The priority of production robotization is determined by the results of a comprehensive assessment in accordance with the preference rank identified during the expert assessment. Preliminary selection of operations is completed by compiling a list of objects of robotization.

The next step is the feasibility study of the selected facilities. The feasibility study ends with the exclusion from the list of robotic objects that do not give an economic effect. In the presence of dangerous and harmful conditions for the performance of production operations, the decision on the need for robotics is made regardless of the results of economic calculations.

Based on the results of the feasibility study, in accordance with the rank of preference assigned to each object of robotization, a comprehensive robotization program is compiled. In this case, it is necessary to provide for the phased introduction of RS and automation of processes. At the first stage, the tasks of creating separate robotic positions and combining them in the RS are solved. At this stage, priority is given to automatic and semi-automatic equipment. The second stage envisages further improvements to systems for servicing RTKs and combining individual RTKs into robotic production lines. At the third stage, the issues of robotization of all auxiliary operations, operations to remove production waste and create an automated process control system are solved.

Preparation of production for the introduction of manipulators and RSs, included in the plans for its technical re-equipment, contains a set of technological, technical and design works (Fig. 2). At the enterprises of the construction industry, the implementation process begins with a detailed analysis of the object of robotization and compiling a group of technical requirements. In the process of its comprehensive critical examination, all the constituent elements of the robotic part of the production process are exposed. In robotic

workplaces, the manufacturability of product designs, its compliance with robotization requirements is additionally investigated, technical and technological documentation is studied, the sequence of operations and the movement of workers is analyzed. The cyclograms of completed operations are built, their temporal and technical indicators are determined. In addition, the nomenclature and product release program in selected areas for robotization are studied. Objects of robotization are analyzed using methods of qualitative and quantitative assessment of possible options for the construction of RS.

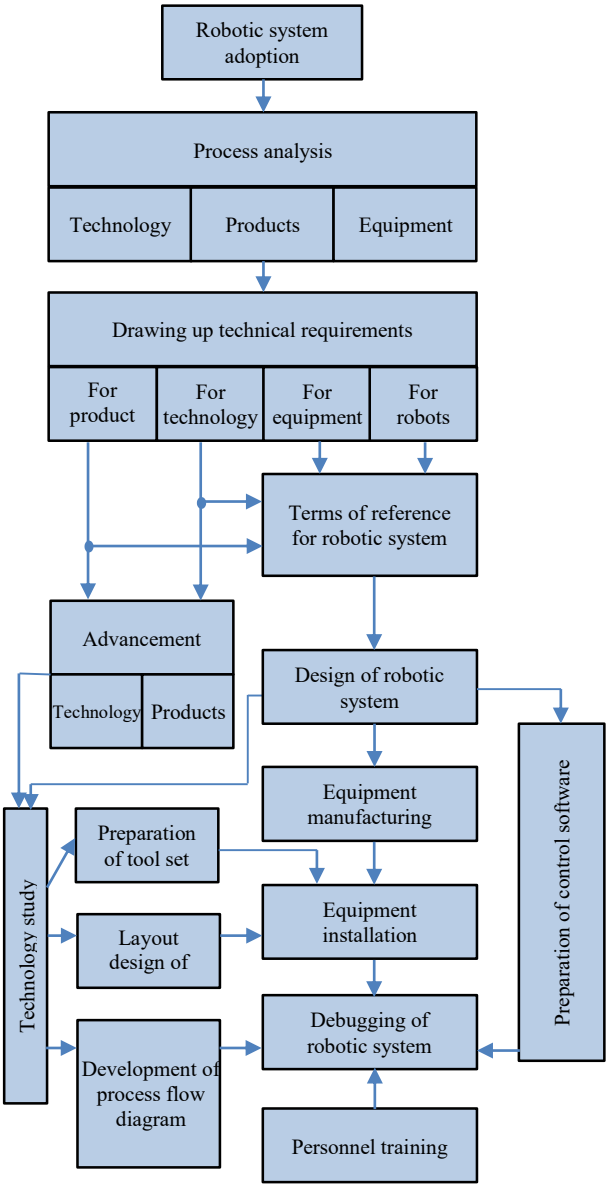

Figure 2. A set of works on the introduction of RS in the construction industry

Based on the analysis, technical requirements are formed for the technology, the main and auxiliary equipment, manipulators, tooling, control systems. The main requirements for the developed RS are set by technological, operational and economic indicators. The first determine the functional characteristics of the robot necessary for its inclusion in the RS, the second determine the ease of maintenance, maintainability, and other operational indicators, and the third establish the capital and operating costs that provide the necessary economic effect.

The formulated requirements serve as initial data for the preparation of technical specifications for the development of the RS and the implementation of works to perfecting the designs of products and their manufacturing technology. On the basis of the technical specifications, RSs are designed, preliminary they are developing a new technology and layout of the complex. When developing a project, when choosing technical means, it is necessary to take into account the productivity of each unit of equipment included in the complex, its mutual coordination with respect to constructive and technical performance. Particular attention should be paid to increasing technical productivity, which takes into account technical interruptions in the operation of the equipment. During the design process, a robot, additional equipment and working bodies are selected. The model of the manipulator or robot is selected based on a comparison of economic indicators for specific operating conditions. In the absence of robots that satisfy the task, it is being maid up the terms of reference for the development of a special design.

Particular attention in the design is given to transport-technological schemes and means of delivery of components and materials. At the design stage of the RS, safety and security equipment, magazine devices, special containers and facilities for the disposal of industrial waste are developed. Based on the results of a preliminary study of the operating technology of the PC, technological equipment is developed and manufactured that meets the basic requirements for the operation of the complex.

An important stage of preparation for implementation is the layout of the RS. When compiling it, much attention is paid to the optimal location of the main and auxiliary equipment, taking into account the technology of work, the safety of maintenance of this equipment and the possibility of its repair.

The final stages of preparation are the manufacture and installation of the RS, the development of process maps, the preparation of control programs, the debugging of individual equipment and the entire complex. Maps are drawn up in accordance with the general rules for the technological preparation of enterprises in the construction industry, determined by the Building Norms and Rules (BNaR).

Installation and debugging of the RS includes the development of an installation plan, the execution of work, the manufacture of an experimental batch of products and acceptance tests. Technological maps are developed after the final selection of the main and auxiliary equipment, means of its automation and tooling design. During production robotization, simultaneously with the design, manufacture and installation of the RS, the issues of personnel training for their maintenance should be addressed. Persons who have undergone special training are allowed to work on servicing robots and RS.

Based on a detailed review of the stages of preparation for production at the enterprises of the construction industry, it should be noted its features in the robotization of processes at construction sites. The main feature of the robotization of operations at the construction site is the non-stationary nature of the performed works, the temporary nature of the installation of equipment, possible changes in the layout and technology when changing construction. In this regard, it is advisable to implement robots and RSs at construction sites based on the use of standard projects for the robotization of certain types of work. Such projects are developed by a specialized organization for the construction of mass buildings based on an analysis of typical technologies for the construction process (Fig. 3).

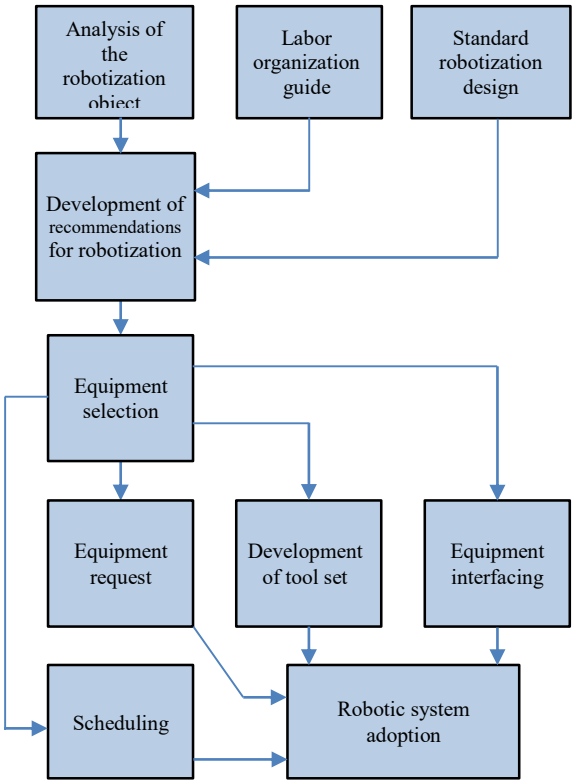

Figure 3. Scheme for the development of standard projects for the robotization of construction works

Typical projects include diagrams of the robotoization process, the composition of the recommended equipment, operation cyclograms of equipment, standard technological maps and basic labor protection measures when working with robots and RS.

The development of standard projects is preceded by a comprehensive analysis of the existing technologies of the robotic type of work and the organization of the construction process. Based on the results of the analysis, recommendations are made for improving the technology. Based on these recommendations and the results of the analysis, the objects of robotization are pre-selected and their feasibility study is carried out, technological schemes of operations are developed, the recommended equipment is selected, typical layout schemes, cyclograms and routings are drawn up. Based on the results of this work, a typical robotization project for this type of work is drawn up. To provide technical assistance to construction organizations on the implementation of manipulators, robots and RSs, it is advisable to prepare labor management guidelines for builders on the basis of standard designs when using robotics.

The process of preparing the construction for the implementation of manipulators, robots and RS during the construction, restoration, repair and reconstruction of buildings and structures begins with an analysis of the construction and technological characteristics of the robot object (Fig. 4). On the basis of this analysis, as well

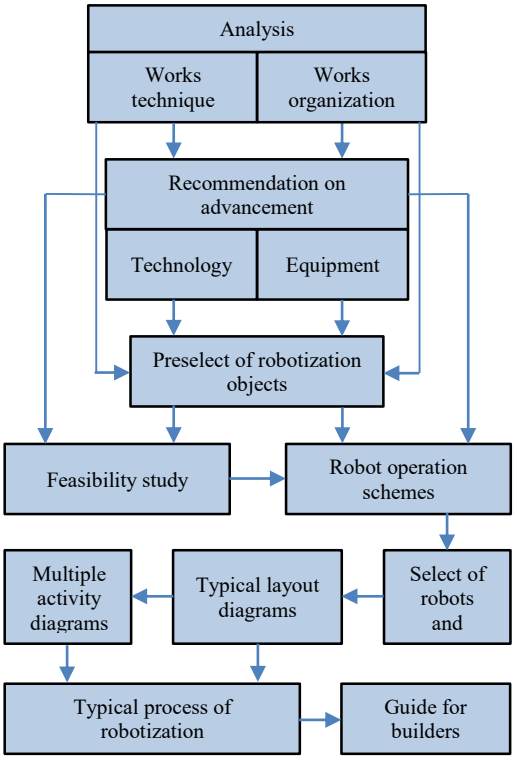

Figure 4. Scheme of works on the robotization of construction processes based on standard projects

as typical projects of robotoization of this type of works, recommendations are developed to improve the technology of robotic operations and modernize the equipment used with the goal of being able to interface with robotic mechanisms. At the next stage of work, it are selected the main and auxiliary equipment, automation tools; it are developed applications for their supply; it are prepared technical tasks for the design of technological equipment; it are developed equipment, devices and means of pairing old equipment with new one. After the completion of design work, equipment is manufactured and adjusted. The final stage of preparation is the development of a project for the production of works. Technological maps for the robotic operations that are part of the project are developed on the basis of standard ones with specific reference to the construction site and local construction conditions. Particular attention should be paid to the development of labor protection measures [15-20].

3 Maintenance of robotic systems

Manipulators, robots and RSs are complex technical devices, the effectiveness and reliability of which largely depends on the organization of maintenance. The low level of this service leads to a significant decrease in the efficiency of the use of automation and robotic means for construction and production processes, and in some cases it can even nullify the effect of their use. The correct construction of a maintenance system for manipulators, robots and RSs and their precise organization lead to an increase in the operating time, reduction of downtime, enhance reliability and, as a result, contribute to the growth of their operation in the production process.

Construction robots and RS as objects of maintenance have a number of characteristic features. They are distinguished by increased complexity, the presence of mechanical, electromechanical, hydraulic, measuring, electronic and other components and devices, which increases the risk of working with them. Therefore, high demands are placed on the labor protection of service personnel. The introduction of robots and manipulators requires not only appropriate technological preparation of production, but also changes in the activities of the technical and technological services of the enterprise, professional and psychological training of workers and engineering personnel.

The use of robots and RЬI at construction sites sets the task of creating a special repair and maintenance service that can provide maintenance of complex equipment directly at the site of construction vn work.

In the general case, maintenance of robotic devices includes a system of measures for preparing equipment for use and its maintenance during operation. In accordance with this, the following main stages of maintenance of robots and RTKs can be distinguished:

- the period of preparation of equipment and control systems for operation,
- preventive maintenance of devices during operation,
- restoration of the operability of devices in the event of failures.

The block diagram of the maintenance of robots, reflecting the listed stages of maintenance, is shown in Fig. 5. It can be seen from it that each stage includes a

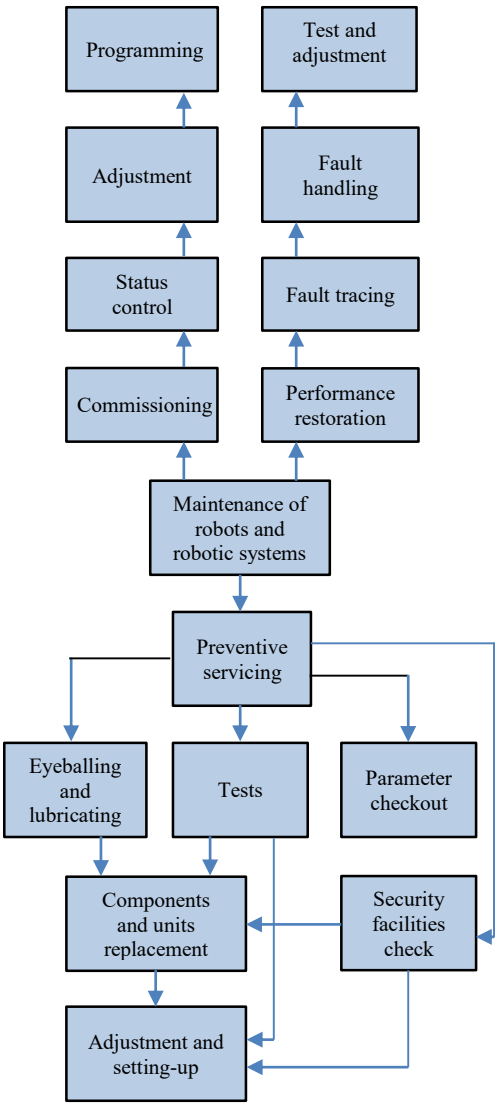

Figure 5. Block diagram of robots and RSs technical maintenance

group of measures necessary to ensure operability, the required reliability and durability of the equipment. So, the period of preparation of robotic facilities for use includes monitoring the status and performance of devices, their configuration and programming. Preventive maintenance includes periodic inspections of

individual devices, components and units of equipment, tests, verification of basic parameters and characteristics, replacement of elements and components, as well as verification of safety equipment. In the process of preventive maintenance, lubrication and adjustment of both individual elements and the equipment as a whole are performed. Faults and failures in the operation of nodes and blocks arising during the operation of robots are eliminated by carrying out restoration work, including troubleshooting, their elimination, as well as the verification and adjustment of devices.

Important indicators of robots and RS as service objects are maintainability, recovery efficiency and time spent on troubleshooting.

Maintainability characterizes the degree of adaptability of robots and manipulators to the prevention and detection of causes of failures in work and the elimination of failures. This characteristic determines the readiness of the equipment for work and is taken into account at the design and development stages. From the point of view of maintainability, robots and systems created on their basis should have handling devices, control systems, information support tools and technological equipment that meet the requirements of convenient access to elements, units and modules when troubleshooting and eliminating failures. The maintainability of robots and RSs depends on unification, interchangeability, availability of troubleshooting systems, as well as the level of preparation of diagnostic tests.

For robots servicing, determining the category of complexity of their repair, as well as evaluating the length of the overhaul period, is of particular importance. These indicators are determined depending on the design characteristics of robots, load capacity, degrees of mobility, complexity of control systems, type of drives, positioning accuracy and other indicators. A major role in robotic servicing is played by troubleshooting time. It is determined by a group of components and includes the time intervals necessary for detecting a failure, preparing a tool, finding a faulty unit and element, troubleshooting, after-sales adjustment and tuning. The time spent on troubleshooting depends on both technical and organizational factors, and primarily on the degree of maintainability, the level of organization of maintenance, training of maintenance personnel and the availability of diagnostic tests.

Carrying out repair work is also characterized by the efficiency of the restoration of failed nodes and systems of robots and technological equipment that is part of the RS. This indicator depends on the quality and reliability of the restoration, its cost, labor costs of maintenance personnel, as well as losses associated with untimely equipment repair.

When using robots in the construction industry, much attention is paid to the preparation period. This maintenance phase is especially important for robots used on construction sites where there are no special conditions for repair service and maintenance. In this case, it is advisable before sending the equipment to a new construction site under stationary conditions of the repair and maintenance service to monitor its condition and operability, to carry out the necessary adjustment and configuration of units and blocks, as well as programming based on the technological maps of the work at this object.

A prerequisite for the performance and reliability of construction robots is the organization of their preventive maintenance. It includes a system of preventive measures that reduce the likelihood of failures. Preventive measures are planned based on an analysis of the particular features of the functioning of all devices and systems of the robot. The choice of the timing, volume and sequence of these measures depends on the nature of the failures, the amount of restoration work, the requirements for reliability and operability of both individual components of the work, and the entire equipment complex. When planning work on preventive maintenance of robots, it is necessary to take into account the nature of failures of individual nodes and elements. Their planned replacement is carried out in case of failures due to wear and tear and for elements subjected to aging. For elements, blocks and devices having a specified service life, a plan for their replacement is drawn up in accordance with the achievement of the maximum operating time. Elements for which the service lives are unknown are replaced by the results of periodic control tests, during which the technical parameters are checked. If limit values are reached, the elements unsuitable for further operation are replaced. Parts subject to rare occasional failures must be replaced if they fail. Their planned replacement is non-forest-like, since it can lead not to an increase, but to a decrease in the reliability of the equipment. Their planned replacement is impractical, since it can lead not to increase, but to reduce the reliability of the equipment.

4 Conclusion

To ensure safe working conditions for construction robots and manipulators, a set of measures is provided that is implemented at the design, installation and operation stages.

The complication of production associated with the introduction of robots, raises the need to address in the process of preparing a set of issues on the organization and operation of robotic systems. In this case, special attention should be paid to ensuring labor safety during the operation of manipulators and robots.

For the selection of objects of robotization in each case, the priority of the set goals is established. First of all, during robotization, attention is drawn to labor-intensive, traumatic and harmful to human health operations, and secondly, to low-prestige, auxiliary, etc.

The main tasks of the maintenance of robotics tools are periodic monitoring of the technical condition of the equipment as a whole and its individual parts, timely detection of precautionary conditions, troubleshooting and restoration of equipment performance.

The effectiveness of the use of robots and RTK in construction largely depends on a clear organization of repair services. At the same time, planning and calculating the nomenclature and the number of spare parts is of paramount importance. During operation, robots and RTK are equipped with spare elements, blocks, replaceable modules. Repair service is provided with the necessary set of tools and devices. The troubleshooting process involves several steps. It begins with finding the failure by external signs and compiling, on the basis of logical analysis, a list of faults that can cause the observed set of failure. After that, the optimal sequence of checks is determined, allowing to find the faulty module, block, functional unit. Then a faulty element is searched. Diagnostic tests allow to simplify the troubleshooting task and quickly find a failed item.

Safety Concept and Architecture for Autonomous Haulage System in Mining

H. Ishimoto and T. Hamada

Mining Solutions Div., Client Solutions Group, Hitachi Construction Machinery Co. Ltd, Japan
E-mail: h.ishimoto.gl@hitachi-kenki.com, t.hamada.at@hitachi-kenki.com

Abstract –

In recent years, automation of mining equipment has been required to improve productivity, predictability, and safety of mining operations. Some major mining companies have begun efforts to automate dump trucks that transport overburden and minerals, eliminating the need for human operators, aiming for reducing labor costs, increasing operating hours, and improving efficiency of vehicle assignment. It is called an autonomous haulage system.

The introduction of an autonomous haulage system requires significant changes in operations management. Particularly, safety needs to be carefully considered.

Conventionally, in manned mining operations, ensuring the safety while at work has largely been the responsibility of site managers, fleet controllers, machine operators, and field workers.

However, when making the machine unmanned, it is necessary that the system bears a part of the function for ensuring safety, which has been conventionally carried out by humans, and that the user appropriately understand and operates the system.

This paper describes the concept of ensuring safety when applying an autonomous haulage system using unmanned dump trucks to mining operations, and a system architecture based on it.

First, we proposed the basic structure of the autonomous haulage system, conducted a risk assessment assuming mine operation using the system, and identified possible protection measures.

Next, we examined the architecture of an autonomous haulage system with a safety function that enables more deterministic performance evaluation while considering the complexity of the system.

This system was installed in an actual mine site, tested and operated, and it was confirmed that the safety functions worked properly. When introducing the system, the safety concept and architecture of the system have been explained to the site safety manager and governmental regulators and have been validated.

1 Introduction

1.1 Background

1.1.1 Industry Trends

Prices of resources such as coal, iron ore and copper have risen sharply since around 2005 due to economic growth in China and emerging countries. During this period, there was a shortage of workers due to the booming mining industry, and so the rise in personnel costs was a problem. In response, major Australian resource development companies have expanded their investment, especially for machine automation, with the aim of unmanned mining in the future.

Due to the subsequent slowdown of the Chinese economy, which caused the global economic downturn, resource prices peaked, and mining companies were required to improve the efficiency of mine operations and reduce operating costs. This change in circumstances, together with the recent development of IoT and AI technology, has become the driving force for accelerating the shift to unmanned mining and machine automation, rather than stopping it.

1.1.2 Demand for Autonomy

In the mining industry, ensuring the safety of workers has been an issue for a long time. Particularly, there is a need to improve the safety and comfort of the operators of machinery operating on the site. In addition, the ESG concept has spread as a method of corporate evaluation in investment activities, and the mining industry is in a situation where improvement of environmental impact and working environment is required.

1.2 Autonomous Haulage System (AHS)

One of the efforts for unmanned or automated mining equipment is the autonomous driving system (AHS: Autonomous Haulage System) of dump trucks. AHS is a system that allows the dump truck to be unmanned and to be centrally managed from the control system in the office to carry out hauling and dumping products. Unmanned dump trucks not only reduce labour costs for operators, but also increase economic benefits, such as extended operating hours by eliminating breaks and shift changes, reduced fuel consumption by an efficient and appropriate driving by computer-controlled operations, and an extended machine life by driving control with less damage to the vehicle body. In addition, safety is expected to be improved by reducing human error during dump truck operation. Furthermore, it is expected that the mine operation itself can be made more efficient by linking the hauling process with the production management system.

The introduction of AHS to actual operation began around 2008, and in recent years the number of deployment cases has gradually increased, especially in iron ore mines in Western Australia. [1][2]

1.3 Safety of AHS

AHS will change dump trucks in a conventional mining haulage operation to unattended. Therefore, many of the roles played by the dump truck operator, including ensuring safety, are replaced by the functions of various systems that are components of AHS.

The operator is not present in the driver's cab of an autonomous haulage truck (AHT) during AHS operation, but a mixed situation of AHT and other manned vehicles in the AHS operation area can occur at any time. In addition, operations involving human intervention such as AHT start/end operations, maintenance/conditioning work, and manual operation for moving inside parking areas and workshops will continue to be performed. Thus, given the actual mining operation and site environment, it is difficult to take intrinsically safe measures such as physically isolating AHT, which is a major hazard source, from humans and manned vehicles. Therefore, it is essential that the system functions play a certain role to ensure safety.

Based on the above, this paper aims to show the AHS safety concept and architecture for safe operation of the mine.

2 AHS architecture

2.1 Overview

Various architectures can be applied to the system configuration that realizes AHS. It is possible to have a completely centralized implementation in which even the actuator control of the dump truck is performed on the cloud server side, and conversely, there may be an autonomous decentralized configuration in which each vehicle determines its own target position and route.

A centralized system has the advantage of reducing the number of in-vehicle devices for dump trucks and facilitating software updates. On the other hand, since the responsiveness of each vehicle control strongly depends on the communication performance with the central control system, there is a problem that the system scale and operation are limited when the wireless communication infrastructure is not sufficient.

The autonomous decentralized system can reduce the dependency on wireless communication, but the dispersion of autonomous operation of each vehicle becomes large. As a result, multiple vehicles may not be properly controlled, and efficient operation may not be realized as the entire system.

As an alternative to these, an intermediate approach is applied to the AHS we have developed (hereinafter simply referred to as AHS). In other words, this is an approach that achieves overall efficiency while suppressing the dependence on wireless communication by giving each vehicle a certain degree of autonomy.

Figure 1 shows the architecture of AHS.

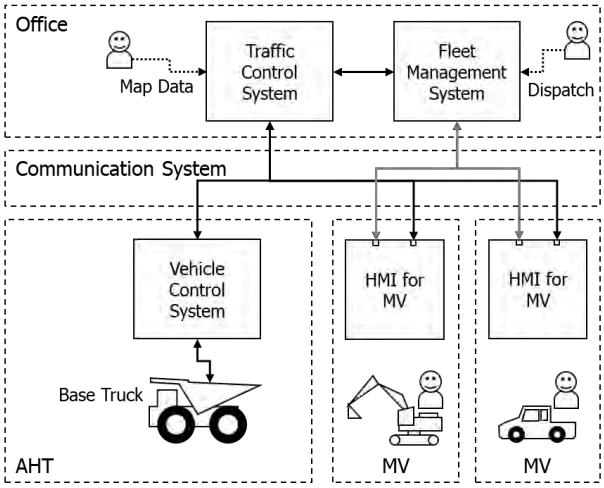

Figure 1. Architecture of AHS

The AHS consists of Fleet Management System and Traffic Control System located in Office, Vehicle Control System installed in AHT, and Communication

System that connects them. The manned vehicle (MV) used in the AHS operation site is equipped with a Human Machine Interface (HMI) that can monitor the operation status of the AHS and the status of AHTs.

The role of each subsystem that constitutes AHS is explained in the following sections.

2.2 Fleet Management System (FMS)

The role of the Fleet Management System (FMS) is to give a dispatch instruction to each AHT. That is, a destination such as a loading place or a dumping place to which the AHT should head is designated according to the current position of each AHT or the loading state. This dispatch instruction includes a method of directly setting a destination by an Office operator and a method of automatically issuing a repeat dispatch instruction based on a preset destination. The dispatch instruction is once passed to the Traffic Control System, converted into smaller driving instructions by the Traffic Control System, and sent to AHTs.

The FMS also displays the operating status of AHTs and the production volume estimated from them.

2.3 Traffic Control System (TCS)

In addition to multiple AHTs, MVs such as excavators, dozers, and light vehicles that are driven by humans also operate on the AHS operation site. The Traffic Control System (TCS) wirelessly communicates with AHTs and MVs, adjusts vehicle traffic throughout the site so that the interference between AHTs or between AHTs and MVs does not occur. The travel route of the AHT is divided into multiple sections, and by allowing the travel of each section exclusively to one AHT, interference between the AHTs is prevented. When the permitted section of AHT and the buffer area set in the traveling direction of MV overlap, the MV operator is guided by the HMI mounted on the MV so as not to enter the permitted section of AHT. At the same time, the TCS issues a deceleration/stop instruction to the AHT to avoid interference. [3]

2.4 Vehicle Control System (VCS)

The Vehicle Control System (VCS) controls the dump truck to move along the route to the destination specified by the FMS based on the TCS-controlled travel-permitted section. The AHT performs route-following traveling while comparing the route map information received from the TCS in advance with the self-position estimation results from the GNSS and IMU. In addition, the AHT detects obstacles with an environment recognition sensor and performs deceleration/stop behaviour as necessary.

2.5 Communication System (CMS)

Communication System (CMS) is responsible for information transmission between FMS, TCS, VCS, and HMI for MV. The CMS also has a function of monitoring the communication status including wireless communication.

3 Safety Concept

3.1 Principle

In the conventional hauling operation, the responsibility for ensuring safety during work has been delegated to appropriate actions and communication between people, such as operation managers, dispatchers, dump truck operators and other vehicle operators. On the other hand, in the AHS operation, it is necessary for the system to take over many of the roles for ensuring the safety, which was performed by the dump truck operator in the conventional operation.

However, it is hard to say that the concept of safety is established in the industry because AHS is still used only in some mines and is not widely used in many mines of the world. In addition, AHS is not a product with standardized structure and function like earthmoving machinery, and system configurations and functions are not common among manufacturers. Therefore, no common understanding has been established regarding the specific methodologies on which safety design is based or the performance target values for safety functions.

Therefore, we considered securing AHS safety based on the following basic policy:

- Compliance with safety requirements based on related international standards.
- Conduct risk assessments based on the operating environment and system architecture.
- Clarification of safety design requirements for protection measures derived from risk assessment.

3.2 International Standards

In 2017, ISO issued ISO 17757 “Earth-moving machinery and mining – Autonomous and semi-autonomous machine system safety”. The revised version was published in 2019. The standard covers systems in general that provide for autonomy in earth-moving machinery, primarily mining equipment and dump trucks in particular, and specifies the requirements that the system must have in its design, the information that the system integrator (which may be the same as the machine manufacturer) must disclose to the user, and the operating conditions that the user must control.

Regarding the safety of the system, it is required to carry out risk assessment according to the principles shown in ISO 12100. What constitutes a safety function in a specific system, and the required safety performance level thereof, cannot be uniformly determined because they largely depend on the operating conditions of the mine. Therefore, ISO 17757 does not provide a common target specification, and system integrators should make decisions based on the results of risk assessment. It is suggested to refer to ISO 13849, IEC 62061 or IEC 61508 for requirements in designing safety related control systems.

We have referred to this ISO 17757 as the basis for our AHS safety concept development and safety design.[4][5][6][7]

However, ISO 17757 does not mention specific procedures for risk analysis of autonomous systems and determination of required performance levels of safety functions. Therefore, we referred to the method proposed in the process industry that applies IEC 61508 or IEC 61511 to plant design.[8][9]

3.3 Layers of Protection

ISO 17757 describes risk management requirements for both AHS system integrators and users. Based on this, it was decided to secure safety based on the concept of hierarchical protection layers which combines system functions and operation management. The concept is shown in Table 1.

Table 1. Protection Layers of AHS

PL#	Protection Layer Category	Provided by
PL4	AHS Safety Functions	System Integrator (OEM)
PL3	AHS Control Functions	
PL2	Physical Barricades / Signage	User
PL1	Site Rules / Education	

At the first layer, user protection measures require AHS operation rules, provision of appropriate procedures, and education/training for workers involved in AHS operation [PL1 Rules/Education]. In the next layer, facilities to prevent human-AHT interference, such as signage and physical barriers that indicate the boundary between the AHT operation area and the manned area (parking area, workshop, etc.), are required. [PL2 Barricades/Signage].

As a protection measure by the system integrator (manufacturer), two layers of AHS control function [PL3 Control Functions] and safety function [PL4 Safety Functions] are provided.

PL3 is a layer for measures devised based on the AHS use cases assumed at present and the system architecture (shown in previous chapter) and comprises a variety of functionalities for realizing the main operation of the system. Each subsystem that constitutes the AHS has functions such as map management, traffic control, route tracking, and environment recognition, and these have the effect as protective measures in addition to realizing efficient operation.

PL4 is a layer of functions intended exclusively to ensure safety regardless of the action of the various functions of PL3 or the occurrence of a failure of the PL3 layer functions. In other words, it is a more universal and primitive protection measure that is less dependent on the functional specification of the system.

In ISO 12100 and ISO 13849, “safety function” is defined as “function of a machine whose failure can result in an immediate increase of the risk(s)”. PL4 is based on this definition. On the other hand, PL3 is regarded as a control function rather than a safety function. This means that a single failure of the PL3 function does not immediately increase the risk. In other words, even if one function of PL3 fails, as long as the function classified in PL4 is effective, the risk is still reduced to an acceptable level and it does not result in an immediate increase in risk.

The protection measures for PL4 or PL3 provided as AHS are designed on the assumption that the protection measures for PL2 and PL1 by the user are functioning properly. Safety cannot be ensured only by the protection measures by the function of AHS.

3.4 Risk Assessment

To extract the requirements that the system and the user should support for ensuring AHS operation safety, a risk assessment has been conducted according to the following procedure based on ISO 12100.

1. Assumed hazardous events due to system malfunction or human error.
2. Devised protective measures that can reduce the probability of occurrence of harm or the severity of harm.
3. Categorized to which layer of the hierarchical protection layers the devised protective measures should be placed.

Table 2 shows examples of hazardous events extracted by the risk assessment. In the actual development process, the probability of occurrence of harm and the severity of harm are estimated for each dangerous event, but they are omitted here.

Table 2. Examples of hazardous events

Origin	Hazardous Scenario	Target of Harm
AHT fault	Unexpected movement of AHT causes a collision with personnel.	Bys
AHT/TCS /CMS fault	AHT deviates from its travel route due to any abnormality in VCS/TCS/CMS, which causes a collision with personnel/MV.	Bys /MV Op
MV Op human error	The MV operator inadvertently enters MV into the AHT travel route, which causes a collision with the AHT.	MV Op
Bys human error	Personnel accidentally approaches the AHT, which causes collides with the AHT.	Bys

MV Op: Manned Vehicle Operator
Bys: Bystander (Field Operator, Maintenance Personnel)

Table 3 shows examples of the major protective measures (PRM: Protective Measure) devised corresponding to hazardous events extracted in the risk assessment. Each PRM is classified into one of layers PL1 to PL4. By applying a combination of a plurality of these PRM to each of the previously assumed hazardous events, the probability of occurrence of harm or the severity of harm can be reduced. PL1 and PL2 are user-controlled measures, and PL3 and PL4 are measures provided by the system integrator.

Table 3. Examples of Protective Measures

PRM type	Description	PL#
Rules / Education	Restrict personnel and MVs from entering the AHS area and AHT traveling routes.	PL1
Rules / Education	AHT start/stop procedure.	PL1
Barricades	Install a protective barrier between the AHS area and the manned area.	PL2
Barricades / Signage	Install AHS area entrance/exit gates.	PL2
AHT mode switching device	Proper placement of AHT start and mode switching devices.	PL3
AHT anomaly detection	AHT stops when it detects a system malfunction.	PL3
AHT deviation detection	AHT stops when it detects a deviation from the given route.	PL3
AHT obstacle detection	AHT stops when it detects an obstacle with the onboard sensor.	PL3
AHT permission control	AHT will stop within the given permit section if the next permit is not obtained.	PL3
AHT indicator	Notify the surroundings of the operating status of the AHT using indicators etc.	PL3
AHT audible warning	External notification of AHT start/start via horn, etc.	PL3
Site info provision	Provision of AHS area map information to MV operator.	PL3
Approach notification	Notify MV operator when MV and AHT approach each other.	PL3
AHT status info provision	Notify MV operator of moving/stopping status of AHT.	PL3
AHT Remote Stop	MV operator or personnel on site remotely stops AHT.	PL4
AHT approach speed limit	Limit the speed of the AHT when the MV and the AHT are close to each other.	PL4
AHT control system shutdown	Shut off the AHT vehicle control system during non-AHS operation.	PL4

The procedure for selecting PL4 safety functions from PRMs provided by the system integrator is described in the next section.

3.5 Selection of Safety Functions and PLr Determination

Figure 2 shows the safety function selection procedure.

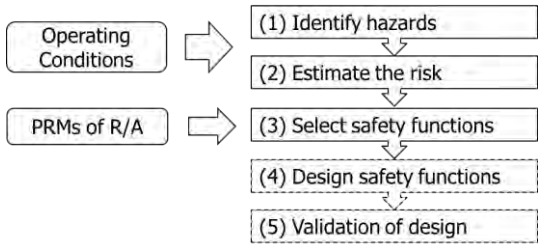

Figure 2. Safety functions selection process

3.5.1 Identify hazards

Accident scenarios due to AHT operation failure are identified as hazards. AHT operation failure means that the AHT does not operate as instructed, or that it operates unexpectedly. The cause of AHT operation failure is not necessarily limited to the failure of the hardware/software that controls the AHT base truck. AHS is a system that operates a dump truck by FMS, TCS, CMS and VCS triggered by human operation input. Therefore, the failure of any of the components that make up the AHS and the error of the person who operates the AHS can ultimately cause the operation

failure of the AHT. (For example, improper destination setting to FMS by a person, input error of map data, error of instruction to AHT due to TCS software bug, loss of operation instruction to AHT due to communication error, etc.)

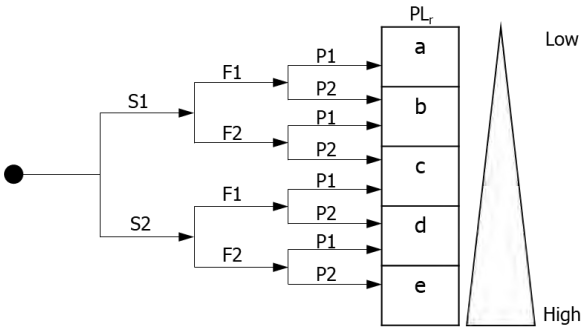
AHS has a large system scale, and the number of hardware and software that constitutes it is also large. There are also various combinations of operations between subsystems. Therefore, it is not practical to perform failure mode and effect analysis (FMEA) on all system components and consequently analyse all possible hazards in the entire system.

Therefore, we decided to conduct HAZOP for the behaviour of AHT, which finally becomes a hazard to humans, and identify the hazard. First, the movement of the dump truck was classified into acceleration, deceleration, steering, stop, and body lifting. Next, based on the HAZOP guide word for each movement, we assumed deviations such as "NO OR NOT", "MORE", "LESS", "REVERSE", and identified the resulting hazards.[8]

3.5.2 Estimate the risk

For all identified hazards, the risk estimation was performed and the required performance level (PLr) for the safety function to reduce the risk of hazard was determined.

For risk estimation, the analysis method using the risk graph (Figure 3) shown in ISO 13849-1, Annex A was applied.



S Severity of injury
S1 Slight
S2 Serious
F Frequency and/or exposure to hazard
F1 Seldom-to-less-often and/or exposure time is short
F2 Frequent-to-continuous and/or exposure time is long
P Possibility of avoiding hazard or limiting harm
P1 Possible under specific conditions
P2 Scarcely possible

Figure 3. Graph for determinating PLr for safety function

The procedure for determining the PLr based on the risk graph is described below.

1 Assume the situation before setting the intended safety function.
2 Estimate the risks caused by the failure of the safety function (in other words, the lack of the safety function). Consider the following parameters:
  2.1 Severity of injury
  2.2 Frequency and/or duration of exposure times to hazards
  2.3 Possibility of avoiding the hazard and probability of occurrence of a hazardous event
3 By selecting the above parameters, PLr to be assigned to the intended safety function is determined.

3.5.3 Select safety functions

Select a specific protective measure that can reduce the risk against the identified hazard from the results of the risk assessment. The selected protection measure is placed as the safety function of PL4, and PLr determined in the previous section is applied.

As a method of actual system design, safety functions are selected from the following viewpoints:

- To enable common risk reduction for more hazards with fewer safety functions.
- Safety functions can be placed independently of control functions.
- Safety-related part of the control system (SRP/CS) that performs the safety function can be downsized and the number of components can be reduced.

Table 4 shows examples of safety functions for each AHT operation scene selected in the above procedure.

Table 4 Examples of Safety Functions

AHT Operation Scene	Safety Function
Unmanned /Autonomous Mode	ASL: Approach Speed Limit
	R-Stop: Remote Stop
Manned /Manual Mode	AHT Control System Shutdown

During AHS operation is being conducted, AHT is in unmanned/autonomous mode. In this case, the situation where the AHT approaches a MV is a major hazard. As a protective measure, when the MV is close to the AHT within a certain range, the traveling speed of

the AHT is limited to reduce the kinetic energy of the AHT and lower the severity of harm. In addition, if the AHT is in low speed, the possibility that the MV operator can avoid the collision with the AHT increases, so that the risk can be reduced. Moreover, the possibility of avoiding a collision is further enhanced by equipping the MV with a device capable of remotely stopping the AHT.

During non-AHS operation, AHT may be used in manned/manual mode. In that case, there is a risk that the AHS function is activated unintentionally and obstruct human operations, resulting in a hazardous event. As a protection measure, the circuit is configured so that the AHT autonomous/manual mode switching device shuts off the power of the AHT control system during manual operation. This will prevent unexpected behaviour of the AHT in manual mode and reduce risk.

For each safety function, PLr based on the risk estimation under the assumption that the safety function is not provided is applied. This determines the target performance of the safety function and enables deterministic evaluation.

Note: The purpose of this chapter is to show the process of developing the AHS safety concept and determining the target performance of the safety function. It is out of scope to assert the need for a specific safety function and show a unified value of PLr for general automation systems for mining machinery. As described above, what kind of safety function is set and how the value of PLr should be are depending on the conditions under which the system is operated and the system architecture, and there is no general specification. Therefore, PLr value of each safety function is not described here.

3.6 AHS architecture with safety functions

Figure 4 shows the architecture in which the safety function components selected in the previous section are added to the AHS main function system shown in the previous chapter.

To provide the ASL function, the MV is equipped with means for measuring its own position and means for wirelessly transmitting the position. The AHT is equipped with means for measuring its own position and means for receiving position information from the MV. The received MV position and the AHT's own position are compared, and if it is determined that they are close to each other, the speed limit control of the base track is activated.

Similarly, to provide the R-Stop function, the MV comprises a wireless transmission means with a stop switch. When the AHT receives the stop signal from the MV, the control for activating the brake and stopping the base truck is activated. The MV transmitter and AHT receiver are shared by both ASL and R-Stop functions.

The communication system that transmits ASL/R-Stop signals is provided independently of the AHS main function communication system (CMS) and is used only for safety functions.

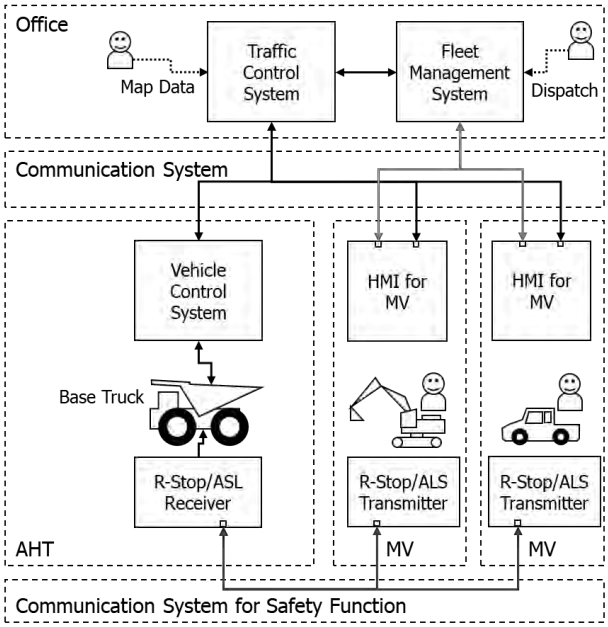


Figure 4. AHS architecture with safety functions

Implementing the system that provides the PL4 safety function independently of the system that provides the PL3 control function as described above has the following advantages:

- The safety function can always be activated as required without being affected by the operating status or malfunction of the main control function.
- The design of the separated SRP/CS becomes relatively easy and its performance can be evaluated deterministically.
- Since the safety function is not easily affected by the specification change of the main control function, it is possible to expand the functionality of the entire system without modifying the safety function.

4 Deployment and Evaluation

4.1 Deployment

With the cooperation of Stanwell Corp, an electric power company in Queensland, Australia, a trial of the AHS of the configuration introduced in this paper is being conducted within the Meandu coal mine owned by the company.[11]

As a result, commercial deployments of the AHS have commenced at the Maules Creek mine owned by Whitehaven Coal, a major coal producer in New South Wales, Australia. [12]

4.2 Evaluation

Mining companies that introduce and operate autonomous/unmanned systems are required to report their safety management plans and/or safety measures to the mining inspector in their state. In that case, the system integrator who provides AHS may also be required to submit the AHS system configuration, safety concept, and functional safety study report. If the information is insufficient, AHS operation in the mine may not be approved.

In preparation for the AHS operational test mentioned above, the safety of the AHS system and operation was reported based on the approach described in this paper and was validated by the mining companies' safety managers and state regulators.

5 Conclusions

We have developed a safety concept for introducing an autonomous haulage system (AHS) for dump trucks in mining operations. This concept is in line with the safety policy of earthmoving machinery and autonomous machine system, which is indicated by international standards.

Specifically, we conducted a risk assessment based on the AHS operating environment and system characteristics, and proposed protection measures for both the user side and the manufacturer side based on the concept of hierarchical protection layers. Hazard analysis was carried out to select the protection measures placed as safety functions, and the method to determine the required performance level of the safety function was established. An AHS architecture was formulated in which the selected safety function is provided independently of the main control function.

AHS based on this safety concept was introduced to an actual mining site. At that time, our approach to system safety was accepted by mining companies and officials, and the effectiveness of this approach was confirmed.

Abstract –

The use of robotic systems on construction sites can efficiently reduce construction time and increase safety by replacing construction workers in monotonous or dangerous operations. Robots for on-site construction applications are challenging and difficult to implement because of the evolving and unstructured nature of construction sites, the inherent complexity of construction tasks, the uniqueness of products, and labor-intensive modeling and commanding, which require significant human effort and expertise. With the development of data-driven techniques such as machine learning and computer vision, more advanced frameworks and algorithms can be developed to increase the level of adoption in the automation of construction robots. To better understand existing challenges and figure out the best strategies to implement high-level autonomous robotic systems for on-site construction, this study (1) summarizes technologies and algorithms used in construction robots and robotic applications in other industries, (2) discusses potential best usage and development of computer vision and machine learning techniques used in related areas to implement higher-level autonomous construction robotic systems, and (3) suggests a preliminary framework that integrates different technologies, such as vision-based data sensing to collect information, advanced algorithm to detect objects and reconstruct models of the built environment, and reinforcement learning to train robots to self-generate execution plans. This will allow construction robots to navigate and localize on construction sites, recognize and fetch materials, and assemble structures per a simulated plan. The proposed conceptual framework could help with the definition of future research areas utilizing complex robotic systems.

Keywords – Automation; Construction robots; Computer vision; Reinforcement learning

1 Introduction

Construction robots refer to robotic systems designed for construction operations, which typically take place in dynamic environments [1, 2]. Construction automation and robotics have been generating much interest in the construction community for the last decades as a way to improve productivity and reduce injuries or fatalities [3, 4]. Repetitive and labor-intense tasks, such as bricklaying, painting, loading, and bulldozing, are good candidates for automation, and the use of robots can assist in reducing labor force, and create safer work environments. However, compared to the robotic systems used in factories/manufacturing, construction robots have more complicated situations. They are exposed to dynamic and unconstructed environments, which means that predefined actions may not be suitable for all circumstances as construction sites and workspaces are always changing. Therefore, robots need to perceive the environment and understand how to react to the changes [5]. Besides, construction tasks comprise many variables, include different materials [6], and have different sequencing and requirements for assembling. This means that the control of construction robots requires a lot of manual effort to preprogram the motion and trajectory of the robotic system [7]. These challenges make it difficult to implement a high-level autonomous construction robotic system. Considering these challenges, to be able to have an autonomous robotic system to execute specific tasks, other technologies such as data sensing techniques and machine learning can be used to deliver unprecedented levels of data-driven support to substitute human efforts and instructions.

This paper presents an objective review of the use of computer vision techniques (CV) and machine learning (ML) technologies that could be used to achieve a high level of autonomy in robotic construction systems. Based on that, suggestions on a possible framework to implement a high-level autonomous construction robotic

system are provided. The rest of this paper is organized as follows. Section 2 summarizes construction robotic applications, discusses challenges currently faced, and provides an overview of CV and ML techniques developed and used in relevant areas that could advance robotic systems applied to construction. Section 3 proposes a possible framework in which CV and ML are used to create an integrated system to achieve autonomous localization, material recognition, and task execution planning. Section 4 summarizes the work presented and provides directions for future research.

2 Application of Construction Robots

In general, construction robots can be classified into four categories: (1) Off-site prefabrication systems, (2) On-site automated robotic systems, (3) Drones and autonomous vehicles (AV), and (4) Exoskeleton wearable devices. For each of these categories, there are several applications. Some examples are summarized in Table 1.

Table 1. Example of construction robot applications

Category	Reference
Off-site prefabrication	[8], [9], [10], [11], [12]
On-site automated and robotic systems	[13], [14], [15], [16], [17]
Drones and AV	[18], [19], [20], [21], [22]
Exoskeletons	[23], [24], [25]

Considering the adoption of each category in the construction industry, off-site prefabrication can significantly help with the advancement of building materials, which follows the same logic and principles of the manufacturing industry. Several building components and structures have already been constructed successfully in this way. Drones and AV applications have already been used widely on construction sites to help with the monitoring process and materials delivery. Exoskeletons pushed the limits of human-robot interaction (HRI). These systems can assist and protect workers performing heavy and dangerous tasks such as lifting heavy loads and are useful to reduce fatigue and facilitate the use of other tools and equipment in awkward positions [26].

However, applications for on-site construction robots have many limitations when compared to other categories. Current on-site construction robots mostly rely on preprogrammed processes to perform single repetitive tasks, such as bricklaying, steel-truss assembly, steel welding, façade installation, wall painting, concrete laying, etc., which do not involve multi-task or multi-robot construction. Current on-site robotic systems assist the construction work but could not take the place of workers and need supervision or assistance from an operator. Having the possibility of on-site construction robots being able to adapt to construction environments and perform multiple tasks without humans' hardcoding or programmed orders is not trivial, and further research is needed to create a high level autonomous on-site construction robot to unleash the great potential and opportunities of such systems. The focus of this paper is in that area.

2.1 Data-driven techniques

The advancement of data-driven techniques such as computer vision and machining learning has dramatically improved the efficiency and accuracy of robotic systems in multiple areas. Different applications in manufacturing, surgery, self-driving vehicles, structure inspection, and maintenance, have benefited from this and experienced improved productivity and accuracy.

Considering how a construction robot should work on a construction site, previous researches focused on the following elements to fulfill the automation of construction robot: (1) localization of the robot, (2) materials (i.e., workpiece) recognition and selection, (3) optimized control and task execution, and (4) monitor and maintenance, the following subsections provide a review of the technologies that could be used in each step (Tables 2 and Table 3).

2.2 Localization

Construction sites are characterized by being unstructured and dynamic. This creates extraordinary challenges for robots to localize and navigate in such environments. On-site robots should be able to avoid obstacles to reach a specific location to execute a given task. That requires extra sensing strategies or modalities to help robots perform work adaptively.

Table 2. CV techniques used in construction robots

Step	Computer Vision Techniques		
Localization	GPS	Camera markers	SLAM (mapping and reconstruction)
Material recognition	Point clouds segmentation	Stereo image (reconstruction)	Edge detection
Task plan execution		VR models simulation	VR, HRI
Monitor control	Point cloud	SLAM	VR

An excellent way to make sure robots find the right position while guaranteeing accuracy is by using cameras and markers. For example, [5] showed that a robot could use a camera and fiducial markers to find the position to execute a construction activity. While that provided reliable position reference for the robot to navigate, it did not consider obstacles. Robots cannot react to the

dynamic changes of the construction site, and the position of the markers needs to be manually modified, which requires a lot of manual efforts.

Table 3. ML techniques used in construction robots

Step	Machine Learning
Localization	Reinforcement learning for path planning and tracking (A*, LQR)
Material recognition	Deep learning or machine learning for Object Detection
Task plan execution	Reinforcement learning for simple task simulation such as bricklaying.

Currently, the most effective way to solve this problem is by using Simultaneous Localization and Mapping (SLAM). For example, [27] used V-SLAM with RGBD camera on an autonomous Unmanned Aerial Vehicle (UAV) platform for asset tracking in an outdoor construction site. [28] proposed a mobile indoor robotic monitoring and data collection framework using RGB sensors and fiducial markers. [29] proposed an autonomous robot equipped with different sensors to collect data used to conduct an automatic assessment of the state of construction. Autonomous navigation was achieved using an Adaptive Monte Carlo Localization (AMCL) algorithm. SLAM provides mapping and localization in an unknown environment and gives feedback for robots to understand the environment as well as estimating their current pose. Other applications based on SLAM include research focused on the modeling and reconstruction of the built environment using point cloud segmentation. For example, [30] proposed an integrated system that automatically provides detailed as-is semantic 3D models of buildings through raw data of point clouds. This system can better deliver environment information into digital models, provide a more reliable platform for robotic execution planning and simulation.

Based on this, reinforcement learning (RL) and optimal control could be used to provide a more robust trajectory planning result to deal with complex and dynamic problems. [31] utilized an A* algorithm to find an optimal sequence of biped robots' feet and hand contacts to cross a complicated terrain. [32] presented a quadrotor controller using iterative linear-quadratic regulator (LQR) algorithm to pass a window with slung load without the need for manual manipulation of the system dynamics, heuristic simplifications, or manual trajectory generation. RL can easily apply the navigation and collision avoidance mechanisms by learning from scratch, via a continuous, self-supervised learning process with less human effort involved and provide much more reliable simulation for more complicated non-linear dynamic systems. RL allows for further advancement of the mobility functionalities of robots.

2.3 Workpiece recognition and selection

The robot needs to go to its workpiece instead of having the workpiece brought to it, which produces a reversed spatial conveyance between the robot and the product [33]. Construction materials (i.e., workpiece) tend to exhibit considerable geometric variation. Due to their substantial size and properties, materials are often susceptible to large deflections and geometric irregularities [34]. Thus, the methods used to sense and identify the material on specific parts of the structure would be crucial for the robot to navigate around the site and find the right place to start the construction work. Previous research has investigated the ability of construction robots to adapt to the actual pose and geometry of their workpiece to perform their work. The following subsections address some of the key elements required.

2.3.1 Model registration techniques

Some approaches in manufacturing register complete 3D CAD models to determine the relative pose of the workpiece to be carried out [35]. However, such approaches are not expected to work well for construction tasks because the geometry of an individual workpiece can deviate substantially from its as-designed shape [36]. Previous studies utilized model registration techniques by matching the corresponding data and information of the workpiece with the registered models to figure out the relative pose between the as-designed object and the actual object. [7] proposed a framework to sense the data of complicated and irregular materials by producing a correlation score between the sensor data and the model to conduct dexterous tasks. These tasks require acquiring enormous and high-quality information from the environment, which requests an advanced integrated sensing system to describe the real world. Besides, the matching process also relies on human efforts or advanced algorithms to provide quick and reliable feedback. There is still great potential for the advancement of techniques and integrated frameworks to generate reliable feedback to on-site robotic systems.

2.3.2 Vision-based techniques

To get precise information and sensor data of the pose and the geometry of the workpiece, many studies used vision-based techniques such as fiducial markers to target desired objects for on-site construction robots. [37] proposed a framework using fiducial markers for robots to set specific waypoints to navigate around the building to gather information. However, the approach required the environment to be fitted with fiducial markers, which may not be ideal for real-world construction applications.

Other computer vision techniques (e.g., stereo images, edge detection, and laser scanning) have been used to find the best algorithm and strategy to identify the

workpiece. Some examples are summarized next.

1. *Stereo images*

[38] showed the rudimentary ability of a robot to identify and pick up tiles using stereo cameras and a suction gripper in a robotic tile installation operation. Stereo images can help with the 3D reconstruction of specific objects; however, the efficiency and accuracy of the learning algorithm significantly limited the shape and categories of the materials.

2. *Edge detection*

[39] and [40] used edge detection to identify simple shape wires; however, their applications might not work well for a wide range of object geometries. The edge detection approach and algorithm are widely developed and greatly used in related areas, such as self-driving vehicles using supervised learning, or a weakly supervised learning framework. For example, [41] proposed a segmentation-detection collaborative network (SDCN) for more precise object detection under weak supervision with less dataset required. With these advancements in object detection techniques, on-site construction robotic system could be further developed to recognize more complicated and specific materials.

3. *Laser scanning*

Another method to get the geometry and pose of the objects is using laser scanning techniques to get the point-cloud data of the object and then clarify the object into different classes. [42] demonstrated that a robotic excavator could use laser rangefinders to adapt its plan to the topology of nearby soil and the pose of a nearby truck for a digging and dumping operation. Similarly, [43] showed that a robot could construct a dry block wall in an adaptive manner by sensing the wall's top course with a 2D laser rangefinder and modifying the installation poses of subsequent blocks accordingly. However, point clouds are massive and do not have specific classifications.

2.4 Task execution and planning

Once the materials are prepared, the next stage is to generate the execution plan. Instead of manually hardcoding the plan and trajectory to execute specific tasks, machine learning techniques can be used to train the robot so that the best trajectories and motions can be autonomously generated. Among multiple varieties of machine learning technologies, RL is the most relevant techniques to the robotic motion and control. RL is a subfield of machine learning where an agent learns by interacting with its environment, observing the results of these interactions, and receiving a reward accordingly [44]. RL enables a robot to autonomously discover an optimal behavior through trial-and-error interactions with its environment.

2.4.1 RL applications

Many studies have contributed to the applications of RL in robotics, included locomotion [45], manipulation [46], and autonomous vehicle control [47]. However, there are very few reinforcement learning-based applications for construction robots. Most of them are in the areas of simple tasks such as grasping objects, in-hand object manipulation, door opening, and simple structures construction. For example, [48] described an iterative decentralized planning and learning method, to generate construction and motion strategies to build different types of three-dimensional structures using multiple quadrotors. [49] presented a framework using an actor-critic algorithm consisting of small autonomous mobile robots and block sources, which allows robots to gather blocks from the sources to build a user-specified structure.

2.4.2 From Single-Agent to Multi-Agent

In early 2016, [50] proposed a novel multi-agent framework along with deep reinforcement learning to learn a single-agent policy.

For large-scale control systems and communication networks, multi-agent reinforcement learning allows collaboration among different agents. The system's behavior is influenced by the whole team of simultaneously and independently acting agents in a common environment. For example, [51, 52] investigated a network which optimally divides the tasks for indoor building environment navigation among a group of robots to determine optimal routes to visit multiple locations. This is crucial for large-scale work, especially construction activities, which allows multiple robots to work simultaneously and can either give feedback to other agents or speed up construction work.

3 Discussion and proposed system

Construction robots have the potential to conduct specific construction tasks autonomously. A possible direction for the evolution of on-site robots is to train them to construct like human beings without humans' hardcoding or preprogrammed orders. This means that after getting the models and instructions from the engineers and designers, robotic systems can automatically make their own decisions and select different materials among various parts of the structure to accomplish complicated tasks. With that in mind, we proposed a high-level (conceptual) on-site autonomous construction robotic framework that combines CV and ML techniques (Figure 1).

3.1 Localization

We propose to fulfill the autonomous localization function by using SLAM algorithms, such as V-SLAM (RGB-sensor, Inertial Measurement Unit), and Laser-SLAM (Kinect) and point cloud segmentation to map and reconstruct the dynamic environment into virtual models. This allows to set up the position of execution by using augmented markers or manual selection.

For path planning in real-world on-site construction, robots should be able to work on large construction sites to fulfill different functionalities such as climbing, getting across holes, and balancing on uneven surfaces. The controllers for that involve complex analytical manipulation of the dynamics, which requires lots of extra effort to program. Reinforcement algorithms seem to be a good fit for more complex robotic applications that allow real-time environment feedback with less error while providing robust control for localization.

3.2 Workpiece recognition and selection

The proposed framework uses a combination of model registration techniques and sensing techniques to find the right materials to use and the installation position of the workpiece. BIM and CAD models are used by previous research to conduct the matching between a pre-designed plan to the material in use. With relation to the virtual models created in the localization subsection, the reconstructed VR models of the environment can also help with the matching of the real-world materials with desired models and provide feedback on the construction process. In general, the next step to recognize and select materials is set up manually with much effort of commanding. In the conceptual framework, with a predefined dataset of materials to use in the designed structure (i.e., stereo images, edge detection, laser scanning), the robots could automatically recognize the materials required through deep neural networks. Even though they are in different shapes or different locations, the robots could tell them apart in different classes. The matching process can provide state and action feedback for robots to generate the execution plan in order to get the required materials when constructing a complicated structure composed of different materials.

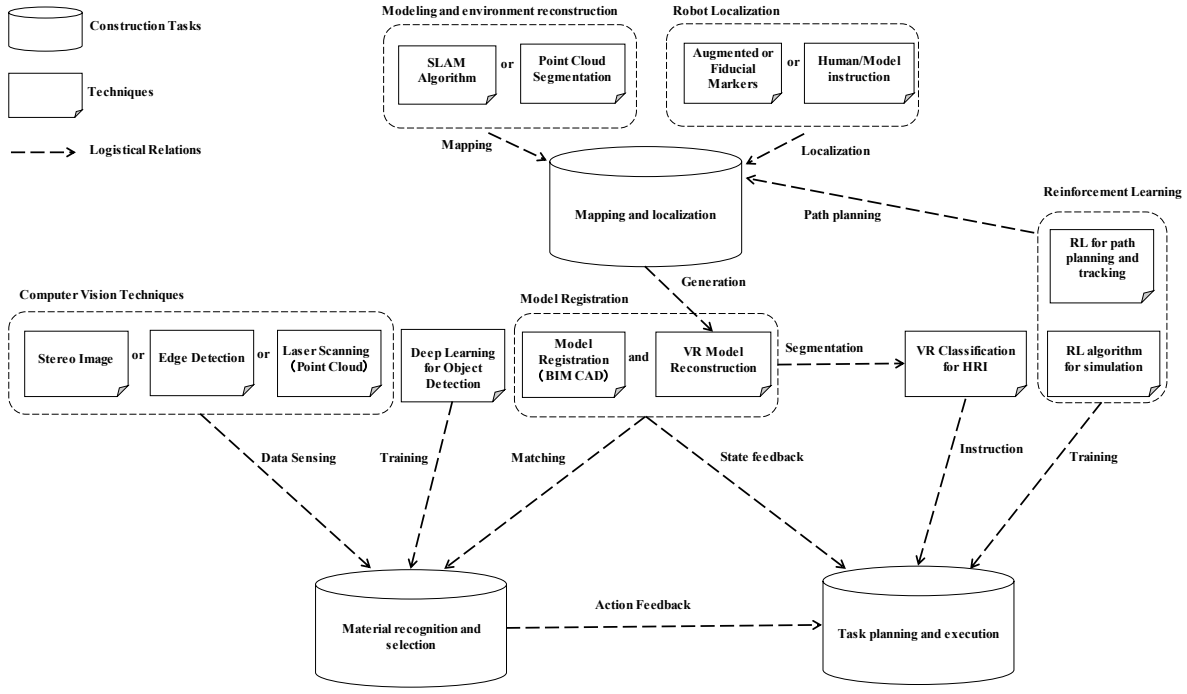

Figure 1. Conceptual on-site autonomous construction robotic system

3.3 Task execution and planning

For the autonomous execution and planning of tasks, there is no doubt that a combination of robotics and reinforcement learning will be very relevant. Some simple tasks (e.g., laying bricks, tying rebar, installing doors), could be done by current computation capacity and frameworks developed. With the information of the environment extracted from the previous step of mapping and information of material, we can describe the state of the robot and task. Then algorithms can be developed with a predefined reward policy to tell the robot what the

demanded motion or execution is. Commonly used is the deep neural network-reinforcement learning framework or inversed reinforcement learning, which can teach the robot to search for the right policy when the environment and state evolve. This can greatly decrease the human interaction with the robot(s) during construction. Besides, the proposed framework allows for the advancement of multiple robots to do the construction at the same time on the same tasks with future development.

4 Conclusions and outlook

Robotic systems have the potential to provide numerous advantages to the construction industry. This paper summarizes and discusses some of the techniques and algorithms that could be used to develop autonomous on-site construction robots further. Based on that, we propose a generic conceptual framework that can fulfill the whole construction process with minimal human interaction. We suggest using computer vision techniques and point clouds with an advanced algorithm to detect, identify, and reconstruct components in the construction environment. The framework aims to train the robot to understand the environment and identify the task and allocated materials in construction sites. Besides, the framework involves virtual reality models to extract and deliver information to robots for simulation and training, which not only guarantees the best solution for construction tasks but also allows the monitoring and controlling process to ensure that the motion and execution of the robots are executed as planned. At the same time, we propose reinforcement learning to train robots to learn like humans so that they can learn from previous errors and the results from previous iterations conducted during the simulation.

However, there are still some big challenges in the implementation of the proposed framework. First, the complexity of the construction site could produce noise to the robotic system, which will greatly influence the efficiency and accuracy. Second, the calculation capacity of the algorithm is not advanced enough to finish a complicated task. Techniques and algorithms are still in development and require extra effort to test and improve. Third, the implementation from the virtual world to the real environment could result in unexpected differences. To solve this problem, more advanced sensing techniques and more accurate models need to be generated in order to make sure the accuracy of the simulation process.

Future work includes testing the efficiency of the proposed framework using a robotic arm to build-up specific applications with computer vision techniques and reinforcement learning algorithms. We will develop and test schemes on mapping and reconstruction of real-world construction environments into virtual models. Tests will be conducted on construction materials from simple shape to irregular shape, as well as from single category to multi-categories. Based on this, we will train the robot to generate its own execution plan, from a single task to complex works that involve multiple tasks. To account for scalability, a multi-agent-based framework that allows several robots to collaborate will be considered.

Abstract –

In the construction of high-rise buildings, the conventional methods for the on-site installation of prefabricated facade modules require considerable manual handling. This unsafe and inefficient practice can be solved through automation.

This paper critically reviews automated Unitized Curtain Wall (UCW) installation and discusses opportunities for future development, as found in adjacent fields. A generalized solution to the installation of UCW modules is applied to analyze the conventional method in safety, economic efficiency, and logistic viability.

Recent automation solutions control wall module vertical transport trajectories with guide rails or redundant parallel cables. Both approaches specialize in capability, leaving many installation scenarios unautomated. Opportunities for improvement exist in efforts to automate crane operations by development of robotic crane end effectors. Localization in uncertain conditions for automated feature detection can be improved by dynamically changing the operator interface. Directions to improve safety and efficiency of UCW on-site installation are identified and recommendations are presented.

1 Introduction

The method chosen to construct the exterior wall of a high-rise building can significantly affect the entire construction process [1, 2]. Consideration of worker safety, economic efficiency, and logistic viability is of high importance in choosing the optimal solution. Potential for construction delays is increased with reliance on shared workspace [1–3] and equipment [1, 2, 4].

The unitized curtain wall (UCW) is a non-structural facade that is potentially compatible with these considerations. UCWs are comprised of prefabricated modules, hence complex designs can be manufactured in low cost, high precision factory environments [5]. The on-site installation procedure is also faster compared to other wall types [5].

High-rise building facades commonly incorporate UCWs, but the conventional method for on-site installation is unsafe and inefficient [1]. During installation, curtain wall modules (CWMs) are lifted by crane, hoist, or telescopic handler to the attachment location and then fixed to brackets which are preinstalled on the building [6]. The conventional installation method requires considerable manual handling to guide the large, heavy, suspended wall modules into position [6]. This presents risk of collision which can cause human injury or damage to the CWM [3].

Automation of the on-site UCW installation procedure is a solution to these issues. However, the current automation solutions are limited in addressing only a small part of the installation procedure [7], or in scope of application [2, 8]. For example, many automation solutions are limited to handling only common types of CWM [2, 7, 8], hence they do not apply to custom designs as in [9].

Automation of high-rise construction, including curtain wall installation, was reviewed by Cai et al. [10, 11]. To increase interdisciplinary communication, it was suggested to review the advancement of basic technologies that can be utilized in high-rise construction [11]. Iturralde et al. explored the task of lifting CWMs from the ground to the attachment location for an optimal automation solution [12]. However, the scope of their research did not include informational tasks.

This paper critically reviews the state of the art in UCW installation methods and discusses the potential incorporation of related mechanical and informational technologies. A generalized solution to CWM vertical transportation from the ground to the installation point and precision alignment with the attachment location is presented. The relations among components of the solution are then discussed and flaws in the conventional

installation methods are identified. Venues for further improvement are then determined through analysis of automation technologies in adjacent fields with respect to the generalized solution.

Section 2 describes the scope and methodology of this review. Section 3 then presents the generalized solution for vertical transport and precision alignment of CWMs, then discusses limitations in the conventional solution. In section 4, venues for improvement are suggested in the mechanical design as well as in the informational processes of sensing, analysis, operator feedback, and operator control. Conclusions and future research directions are then presented in section 5.

2 Research Scope and Methodology

The UCW installation procedure is described by Taghavi et al. [6] and Yu et al. [7]. The procedure comprises of designing the curtain wall, manufacturing CWMs, delivery to the construction site, vertical transportation to the installation point, alignment with the attachment location, and attachment of CWMs to the building. Within this procedure, the attachment interface on the building side can be prepared before, or at the point of, module attachment [6]. The scope of this paper is limited to the tasks of CWM vertical transportation and alignment with the attachment location. These tasks are particularly dangerous in the conventional procedure, while there is potential to significantly improve both safety and economic efficiency through mechanization and automation [1–4, 13].

This review includes literature directly related to UCW installation as well as literature from other fields where the mechanisms and processes are relevant to UCW installation. The reviewed mechanisms and processes are categorized in Figure 1.

The literature search mostly utilized the search engine ‘Google Scholar’ as a means to reduce bias towards specific research fields, conferences, or journals. Search keywords that were identified by Cai et al. [11] were utilized. The most relevant were ‘curtain wall’, or ‘facade’, with ‘installation’, ‘assembly’, ‘automation’, or ‘robot’. Other keywords were identified through relating mechanisms and processes utilized during UCW installation. For example, ‘crane’ was combined with ‘vision’, ‘mapping’, ‘localization’, ‘skew control’, and ‘operator assistance’. Results were filtered by title and then abstract, based on relevance. Further literature was found with the snowball methodology; by following the citations found in highly relevant literature.

Where large volumes of similar literature were found, only representative samples were selected to be discussed in this review. This increases the breadth of the review, as the review is intended to broadly survey the applicable technologies rather than focus on the individual implementation of each. The selection criteria weighed year of publication, number of citations, and relevance to UWC installation.

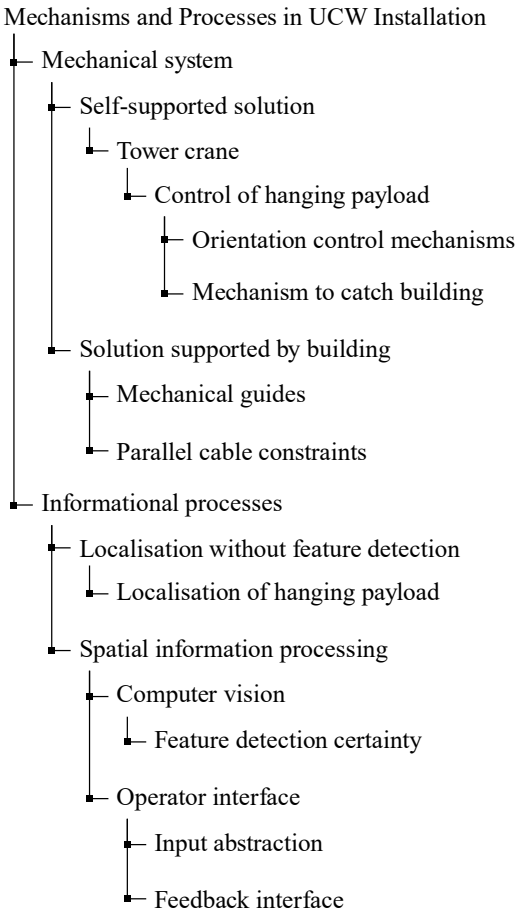

Figure 1. Reviewed mechanisms and processes

3 The UWC Installation Method

A generalized solution to CWM vertical transportation and precision alignment is presented in Figure 2. The desired state of the system has the CWM aligned to the attachment location. To achieve this, the decision-maker commands the hardware controller, which actuates the mechanical system toward the desired state. The state of the system is sensed, and the sensed information is pre-processed by the analysis unit before being fed back to the decision-maker. Information may also be sent directly from the sensors or analysis unit to the controller, creating an inner feedback loop to stabilize the system state by suppressing deviations from the command signal.

There are two main conventional UCW installation methods: direct and staged. Figure 3 presents the direct method. In this approach, CWMs are lifted directly from

the ground to the attachment location with a crane or hoist. This method is used as a basis for comparison, rather than the staging methods described in [1, 3, 6, 7], as it is more similar to the most recent automation solutions [1, 2, 4, 6, 9]. The direct method is most appropriate for large and heavy CWMs. It is faster to install UCWs that are comprised of larger modules [2, 3, 14]. Additionally, by not requiring on-floor staging, the impact on other construction operations can be reduced [1, 2]. This follows the lean construction methodology of decoupling operations.

In the direct conventional method, the operator of the crane or hoist performs analysis and decision-making. Their role is to send commands to the hardware controller based on feedback from the sensors. The hardware controller actuates the mechanical system based on the operator's input. Feedback from crane pose measurement sensors allows tracking of the command and deployment of anti-sway technologies [15]. These sensors also feedback to the operator's user interface.

The crane 'dogman' is situated at the installation point. They perform sensing and analysis of spatial information for localization, and feedback this information to the operator [16]. In the case of a 'blind lift', where the crane operator cannot see the CWM directly, the operator is entirely dependent on the dogman. The dogman also performs decision-making and actuates the system to control the orientation and position of the CWM during the alignment phase. With their interdependent responsibilities, the crane operator and dogman must operate in unison. Hence the installation speed is limited by the speed of communication between the crane operator and dogman [17].

This indicates that the safety and efficiency of UCW installation can be improved through automation of the work conventionally performed by the dogman. The effectiveness of removing the dogman is supported by the results of research to automate crane operations, as applied in adjacent fields. Crane operator performance can be improved in safety and efficiency through utilization of automated systems to sense, analyze and feedback spatial information [13]. Mechanization of payload orientation control with an active rotary crane hook is economically beneficial and greatly increases safety [18]. Combining an active rotary crane hook with automated alignment sensing and analysis unit can increase the speed of alignment operations [19].

The solution to safe and efficient CWM vertical transportation and precision alignment requires unison in communication between the systems that perform decision-making, control, actuation, sensing, and analysis. The utilization of a dogman impedes effective communication. The minimum requirements to remove the dogman are automation of sensing and analysis, and mechanization of precision positioning.

4 Discussion of Technologies Relevant to UCW Installation

This section explores opportunities for improvement in each UCW installation mechanism and process, with the objective to eliminate the requirement of a dogman in CWM vertical transportation and precision alignment. It is assumed that an operator will be required, hence fully autonomous path planning and logistics is not explored.

4.1 Mechanical System

Mechanical requirements of the solution are CWM loadbearing, vertical transport to the attachment location, and precise position and orientation control with 1mm tolerance [8, 20].

To better interface CWMs with robotic tools, many automation solutions require specific or custom UCW designs [1, 2, 12]. This also simplifies the automation of processes that vary significantly with variation in curtain wall design, such as the automated fixing of an aligned CWM to the building. However, limiting the application of the solution to compatible designs of curtain wall could cause long term problems. For example, the solution by Friblick et al. [1] does not allow for CWMs to be installed with any procedure other than the intended procedure. Hence, repairs to and disassembly of the proprietary mechanism may require special parts and tools that have ceased being produced during the lifespan of the UCW. Thus, we mainly highlight solutions that are compatible with existing designs of curtain wall.

The most appropriate class of robot for performing high-rise UCW installation without on-floor staging, has previously been assessed as the hanging robot [12]. A challenge for hanging systems is to control all degrees of freedom (DOF) with the precision required for the alignment operation. In the conventional solution, a single vertical hoist cable usually supports the CWM. This system is highly underactuated and susceptible to wind induced oscillations [21], hence the need for a dogman to perform fine position and orientation control.

Two approaches to control a hanging system are to either suppress oscillations with control systems or to introduce additional kinematic constraints. Given the large workspace, the only practical available stationary reference for constraint is the building that is under construction [12]. For example, an effective strategy is to attach guide rails to the building and hoist CWMs along the single remaining DOF [1, 2]. In constrained systems, it is often required for the building to support the load of the installation system and CWM. This increases potential to significant cost reduction [1–3]. Conversely, this may not be practical if the geometry of the building is not suitable or if higher floors are not yet completed. The following discussion is divided into solutions that require the load of the CWM to be supported by the building, and solutions that can independently support the load.

4.1.1 Self-Supported Solutions

Tower cranes are, to the best of our knowledge, the only independent load support structure deployed in high-rise UCW installation. The lack of utilization of other types of support body in high-rise construction indicates that no other independent support structure is practical, backed by the analysis by Iturralde et al. [12]. In the crane supported installation method, any geometry of CWM can be lifted to any attachment location that is not below overhanging building geometry. Hence, this method can be deployed to almost any application. The requirement of situating a tower crane on-site is typically satisfied due to the requirements of other on-site construction operations, and the crane can be shared amongst these operations [1].

To achieve the positional accuracy required for UCW installation, all vibrational modes of the suspended CWM should be suppressed. For a load supported by a single vertical cable, such as a crane suspended load, while allowing for elasticity of the cable, there are 6 DOF of vibrational modes. They are sway (pendulum swinging of the hook with 2 DOF), roll (payload tilting about the hook with 2 DOF), skew (rotation about the cable axis with 1 DOF), and heave (linear oscillation along the cable axis with 1 DOF) [22]. Based on a 2017 review of crane control systems [21], most research considers only the sway modes with a few considering the roll modes. Very little research considers skew [23] or heave [21].

Heave, roll, and sway oscillations can be controlled with regular tower crane motions; however, control is underactuated. Furthermore, the rotational motion of the jib about the tower (slewing), has highly coupled non-linear dynamics, making control of the payload very difficult [21]. Hence, to achieve the positional accuracy needed to install a CWM, an additional mechanism is required.

With the assumption that the alignment roll orientation is consistent for each application and does not need to be changed often, the roll orientation can be manually set to the aligned orientation before the lift operation by adjusting the rigging configuration. In this case, pre-setting the roll orientation and passively or actively suppressing roll oscillations does not limit the system capabilities. If this assumption is not valid, then a mechanism that translates the center of mass relative to the hook can adjust roll orientation by small angles [24].

Active skew control is necessary to perform alignment with complex building geometry or when using slewing cranes [25]. Several devices have been developed which utilize heavy flywheels to exert skew torque through conservation of angular momentum [19, 26]. These devices can become saturated and must

be heavy to be effective. Another method of skew control is seen on harbor cranes. For slewing harbor cranes, skew control is achieved with an active rotary crane hook (also known as a 'Rotator' or 'Power Swivel') [23, 25, 27, 28]. For system stability, at least two separated cables must connect the trolley and hook block. Full scale outdoor experiments show that very small skew error is achievable [25], likely to a degree that is sufficient for UWC installation.

To aid in vibration suppression when the CWM is near to the building, the building and the previously installed CWMs can act as reactionaries. A manipulator can take hold of the building and drive the CWM into position by utilizing the sway degrees of freedom [29] or an extendable hook attachment [30]. For the gripper type, inspiration can be taken from harbor crane operations, where the spreader is mechanically aligned to the target container with 'flippers'. The flippers are driven closed onto the edges of the container from all directions, mechanically forcing the parts into alignment.

For the swaying manipulator to catch the reactionary, an impulsive load will be generated. Thus, to prevent damage to the building or CWM, dampening of the collision is required. This problem has been investigated in research to assemble suspended large steel beams, where a pre-acting control strategy has been proposed [29]. An adaptation would need to be made for the swaying crane end-effector to catch the building instead of the other way around.

4.1.2 Load Supported by the Building

Rather than lifting CWMs to the attachment location and then catching the building for stability, CWMs can be guided through a constrained path throughout the entire lift. As risk of damage by collision with the building is eliminated, the lift path can stay close to the building for the entire lift [1–3]. This allows for performing the lift with a hoist that is mounted on the building, thus eliminating dependence on the expensive tower crane. The building can also support any constraining fixtures.

Kinematic constraints in current UCW installation methods include guide cables [3] or guide rails [1, 2]. These constraints limit application to geometrically prismatic buildings that can support the mass of the hoist and CWM from the location of the hoist. Furthermore, the guide rails themselves must be installed without the aid of guide rails, requiring dangerous manual labor. An alternative approach is to constrain the orientation with tensioned cables, terminated at, and attaching each corner of the CWM to the ground [31]. However, guide cables may not be feasible for automated alignment due to interference with the already installed CWMs.

In another approach, a redundantly cable-driven parallel robot for UCW installation is currently in development [6]. Tensioned cables connect the robot to the corners of the building face, over-constraining the floating robot. Even with this design, to achieve 1mm precision with the end effector, a secondary robot arm is attached to the cable suspended base through a passive damper [8, 32]. Hence this robot has many DOF, which is not ideal for cost or maintenance. Another limitation of the design is that for flat faced buildings, the constraint cables will be closely in-plane, which leaves the design sensitive to out-of-plane disturbances [33]. Additionally, the cable tension must increase as the angle of the cable from vertical increases [33]. Very large cable tension would then be required to install the top row of CWMs which the building may not be designed to withstand.

The main challenges for the mechanical system to vertically transport and precisely align CWMs are to achieve high positional accuracy and suppress vibration. Supporting the load of the system with the building has many advantages but is not suitable for every application. Supporting the CWM with a tower crane can be deployed to almost any application, but vibration suppression is more difficult. A specialized crane end effector is a potential solution to this problem.

4.2 Informational Processes

The hardware controller requires feedback of the system state to perform command tracking, and the decision-maker requires feedback of spatial information to perform path planning (Figure 2). The state of a crane system is typically characterized with pose and load measurements [27, 34], while the spatial information to feedback is dependent on the required input.

4.2.1 Localization Without Feature Detection

Measurement of the system state is a requirement of setpoint command tracking and oscillation suppression. The positional tolerance requirement of the alignment task is 1mm [8, 20]. Hence the position of the CWM relative to the attachment location needs to be measured to this tolerance. If a map of the workspace is acquired, then accurate measurement of the pose of the system is sufficient for localization.

The state of the art techniques in crane pose measurement to estimate the payload location are insufficient in accuracy and reliability for application to CWM alignment [34]. However, the nature of UCW installation separately requires both large payload displacement and accurate positioning. Hence it may be practical to utilize separate measurement systems for each task. Pose measurement can be utilized during vertical transport, as well as to deploy anti-sway technologies.

A challenge in pose measurement is determining the location of the hanging payload. The sway angle of the cable can be measured by aiming a camera horizontally

at the top segment of the cable [35]. Robustness to changes in background light levels can be achieved by utilizing an infrared camera and emitter [36]. Sway and skew can be measured together by fusing the data from an inertial measurement unit (IMU) placed on the hook block, with feed from a camera pointing down from the top of the hoist [34]. However, the reliability of computer vision techniques to identify the payload with a downward pointing camera is subject to lighting conditions, hoist length, and similarity between the colors in the background to the payload.

4.2.2 Measurement, Analysis, and Feedback of Spatial Information

Measurement of spatial information can supplement the low accuracy of crane pose measurement. CWM alignment can be measured relative to a fiducial feature of the target, by utilizing a camera or laser scanner mounted on the crane hook block. For example, a camera mounted on a crane spreader can reliability detect and locate the lock holes of shipping containers [37]. Relative alignment to adjacent CWMs can be measured accurately with computer vision utilizing structured lasers by analyzing the gaps between CWMs [38]. Error accumulation from relative measurements can be corrected by aligning measurements taken at a known location to a CAD model of the building [9].

In case of low certainty in feature detection, the operator can assist in analysis. For example, the operator can select the locations of bolt holes from a camera feed to provide a region of convergence to the feature detection algorithm [39]. After the alignment target has been identified, the controller can then perform path planning and complete the alignment semi-autonomously. This requires abstracting the operator input into higher level actions and programming the controller to decompose the task into actuator inputs [40]. This separates their decision from the action generated by internal feedback. This separation is beneficial, as absence of separation creates conflict between the operator and internal feedback anti-sway systems [15].

Another source of conflict in the operator interface is feedback. Depending on the operators perception of a tasks difficulty, feedback may be interpreted as either helpful or distracting [13]. To keep feedback relevant to the current task, it may be appropriate to use separate interfaces for large payload displacement and accurate positioning. Since these tasks are completed separately, the interfaces will not interfere with each other.

Only the required feedback should be provided to the operator [13]. Providing too much feedback increases the operator's mental workload in performing analysis, which increases their reaction time. Pre-processing and analysis of camera feed to draw attention to the relevant information is common solution in research. A map can be generated by piecing together images captured by an overhead camera at different crane orientations [41]. The height of obstacles can be highlighted by thresholding rangefinder data [42]. However, trials of an operator feedback system indicated that a raw camera view should still be provided [43], which may increase operator trust in the system and also provide a fallback in case of poor operating conditions for automated analysis.

Lee et al. fused sensor data with the CAD model of the construction site [43]. The simulated camera views were feed back to the operators display. It was concluded that split 2D top and side views are easier to interpret than a 3D view. Additionally, the interface for altering the feedback display should be simple and preferably hands free. In a similar approach, Chen et al. pre-processed sensor data with a game engine to create a 3D workspace visualization [34]. This is presented to the operator through a similar interface which is manipulated with voice control.

The main challenges in automating the informational processes required for UCW installation are precise localization of CWMs and managing the information feedback to the operator. Sensing of the system pose is inadequate in accuracy for alignment, but relative localization with computer vision is viable. Dynamically changing the control and feedback interface is a potential solution to keep the user interface relevant to the current task.

5 Conclusions

The UCW installation automation solutions currently deployed and under development are limited in scope of application. Limitations include requirement for the building to support the transport mechanism, requirement of custom designs of curtain wall, incompatibility with complex building geometries and existing designs of curtain wall, and solution complexity.

Research to automate large steel beam assembly provides potential solutions to better constrain a CWM. Compared to construction operations, a high level of precision and automation is achieved in harbor crane operations to move shipping containers. The requirement of a dogman is removed by introducing an active rotary crane hook, and high positional accuracy is achievable through control systems.

Measurement of the pose of a crane to estimate the payload location is insufficiently accurate for CWM alignment. Computer vision can be used instead. Operator input can be combined with automated analysis to improve feature detection. The operator is a feedback controller, and hence their interface is an essential part of the system. Removing the lag caused by the slow communication between the dogman and the operator can improve both safety and installation speed. Pre-

processing of feedback and careful choice of the relevant information to feedback is required.

Further research is recommended to develop an automated UCW installation solution that is widely applicable to different types of curtain wall, building geometry, and building load capacity; addressing situations where the more specialized solutions do not apply, for example, in refurbishing projects or when installing unusually shaped CWMs. The solution should primarily aim to mechanize and automate the tasks that are conventionally completed by the dogman. This will result in a safer and more economically efficient installation methodology.

E-mail: sei@arch1.t.u-tokyo.ac.jp, gondo@arch1.t.u-tokyo.ac.jp

Abstract –

In Japan's construction industry, techniques of producing complex three-dimensional (3D) formwork at construction sites are conventionally developed using the sophisticated skills of carpenters. Inspie of the development of digital technologies, the production of free-form shapes faces considerable cost and time management risks that require pragmatic solutions. In the efficient building of free-form shapes, the continuous surface should be divided into portable elements for formulating production plans and for making products in the factory. The products should then be installed and assembled at the construction site. Hence, new methods with computational design are assumed to require an approach different from the traditional processes of designing and constructing with two-dimensional (2D) drawings.

This research aims to analyze the productivity of these conventional means and propose a New Method of constructing free-form formwork for real-scale buildings.

First, we focused on how the designed geometric coordinate information is translated for construction on complex wooden formwork. We revealed how these shapes were realized by carpenters, and organize cases from 1991 to 2020 to see how the existing Japanese wooden formwork technology can realize double-curved surfaces.

Second, we focused on a completed project that has a 5,100 m^2 free-form RC roof constructed using the nonuniform rational B-spline (NURBs) curve and conventional production methods. Additionally, we analyzed the project's production time and cost from the construction records and revealed that the methods heavily depended on on-site labor.

Finally, based on the analysis results, we propose a production method in which curved surfaces are divided into portable units to reduce on-site labor and ensure high accuracy. We also analyzed its productivity through some assembly experiments. The labor cost of the New Method is lower by 93% than that of the existing method.

1 Introduction

1.1 Background and purpose of the study

In Japan's construction industry, techniques of producing complex three-dimensional (3D) formwork at construction sites are conventionally developed using the sophisticated skills of carpenters [1]. The development of digital technologies, especially 3D computer-aided design (CAD) and 3D structural analysis, has recently facilitated the design of even free-form shapes. However, the production of such free-form shapes still has considerable risks in cost and time management. In addition, in recent years, it has become difficult to maintain these skills due to Japan's aging population and shortage in carpenters. These problems require pragmatic solutions. To build free-form shapes efficiently, one should divide the continuous surface into portable elements for formulating production plans and for making products in the factory. The products should then be installed and assembled at the construction site. Hence, new methods with computational design are assumed to require an approach different from the traditional processes of designing and constructing with two-dimensional (2D) drawings. Creating complex and continuous shapes on the architectural scale requires considerable time and money, given the need to adjust the details of each part and assemble them at the construction site.

This study aims to develop a construction method that optimizes productivity throughout the building process—from design to on-site-assembly—by combining digital fabrication with conventional wooden construction techniques on the actual building scale. This study focuses on methods in the Japanese construction industry and assumes the proficiency and costs of labor to be those in Japan.

1.2 Methodology

First, we analyze and organize cases after the emergence of CAD to see how the existing Japanese wooden formwork technology can realize double-curved surfaces, which are difficult to reproduce with wooden formwork. Second, we examine the current situation of free-form shape production by surveying an example of a free-form reinforced-concrete (RC) roof construction project that was realized using conventional construction methods in Japan and nonuniform rational B-spline (NURBs) surfaces, which have become a mainstream method for describing 3D geometries since the 2010s. And we analyzed the time and cost of its construction process. Third, we developed a production method in which curved surfaces are divided into portable units to reduce on-site labor and ensure high accuracy. Fourth, by analyzing and comparing the time, cost, and shape reproducibility of the new method with those of the conventional construction method, we offer an ideal method of constructing free-form buildings.

2 Classification of construction methods of wooden formwork with double-curved surfaces

2.1 Classification of construction methods

In the classification in the graphic science, curved surfaces can be divided into two typologies: ruled and double-curved surfaces [2]. A ruled surface, such as a cylinder or hyperbolic paraboloid surface, can be defined as a linear trajectory that moves smoothly with a one-degree-of-freedom parameter. This type can be further classified into single-curved surfaces, such as columnar and conical surfaces, and warped surfaces, such as bipolar parabolas and spirals with torsion. Because these curved surfaces can be considered an accumulation of straight lines, they have been used in architectural design since the 1960s before the advent of CAD. By contrast, a double-curved surface does not have such a linear element and is thus difficult to regard as an accumulation of linear elements. In particular, free-form and double-curved swept surface shapes are difficult to accurately define in two-dimensional drawings. Around 1990, CAD began to penetrate the field of architectural design and has since made it possible to construct such surfaces.

In this study, buildings with double-curved surface RC elements constructed using wooden formwork were selected from issues of the most widely read monthly architectural design magazine in Japan, Shinkenchiku, published between January 1991 and May 2020. The number of buildings extracted was 72. Formwork methods for double-curved surfaces described in the magazine and other materials can be categorized into the following (Table 1).

(1) Small unit
(2) Radial unit
(3) Rectangle unit
(4) On-site construction: beams and joists
(5) 3D grid

(1), (2), and (3) are supposed to be made in the factory and assembled or joined on-site to make a larger surface. (4) and (5) are based on on-site production, and the use

Table 1. Classification of construction methods for double-surface formwork

	Figure	Method	Structure	Characteristics of the method	Sheathing board	Cases	Number
1		Small unit	Wooden ribs/foam	-Method for small objects, columns or slab edges	Narrow cedar boards	OMOTESANDO KEYAKI bldg.	1-c
2		Radial unit	CNC cut wooden ribs	-Method for surfaces close to the rotating shape -Often be made as fabricated unit	Veneers lamination	Kawaguchi city "Meguri-no-mori Crematorium in Kakamigahara	2-a
					Narrow boards	Yasko Kawagoe Museum	2-c
3		Rectangle unit	CNC cut wooden ribs	-Method to make large curved surfaces by joining factory-produced square units in the construction site	Veneers lamination	Kawaguchi city "Meguri-no-mori Hokkaido-Daikannon	3-a
					Hot pressed board	Inumori Hall, Kagoshima Univ.	3-b
					Flexible plywood	Gokayama Seikatsukan Science Hills Konatsu	3-d
4		On-site construction: beams and joists	Beams:CNC cut boards, Square timbers	-Method based on on-site assembly of beams, joists and sheathing board	Narrow boards	Crematorium in Kakamigahara Kawaguchi city "Meguri-no-mori	4-c
			Joists:Narrow boards		Flexible plywood	Island City Central Park "GRIN GRIN" Ginan Town Hall	4-d

of digital fabrication at factories is limited to the cutting of parts according to CAD data or on-site positioning.

According to how the sheathing plates are generated, construction method are further classified into the following categories.

(a) Thin veneer lamination
Three or four layers of thin and narrow veneer (3 mm) strips are laminated and glued to create a cylindrical shape with a large curvature.
(b) Hot press
Multiple laminated veneers with adhesive are heated and pressed against the male and female molds. Since the structure is made from a single plate, a seamless surface can be made with high accuracy.
(c) Use of narrow boards
Cedar or plywood strips with a width of 100–300 mm are fastened to joists (method (4)) on-site. Although the surface that can be reproduced is not as large as those in (a) and (b), it is easy to work on and can be assembled at the construction site.
(d) Use of flexible plywood
This is mainly employed in conjunction with (3) and (4). Flexible plywood is used and can be applied according to the shape of the small curvature surface.
(e) Use of fabric material
Fabric is used as a sheathing plate that needs to be followed by the movement in accordance with method (5).

Next, we explain the characteristics of each method (1)–(5) combined with the sheathing board method (a)–(e) with several case studies. Explains of These cases are based on construction plans prepared at the construction phase, or construction reports published in magazines.

2.2 Small unit

Small-scale units are used for the formwork of specially shaped elements, such as columns and slab edges. In ”OMOTESANDO KEYAKI bldg.”, designed by Norihiko Dan, each outer pillar is inclined and twisted, so the cedar board for finishing was glued to the foam that was hollowed out along the column’s outlines (1-c) [3].

2.3 Radial unit

For curved surfaces whose shape is close to rotating or convex shapes, the frame of the formwork is assembled radially. Radial structures are difficult to assemble at construction sites, so smaller ones are often made into units. In “Kawaguchi City Meguri-no-Mori” designed by Toyo Ito, the radial units were applied in a 2.6 m x 2.6 m area of the large curved column section. Sheathing plates consisting of four layers of 3 mm-thick veneer strips were affixed to the rib structures (2-a). Since the bottoms of the pillars gradually thin, the veneer was applied by twisting to follow the narrow cylindrical shape. Since the columns are 3–5 m high, they were divided into three sections and assembled at the site [4].

2.4 Rectangle unit

Large curved surfaces are made by joining factory-produced square units side by side on a grid to shorten the work at the construction site and ensure shape accuracy. In Japan, 1820 mm × 910 mm plywood board is common; the units are often made in a size of about 1.8 m × 0.9 m or 0.9 m × 0.9 m, with ribs lined up at a pitch of about 300 mm or 450 mm to create a guide for the shape. In the construction of the Gokayama Seikatsukan roof, designed by Elias Torres, the formwork was divided into 1,700 mm × 850 mm units (3-d) [5]. In the construction of Hokkaido’s Daikannon, a large RC Buddha sculpture designed by Ishimoto Architectural & Engineering, a scale model created by a sculptor was used to measure coordinates by physical contact, and a ring-cut model was made in the height direction. Based on these coordinate data, the shape between the contour lines was reproduced by carpenters by bending cedar and veneer boards (3-c) [6].

2.5 On-site construction: beams and joists

This method is based on the on-site assembly of the formwork, wherein beams, joists, and sheathing plates are placed on support pipes. For the roof of Building for Island City Central Park “GRIN GRIN”, designed by Toyo Ito, square timbers were used as beams for the small curvature of the roof; they were poured over the supports and then attached with plywood.

Square timber beams were pulled from the bottom with a turnbuckle to recreate the shape of the model at the site (4-d) [7]. However, this method was not able to achieve the expected level of shape accuracy. Based on this experience, steep and precise formwork was realized at the Crematorium in Kakamigahara (designed by Toyo Ito) by using CNC (computer numerical control)-cutting beams and layering a few layers of 12 mm-thin cedar boards on them to make flexible and strong joists (4-c) [8].

2.6 3D grid

This method was used in the 1990s to assemble bending wood or bamboo on a grid with rotatable joints. At the Naiju Community, designed by Shoei Yo, bamboo cage-like surface materials were assembled on a flat ground, and the roof’s shape was created by adjusting the shape of the cage over props. The sheathing board is made of fabric material; the shape can be adjusted on-site.

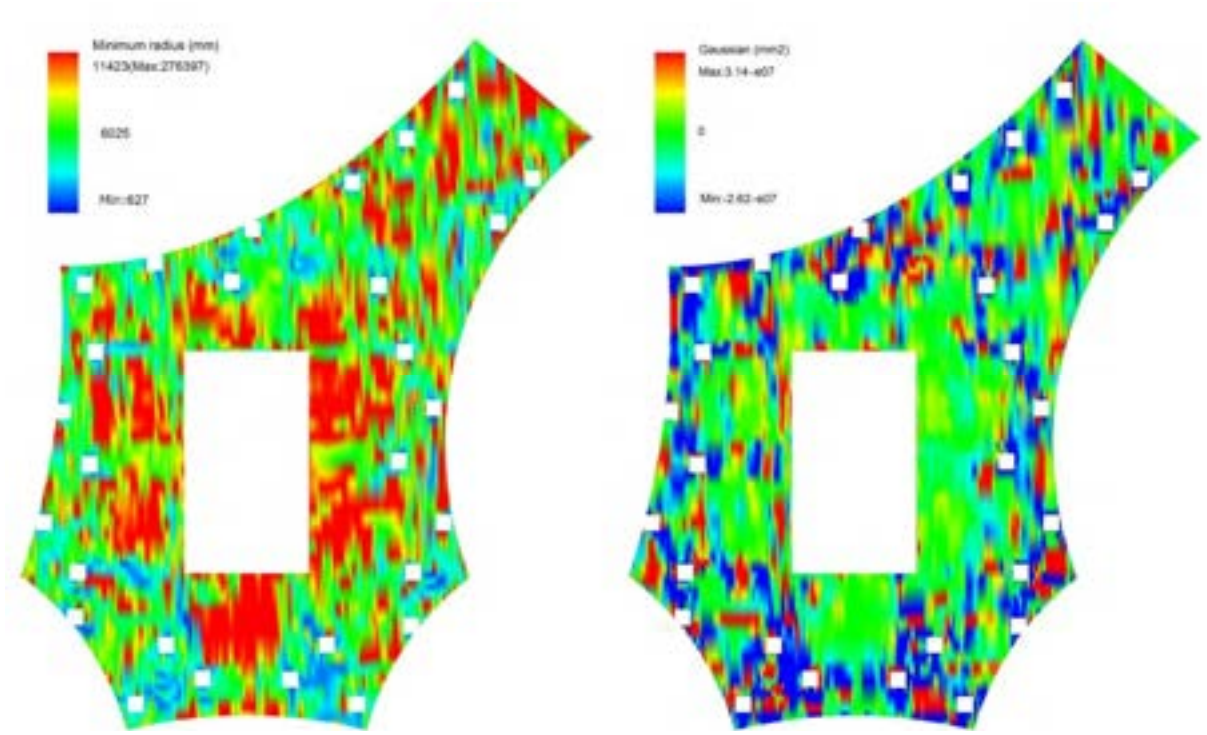

Figure 1. Minimal curvature and Gaussian curvature distributions on roof surface of Kawaguchi project

The fabric and bamboo were left behind after the concrete was poured to become the finishing material [9].

2.7 Summary

In Chapter 2, we classified construction methods for frames and sheathing plates for double-surface formwork. Each method is employed according to the shape of the curved surface, and all of these methods depend on-site work and the skills of formwork carpenters. The choice and combination of methods depend largely on the experience of formwork fabricators and carpenters. There are no previous studies comparing the productivity, shape accuracy, and price of these techniques or optimizing these methods.

3 Analysis of productivity of conventional construction methods

3.1 Outline of example of free-form RC roof formwork constructed with conventional methods

We focused on a completed project which has 5,100 m^2 free-form roof made from a 200 mm-thick RC slab using a conventional formwork construction method. We analyzed the production time and cost of the method from the construction records of the general contractor and found that the method heavily depend on on-site labor. The target is "Kawaguchi City Meguri-no-Mori" (hereafter the "Kawaguchi project"), designed by Toyo Ito & Associates, Architects and Sasaki Structural Consultants. The curved roof is supported by concrete-covered steel columns, and the shell structure was designed with computational morphogenesis (Fig. 1).

For constructing the main part of the roof, a method was adopted to build a curved formwork, with hand-bent joists and sheathing built on-site and installed with machine-cut beams. These beams were bridged on telescopic steel props placed on a Japanese traditional module grid measuring 915 mm. Each joist on the beams comprised four layers of 12 mm-thick pine strips (100 mm wide), and sheathing (also made from 12 mm-thick pine strips) was bent and installed manually at the construction site (hereafter the "Kawaguchi method," 4-c, Fig. 2) Box forms (2-a, 3-a, 3-c) were adopted for the areas where the curvature changes abruptly (columns and roof edge) [4]. This chapter retrieves and analyzes productivity and shape accuracy data from the construction records of the Kawaguchi project's general contractor.

3.2 Analysis of production time

In this project, on-site formwork production lasted from November 2016 to May 2017. A total of 1,883 man-days over 136 working days, excluding holidays, were needed for producing the curved roof formwork. On average, 13.8 people were working each working day,

Figure 2. Work procedure of formwork for Kawaguchi project's free-form roof

with a maximum of 33 man-days. The man-hours at each stage of the formwork's installation in the main part of the roof are shown below.

1. Placing temporary supports: 408 man-days
2. Installing beams: 192 man-days
3. Installing joists: 320 man-days
4. Installing sheathing panels: 320 man-days
5. Adjusting levels and fixing: 288 man-days

Each laborer in this set of data worked eight hours a day, and the areas analyzed included the curved roof, the columns, and the joints between the roof and the wall, totaling 5,112 m^2. The total working hours of these stages were 1,528 man-days, and the average working time per construction area was 2.39 man-hours/m^2.

3.3 Shape accuracy analysis

In this construction project, before the concrete's placement, the general contractor measured the height coordinates of each point on the formwork's surface just above the prop with a light wave rangefinder. The prop's height was adjusted whenever there was a difference of more than 20 mm between the height of the formwork and that of the 3D model.

Because the top of the glass curtain wall's mullion was in direct contact with the concrete slab, the construction manager had to carefully manage the height of each contact point. Therefore, every month following the removal of the formwork, the roof slab's height was measured at each of the 153 mullion locations, and these data were fed back to the mullions' production length. Creep or deformation of the concrete slab was expected in the long-spanning area. Thus, the heights of several points in the middle of the span were also measured, and height displacement was checked to prevent any sudden transformation.

The data showing the height of these points immediately after the formwork's removal can be used as a data sample that shows the shape accuracy of the formwork at arbitral points on the surface. Fig. 3 shows the distribution of the height error for each measurement point.

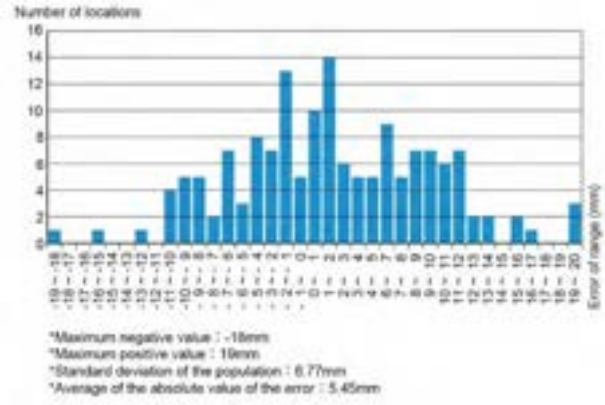

Figure 3. Distribution of height error of form

Table 2. Details of calculation of construction costs for Kawaguchi method's formwork

	Specification	Unit	Unite price(JPY)	Units per square meter	JPY/㎡	Calculation basis of unite price
material cost						
Machine-cut beam	h=100mm・double side / 915mm pitch	m	1,000	1.092 pieces/㎡	1,092	interviewes
Joist	75mm×t13mm×300mm pitch×4layers（4m length）	pieaces	500	3.3 pieces/㎡	1,650	interviewes
Sheeting panel	75mm×t13mm（4m length）	pieaces	500	2.79 pieces/㎡	1,666	interviewes
Telescopic steel props		pieaces	2,000	1.31pieces/㎡	2,620	the construction estimation standard [10]
Beam setting material		pieaces	170	1.31pieces/㎡	222	the construction estimation standard [10]
Square timber for bottom		㎡	33,000	0.032㎡/㎡	1,069	the construction estimation standard [10]
Prop joint connector		pieaces	1,890	0.76 pieces/㎡	1,436	the construction estimation standard [10]
Fixing clamp tool	150 days rental	pieaces	600	2.621pieces/㎡	1,575	interviewes
Fixing chain	150 days rental	㎡	400	1	400	interviewes
labor cost	2.39 man-hour/㎡	man-hour	3,075	2.39 man-hour/㎡	7,349	the construction estimation standard[10]
Total					19,079	(JPY/㎡)

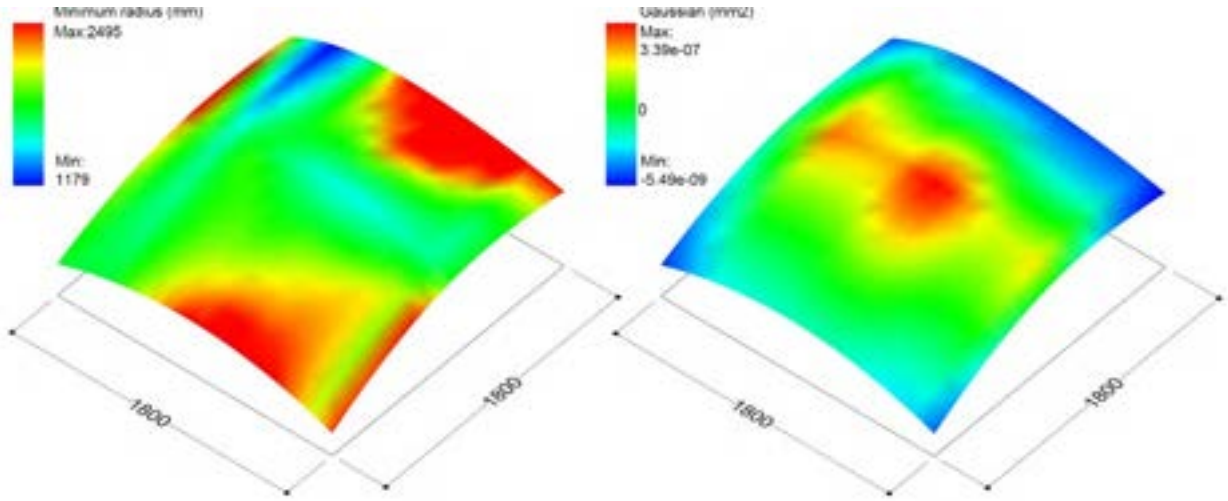

Figure 4. Minimal curvature and Gauss curvature distribution of target shape of new method's experiment

3.4 Cost analysis

We also calculated the cost per square meter of constructing the Kawaguchi project's formwork. The amount of material required to produce the formwork was calculated based on the project's construction plan papers.

We consulted periodically published standard construction estimation books [10] to find unit prices for each material, and asked contractors to fill in the missing data. The labor cost per square meter was calculated from the man-hours calculated in 3.1. The sum of the material and labor costs was regarded as the construction cost. Table 2 shows the process of calculating the total construction cost, which was 19,079 JPY/m^2.

4 Development of new unit construction method

4.1 Outline of new method

The cost analysis in Chapter 3 shows that labor costs account for 39% of the total construction costs, while the time taken to place temporary supports accounts for 27% of the total on-site assembly time. The time taken on-site to laminate five layers of a 100 mm-thick narrow board (joists and sheathing plates) accounts for 42% of the total construction time.

Therefore, in this chapter, we develop a new formwork method (hereafter "New Method") that uses factory-manufactured units to minimize on-site labor and reduce total costs. New Method proposes a way to use factory-manufactured 900 mm × 900 mm units instead of bending and assembling wooden boards at the construction site. It uses a rigid unit to reproduce surfaces with various curvatures (3-c). This system makes it possible to select a method for generating curved surfaces by matching the curvature of each part by dividing the surface into units. The overall cost and time required to construct the whole formwork are also optimized.

The experimental formwork units comprise a folding support system and a bent wooden sheathing panel that is reinforced by curved beams cut by CNC machines. Both the support unit and the sheathing panel can be manually operated by two laborers. Each part is manufactured in a factory and then assembled and fixed at the construction site to create an architectural-sized formwork with a free-form roof surface.

4.2 Outline of analysis subject

4.2.1 Sample shape

We extracted a sample shape measuring 1,800 mm × 1,800 mm from Kawaguchi's free-form roof to compare New Method with the Kawaguchi method. The sample area had the highest amount of curvature on the Kawaguchi project's roof (except for the column area, where the box form method was adopted). The minimal radius was 1,179 mm, and the maximum Gaussian radius was 3.39e-07 (Fig. 4).

In this experiment, we made a free curved surface using four 900 mm × 900 mm units fabricated in the factory to compare the assembly times and costs of New Method and the Kawaguchi method.

4.2.2 Fabrication of test specimen

The test specimen was fabricated at a wood machining factory, which is good at compregnating and bending such sawn veneer. Each unit comprised two parts: one for the support system and another for the sheathing panel (Fig. 5).

Figure 5. New Method's formwork unit

Part 1. Support system

The supporting part was formed of a bottom plate and two sideboards. These were connected by two hinges at each end of the boards, meaning that the support unit could immediately be extended from a flat folded state. The adjacent units were rotated by 90° alternately and placed side by side. The tops of the sideboards were connected to an adjacent unit with screws at the edges.

Part 2. Sheathing panel

The sheathing panel was made of narrow boards (100 mm wide and 12 mm-thick) that were bent along a 300 mm grid of CNC-cut walls. The gap between each board was filled with a coating putty to ensure they were watertight. The sheathing panel was fixed onto the sideboards of the support system and screwed with a joint board.

The total cost of producing each unit was 20,000 JPY, and the working hours of each stage of the production process in the factory are shown below.

1. CNC-machine cutting: 0.5 man-hours
2. Assembling and setting the sheathing panel and the support: 6 man-hours

4.3 Analysis of workability and cost

In this section, we analyze the assembly process of New Method by dividing it into five sub-processes and measure each process's working time and compare the experimental results with the assembly time of the Kawaguchi project's on-site formwork.

4.3.1 Analysis of production time

The time taken to assemble the four formwork units was measured and analyzed in a factory's woodworking laboratory. Two unskilled workers conducted the construction experiment. All parts were folded at the beginning of the assembly process. At the end of the assembly process, all parts were assembled and joined in their designated positions. Table 3 shows the measured time for each sub-process.

According to the experimental results, New Method's assembly process takes 0.283 man-hours/m^2, which is approximately 12% of the working time of the Kawaguchi method's on-site process.

Table 3. Time for each assembly process in New Method

Process	Time (s)	Time per area(s/m2)
Transport and placement of support parts	410	126.5
Joinning of support parts	120	37.0
Transport and placement of sheeting panel parts	260	80.2
Joinning of sheeting panel parts	750	231.5
Others(preparation,transport)	110	34.0
Total	1650	509.3
Man-hour per square meter for total assembly process (man-hour/m2)		**0.283**

4.3.2 Analysis of shape accuracy

The 3D coordinates of the assembled formwork surface's shape were measured at a pitch of 100 mm using a 3D laser distance-measuring machine. We used a fixed-type surveying instrument that can calculate the 3D coordinates and angles of any point on the measurement

object's surface through laser irradiation. The laser measures with an accuracy of ±1 mm at a distance of 10 m.

The distance error between each point on the specimen and the 3D model's surface was then measured, and the accuracy of the sample's shape was analyzed. Total Number of measurement points is 360.

Maximum negative error value: −7.4 mm
Maximum positive error value: +6.3 mm
Standard deviation of the population: 1.96 mm
Average of the absolute value of error: 1.86 mm

The surface error of New Method was much smaller than the construction error of the Kawaguchi method. The Architectural Institute of Japan recommends that such formwork's form accuracy error be maintained within ±20 mm [11] ; therefore, New Method has sufficient shape accuracy for this formwork's construction.

4.3.3 Cost analysis

The cost of constructing the formwork of New Method is detailed below.

1. Material cost: 24,600 JPY/m^2
2. Labor cost: 481 JPY/m^2 *1
3. Total direct cost: 25,081 JPY/m^2

*1: Non-professional labor cost:
1,700 JPY/man-hour[10]

The overall cost of formwork construction of New Method is higher by 31% than that of the Kawaguchi method.

5 Conclusion and discussion

In this study, we explained the conventional Japanese construction method of double-curved surface formwork. Based on examples of curved surface structures from the past 30 years, we classified and organized these methods by the structure and sheathing plate.

We then focused on a case study of a completed project with a 5,100 m^2 free-form RC roof built with conventional construction methods. We also analyzed these methods' time and cost of production based on the general contractor's construction records. The study results revealed that these methods depend heavily on on-site labor.

We then developed a new production method for reproducing curved surfaces with high shape accuracy without relying on existing advanced carpentry skills and field labor on-site works. We analyzed its productivity by performing assembly experiments. The proposed method reduced the project's on-site labor costs by 93% compared with those of the existing method.

In future studies, a more systematic and cost-optimized formwork program should be created by developing a cost- and time-efficient construction method that delivers a product with the accuracy required for the curvature of the area.

Abstract –

Cable path optimization is a commonly encountered problem in industrial construction projects. Numerous designs are technically feasible but are associated with varying construction costs and effort. Hence, selecting the right network is deemed a critical decision. Multiple shortest path algorithms could be deployed to identify the optimal solution. Although they could potentially identify solutions of equal values, there could be differences among their performance which become more significant as the project size increases. Thus, this study compares the results of applying three shortest path algorithms, Dijkstra, A* and Bellman-Ford, in finding the shortest paths for power and instrument cables in an industrial facility project. Moreover, it presents an integrated methodology that combines different software to help practitioners experiment with different scenarios in a fast and systematic manner and make decisions accordingly: (1) Build a 3D model of the project under study, (2) Design a database for data retrieval and management, (3) Import data from the model into the database, (4) Develop a code that reads from the database, finds the optimal paths for the planned cables in the facility, and writes the results back into the database, and (5) Import the obtained results into NavisWorks for visualization and validation purposes. The results have shown that the three algorithms identified the same paths for six cables. Yet the optimal path found using Dijkstra and A* for the seventh cable was one node longer than that identified using Bellman-Ford, but the three paths were of equal weights. Generally, Dijkstra and A* exhibited a close performance. Meanwhile, the main difference between Dijkstra and A*, on one hand, and Bellman-Ford, on the other hand, lied in fact in the time needed to solve the optimization problem. The percent difference between Dijkstra and Bellman-Ford's runtimes for one of the cables reached 4,800% making Dijkstra superior with respect to runtime. Even though the impact of the runtime difference is considered insignificant within the scope of this study as it is in the range of milliseconds, its criticality would increase as the size of the network increases. Therefore, a proper selection of the optimization algorithm would support a rapid and efficient decision-making process.

1 Introduction

Construction projects entail critical decisions in connection with planning, developing and executing major engineering elements, which would have a severe impact on cost and time savings if not dealt with in a responsible manner. In particular, the issue of planning and designing cable networks on industrial projects is of great concern for construction managers and owners, specifically with respect to cost implications. The main problem encountered in such networks is their complexity as deciding on the optimal solution with respect to different considerations is not a straightforward decision. Cable network optimization is, thus, one of the several optimization problems in construction that need supportive methods, such as mathematical techniques, to help in identifying the most feasible solutions [1]. Examples of similar optimization problems comprise time-cost trade-off [2], resource levelling [3], site layout optimization [4,5], planning and allocating equipment [6], among others.

Mathematical algorithms have a great potential in solving complex problems, specifically those including a large number of alternative solutions given the numerous possible permutations [2]. For cable network problems, specific algorithms are found that deal with identifying the optimal path for a given connection. Three of the most

prevalent algorithms used to determine the shortest path between two nodes are Dijkstra, A* (A-star) and Bellman-Ford [7]. Similar algorithms prove to be highly useful for various applications given their ability to account for factors other than distance when identifying the optimal path [8]. For instance, the Dijkstra and A*, along with other algorithms, were evaluated for their performance and accuracy in finding the optimal path on construction sites considering multi criteria requirements, including travel distance, safety and visibility [8]. Such studies offer a detailed comparison between the different algorithms to help specify what type of problems best fit each algorithm.

While the literature offers a plenty of studies comparing shortest path algorithms in different contexts, the construction industry literature remains in shortage for research discussing opportunities for the application of shortest path algorithms in a systematic manner specifically for cable networks. Given the potential cost and performance impact of cable network design on construction projects, this paper aims at presenting an application of the shortest path method to find optimal paths for a set of pairs of start and destination nodes for power and instrument cables in an industrial facility. The optimal path in the context of this paper represents the shortest path for connecting the cables in the facility while achieving minimum costs that are dictated by the type of trays that cables pass through. The paper achieves this by utilizing the commonly used algorithms: Dijkstra, Bellman-Ford and A* algorithms. The performance of these algorithms is also compared based on the number of connection nodes in the identified shortest paths, the total weight of the paths, and the computation duration (i.e. runtime) to recommend the most suitable algorithm for this type of problem.

The main contribution lies in presenting a convenient approach for solving a critical practical problem on industrial projects while analysing some key points of departure whenever considering similar problems on different projects.

2 Literature Review

2.1 Overview of the Selected Algorithms

Although various algorithms could yield similar results, they exhibit distinct properties such as speed, efficiency, and computation method. This section provides a brief and general overview of the three algorithms employed in this study.

2.1.1 Dijkstra Algorithm

Theoretically, Dijkstra is considered the most common algorithm for finding the shortest path in network problems having a single-source (i.e. one source node) [7]. It is a straightforward and simple algorithm which has gained popularity in network optimization field [9]. In Dijkstra, the number of nodes is specified, and the node which represents the source is just one specific vertex while the destination could include several vertices [10]. Thus, this algorithm is beneficial when the destination is unknown [11]. The function of this algorithm f(n) is equal to g(n), where g(n) is the cost of the path from the source node to the destination node, n [11].

Dijkstra's time complexity is computed by O(n2), where n is the total number of nodes [9], [12]. Hence, in case of problems that are relatively large, Dijkstra is successful as it has a time complexity of an order of n^2. However, the algorithm is generally considered to take a long time and waste resources due to the blind search it performs [11], [13]. Dijkstra adopts the "Greedy Best First Search" approach, and it takes a big search area prior to reaching the destination [11]. It works by going equally in all directions [11] and terminates after visiting all the nodes [14].

2.1.2 A* (A-Star) Algorithm

Another common algorithm for solving the shortest path problem is A*. A* comprises the summation of two functions; a function, g(n), that constitutes the exact cost of the path extending from the start node to node n, and a heuristic function, h(n), that represents an acceptable estimated cost to reach the destination node [12]. The heuristic function provides an estimate of the best path from any node to the destination node, where the order of this estimate defines how the nodes will be visited [11]. A* uses the "Best First Search" approach in which the node with the best heuristic value is chosen to be visited first [15]. The algorithm focuses only on the region in the direction of the goal [12]. However, there is no assurance that optimal solutions will be obtained with the use of heuristics [16].

The performance of A* is significantly impacted by the choice of the heuristic function. In fact, heuristics are used as guidance to improve performance, and they affect the time complexity of the algorithm [12]. If h(n) is exactly equal to the cost required to move from node n to the destination node, the algorithm will only follow the optimal path, without expanding into anything else, resulting in a high search speed. The path to the goal node can be discovered even faster if h(n) overestimates the cost required to reach the destination node from node n. Yet the cost of the identified path might not be the most favorable one in this case [12]. The time complexity is O(n log n), where n is the number of nodes [11]. A* is usually efficient when both the start node and the target node are known [11].

Overall, it can be said that the main difference between Dijkstra and A* algorithms is the heuristic

function h(n) used in A*. In fact, if the value of h(n) is set to zero, A* will give the same outcomes as Dijkstra [12]. Since A* uses the "Best First Search", it is considered faster than Dijkstra which adopts the "Greedy Best First Search" approach [11].

2.1.3 Bellman-Ford Algorithm

Similar to Dijkstra algorithm, Bellman-Ford is a traditional algorithm used for solving shortest path problems from a single-source node [17]. However, Bellman-Ford algorithm can run in a distributed manner unlike the Dijkstra algorithm which is a global algorithm and cannot run easily in a distributed manner [18]. In this sense, distributed algorithms, being subtypes of parallel algorithms, are characterized by the ability of the nodes to keep track of the shortest distances between themselves and the other nodes, while communicating with its neighbour nodes by transmitting messages over the links [19]. Thus, unlike Dijkstra, parallelization takes place in Bellman-Ford easily [20], [21]. Additionally, Bellman-Ford has a looping behaviour, where iterations occur over all edge connections in order to continuously update the nodes until the final distances are reached. However, this reduces Bellman-Ford's efficiency in comparison to Dijkstra's [20], and this is considered a major drawback of the distributed Bellman-Ford algorithm [19]. As for the runtime of Bellman-Ford algorithm, it is O(nm), where n is the number of nodes and m is the number of edges [22]. Bellman-Ford is also dominant in solving the majority of routing problems which have various constraints and occur in a flat network found in an autonomous system, where the primary objective function is the minimum node count [23].

2.2 Some Applications of Shortest Path Algorithms in Construction

Various optimization problems that require the use of shortest path algorithms are found in the construction industry. Material flow on construction sites is an example of similar problems. Optimizing material flow and reducing travel time are valuable as cost and time are impacted by the path that the materials go through [8]. Moreover, optimizing site layout to minimize travel distances can boost production rate as wastage and working time are reduced [8].

Shortest path algorithms are also used in transportation applications. Related examples include in-vehicle route guidance systems that require an immediate response upon request for information and identify vehicle routing and scheduling. Accordingly, a rapid identification of the shortest paths is needed [24]. Moreover, with the use of intelligent robots in construction, there is a need for planning their movement path on site. The focus is on finding an effective and short path that is also collision-free from the initial position to the final position, by avoiding both stationary and movable obstacles [25].

Other applications are focused on optimizing some more important aspects of construction operations while trying to minimize the travel distance. Lei et al. [26] developed a generic algorithm to manage the movement of large mobile cranes used to lift prefabricated units on site while taking into account the site constraints including the congestion of different site areas, the geometry of lifted items and the configuration of cranes. This aims at saving time, satisfying safety and efficiency requirements as well as minimizing the risks of failure and accidents' occurrence on site.

3 Problem Description and Modelling

Designing paths for power and instrument cables within a project requires identifying the shortest feasible paths in order to minimize costs accompanied with their installation. The project presented in this paper deals with this problem of finding the optimal solution for connecting five power cables and two instrument cables between pre-specified source and destination points. The project under study is an industrial facility of which the network consists of a total of 6,155 nodes. These nodes are connected via different types of trays which are modelled as edges. Edges are grouped into three different categories based on their type:

- Category 1: It accommodates the extension of power cables only and is, thus, designated as "CTP".
- Category 2: It accommodates the extension of instrument cables only and is, thus, designated as "CTI".
- Category 3: It accommodates the extension of both types of cables and is, thus, designated as "All".

The nodes and edges of the network are modelled as shown in Figure 1 below. In the 3D model, a CTP is represented by a red line, a CTI is represented by a blue line, and the "All" type is represented with an orange line. The total number of edges is 9,711.

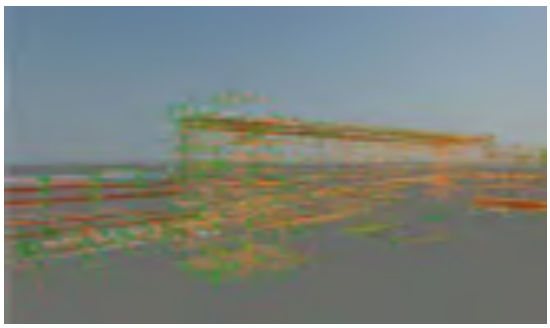

Figure 1. Network Model

Given equal lengths, different types of trays/edges differently impact the final cost. Thus, the type of each edge must be considered when finding the optimal path. This is achieved by factoring a cost-related weight into the total weight. Accordingly, for each tray type, a weight multiplier is computed to reflect its cost. This multiplier is used to adjust the distances between the nodes reflecting cost considerations for each edge type. Different edge types and their corresponding multipliers are summarized in Table 1 below.

Table 1. Weight Multipliers for Weight Groups

Weight Group	**Multi-plier**	**Weight Group**	**Multi-plier**
Cable Tray	1	Field Run to Tag	25
Cable Tray Angled 3D or Rotated	1.5	Ignore	1000
Cable Tray Angled East Vertical	1.5	Jumper Manual	15
Cable Tray Angled Horizontal	1.5	Steel Jumper	15
Cable Tray Angled North Vertical	1.5	Steel Tray Connect	1.1
Cable Tray East	1	Structural Steel	10
Cable Tray Elbow	1.5	Structural Steel Angled East Vertical	15
Cable Tray North	1	Structural Steel Angled North Vertical	15
Cable Tray Vertical	2	Structural Steel East	10
Cable Tray Jumper	1.5	Structural Steel North	10
Cable Tray Steel Jumper	1.5	Structural Steel Vertical	20

4 Methodology

The study presents a structured methodology that integrates multiple software to help decision makers find optimal network solutions quickly and efficiently. The methodology has been devised based on the following steps:

1. Build a 3D model of the cable network under study.
2. Design a database to store relevant data and identify the properties of nodes and edges. Microsoft Access database is used in this study. The database comprises five different tables as summarized in Table 2.

Table 2. Access Tables and Attributes

Table	Attributes
Nodes	ID, x, y, and z coordinates
Edges	ID, start node, end node, edge length (i.e. distance between nodes), edge type, edge category
Weight Groups	Edge type, weight multiplier
End Points	Source node, destination node
Shortest Paths	Tag (i.e. cable), start node, end node, sequence number (i.e. the position of the connection edge (node1, node2) in the path)

2.1 Extract the (x, y, z) coordinates of nodes from the 3D model of the facility and import them into the database.

2.2 Compile data on the edges which are represented by the nodes they connect. Identify and record the types of different edges as well as their lengths. The lengths of edges are computed using the Euclidean distance (Equation 1). Note that this distance is to be multiplied by the weight multiplier to obtain the total weight used for path optimization.

$$d = \sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2 + (z_2 - z_1)^2} \quad (1)$$

2.3 Identify the source node and destination node for each cable of the seven cables.

3. Develop a program that retrieves data from the database, identifies the shortest path, and exports the optimal path back into the database. Python programming language is used in this study; Python is widely used in numeric computation and includes libraries that help in data analysis and modelling of data [27]. The problem presented in this paper benefits from the built-in libraries, mainly NetworkX and pyodbc. NetworkX is a package used for the creation and the study of complex networks and includes standard shortest path algorithms [28]. pyodbc is an open-source Python module that allows accessing ODBC databases [29] and is used to establish a direct connection to the Access database. For each cable, the developed program performs the following tasks:

3.1 Retrieve relevant information from the database using SQL queries. Based on the cable type (power vs. instrument), the queries select the edges belonging to the categories that are compatible with the cable type. They also select a total weight column calculated by multiplying the distance by the weight multiplier.

3.2 Build a weighted graph from the nodes and the

available weighted edges.

3.3 Identify the shortest path using Dijkstra, A*[1], and Bellman-Ford algorithms from Networkx library.

3.4 Compute the total weight of the identified paths using the three algorithms.

3.5 Compute the time taken by each algorithm to identify the shortest path (i.e. runtime). The runtime is computed to compare the performance of the algorithms.

3.6 Select the path with the lower total weight if there is a difference between the weights.

4. Store the nodes of the identified shortest path back into the database.

5. Store the shortest path nodes in XML structure format that is readable by NavisWorks to visualize and verify the shortest path.

The presented methodology is illustrated in Figure 2.

5 Results and Comparison

The three algorithms found the same shortest paths for six sets of source and destination nodes out of the seven sets. Nevertheless, the shortest path identified for one set using Bellman-Ford passes through 100 nodes while those found using Dijkstra and A* require 101 nodes. However, the three of the identified paths have the same total weight indicating that both solutions are equally favourable given the imposed optimization criterion (i.e. minimal total weight).

The identified shortest path nodes for each set were imported into NavisWorks and highlighted. Figure 3 illustrates the shortest paths for three of the cables. The paths are highlighted in blue. It could be noted that the optimum path between the source and destination nodes is not necessarily the path with the shortest distance between them. As illustrated, the first path bypasses the location of the destination point before it returns back to it. This is a result of factoring costs of different types of edges in the total weight of edges.

The results of the three algorithms for each set are summarized in Table 3. Dijkstra and A* algorithms generally showed close performances with respect to runtime. Meanwhile, Bellman-Ford exhibited a lower performance in terms of computation speed as compared to the other two algorithms. The percentage difference between Dijkstra and Bellman-Ford's runtimes for the first cable reached 4,800% as it took 0.0980 and 0.00200 seconds to identify the optimal path using Bellman-Ford and Dijkstra, respectively.

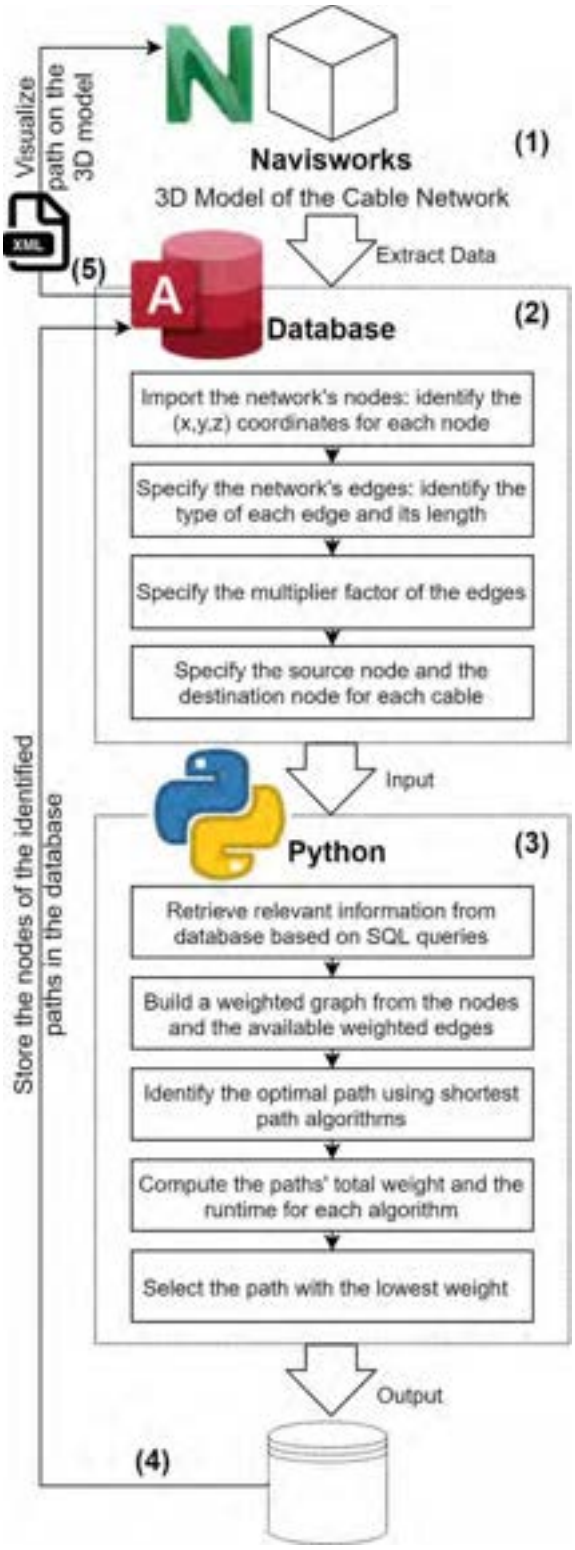

Figure 2. Methodology

[1] The Euclidean distance is used as the heuristic function for A* algorithm

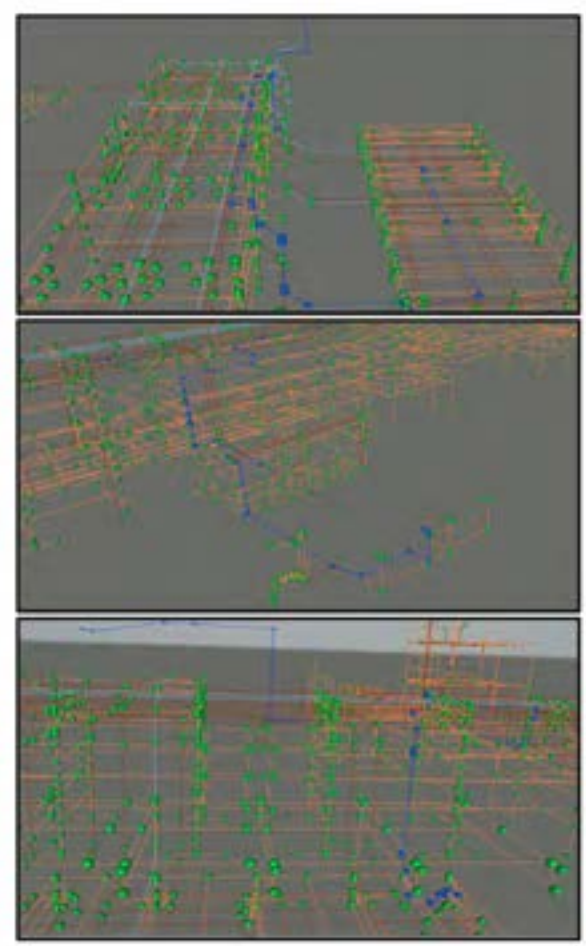

Figure 3. Shortest Paths in NavisWorks

The obtained results have shown that there is no significant difference between Dijkstra and A* algorithms. This could be attributed to the fact that the heuristic estimates (the Euclidean distance) of the A* algorithm are lower than the actual cost (the weighted distance) of moving from the nodes to the destination nodes. Consequently, the algorithm expands more nodes and, hence, takes a longer computation time. On the other hand, Bellman-Ford's underperformance in terms of speed was anticipated as a result of its looping behaviour. Although the difference between their performances is in the order of milliseconds, it becomes more significant as the size of the problem increases (i.e. as the number of nodes and edges increase). As the algorithm runtime is considered a major determinant in selecting the most convenient algorithm for a specific application [30], it could be concluded that Dijkstra and A* algorithms are deemed more suitable for solving a similar type of problems.

Table 3. Shortest Paths Results

Dijkstra			
Cable	Number of Nodes	Runtime	Weight
Test 1	45	0.00200	611.929

6 Conclusion

Shortest path algorithms have been proven effective in providing support for decision makers when solving complex path-defining problems. On construction projects, these algorithms were used for diverse problems to attain optimal solutions. This paper considers the problem of selecting the shortest path for power and instruments cables in an industrial facility. The Dijkstra, Bellman-Ford, and A* algorithms were adopted to find the shortest path while considering the total weight of the edges. The total weight for this problem is dependent on both the distance and the cost subject to the type of each edge/tray.

Using the developed Python program to identify the shortest paths, results showed that all algorithms gave the same paths for six cables out of the seven cables. Additionally, the total weight is found to be the same across all tests indicating that these methods were equally efficient in finding the optimal solution given the optimization criteria. However, the results showed that the Dijkstra and A* algorithms had a better performance than that of Bellman-Ford with respect to runtime in all of the cases. Specifically, the difference between

Dijkstra's and Bellman-Ford's runtime reached 1,524% in one of the cases. Although for this case the difference is only in milliseconds, the difference between their performance becomes more significant in larger scale problems.

The paper also presented an integrated approach that combined different software platforms to automate the process of inputting data, computing the shortest path and then plotting this path in 3D format for visualization. The problem represented a case on the importance of using the shortest path method when dealing with decisions that are complicated by nature. Construction projects could benefit from using such algorithms and integrated approach for helping in various decision-making processes.

The methodology presented in this study could be extended to address the previously mentioned applications of shortest-path algorithms in construction. Today, with the continuously increasing level of automation in construction, the problem of finding the collision-free shortest paths for mobile robots on construction sites is of a particular importance. Hence, a case study on mobile construction robots shall be addressed in a future study. Efforts shall be devoted to select a case study of a larger size to demonstrate the impact of the performance of the different algorithms on the efficiency of solving the problem.

Abstract –

An ideal Design-Construction Interface is assumed in the decision making process of initiation and planning. The uniqueness, site conditions and contingencies cannot be envisaged and incorporated in its entirety in all projects. Constructability in resonance to the appropriate technology becomes paramount in deciding the material, structural forms and construction methodology. The construction industry is gradually evolving to a manufacturing and product delivery process where design for Manufacturability and Assembly takes precedence. Optimization of targeted values viz logistics, manufacturability, assembly, maintenance, lifecycle cost and ergonomics becomes critical to ensure smooth execution of the Project. The data collected from a pre cast construction project is analysed to map the degree of ease in Design-Construction interface and compared with a framed structure to draw parallels with respect to constructability as a target in value engineering. The objective of the study is to examine the components of constructability in Design Process to optimize effort and resources. Target Value Design gives the stakeholders more rationale inputs for monitoring and decision making. The study attempts to predict the future of manufacturability and constructability in construction where smooth assembly with minimum labour is essential for value addition. The bottom up approach of new policy initiatives and better communication between stakeholders promise more refined designs in future where technology will be pushed to achieve design optimization.

Keywords –

Constructability; Design Optimization; Value Engineering; Design-Build; Target Value Design; Manufacturability; Assembly

1 Introduction

It is an intriguing task for designers across the globe to take a foolproof final print of the drawings and precedence diagrams incorporating all possible changes during execution of a Project. Unfortunately we do not have the ability to speculate and predict the future. But we do have the ability to learn from the past and adopt better practices in the next project. An ideal condition is assumed by the planners while formulating the conceptual design. Building construction industry suffers greatly from cost and time overrun due to oversights in planning and design inaccuracies. The success of a project is decided by the Value it provides to the user. To provide 'Value' to the client, the concept and its execution has to be well coordinated to provide the best performance. The term Design encompasses all activities in the design studio including concept, schematic, design development, preparation of tender documents and entering into a legally valid contract for construction. According to Jergeas et al. [1] and Cleland [2], efficient management of the relationship between the project and its stakeholders is an important key to project success. Conceiving the plan in a broader framework and executing it with minutest detail with optimization of all resources is possible only when the details are constructible. For this to happen, communication between stakeholders is must. In their study of critical success factors across the project's life cycle, Pinto and Slevin [3] emphasize the importance of interaction with the clients throughout the duration of the project. Almost 40% of the change orders or deviation orders are rooted in the design phase [4] and 30% cost escalation is attributed to poor communication during design phase [5]. This amply highlights the importance of reducing the change orders during execution phase and targeting constructability from the planning stage. Constructability translates to be the ability to construct something with appropriate technology within a specified budget and schedule producing intended value. Value Engineering has to be an integral part of constructability as its prime aim is to increase value than to reduce cost [6]. The design table is very much a place where the fate of the project lies and decides the value it will generate. The constructability and value generation is critically analysed in adopting an emerging technology like pre cast construction to draw lessons in design optimization along with procurement management challenges.

2 Constructability and Value

Right from the very first house human beings constructed, the intended purpose was his concern. 50,000years ago the concern was only to provide shelter from weather and safety from wild animals. The need to design a product was felt when he realized that the final outcome was not matching the imagined one. As we evolved the scope got expanded towards gaining more utility from the same effort. The difficulties faced during execution were traced back to the plan and it was realized that the lessons learned should be incorporated in the next design. Target Value Design gives the stakeholders more rationale inputs for monitoring and decision making. Target Values have to be identified to incorporate in the design process which might vary for each stakeholder. The study aim to define values in a design process for optimization of resources. Forensic Schedule Analysis of a pre-cast housing project is carried out to study the Design-Construction interface fault lines which cause hiccups in achieving intended values. The study examines the various constructability factors influencing the smooth interface from design to construction and critically examine the bottlenecks. For this purpose the concept of Value needs to be addressed in a more objective way.

2.1 Value in Design

Value is a set of concerns with respect to cost and function. It has a futuristic component which is based on a various inputs and assumptions. It can be expressed as ratio of design function to cost. It is quite obvious that in order to increase value, the cost has to be reduced or the design functions have to be increased. But while preparing a tender document, in the process of procurement, the price is the only readily available factor. A correlation between price, cost and value need to be established to define the target values in design. Table 1 illustrates the comparison of price, cost and value with respect to various functions as obtained from focus group discussions with stakeholders in construction projects. It can be seen that value is a user's utility perspective through opinion. This opinion could be based on a single factor or a combination of factors. The comparison illustrates that price is related to past tense, cost to present tense and value in future tense when we evaluate a facility or a project at planning. The price comes from the market and documented in the schedule of prices by various agencies and the cost is budget at completion of the project. The value is an opinion which goes back to market as set of benchmarks with respect to utility of the product or service**.** Figure 1 gives the flow chart of value generation in a typical construction project.

Table 1. Comparison of Price, Cost and Value

Price	Cost	Value
Amount paid for acquisition	Amount incurred in production	Utility of a product or service
Ascertained from consumers perspective	From producers perspective	From users perspective
Estimates through policy	Through fact	Through opinion

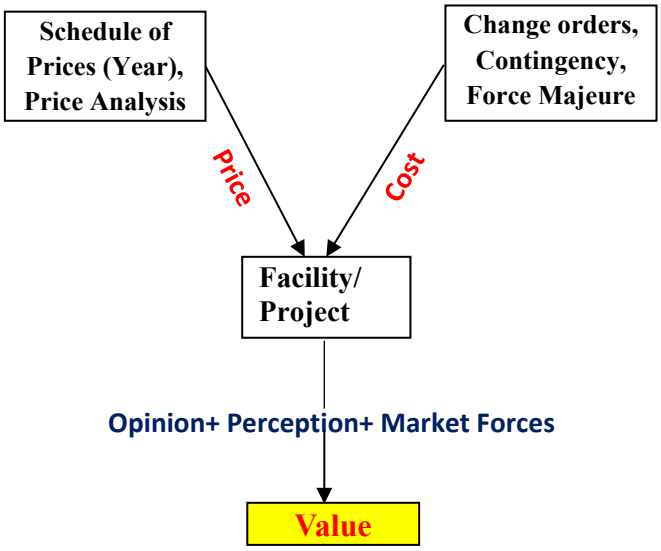

Figure 1. Interaction of Price, Cost and Value

Price is a fixed factor compared to cost and value. It is obtained from schedule of prices which is periodically updated by regulatory bodies. In a Project it makes sense to plan cost cutting, but not price reduction. Price of materials are fixed with respect to time and location. These are 'fait accompli' and we can only opt for the most suitable in terms of economy, quality and availability. Cost is what the client pays to own a facility [7]. Once the BOQ is prepared the price factor has been considered. But the cost factor eludes the designer as that is depended on change orders, contingency and force majeure. Value is a promise in future which is based on opinion, perception and market forces. In order to optimize the value what should we aim for? The answer probably lies in the way we produce an automobile or an aircraft. Though a civil engineering project cannot be templated into a product manufacturing process, many

lessons can be drawn from the evolution of assembly line manufacturing process which revolutionized the industrial production of construction materials.

2.2 Constructability in QFD

Quality Function Deployment in construction industry is not often practiced due to its invisibility compared to other manufactured products. A direct translation of QFD concept from an automobile production unit may not suit a building contractor. Customer's aspirations from a car varies greatly from a building or an apartment. Constructability is the synthesized end product after analyzing all QFD inputs. Table 2 illustrates the conflicting yet complementing requirements of users and designers while planning a pre-cast apartment building. Customers are often smitten by the cost not by the value. At the same time cost eludes the designers as they are indulged in price. These conflicting demands in constructability makes it more challenging to set specific targets for planning the project.

Table 2. QFD requirements of Customers and Designers for a Pre-Cast facility

Customer	Designer
Should be Earth Quake proof	Monolithicity of connections
Smooth finish	Vibro Compaction
Low maintenance cost	Easy access to MEP lines
No disputes	EPC Contract
Affordability	Break even quantity
Fast delivery	Steam curing of RCC members
Quick assembly	Cranes part of inventory

2.3 Genesis of Pre-Cast Technology

The pre-cast construction technology was emerged as a natural evolutionary process by improving on the lacunas of cast-in-situ construction. The advancements in reinforced concrete technology and feasibility of slender sections made designers to take a bold step towards treating the concrete members like steel. From the table 1, it is very evident that the industry has adopted pre-cast technology for achieving value by taking advantage of certain unique features of the new technology.

Table 3. Comparison of Pre-Cast vs. Cast-in-Situ

Pre-Cast	Cast-in-Situ
Cast and cured in manufacturing plant	Members are cast at construction site
Accelerated curing required	Normal curing time
Faster Construction	Slow Construction
Greater control on quality	Less control on Quality
Not hampered by adverse weather	Severely hampered by weather
Assembly based	Activity based
Minimum waste	Considerable Waste

From construction activity, the entire process got converted to a manufacturing process to add value. In an evolutionary curve we can see that steel overtook cement concrete as a preferred material for fast track construction. Though the shift towards steel for many high rise buildings in mid-20th century happened intuitively, a closer look will show that it was a natural option for the rapid rebuild of post war Europe. True to the old adage, necessity was the mother of invention and a solution emerged with less labour, time and superior finish. It is interesting to note that though the technology is not based on any new theory, the adoption happened by default, not by design. The reason is more value generation through manufacturing and assembly. Pre cast system is widely used now in many repetitive structures and claddings due to its versatility to act both as architectural and structural material.

2.4 Cost Benefit Analysis and Break Even Quantity

The actual value of pre-cast is often misunderstood as the direct cost of structural components will be high compared to the cast-in-situ framed system [8]. The components have to be manufactured in a pre-cast plant and transported to the site. Huge initial investment of casting plant and steam curing facility can be justified only with a minimum assured order of repetitive nature. This technology is ideally suited for housing sector as the layout is similar and slabs are spanning less than 5m. The Cost Benefit Analysis in figure 2 shows that minimum number of 800 units have to be constructed to make the rate comparable to the conventional cast-in-situ technology.

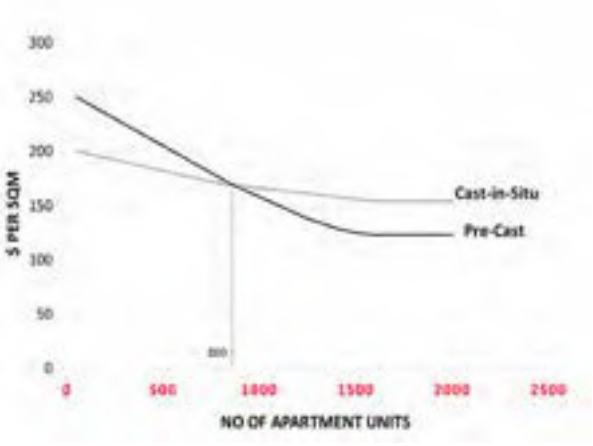

Figure 2. Break Even Quantity for Pre-Cast feasibility

This break even quantity is specific to a turnaround distance as the distance of plant increases from the construction site, the cost changes. Figure 2 shows the data collected from Delhi, India. The construction firm which invested almost $7 million on the plant definitely had a look at the national policy on the housing sector which pledged 1.5 % of GDP towards the cause.

3 The Design Targets

Having defined the relation between Price, Cost and Value; it's time to fix the design targets specific to the intended value. They could be Assembly, Modularity, Manufacturability, Maintainability or Logistics (AND/OR). These target values may be required in varied quantities as per the design optimization which should fit in the cost and time framework. The present study is focusing on Precast Technology and obviously the targets have to be assembly, manufacturability and logistics.

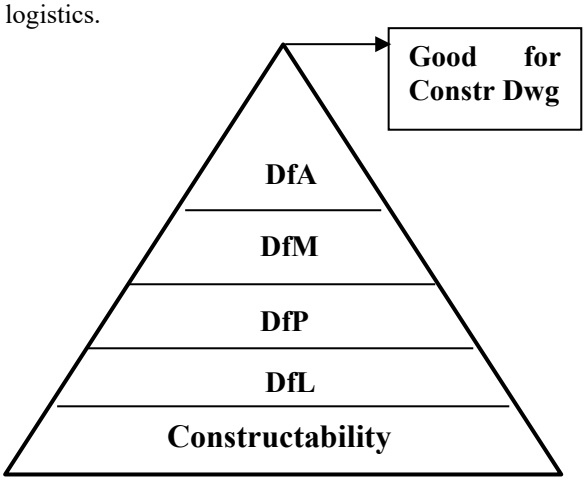

Figure 3. Target Value Triangle

A close examination will show that the relative importance of Assembly and Manufacturability is more predominant than logistics or transportability. Location of a manufacturing plant can be selected as per the logistical requirement but if the components are not fit for assembly, there is no scope to perform any repair on site. Taking them back to the plant for changes will incur huge financial burden which may derail the whole financial plan. The target value triangle for the pre cast construction project is shown in figure 3. As time progresses, the influence of design aspects of logistics starts reducing and manufacturability increases. The iterative design process zoom in on to design for Assembly as the prime target to achieve in the design process and constructability remains the superset of Logistics, Manufacturability and Assembly.

3.1 Design for Logistics (DfL)

The Pre-Cast components have to be manufactured in a location which makes the turnaround time logistically feasible and economically viable. The location of the plant has to be decided based on the availability of the raw material and resources. The logistical challenges involves setting up the Pre-Cast plant, Transportation of raw materials and Transportation of manufactured components to the construction site. The dimension of vehicles for the above purpose will be governed by the size of the building components and their weight. The maximum height clearance permissible under the rail bridges and fly overs on the way plays an important role in this logistical planning. Once the location of manufacturing plant is fixed, rest of the parameters will be dependent on this aspect of logistical baseline. Figure 4 shows the map of three sites A, B, C and the location of the pre-cast plant, P. The location of plant is so selected that the time to reach each site is almost same. The plant is sited based on the logistical feasibility which has a direct bearing on the overall cost and thereby being a value deciding factor.

3.2 Design for Manufacturability (DfM)

The components have to be pre cast in the plant and assembled at the site. This assembly operation will be requiring cranes. That infers to the correct size and shape of components which will make the assembly easy. Assembly will govern manufacturability. The beams, columns, floors and walls have to be cast in the casting yard. The dimensions of structural components have to be fixed and ready mix concrete is poured using automated systems. How can compaction be achieved? A normal vibrator cannot be used as it will consume more time and will result in non-uniform compaction. The casting bed has to act as a vibrator to save time and effort. This important criteria for casting bed design and the cost

involved is a governing factor in manufacturability. The components have to be cured for required period to attain full strength and this for fasten the process, a steam curing facility has to be set up. All members should be hoistable using cranes as they will be moved several times once removed from casting bed. The location of these lifting hooks will have to be decided on the drawing table as they are part of structural analysis process. Table 4 lists the criterion considered for manufacturability of pre-cast technology.

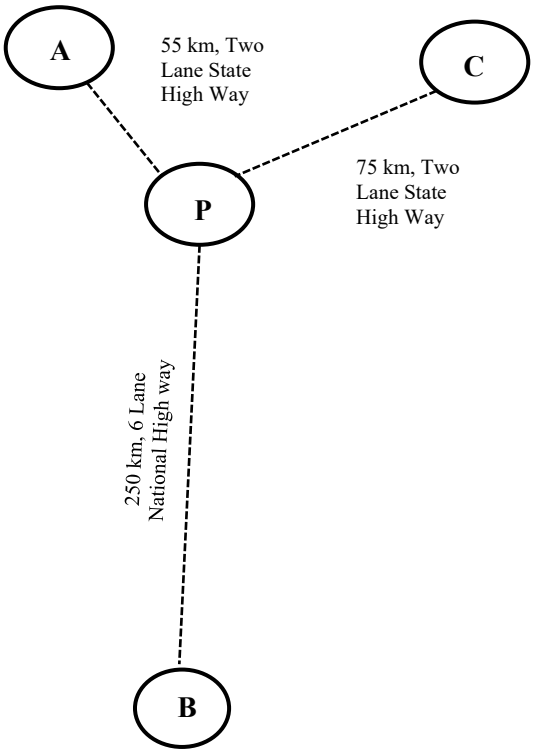

Figure 4. The Location of Plant P, with respect to sites A,B and C

Table 4. The Manufacturability criterion

Criterion	Manufacturability
Concreting	Automated Concrete Pouring Facility
Compaction	Vibro Compaction of Casting Bed
Curing	Steam Curing Facility
Mobility of Components	Overhead Crane in the Plant
Execution at Site	Limiting the weight of each components to the crane capacity at site

3.3 Design for Assembly (DfA)

Assembly of various structural components at site has to be in perfect sequence to ensure a smooth execution. Unlike the cast-in-situ method, the pre-cast members lack monolithic connection. The structural analysis is carried out based on certain rigidity of connection and these design assumptions have to match with the site conditions. In reality, the DfA is the most important factor in a pre-cast design process. If the connections are not strong enough, catastrophic failures might happen. After the structural analysis and design, a scaled model may be tested in lab condition to ensure that the assumptions are correct. The cost for these tests has to be borne part of the Research and Development effort rather than in the estimates of the design at hand. These are part of the initial investments as it is practically impossible to carry a destructive shake table test every time. The results of the initial test can be interpolated or extrapolated in subsequent designs as the case may be.

After taking into account of logistics and manufacturability, the ease of assembly takes precedence. The aspect of assembly is so important that the structural design has to be carried out by taking these assembly into consideration. The design of floor slabs will illustrate this aspect in detail. Unlike a cast-in-situ slab, the pre cast slab has many functions to perform. It should have shear connectors to ensure connection between next slabs, it has to give a smooth floor finish and it should be easily liftable by crane. These functions are possible only when the design is robust, flexible and innovative. A lattice girder reinforcement is specifically manufactured for the purpose and this girder serves many purpose. Figure 5 shows the manufacturing process and figure 6 [9] shows slabs stacked after curing process which are ready to be transported to the site.

Figure 5. Lattice Girder Manufacturing (Courtesy: BG Shirke Group of Companies)

Figure 6. Shear key as Lifting Hook in Lattice Girder

4 Monitoring and Control

The traditional monitoring and control process is designed to keep the budget always on track and effect minimum change orders. The stakeholders involved are reacting to the precedence diagram actual unravelling on site. In pre-cast system, the construction activity has been converted to an assembly process. So the monitoring process almost reduces to an assembly supervision as there are very few decisions to be taken during construction. The scope is fixed in pre-cast the moment construction drawings are issued to the casting plant and no change order with respect to architectural or structural is feasible. This lack of flexibility is accounted for by numerous design iterations after repeated interactions with stakeholders.

5 Procurement Management

PMBOK has covered forty nine processes in ten knowledge areas and five process groups in its 6th edition [10]. The processes involved in procurement management is limited to plan, conduct and control. In conventional construction management, the procurement is a reaction to what is designed. But when we plan to adopt an assembly based technology, the procurement management cannot be independent of the design process. The Design-Build format suits procuring the pre-cast systems as the bid preparation is challenging when it comes to design and estimation. In an open competition to bid for a specific design, the purpose of providing equal opportunity and level playing field is not achieved. Moreover the DfA challenges will make the design favour a particular firm who has adopted a specific dimension for their projects in hand. Using design-build procurement format, the owner saves time and effort by executing only one contract with a design–builder, who takes responsibility for completing both the design and construction of the project [11]. The Engineer, procure and Construct (EPC) model is often considered synonymous with Design-Build one in function as both shift the design and build responsibility and a bigger portion of risk to the contractor [12]. In EPC mode the contractor is often entrusted with the desired output in the case of a production facility. In a construction project like precast mass housing, design-build provides more value. The evolution of any technology has taken considerable settling time before the rest of the world catches up with a universally accepted price for procurement. A market survey will show that construction firms which innovated to adopt faster and durable construction technology are faring better than those who continued with older ones. From clients perspective, (s)he may opt for any technology or procurement format which gives a better return. In the Design-Build system, the designer, the builder and the consultant, all could be rolled into one due to uniqueness of technology and there may be very less control by the client over the Project once the design has been finalized. But the designer has to ensure assembly, manufacturability and logistical feasibility by taking the client on board. Keeping the architectural, structural and MEP changes out of purview, the Work Breakdown Structure and the activity precedence diagram can now be fixed. This facilitates the designer to provide exact quantities for the QS team which makes their task of estimation much effortless and almost accurate.

5.1 Design for Procurement (DfP)

Design for Procurement (DfP) is also an important parameter in construction when it comes to innovative and emerging technologies. Every exotic design cannot be constructed and every technological feasibilities are not buildable on ground. There is a fine line between building a design and design something buildable. In the former case, the procurement team is searching for solutions which were not considered by the design team. In the latter, design office is involved in the procurement decisions. In the pre cast example, the activities are designed to be repetitive so that once the components are manufactured, transporting and assembling completes the construction process. The design is tailor made for procurement to suit a Design-Build system so that the facility is built by the firm which designs it, thereby eliminating communication hiccups between a consultant and contractor. But is this killing fair competition and leading to monopoly of business? This question lingers on with all new innovations where very few people are experts initially. Any technology can compete for design parameters like minimum waste generation, faster construction and minimum cost per unit plinth area. The fittest and adaptable will survive and probably the theory of evolution is applicable to construction industry too.

6 Modularity: The Modern Solution for Constructability

Modularity has emerged as a modern day solution to ease the construction complexity. The design complexity of assembly can be smartly eliminated in the modular approach. Similar to the pre cast technology, on a larger scale modularity reduces the project cost [13]. The concept of modularity was borrowed from the shipping transportation containers which offered quick loading and unloading of cargo from ships. The uniformity of the containers and cranes made the cargo handling very smooth saving billions of dollars in demurrage. This path breaking idea can be simulated in construction too where the rooms are relatively small in dimension. The design for modularity assumes complexity as the height of the building increases due to higher seismic design requirements. Unlike a pre cast building, a modular building is 100% reusable and relocatable having few beam-column-slab connections. In modular system, rather than member strength, the geometry is holding the structure together.

7 Constructability in Design Optimization

It is quite evident that constructability is a function of many parameters like assembly, manufacturability, logistics, procurement, cost and time. In order to take the best out of technology, we have to move away from the traditional network crashing mindset to dynamic parameters mentioned above. The time saving techniques employed by the defense forces may not fit for a building project. The forces may not be worried about the budget but in construction projects, the client is worried about the cost. It is imperative that constructability has to be considered as the benchmark for value generation. The figure 7 depicts the relative importance of various design targets to mix and match the optimum one. The most suitable targets can be given more weightage and design optimized according to the technology involved.

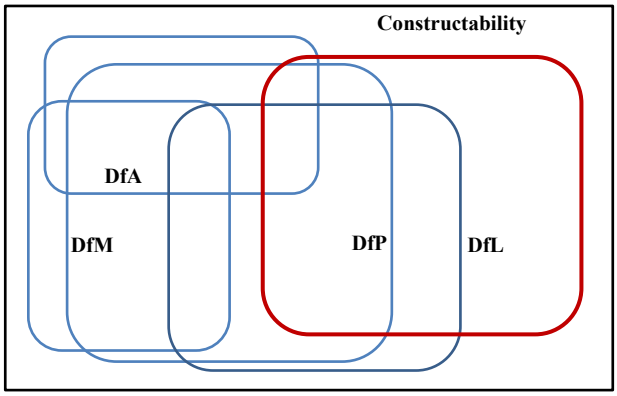

Figure 7. Design Targets in Constructability

Constructability is pitched as the superset in which various other design target sub sets are accommodated as per the requirement. It is more of a tailor made solution rather than pre fixed one. The study reveals the relevance and influence of procurement management on constructability and importance of value generation in construction industry.

8 Stakeholder Synergy and Design Optimization

Better communication between stakeholders is a pre requisite for optimizing the effort and resources. This can be achieved by clash detection at an early stage. Design is a cocktail of disciplines and technologies which often lack the similar wavelength of people and ideas. The diverse opinions and assumptions need to fit in to the design parameters suitable for the project in hand. Communication between stakeholders is highly influenced by the structural system and procurement methodology. The constructability components like DfA, DfL, DfM and DfP is examined for a specific technology ie Pre-Cast. Similar analysis of design targets might have to be carried out for other construction methodologies too. It is pertinent to mention that in the example of Pre-Cast the procurement mode was Design-Build as the builder was responsible for the architectural, structural and MEP design. Better stakeholder synergy is achieved in this case as one stakeholder viz consultant has been eliminated. Previous studies have established that 40% of the change orders are rooted in the design phase and 30% cost escalation is attributed to poor communication during design. At the same time it has to be noted that each facility is unique and a tailor-made approach have to be adopted for different scenarios. The design team has to work out the best cocktail of design targets to achieve maximum value for the project not compromising on stakeholder synergy.

9 Conclusion

The human race has travelled a long journey from Pyramids to Burj Khalifa. As the theory of evolution has proved, only the ergonomic design will be passed on and imbibed by the next generation. Economic viability with desired value will remain the sole criteria for the project's success in the modern world. Only constructible designs will be executed and a trade-off will be arrived between design and construction which could be an iterative process to reach at minimum financial burden, carbon foot print and maximum value for money. The monitoring and control techniques like EVM will be helpful only when Design-Construction interface is hitch free. Construction is a nation building exercise where each activity is contributing towards the GDP. The study validates ample reasons to predict a symbiotic relation

between various procurement options and technologies to achieve targeted values. Design and Construction will remain complimentary activities with the constructability deciding the success and client satisfaction. The study predicts that constructability coupled with smooth assembly using minimum labour is essential for value addition. The bottom up approach of new policy initiatives and better communication between stakeholders promise more refined designs in future where technology will be pushed to achieve design optimization.

Abstract –

Falls are the leading cause of construction site accidents and made up more than 60 percent of all construction-related deaths in 2018, according to the Korea Occupational Health and Safety Administration (KOSHA). Accordingly, the government conducts intensive management and supervision of scaffolding and scaffolding installation at small sites while inducing safe working environments through support for system scaffolding installation. However, the timing of scaffolding installation for external work varies by site, and visiting inspections of more than 400,000 sites annually are practically limited. In particular, in the case of small sites, the work is often carried out with a high risk of falling accidents due to installation or defects that do not comply with KOSHA rule and the occurrence of accidents is frequently reported. To solve these limitations, information on whether the right amount of scaffolding has been purchased and installed at the right time according to the size and shape of each site needs to be managed by a systematic method.

In this paper, we propose a framework for verifying the adequacy of the installation of scaffolding needed at the individual construction site using blockchain technology. The system provide Dapp, an application that runs on the block chain server, so that General contract (GC) and Supplier can enter information related to ordering and procurement of scaffolding. The core information required to determine the adequacy of scaffolding installation is stored in a non-modifiable form using the distributed ledger storage technology of the block chain. As a result, scaffolding installation adequacy can be automatically verified through the algorithms that can compare the installation schedule and quantity calculation with the actually purchased quantity.

It is anticipated that using the proposed framework, government agencies can identify the safety levels of individual sites without on-site visits.

Scaffolding; Blockchain; Framework

1 Introduction

The death rate of domestic industrial accidents has been the highest among Organization for Economic Cooperation and Development (OECD) countries for decades. In addition, half of the domestic casualties occur in the construction industry. Particularly, the fall accident occurred from temporary structure shows high rate especially in a small site where facilities such as scaffolding are not installed [1].

Besides, according to the analysis data of major disasters in the construction industry over the past five years, 448 people died during scaffolding-related work, accounting for 23 percent of the total (2,134). Accidents occurred 63 percent at small and medium-sized sites (with a construction amount of less than 2 million USD), 44 percent due to the use of conventional steel pipe scaffolding, and 38 percent in housing-amenities construction [2]. Therefore, to prevent the risk of falling at the construction site, it is necessary to manage the appropriateness of scaffolding for more than 400,000 small and medium-sized sites annually [3]. However, at the construction site in Korea, the importance of scaffolding is still not recognized, and it is neglected for several reasons such as shortening the period and reducing costs.

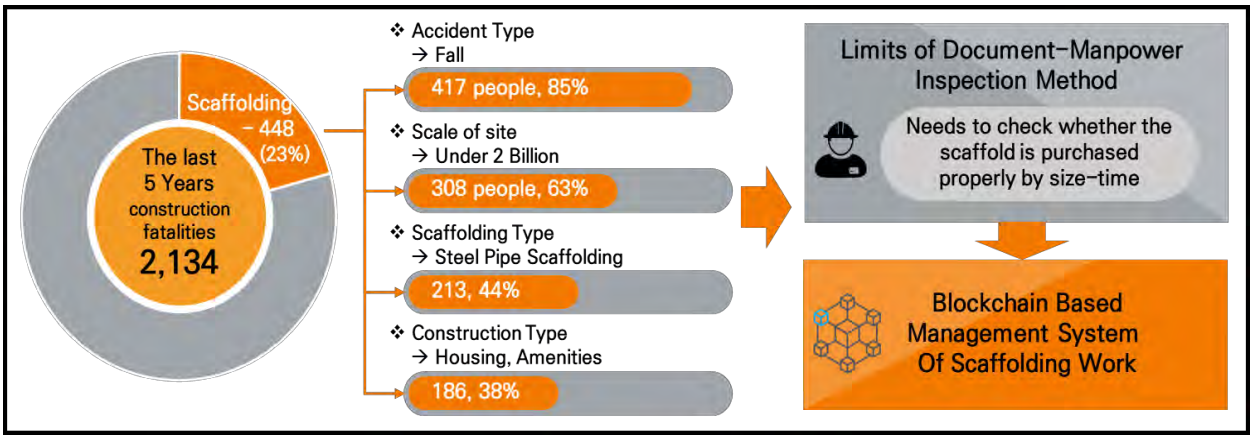

Figure 1. Construction Disaster Statistics by KOSHA (2015~2019)

Accordingly, the government induced on-site safety through a scaffold installation support system such as a clean project, and conducted inspections mainly on small and medium-sized construction sites that are vulnerable to safety accidents, but there are limitations in conducting inspections due to manpower based checking and document-oriented records. Therefore, for efficient management, it is necessary to manage information on whether the appropriate amount of scaffold is purchased and installed at the right period according to the size and shape of each site. For these reasons, this study intends to propose a blockchain-based framework for verifying the adequacy of scaffold that can automatically discriminate the information generated in the process of scaffolding work by a system other than a person and simultaneously secure the reliability of the generated information.

2 Literature Review

2.1 Scaffolding-Safety

Scaffolding is a temporary structure that is assembled and installed around a structure in order to install a construction passageway or work plate to facilitate high-rise work [2]. Due to the development of construction technology, the number of high-rise works has increased compared to the previous one, as the buildings are gradually becoming taller and larger. Therefore, as the importance and utilization of scaffolding in the field has expanded, the importance of safety issues related to scaffolding work has been emphasized.

As for the main research related to scaffolding, studies on accident analysis and countermeasures related to scaffold-safety, scaffold modeling using BIM, and risk identification are in progress. First, as research related to scaffolding and safety, Hola [4] analyzed accidents involving falls from scaffolding, which took place in Poland in the years 2008-2015. In addition, this study deduced that the biggest influence on the formation of accidents came from a lack of or inadequate equipment that secures work posts on scaffolding, and also improper collective protection measures e.g. roofing or protective nets, poor stability of scaffolding or its components and also an inadequate spatial structure of scaffolding. Kim [5] analyzed accidents that were caused by scaffolding during a fall disaster occurring at a domestic construction site. Besides, a variety of key factors affecting the fall was drawn from four aspects: worker, manager, material and construction, and design. Sakhakarmi [6] proposes a method that can be used during operation to make an automated safety prediction for scaffolds. It implements a divide-and-conquer technique with deep learning. This study emphasized that implementation will enhance the reliability of automated safety assessment systems on construction sites. Pienco [7] presented the results of analysis of 100 full-scale scaffolding structures in terms of compliance with legal acts and safety of use. He examined scaffolds in Poland located at buildings which were at construction or renovation stage from 2016~2017. Based on the analyzed scaffoldings, the most common errors concerning assembly process and use of scaffolding were collected.

Also, diverse researches are conducted related to scaffolding using BIM include automatic scaffolding design, risk identification through scaffold modeling, and safety planning. Kim [8] presented a framework and algorithms to integrate temporary structures to the automated safety analysis. Focusing on scaffolds, this research integrates temporary structures into an automated safety checking approach using BIM. Also a safety planning platform was created to simulate and visualize spatial movements of workers using scaffolding. Computational algorithms in the platform

automatically identify safety hazards related to activities working on scaffolding and preventive measures can be prepared before the construction begins. Kim [9] developed a rule-based system that automatically plans scaffolding systems for pro-active management in Building Information Modeling (BIM). Their computational algorithms automatically recognize geometric and non-geometric conditions in building models and produce a scaffolding system design that a practitioner can use in the field. We implemented our automated scaffolding system for commercially-available BIM software and tested it in a case study. project.

2.2 Blockchain Technology

Blockchain as a Distributed Ledger Technology (DLT) is a distributed data logging and maintenance system that depends on and is ensured by the consensus mechanism implemented by the agents. The autonomy and updating of the information contained in the blocks are subject to verification and authorization by all participants [12]. All participants with transaction data and management authority form a peer-to-peer (P2P)-type network to verify the previously centrally managed data by all participants within the network to ensure data integrity and reliability. The types of blockchains classified according to their characteristics include public blockchain that anyone can participate in, private blockchain that can only participate with permission, and consortium blockchain [10]

Table 1. Classification of Blockchain

	Participant	Anonymity	Usecase
Public Blockchain	Anyone	o	Bitcoin
Private Blockchain	Optional	x	Nasdag's Linq
Consortium Blockchain	Optional	x	Hyperledger Fabric

A representative function of blockchain is smart contract. A smart contract is a system that automatically fulfills a contract when all programmed conditions are met. Previously, a lot of documents were required until the contract was concluded and executed, but smart contract is a technology in which the terms of the contract are specified in computer code, and the contract is made when the terms are met.

Although the applying blockchain technology and smart contracts in the construction industry has not yet been conducted, many researches have been done to apply to the construction industry in recognition of the advantages and necessities of each technology. Major research areas related to construction include procurement, payment, and data reliability through connection with BIM.

Wang [11] proposed a blochchain-based information management model. The study suggests that proposed model can enhance real-time information communications among the different stakeholders and improve the efficiency of supply chain management. Besides, they also mentioned that through an adjustment in the smart contract, the model can also be applied to tackle issues in other traditional supply chains. Kim [12] proposed a procurement management system that applied Block Chain and Big Data technology within the construction industry. Through this, he emphasized that information generated as the project progresses can be applied to Block Chain to secure the immutable information and records, and that distributed network interworking can contribute to minimizing conflicts between project management and project entities by contributing to increased connection and reliability of information. Giuda [13] emphasizes that the progressive introduction of BIM based on the blockchain technology can provide a trustworthy infrastructure for information management during the design, tender, and construction phases. Luo [14] proposed a blockchain-based smart construction contract framework for semiautomatic execution of construction contracts for interim payments. They developed a smart contract implementation framework that satisfies the sequential approval process requirements in a distributed environment such as the construction industry by utilizing blockchain technology. Kang [15] emphasized that through smart contracts, transactions between interested parties can be managed in a decentralized manner, reducing the risk of contract changes and inducing reasonable transactions with transparent transaction terms. Besides, he also proposed that an Ethereum-based smart contract could be solved, which is difficult to solve with the centralized control method of the current construction industry. Lanko [16] referred that almost none of the fields of human activity can do without supply chain management. Therefore, in this study, the necessity and limitations of blockchain technology application were presented by taking the manufacturing process and delivery process of ready-mixed concrete as an example. Turk [17] emphasised that blockchain has the potential to address some issues that discourage the industry to use BIM such as confidentiality, provenance tracking, disintermediation, non-repudiation, multiparty aggregation, traceability inter-organizational recordkeeping, change tracing, data ownership, etc. Moreover, they also mentioned that on the construction site, blockchain could improve the reliability and reliability of construction logbooks, works performed and material quantities recorded. San

[18] referred that the application of blockchain technology can improve the construction process that shows the limitations of centralized technology in the current construction project lifecycle. In addition, Dakhli [19] emphasized that block chain technology can improve the limitations of the design and construction process and reduce costs.

2.3 The necessity of Blockchain Framework

Recently, interest in the smart contract technology, which is automatically traded when the reliability and security of data and conditions are met through the distributed ledger, a representative characteristic of blockchain, is growing in all industries. In particular, the construction industry expects that the problem of chronic distrust in the construction industry will be resolved if transparency and completeness of transactions can be secured in subcontracting, material delivery, and real estate transactions. For this reason, various blockchain platforms and functions are developed and continued research is conducted according to the purpose of utilization. However, there is no research on safety management related to scaffolding construction based on blockchain technology. In this regard, the blockchain-based framework that determines the adequacy of scaffolding installations presented in this study is needed.

Furthermore, the framework to be proposed in this paper is expected to improve the limitations of the existing construction management process by using reliable data and the decentralization of information through distributed storage, a typical characteristic of blockchain technology.

3 Proposing Framework

3.1 Framework Overview

The framework proposed in this study is focused on preventing falls during scaffolding operations that are severe in the construction industry. To this end, the framework will be designed as a system process that manages the suitability of scaffolding installation by discriminate the purchase of scaffolding quantities.

1) The proposed framework utilizes a Hyperledger fabric, a kind of Consortium blockchain, so that only designated users can have access to data. Through this, we will give authority only to construction participants such as GC, suppliers, and inspection agency. Then we will configure the scope of data access differently according to the characteristics of each participant.

2) As a technical method for automatically verifying scaffolding-related power generation information, a structure will be designed that automatically calculates the time and quantity of scaffolding installation based on design information such as 4D-BIM, compares them with the order-procurement information entered through the app, and stores the results in the block chain system.

3) Blockchain technology utilizes core composition technologies such as channel composition for authority setting by participating parties, consensus algorithm for ledger records and viewing, and guarantee policy. We will set up Membership Service Providers (MSP) for channel configuration and form a system for data access and verification in conjunction with the blockchain network. We will also design a separate system structure of the On-Chain, Off-Chain network to prevent overload of the blockchain network.

4) The key demand for this framework is the Government Inspection Agency, which conducts on-site inspections. It is intended to design a system structure that can store information that needs to be verified when checking the appropriateness of scaffolding at individual sites of this system in a blockchain manner and provide the information needed for verification from the inspector's point of view.

3.2 Key functions of Blockchain Framework

This section describes the core functions of the framework proposed. The framework utilizes various key technologies in the blockchain to identify the entered data and store the identified data as reliable data. Key functions are as channeling, smart contract, text mining, consensus algorithm and on/off chain.

- *Channeling*

Channeling defines participants who participate in scaffolding-related activities of construction projects and sets different access authority to information by subject. Channel composition can be divided into groups that generate information through scaffolding-related activities and groups that view them. The first group that generates information is a supplier that procures scaffolding and a contractor that orders scaffolding. The supplier grants authority only to the relevant field channel, so that information from other sites cannot be viewed, preventing sensitive information such as order history and cost from being shared with other suppliers. The contractor grants authority to all managed sites so that data can be provided and viewed for scaffolding. The inspection agency is designed to allow access to all data, such as ordering-procurement data and discrimination results so that it can be determined whether appropriate scaffolding is installed.

- *Smart Contract*

Smart contract is one of the key functions of the

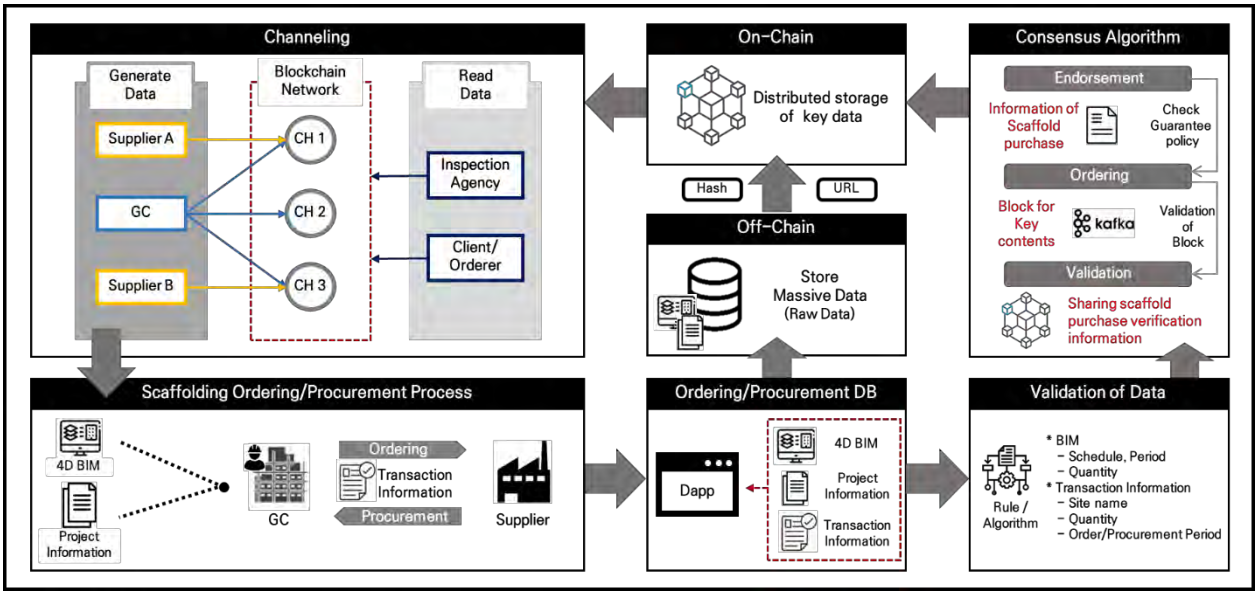

Figure 2. Blockchain-based scaffolding management process and key features

blockchain. It implements functions such as reading and storing data from the blockchain server so that the algorithm on the application can compare the data entered in the order-procurement process with the key data such as area, time, and installation quantity identified in the 4D BIM data.

- *Dapp*

Dapp is an application that works on distributed ledger systems. It is used by the transaction participant to input information generated during the ordering and procurement process and basic information of construction. In addition, Inspection agency can view the scaffold installation suitability and related data derived through data verification.

- *Consensus Algorithm*

This algorithm automatically uploads discriminative data from verification of proper scaffold purchase to On-Chain to prevent forgery of data due to third-party intervention that may occur before being recorded in distributed ledger. In addition, by checking the authority of the viewer, it is possible to prevent ledger access by unauthorized users to the corresponding blockchain network or channel.

- *On-Chain / DLT*

This technology is a function to store verified data on the blockchain. Every participant in the channel maintains a copy of the ledger on its own and the copy goes through a consensus process to keep it consistent with the copies of all other peers. Through this, it is possible to prevent forgery and falsification of all scaffolding-related data input to the ledger and ensure data reliability.

- *Off-Chain*

Off-chain is a method of recording data outside the blockchain. If large capacity data is stored in the on-chain, processing speed may be reduced and overload may occur. To prevent this, massive data (photo, BIM, etc.) is stored in a single DB outside the block chain and the hash and URL of the data are recorded in the distributed ledger.

4 Scenario of proposed framework

In this section, we would like to present a sample scenario of the proposed framework to demonstrate the process of the entire framework.

Based on the basic information of the project and the 4D-BIM, the GC calculates the amount of scaffolding installed by construction period. Then, order the materials from the supplier and receive them. Through the ordering-procurement process, information about the transaction between GC and supplier is generated, such as ordering and procurement quantity and ordering time. The generated transaction information is uploaded by the participant through the dapp. Then uploaded data is verified through the data comparison algorithm to discriminate whether the proper scaffolding purchase and installation.

For verification, key information of each original

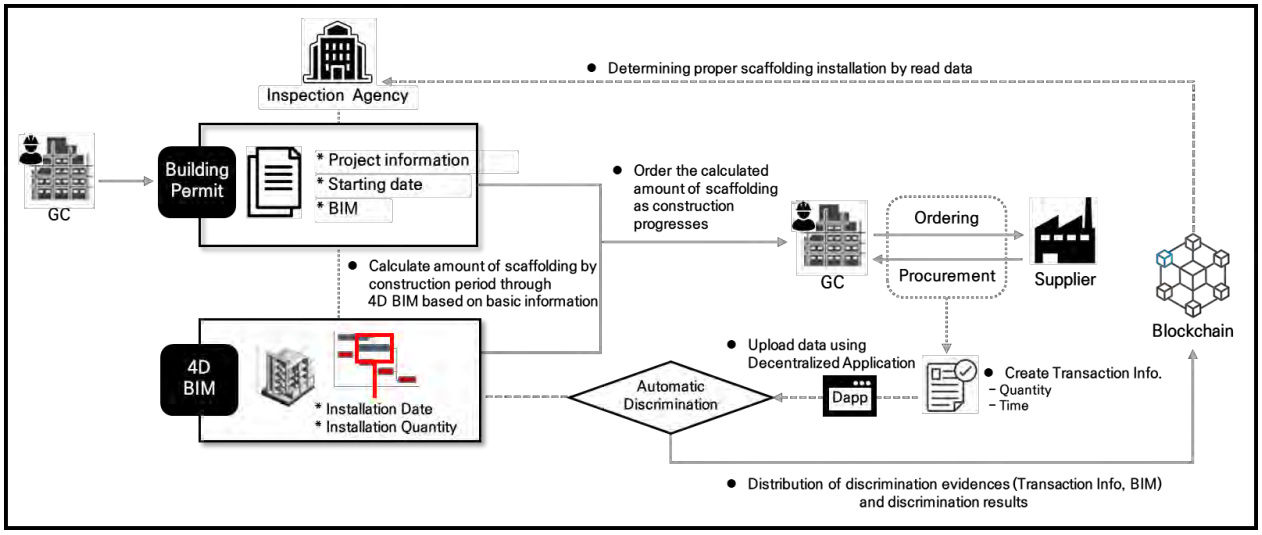

Figure 3. Example scenario of Framework

data is used (shown in figure 4). First, information about the scaffolding quantity required according to the progress of the construction is collected through the area, the scaffolding quantity calculated, and the construction schedule data from 4D-BIM. This data is compared with major data among transaction information such as order quantity and procurement time uploaded through dapp to determine whether the necessary scaffolding is prepared on site at the appropriate time. After that, the results of the verification will be distributed and stored in the blockchain network through a consensus process along with key information such as transaction information and 4D-BIM. At the same time, massive data such as 4D-BIM data is stored separately in off-chain to prevent overload of the blockchain system, and only hash or URL of the data is stored on-chain together. Finally, the inspection agency checks whether the proper amount of scaffolding has been purchased by viewing the stored data and checks whether the proper scaffolding is installed or not. And it will determine whether an on-site inspection is necessary. Moreover, if such data were accumulated later to form big data, it could be used to calculate and verify the necessary scaffolding quantities depending on site characteristics, even without BIM. And it is expected that this could be reflected as a big advantage in small sites where BIM is

not available in the field due to costs and other issues.

In addition, this framework can be applied not only to the scaffolding proposed in the study, but also to various supplies. For example, ready-mixed concrete is also worked through the process of 'Quantity calculation-Order&Procurement-Installation'. Although there are differences in several processes such as quality verification in the intermediate process, it is expected that it can be applied as similar processes are being conducted in a large framework. As such, it is expected that the proposed framework can be applied to various supplies of construction work to improve the current construction process.

5 Conclusion

The construction industry is becoming increasingly high-rise, large-scale and complex due to the development of technology. As a result, the proportion of dangerous work and complaint work is increasing, and the frequency of 'falling' is increasing. However, at the construction site, there are still many small construction sites do not recognize the importance of the scaffolding that should be basically installed to prevent fall accidents and do not properly install it even if it is omitted or installed. Recognizing this situation, the government has proposed counterplan such as increasing the number of on-site inspections. However, they still has difficulties due to lack of manpower.

For this reason, this paper proposed a blockchain framework to determine whether the proper scaffolding is installed according to the characteristics of the construction site and to ensure the reliability of the information. The proposed framework secures the reliability of data such as project information, scaffold purchase information and BIM through distributed ledger technology. In addition, it also can verify the suitability of scaffolding installation automatically by compare and determine scaffolding-related information

By using the proposed framework, the inspection agency can check the results of the adequacy of scaffolding installation utilizing blockchain network without the need to visit the site, which requires a lot of manpower. Ultimately, it is anticipated that efficient management will reduce the occurrence of accidents at the construction site.

If a method to acquire the state of the scaffold installed in the actual site is devised, it will be possible to more effectively verify the suitability of installing the scaffold. For example, on-site manager uploads and confirms the installation status of a scaffold on the site as a photo, or a method of confirming the installation status of a site scaffold through CCTV installed on the site. As an available technology, it is expected that scaffolding can be identified and confirmed through images acquired in the field using image recognition technology.

Abstract –

Façade condition assessment for buildings is essential to public safety in cities. Currently, twelve major cities across the U.S. ensure the building façade safety with mandatory façade inspection programs. Even in major cities with the façade inspection programs, there have been seventeen falling debris accidents reported in 2019, three of which were fatal. These accidents indicate a need to improve the current façade inspection practice. Shadowing work conducted by the research team with expert inspectors on three buildings, and analysis of façade inspection programs and guidelines show that inspectors check façades based on defect types or on façade components, whereas existing documentation to guide inspectors are based on major material types. This mismatch results in inspectors checking façade components based on their experience, which might not align well with the expectations of agencies. Systematic and detailed assessment guidance is necessary to get a comprehensive and consistent façade inspection. Towards such systematic guidance and to understand the underlying reasons for continuing accidents, this paper provides the details of an approach to identify generic vocabularies and the relationships between major entities that play a role in the inspection domain for systematic inspection processes. To identify these, we developed a data-driven approach that analyzed around 100 façade inspection reports that were filed to the NYC Department of Buildings (DOB) during the past inspection cycle (2014-2019). Among the twelve major cities, New York City (NYC) has the longest history of façade inspection, and most buildings (14,000) enrolled in the façade inspection program. We believe that study about NYC buildings can provide a general understanding of inspection requirements in other cities where similar problems exist. The developed mechanism is based on natural language processing and unsupervised machine learning techniques and is used to extract the vocabularies of façade elements, defect types, associated defect attributes, and mapping between them. The results also provide the mapping relationship of façade components and defect types for a specific façade type (e.g., stone/limestone). This work provides the foundation for an ontology to be used to systematically guide façade inspection for any given building.

Façade inspection, Report analysis; Natural Language Processing (NLP); Unsupervised learning.

1 Introduction

Twelve major cities in the U.S. have a façade inspection program to ensure the safety of buildings. Accidents and incidents caused by debris falling from building façades, however, are still happening in cities. For example, in the past year (2019), 17 accidents due to debris falling occurred in the U.S., causing deaths and injuries. The past decade has shown that more than 700 complaints about façade safety were received annually by the department of buildings (DOB) in the city of New York (NYC) [1]. These accidents and complaints indicate a need to improve the current façade inspection practice.

Shadowing of façade inspectors by the authors resulted in the identification of several challenges in the current façade inspection practice [2]. One of these challenges is the lack of a comprehensive and detailed checklist that can serve as a guideline to a systematic inspection that is based on defect and façade component types instead of material types. Current façade inspection regulations in different cities and international guide for standard periodic façade inspections published by the standards organization [3] cover information on conditions of buildings that need an inspection, length of inspection cycles, general and close visual inspection of façade, and reports formulation and submission. Information about what defect types need to be checked and what associated attributes are essential for façade safety assessment, however, is missing from the

regulations and practice standard documents. Aside from the regulations and practice standards, a few glossaries formulated by industry professionals aim to provide descriptions and illustrations of defect types for different façade materials [4-6]. The glossaries are only for educational purposes and are not integrated into any guideline for defect identification in the façade inspection practice. Façade inspection is still a practice that relies solely on the personal experience of each inspector and company-specific templates. Figure 1 shows an example of different inspection results in two inspection reports for the same brick masonry building and its roof.

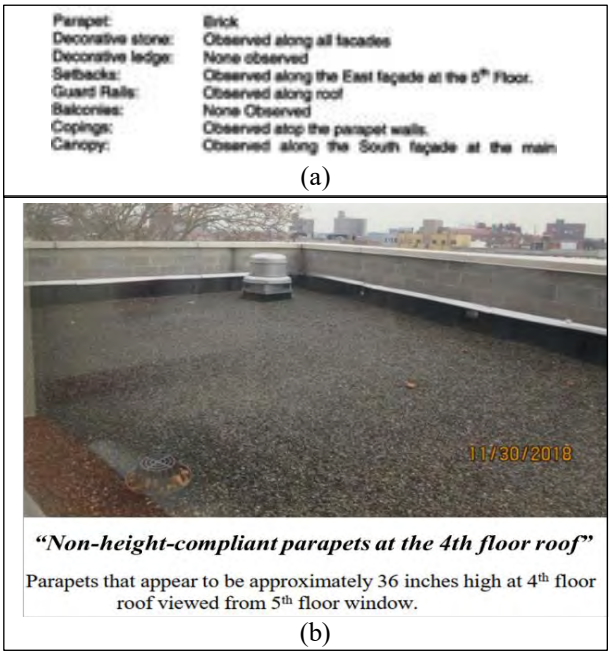

Figure 1. Examples of different inspection results for the same roof. (a) Previous inspector (Cycle 7) only mentioned the existence of a parapet. (b) The current inspector (Cycle 8) checked the height of the parapet with respect to the code compliance.

For safety concerns, the height of parapets should comply with the construction code that was applicable when the building was constructed. The inspector, who conducted the inspection work in the prior cycle, only mentioned the existence of a parapet at the roof (Figure 1a) and its material type as the information collected for the parapet. The inspector we shadowed, however, also checked the height of the parapet, compared it to the requirements in the code, and identified that the height of the parapet is not compliant with the applicable building code (Figure 1b). Such differences of what components to check, what specific parameters to check for each façade component are common, and show a need for a checklist that the inspectors can follow to conduct an in-depth and comprehensive inspection regardless of their experience.

Shadowing work and the review of submitted reports showed that the inspection is conducted per façade component and is not based on material types. For example, when an inspector is checking a balcony, he/she will check the concrete panels for cracks, the railings for connection stability, and compliance of spacing between railings and their heights to the code altogether, instead of checking cracks in all concrete components at once. One example of this component-based practice is provided in Figure 2. The inspector, who submitted the report, grouped the observed conditions based on the façade components (i.e., openings). The current façade condition glossaries, however, summarize the defect types based on façade materials (e.g., concrete, metal) and there is a need to know which defects are applicable to which façade components for a comprehensive and consistent façade inspection.

Condition: The windows were observed to be in satisfactory condition during the critical examination (see photo #13).Classification: SAFE b.* ***Window Sills*** *Description: The windowsills are constructed of brick masonry. Condition: The windowsills were observed to be in satisfactory condition during the critical examination. Classification: SAFE*

Figure 2. Façade inspection report grouping the conditions based on façade components.

Towards a comprehensive façade inspection guidance, what is needed is the knowledge of how defect types (and defect-related attributes) map to façade component types, and the comprehensive vocabularies for these defect types, defect attributes, and façade component types. The objective this paper is to identify this mapping and the vocabularies of the defect, attribute, and façade component types. With this objective, we developed an approach using bidirectional long short-term memory (bi-LSTM) model to automatically analyze around 100 façade inspection reports that were submitted in the past inspection cycle (2014-2019) for buildings in NYC. Here, the assumption is that inspectors' practice is reflected on the inspection reports they submit and can be leveraged for investigating the relationships between façade components and defects, and expanding the available material-specific vocabularies towards component-specific vocabularies. This paper provides an overview of the developed bi-LSTM model and the results of this mapping and resulting vocabularies of façade components, defect types, and defect attributes. These findings also lay the foundation for an ontology for systematic and comprehensive façade inspection.

2 Literature Review

Here we present a synthesis of previous researches on urban façade inspection, structural health monitoring, and the application of natural language processing (NLP) in the civil engineering domain.

Previous researches on façade inspection and structural health monitoring were mainly focused on automatic defect detection using digital data, particularly point clouds and images. Researchers developed algorithms to detect cracks [7-9], moisture [10], spalling [8, 9], vegetation [8], and efflorescence [9] on concrete, masonry, and steel surfaces. Several algorithms are able to quantify the defects, such as the area of spalling [11] and the width of cracks [7] automatically or manually on 3D models [12]. Although these studies provide a handful of defect types/attributes on a select type of materials, their focus is not aligned with this study that aims to define the vocabularies of defects, component types, and the mapping between them for improvement of the façade inspection practice.

Previous NLP applications in the civil engineering domain aim to extract essential information such as condition assessment information from bridge inspection reports, or project relevant information from unstructured construction documents, or regulatory information from building codes with different machine learning models [13-15]. Although there are NLP applications in the domain, the analyzed documents are semi-structured or structured with logical-connected words (e.g., "*equal to*" and "*less than*" represent quantification compliance in the building codes) or with known defect types (e.g., crack, spall, efflorescence, etc.) and rating categories (e.g., minor, moderate, severe) [16], which can be analyzed with rule-based information pattern matching. Different from previously studied document types, façade inspection reports are personal narrative descriptions written without guidance or specific templates. Thus, this unstructured nature of the inspection reports requires unsupervised learning to find relevant words (e.g., parapet, crack, diagonal), label them correctly (e.g., façade component, defect type, defect attribute) within the context of a report, and maintain the relationships between these labels. We implemented a natural language processing (NLP) algorithm to identify the vocabularies for façade components, defect types, defect attributes, and the hidden relationships between façade components and defect types. Long short term memory network (LSTM) is one of the Recurrent Neural Network (RNN) architectures and is known to be suitable for processing sequence data (e.g., time-series, speech sequence, and text) because LSTM preserves information about the data that the model sees earlier in a sequence. Unlike general sequential data processing, NLP has a feature that the context in a sentence is defined by the interrelationships among words in both backward and forward directions. Since the unidirectional LSTM passes input information forward only, bidirectional LSTM is more proper for automated understanding of natural language. In addition, the conditional random field (CRF) is a statistical modeling method that is widely known for its high performance in predicting a label for sequence data. Adding CRF as an output layer in the bi-LSTM model (i.e., bi-LSTM-CRF model) is proved to outperform previous state-of-the-art models in the information labeling tasks [17]. It has been utilized in the approach presented in this paper. To further improve the performance of NLP models, skip-gram models, which are unsupervised learning models and can precisely capture the semantic (i.e., meaning) and syntactic (i.e., grammatical structure) relationships between words [18]in a context. Previous research studies trained skip-gram models with general English text and used them to improve the performance of machine learning models on extracting information from documents (e.g., [13]). In this study, we trained a skip-gram model with domain-specific text (i.e., façade inspection reports text). We used it to generate the dependency information that was included in the input of the machine learning model to boost the performance of the model.

3 Research Method

To obtain comprehensive vocabularies for façade components, defect types, and their attributes together with the mapping relationship among those, we developed an algorithm that is capable of extracting key information in unstructured inspection reports. In a nutshell, this algorithm includes a trained bi-directional long short term memory (bi-LSTM) model, boosted with outputs of an unsupervised skip-gram model developed by the research team to capture semantic and syntactic relationships between words (as detailed in section 4).

For the training of the bi-LSTM models that we enhanced with domain-specific skip-gram models, first, we needed to generate initial vocabularies of façade components, defect types, and defect attributes. For this purpose, we reviewed current façade inspection practice standards [3], local laws/regulations [19], and façade condition glossaries [4-6] to generate defect types and attributes vocabularies. Similarly, we reviewed building component libraries of 3D modeling tools (e.g., Revit libraries) and building classification models (e.g., Uniformat) to prepare the façade components vocabulary. We defined four labels, which are ***façade-component***, ***defect-type***, ***defect-attribute***, and ***others*** (i.e., information that is irrelevant to façade conditions), to automatically label worlds in reports. The details of this approach are provided in the next section.

4 Boosted Bi-LSTM model for mining of inspection reports

Figure 3 provides an overview of our approach. Data preprocessing (step 1) and labeling (step 2) steps are provided in section 4.1, dependency information provided by the skip-gram model (step 3) is presented in section 4.2, and the utilization of the model to identify vocabularies and mapping relationships (step 4) is discussed in section 4.3.

4.1 Preprocessing and labeling of the text

We obtained around 3,000 façade inspection reports that cover all the seven façade types in document format from the NYC DOB database. For this study, we analyzed 100 inspection reports for only stone limestone façade buildings. Preprocessing starts with using a parser to extract the raw text from the sections where inspectors describe their findings and splitting the raw text into indexed sentences with the sentence tokenizer. The indexed sentences were tokenized into words (i.e., separating a given sentence into the list of its words), then lemmatized (i.e., returning to the root form of the words) to eliminate the influence of different tenses, plural forms, verb/noun differences. The part-of-speech (POS) information of each token (e.g., noun, verb, adverb, adjective, etc.) was used to achieve a more accurate lemmatization. For instance, the word "*rose*" can be the past tense of "*rise*" or the flower. Depending on the POS of the word, the result of lemmatization differs. These lemmatized sentences were temporarily used in the labeling process to eliminate labeling errors due to the different formats of the words in the text and the identified vocabulary list. Next, we labeled the preprocessed and lemmatized text using the Inside-outside-beginning (IOB) tagging mechanism. With this tagging mechanism, we are able to label compound words that are consisted of multiple words with the beginning token (i.e., a word in this context) and inside tokens. The "**I-**" tag stands for "inside" of a label, referring to the subsequent word in a compound word (e.g., "*escape*" in "*fire escape*"). The "**O**" tag stands for "outside" of a label, referring to the irrelevant word. The "**B-**" tag stands for "beginning" of a label, referring to the first word in a compound word (e.g., "*fire*" in "*fire escape*"). For example, in the term "the window lintel", "window lintel" should be labeled as a single ***façade-component***. Using IOB tagging mechanism, the word "*the*" is labeled as "**O**", and "*window lintel*" will be automatically labeled as [window (B: façade-component) lintel (I: façade-component)]. The label categories we used are façade components, defect types, defect attributes (i.e., length, width/depth, direction, location, material, number of floors, and façade sections), and others.

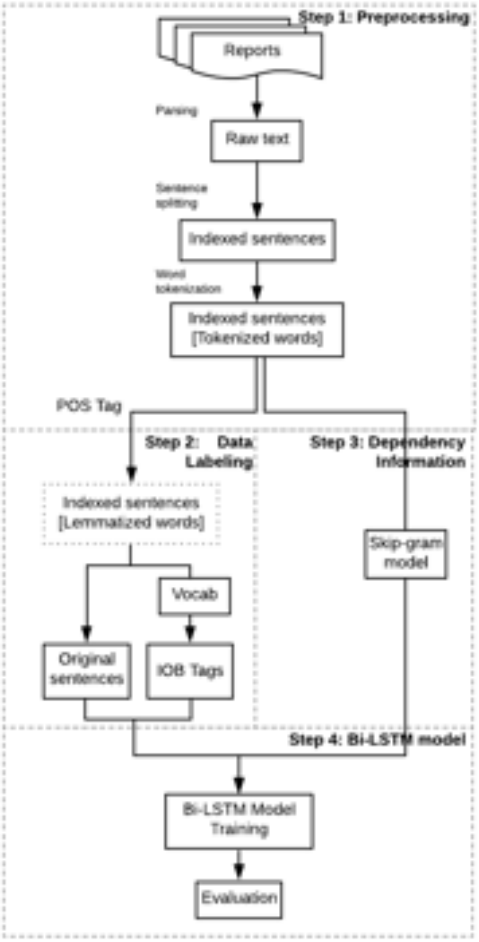

Figure 3. Overview of the developed approach.

Figure 4 provides an example of a sentence from the reports and its labeling result. If there are no compound words, each identified word that corresponds to one of the four label categories will be labeled with "**B**". All the other words that are not of interest in this labeling process are to be labeled as "**O**" (i.e., others).

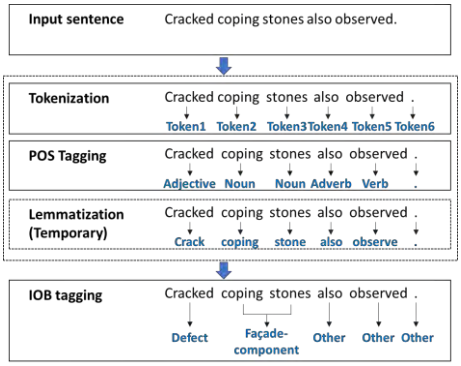

Figure 4. An example of a sentence preprocessed and labeled with the IOB tagging mechanism.

4.2 Obtaining dependency information through the domain-specific skip-gram model

Word embedding is the process of vectorization of words to convert natural language into a computer-readable format based on the extracted features of the language. Word embedding approach takes a large input of tokens, projects them to a vector space, and assigns each unique token a corresponding vector for the representation in the vector space. In this study, we used two word embedding approaches to compare the results of the bi-LSTM model with and without dependency information. These two embedding approaches are the one-hot encoding, which does not provide dependency information between words, and the skip-gram model, which includes the dependency information in the word embedding process. One-hot encoding is a vector representation of word in binary vector format (e.g., *crack = [1,0,0], window = [0,1,0], maintenance = [0,0,1]*). Since the vectors represent words in binary value, one-hot encoding cannot provide the similarity/distance between words. On the other hand, the skip-gram model is an unsupervised learning method for word embedding that uses vector space to capture and represent the semantic and syntactic relationships between words efficiently. Semantic refers to the word meanings and relations, and syntactic refers to the rules of a language and grammatical arrangement of words in sentences. For example, sentences like "*window identifies crack*" ("subject"+ "verb" + "adjective") is a syntactically correct sentence, but it is not semantically correct. After the word embedding, all the input words are mapped into the N-dimensional vector space ($word_1 = [v_1, v_2, v_3, v_4, \ldots, v_n]$). Since the mapped words are using vector representation (e.g., word "*crack*" is represented as [-0.478, 0.917, 0.196, -0.443, -0.978, …, -0.207]) with respect to the other words in the same context, the skip-gram model can perform analogical reasoning precisely. In other words, if two words are placed at similar locations in two different sentences, and the meaning of the terms are similar, then the distance between those two words is relatively small in the vector space if the same pattern is observed often by the skip-gram model. For example, given the following two sentences from a report: (1) "*We recommend repairs to be made to correct these deficiencies by February*." (2) "*We recommend timely maintenance to repair the SWAMP condition observed our inspection*." In vector space, the distance between "*repairs*" and "*maintenance*" is relatively small. Figure 5 presents an example for a simplified 2D projection of the vector space showing the distance between "*repairs*" and "*maintenance*".

Previous studies indicate that the skip-gram model trained with general English text improves the information labeling model performance [13]. In this study, we trained a skip-gram model with the façade inspection reports and included the dependency information, which is represented by vectors generated from the skip-gram model, as part of the input for the bi-LSTM model.

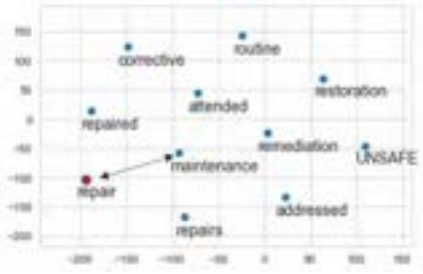

Figure 5. An example of the tokens "repair" and "maintenance" in projected vector space.

4.3 Identifying vocabularies with the boosted bi-LSTM-CRF model

In this study, we built and trained a bi-LSTM-CRF model boosted with skip-gram model outputs. The input for the bi-LSTM-CRF model is the labeled sentences (i.e., the output of step 2 in Figure 3) and the dependency information (i.e., the output of step 3 in Figure 3). Figure 6 provides an illustration of the boosted bi-LSTM-CRF model with a short sentence as an example. The model has an input layer, where the preprocessed sentence "*Exterior wall has crack*." is converted into vector representation by word embedding as input into the bi-LSTM layers. Then, the LSTM model learns from the input data in both forward and backward propagations to update the parameters. The output of bi-LSTM is then inputted to the CRF layer to refine the relational information between tags. The CRF layer works as a classifier to predict the label of each token and improves the performance of the model because it can learn the constraints of labels based on their positions. Constraints such as "inside labels (i.e., I) cannot exist without beginning labels (i.e., B)", and "I of one label cannot appear after B of another label (e.g., 'I-defect' cannot appear after 'B-component')" are learned by this layer. After the CRF layer, the final output of this bi-LSTM-CRF model is the labels for each token in the sentence.

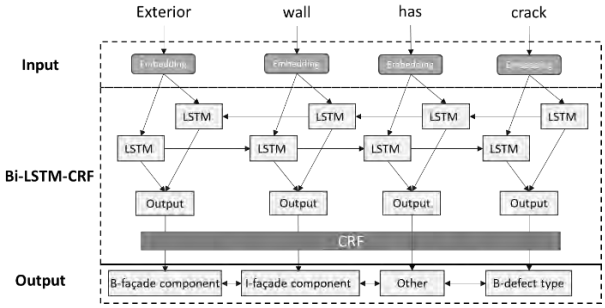

Figure 6. Illustration of bi-LSTM-CRF models with an example sentence.

4.4 Model development

The sentences extracted from the reports were randomly separated into training (i.e., data that is used to build the models), validation (i.e., data that is used to prevent overfitting problem in the training process), and testing (i.e., data that is used to test the performance of the models) sets with 7:2:1 ratio. We trained two bi-LSTM models with one of them included the dependency information provided by the skip-gram model and the other one using one-hot code input. We trained the models with the training set, and the validation set was used to fine-tune the models and avoid the overfitting problem. The testing set remains unseen by the model and is used for model performance evaluation. After we trained and optimized the models, the sentences in the testing set are labeled by the model. The output labels are compared with the labels provided by the IOB tagging mechanism. We calculated the F_1 score, precision, and recall for model performance evaluation using Equations 1-3, where TP represents true positive (i.e., the number of tokens that were correctly labeled), FP represents false positive (i.e., the number of tokens that were mislabeled), and FN represents false negative (i.e., the number of tokens that should be labeled but were missed). The evaluation metrics can be calculated with the following rules. Precision is the ratio of correctly labeled tokens to all the tokens that are labeled in the testing set for each label (Equation 1). The recall is the ratio of the correctly labeled tokens to the total number of correct labels expected to be labeled in the testing set for that label (Equation 2). F_1 score is the weighted average of precision and recall (Equation 3). The performances of both models are evaluated using stone/limestone façades.

$$Precision = \frac{TP}{TP + FP} \quad \text{Equation(1)}$$

$$Recall = \frac{TP}{TP + FN} \quad \text{Equation(2)}$$

$$F_1\ score = 2 \times \frac{Precision \times Recall}{Precision + Recall} \quad \text{Equation(3)}$$

5 Preliminary results and discussions

This section provides the results of the labeling process using the developed boosted bi-LSTM-CRF model. The results are provided for reports analysis of stone/limestone façades.

5.1 Preliminary results of vocabulary identification in stone/limestone façade inspection reports

For stone/limestone façade buildings, 100 façade inspection reports were available, and 1771 sentences were extracted from the reports. The training, validation, and testing sets had 1272, 319, and 180 sentences, respectively. After preprocessing and IOB tagging, there were 3446 tokens labeled as façade components, 190 tokens labeled as defect types, and 256 tokens as defect attributes in the training set. Table 1 shows the precision, recall, and F_1 score for each label category identified by the developed approach. As shown in Table 1, the left columns with normal text show the model performance when the input data does not include dependency information. The right columns with bold text show the model performance when we include the dependency information as part of the input. The model performs well in the vocabulary labeling for façade components, defect types, and defect attributes given their consistently high scores in precision and recall. The labeling performance for both façade components and defect types has been improved approximately by 10% by including the dependency information, while the labeling performance for defect attributes did not change much by including the dependency information. Resulting vocabularies after the trained model is finalized for stone/limestone façade are discussed with respect to their categories.

Vocabulary for façade component types: For façade component types, a total of 38 component types (e.g., cornice, storefront, column, mortar joint, coping stone, etc.) were identified for stone/limestone façades as a result of this automated report analysis. All the identified façade component types were covered by our initial vocabulary, and no additional façade components were expected to be identified.

Table 1. Precision, recall, and F-1 score for labeling (with/without dependency information).

Label category	Precision		Recall		F-1 score	
Dependency information	w/	**w**	w/	**w**	w/	**w**
Façade component	0.78	**0.88**	0.85	**0.91**	0.82	**0.90**
Defect type	0.62	**0.76**	0.59	**0.74**	0.61	**0.75**
Defect attributes	0.91	**0.91**	0.74	**0.77**	0.82	**0.83**

Bold w: model performance with word embedding information. **w**: with; w/: without.

Vocabulary for defect types: There were 12 defect

types identified by the automated report analysis of stone/limestone façade inspection reports. These include cracking, peeling, missing, hazardous condition, removed, spalling, corrosion, displacement, bulging, delamination, chipping, and hollow. Certain defects such as deformation, misalignment, and loose that are important to the safety condition assessment were not mentioned in the reports.

Vocabulary for defect attributes: The defect attributes included in the inspection reports of stone limestone buildings are location (e.g., corner, roofline, floor line, joint, etc.), direction (e.g., horizontal, vertical, inward, etc.), material (e.g., paint, rust, etc.), section (i.e., east/west/north/south façade), area (e.g., square feet), and related deterioration (e.g., chalking, staining, discoloration, etc.). Among all the defect attributes, related deteriorations, and façade section information was not identified correctly by the approach.

5.2 Mapping relationship between defect types and façade components for stone/limestone façades

An important outcome of the trained models is the discovery of the unknown mapping relationships between façade components and defect types, which are required for a systematic component-based façade inspection guidance. The mapping relationships identified for the stone limestone façades are provided in Figure 7. Numbers in each cell indicate the frequency of the "façade component-defect type" pairs that appeared in the façade inspection reports. The frequency of identified pairs is normalized over the defect types to show the most frequent defect types on each façade component. The density of color in each cell represents the normalized results. The underlying assumption here is that the vocabularies appeared in the same sentence is describing one defect observed on a façade component by the inspector. For stone/limestone façades, 38 building elements and 12 defect types are identified from the façade inspection reports. When the figure is analyzed vertically, it is possible to identify the relations discovered between façade elements and a given defect type. Crack is the defect type that relates to most of the façade elements to be inspected for stone/limestone façades and is related with 30 out of 38 façade elements. Hazardous condition (associated with 15 façade elements), spalling (associated with 14 façade elements), and peeling (associated with 10 façade elements), are defect types that rank high in mapping to façade components. Delamination and chipping, both associated with 6 façade elements, are defect types that rank low in mapping to façade components. Hollowness, which is only associated with coping, is the defect type that relates to the least number of façade components.

When Figure 7 is analyzed horizontally, it is possible to observe what types of defects are applicable to a given façade component. Among all 38 façade elements, brick pieces (that require inspection for 11 different defect types), copings (that require inspection for 10 different defect types), parapets (that require inspection for 9 different defect types), and lintels (that require inspection for 8 different defect types) are the façade components that have the highest number of defect types associated with them. On the other hand, glass panels, columns, window panels, ladders, entrance doors, and fascia are the façade elements that only have crack associated with them.

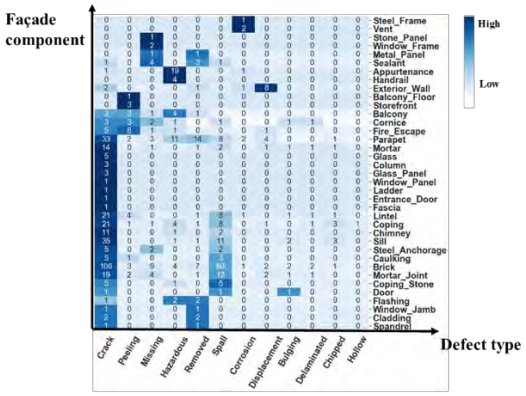

Figure 7. Mapping of façade components and defect types for stone/limestone façades

6 Conclusions

In this study, the authors proposed an automated approach for analyzing façade inspection reports to extract vocabularies for critical façade inspection information (e.g., defect type, façade component types) and discover the undocumented but critical information on how defect types map to façade component types. This information is needed to streamline the façade inspection process by providing the flexibility for inspectors to organize their inspection findings per façade component type or per defect type. A natural language processing approach, combined with an unsupervised skip-gram model, was developed and trained using NYC façade inspection reports. By comparing the labeling results, we proved that including the dependency information can improve the performance of bi-LSTM-CRF in information identification and labeling. NYC has the longest history of the façade inspection program and the largest number of buildings that need inspection regularly-hence it has been used as a test site. The analysis conducted in this study can shed light on other cities where an in-depth understanding of the façade inspection practice is needed. As an immediately following work, the authors will analyze the façade inspection reports of buildings with other façade types

(e.g., brick masonry, metal panel) and include a larger set of reports to improve the performance of the approach. The vocabularies developed and the mappings identified in this study can be helpful for future research that aims to provide a model-based comprehensive guide for the façade inspection practice.

Abstract –

As is well known, resident engineers on site might plan a heuristically deterministic construction schedule by PERT/CPM program. Since it is boring and time-consuming to gather, edit and input field data into the PERT/CPM program, however, there are very few opportunities to revise the construction schedule on daily works. This paper proposed an easy-to-use and -learning method to plan and revise construction schedule and to do ensemble forecasting construction schedule. First, this paper outlines this study and analysis methods to calculate daily real operational hour and rate based on 3-axis acceleration excited by machine operation. The 3-axis acceleration response values could be collected by sensor built in on-board smartphone for construction machine. In addition, the paper explains methods applied to the machine hour data and rate, to determine shape parameters of Beta distribution, to execute bagging based on samples from the Beta distribution, and to conduct ensemble forecasting of construction schedule. Finally, this paper discusses lesson learned from the empirical study and discussion of predictability of the ensemble forecasting of construction schedule.

Keywords –

Real operational hour and rate; LOESS; Hampel filter; Beta distribution; Ensemble forecasting

1 Introduction

As is well known, resident engineers on site plan heuristically deterministic construction schedule by PERT/CPM program. However, since it is boring and time-consuming to gather and edit field data into the PERT/CPM program, there are very few opportunities to revise construction schedule on day-to-day works.

Largely, scheduling construction schedule for mechanized earthworks are grouped into the following three types:

Type 1: Push works such as dozer operation, which means "make-to-stock process" in which the earthworks are not constructed based on actual demand,

Type 2: Pull works, which means "make-to-order process" in which the earthworks are cyclic distributions based on actual demand, for examples, LHD (Loading, Haulage, Dumping), concrete placement, etc., and

Type 3: Labour-intensive works such as reinforcement bar processing assembly, formwork assembly and disassembly, constructing slope frame, etc.

Due to limitation of space, our inquiring minds in this paper focuses on the Type 1 “dozer operation,” and proposals of easy-to-use and -learning methods to analyse and revise construction schedule and to do ensemble forecasting of the construction schedule. As for study on the type 2 and type 3, we intend to report at the ISARC 2021.

Here, we focus on automation as follows:

- Gathering and calculating data as to daily machine operational hours and rates,
- Repetitively calculating and learning on real operational rate sequence and pitch times for each of work-in days,
- Doing ensemble forecasting of construction schedule, and
- Generating infographics such as time series graph of real operational hour and rate sequence, and diagram of comparison between as-planned and as-built productions in order to grasp the current situations and evaluate the productivity.

This paper unfolds as follows:

First, this paper outlines this study on ensemble forecasting of construction schedule of mechanized earthworks. Secondly, this paper describes analysis methods being applied in this study, for example, LOESS (locally weighted scatter plot smooth) to capture time-series features, and Hampel filter to finding abnormal observations latent in daily real operational hour and rate sequence. In addition, the following methods are described:

- To determine shape parameters (alpha, beta) of Beta distribution, and

- To conduct bagging by samples from the Beta distribution, and do ensemble forecasting of construction schedule.

Thirdly, this paper provides empirical study on the above methods. Finally, this paper discusses lesson learned from the empirical study and discusses about possibility to detect features and abnormality latent in time-series of real operational hour and rate, and predictability of the ensemble forecasting of construction schedule.

2 Outline of this study

2.1 Overview of this Study

Image of dozer operation supposed in this study is shown in Figure 2.1.1.

Figure 2.1.1. Image of dozer operation supposed in this study

In the dozer operation in Figure 2.1.1, readings of 3-axix acceleration, 3-axix angular velocity, and GPS position (latitude, longitude) are automatically gathered from on-board smartphone for dozer. And then, daily machine hour and rate could be automatically calculated from triaxial composite value of the 3-axix acceleration, Besides, as shown in top right of Figure 2.2.1, dozing trajectory and area could be visualized based on GPS data.

Generally speaking, M/M/c queueing theory might be applied to cyclic LHD operation. For simplicity and efficiency of discussion in this study, it is supposed that daily dumping volume is heuristically determined by the initial plan. Needless to say, dividing the day-to-day dumping volume by the dozing area on that day could give us the value of the thickness of embankment on that day.

2.2 Analysis Methods being Applied

This study supposes the workflow as shown in Figure 2.2.1 to analyse daily operational hour and rate and do bagging based on the Beta distribution, which is one of ensemble methods in machine learning, and to do ensemble forecasting of construction schedule.

Finishing ensemble forecasting of each of work types leads to PERT/CPM program. However, our inquiring minds focus on one dozer operation for embankment in this paper.

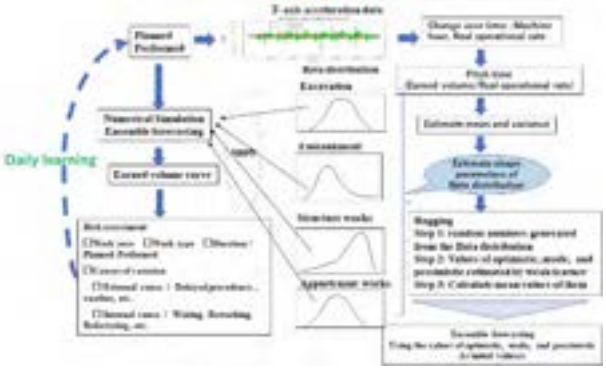

Figure 2.2.1 Workflow to analyse the dozer operation

Data collection and analysis methods applied in this study are described below.

1. Points on Construction(PoC)

The PoC takes sensor-based event detection approach to track a fleet, which is complement of construction machines, dump trucks and workers which are working together on site, and to automatically and real-timely gather a set of readings related to events occurred by the fleet activities as shown in Figure 2.2.2 [1],[2].

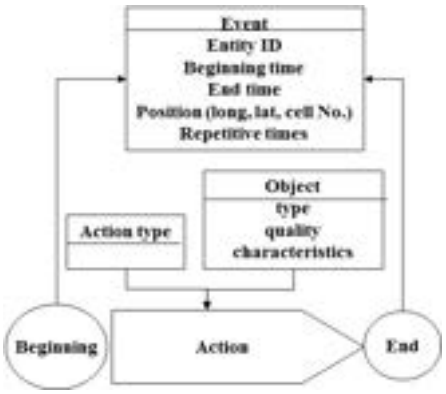

Figure 2.2.2. Image of sensor-based event detection approach

In this approach, construction machine behaviour from beginning to end could be automatically observed by sensors built in smart phone (e.g., 3-axial accelerometer, 3-axial angular velocity meter, GPS receiver, and communication module), and otherwise recognized by a button pressed event, that is, pushing predetermined function key on the smart phone by the operator. Construction machine has on-board smart phone whenever it is being operated. And then, the smart phone automatically sends the data set of readings via the Internet to store them into the database. Readings captured by the PoC consist of time, longitude, latitude,

direction, speed, 3-axis acceleration, 3-axis angular velocity, and son.

2. Calculation of real operational hour and rate

Composition value of 3-axis acceleration is gained by

$$force = \sqrt{ax^2 + ay^2 + az^2} \quad (1)$$

,

where force: composition value, ax: lateral acceleration, ay: longitudinal acceleration, and az: vertical acceleration.

Figure 2.2.3 shows images of variance values of the forces by each of the dozer operations.

Figure 2.2.3 Images of variance values of the forces by each of the dozer operations

It is assumed here that variance values of force generated by idling and driving might be smaller than ones by pushing, spreading and compacting material. Therefore, events with time stamps, which have variance values of forces larger than the predetermined threshold, are extracted and then the operation hour could be calculated. In addition, dividing the daily operation hour sequence by the work hour on that day gives us the corresponding real operation rate sequence.

3. Bagging method

Bagging method is one of the ensemble methods in machine learning. The bagging often considers homogeneous weak learners, and learns them independently from each other in parallel and combines them following some kind of deterministic averaging process [3], [4].

Mean and variance of the averaged real operational hour and rate sequence determine shape parameter (alpha, beta) of Beta distribution**,** and then bagging by samples at random sampling with replacement from the Beta distribution would be executed

4. LOESS (locally weighted scatterplot smoothing model) [5]

The LOESS is a non-parametric approach that uses a weighted, sliding window and coverage to fit multiple regression in local neighbourhood. A weight is Tukey's tri-weight function as follows:

$$W(u) = \begin{cases} (1-|u|^3)^3 & |u| < 1 \\ 0 & |u| > 1 \end{cases}. \quad (2)$$

The weight sequence is defined by

$$w_i(x_0) = W\left(\frac{x_i - x_0}{h(x)}\right), \quad (3)$$

Incidentally, f(x) is approximated by a polynomial, that is, a quadratic approximation shown by

$$f(x) \approx \beta_0 + \beta_1(x - x_0) + \frac{1}{2}\beta_2(x - x_0)^2 \quad (4)$$
$$for\ x \in [x_0 - h(x_0), x_0 + h(x_0)]$$

To estimate $f(x_i)$, find the $\beta = (\beta_0, \beta_1, \beta_2)^T$ that minimizes

$$\hat{\beta} = \arg\min_{\beta \in R^3} \sum_{i=1}^{n} w_i(x_0)\left[Y_i - \left\{\beta_0 + \beta_1(x - x_0) + \frac{1}{2}\beta_2(x - x_0)^2\right\}\right]^2 \quad (5)$$

5. Beta distribution

As is well known, the mean of Beta distribution is given by:

$$\mu = \frac{\alpha}{\alpha + \beta} \quad (6)$$

If α > 1, β > 1, the mode by

$$m = \frac{\alpha - 1}{\alpha + \beta - 2}, \quad (7)$$

where m is the mode, and the variance by

$$\sigma^2 = \frac{\alpha\beta}{(\alpha + \beta)^2(\alpha + \beta + 1)}. \quad (8)$$

In addition, relationships among mean and variance of data sequence, and shape parameters (α, β) of Beta distribution are represented as follows:

$$\alpha = \mu\left(\frac{\mu(1-\mu)}{\sigma^2} - 1\right) \text{ and} \quad (9)$$

$$\beta = (1-\mu)\left(\frac{\mu(1-\mu)}{\sigma^2} - 1\right). \quad (10)$$

6. Ensemble forecasting of dozer operation schedule

Procedure of conducting ensemble forecasting of dozer operation schedule is shown below.

Step 1: When number of days elapsed becomes one third of process days of dozer operation, let put the day the 1st milestone, and the two third one the 2nd milestone. Calculate mean and variance of the real operation rate sequence at each of the milestones, and then specify the corresponding Beta distribution.

Step 2: Repeat n times to generate random number sequences with replacement from the Beta distribution.

Step 3: As for each of the random number sequences, calculate summary statistics that includes mean, standard deviation, variance, min, max, median, mode. and quantile.

Step 4: Average the summary statistics and then let put the 1st quantile be equal to optimistic, the mode be equal to most likely and the 3rd quantile be equal to pessimistic.
Step 5: To do ensemble forecasting, we would utilize the LOESS model, where each of the values such as optimistic, most likely and pessimistic are used as the initial value. And then ensemble forecasting should be executed from the 1st mile stone to the 2nd mile stone, and from the latter to the end of schedule
7. Quantitative performance indexes as to performance evaluation

The Performance index (PI) is depicted by coefficient of concordance, which is a ratio of the precedent rate to the successive one in each of work cells. The PI is given by:

$$PI = \frac{S}{P}, \qquad (11)$$

where S is successive rate; P is precedent rate.
8. Detecting probably abnormal events

Probably abnormal events could be found by median absolute deviation (MAD). The absolute deviations from the median is absolute deviation around the median, which means a robust measure of central tendency, and is not sensitive to the presence of outliers. Besides, given a vector of data, find peaks in ranges of data that exceeds a set threshold. Hampel filter is utilized in this study [6]

3 Empirical Study

3.1 Outline of materials handled in this Empirical Study

Materials handled in this empirical study are dozer operation on river embankment construction, which outlines [7]:
1. The crown width is equal to 7m, the high-water level is equal to 10m, the free board of levee is equal to HWL+2m,
2. The front and back slope gradient is equal to 1:2 and 1:3, respectively, and the embankment length is equal to 877m,
3. The material of dike is sandy soil, and process days is equal to 91 days.
4. The dozer operation in the embankment works as follows:

- The earthmoving volume: 81,600 m3,
- The volume of dozer operation: 80,400 m3,
- The dozer class is 15 ton (D6),
- Number of dozers is equal to 3, and so Dozer volume per one dozer becomes equal to 2,800 m3.

3.2 Work Suppositions

Below are some more details on the work suppositions in this empirical study.

1. Let the embankment area be partitioned into the three work cells and focus on one dozer operation in one of the work cells.
2. Let rainy day, day off, etc. occur based on Poisson arrival

Let work out days be random number sequence generated by rpois (91, 0.28), and then we could gain number of work-in days “74” and umber of work-out days”17”.
Therefore,

- The compacted volume per one dozer for a day is almost equal to 362 m3 (80,400/74/3), and
- The earthmoving volume by one dozer per a day is almost equal to 368 m3 (81,600/74/3).

3. Setting two milestones

Let set the 1st milestone at the point where one third of the process days intersects with 25% of the as-planned production volume and the 2nd milestone at the point where two third point of process days with 75% of the as-planned production volume. Here, we get the baseline curve, which goes along theses milestones, shall be utilized as reference line to compare with as-built production volume.
4. Handling work out days

Values at work-out day in pseudo-random number sequence of real operation rates are replaced by almost equal to zero, that is, sqrt(.Machine$double.eps)= 1.490116e-08;
5. Pseudo-real operation rate sequence

Let pseudo-real operation rate sequence be generated as follows:

- From beginning until the 1st milestone: the mean 0.3 plus rnorm(26,0,3)/100
- From the 1st milestone until the 2nd milestone: the mean 0.46 plus rnorm(27,0,2.5)/100, and
- From the milestone 2 to the end: the mean 0.4 plus rnorm(38,0,2)/100.

Let the pseudo real operational rate be regarded as hand-on real operational rate on site.

3.3 Pseudo-real operation rate sequence

Figure 3.3.1 shows pseudo-real operation rate sequence with the LOESS smoothing line and red cross marks detected by the Hampel filter as mentioned above.

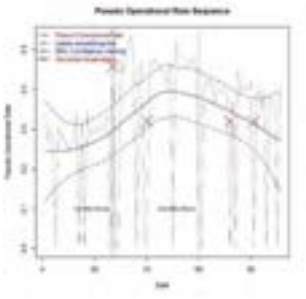

Figure 3.3.1 Pseudo-real operation rate sequence with LOESS smoothing line and red cross marks

Although the LOESS smoothing line shows time series feature very well, values at work-out day incline to push it down as a whole. Here, the sliding window width is 7.5. The smaller its value becomes, the more the predicted curve finely engraved along the original line graph. The red cross marks in Figure 3.3.1 means abnormal observations deviated from the median, which could be found by Hampel filter, where values on work-out days are replaced by the mean value of data sequence in order to avoid detection of ones on work-out days.

Figure 3.3.2 shows performance indexes as to the pseudo-real operation rate sequence. Similarly, the red cross marks in Figure 3.3.2 means abnormal observations deviated from the median.

As for the abnormal observations in both of Figure 3.3.1 and Figure 3.3.2, run length is not seen. Considering work suppositions here, probably, the causes of abnormal observations might be holiday, rain, machine failure, or something like that at the day before.

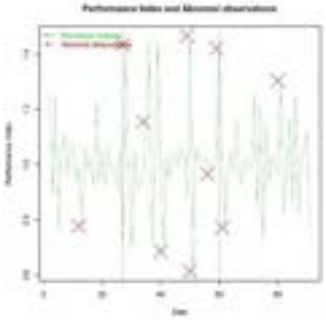

Figure 3.3.2. Performance indexes with probably abnormal observations

In daily construction control, the pseudo-real operation rate sequence with the LOESS smoothing line and observed abnormal ones might be drawn by each of work cells, leads to field inspection to explore the potential causes.

3.4 Productivity assessment

From our long experience in construction field, productivity by dozer operation is gained by the following equation.

$$Q=60*q*f*E/Cm \quad \#(m3/hr) \text{ and} \qquad (12)$$

$$Cm=0.027*L+0.55, \qquad (13)$$

where Q： hourly production quantity(m3/hr), q： bank quantity per one cycle of dozing, f： soil conversion factor, E： work efficiency, and Cm：one cycle time.

Table 3.4.1 shows hourly production quantity by dozing (m3/hr).

Here, let put q=44 m3, f=0.9, E=0.8, L=50m, Cm=1.9 min, work hour per day=8 hr, and then t
Cm =1.9 and Q=1000.421 m3/hr are gained.

Applying the LOESS model as mentioned above to the data in Table 3.4.1 gives us productivity curves in Figure 3.4.1. Comparing actual productivity with the productivity curves in Figure 3.4.1 enables us to evaluate productivities for each the work sells.

Table 3.4.1 Hourly production quantity by dozing

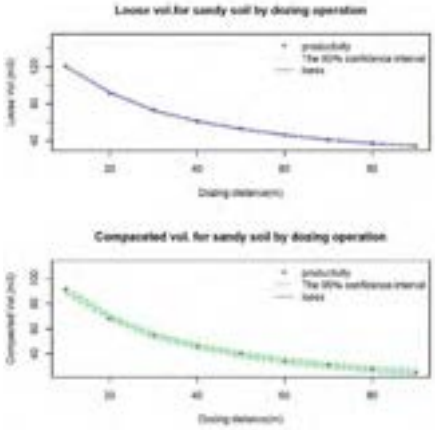

Figure 3.4.1 Productivity curves by the LOESS model

Multiplying the pseudo-real operation rate sequence in Figure 3.3.1 by the Q value gives the accumulative production sequence in Figure 3.4.2, which could be utilized as a reference line to compare with ensemble forecasting lines. Also, the accumulative production curve in Figure 3.4.2 shows speed of construction.

There are two important evaluation points of productivity, which are the 1st milestone and the 2nd milestone. It is very important to seriously grasp the actual states in each of work cells at the 1st milestone and to project work process toward to the 2nd one. In our bitter experience, problems latent in work progress incline to break out at the 2nd evaluation point, and then it might often compel us to rush-works.

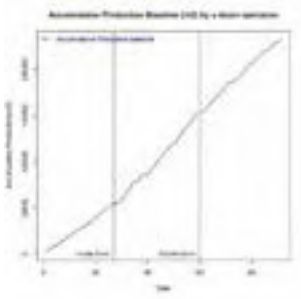

Figure 3.4.2 Accumulative production curve

3.5 Ensemble forecasting

Although doing the pessimistic, optimistic and most likely ensemble forecasting, respectively, this section reports the infographics on just the most likely one. That's why space did not permit us to insert the infographics on the pessimistic and optimistic ones.

3.5.1 Ensemble forecasting at 1st milestone

1. Shape parameters (alpha, beta) of Beta distribution

The equations (9) and (10) determine shape parameters (alpha, beta) of Beta distribution. From the descriptive statistics at the 1st milestone in Table 3.3.1, the mean "0.257" and the variance "0.014" give us B(13.382, 38.68).

2. Bagging method

At the 1st milestone, let repeat five times to extract 10,000 samples from B(13.382, 38.68) by random sampling with replacement, it leads to values at each of the five times the weak learner as shown in Table 3.5.1.1.

As described before, in the bagging method values at the weak learners are averaged. Table 3.5.1.2 shows the average of Table 3.5.1.1. Here, Let put

- 1st Qu=pessimistic,
- mode=most likely, and
- 3rd Qu=optimistic.

Table 3.5.1.1 Values at each of the five times the weak learner at the 1st milestone

	1st-	2nd-	3rd-	froth-	fifth-
Min.	0.00088	0.003006	0.00088	0.00088	0.001775
1st Qu.	0.161531	0.16108	0.163922	0.16458	0.160241
Median	0.262068	0.26198	0.262268	0.264431	0.264399
Mean	0.254653	0.254057	0.255458	0.256171	0.255417
3rd Qu.	0.353164	0.351715	0.352772	0.355252	0.354979
Max.	0.45866	0.458455	0.458458	0.458458	0.458458
Variance	0.013989	0.013904	0.0137	0.013822	0.01403
Mode	0.070389	0.416551	0.136546	0.334552	0.138386

Table 3.5.1.2 Average of Table 3.5.1.1

Min.	0.001059
1st Qu.	0.163119
Median	0.262625
Mean	0.255609
3rd Qu.	0.353726
Max.	0.458514
variance	0.013796
mode	0.207936

The most likely ensemble forecasting from the 1st milestone to the 2nd milestone are shown below.

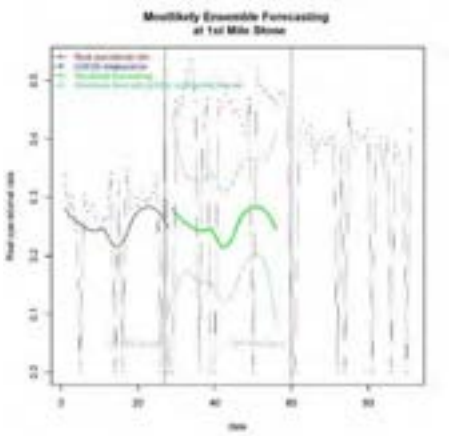

Figure 3.5.1.1 Most likely ensemble forecasting from the 1st milestone to the 2nd milestone

3.5.2 Ensemble forecasting at 2nd milestone

In the same way as mentioned above, let repeat five times to extract 10,000 samples from B(13.382, 38.68) by random sampling with replacement, it leads to values at each of the five times the weak learner at the 2nd milestone, and then average them. Similarly, the descriptive statistics at the 2nd milestone gives the mean "0.319" and the variance "0.03", and so the Beta distribution ~ B (6.9223, 14.7777)

The most likely ensemble forecasting from the 2nd milestone toward the completion are shown in Figure 3.5.2.1. The ensemble forecasting value is a bit larger than the determined production at the completion.

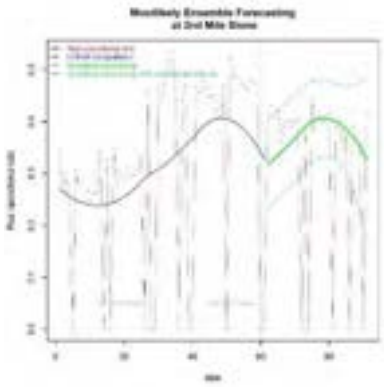

Figure 3.5.2.1 Most likely ensemble forecasting from the 2nd milestone to the completion

3.5.3 Comparison between Accumulative Production Baseline and Most Likely Ensemble Forecasting Line of Production

Figure 3.5.3.1 shows comparison between the accumulative production baseline in Figure 3.4.2 and the most likely ensemble forecasting line of production to the completion.

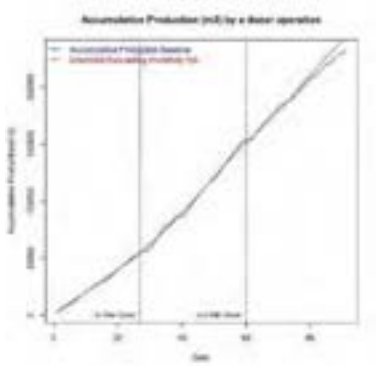

Figure 3.5.3.1 Accumulative production baseline and most likely ensemble forecasting line of production to the completion

4 Lesson Learned from Empirical Study

In this chapter, lesson learned from the empirical study is described and discussed.

As is well known, smoothing line method, for examples, simple exponential smoothing (SES), LOESS, and beta regression model, could show time-series features very well. The SES and the LOESS are non-parametric methods and could be easily handled without specific distribution. The LOESS could be easily used for extrapolate prediction. Whereas, the SES is not easily handled for extrapolate prediction. Beta regression model literally assumes Beta distribution. In many situations, scheduling problems assumes Beta distribution, and so the Beta regression model looks like to be more consistent than others. Concretely, GLM (generalize linear model) with logit function are used to the calculation of the Beta regression model. Incidentally it is prediction based on the logit transformed scale [7],[8]. However, relationship between logit distribution and Beta distribution is unclear.

Originally, interpolated prediction could be easier handled than extrapolated one. Therefore, with ensemble learning with the LOESS model, in other words, simulation-based ensemble forecasting in long term, is utilized in this study.

Although data analysis is generally expensive and time-consuming, the automatic analysis methods proposed in this study is easy-to-use and -learning and cost-effective for daily repetitive learning and automatically execute to find probable causes of unacceptable performance.

On-site usage of the ensemble forecasting method proposed in this paper forks two folds. The first is daily ensemble forecasting in short term, for example, ten-days productivity. The second is periodic ensemble forecasting in long term, for example, forecasting from the 1st milestone to the 2nd milestone, and from the 2nd milestone to the end. The second one is illustrated in the chapter three.

Figure 4.1 shows image of the ensemble forecasting for ten-days productivity. Work hack here is shown as below. As mention before, the hourly productivity "Q" by dozer operation is gained by the equation (12) and (13). During the first ten days from the dozer operation start, multiplying daily real operation rate in-suite gained from the PoC by the value "Q" could give the daily productivity by dozer operation, and then do ensemble forecasting for the first ten-days productivity.

Figure 4.1 Ensemble forecasting for ten-days productivity

In the meantime, both of average of pushing distance for spreading fill material and dumping volume of fill material by the number of arrivals of dump trucks could be calculated by GPS data, and also the real operation rate in-suite could be gained from the PoC each day. And then the "Q" values could be gained on that day. Similarly, ensemble forecasting in the coming ten-days productivity could be executed. Moreover, these data could give us the dozer operation area, the thickness of spreading earth on the ground, and the progress rate to the target volume each day.

The above procedure enables us to repetitively do ensemble learning regarding scheduling of dozer operation, as considering environmental and ground condition.

It can be seen from the empirical study that show predictability of the ensemble forecasting of construction schedule. When watching transition of real operational rate sequence and finding abnormal observations as shown in Figure 3.3.2, the following matter shall be examined:

1. Appearance of new phenomena
2. Disappearance of existing phenomena
3. Sift change in mean and variance
4. Trend of increase or decrease

Looking around performance chart summary in each work cells and works backward from the 2nd to 1st milestones enables us to understand should-can-will-did works and to improve the working practices required

from now on. On the other hand, looking ahead the ensemble forecasting at the 2nd milestones could inform us what the prospects are until the completion.

In practice, watching hand-on real operational rate sequences in each of work cells could give us information on which activities are most fragile and opportunities to examine resource allocation and reduction of lead time in each of work cells. Here, Infographics with early precautions (refer to ANSI 2535.5) such as charts, tables, and ensemble forecasting of construction schedule could provide a snapshot of work in progress over daily, weekly, bi-weekly or monthly.

These infographics would be automatically displayed on the dashboard of the remote real-time monitoring system [10]. These infographics would play a role in:

1. Thinking and decision-making support to:
- Provide workers with opportunities to recognize potential hazards, develop proactive countermeasures and start monitoring; and
- Pick a set of building block of information at the right level of abstraction and at the right time, and
- Stimulate or guide worker's creative thinking, i.e., indication or hint; and
2. Communication support to:
- Save or share information and mail back and forth to each other; and
- Help workers structure conversation and keep track of tasks.

The further development and research on this study are listed below:

1. Conducting hand-on verification and validation of the methods proposed in this study, and then we intend to report the results of this filed test at the ISARC 2021,
2. Applying M/M/c queueing theory to cyclic works such as LHD, concrete placement works, etc., and
3. Developing algorithm ensemble forecasting for each of work types including LHD and labour-intensive works, and integrated with PERT/CPM programs.
4. Cyber-agent, that is, computerized agent who work for ensemble forecasting of construction schedule. The cyber-agent here is a virtual engineer or line-manager who inhabit within a cyberspace composed of computer systems. The cyber-agent will passively or actively walk through the cyberspace to help workers explore and capture critical factors latent in a large amount of information that may go into making decisions [11].

In closing, we would like to say that any help and suggestions on this study would be heartedly appreciated.

Abstract –

Traditional project delivery methods are inflexible for projects that require a high level of collaboration among project teams as well as present challenges to innovative design and construction approaches. In today's era, projects are executed at a faster pace at the early stages of scope definition. This causes a high cycle of requests for information (RFI), change orders, and disputes. To address this issue, a framework for implementing IPD to a medium-size energy project from the engineering phase to the commissioning phase was developed. The framework consists of 1) project stakeholders classification; 2) disciplines identification; 3) relationships, responsibilities; and objectives matrix, and 4) monitoring, control, and feedback. The framework was implemented using Building Information Modelling (BIM) platform and project Document Management System. Synchronizing everyone's objectives in the framework and ensuring these objectives are achieved is a strategy for the success of the project's delivery. The framework was implemented using actual project and was able to enhance design and construction coordination and reduce project cost by 20% and cut project duration by 25%. However, stakeholder coordination and availability of technologies pose a challenge for the successful implementation of the framework.

Keywords –

Integrated Project Delivery; Building Information Modeling; Construction Information System; Construction

1 Introduction

Increased collaboration in the architecture, engineering, and construction (AEC) industry is integral in responding to construction deficiencies within complex projects. These deficiencies are common among nearly all projects and, within traditional delivery methods, responses to them include late, disconnected decision making that results in more rework, schedule overrun, and a high number of requests for information (RFI). The American Institute of Architects defines integrated project delivery as "a project delivery method by a contractual agreement between a minimum of the owner, design professional, and builder, where risk and reward are shared and project team's success is dependent on project success" [1]. Since its introduction to the industry about 15 years ago, professionals have had a high level of optimism for Integrated Project Delivery (IPD) becoming a reliable and accepted delivery method [2].

Construction projects are complex, dynamic in nature and subjected to cost, time, and scope deviations. When these deviations inevitably occur, workers investigate and often submit an RFI to the architect. IPD has provided an approach to communication problems that results in ongoing collaboration and quick responses to deviations. In general, the latest uses of IPD on projects have mainly produced fewer change orders, decreased project timeline, fewer costs, and incidentally fewer requests for information [2]. However, the limitations of IPD still exist. The current research on IPD has dealt with its performance, potential collaboration techniques, pairing with BIM, contractual implications, and adoption into the industry. There is a knowledge gap on the structure of implementation, the mechanism of interactions among the project players (design and construction), and required supporting technology. We claim these are three elements responsible for the failure associated with IPD implementation.

Building Information Modeling (BIM) is a powerful technological tool that provides a rich 3D model with digital information of the project to stakeholders. Furthermore, and more importantly, BIM acts as a "shared knowledge resource for information about a facility (physical and functional) forming a reliable basis for decisions during its lifecycle from inception onward" [3]. BIM has closed many gaps on the issue of interoperability and is most efficiently used in conjunction with a document management system and a common information exchange software, such as

Industry Foundation Classes (IFC) or BIM Cloud, that tackles the difficulty of diversity between software [4]. Future research efforts need to focus on a sophisticated and diverse implementation of BIM and the associated technologies to support the smooth adoption and implantation of the IPD [5], additionally the socio technical implications in the flow of production within a given project [6].

IPD is an emerging method of delivering complex projects and projects that require a higher overlap between design and construction. This method is an efficient tool to apply when integrated collaboration, cost, and schedule are major constraints for the successful delivery of the projects. However, implementing this method successfully in the AEC industry continues to be a challenge, especially for medium size projects or inexperienced project stakeholders with IPD. Other challenges are also observed in selecting the right technology for implementation (BIM, cloud based-data management system for design and as-build data, and the implementation infrastructure).

This paper proposes a framework to assist owners to implement IPD to medium-sized projects and allow them to measure project performance based on several metrics. These metrics include customer satisfaction, safety, quality, cost, and schedule. The framework is made possible by IPD and BIM implementation and describes the relationships and responsibilities of stakeholders within each phase of the project lifecycle.

2 Literature Review

2.1 Why IPD Should Be Implemented

The AEC industry has struggled for a long time with low productivity, cost overrun, schedule delay, and a high number of change orders and rework. One of the main reasons for these issues is impeded in the rigid mechanism of delivering projects. In comparing IPD with other delivery methods, IPD produces fewer change orders, cost savings, and a shorter schedule [2]. Additionally, traditional project delivery methods contain ten RFI per one million dollars and a 2-week processing time, compared to an IPD project, which contains two RFI per one million dollars and 1-week processing time [7]. IPD represents a hope to overcome many of the problems that the AEC industry faced for decades without a rigorous solution. Many studies have shown that the AEC industry is the only industry that did not show signs of productivity improvement for a long time and still this issue continues to be the main cause for high waste in the construction industry. IPD has proven its ability to increase efficiency and save resources in construction projects. However, successful implementation of the method represents the main hurdle in current practices.

2.2 Basic Strategies for Implementing IPD

There are 2 basic strategies for implementing IPD in the AEC industry: heavy collaboration among project stakeholders and adopting an advanced design and data management system.

To achieve collaboration, it is helpful to use a platform that allows for shared knowledge between major parties. The “big room” in design refers to the physical shared space for early design development that includes all necessary parties. For medium-sized projects, the big room can be tricky to maintain because many of the employees might have several projects at once and may not be in the same geographic area [8]. This obstacle was carefully weighed in our implementation of a virtual big room with many participants, similar in principle to past research [8][9].

Along with collaboration, the right technology must be used. BIM provides an integrated platform for live feedback and collaboration. BIM gives foresight to the different proposed possibilities of the project beforehand and visualizes necessary changes during for clarity of the project managers [10]. In the Autodesk HQ construction case study, a BIM execution plan was established and moved forward with at-risk subcontractors having been BIM-enabled [11]. This allowed for constant feedback during the design phase from the builders who knew construction processes well.

IPD allowed for scope changes totaling 30% in this project [11]. Furthermore, when a hefty design change was requested from the owner, the design firm acted quickly to provide a virtual walkthrough using BIM of the proposed change within a week of the request, allowing the owner to make an informed decision on the change [11]. The integration capabilities of BIM make it appealing to any construction project because of its time and cost estimation capabilities [12]. BIM is most useful in an IPD project because of its allowance for multi-user access and contributions to the model [4]. The following is an excellent descriptor of how BIM can aid in IPD:

“The project team can deal and interact with a unified model when a composite model is built from an amalgam of various disciplines’ models. Having this capability, and through the different phases of a construction project, BIM can coordinate the design, analysis, and construction activities on a project and, therefore, results in integrity of projects.” [13]

2.3 Gaps in prior research

It is crucial that we identify the basic components of IPD which include a multi-stakeholder contract, rigorous collaboration and coordination, and technology usage.

However, we also identified a knowledge gap with a few implementation factors. We are defining this necessary knowledge gap as:

The methods of collaboration between stakeholders and their subsequent responsibilities during each phase of construction in IPD.

This gap demands a system to define the methods of collaboration, which includes classifying the stakeholders, defining the relationships, responsibilities, and objectives between stakeholders, and monitoring the construction through constant feedback. If chosen to perform, stakeholder analysis and classification are usually done by the project manager [14], but in our IPD framework, the responsibilities will be distributed among the major stakeholders based on the accepted framework. This is supported by the conclusion that an iterative process that includes cooperation between major stakeholders on their classification is more effective than considering it a desk task by one individual [14]. A simple classification of stakeholders includes key members, key supporting participants, tertiary stakeholders, and extended stakeholders [15]. An IPD framework has been defined in the past with macro and micro aspects, but we are more interested in one of the micro aspects: information design [16]. In IPD, information must be the common basis of understanding for all stakeholders, and information must be accessible, available, and reliable [16]. Due to the lack of research linking information design to collaboration, we are interested in the relationships shared between stakeholders as they utilize our information framework.

3 Integrated Project Framework

IPD is set apart from other delivery methods in the unique early stages of project planning and communication, wherein every player in the project, regardless of their role, must be incorporated into planning and development before the design is finalized to optimize the usage of IPD. This enhanced collaboration is hard to achieve and requires shared project planning goals and a rigid strategy for communication. For us, this meant putting a system in place so that the implementation of the technology is smooth. The following system is a step by step procedure through the entirety of the project that can be agreed upon by the major stakeholders. The system has been divided into 5 stages: qualification, bidding, pre-construction,

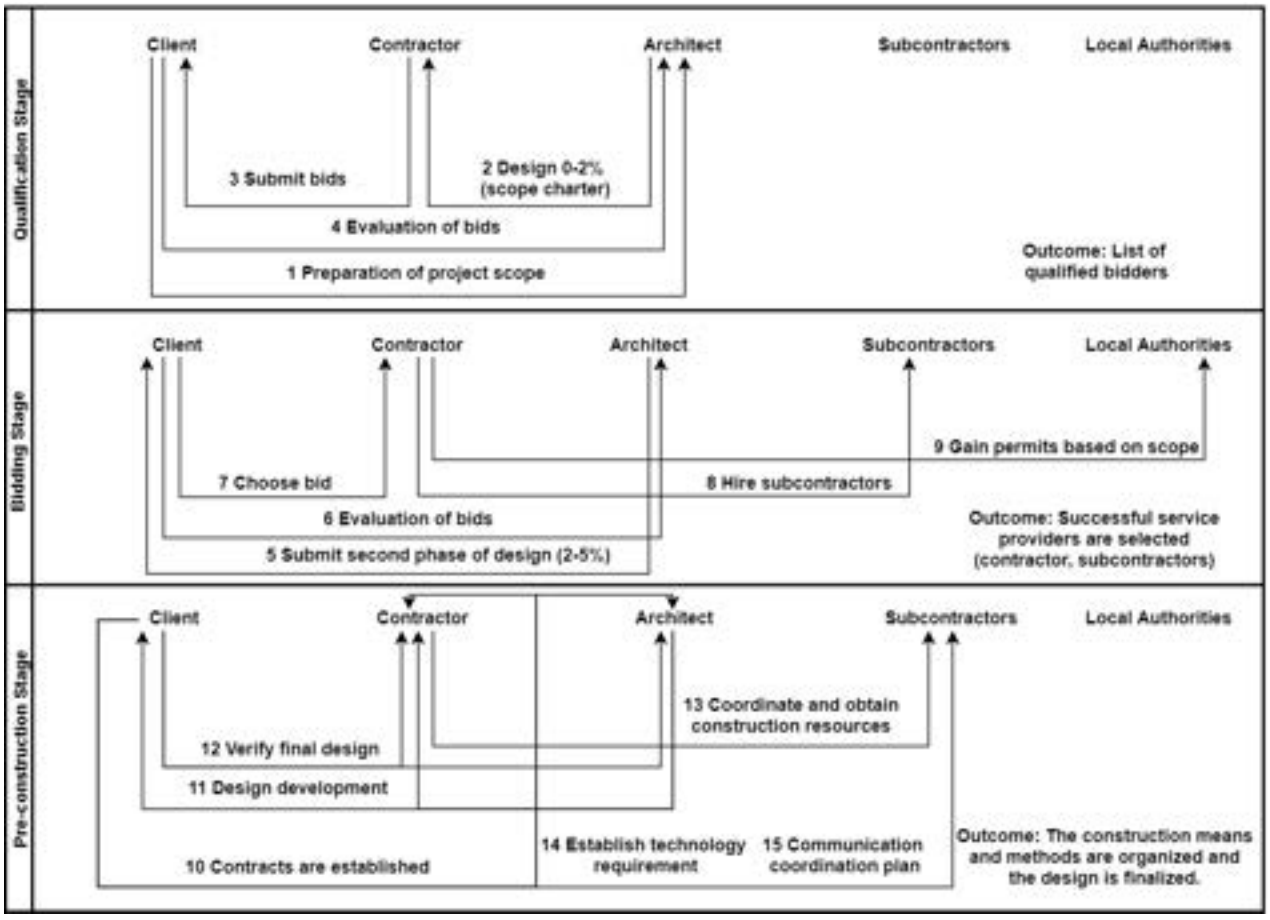

Figure 1. First 3 Stages of the IPD Implementation Framework

construction, and closeout as illustrated in Figure 1 and Figure 2. Each step is organized chronologically, and the final step of each stage is followed closely by the first step of the next stage. The most important phase in our research, the construction stage, contains many moving parts and will be organized in a different way than the other stages.

3.1 Qualification Stage

The first stage is named the qualification stage because the main outcome of this stage is the client having a list of qualified bidders, as shown in Figure 1. This stage is an early stage in the project and should involve the client and the architect only. This is because there is a need to create the project framework and the scope charter. The project's goals and expectations come from the client and are communicated to the architect for better refinement. This stage begins with the client preparing the project scope and delivering it to the architect, who reviews the scope and develops a high-level schematic design. The high abstract of the project's scope lays out the project's goals and necessary design and construction work, and a clearly defined scope main framework necessary in avoiding design delays and cost overruns [17]. Then, the architect will begin the design based on the initial scope of work and the schematic designs. Up to 2% of the Front End Engineering Design (FEED) put together by the architect along with Request for Qualification (RFQ) is shared with the client so the client in collaboration with the architect solicits interested prime contractors in executing the project within the IPD environment. The interested contractors will then submit the qualification to the client for evaluation. In IPD, this step includes the architect evaluating the bids with the client because of the architect's knowledge of the design. The qualification stage results in the client having a list of qualified service providers, which allows the team to move into the bidding stage.

3.2 Bidding Stage

In the bidding stage, there are a variety of steps required which involves every party, as shown in Figure 1. The outcome of this stage is that the service providers are selected, which includes the contractor and subcontractors. This stage begins with the architect submitting the second phase of design (2-5%) to the client, followed by the bidding for the project by the selected list in the first stage, then the successful bidder will be selected. All submitted bids must include the major subcontractors and their qualifications for the successful implementation of the IPD. This step is very essential to ensure every stakeholder is going to function in an integrative type of design and construction environment. Contractual obligations and terms are stated in this stage among all parties. Clear expectations of schedule, tasks, deliverables, coordination, cost, frequency of data update, and meetings are stated at this stage. From the authors' experience, the mechanism of implementation can be overwhelming to many subcontractors due to the unfamiliarity with the IPD. Equality important, the implementation technology platform for all parties involved should be created at this stage through the Technology Execution Plan (TEP). Subcontractors should be involved in creating the TEP and should have access and be familiar with the implementation infrastructure.

3.3 IPD Technology Requirement

Technology infrastructure is the most important aspect of IPD implementation. There is no doubt that IPD became a choice for many owners due to the development of design approaches such as BIM and project data management. Incorporating BIM approach into the IPD process allows project team to utilize the information in an integrative environment. For example, information from design, procurement, construction, quality, and other areas is being received and processed in a way it allows everyone to be informed. This high level of information management is essential for the fast pace of the IPD. To achieve this, however, a technology infrastructure must be accessible to those who are involved. BIM is the main platform to use for design, construction, and commission for the proposed method. The issue that can create problems in using BIM in IPD environment is the interoperability of the project 3D files.

The next part of the technology infrastructure for the IPD is having a system that handles the information receiving, using, and transferring. Many cloud-based tools available such as Procure and Aconex that can be utilized for managing the project information. The strength of the cloud-based tool in the multi-organizations project collaboration, where data can be stored and accessed efficiently. Tasks that include document and correspondence management, workflow automation, request for information, change orders, BIM file management, and more can be reviewed and addressed.

3.4 Pre-Construction Stage

The pre-construction stage contains many vital responsibilities that must be performed effectively for construction to even be possible, as shown in Figure 1. In this stage, the implementation of the technology infrastructure is tested. Flaws in the IPD technology system should be captured in this stage to modify the TEP. Flaws represented through subcontractors include not having the proper technology or the lack of required

subcontractors' crew training. For instance, a mechanical subcontractor might be using an IFC complying tool to model the mechanical design part, but files generated from this tool are not properly interoperable with another parametric model generated by the electrical subcontractor. The outcome of this stage is to define the major construction means and methods. After ensuring all project parties are familiar with the project scope and technology, contracts between the contractor and the major stakeholders are established. This includes defining many details, such as the level to which risk and reward are shared, the possible incentives for quality construction, and more. The level of integration of the project, or level to which IPD is implemented, must be defined in the contract and must be agreed upon by all major stakeholders. Following this, an intensive collaboration between the client, architect, and contractor ensues with the goal of developing the design further. IPD is unique in that it brings these 3 major stakeholders into the "big room" before construction is initiated so that any inconsistencies between the design and construction can be worked out. Developing the design among these stakeholders carries through the construction stage but is initiated in the pre-construction stage. The client will verify or request changes to the in-progress design with the architect and the contractor. After verification, the contractor will organize the obtaining of construction resources alongside the subcontractors. Finally, the client will clarify to the architect, contractor, and subcontractors the plan of communication between the stakeholders, which includes the updating of BIM, a communication software, and regular "big room" meetings, and the client will distribute access to the agreed upon technology which will be utilized throughout the project.

3.5 Construction Stage

The construction stage must be closely monitored throughout because there are many actions and cycles working all at once. The outcome of this stage is that the design and construction of the project are finished. The technology platform holds IPD together, as displayed in Figure 2. BIM is the technology that collects and analyses data from every important member during construction. This stage works in a cyclic process and casual feedbacks fashion. For example, if a major stakeholder (architect, contractor, client, or subcontractor) encounters a design or construction issue, they report the issue using the proper technology tools so all other stakeholders can receive the information about the issue. The responsible stakeholder will then update the project data management system (BIM tool) with the necessary answer and information to move forward, whether that be a slight change in design or major change order. Since the subcontractor has continual access to BIM, this process takes the least amount of time in an IPD setting. Processes like these can start on the construction site or from the desk of the client and flow through BIM quickly and efficiently. Useful information that can be accessed in BIM in the construction stage includes equipment, construction processes, materials, quality, subcontractors' contributions, RFIs, change orders, safety guidelines, and environmental compliances. This information is inputted into BIM and used by stakeholders to perform project status tracking, information management, and activity scheduling. These three functions of BIM are optimized by stakeholders through heavy collaboration and on-site monitoring. Project status tracking demands accurate reporting and documentation on design changes which limits contractual issues and cost overruns. Information management of BIM data helps to limit the number of inconsistencies between design and construction. Activity scheduling requires ongoing communication on-site so that stakeholders can plan accordingly to minimize the project's timeline. Through the construction stage, the design is constantly being changed and approved in BIM. The construction project is finished in this stage.

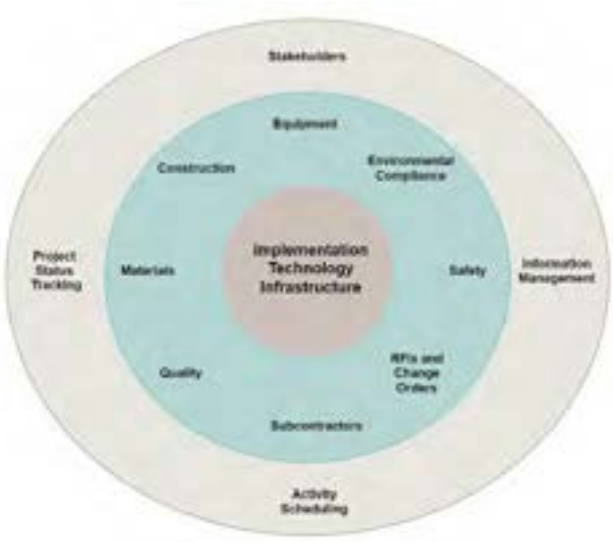

Figure 2. Construction Stage

3.6 Closeout Stage

The closeout stage is an often-overlooked part of the project but must be carried out to ensure success. The client will start by making sure that the design changes inputted into BIM were fulfilled in construction. Then, the client and contractor will evaluate the success of the project based on 5 metrics in Figure 4: customer satisfaction, safety, quality, cost, and schedule. Finally,

the client will fulfill the obligations laid out by the contract to the contractor, architect, and subcontractors. Risk and reward sharing are important parts of the contract and are based on the accurate success evaluation of the project. The outcome of this stage is that the final project is evaluated based on 5 metrics and the contractual obligations are fulfilled.

4 Project Success Metrics

There are a variety of factors to consider when determining the success of a project delivery. Some of the main performance metrics considered are execution schedule, project cost, client satisfaction, changes, quality, and safety. Similarly, the success of the project delivery can be measured by interactive processes, contractual arrangements, and project characteristics and participants [18]. Table 1 contains the project success criteria that the authors used to measure the satisfaction of the project stakeholder of using IPD.

4.1 Customer Satisfaction

We measure customer satisfaction by the number of legal claims made by the client and the potential for future business with the other stakeholders. The claims refer to if a mistake in construction is large enough the client will submit a legal claim against the contractor, which adds more time to the closeout stage. The potential for future business refers to the level of project satisfaction of the client based on the specific work of each stakeholder and if the client would do business with them again. A low number of legal claims and a high level of potential for future business results in good customer satisfaction.

4.2 Safety

We measure safety by the number of incidents in construction that occurred and the lost-time due to injuries. The number of incidents is the number of construction accidents by the workers; a high number of incidents reflect poorly on the project's safety. The lost-time due to injuries refers to the time delays after an incident has occurred. A low number of incidents and a small amount of lost time due to injuries results in good project safety.

4.3 Quality

We measure quality by the number of non-conformance reports, the punch list, the number of RFIs, and construction rework. Non-conformance reports refer to those reports that list the failures of adherence to construction and environmental regulations of the final project. The punch list is the report made by the contractor that contains the deviations between the contractual specifications and the final construction product. RFIs, or requests for information, refer to the requests made by the contractor or subcontractors for more information if there is a gap in knowledge of a part of the design. Construction rework is the amount of rework done on the project because of structural or design failures. A low number of non-conformance reports, a small amount of deviations on the punch list, a low number of RFIs, and a low amount of construction rework results in good project quality.

4.4 Cost

We measure cost by cost overrun, change order cost percent, RFIs per unit price, and markups percent. Cost overrun refers to the extra cost to finalize the project based on the original cost laid out by stakeholders. Cost overrun percent is the difference between the actual project cost and the award price over the award price (1).

$$Cost\ Overrun\ \% = \frac{Actual\ Cost - Baseline\ Budget}{Baseline\ Budget}\ x\ 100 \quad (1)$$

Change orders are the requests to add or delete certain parts of the design when in construction. The change order cost percent is the total cost of all the change orders submitted over the actual total project cost (2).

$$Change\ Order\ Cost\ \% = \frac{\sum Change\ Orders\ \ Cost}{Baseline\ Budgte}\ x\ 100 \quad (2)$$

The percentage of the cost impact of the RFIs is the total cost of the add work due to the RFI answers over the project budges cost (3).

Table 1. Project Success Metrics

Customer Satisfaction	Safety	Quality	Cost	Schedule
Claims	# of Incidents	Non-Conformance Reports	Cost Overrun	Schedule Overrun
Future Business	Lost-Time-Injuries	Punch List	Change Order Cost %	Constructability
		# of RFIs	Markups %	
		Rework		

$$RFIs\ Cost\ \% = \frac{cost\ of\ added\ scope\ due\ to\ RFIs}{Baseline\ Budget} \text{x}100 \quad (3)$$

The markup percent is the profits for each stakeholder based on the final product. A low cost overrun, a low change order cost percent, a low RFIs per unit price, and a high markup percent result in good project cost.

4.5 Schedule

We measure schedule by schedule overrun and constructability. Schedule overrun is how much construction deviated from the project timeline and is most easily measured by schedule delays, which are defined as the difference between the actual duration and the baseline duration over the baseline duration of the project (4). The actual duration is how long the project took and the baseline duration is the construction time reported by the planned timeline.

$$Schedule\ delays\ \% = \frac{Actual\ Duration - Baseline\ Duration}{Baseline\ Duration} \text{ x } 100 \quad (4)$$

To evaluate the added time to execute the scope described in the RFIs, the RFIs Time % is calculated by finding the total extra time needed to execute the RFIs scope over the baseline duration (5).

$$RFIs\ Time\ \% = \frac{Total\ time\ added\ due\ to\ RFIs}{Baseline\ Duration} \text{ x } 100 \quad (5)$$

The constructability is how easily the project was constructed and kept close to the timeline. A low number of schedule delays and a high level of constructability results in a good project schedule.

5 Preliminary Results and Analysis

The presented framework was developed and implemented for a medium-size gas plant of 120-million-cubic-foot-per-day capacity. The project owner's objective was to complete the design, construction, and commissioning of the project in less than 2 years. The project contract was a Guaranteed Maximum Price (GMP) of 263 million dollars. The IPD implemented was described in the previous sections. The project was completed in 20 months with an actual budget of $220 million dollars. The framework reduced the project cost by 20% and cut project duration by 25%. There was zero Lost Time Injury (LTI). The changes in the project scope were minimal and were easily accommodated. The execution design and construction team established design and construction gates (milestones), which meant if a milestone stage in the design was completed, reviewed, and approved, then there was no need to go back for changes. This was because the next stage involved major equipment sizing and manufacturing. The required equipment usually is of long-lead items and needed to be procured early enough to get manufactured by vendors. Similarly, other critical design gates involved major pipes sizing and power load determination. However, the implementation of the proposed framework involved tedious coordination and high caliber management and engineering skills. The team selected to work on this project was very experienced and of different years of experience. Another major challenge was ensuring the functionality and interoperability of infrastructure technology. Furthermore, some of the vendors on the project were from overseas and ensuring their attendance in the coordination meetings was a difficult task to achieve all the time. The next phase of this IPD framework is to track and analyze the project's performance indicators and then refine the framework for a wide-scale implementation.

6 Conclusions

Integrated project delivery is groundbreaking for the construction industry, but still new and challenging to implement. Forming the right project team that is committed to the main aspects of IPD is essential to the project's success. Consistent collaboration and usage of the right technology must be considered when delivering an IPD project.

The framework we have laid out focuses on the relationships between stakeholders and their responsibilities during each stage of an IPD project. By adhering to this system, the client can keep the project delivery organized and maintain the efficiency of the contributions from each team member. Our project success criteria are based on the framework and on the researched effects of IPD projects.

We acknowledge the many moving parts of a construction project and advise any clients who want to use our system to plan accordingly because IPD takes a large amount of work to efficiently implement. There are still gaps of knowledge, mainly in the construction stage, due to the increasing capabilities and benefits of construction monitoring in IPD. Similarly, the technology used in the construction stage demands much organization and coordination between stakeholders. IPD linked with BIM has the potential to change the construction industry through increased planning and further research into the relationships between the two.

Abstract –

Research towards automation of heavy construction machines for efficient and safe construction processes that are robust to various environments and disturbances has been conducted for many years. In this paper, we show two contributions towards this objective. Firstly, we explore the use of reinforcement learning to automate construction machines. Secondly, we evaluate the effectiveness of three methods to reduce learning time of reinforcement learning: designing reward function, pre-training with BC, and changing frame-skip rate. The reinforcement learning approach is expected to gain robustness against disturbances through learning. We run experiments on two different realistic tasks. The first task is to reduce sway of a load suspended from a mobile boom crane, behaving as a single pendulum. The second task is to load an excavator bucket with soil with a hydraulic excavator. We demonstrate the effectiveness of algorithms using the reinforcement learning approach on the commercial simulator, Vortex Studio developed by CM Labs Simulations.

1 Introduction

For many years, automation of heavy construction machines has been studied to improve safety, work productivity, and construction quality. However, it has been pointed out that even recent studies lacks consideration of model uncertainties [1], parameter variations, and disturbances [2].

Reinforcement learning combined with neural networks has been shown to be an effective framework for solving complex problems. In reinforcement learning, an agent interacts with the environment through trial and error and learns the optimal control method based on signals from the reward function. Various problems in robotics are naturally expressed as reinforcement learning problems [3]. Using reinforcement learning, robots can autonomously find optimal movements and gain robust movement by gaining experience in dealing with various disturbances.

Reinforcement learning has had a great success in the game field [4], but is more difficult to apply in robotics [5]. Since reinforcement learning improves the controlling policy in an incremental manner, an initial movement is almost like a random movement, which can be sometime dangerous in the real-world tasks. Furthermore, agents need to learn in a wide variety of environments in order to prevent over-fitting to the specific environment and improve the robustness against the environment changes. However, this type of learning requires a lot of time and cost to prepare such environment in the real world.

A simple way to solve the above problem is to use a simulator [6][7]. One can easily create a wide variety of environments and simulation is completely safe i.e. the virtual construction machine will never be damaged even if it accidentally crashes in the learning phase. We chose to use Vortex Studio as a simulator which is specialized in construction machine models and can perform high-precision physical simulations quickly.

The biggest problem we face when using

reinforcement learning is sample efficiency. Generally, more than millions trial and error iterations are required to achieve human-level performance. Although simulators can generally run tasks much faster than real time, it still needs a couple of weeks to complete learning which hinders the efficiency of experiments.

Various reinforcement learning algorithms have been proposed to improve sampling efficiency such as distributed learning [8][9][10], transforming or adding reward functions such as reward shaping[11] and intrinsically motivated function[12], mixing imitation learning and reinforcement learning [13] and changing frame-skip, the number of frames an action is repeated before a new action is selected [14].

In this paper, we define two tasks for the construction machines and apply reinforcement learning for these tasks. We also introduce and evaluate some of the techniques for improving sample efficiency. In order to implement these techniques, we made some modification to the Vortex Studio simulator, which was originally not intended for reinforcement learning use and convert it to a "Reinforcement learning ready" simulator. In this paper, our contributions are:

- We introduce reinforcement learning for the following two tasks as shown in Figure 1: The first task is to reduce sway of a load suspended from a mobile boom crane, behaving as a single pendulum. The second task is to load an excavator bucket with soil with a hydraulic excavator. We show that reinforcement learning is one of the effective methods that can perform as well as humans in the automation of construction machine.
- We evaluate the effectiveness of the three methods to improve sample efficiency for reinforcement learning: designing reward function, pre-training, and changing frame-skip rate.
- We provide examples of practical methods on how to parallelize learning when applying reinforcement learning algorithms to domain-specific simulators that are not for reinforcement learning.

The paper has been organized as follows. Section 2 describes the fundamental concept of reinforcement learning. Section 3 describes the methods applied to improve sample efficiency. In Section 4, we describe the detail setup of the experiments. In Sections 5, we mention some considerations and ideas for performing high-speed learning with a simulator that is not built for reinforcement learning. In Section 6, we describe the experimental results performed on crane or excavator tasks. Section 7 presents the summary and conclusions of this paper and discusses future work.

2 Preliminary

2.1 Reinforcement learning

In this section, we provide a definition used in reinforcement learning [15] focusing on the case the environment E as a finite-state Markov decision processes (MDP). An agent maximizes cumulative rewards by selecting an optimal action from all actions $A = \{a^1, \dots, a^k\}$ an agent can select, in discretized timesteps in some state $s \in S$ of an environment E,where k is the number of actions the agent has. Rewards are the criteria by which an agent learns good or bad behavior. At every timestep t, an agent takes an action $a_t \in A$ when in state s_t. After that, an environment transitions to next state s_{t+1} by transition function $s_{t+1} = T(s_t, a_t)$ and the agent gets a reward $r_t = R(s_t, s_{t+1})$ where T gives the state transition and R gives the reward. To evaluate how much the action performed in a certain time step has contributed to the total cumulative reward, we consider the estimated reward

$$G_t = r_{t+1} + \gamma r_{t+2} + \cdots + \gamma^{T-t-1} r_{\mathrm{T}} = r_{t+1} + \gamma G_t \quad (1)$$

, where $\gamma \in (0, 1]$ is the discount factor, and T is the time when the episode ends. An agent learns a policy $\pi(s_t)$ that maximize cumulative expected rewards until the end of episode. In reinforcement learning, an optimal policy $\pi^*$is obtained by interacting with the environment until the action-value function

$$Q_\pi(s_t, a_t) = \sum_{s_{t+1}} T(s_t, a_t)\,(R(s_t, s_{t+1}) + \gamma G_{t+1}) \quad (2)$$

converges.

Generally, it is difficult to model real transition functions T. The use of model-free algorithms to approximate action-value function

$$Q_\pi(s_t, a_t) \approx R(s_t, s_{t+1}) + \gamma \max_{a_{t+1}} E[Q_\pi(s_{t+1}, a_{t+1})] \quad (3)$$

is now mainstream [16].

In this paper, we use the PPO algorithm[9], which is well known as the stable model-free algorithm and support distributed learning. Distributed learning is the way to learn effectively by replicating the agent and the environment, having the agents act in each environment and gaining a lot of experience. With distributed learning we can speed up the learning. The algorithms in [9] is composed of Actor-Critic network architecture. Actor-Critic is common methodology for Critic to encourage Actor to update the policy, and there are various implementations such as making the Actor and the Critic in different networks or sharing a part of the network.

2.2 Imitation learning

Imitation learning is another approach to create an agent. It learns an optimal policy from demonstrations of expert human by imitating. A simple approach to imitation learning is behavior cloning (BC) [17], which learns a policy from demonstrations of successful behavior through supervised learning.

Pure imitation learning methods cannot exceed the capabilities of the demonstrations. In addition, a huge number of demonstrations is required when applying it to actual tasks because it is not possible to respond to scenes that are not in the demonstration.

Imitation learning can also be used to boost the learning efficiency of reinforcement learning by using the learned policy of BC as an initial policy of reinforcement learning.

3 Method

In this section, we describe three methods to improve the sample efficiency of reinforcement learning in detail. All of these methods are ways to simplify the state space that the agent explores. Figure 2 shows how the state space is simplified by each method. Even if the state space is continuous, the reachable state space is discretized by time, so we represent the state space by grid world.

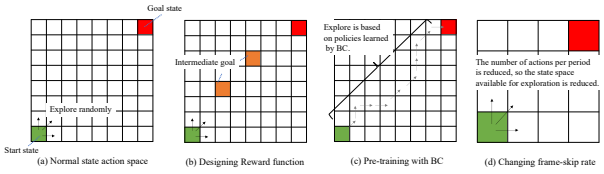

Figure 2. State space is how simplified by each method.

3.1 Designing Reward function

The simplest form of reward is a binary reward, that is, an agent gets a positive reward when an agent achieves the desired state at the end of an episode, otherwise a negative reward. This form of reward leads an agent to get desired policy. The problem with this reward is that the agent is essentially exploring by random actions at first, and therefore cannot learn good behavior at all until the agent is able to earn the reward. This is especially problematic when the state space or action space is large, as it takes longer to explore and the possibility that the agent gets a reward is lower.

To avoid this problem, there is a way to give a reward at each action or state that will lead to the final goal. This type of reward is called as a dense reward. While this can improve learning speed, you need to design dense reward function carefully otherwise the learned behavior may be different from what we actually want.

In this paper, we presented two results for each task: sparse reward and dense reward.

3.2 Pre-training with BC

In general, RL uses random behavior as an initial policy, which is one of the reasons for low sample efficiency of the RL algorithms. As mentioned in 2.2, exploration can be performed efficiently by properly initializing the policy using imitation learning[13].

In this paper, we combine BC [17] with the PPO algorithms[9]. Unlike [13], we use the model trained in BC as the initial value of the model for reinforcement learning.

3.3 Changing frame-skip rate

Another way to speed up learning is to change the frame-skip rate[14]. Frame skipping is the technique to repeat the same action for several frames. Increasing the frame-skip rate has the effect of coarsening the granularity of action. The coarsening of the granularity of the action reduces the state that can be reached within a certain time step. As a result, the combination of state and action spaces is reduced, which simplifies the task.

Increasing the frame-skip rate will also be very important when applying reinforcement learning to real construction machines because it allows the granularity of a single action choice to be changed and the overall action to be smoother. Increasing the frame-skip rate reduce not only productivity but also fuel efficiency and machine fouling and wear. However, simply increasing the frame-skipping rate does not allow for fine-grained action, and thus does not explore the state space that makes the task successful and may prevent agents from achieving their goals. Trade-offs between fineness of action and learning time should be considered, depending on the task and state in order to decide the appropriate number of frame skips. In this paper we tried two patterns about frame-skip rate, no frame skip and 19 frame skips.

4 Experiments

In our experiments we aim at answering the following questions:

1. Does reinforcement learning work to solve realistic construction machine tasks?
2. Which is the most effective method to reduce learning time?

We evaluate our approach on two different realistic construction tasks, anti-sway crane and loading the soil with an excavator. We used the stable baselines framework [18] as the basis for our implementation in

this experiment. The network architecture of our system is depicted in Figure 3. Both policy network and value network have 3 fully connected layers, and each network are independent.

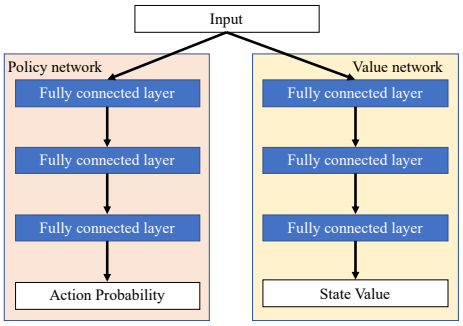

Figure 3. The network architecture of our system.

The Learning is performed on a single machine with an Intel Core i7-8700 and GeForce GTX 1070.

The hyperparameters we used, are same as the default values defined in [18].

4.1 Simulators

CM Labs' Vortex Studio provides a virtual environment for real-time simulation of complex multibody systems. In Vortex, each rigid body is formulated using six degrees of freedom, and these bodies can be connected with several constraint types with varying numbers of linear and/or angular degrees of freedom. The toolkit supports equality as well as inequality constraints, e.g., contacts, which can be holonomic or nonholonomic. Vortex employs the method of Lagrange multipliers together with a direct solver and a semi-implicit integration scheme for stable and fast multi-body simulation. With its optimized core for fast and real-time simulation and its advanced graphical capabilities, Vortex has various applications including operator training, mission planning and design. Furthermore, there are some modules provided in Vortex for particular applications. We used the Cable system module and the Earthwork system module for this study which differentiates Vortex Studio from other real-time simulations [19].

4.1.1 Vortex Cable system simulation

Vortex Studio's Cable Systems provides a realistic simulation of heavy-equipment cables. These extended capabilities ensure real-time behavior by allowing cables to adjust to bends while distributing mass and forces correctly. It can predict cable behavior with minimum number of segments to simulate, which the number of segments changes depending on the curvature of the cable using Adaptive Cable method. This allows Vortex to consider all bending/axial/torsion stiffness and damping to simulate the real cable behavior without falling behind the time step as required by real-time simulation.

4.1.2 Vortex Earthworks system simulation

The Vortex Earthwork Systems module is tailored to the needs of high-fidelity, real-time earth-moving simulations, and employs physically based soil deformation algorithms. Terrain deformations, caused by earth-moving tools such as buckets, and the corresponding terrain reaction forces, are captured in real-time and full two-way force coupling with other simulation entities is modelled. The interactions between machine and soil are fully simulated, allowing soil to be cut, compressed and spilled, all inside an interactive environment by using a hybrid particle-based and mesh-based soil simulation method [20].

4.2 Task 1: Crane

In this task, the goal is to control the relative position shift and speed of the suspended load (the rotation of the load is not taken into account in this experiment) as shown in Figure 4, so this crane is regarded as a single pendulum.

Figure 4. At first, the load suspended by the crane is intentionally shaken a certain amount. After a certain time, the operational agent reduces sway of a load suspended from a mobile boom crane.

4.2.1 Experimental setup

We model the components of the crane task as shown in Figure 5. In this figure, x_{diff} and y_{diff} are distance between boom tip coordinate to load center coordinate, $|v|$ is absolute value of speed of the load, $|a|$ is acceleration of the load. We stack these 4-dimensional data for 3 timesteps and use them as input for reinforcement learning model.

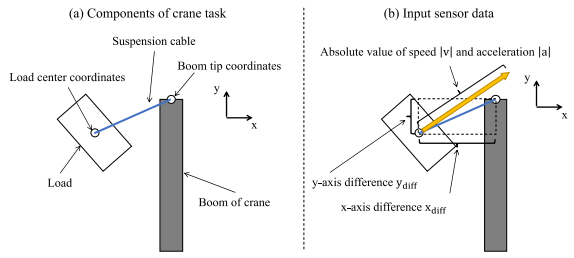

Figure 5. (a) Components of crane task (b) Input

sensor data.

We define the agent actions as elevation and boom as shown in the Figure 6. While PPO [9] can handle both continuous and discrete action spaces, we use the discretized elevation action out of 3 and the discretized boom action out of 5. The reason to use the discretized action is to speed up the learning.

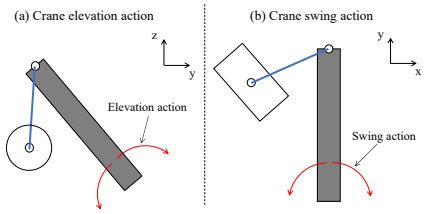

Figure 6. (a) Crane elevation action (b) Crane swing action.

We set one episode to consist of a maximum of 600 steps to use the framework of reinforcement learning. We define the episode success condition as maintaining $|x_{diff}|$ and $|y_{diff}|$ below 1.5 m and speed $|v|$ below 1.5 m/s for 60 steps. We define the episode failure conditions as follows:

- The acceleration of the suspended load exceeds a certain threshold
- The suspended load collides with another object (ground or crane body)
- 600 timesteps elapse without reaching episode success condition

4.2.2 Method detail

Details of each method to be compared in the crane task are presented below.

Base condition: We define the base method as follows:

- $+1.0$ reward when episode reaches success condition, and -1.0 reward when episode reaches failure condition (sparse reward)
- Learning starts from scratch (random actions)
- No frame-skip

Designing reward function: We design the dense reward function as follows:

- For every step, reward is given according to the following function

$$r_t = \frac{1.0}{\max\left(1, \sqrt{x_{diff}^2 + y_{diff}^2}\right)} \quad (3)$$

- $+(960 - current\ step)$ reward when episode success condition
- -1.0 reward when episode failure condition

Pre-training with BC: We do not attempt pre-training with BC because the algorithm in [18] doesn't support BC with multi-discrete actions.

Changing frame-skip rate: We change frame-skip rate to 19.

4.3 Task 2: Excavator

In this task, the goal is to load more soil in a single excavation with a hydraulic excavator as shown in Figure 7.

Figure 7.The agent operates only the bucket part. The agent scoops as much soil as possible in accordance with the movement of the excavator that follows a certain trajectory.

4.3.1 Experimental setup

We model the components of the excavator task as shown in Figure 8. In this figure, y_{diff} and z_{diff} are distance between the excavator body to the bucket, v_y and v_z are value of speed of the bucket, n is an actuator force of the bucket cylinder, θ is a bucket angle, w is the Weight of the soil in the bucket. We stack this 7-dimensional data for 3 timesteps and use them as input for reinforcement learning model.

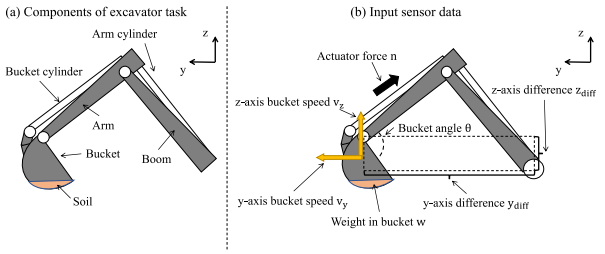

Figure 8. (a) Components of excavator task (b) Input sensor data.

We define the agent bucket action as shown in Figure 9. We discretize the bucket action into 11 values.

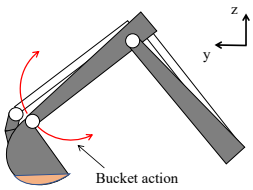

Figure 9. Excavator action.

We set one episode to consist of up to 460 steps to use the framework of reinforcement learning. We define the episode success condition to be $w \geq 1800$ after 460 steps have elapsed. We define the episode failure condition to be the lack of satisfaction of the success condition after 460 steps have elapsed.

4.3.2 Method detail

Details of each method to be compared in the excavator task are presented below.
Base condition: We define base method as follows:

- $+w/1800$ reward when episode reaches success condition, and -1.0 reward when episode reaches failure condition (sparse reward)
- Learning starts from scratch (random actions)
- No frame-skip

Designing reward function: We design the dense reward function as follows:

- Every step, $+1.0$ reward is given when $w \geq 1800$
- $+w/1800$ reward when episode success condition is satisfied
- -1.0 reward when episode failure condition is satisfied

Pre-training with BC: To perform pre-training with BC, we collected 120 expert demonstration data on the simulator.
Changing frame-skip rate: We change frame-skip rate to 19.

5 Implementation

In order to implement distributed learning with Vortex simulator, we consider three options, as shown in the Figure 10.

Figure 10. (a) Launching multiple processes on a single machine. (b) Creating multiple environments on a single physical simulator process. (c) Provide multiple machines on which the physical simulator process can run.

There are cases that GUI operation is the only way to advance the time of the simulator. In this case, Method 1 take much time due to the interaction with the GUI, but this can be resolved by using the Vortex python language scripting API to run the simulation. However, each process of the multiple simulators needs memory and CPU which requires a high-performance computer.

Method 2 needs only one process, so it is efficient in terms of memory and CPU. However, if the simulator is unable to reset each separate environment in the process to its initial state individually (synchronous parallel environment) as in Vortex, one needs to develop a new function module to summarize the environment state in the process because it is a requirement of the OpenAI gym interface, which is de facto interface and is assumed by many reinforcement learning frameworks. Moreover, as shown in the Figure 10, in the case of synchronous parallel environments, unlike asynchronous parallel environments, all environments need to reach the end of the episode. This may lead to a deterioration of the sample efficiency.

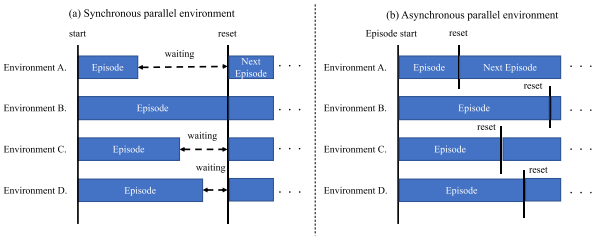

Figure 11. Progress of episodes in synchronous and asynchronous parallel environments

Method 3 is very simple but requires multiple computers.

Method 1 or 2 and Method 3 can be used together, and faster learning is expected. In our experiment, we adopt Method 2, which requires the lowest machine cost and is expected to achieve better performance than Method 1.

Note that Vortex simulator plan to develop an asynchronous parallel environment, so it will resolve the problem of sample efficiency in the future.

6 Results

In this section, we evaluate how each method contributes to each task success rate and learning speed. The results are showed in the Figure 12. The success rate is measured through 100 trials. We also show the task

success rate using the best performance model after learning. Table 1 shows the best success rate for each method on the simulator.

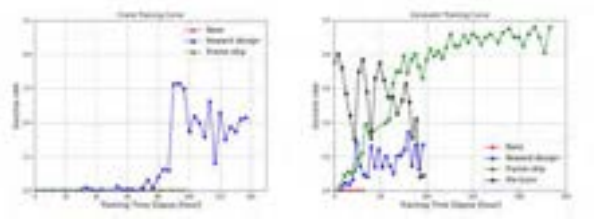

Figure 12. Learning efficiency for each method (left) crane (right) excavator

Table 1. Task success rate

Task	Success rate by methods, %			
	Base	Designing Reward function	Pre-training with BC	Changing Frame-skip
Crane	0	63	-	0
Excavator	0	34	80	96

6.1 Base condition

In both tasks, the base condition had no success, while other methods are starting to succeed at the same point in learning time. This indicates that the base condition needs more learning time and the other methods make learning more efficient.

6.2 Designing the reward function

In the crane task (see Figure 12 left), this method was the only one that worked. It reached about 60% success rate, and then the success rate dropped off. And also, in the excavator task (see Figure 12 right), this method had about 30% success rate. This indicates that the designed reward function is not directly related to the success of the task.

6.3 Pre-training with BC

Pre-training with BC took almost 1 hour wall-clock time to converge. In the early stages of learning, BC gave a high performance, but as the learning progressed, the performance gradually decreased. We believe that it is because the form of reward is different between BC and PPO.

6.4 Changing Frame-skip

The frame skip method achieved 96% success rate in the excavator task, whereas the crane task did not succeed at all. This indicates that the exploration for a good frame skip rate for each task or scene will yield good results.

7 Conclusion & Future work

In this paper, we demonstrated through simulations that reinforcement learning works effectively for two tasks: reducing sway of a load suspended from a mobile boom crane and loading an excavator bucket with soil with a hydraulic excavator. In addition, we confirmed the effectiveness of three methods to reduce learning time of reinforcement learning: designing the reward function, pre-training, and changing frame-skip rate. Finally, we provided examples of practical methods on how to parallelize learning when applying reinforcement learning algorithms to domain-specific simulators that were not originally designed for reinforcement learning.

In future work, we intend to compare our reinforcement learning algorithms with an existing control method on simulation. We also consider that the current learning on simulation is not tolerant to transfer to the real world. In recent years, methods to close the reality gap has been widely studied [21][22][23]. It is necessary to apply these methods to smoothly transfer learning result of simulation to real world operation.

Abstract -

In contrast to conventional serial robot arms, a cable robot offers special characteristics which make it predestined for usage in automated construction: Cable robots use a robust and simple mechanical layout, including a frame, motor-driven winches, pulleys and cables connected to the end effector in a parallel kinematic structure. Derived from BIM data, suitable trajectories need to be generated for every payload, e.g. as set values for the robot control. This paper focuses on the generation and optimization of such trajectories, considering several requirements and optimization criteria, using a hybrid particle swarm algorithm for global optimization. The optimization costs include transportation time, cable forces, collision avoidance, stiffness and movements of the pulleys. Some of these criteria are in conflict of aims, e.g. a short transportation time and low cable forces, which is resolved by weights in the cost function.

Keywords -

Cable Robot; Optimization; Path Planning; Construction

1 Introduction and State of Art

Over the last decades, repeatedly, the automation of bricking was considered. Projects in the 1990s, such as ROCCO, with a payload of around 500 kg and a range of up to 8.5 m [1], and BRONCO [2], use modern and economic approaches, using conventional industrial robots, partly on mobile platforms.

At ETH Zurich, mobile platforms have also been equipped with robot arms to investigate automated construction processes, initiated by Gramazio and Kohler in 2011. Different sensor concepts and tools were tested in installations such as “Endless Wall”, “Stratifications” and “Fragile Structure” [3, 4].

Currently, the Australian company Fastbrick Robotics is developing large manipulators called Hadrian and HadrianX , which are designed to bring building blocks along a large manipulator arm via belt conveyors to a desired position on the building site, using special bricks.

In parallel, the American company Construction Robotics LLC offers the SAM (Semi-Automated Mason). SAM employs a conventional serial robot on a movable platform or mounted on a large manipulator to achieve all the necessary poses on the construction site. According to Brehm [5], SAM is designed as a semi-automated system that is able to increase the productivity of a bricklayer by a factor of five, whereby the bricklayer is still responsible for creating the calibrating layer, the joints and setting the corners. SAM works with small-format bricks with grouted butt joints, which are applied using the dipping method.

2 Concepts for Bricking using Cable Robots

To construct a building by a robot, the size of the required workspace is supposed to be one of the dominant technical challenges. Here, cable robots offer outstanding advantages in terms of workspace size, stiffness, modularity and mobility [6, 7, 8]. Currently, first feasibility studies on cable robots for application in bricking have been done in lab scale. To extend this to practical full scale experiments, recently projects have been initiated that face specific technical challenges for the prototype, which are discussed here in short.

To allow for fast assembly and dismantling, and easy adaption to variable dimensions of the building to be constructed, the frame of the cable robot providing suspension of the end effector must consist of lightweight modular elements. Still, stiffness and constructive accuracy should not be less than with a fabricated steel construction. Here, good calibration procedures for setting up the geometric parameters (e.g. pulley positions) are needed in the future. Furthermore, the lower cable deflection pulleys – see Figure 1 – must be vertically movable in order to avoid collisions between cable and building during the construction process with a growing building structure. For good model accuracy – and thus for good positioning accuracy of the system – the guides of the deflection pulleys must be correspondingly precise.

Furthermore, the robot’s end effector – realized as a platform connected to the cables, carrying the brick gripper and a set of sensors – needs a home position, e.g. for revision purposes. As the ground is blocked by the building, it is necessary to construct a set-down position on the upper frame structure.

Another component specifically to be developed for this application is the brick gripper. For the exact positioning

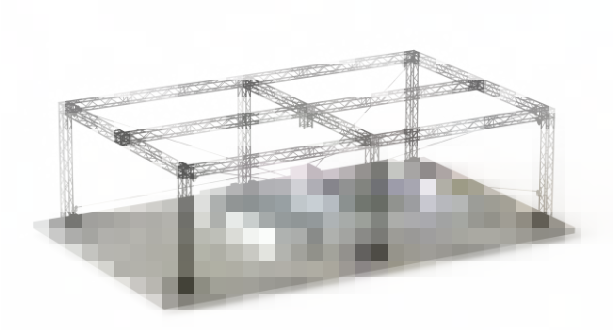

Figure 1. Principal CAD drawing of a cable robot for automated construction sites

of the brick, the brick must be gripped in a precisely defined way in order to guarantee a defined brick placing process. A sophisticated sensor concept for detecting both the stone to be gripped, as well as the objects and bricks already placed, is essential. In addition, the stone gripper must generate the gripping force passively to avoid the brick falling down in the event of power loss. Still, a form-fit gripping of the stone is not possible when using conventional bricks and mortar to be applied to the brick.

The use of a cable robot on a site also places special demands on the protection class of any components. The robot must be designed to be protected against dust and dirt and the influence of different weather conditions. The safety concept for working on a construction site must also be reviewed, which may require the design of new functions, such as the self-locking gripper.

3 Methodology

While the realization of the prototype components is a complex mechatronic task, another open issue is the model-based optimization of the robot and its behaviour. In this work and as a first step, the motion of the end-effector as well as the motion of the lower four cable deflection pulleys is optimized for the bricking process. This is resolved by a comprehensive physical model discussed in this work, and the careful formulation of a numerical optimization problem.

4 Numerical Optimization Approach

To be able to optimize the cable robot behaviour for bricking, its physics and properties will be modeled in the next sections.

The numerical optimizers to be used base on defining a vector of scalar parameters to be optimized, their boundaries and a scalar cost function. Thus, the properties to be optimized need to be modeled and evaluated resulting in a scalar cost function for each property. The formulation of those scalar cost functions will be given in the following.

Noteworthy, the different cost functions, each representing a property to be optimized, need to be merged. In this work, the multiobjective optimization is resolved by simply adding the single cost values $\mathcal{V}_\chi$ using weights $\mathcal{W}_\chi$ where all properties changing along a robot motion are discretized in n_s time steps, see section 5.

Some properties are subject to physical limits. As some of them are not parameters but result of the models to be developed, the question of considering those boundaries arises. Thus, this work uses penalty terms $\mathcal{P}_\chi$.

Accordingly, the total cost $\mathcal{V}_{\text{total}}$ is computed by summarizing the costs and penalties for all properties χ over all n_s time steps .

5 Trajectory Modeling

The trajectory describes the motion of the robot as a path defined over time. Accordingly, it covers information on pose, velocity and acceleration. Hence, a model for the description of these quantities must be found that allows a parametrization by the numerical optimizer. Here, splines – i.e. a composition of interconnected polynomials – are a popular choice. Within this work, only the platform position $\boldsymbol{r_P}$ with three degrees-of-freedom (DOF) as well as the lower four pulley positions $\boldsymbol{s}$ may change over time and thus are described by splines. As shown in table 1, for the platform position, six parameters per DOF are added to the optimization variables, resulting in 18 parameters for the description of the translational movement in three DOF. Note, rotations are not performed. Additionally, per segment a time duration $t_k, k = 1, 2, 3$, is defined as an optimization parameter, which adds three parameters. Resulting, the vector of optimization parameters contains 18 + 3 = 21 elements subject to numerical optimization.

Four parameters per pulley are added to the optimization variables, resulting in 16 parameters for the description of the movement of the four lower pulleys. The segment times are copied from the platform motion. Summarizing, 21 + 16 = 37 parameters are used in the numerical optimizer.

To evaluate the properties of the robot along a motion described by these splines, each spline needs to be discretized. Let $\dot{s}_i(q), i \in \{1, 2, 5, 6\}$, be the velocity of the lower pulleys along the linear axis at the q^{th} discretization step of one spline segment, n_{s_k} be the number of discretization points along one spline segment and n_k the number of spline segments.

While $\boldsymbol{r}_P$ and $\boldsymbol{s}$ as well as their temporal derivatives can be efficiently bound at the knots by limits (see table 3), they need to be bound along the whole trajectory as well. Thus, they are checked on each step and penalty terms $\mathcal{P}_{\text{traj}}$ and $\mathcal{P}_{\text{pulleys}}$, respectively, are associated. Noteworthy, as high robot dynamics per se are desirable, but already reflected by time, $\mathcal{V}_{\text{traj}} = \mathcal{W}_{\text{traj}} = 0$.

Table 1. Description of spline and optimizer parameters.

	Start (1st knot)	2nd knot	3rd knot	Goal (4th knot)
Spline segment	1	2	3	
Platform position; one spline per DOF; i.e. three splines in total				
Spline order	7	7	7	
Constraints	$\boldsymbol{r}_P$ is given; $\dot{\boldsymbol{r}}_P, \ddot{\boldsymbol{r}}_P, \dddot{\boldsymbol{r}}_P$ are set to zero	$\boldsymbol{r}_P, \dot{\boldsymbol{r}}_P, \ddot{\boldsymbol{r}}_P$ are parameters, $\dddot{\boldsymbol{r}}_P$ is set to zero	$\boldsymbol{r}_P, \dot{\boldsymbol{r}}_P, \ddot{\boldsymbol{r}}_P$ are parameters, $\dddot{\boldsymbol{r}}_P$ is set to zero	$\boldsymbol{r}_P$ is given; $\dot{\boldsymbol{r}}_P, \ddot{\boldsymbol{r}}_P, \dddot{\boldsymbol{r}}_P$ are set to zero
$\sum$ of constraints per DOF	4	4	4	4
$\sum$ of optimization parameters in total	0	3×3	3×3	0
Pulley position; one spline per pulley; four splines in total				
Spline order	3	5	3	
Constraints	$\boldsymbol{s}$ is a parameter; $\dot{\boldsymbol{s}}, \ddot{\boldsymbol{s}}$ are set to zero	$\boldsymbol{s}$ is a parameter; $\dot{\boldsymbol{s}}, \ddot{\boldsymbol{s}}$ are computed from first segment	$\boldsymbol{s}$ is a parameter; $\dot{\boldsymbol{s}}, \ddot{\boldsymbol{s}}$ are computed from last segment	$\boldsymbol{s}$ is a parameter; $\dot{\boldsymbol{s}}, \ddot{\boldsymbol{s}}$ are set to zero
$\sum$ of constraints per pulley	3	1 (1st segment); 3 (2nd segment)	1 (last segment); 3 (2nd segment)	3
$\sum$ of optimization parameters in total	4×1	4×1	4×1	4×1

To avoid collisions (see section 6.3), a reconfiguration of the cables might be necessary. Yet, in terms of power consumption, all movements of the pulleys require energy and are thus associated with costs. A detailed dynamic modeling of the pulley movement is neglected in this paper. For simplicity, viscous friction with a friction constant μ_f is assumed and results in costs for movement of the pulleys, scaled down to one pulley.

$$\mathcal{V}_{\text{pulleys}} = \frac{1}{4} \sum_{k=1}^{n_k} \sum_{q=1}^{n_{s_k}} \left(\|\dot{s}_1\| + \|\dot{s}_2\| + \|\dot{s}_5\| + \|\dot{s}_6\| \right) \mu_f \quad (1)$$

As the robot motion should be completed as fast as possible, the segment durations t_k can be simply summarized to the total time t_{total}. The cost function $\mathcal{V}_{\text{time}} = \left(t_{\text{total}} - n_k\, t_{\min}\right) \frac{1}{n_k\, t_{\min}}$ computes a value with respect to the smallest possible time. Furthermore, it puts this difference in relation to the smallest possible time, which allows an interpretation. The minimum reachable cost value is zero. As all t_k are directly defined as optimization parameters, their limits (see table 3) can be directly considered by the optimizer avoiding penalty terms, i.e. $\mathcal{P}_{\text{time}} = 0$.

6 Modeling

6.1 Kinematics and Dynamics

The cable robot, as shown in Figure 2, is referenced in the inertial coordinate system $\mathcal{B}$. The end-effector carries the platform-fixed coordinate-system $\mathcal{P}$. The

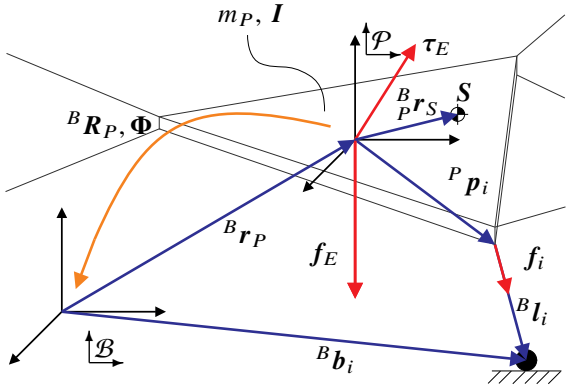

Figure 2. Cable-robot model parameters

robot is driven by m cables and has n degrees-of-freedom and therefore a redundancy of $r = m - n$. The posture in the inertial coordinate-system, consisting of position ${}^B\boldsymbol{r}_P$ and orientation $\boldsymbol{\phi}$ of the platform, is ${}^B\boldsymbol{x}_P = [{}^B\boldsymbol{r}_P\ \boldsymbol{\phi}]^{\mathrm{T}}$. The rotation matrix ${}^B\boldsymbol{R}_P$ describes the orientation of the platform with respect to $\mathcal{B}$, in the means of roll-pitch-yaw angles. ${}^B\boldsymbol{l}_i$ are the cable vectors, obtained by the inverse kinematic.

$${}^B\boldsymbol{l}_i = {}^B\boldsymbol{b}_i - \underbrace{({}^B\boldsymbol{r}_P + {}^B\boldsymbol{R}_P\, {}^P\boldsymbol{p}_i)}_{{}^B\boldsymbol{p}_{B_i}}, \quad 1 \le i \le m \quad (2)$$

The cables enter the workspace at the end of the base vectors ${}^B\boldsymbol{b}_i$, which are derived by using inverse pulley kinematics, see [9]. As introduced, the system can be

reconfigured by moving the pulleys along a straight line in vertical direction. The attachment points of the cables at the platform are ${}^{P}\boldsymbol{p}_i$. The cable force vector $\boldsymbol{f} \in \mathbb{R}^{m\times 1}$ contains all cable forces f_i in direction $\boldsymbol{v}_i$ of each cable i. Every i^{th} cable exerts the tension $\boldsymbol{f}_i$ on the platform.

$$\boldsymbol{f}_i = f_i \cdot \frac{\boldsymbol{l}_i}{\|\boldsymbol{l}_i\|_2} = f_i \cdot \boldsymbol{v}_i, \quad 1 \le i \le m \tag{3}$$

The static force equilibrium at the platform is given by

$$-\boldsymbol{w}_E = \begin{bmatrix} -\boldsymbol{f}_E \\ -\boldsymbol{\tau}_E \end{bmatrix} = \begin{bmatrix} \boldsymbol{v}_1 & \dots & \boldsymbol{v}_m \\ \boldsymbol{p}_1 \times \boldsymbol{v}_1 & \dots & \boldsymbol{p}_m \times \boldsymbol{v}_m \end{bmatrix} \begin{bmatrix} f_1 \\ \vdots \\ f_m \end{bmatrix} = \boldsymbol{A}^{\mathrm{T}} \boldsymbol{f}. \tag{4}$$

Herein, $\boldsymbol{A}^{\mathrm{T}}$ is the structure matrix of the robot and the forces and torques at the platform are included in $\boldsymbol{w}$. Setting up Newton-Euler equations [10] in $\mathcal{B}$, one obtains

$$\underbrace{\begin{bmatrix} m_P \boldsymbol{E}_3 & -m_P {}^{B}_{P}\boldsymbol{R}_S \boldsymbol{\mathcal{H}} \\ m_P {}^{B}_{P}\boldsymbol{R}_S & {}^{B}\boldsymbol{\theta}_P \boldsymbol{\mathcal{H}} \end{bmatrix}}_{\boldsymbol{M}(\boldsymbol{x}_P)} \underbrace{\begin{bmatrix} {}^{B}\ddot{\boldsymbol{r}}_P \\ \ddot{\boldsymbol{\phi}} \end{bmatrix}}_{\ddot{\boldsymbol{x}}_P} + \dots$$
$$+ \underbrace{\begin{bmatrix} m_P \left[(\dot{\boldsymbol{\mathcal{H}}}\dot{\boldsymbol{\phi}}) \times {}^{B}_{P}\boldsymbol{r}_S + (\boldsymbol{\mathcal{H}}\dot{\boldsymbol{\phi}}) \times ((\boldsymbol{\mathcal{H}}\dot{\boldsymbol{\phi}}) \times {}^{B}_{P}\boldsymbol{r}_S) \right] \\ {}^{B}\boldsymbol{\theta}_P \dot{\boldsymbol{\mathcal{H}}}\dot{\boldsymbol{\phi}} + (\boldsymbol{\mathcal{H}}\dot{\boldsymbol{\phi}}) \times ({}^{B}\boldsymbol{\theta}_P \boldsymbol{\mathcal{H}}\dot{\boldsymbol{\phi}}) \end{bmatrix}}_{\boldsymbol{K}(\boldsymbol{x}_P, \dot{\boldsymbol{x}}_P)} \dots$$
$$\dots + \underbrace{-{}^{B}\boldsymbol{w}_E}_{\boldsymbol{Q}(\boldsymbol{x}_P, \dot{\boldsymbol{x}}_P)} = {}^{B}\boldsymbol{A}^{\mathrm{T}} \boldsymbol{f}. \tag{5}$$

The mass of the platform is m_p and its inertia tensor is ${}^{B}\boldsymbol{\theta}_P$. $\boldsymbol{E}_3$ is a 3×3 identity matrix. Matrix $\boldsymbol{\mathcal{H}}$ and its time derivative $\dot{\boldsymbol{\mathcal{H}}}$ can be obtained from the kinematic Kardan equations [11]. Matrix ${}^{B}_{P}\boldsymbol{R}_S$ is a transformation matrix between the center of gravity and origin of the platform coordinate system. $\dot{\boldsymbol{x}}_P$ and $\ddot{\boldsymbol{x}}_P$ are the first and second time derivative of the end-effector pose $\boldsymbol{x}_P$. The vector from the platform coordinate system to its center of gravity is ${}^{B}_{P}\boldsymbol{r}_S$. $\boldsymbol{M}(\boldsymbol{x})$ is the mass matrix of the platform, $\boldsymbol{K}(\boldsymbol{x}_P, \dot{\boldsymbol{x}}_P)$ contains Coriolis and centrifugal forces and torques and $\boldsymbol{Q}(\boldsymbol{x}_P, \dot{\boldsymbol{x}}_P)$ holds all remaining forces and torques including gravitational forces, friction and disturbances.

To obtain set point cable forces for the control, based on a desired trajectory, eq. (5) needs to be solved for $\boldsymbol{f}$ with a given $\boldsymbol{w}$. As the cable can only pull put never push, a minimum tension $f_{\min}$ in the cables is necessary. To avoid cable breaks, the cable forces must not exceed a maximum tension $f_{\max}$. Several well-known methods exist to solve this problem [12], which differ e.g. in real-time capability or the resulting force level.

As cable forces correspond to the power usage of the system, low cable forces are desired in terms of costs. Let $\boldsymbol{f}(q)$ be the cable force distribution at the q^{th} discretization point of one spline. Per spline, the magnitude of the cable forces along each spline segment is summarized and then weighted using the time per spline t_k.

$$f_w(k) = \frac{t_k}{t_{\text{total}}} * \frac{1}{n_k} * \sum_{q=1}^{n_{s_k}} \sum_{i=1}^{m} f_i(q) \tag{6}$$

Based on the weighted forces f_w, the average cable force with respect to one cable throughout the whole trajectory is calculated using the total number of discretization points n_s and the number of cables m. Further on, the value gets normalized with respect to $f_{\min}$ to allow for zero costs when the optimal value is reached. The resulting costs for cable forces are

$$\mathcal{V}_{\text{force}} = \Big(\sum_{k=1}^{n_k} f_w(k) * \frac{1}{n_s} * \frac{1}{m} - f_{\min} \Big) * \frac{1}{f_{\min}}. \tag{7}$$

To cope with invalid cable force distributions in the optimization process, a penalty term is added to $\mathcal{P}_{\text{force}}$ as soon as at one time step, the cable forces are beyond the force limits (see table 3) and thus invalid. To allow the optimizer to iteratively resolve disadvantageous trajectories, each additional time step with invalid forces adds another increment to $\mathcal{P}_{\text{force}}$.

6.2 Stiffness

Stiffness is a critical issue for large and elastic manipulators such as cable robots. Assuming a linear behavior, the stiffness can be described by a spring equation such as

$$\delta \boldsymbol{w} = \boldsymbol{K}(\boldsymbol{x}_P) \delta \boldsymbol{x}_P, \tag{8}$$

where $\delta \boldsymbol{w}$ is the reaction force caused by a displacement $\delta \boldsymbol{x}_P$ that occurs due to a stiffness defined in a diagonal matrix $\boldsymbol{K}$, where the latter is determined for a platform position $\boldsymbol{x}_P$. $\boldsymbol{K}(\boldsymbol{x}_P)$ is computed according to [13, 14] as

$$\boldsymbol{K}(\boldsymbol{x}_P) = \underbrace{-\frac{\partial \boldsymbol{A}^{\mathrm{T}}}{\partial \boldsymbol{x}_P} \boldsymbol{f}}_{\boldsymbol{K}_g} + \underbrace{\boldsymbol{A}^{\mathrm{T}} \boldsymbol{K}_l \boldsymbol{A}}_{\boldsymbol{K}_c}, \tag{9}$$

which includes two matrices $\boldsymbol{K}_c$ and $\boldsymbol{K}_g$. $\boldsymbol{K}_c$ denotes the so-called passive stiffness which simply describes the elastic behaviour of the cable and might also include the stiffness of the winch position controller. $\boldsymbol{K}_g$ is the active stiffness of the system. Contrarily to the passive stiffness, it does not depend on elasticity effects such as compliance of a material. Instead, it reflects the attempts of the system to return to its force and torque equilibrium position once the platform is subject to a position disturbance. This behaviour only depends on the geometry and pose of the system, condensed in $\boldsymbol{A}^T$.

Now compliance matrix $\boldsymbol{C}$ allows to compute the displacement for a given disturbance wrench.

$$\delta \boldsymbol{x}_P = \boldsymbol{K}^{-1} \delta \boldsymbol{w} = \boldsymbol{C} \delta \boldsymbol{w} \tag{10}$$

As this includes both translational and rotational motions, a diagonal homogenization matrix $\boldsymbol{J}_v$ according to [15, 16] can be employed, i.e. $\boldsymbol{A}_h^{\mathrm{T}} = \boldsymbol{J}_v^{-1} \boldsymbol{A}^{\mathrm{T}}$, which can be used instead of $\boldsymbol{A}^{\mathrm{T}}$ in eq. (9), allowing to apply eq. (10) to get a homogenized displacement $\Delta \boldsymbol{x}_{Ph}$. The magnitude of this displacement $\kappa = \|\Delta \boldsymbol{x}_{Ph}\|_2$ gives a scalar measure for the stiffness which can be used as part of a cost function. Within this paper, the disturbance force $\boldsymbol{w}$ includes two wrenches: First, the gravity is included as it leads to relevant position deviations, espcially in upper parts of the workspace, see Figure 3 and Figure 4. Second, it includes the influence of constant cross wind of $7 \frac{m}{s}$ (4 Bft), modeled by the drag equation. Cross wind might lead to hardly predictable oscillations of the platform. For both wrenches, a high stiffness is desirable for the generated trajectories to minimize their effects.

Let $\kappa(q)$ be the displacement criterion at the q^{th} discretization step of one spline. The sum of $\kappa(q)$ over one spline segment is weighted using the time per segment.

$$\kappa_w(k) = \frac{t_k}{t_{\text{total}}} * \frac{1}{n_k} * \sum_{q=1}^{n_{s_k}} \kappa(q) \tag{11}$$

Following, the total cost for stiffness throughout the whole trajectory is calculated based on the weighted sum $\kappa_w(k)$.

$$\mathcal{V}_{\text{stiff}} = \sum_{k=1}^{n_k} \kappa_w(k) * \frac{1}{n_s} \tag{12}$$

As there is no bound defined for stiffness is this work, $\mathcal{P}_{\text{stiff}} = 0$. In future work, requiring a minimum stiffness could be easily considered.

6.3 Collision Detection

As cable robots might use a high number of cables, collisions and their avoidance are crucial. The methods in this section were derived from [17, 18]. Within this work, only collisions between the lower cables and obstacles as well as between platform and objects are considered. In this simulation, the only obstacles on the site are the bricks which might be either on a pallet delivered by the supply chain, or already placed as part of the building. Accordingly, the poses of all objects on this simplified site are known. Generally, also collisions between the cables with each other and between cables and platform can be taken into account, but as the application at hand avoids platform rotations and uses a simple geometry – where the corners of the platform are connected to the corresponding corners of the frame, avoiding interference – those cases are neglected.

The employed approach bases on the Separated Axis Theorem as presented by [18]. Here, obstacle bounding volume and end-effector bounding volume are calculated by axis-aligned bounding boxes (AABB).

Using the AABB approach, intersection tests in all axes are simple. Furthermore, the Euclidean distance d between two objects can be determined. Noteworthy, in this work, the distance is measured using two approaches: For measurements between end-effector and obstacles, face-to-face distances $d_{ee}(q)$ are computed. Face-to-center distances are applied for measurements $d_{c_i}(q)$ between each i^{th} cable and obstacles. In case of multiple obstacles, the smallest distance to the nearest obstacle in each discretization step is taken into account for the cost function. If any of the distances falls below the minimum distance $d_{\min}$ or $w_{\min}$ (see table 3), respectively, costs are applied to avoid collisions within the trajectory. To calculate the cost in each discretization step q, the distances d are fed to an arbitrarily chosen nonlinear function

$$\mathcal{D}_{\text{EEOB}}(q) = \left(3(1 - \frac{d_{ee}(q)}{d_{\min}})\right)^3 \tag{13}$$

which avoids the objects getting close to each other. The total costs for collisions between end effector and objects are given by the sum

$$\mathcal{V}_{\text{EEOB}} = \frac{1}{n_s} \sum_{k=1}^{n_k} \sum_{q=1}^{n_{s_k}} \mathcal{D}_{\text{EEOB}}(q). \tag{14}$$

Similarly, the cost for collisions between cables and objects are calculated by an arbitrarily chosen nonlinear function that basically multiplies a weight to eq. (13)

$$\mathcal{D}_{\text{CAOB}}(q) = \sum_{i=1}^{m} \left(3(1 - \frac{d_{c_i}(q)}{w_{\min}}\right)^3 * \frac{1}{10} \tag{15}$$

and summarized as

$$\mathcal{V}_{\text{CAOB}} = \frac{1}{n_s} \sum_{k=1}^{n_k} \sum_{q=1}^{n_{s_k}} \mathcal{D}_{\text{CAOB}}(q). \tag{16}$$

Whenever a step q along the path leads to a collision, penalties $\mathcal{P}_{\text{EEOB}}$ and $\mathcal{P}_{\text{CAOB}}$, respectively, are added each time. This holds for collisions between cables and objects as well as the end effector and objects. To save computation times, all bricks of a completed layer in the building are represented by a common box.

7 Discussion of Results

The models employed and the optimizer were set up using an installation plan for a small building. Table 3 lists

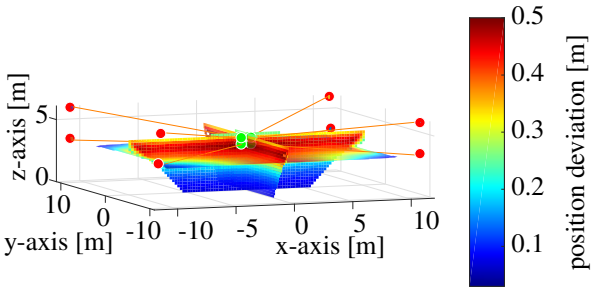

Figure 3. Stiffness in the workspace with lower pulleys upwards. The applied wrench $\delta \boldsymbol{w}$ includes crosswind of $7\frac{m}{s}$ (4 Bft) and platform weight of 100 kg, but no brick.

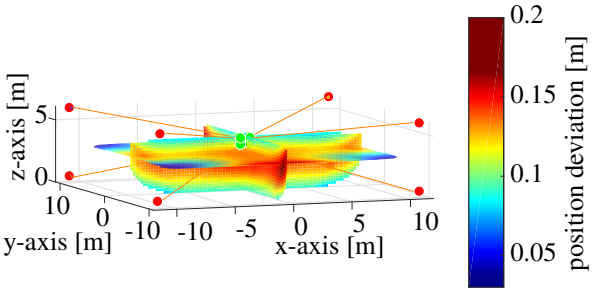

Figure 4. Stiffness in the workspace with lower pulleys downwards. The applied wrench $\delta \boldsymbol{w}$ includes crosswind of $7\frac{m}{s}$ (4 Bft) and platform weight of 100 kg, but no brick.

Table 2. Costs $\mathcal{V}$ and weights $\mathcal{W}$. *a) without stiffness optimization. *b) with stiffness optimization. *c) save overhead trajectory

$\mathcal{V}$	*a	*b	*c	$\mathcal{W}$
$\mathcal{V}_{\text{time}}$	11.8732	11.2863	39.0000	0.5

the applied parameters. For computational efficiency during the optimization, only few time steps were used within the prime calculation of the optimizer, see table 3. Noteworthy, for higher accuracy, a final computation including a penalty check was carried out with a increased resolution of $[n_{s_1}, n_{s_2}, n_{s_3}] = [30, 29, 29]$. For the numerical optimization, MATLAB's particleswarm() with a hybrid setting – which basically appends a gradient decent using fmincon() – was chosen. These methods support parallel computing to speed up the simulation. The swarm population size was set to 60 and the maximum iterations to 1000.

Noteworthy, the moving masses of the platform change if a brick is picked. In optimization procedure, mass and inertia of both platform and brick are considered in the dynamics model, transformed with respect to $\boldsymbol{x}_P$ located at the bottom of the brick. The results reflect the compromise found as a consequence of the – partly contrary – cost functions. Under the influence of platform and payload mass in gravity, the lower parts of the workspace are favorable as they provide an advantageous angle of attack for the cables and thus lower cable forces.

A trajectory not considering stiffness is shown in Figure 5. Here, brick no. 300 was arbitrarily chosen, starting its motion at $r_{\text{start}} = [-5.747, -0.876, 0.748]^{\text{T}}$ and placing the brick at $r_{\text{goal}} = [0.0875, 6.922, 0.748]^{\text{T}}$ after a motion time of 3.8619 s.

As introduced in section 4, the total cost function chosen in this work is

$$\mathcal{V}_{\text{total}} = \sum_{\chi} \mathcal{W}_{\chi} \times \mathcal{V}_{\chi} + \mathcal{P}_{\chi} \tag{17}$$

where $\chi \in \{\text{time, traj, force, EEOB, CAOB, pulleys}\}$.

On the other hand, stiffness influences the result of the optimizer, both regarding platform trajectory and lower pulley motion. This is illustrated in Figure 3 and Figure 4. Obviously, the stiffness massively varies within the workspace, and the pulley position has a major impact. As a rule of thumb, the lower pulleys down configuration shown in Figure 4 has clear advantages over the lower pulleys up configuration shown in Figure 3. Noteworthy, the active stiffness term $\boldsymbol{K}_g$ takes advantage from high cable forces which on one hand, contradicts $\mathcal{V}_{\text{force}}$, see eq. (7), and on the other hand increases stiffness at the workspace boundaries. Still, eq. (17) applies where now $\chi \in \{\text{time, traj, force, EEOB, CAOB, pulleys, stiff}\}$. Accordingly, including $\mathcal{V}_{\text{stiff}}$ in $\mathcal{V}_{\text{total}}$, the motion of platform and pulley for brick no. 300 changes, as shown in Figure 5. Table 2 shows the resulting cost functions in comparison. An interesting finding is, that for the chosen parameters settings, the trajectory optimized for stiffness as well is even faster requiring 3.6859 s, but at the price of generally higher forces and faster pulley motions. Collisions were totally avoided in both cases along all trajectory steps. All penalty terms were zero upon convergence of the optimizing process.

While the spline-based approach provides maximum flexibility for optimization, the resulting motions might be

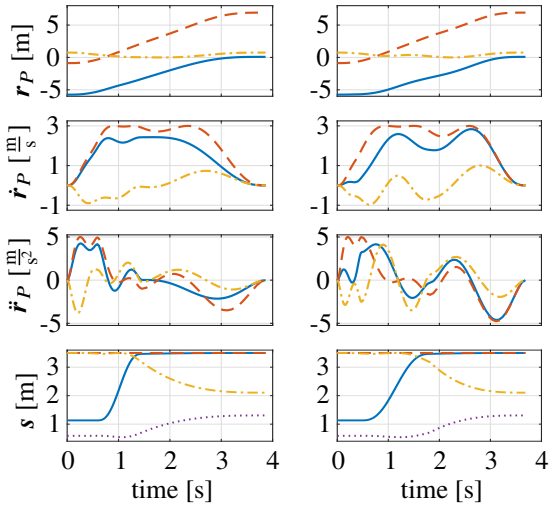

Figure 5. Optimized trajectories and pulley motion. Left: without stiffness optimization. Right: with stiffness optimization. Top three plots: Solid blue line: x-component of the vector. Dashed red line: y-component of the vector. Dash-dotted orange line: z-component of the vector. Bottom plots: Pulleys $[1, 2, 5, 6]$: Solid blue line, dashed red line, dash-dotted orange line, dotted magenta line.

unintuitive for any potential personnel on the site. Thus, in parallel, a slow simplified, unoptimized straight line trajectory over head level with fixed time was performed that is collision-free: It vertically lifts the brick to a height of 2 m above current wall height, horizontally moves to the goal position and vertically moves down to place the brick. The pulleys remain at the current wall height plus $s_{\min}$. For completeness, the results are given in table 2 as well. Clearly, since this trajectory is fully predefined at low dynamics, it is not optimal in comparison.

8 Conclusion and Outlook

This contribution introduced the models, the optimization problem and the solution approach to optimize the trajectories of a cable robot for automated bricking. The results indicate that the choice of the cost functions and their weights have a major impact on the trajectory and allow a tuning regarding preferences like transport time, stiffness and cable tension level. Collisions and paths outside the workspace could be effectively avoided.

This work will be extended by additional spline formulations and more effective parallelization in the future. The generated trajectories will be tested on real prototypes.

Abstract –

Machine learning techniques have been successfully implemented for the identification of various construction activities using sensor data. However, there are very few studies on activity recognition in the automated construction of low-rise residential buildings. Automated construction is faster than conventional construction, with minimal human involvement. This requires high accuracy of identification for monitoring its operations. This paper discusses the development and testing of machine learning classifiers to identify normal automated construction operations with high precision. The framework developed in this work involves decomposing the activity recognition problem into a hierarchy of learning tasks in which activities at the lower levels have more details. The top recognition level divides the equipment states into two classes: 'Idle' and 'Operations'. The second recognition level divides the 'operations' into major classes depending on the top-level activities performed by the equipment. The third recognition level further divides the activities into subclasses and so on. Since the number of classes and the similarity between them increase with the recognition level, identification becomes extremely difficult. The identification framework developed in this study classifies operations belonging to the parent class at each level in the hierarchy. The efficacy of this framework is demonstrated with a case study of a top-down modular construction system. In this construction system, the modules of a structural frame are assembled and lifted starting with the top floor followed by the ones below. The accelerometer data collected during top-down construction is used to identify the construction operations. The proposed framework shows superior performance over conventional identification using a flat list of classes.

Keywords –

Automated Construction; Construction Monitoring; Machine Learning; Accelerometer

1 Introduction

Construction operations are monitored for several purposes like the determination of cycle time, productivity, fuel consumption, quality of work and possible failure conditions [1]–[3]. Identifying the activity with reasonable accuracy is sufficient for these purposes. However, for the development of a monitoring system to ensure safety, high accuracy of identification is necessary.

Automated construction is faster than conventional construction, with minimal human involvement. In a fast automated construction system, an undetected faulty operation might cause catastrophic accidents [4], [5]. Besides, the level of detail required in this activity recognition problem is also higher. If an operation is detected as faulty in ongoing automated construction, the details like which operation, the stage of construction in which it happens and its location, have to be identified to take appropriate corrective actions. Hence, the operation identification problem has to be carefully formulated to develop a monitoring system.

Existing studies on equipment activity recognition aim to improve the identification results by exploring advanced machine learning techniques, training options, hyperparameters, features extracted and also by carefully selecting the data [6]–[9]. The current study examines the significance of problem formulation in activity recognition.

The main objective of this study is to identify automated construction operations with high accuracy. A hierarchical operation recognition framework has been developed in this study which involves decomposing the activity recognition problem into a hierarchy of learning tasks. At the top level, equipment states, 'idle' and 'operations' are identified. The activities at lower levels have more details. The performance of this framework is compared with that of the conventional approach to operation recognition which involves a flat list of classes to be separated. The two approaches were evaluated using data from an automated construction system (ACS)

prototype. Acceleration data collected from the structure is used for operation identification. Both approaches use artificial neural networks (ANN) as the learning algorithm.

2 Equipment activity recognition methods

Advancements in computing technology have opened a wide range of possibilities for automated activity recognition. There are mainly three methods for automated activity recognition: sensor-based methods, computer vision-based methods and audio-based methods [3]. In some cases, a combination of these methods is also adopted.

Sensor-based methods capture the characteristic signals associated with operations [10]. Accelerometers, gyroscopes, inertial measurement unit (IMU) and Global Positioning System (GPS) are some of the widely used sensors for activity recognition [6], [8], [11]. Sensor-based methods can be reliably applied to chaotic construction sites where equipment is often beyond the line of sight. A broad range of studies explored various supervised learning methods, starting from simple ANN, K-nearest neighbour (KNN), logistic regression, Support vector machine (SVM) to deep learning methods in recent times [7], [8], [12], [13].

Vision-based methods have the potential to identify any type of equipment if ambient conditions are favourable. Images or videos of the construction equipment are used for activity recognition. Initial studies used SVM and 2D motion descriptors for activity recognition from spatiotemporal data [14], [15]. More recent studies explore deep learning methods for automated labelling of activities in video data [2], [16]. Major limitations associated with the vision-based methods include high sensitivity to ambient conditions, obstructions, cost of implementation and need for large storage space.

Audio-based methods can be used to identify any equipment that generates sound. Numerous machine learning classifiers were implemented for sound classification. Some of the most popular classifiers are KNN, SVM, ANN, Hidden Markov model (HMM) and deep neural networks [17]–[20]. Microphones can capture the data from all directions without getting affected by visual obstructions [3]. This data is not biased by the skill level of the operator. However, not all equipment can be identified by this method. Data collecting for these methods can be challenging for noisy construction sites.

The current study attempts to identify operations of an ACS prototype for low-rise buildings. Acceleration data is used for activity recognition. ANN is one of the best performing machine learning classifiers for equipment activity recognition. Hence, ANN with a simple architecture (single hidden layer) is selected for the current study.

3 Methodology

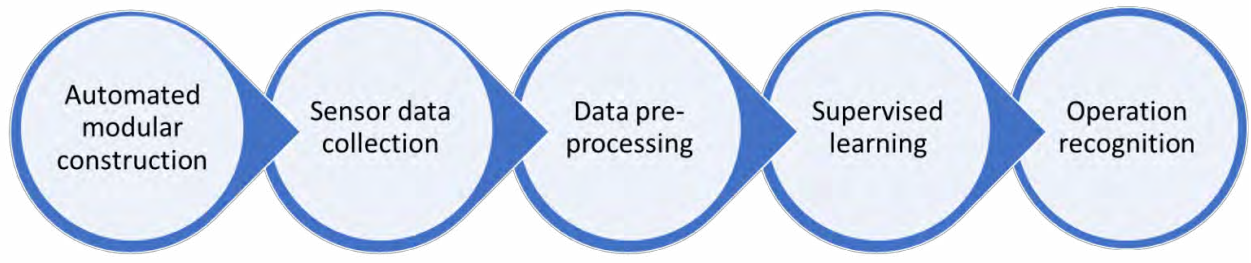

Figure 1. Methodology for operation recognition

Figure 1 shows the methodology adopted for this study. Acceleration data is collected during the modular construction of a structural frame using an Automated Construction System (ACS) prototype. After pre-processing, the data is supplied to the operation recognition framework. This machine learning-based framework identifies the operations that are organized hierarchically into 4 recognition levels (RL). Two approaches are compared: a) Conventional approach using a flat list of classes to be identified, and b) Hierarchical operation recognition framework. Each step of the research methodology is described in detail in the following sections.

3.1 Automated modular construction

The automated top-down construction method is adopted for the construction of the structural frame in this study [4], [5], [21], [22]. This method is mainly developed for the modular construction of low-rise buildings. For automated top-down construction, the main load-bearing parts of a structure are divided into smaller components. The modules of the beam and column are assembled sequentially, starting from the topmost parts of the structural frame. After the assembly of the first set of components, the completed structure is lifted to a certain height. The modules of the column are

added to the existing structure and lifted it again in the next operation cycle. Since the structure is completed from top to bottom using an ACS, this method is called automated top-down construction.

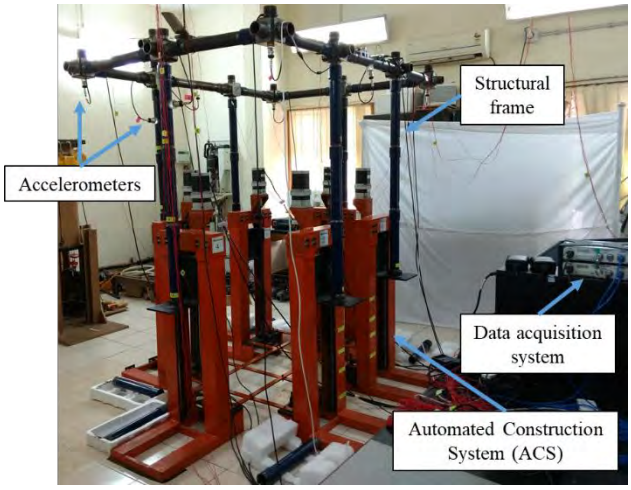

Figure 2. Data collection during automated modular construction

Figure 2 shows the laboratory prototype of the ACS and the structural frame developed for this study. The ACS consists of 6 lifting machines. Each of these machines is capable of operating individually for lifting or lowering of specific support and as a group for simultaneous lifting or lowering of all supports (coordinated lifting or coordinated lowering). The structural frame modules are made of standard steel pipe sections with external threading on both edges. They are connected by couplers and universal joints with internal threading. The structure has redundant columns to ensure stability during top-down construction. Each column of the structure is supported by a lifting platform of the ACS.

At the beginning of the top-down construction, the top most beam and column modules are connected and supported by these lifting platforms. This idle condition before the beginning of the operation cycle is termed as 'Idle_CS0' where CS0 refers to Construction Stage 0. This is followed by the first operation cycle of top-down construction. The operations involved in one cycle are given below [21].

1. Coordinated lifting
2. Lowering support 1
3. Assembling module of column 1
4. Lifting support 1 till the load is transferred from column 1
5. Repeat steps (2) to (4) for other supports (support 2 to support 6)

One cycle of the top-down construction finishes one stage of construction (CS). Two cycles of operations were carried out for one set of experiments. Totally 6 sets of experiments were conducted for the study.

3.2 Data collection

Acceleration data was collected from 8 different locations on the structure during automated construction (Figure 2). Monoaxial piezoelectric accelerometers (measurement range: -5g to +5g, sensitivity: 1000 mv/g) were installed on the topmost beam-column assembly for this purpose. The data is acquired through HBM universal measuring amplifier (model: QuantumX MX840B) at 200 Hz sampling frequency. The timestamps of all operations were manually recorded in a time tracking excel sheet. These sheets were compared with the timestamps of the acquired data for generating operation labels required for supervised learning.

3.3 Data pre-processing

The acceleration data collected using HBM data acquisition software is exported to Microsoft Excel and MATLAB files for analysis. Based on the studies of equipment activity recognition, 5 time-domain features and 5 frequency domain features were extracted from the raw data [6], [11], [23]. The time-domain features include mean, variance, interquartile range, peak and root mean square error. The period of the signal and signal energy were extracted through autocorrelation of the signal. The other frequency domain features include the three prominent frequencies from the Fast Fourier Transform (FFT) of the signal. Totally 80 features (10 features x 8 sensor locations) were extracted from the raw acceleration data.

3.4 Supervised learning and operation recognition

In previous studies, supervised learning techniques have demonstrated superior performance compared to unsupervised learning techniques for unbalanced datasets [6], [14]. The current study adopts Artificial Neural Networks (ANN) for the classification of automated construction operations.

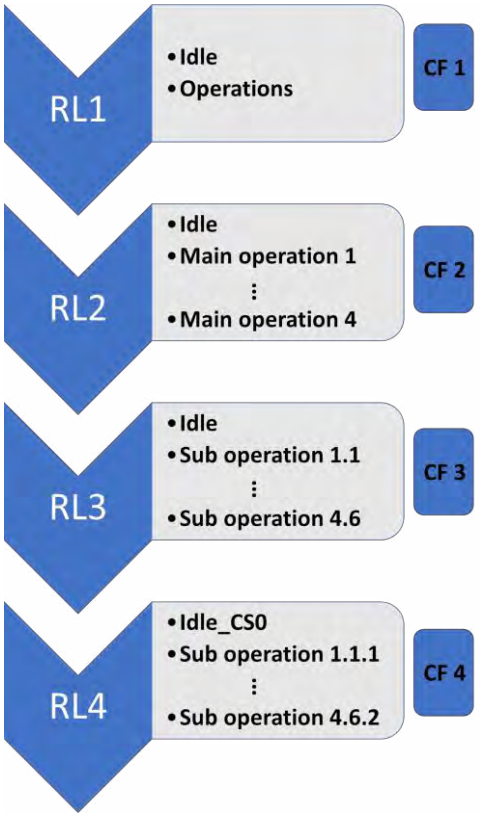

Figure 3. Conventional approach for operation recognition

The identification problem has 4 recognition levels (RL) as follows.

- RL1: Recognizes whether the ACS is 'idle' or 'operating'
- RL2: Recognizes the major operation categories
- RL3: Recognizes the sub-operation categories
- RL4: Recognizes stage of construction

The conventional approach for operation recognition uses a flat list of classes to be separated. However, in order to test the performance of this approach at different recognition levels, the identification problem is divided into 4 different identification tasks, one task per RL (Figure 3). An ANN classifier is assigned to each identification task. The classifiers are named as CF 1, CF 2, ..., CF 4, represented by blue boxes in figure 3. The operation categories identified are given as a list next to it. The actual operation categories identified by the classifiers are given in Table 1. The complexity of the identification problem seems to increase from RL1 to RL4 in this approach.

Hierarchical operation recognition framework is developed by considering the hierarchical relationship among the operations (Figure 4). If the major category of an operation is identified with high accuracy, the further identification task can be simplified by exploring the subcategories of that operation. This idea is the basis of the hierarchical operation recognition framework. The main

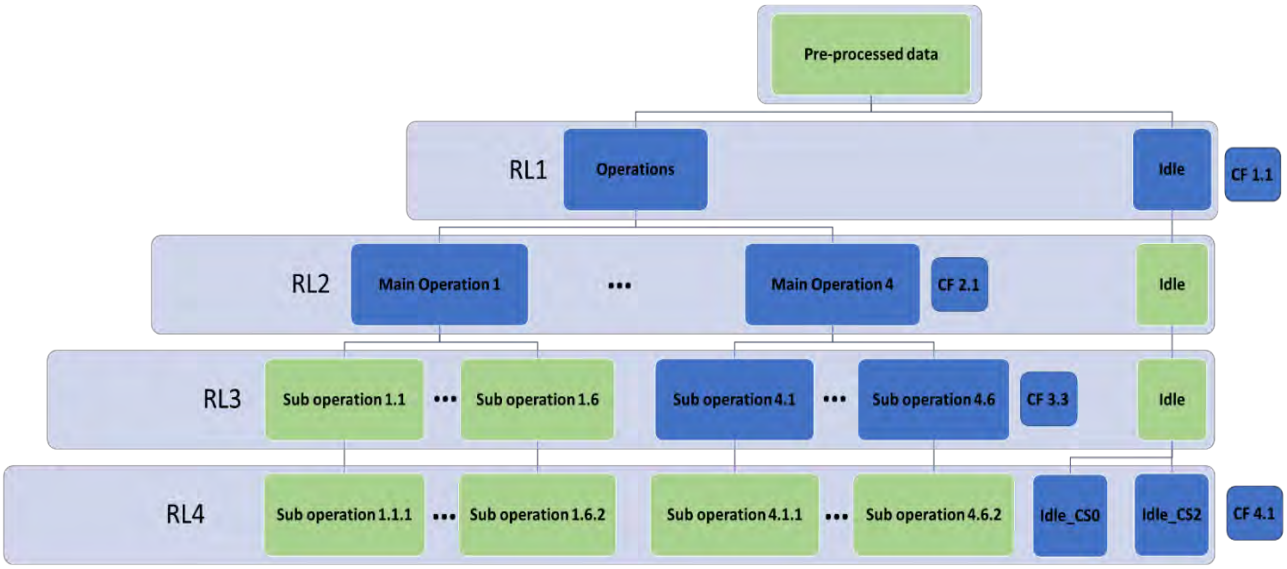

Figure 4. Hierarchical operation recognition framework

Table 1. Classifiers in operation recognition frameworks

Recognition Level	Classifiers in conventional approach	Classifiers in hierarchical operation recognition framework	Name of Classes
1	CF 1	CF 1.1	Idle
			Operations
2	CF 2	CF 2.1	Idle
			Coordinated Lifting
			Lowering Support
			Assembling Column Module
			Lifting Support
3	CF 3	CF 3.1	Idle
			Coordinated Lifting
			Lowering Support 1 ... Lowering Support 6
		CF 3.2	Assembling Column Module Step 1 … Assembling Column Module Step 6
		CF 3.3	Lifting Support 1 … Lifting Support 6
4	CF 4	CF 4.1	Idle_CS0
			Idle_CS2
		CF 4.2	Coordinated Lifting_CS0
			Coordinated Lifting_CS1
			Coordinated Lifting_CS2
		CF 4.3	Lowering Support 1_CS1 Lowering Support 1_CS2
		…	…
		CF 4.8	Lowering Support 6_CS1 Lowering Support 6_CS2
		CF 4.9	Assembling Column Module Step 1_CS1 Assembling Column Module Step 1_CS2
			…
		CF 4.14	Assembling Column Module Step 6_CS1 Assembling Column Module Step 6_CS2
		CF 4.15	Lifting Support 1_CS1 Lifting Support 1_CS2
			…
		CF 4.20	Lifting Support 6_CS1 Lifting Support 6_CS2

the identification problem is divided into a hierarchy of simple identification tasks across the RLs. Hence, there can be more than one identification task per RL. The classifiers are named as 'CF RL.n' where the first index RL represents recognition level and n denotes the number of the classifier in that RL. For clarity, only one classifier is shown per RL in figure 4 The classifier and the operations classified are shown in blue boxes. This figure is also for the representation of the concept of hierarchical operation recognition framework. The actual details of the framework are given in Table 1.

The performance of all classifiers is assessed through k-fold cross-validation. This avoids the problem of overfitting to the given data. The classifiers in RL1 to RL3 are 10-fold cross-validated and those in RL4 are 5-fold cross-validated for both identification frameworks. The predicted class labels were compared with the digital

record of actual class labels to estimate the accuracy of identification. The accuracy is computed as given in equation 1.

$$Accuracy = \frac{Number\ of\ samples\ correctly\ identified}{Total\ number\ of\ samples}\ x\ 100\ \% \quad (1)$$

4 Results and discussion

Table 2. Summary of operation recognition results

Recognition level (RL)	Conventional approach for operation recognition		Hierarchical operation recognition framework	
	Classifiers	Overall accuracy per RL (%)	Classifiers	Overall accuracy per RL (%)
1	CF 1	99.58	CF 1.1	99.58
2	CF 2	99.18	CF 2.1	100.00
3	CF 3	95.92	CF 3.1 - CF 3.3	99.07
4	CF 4	84.56	CF 4.1 - CF 4.20	99.19

The operation recognition results are summarized in Table 2. For comparing the performance of the two approaches, the prediction accuracy of all classifiers in the hierarchical framework is combined to estimate the overall accuracy per RL. The classifier CF 1 and CF 1.1 are assigned with the same identification task: classifying 'idle' and 'operations'. Hence the accuracy of identification is also equal. At RL 2, the hierarchical framework performs slightly better than the conventional approach with 100% accuracy. Meaning all main operations were identified correctly. CF 2.1 removes the 'idle' from the classes. This is the reason for improved accuracy.

RL 3 onwards there is a significant difference in the problem formulation. The hierarchical framework has focused classifiers for the identification of sub-operations at RL3. Hence the operations were better identified in this framework. At RL 4 where the construction stage is to be identified, there is a significant difference in performance between two recognition frameworks.

While the hierarchical framework consistently delivers accuracy close to 100%, the performance of the conventional approach continuously declines with the increase in the recognition level. Even though both approaches use the same machine learning algorithm, their performances are different. The results emphasize the importance of problem formulation in activity identification.

5 Conclusions

This study proposes a robust framework for identifying automated construction operations with high accuracy. The hierarchical operation recognition framework formulates the identification problem into a hierarchy of learning tasks. The performance of this framework is compared with the conventional approach to operation recognition using a flat list of classes representing activities.

Both approaches use ANN as the learning algorithm. Even though their performances are comparable at the top level, the hierarchical framework outperforms the conventional approach while identifying operations with minute levels of details. Most previous activity recognition studies have attempted to improve the performance by carefully selecting data, and exploring learning algorithms, training options, parameter selection and features extracted. This study shows that the problem formulation can make a tremendous difference in the performance.

Abstract -

The following paper is discussing the potential excavation systems and development of the production tool system of a small-scale mining robot. The limitations of power and weight increase the complexity of the design of the production tools immensely. Each excavation method's efficiency is depending on the material to be excavated, the available power and the machine's capability of handling the reaction forces. In this paper, different, individual excavation methods will be compared and analysed for their applicability. This includes conventional, alternative and combined excavation tools. The individual technologies are assessed in terms of their efficiency and feasibility by surveying existing technologies and analytical studies. The contribution of this paper is a summary of viable excavation methods for small-scale robotic miners.

Excavation; Production Tools; Robotics; Small-scale Mining

1 Introduction

Upcoming challenges in mining due to sustainability and ecological aspects require additional efforts in research and development. The trend towards zero personnel in underground mining demands full mechanization and automation of the mining process up to the use of fully autonomously operating robots. To reduce the residue risk to a minimum for workers in harsh conditions, it is indispensable to develop automated mining machines, which can take over the hazardous parts of the mining operation. Some of the work is already done entirely by independently working machines, but there is still personnel needed for many different tasks (e.g. maintenance). Possible tasks for robots in mining are the maintenance of machinery, exploration (e.g. abandoned mines) and selective mining (especially in difficult to access areas). [1, 2]

Today we see early research and development in robot technology [2], which are expected to replace the human workforce in underground mining within the next 30 years, see figure 1.

Figure 1. Robotics in mining - Prospect

The progress during this timeline can be divided in 3 parts, which will all develop consequently. Ongoing researches focus on the development of new mining and perception systems and also on sustainable mining ecosystems. The goal of the next 10 years is to create first industrial pilots, which can operate semi-autonomously in "small deposit scenarios". Eventually, the vision for 2050 is to have completely autonomous systems, which are able to work in ultra-depth scenarios.

In this paper, excavation methods are assessed in terms of their applicability for a small-scale mining robot.

Scope of this robot are exploration and selective mining underground, under water and in slurries. One of the key components of this robot is the production tool system, capable of mining hard and abrasive rock. Considerably low weight and power are challenges to be overcome in this project.

2 Excavation methods

In mining, the excavation of material can be performed by many different methods. For the subsequent analysis, the excavation methods are classified in four main categories: drilling and blasting, mechanical excavation, alternative excavation and combined excavation (figure 2).

Figure 2. Classification - Excavation methods

2.1 Drilling and blasting

The drilling and blasting method is one of the most used excavation methods for extracting large amounts of hard rock [3]. Drilling the boreholes is usually done by automated drill rigs, equipped with specifically selected drills. Standardized drilling methods are electro-hydraulically, rotary or rotary-percussive drilling (explained in section 2.2.1). Applications of drilling and blasting can be found in rock excavation and tunneling. [3, 4, 5]

Drilling and blasting is known for its generic applicability, the high production rate and the high grade of fragmentation. Especially when mechanical excavation reaches its limits, drilling and blasting proves its effectiveness. On the other side, drilling and blasting requires a series of individual tools, the blasting process is accompanied by some side effects (noise, vibration and toxic fumes) and represents generally a discontinuous excavation process. [3]

The low reaction forces of the drilling process and the capability of excavating very hard material are beneficial f or t he r ealization o f t he m ining r obot and therefore, the applicability to a robotic-miner will be assessed in more detail in section 3

2.2 Mechanical excavation

Mechanical excavation is next to drilling and blasting the second main excavation technique in mining [3, 5]. Compared to drilling and blasting, mechanical excavation has some benefits [3]:

- Safer operation
- Potential for selective mining
- Continuous excavation

In this section conventional mechanical excavation methods are described and analysed in terms of their applicability to a robotic miner.

2.2.1 Drilling

Drilling is mainly used as one link in the chain of an excavation process (e.g. drilling and blasting) or as an auxiliary tool, but not as a standalone excavation method due to the low production rate. Further applications are drilling well holes and material collection by sample drilling [6].

Drilling is a comparatively easy technology and is able to excavate small amounts of both soft and hard rock with the suitable technology. State-of-the-art drilling methods used, are:

- Tophammer drilling
- Down-the-hole-hammer drilling
- Rotary drilling
- Core drilling

In section 3 drilling will be analysed in more detail in connection with the applicability assessment of drilling and blasting.

2.2.2 Partial-face cutting

Partial-face cutting machines are excavating only a part of the rock face at a time and are known for their mobility and flexibility. The cutting head is a rotating drum, equipped with picks and mounted on a boom. During the cutting process, only a number of the entire amount of picks is in contact with the rock to be excavated. [3]

With a partial-face cutting head, large volumes of soft to medium hard rock can be excavated, curves be cut and tunnels be created. [3, 7]

In the mining industry, partial-face cutting machines (e.g. roadheaders) are mining machines with usually high mass

and weight to be able to penetrate the rock. The machine needs to withstand the high reaction forces resulting from the cutting process.
