Reusing existing ontologies can save time taken to build the ontology from scratch. Several online ontology libraries were searched, such as the Ontolingua, DAML, and DMOZ; however, no relevant ontologies were found. Current bridge maintenance ontologies focus on the static information of bridge components rather than the rehabilitation project process, and therefore, such ontologies were not adopted [1, 10]. Nevertheless, there are some ontologies including common taxonomies of construction task and constraints [5, 6, 11, 27] which fit the scope of CBRPMO and thus were adopted as reference for the following steps.

3.3 Collecting domain terms

Critical terms of concrete bridge rehabilitation were identified in this step, including project entities, e.g. tasks/procedures, constraints, and project participants, their attributes (e.g. the finish date of a task), and relations between entities. Five types of relations were identified: 1) between tasks and procedures; 2) between procedures and constraints; 3) between constraints, i.e. if one constraint is not removed timely, the removal of its related constraints related may also be delayed; for instance, if design drawings are not provided, working plans depending on the drawings can be delayed; 4) between tasks/procedures and participants supervising the task/procedures; and 5) between constraints and participants responsible for constraint removal.

Table 1. Profiles of focus group participants

Expert No.	Years of experience	Area of expertise
1	8	Application of ICTs in infrastructure projects
2	8	Construction management
3	10	Bridge design and construction
4	11	Bridge maintenance and rehabilitation
5	13	
6	15	

Reviewing related documents is a common approach to realise this step [9, 17, 19]. This study reviewed 11 manuals and 52 cases reports in China, North America, and Australia, because of the large volume and rich experience of bridge maintenance in these regions [1, 13]. A focus group was organised to refine the findings. Six experts from both academia and industry were invited, who were selected based on experience and expertise of bridge maintenance [20] (see Table 1). This is necessary because the initial findings can be biased to the authors' knowledge and thus need to be modified by experts. Moreover, the documents do not adequately reflect the third to fifth relations which are complex to model. For instance, some material constraints can affect removal of equipment constraints, whereas the opposite scenario can occur for other constraints pairs. The relations of supervision and constrains removal also vary among projects. In addition, the documents do not consider the strength of the second and third relation, i.e. a procedure or constraint is more likely to be affected by some constraints if their removal is delayed, which is important to identify critical constraints.

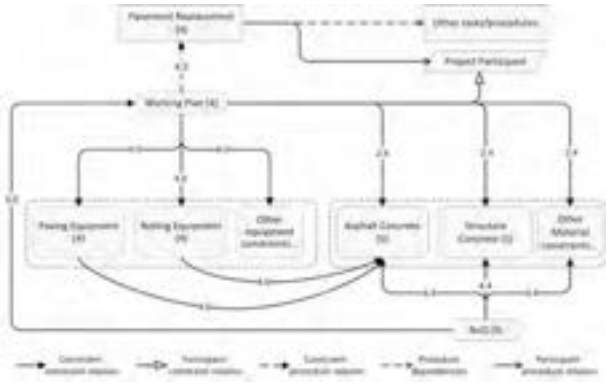

Figure 2. Partial view of the obtained relations (the numbers in this figure indicate the level of the class in the constraint hierarchy in Figure 5)

The results of this step include a terminology and knowledge of relations. The terminology maps tasks and procedures to constraints, and participants while records attributes of these entities. The obtained relations are shown in Figure 2. It should be noted that: 1) constraints are divided into groups (Figure 5) to facilitate relations setting-up; 2) only direct relations are considered; for instance, the bill of quantities directly affects material delivery, but it can also indirectly affect equipment supply by affecting working plans that determine the equipment, but such relation is addressed by the work plan; 3) relation strength ranges from 1 to 5, and larger numbers indicate higher strength; 4) Strength is rated at the most specific sub-classes of the constraint hierarchy under which, according to the experts, constraints have similar impact on others and thus can share the strength (see Figure 2); 5) because of the reliance on project conditions, experts only provide common practices for the fourth and fifth relations; for instance, sub-contractors often provide labour. Thus, such relations can be setup in specific projects.

3.4 Define Classes and Classes Hierarchy

In this step, classes are extracted from domain terms, using a mixed extraction approach where the most salient classes are extracted first, which are generalised and specialised. For instance, the term 'Deck System Replacement' is extracted, and then, 'Replacement' is extracted as its super-class, while terms like 'Pavement Replacement' and 'Auxiliary System Replacement' are extracted as its sub-classes. The classes are divided into four groups: rehabilitation task, constraint, project participant, and procedure. Each group forms a taxonomy and can be expanded up to the fifth level (as shown in the white boxes in Figures 4-6). A high-level overview of the CBRPMO is shown in Figure 3.

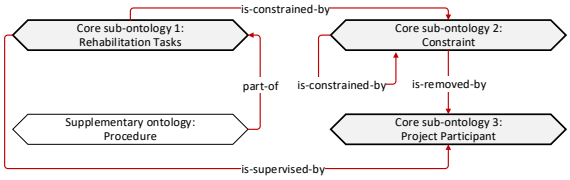

Figure 3. High-level overview of the CBRPMO

The taxonomy of rehabilitation tasks is shown in Figure 4. It should be noted that a task is often formed by procedures so that some procedures can proceed without removing all constraints. Thus, a taxonomy of procedures is built, with four basic classes: preparation, inspection, execution, and acceptance. A task can have some or all of these procedures, and a procedure can be detailed and expanded.

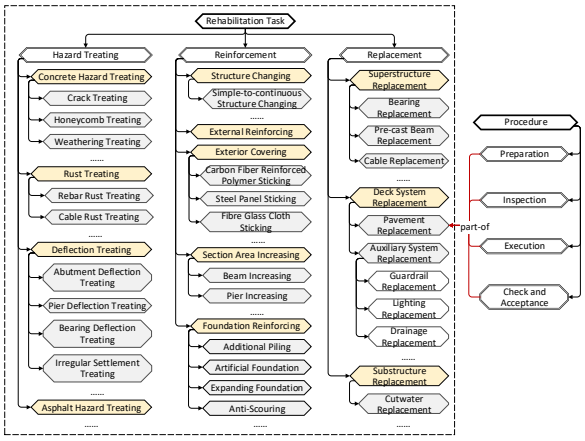

Figure 4. Overview of the tasks' taxonomy

The constraints taxonomy is shown in Figure 5. The engineering constraints refer to the absence of drawings and approvals, supply chain constraints include late delivery of materials and equipment, and site constraints hinder work of on-site crews [2].

The project participant taxonomy is shown in Figure 6. This taxonomy is mainly divided by responsibilities of participants, while project-level participants are first divided by project phases.

Figure 5. Overview of the constraints' taxonomy

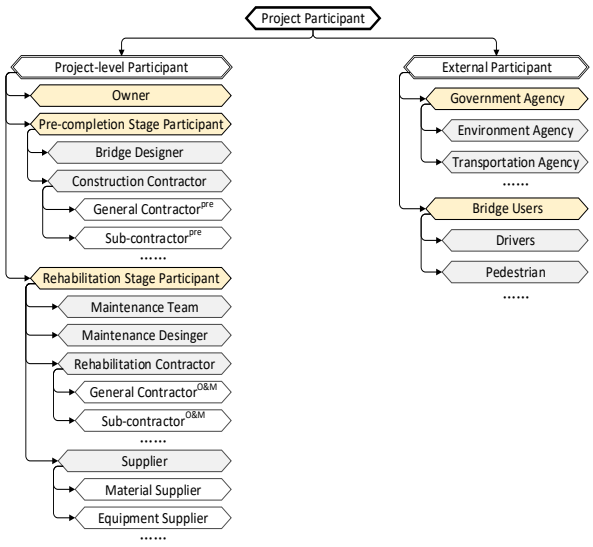

Figure 6. Overview of the taxonomy of project participants

3.5 Define Properties

Properties are relations that connect two classes or a class and its attributes, forming a subject-property-object triple [21]. There are three types of properties, i.e. object, datatype, and annotation properties. Object properties

describe relations among classes and instances of classes (Step 7), e.g. the 'is-constrained-by' relation between procedures and constraints and between two constraints. Datatype properties describe quantitative or qualitative attributes of classes and their instances. For instance, the 'Constraint' class has a 'has-planned-removal date' property linking the constraint to its expected date of removal. Annotation properties add explanations of classes, instances, and other properties. They can be applied to set relation strength between constraints and between procedures and constraints. Figure 7 shows examples of object properties while Figure 8 shows examples of datatype and annotation properties.

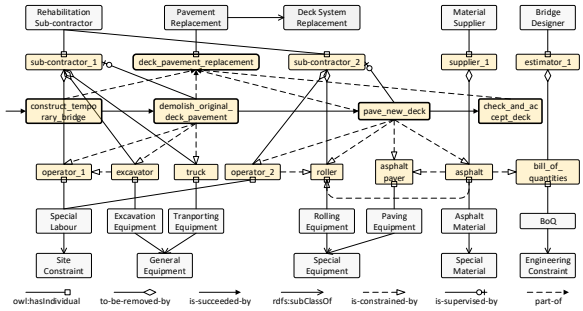

Figure 7. Properties in the CBRPMO

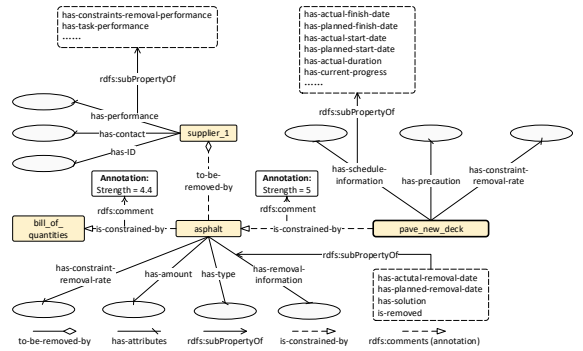

Figure 8. Properties in the CBRPMO

3.6 Define facets of properties

Facets can enrich semantics of properties, including cardinality restrictions, characteristic settings, and domain and range restrictions. Cardinality restrictions specify the number of values that a property can have, for instance, the 'has-actual-finish-date' property has a single cardinality because a task has only one actual finish date. For characteristics, object properties in the CBRPMO can be normal (no characteristics), transitive, symmetric, asymmetric, and invertible. A detailed introduction of characteristics can be found in [22]. Domain and range restrictions specify the type of the subject and object of a property, respectively. The type can be either datatypes or classes. For instance, the domain of 'has-actual-finish-date' and 'is-constrained-by' should be 'Date' datatype and 'Constraint' class, respectively. Properties and their facets are defined at the class level, which are inherited by instances of the class. For instance, during instance creation (Step 7), a task instance cannot be connected to a constraint instance through the 'is-supervised-by' because the property's range, i.e. object, is restricted to 'Project Participant'.

3.7 Create Instances

Instances represent specific and physical entities of abstract classes. For instance. the 'asphalt paver' and 'roller' in Figure 7 are instances of the class 'Special Equipment'. Instances creation is project dependent and should be performed during ontology implementation. The number of instances depends on the complexity and scale of the project whereas the names of instances can be flexible as long as they are consistent. Finally, as mentioned, properties of instances should comply with definitions of their classes.

4 Case Study

For a new ontology, its semantic and syntactical correctness must be verified. Semantic validation should be completed before implementing CBRPMO in real projects. This can be realised by asking competency questions, consulting experts, and ontology alignment. CBRPMO is a new ontology and there are no similar ontologies for cross comparison. Hence, the first two methods were adopted. Asking competency questions is a simple way to check semantics of CBRPMO[23]. Such questions should echo questions in A5 of Step 1 and cover both classes and instances, such as: 1) how many sub-classes do certain constraint classes have; 2) what are the constraints of certain constraints and procedures; 2) what are the planned/actual finished date of certain procedures; and 4) who are the participants responsible for removing certain constraints? Artificial instances (created by the authors for validation) can be created, and the CBRPMO is checked if it contains enough information to answer the questions.

Above self-checking was performed by the authors periodically during ontology development, which to some extent ensured semantic correctness of CBRPMO. In addition, the initial CBRPMO (i.e. without instances which should be created during implementation in practice) was sent to experts of the focus group mentioned before. The authors explained each class and property, e.g. the definition of the class and reasons to setup the property, to the experts to further validate semantic correctness and modify the ontology.

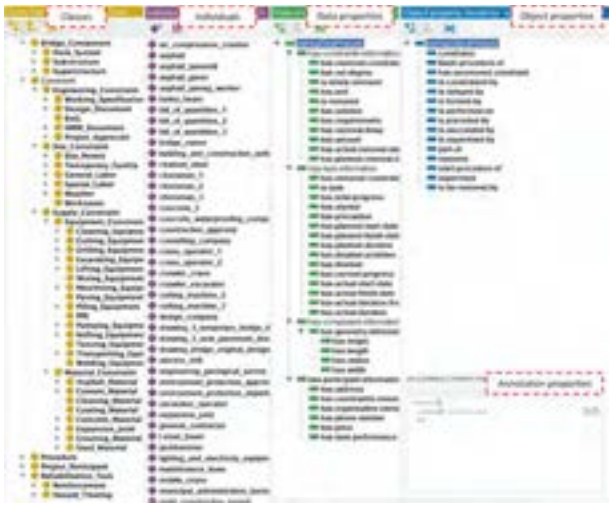

Figure 9. Partial review of the CBRPMO in the Protégé

On the other hand, syntactical validation checks the CBRPMO against ontology syntax, e.g. subsumption, equivalence, and consistency. Syntactical validation should be performed in both ontology creation and implementation phases. The validation can be realised by the Pellet reasoner which can detect syntactic errors in ontologies automatically. Whenever the CBRPMO was modified because of either self-checking or specific project conditions, the reasoner was ran to ensure the CBRPMO can pass syntactical validation [23].

The CBRPMO was implemented in a real project to demonstrate its usefulness for information management. This requires three components. 1) The ontological base. 2) A tool that can edit the ontology, where Protégé 5.50 was adopted. 3) A reasoner, i.e. Pallet, which interacts with the ontology by sending and interpret queries.

A rehabilitation project performed on the Jinghu bridge in Zhejiang, China, was selected to validate the CBRPMO. The bridge is a suspension bridge which is 415-m long. The rehabilitation took about five months (May to October 2018). The CBRPMO was implemented by creating instances and setting up and modifying properties between the instances by combing domain knowledge previously obtained and project specific information, such as information provided by the project team and information in project documents, e.g. work plans and equipment and material inventories. The resultant ontology in Protégé is shown in Figure 9.

The case focused on the deck pavement replacement task because it was the most time-consuming (more than 4 months) and labour-intensive task and it required more constraints than other tasks. It was assumed that the project manager wanted to search for information of the task. Instead of looking for information scattered in project documents or systems manually, the CBRPMO encoded relevant information to support efficient queries using SPARQL, which is demonstrated in Figure 10. To reflect the traditional method of searching information, the same information was manually searched by the authors in project documents and management systems. Then, the searching time was cross compared to show capability of the ontology.

Figure 10. SPARQL queries and results

Query 1 (Figure 10 (a)) not only shows constraints of a procedure (e.g. steel materials for temporary bridge construction) but also requirements (e.g. type and amount) of constraints, so that the manager can arrange constraint removal more easily.

Query 2 (Figure 10 (b)) can rapidly retrieve related information (e.g. contact information) of project participants (e.g. asphalt supplier), which can facilitate communication between the participants.

Query 3 (Figure 10 (c)) can show detailed activities and precautions of a procedure (e.g. new deck pavement). Such information can be generally required by onsite foreman and supervisors to supervise work sequences and quality.

Query 4 (Figure 10 (d)) can answer questions related to solutions to unremoved constraints (e.g. rain), serving as remedial actions when delay occurs.

The information of query 1, 2 and 3-4 was scattered in a project meeting record, an address book, and a work plan, respectively. A few information (e.g. certain steel materials to construct the temporary bridge) needed consulting the project team, which further increased the searching time. Table 2 compares the searching time through the CBRPMO and manual approach. It turns out searching time can be reduced significantly when the information from scattered sources is integrated.

Table 2. Comparison of searching time

Query	CBRPMO	Manual searching

1	0.13s	562s
2	0.08s	116s
3	0.09s	77s
4	0.11s	108s

In addition, the CBRPMO can also identify critical constraints of procedures and tasks. Specifically, the ontology forms a network with classes and instances as nodes and properties (i.e. relations) as edges. Hence, network measures (i.e. in-degree and out-degree) can be computed for every constraint instance, where the former reflects vulnerability (i.e. how many constraints can affect it), while the latter reflects its impact (i.e. how many other entities it can affect). The in- and out-degree of a constraint instance is computed by counting the number of inward and outward properties, weighted by the relation strength stored in annotation properties. Constraints with high degree are regarded as critical.

Figure 11 illustrates critical constraints at different levels. Figure 11(a) shows results at the procedure (i.e. new deck pavement) level. The vulnerable constraints include workspace, approvals, and equipment. Thus, more attention should be given to their constraints and responsible participants to minimise delay. Figure 11(b) shows constraints with greater impact on others at task (i.e. deck replacement) level, including engineering drawings, approvals, permits, and temporary facilities. Thus, they should be closely monitored, additional buffer should be assigned to procedures constrained by them, and remedial solutions should be proposed to mitigate impact when their removal is delayed.

Figure 11. Identification of critical constraints

5 Discussion and Conclusion

Successful rehabilitation projects are important for bridge maintenance. Such projects require effective integration of project information. The challenge is that such information is often buried and scattered in project documents and systems. However, studies on bridge rehabilitation are limited to engineering techniques and methods, which do not cover information management. In addition, although ontologies are effective tools to manage heterogenous and unstructured information, previous ontologies in the construction sector focus on integrating information of static objects of vertical building and bridge inspection and evaluation [4, 16]. However, bridge rehabilitation projects have specific information, e.g. specific constraints and tasks. Thus, existing ontologies cannot be directly applied. The proposed CBRPMO focuses on the rehabilitation stage therefore can bridge the gap. The CBRPMO was built by reviewing rehabilitation knowledge in case reports, manuals, standards, and related studies, which was refined through a focus group. As such, the CBRPMO covers sufficient knowledge in the bridge rehabilitation domain and can integrate scattered information of constraints, tasks and procedures, and participants in a software neutral environment.

The CBRPMO is an effective tool to integrate and search for various information in scattered sources, such as constraints of procedures, information of participants, solutions of unremoved constraints, as well as critical constraints. Moreover, extensibility and flexibility are important for ontologies. The CBRPMO can be merged with existing ontologies without major modifications. For example, the 'Procedure' class can be linked to bridge components in ontologies developed by [16, 17] through an object property 'is-performed-on'. However, currently, the CBRPMO was built manually, which can be time-consuming and inefficient. Therefore, the future studies will focus on automating development of the CBRPMO. For instance, information extraction methods can be employed to extract information from source documents for ontology development (e.g. manuals and standards) then automatically identify relevant classes and properties. Nevertheless, this study still lays a basis (e.g. the basic framework of the ontology) to implement those advanced techniques.

To this end, it can be argued that the CBRPMO has made a contribution by expanding ontologies in the bridge sector to cover the rehabilitation stage while it is also compatible with previously developed ontologies. As demonstrated in the case study, when the CBRPMO was implemented in projects, the project teams can access critical information for project management quickly rather than manually searching the scattered documents. Thus, enormous time can be saved, and the efficient exchange of information can also facilitate informed management decision-making.

IoT Enabled Framework for Real-time Management of Power-Tools at Construction Projects

Ashish Kumar Saxena[a], Varun Kumar Reja[a], and Koshy Varghese[a]

[a]Department of Civil Engineering, IIT Madras, India
E-mail: ashishsaxena816@gmail.com, varunreja7@gmail.com, koshy@iitm.ac.in

Abstract-

Real-time monitoring of the condition of equipment enhances effective decision-making in terms of machine maintenance and operational efficiency. This study presents a multi-layered system architecture to monitor the real-time health of a sensor-integrated hand-tool. The architecture is designed based on specific components, features, and requirements of each layer. The study discusses the flow of information in the system and addresses compatibility issues. The selection of required hardware and software was made based on the applicability and compatibility of various available alternatives. The selected modules were a sensor unit, an open-source IoT Platform, and a Wi-Fi Module. A prototype of the sensing unit was developed and was integrated with the tool for conducting the experiments to acquire the vibration data. The experimental setup was designed, and the free-run mode and drilling-mode acceleration data were generated. The obtained real-time acceleration plots indicate that the overall IoT system performed as intended. The quality of the data was verified using the Western Electric rules. The study extends the framework to a warning system using a freeware web-service, which operates sequentially. Upon arriving at the threshold value of acceleration, the web-service automatically sends a warning message to the maintenance team for on-time maintenance.

1 Introduction

"*Global Construction 2030*" estimates the construction output to grow by 85% worldwide by 2030 [1]. As per the empirical data and prediction of this study, this growth will be accompanied by the increasing use of small power tools that are essential to improve the productivity of the workforce. As practical experience and productivity logic demonstrates, timely and continuous availability of the tools ensures uninterrupted work at the sites. The relevance of smooth-functioning machines in operational sites may be derived from the survey conducted by one of the leading asset manufacturers Hilti Corp., which clearly quotes that "*On average of 90 hours a month are spent searching for assets across construction sites*." [2]. Apart from theoretical study and predictions, industry professionals also equate the loss in productivity with mismanagement of power tools, which results in tools going unaccounted and undocumented or noticed only when there is a requirement of the machine, thus furthering machine-attrition, waste, and loss of time. These seemingly minor losses can cumulatively result in overall delays in the project, causing heavy monetary and reputation loss. Addressing such loss is thus imperative from an academic as well as industry point of view. The mismanagement can be due to inconsistent implementation and monitoring.

Tools that are not maintained properly can perform below par or disrupt work through breakdowns, adversely affecting, not just their own functions but also of the interconnected tasks. As evident from most of the studies, most construction sites lack a systematic surveillance and maintenance strategy [3]. Currently, the best practices in tool maintenance rely on periodic maintenance either as specified by the manufacturer or when there is an apparent malfunction. However, technological advancements have made it possible to monitor and calibrate the characteristics of a tool in operation in more reliable, robust, and consistently cumulative manner. Based on the pattern changes in functioning tool characteristics; proactive and pre-emptive maintenance measures may be taken to resist machine attrition. Such measures can minimize operational interruptions and ensure the optimal performance of tools and workforce.

The objective of the study is to develop and test a framework for an IoT Enabled predictive maintenance schedule using real-time data. This will also facilitate remote monitoring of assets, making decision-making more efficient and rational. Most importantly, it will

aspire to offer a model that may be mapped on to complex situational systems, ensuring optimal machine productivity and safety with multiple monitoring frames.

As per a survey on power tools, drilling machines are among the most widely used hand tools in the construction industry [4]. As drills are constantly utilised on demanding tasks, they tend to require constant monitoring and maintenance to ensure the best performance. The scope of the current study is limited to the monitoring of hand-held drilling machines.

In terms of structure, this paper is broadly divided into four sections. The first section reviews the current practices in the field of equipment health maintenance. The second section explains the system architecture and design. This section explains the individual layers and their components and the flow of data across them. The third section studies the various parameters that affect the health of the machine. This section also describes the experimental setup and documents the results obtained. The final section discusses the results and intends the integration of the proposed framework with MathWorks' '*Predictive Maintenance Toolbox*' and its use in Machine prognostics. This section concludes the study with discussion on the future research scope in the domain of maintenance studies.

2 Review of Maintenance Planning

This section presents a brief review of maintenance planning and discusses the potential of IoT technologies for construction management.

2.1 Maintenance Planning

Equipment require maintenance due to various factors, ranging from systemic to situational. Usage patterns and ageing of the machine are key factors causing a decrease in reliability and functional ability of an equipment over time [5]. Most construction sites follow a time-based maintenance schedule for pragmatic purposes and in compliance to conventional industry requirements. Figure 1 shows a comparison of the three broad types of maintenance strategies in the industry [6].

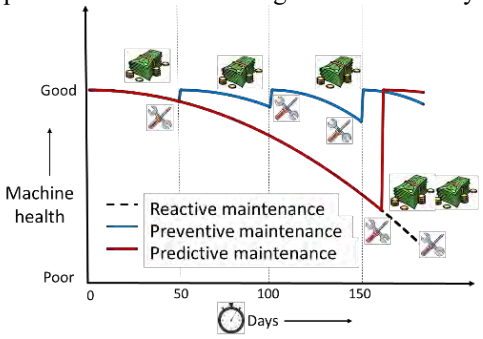

Figure 1. Maintenance Strategies based on MathWorks

The figure shows a trade-off between the usable life of the machine and the potential cost incurred in the maintenance. It clearly states that the predictive maintenance strategy is the most suitable among the three strategies, considering the improvement in the useful life in a more cost-efficient manner. This ensures pre-emptive measures and utilization of the machine and its components apropos of the designed life. This also confirms a method most suited to address unforeseeable interruptions based on its immediate condition.

Predictive Maintenance or Condition Based Maintenance (CBM) is based on monitoring of the visible performance parameters that indicate the deterioration of the machine. Some of these parameters for a drilling machine include vibration threshold, Rate of penetration (ROP), and temperature rise. Vibration-based condition monitoring can facilitate early detection of the problem, improve maintenance procedure, and avoid catastrophic failures which will ensure fullest functionality and uninterrupted usage of the machine [7]. CBM ensures that each component receives customized care, which also addresses the overall health and smooth functionality of the machine.

2.2 Potential of IoT technologies

Recent studies have shown the potential of sensor integrated automated systems to address abrupt impediments and perform customized micro-management of machines. The systems find a variety of applications in the field of personnel management, prefabrication, material management, and enhancing safety and quality at construction sites [8]–[10]. These systems allow detecting, analysing, measuring, and processing various changes like change in position of resources, the dimension of a facility, and textural appearance that occur in construction sites. Practitioners have appreciated the contribution of IoT based systems for batching plant monitoring, diesel generator utilization, and asset tracking systems for heavy machinery such as tower cranes, transit mixers, and trucks. Moreover, applications such as early flood detection (warning) system, predicting the location of workers in construction sites are thought-provoking ideas that can be utilised for efficient construction management. As most of the work in the field of IoT is focussed in monitoring the heavy machinery, workforce management, inventory management, and progress forecasting, power tools have been almost kept out of the scope of the IoT implementation. Hilti Corp., Trackinno, Qubes, and BOSCH are some of the pioneers in the field of automated power tool management system but most of the innovations in this field serve administrative purposes. These include maintaining a database of the tool, automatic utilization reports, and warnings about the pre-loaded maintenance schedule [11]–[13].

In Construction 4.0, an automated CBM framework can facilitate real-time health monitoring of the machine without any human intervention. This will reduce the chances of errors due to human involvement, such as delayed, misinterpreted, and manipulated information. IoT enabled system frameworks can enable real-time data transmission from the machine to the managers. The use of appropriate sensors is a crucial aspect of any IoT system for customized control and overall functionality. Understanding the behaviour of Micro-Electro-Mechanical Systems (MEMS) and the characteristics of an accelerometer or gyroscope allows designers to design more efficient and low-cost products for high-volume applications [14]. Various types of sensors, like RFID sensors, sound, and vibration sensors can discover the changes in the patterns of the data and can be part of an effective warning system, connecting each machine component to the overall machinery.

The selection of suitable sensors is a vital part of an IoT system, which integrates information and pre-emptive action through triggers and warning signals. There are various types of sensors ranging from a simple temperature and pressure sensor to a very sophisticated MEMS sensor such as MPU6050 and ADXL345, which can be selected based on specific situational requirements. Studies show that MEMS sensor-based systems have the potential to transfer the data over a network to an IoT platform using micro-controllers and Wi-Fi connectors [15]. The current study tries to create a warning system based on the real-time vibration values from the tool.

The literature on various IoT based frameworks shows that some of the major challenges in the implementation of IoT based system are privacy, security, and power consumption requirements of the system. The dynamic, complex, and often unpredictable nature of the environment at a construction site is also considered to be one of the major challenges along with the interoperability of different data formats, extendibility, and middleware challenges such as reliability and usability [16]. Some of the researchers have identified and argued that the failure of the IoT implementation could be attributed to scalability, adaptability, connectivity, maintainability, and inter-compatibility of the IoT components [17]. The current study averts the compatibility issue by identifying the resources that are fulfilling the requirements of the layers of a typical IoT system architecture. In the process, it aims to offer a reliable and elegant model where the practical impediments can be addressed and redressed at low cost.

3 System Architecture & Design

The overall system architecture and component-based design is a key part of this work. Figure 2 shows the layered architecture, the specific components, features, and requirements for each layer. These requirements of the layers are based on literature, on-line forums, and discussions held with the industry practitioners. Enabling the implementation in a constrained and complex environment requires a well-defined and robust IoT architecture [17]. Resource constraints such as low memory, bandwidth, and processing can pose challenges to practical implementation of IoT. This section discusses the details of each layer and the components required to implement this architecture for monitoring hand-held drilling equipment. The resources identified are found the best to serve the purpose of the study while fulfilling the specific layer requirements with their unique conditions. The resources are selected based on a comparative study of their counterparts, considering the future scope, cost and spatial benefits. As the MPU6050 sensor is a 6DOF with an integrated accelerometer, gyroscope, and a thermal sensing unit, it is expected to serve a wider range of applications at a reasonable cost. This also solves the issue of space constraint, by using single sensor that has multiple sensing units.

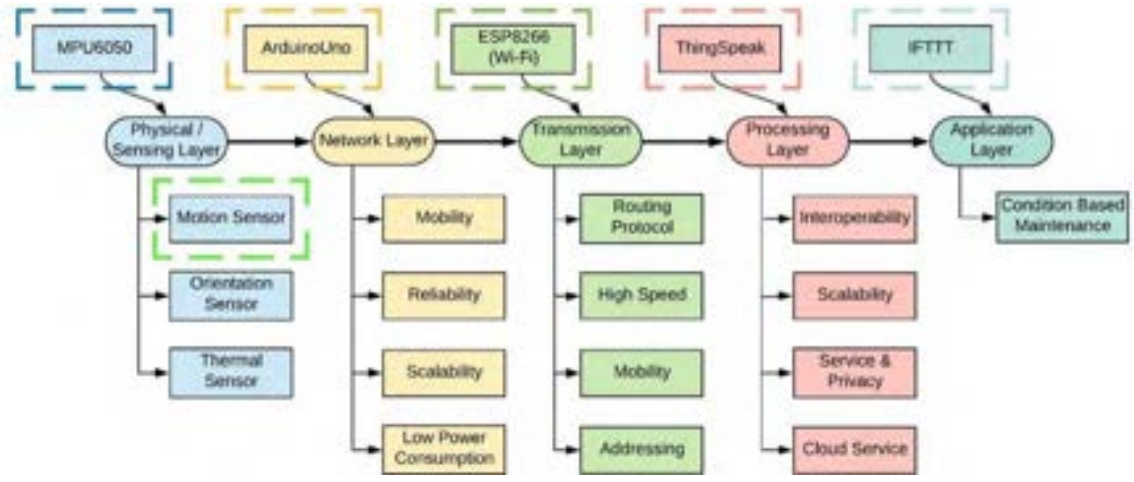

Figure 2. Resource identification in the IoT architecture layers

3.1 Multi-layered Architecture

A brief description of the architecture is as follows:

3.1.1 Physical / Sensing Layer

This layer senses the data through various sensors. It uses MPU6050, an MEMS sensor that measures acceleration, velocity, orientation, displacement in addition to the temperature sensing. This study uses the acceleration readings only, however angular and thermal sensing can add to the value and space utilization of the sensor over others. The "InvenSense document for the specification of MPU6000 and MPU6050" provides information about the connections and the key pin-values. The sensitivity of the accelerometer can be adjusted between ±2g to ±16g, to customize the requirement.

3.1.2 Network Layer

This layer acts as a communicator and transfers the data to the network through the Wi-Fi module. It uses ArduinoUNO, an open-source microcontroller which is equipped with pins for digital and analog input/output data. The sensor and the Wi-Fi module are connected to the Arduino by jumper wires. Arduino collects and transmits the data as per the code written in the IDE (Integrated Development Environment) [18]. The IDE is a cross-platform application that supports coding in most of the computer languages such as java, python, MATLAB, C, or C++. The necessary codes are available on github.com, which can be modified and be uploaded in the editor. The system should meet the minimum requirements to use the Arduino editor smoothly [19].

3.1.3 Transmission Layer

This layer comprises of a Wi-Fi module that transfers the data over the network without the use of any cable or direct communication material. In the current study, ESP8266, an economic Wi-Fi module is used that transmits the data to the IoT platform. The major impediments to the effective functioning of the module is poor network connectivity and volume of data being transferred. The quality network connectivity can affect the time in transferring the data and thus affect the overall functioning of the entire unit.

3.1.4 Processing Layer

This layer contains an IoT platform that is designed to enable a symbiotic relationship between the functioning machines and the maintenance personnel. ThingSpeak is chosen as the IoT platform here, which is an open-source platform and allows a more flexible and interactive interface. Real-time data collection, data analysis, data processing, data visualization, and message transmission are some of the key features of this platform. It is an intuitive, interactive, and inclusive operating system accommodating a wide range of user interfaces enabling a reliable monitoring environments such as C, Node.js, Python, and MATLAB.

3.1.5 Application Layer

This layer facilitates actuation from mobile or web-application for the end-users. IFTTT is a freeware web-based service that triggers the notification as soon as a certain condition is met. It uses real-time APIs (Automated Program Interface) to trigger the event and execute the action [20]. It can thus on auto-pilot mode and generate unique and relevant responses addressing complex and fast-changing situations. It also minimizes human intervention and the errors that can emerge from the same during dysfunctional moments that can potentially create disasters and hazards at workplace.

3.2 Flow of data

After identifying the resources for the study, a framework for the flow of data is necessary. Figure 3 shows a schematic diagram for the flow of data from the point of sensing to the point of notification. The diagram also considers the function that is to be performed in conjunction with each IoT ecosystem layers. This subsection explains interactions and interconnectedness among the various resources and the unique roles they play in the proposed framework.

MPU6050 sensor senses the three directional motion

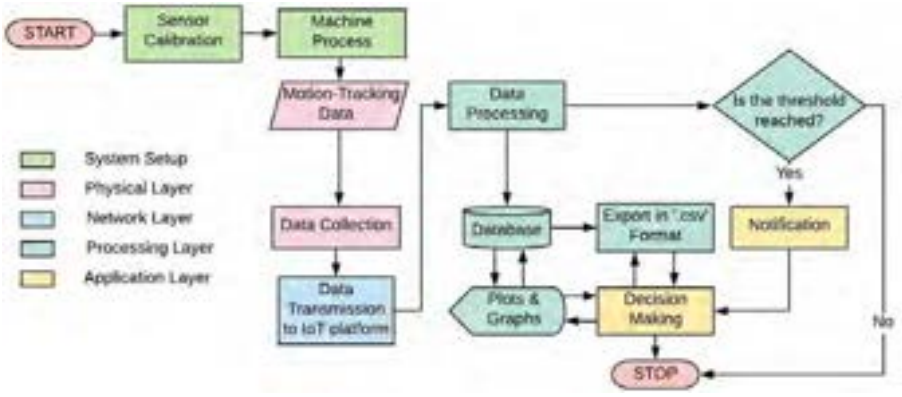

Figure 3. Flow Proposed system

of the machine. ArduinoUNO acts as a communicator for storing and transferring the data to 'ThingSpeak' through Wi-Fi module ESP8266 and data customization as per the application. The ArduinoUNO coding uses I2C library for transmission and easy functioning. ThingSpeak allows us to create channels to visualize the data. The data is transferred to the channels using the respective APIs, which ensures that correct data is used for analysis.

Moreover, ThingSpeak has an integrated 'Predictive Maintenance Toolbox' that facilitates the deployment of an analytical algorithm. A suitable algorithm can be used for estimating the Remaining Useful Life (RUL) of the machine. Another web-based freeware service IFTTT enables to create an event in order to run the system in real-time. The event includes the HTTP link of the ThingSpeak channel, threshold value, and the message that is to be displayed while notifying. The notification can be sent through Email or SMS. As soon as the threshold condition is met based on the data analytics, IFTTT triggers the alarm to the O&M team for timely intervention and maintenance.

4 Experimental Methodology

Having set up framework for the study, an experiment is designed to check the functionality of the proposed system. As already discussed, many performance parameters can be visible and reliable indicators of the machine's health. Figure 4 shows the cause and effect of the parameters that affect the performance indicators of a machine. A drilling operation includes multiple changes in the working environment of the machine. It can be understood from the literature and discussions held with the practitioners that one of the most explicit and easily recognisable indicators of the health of a machine is the amount of vibration produced. The amount of vibration largely depends on the age and size of the machine and drill-bits, the pressure applied while drilling, type of material drilled, and continuous usage of the machine. Process instabilities and wearing out of the cutting tool can be easily recognised by the changes in vibration patterns.

The interdependency of the indicators, as shown in Figure 4, allows us to explore further the effect of these input parameters on the performance indicators. Based on the discussions, the scope of the current study is limited to the accelerometer readings only, but the framework presented is theoretically applicable to all sensor-based systems with a suitable selection of sensors.

The experimental runs were conducted for various combinations of varying drill bit diameter (D: 5mm, 6mm, and 8mm) and plywood thickness (T: 12mm and 19mm) to check the variations in the acceleration produced in the machine, Rate of Penetration (ROP), and Time of Penetration. Figure 5 shows a schematic diagram for the proposed experimental setup.

The sensor-system comprising of MPU6050, ArduinoUNO, and ESP8266 is attached to the drilling machine. The material to be drilled is fixed in a firm place to prevent its movement. The sensor-system transmits the data to the ThingSpeak platform, which plots graphs, displaying the real-time acceleration produced in the three directions. Once the acceleration crosses the threshold (pre-fixed value), a warning is sent to the maintenance engineer for action. The data can also be downloaded in '*.csv*' format for records and further analysis. Thus, this model allows innovative intervention as well as archiving of data for production of templates that may be drawn on for future references.

4.1 Data Processing

Statistical Process Control (SPC) suggests the minimum number of data points to check the appropriateness of the experiment in Eq. (1):

$$ARL = \frac{1}{p} \quad (1)$$

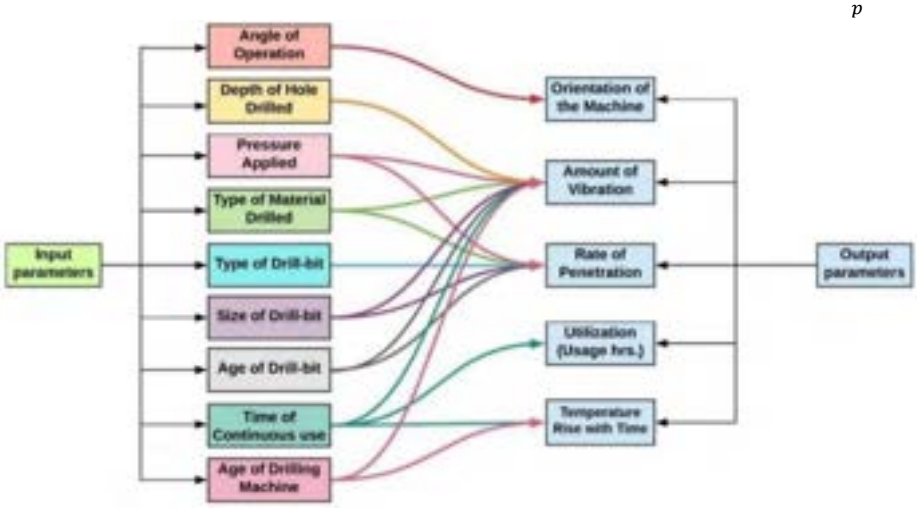

Figure 4. Factors affecting the performance

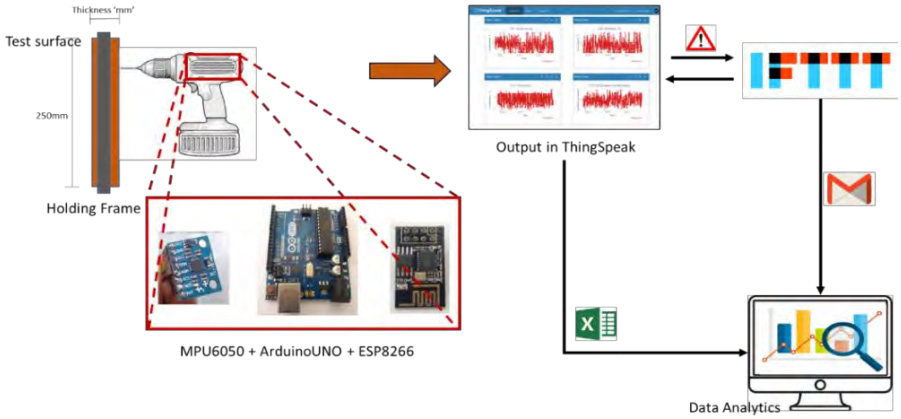

Figure 5. Schematic Diagram for Experimental Setup

For ±3σ control limits, p = 0.0027. Substituting value of 'p' in in Eq. (1) we get, ARL = 370 data points [21].

The trial runs were conducted for different D-T combinations to estimate an average penetration time for each combination. The code (ArduinoIDE) is adjusted so that the number of points is not less than 370. A drilling run is continued until the hole is perfectly penetrated.

As the individual resultants in the three directions may not justify showing the real motion produced in the machine, the Resultant (R) of the three accelerations is calculated using Eq (2) :

$$R = \sqrt{A_x^2 + A_y^2 + A_z^2} \quad (2)$$

The threshold value or the control limit (±3σ) for a D-T combination is determined from the RMS value of acceleration. For the scope of this study, the '+3σ value' is fixed as the threshold value to trigger the warning for maintenance. The trigger request is completed with a ThingHTTP, which initiates the predefined HTTP requests with an API key. Additionally, a GET request from the web when the threshold is reached and triggers the Webhooks at IFTTT which sends an Email with a customized message prompting immediate action.

Similarly, runs were conducted for the various D-T combinations and the free run condition. The results are discussed in the next section.

5 Results

The experiments were performed for various D-T combinations, and the results are shown in Figure 6 and Figure 7. Figure 6 shows the RMS Acceleration for a free run condition that gives a reliable idea about the inherent vibration in the machine when in operation. Figure 7 depicts a comparison of the ranges in which the value of RMS acceleration lies for the different D-T combinations.

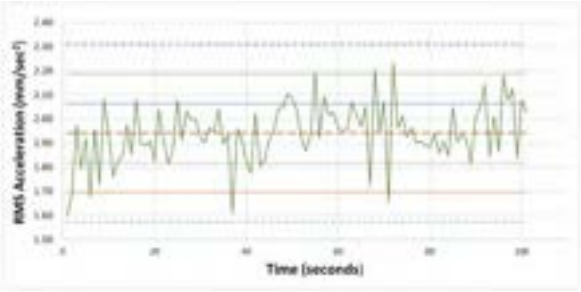

Figure 6. Observation for Free-run condition

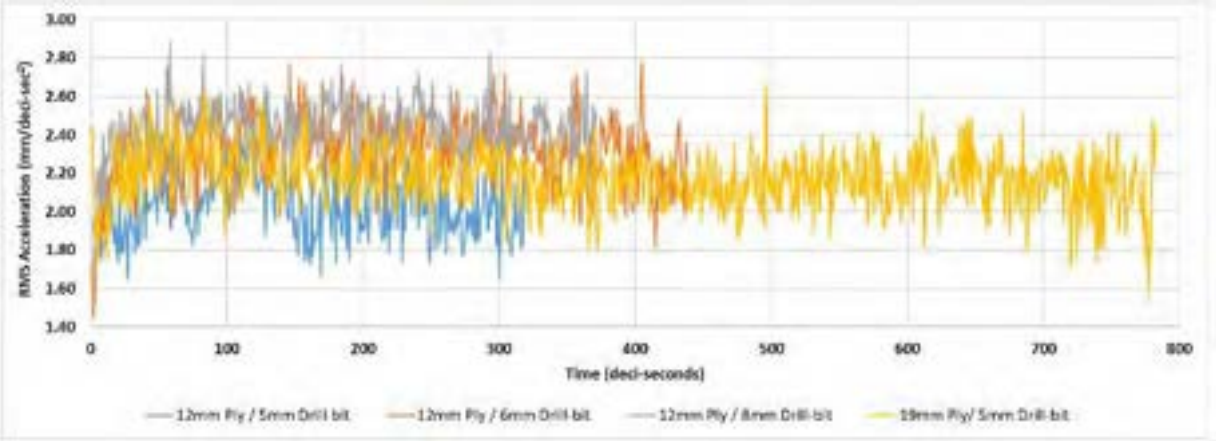

Figure 7. RMS acceleration for 12mm plywood and 5mm, 6mm and 8mm drill-bit diameter.; 19mm plywood and 5mm drill-bit diameter

The receipt of data on the IoT platform and the triggering of the Webhooks event named "Threshold Reached!" confirms that the proposed framework performed as expected. Figure 8 shows screenshots of the creation of ThingHTTP and warning received.

Figure 8. Setting up Threshold in ThingSpeak & receiving a warning from IFTTT

The quality of the data is checked using the 'Western Electric Rule', the results of which are summarized in Table 1. These rules are in accordance with the statistical norms and suggest that the quality of data is controlled under experimental as well as industrial conditions [21]. As there are no outliers in the plots, this explains the potential of the system to be used in sophisticated and controlled experiments across various situational frames.

Table 1. Western Electric Rules to check process control

S. No.	Decision Making Rules	Free-run	12P-8B	12P-6B	12P-5B	19P-5B
1	One or more points outside of the control limits	No	No	No	No	No
2	Two of three consecutive points outside the two-sigma warning limits but still inside the control limits.	No	No	No	No	No
3	Four of five consecutive points beyond the one-sigma limits.	No	No	No	No	No
4	A run of eight consecutive points on one side of the center line	Yes (1)	Yes (1)	Yes (1)	Yes (2)	Yes (3)

6 Discussion and Conclusion

The smooth functioning of the proposed system architecture and components validate the functionality of the system for the current scenario. This study facilitates the implementation of an effective IoT system for real-time health monitoring of a hand-held drilling machine. Testing the acquired data against the Western Electric Rules suggest that the quality of the experiment was controlled, and the exhibited framework can be used for a variety of applications in accordance with the selection of appropriate sensors. The successful functioning of the framework ensures that the tools can be monitored continuously and remotely through an inexpensive system, which is also practically easy to maintain.

The experimental setup plots the real-time acceleration data from the machine while in operation on an IoT platform. Vibration is one of the visible performance indicators of the machine's health, and can be used in the study of Machine Prognostics. This involves the estimation of RUL of the machine, which is a well-framed four-staged procedure. The process includes Data Acquisition, Health indicators (HI) construction, Health Stage (HS) division, and finally the RUL prediction. Various approaches, such as the statistical model-based (Random co-efficient, AR models, etc.), AI approach, Physics model-based approach, have been developed to display various strategies to predict the RUL [22]. The selection of an approach for RUL estimation is based on the type of application. For the scope of the current study, the RMS value of the resultant acceleration is considered as the threshold value for triggering the warning system.

Furthermore, the ThingSpeak platform has an integrated Toolbox for Predictive Maintenance supported by MathWorks. An appropriate algorithm can be deployed on the cloud using ThingSpeak and MATLAB prediction server to estimate the real-time RUL. This will monitor the health of the machine and warns once the threshold is achieved. These thresholds can be specific to the type and make of the machine. The presented framework facilitates keeping track of the used life of a machine, which is useful during the inter-site transfer of the machine. This can also enable the site management to have stricter surveillance over the hand tools and make more informed and intelligent procurement strategies.

Preliminary analysis should be conducted to decide the position of the sensor on the equipment, as the vibration data obtained will be sensitive to it. In this study, the sensor was attached based on the driller's convenience, at a place where it was assumed that the vibration is maximum. In some cases, the limited connectivity at construction sites due to the remote location is a challenge for the proposed architecture as it may result in delayed information due to the restricted transfer of data across the interconnected layers.

The predictive approach showcased here is expected to save a considerable amount of time, cost, and effort than what is conventionally required in the reactive or preventive approach. It will also allow end-users to utilize the machine up-to its design life. The system can be an appropriate tool for the manufacturing industry to design the components having similar operational lives.

The potential of advances in Machine Learning and Artificial Intelligence in conjunction with more

sophisticated sensors such as Hall sensor and tip-pressure sensor can make the system more robust and extensive. Furthermore, the system is expected to flourish with a substantial amount of data coming from the industry and using more advanced degradation models of ML learning integrated with AI. This study can be a robust and elegant template for future research on maintenance strategies.

Abstract –

During the early phases of building design, the architects create many variants and make important decisions about different design aspects and details mostly based on their own experience and know-how. In order to reduce the risks brought by arbitrary decisions, a lot of effort was put into developing simulation tools. However, most of these simulation tools require more elaborate details as what is available during these early phases, or they will provide some cumbersome results via oversimplification. Therefore, it is equally important to develop a communication tool enabling the earlier integration of suggestions given by diverse domain experts. Hence, a research based on the concept of adaptive detailing has been made by Zahedi and Petzold since 2018, according to which those suggestions and feedback provided by multiple domain-experts could be documented using a minimized machine-readable communication protocol based on BIM [1]. Consequently, an online platform for supporting the collaborative work through adaptive detailing at early stage of design is developed in this paper. This paper focuses on the Optimization of workflow and effectiveness of user interface in this platform. As evaluation of this platform, a user-study was carried out among students and practitioners in AEC industry. The result of user-study not only practically verifies the usefulness of this tool, but also implies the difficulty in transforming the daily communication mode into digital platform.

Keywords –

Building Information Modeling; Early Design Phases; Adaptive Detailing Strategies; Computer Supported Collaborative Work

1 Introduction

The integration of Building Information Modeling (BIM) applications at early stage of design have great impact on the final design and overall cost, while the additional costs resulting from design changes in early phases are also significantly lower [1]. Furthermore, the main idea of BIM is about the exchange of information including 3D-models with semantics among the participated domains [2]. For the reasons above, early collaborative work is of great importance to improve efficiency of design in a project.

However, according to our online survey 31.5% of the students or practitioners from the Architecture, Engineering and Construction (AEC) industry have tried BIM software as communication tool before at early stage of design, whereas 78.9% of them use BIM products for 3D modeling in design phase. Those statistics prove that more attention should be put on developing BIM tools for communication in design phase, so that diverse domain-experts could better help the architects by providing suggestions from their point of view.

This work aims to develop an online communication platform with optimized workflow and user interface, based on literature review on computer supported communication and collaboration, as well as on other BIM based communication tools on the market. The effectiveness of this platform would be validated during a user-study at the end of this paper.

2 State of the Art

2.1 Adaptive Detailing Strategies, Multi-LOD, and Building Development Level

Although many model-based planning tools are currently available, they require extensive input data and detailed model construction even in the early design phase. However, a model that is too precise and reliable can lead to incorrect assumptions and evaluations, such as in energy calculations or structural analyses, which affect planning decisions in all planning phases [2][3]. In order to close this gap, the research unit FOR2363 from German Research Foundation (DFG) is developing methods for the evaluation of architectural design

variants in the early stages of their development by means of adaptive detailing strategies that allow the detailing and evaluation of alternative, partially incomplete and vague building models [4]. This research project is also called Early BIM. To allow the explicit expression of potential information vagueness in the design phase, the research group develop a multi-LOD meta-model. Under the case of that, it is possible to define the uncertainty of information as well as building components at different LODs in a design variant [3]. A new concept called Building Development Level (BDL) is therefore introduced to describe the maturity of building models at difference design stages [3]. The BDL concept is also used in this project as milestone for new requirement of decision making.

2.2 Computer Supported Communication and Collaboration

To further promote communication and cooperation in the BIM field, the introduction of a research area called Computer Supported Cooperative Work (CSCW) is unavoidable. CSCW investigates on an interdisciplinary basis how individuals cooperate in working groups and how they can be supported by information and communication technology [5]. In this section mainly the socially acquired phenomena of CSCW research are described, whereas the technological aspects are explained afterwards in section 2.3.

Communication between the cooperating partners is the prerequisite for cooperation. The goal of cooperation is to coordinate the work processes and technical interfaces of the project participants as optimally as possible and to ensure a consistently efficient use of information [6].

2.3 File Formats for BIM Based Communication

The best-known collaboration format is the BIM Collaboration Format (BCF) from buildingSMART, which supports workflow communication in BIM processes. Project participants can use it to create various topics, such as problems, proposals and change requests. The BCF also allows the structured description of model conflicts or defects. Among other things, the camera position and the viewing direction are transmitted for the representation in the 3D model.

Since version 2.0, the BCF format also offers schematized files and machine-readable topics. However, this format is mainly used as comment based and human readable [4]. Therefore, based on the concept of adaptive detailing, and for better documenting suggestions and feedback provided by multiple domain-experts, a minimized machine-readable communication protocol based on BIM was developed by Zahedi and Pezold [6].

Using this protocol, a Feedback package contains information about:

- missing details in a design variant that are essential for a certain simulation to be performed
- suggested options to fulfill those missing details.

Further details about this minimized BIM-based communication protocol is discussed via demonstrative examples by Zahedi and Petzold [4][7]. Using this computer-interpretable protocol in communication tools can largely reduce the misunderstanding incidences in the whole progress.

2.4 BIM Based Communication Tools

With the development of software in AEC industry, many solutions which were mostly used for IT companies are now also integrated in BIM applications. For example, the ticket system, mainly used for tracing every request from the start until its completion, was firstly used in IT companies where a huge number of requests are produced in daily basis, is now widely embedded in BIM communication tools. Those tickets are normally shown in a dashboard and named “issues” or “tasks” in BIM based communication tools. Other frequently implemented functions are, for instance, presentation of the up-to-date overall information about the project, message notification, 3D visualization, marking and commenting on models, merging the partial models, preview of interim document, etc. The most popular BIM based applications such as Autodesk BIM 360, BIM Plus from Allplan, thinkproject, etc. have included all of these functions. However, the visualization mode of different types of data is seldom discussed. To fill this gap, various types of viewing mode or graphics will be provided in this project and tested via user evaluation.

3 Concept and Methodology

Practitioners in AEC industry are long used to conventional communication media such as face-to-face meetings, telephone, fax and email. However, for better decision making and more efficient information exchange in early design phases, it is reasonable to integrate BIM common data environment into the communication tool. In this way, the function for file exchange, preview of design variant and intuitive comparison of simulation results can be feasibly embedded (Figure 1).

As Lubich in Figure 2 suggested, the proper way to develop a CSCW tool starts from representing the working environment. In this case it means to explain how communication between project participants actually works, or what the conventional working environment in the construction industry is. Turk

explains that the most important activity in the construction industry is not "processing", such as problem solving or decision making, but maintaining a network of conversations in which requests and commitments lead to a successful completion of the work [8].

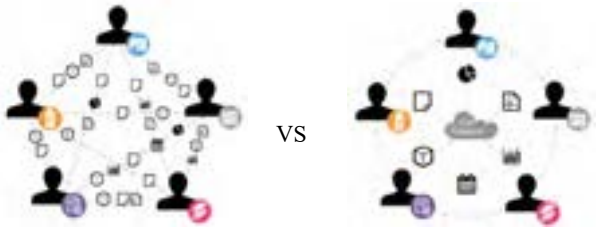

Figure 1. Compared to conventional communication, different communication methods are integrated into the new web-based platform.

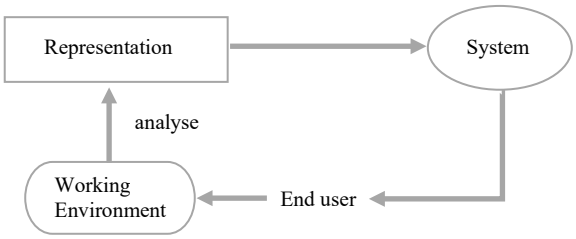

Figure 2. Development cycle of computer-aided collaboration software [9] (first orally presented by J.E.Dobson in 1991)

As we can observe in real working environment, it might possibly happen that an architect asks a civil engineer to check about the load-bearing structure, and the engineer accepts the request. Several days later the architect asks the engineer about whether the simulation result is generated or not. And finally, the engineer informs the architect that the task is finished. Of course, in most cases this process doesn't run smoothly, and there are normally special occasions happening during the process. Winograd and Flores have named such an interaction "conversations for action – those in which an interplay of requests and commissives are directed towards explicit cooperative action" and have therefore mapped the possible answers at each point in a conversation in an example model (see Figure 3) [10][11].

In this model, for example, one party (A) asks a question to another party (B). The request is interpreted by each party to meet certain conditions. After the initial statement (the request), B can accept (thus commit to meet the conditions), reject (to end the conversation), or make a counteroffer with alternative conditions. Each further confirmation has its own possible continuation (e.g. A can either accept, reject, or offer again the counteroffer from B). This diagram is not a model of the mental state of a speaker or listener but shows the conversation as a "dance" in which the actions create the structure or termination of the conversation.

To further use this model in the implementation part, it is translated into a graphical specification language, the Business Process Model and Notation (also known as BPMN) (see Figure 4).

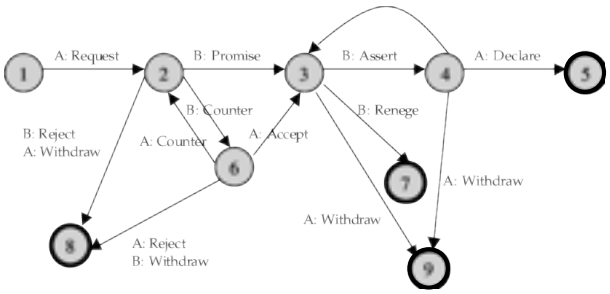

Figure 3. The basic conversation for action process model [10]

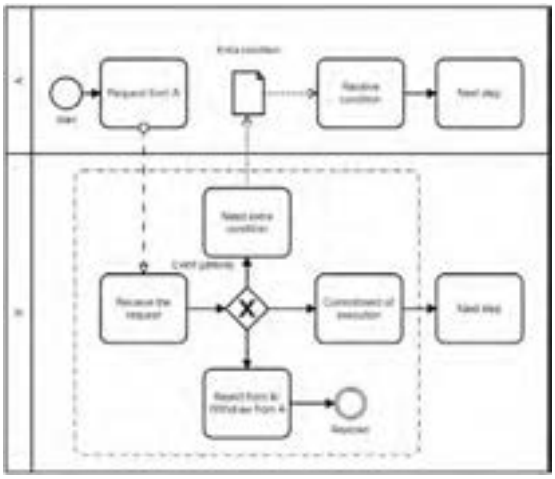

Figure 4. Simplified BPMN of the "conversation for action" model adapted to Maaß, 1991 [11]

4 Implementation

The implementation of optimized communication tool is carried out in two steps: 1. Definition of proper workflow of communication (corresponding to "Representation" in Figure 2); 2. Developing the tool (same as "System" in Figure 2).

4.1 Definition of optimized communication workflow in the platform

In the beginning of this step, a few concepts which are very often used in the workflow must be clarified:

- VARIANTS are the different versions of the design, which architects offer as a proposed solution.
- OPTIONS refer to the suggestions for the missing parts in variant which are provided by domain experts. The architects then may choose one of these options to fulfill the requirements for simulations.
- REQUEST contains the information of an action that the architects ask domain experts to execute, for instance, the request of simulation or request of options for missing parts. It is a kind of "Request for Information" (RFI), which is often used in business processes for collection of information and making decisions.
- FEEDBACK is the message that domain experts give to the architects including their reaction on the request, such as rejection, agreement, as well as further information. There could be three types of feedbacks: 1. Interim report on missing values which are necessary for the analysis or simulation; 2. Interim report with options; 3. Final report on simulation results and evaluations of various variants. Since a file format "feedback package" especially for the case of communication is invented [4][7][13], it will be used later for accurate expression of the feedback.

The workflow of this whole communication system is divided into three scenarios (Figure 5):

1. Request for analysis
   At a certain point, the architect needs simulation results and evaluations from other specialist planners. Therefore, he sends the planner a request for analysis by ticket. Using the ticket system, the whole process can be monitored and managed. General Information such as actor, deadline of the request and the processing status of each request/ticket can be displayed. According to the conversation to act model [11][12], there can be three possible types of reaction to any request for an action [4][7][13]: accept, reject or counteroffer with alternative conditions. If some geometric details or semantic information, which are necessary for further analysis, is missing, the specialist planner will give a feedback to the architects.

2. Request for options and update the variant
   In this case, after step 1, the architect receives a feedback with a message containing the missing values. Then he precedes to ask for options to continue the process. Although in the normal working environment, mostly an architect makes decisions based on his knowhow, but using adaptive detailing he could ask for experts' opinion via request for options.
   After the request, options for missing components, their consequences on analysis results, as well as a comparison between options will be packed up and sent back to the architect as feedback. The Architect would then evaluate the properties of each option, make a choice, and complete the variant model. The variant is therefore updated during the process.

3. Execution of simulation and optimize the variant
   The execution of the simulation can only be

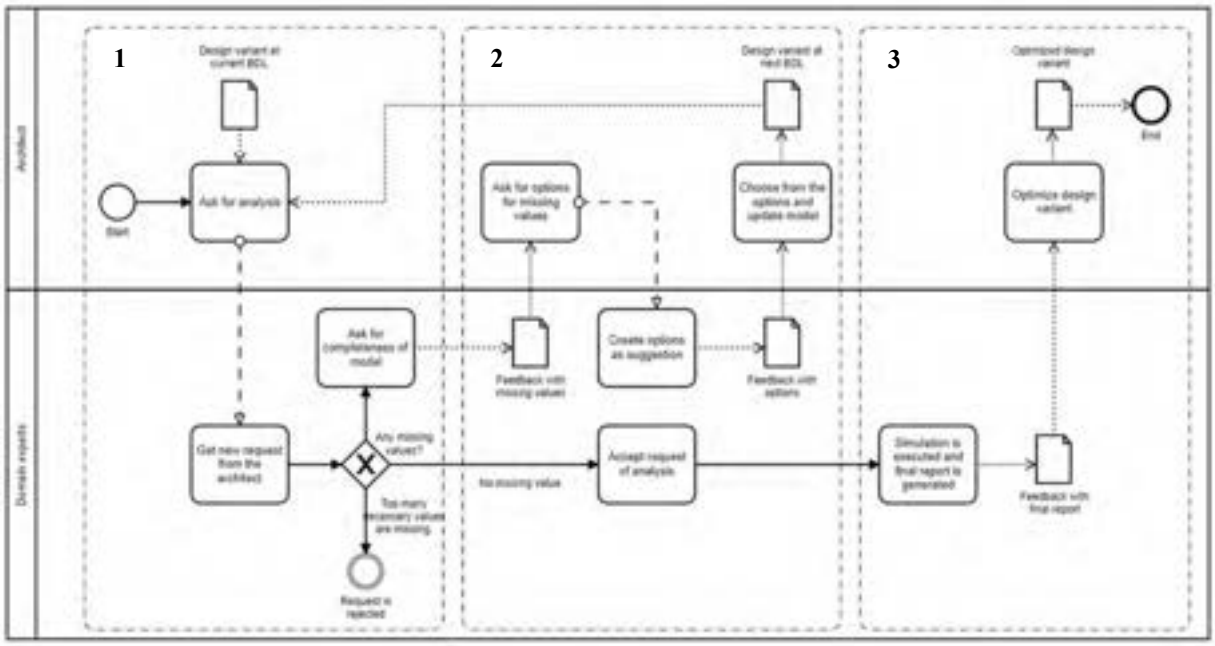

Figure 5. BPMN of the conversation for action Process between architects and specialist planners

achieved if the coordination model has already been checked by all the domain experts and has no more missing values. After the simulation, each domain expert submits a report with simulation result of the variant and their suggestions for optimization. The architect then collects all reports and accordingly improves the variant.

The objective of this whole workflow is to let domain experts give suggestions from their point of view as early as possible. It consequently prevents the case of endless revising on design model and reduces the potential problems which can become big issues in later phases.

4.2 Building the web-based communication tool with ideal user interface

4.2.1 Design of user interface

After the communication process is created, the functions in optimized workflow are first summarized in Table 1, so that the required items and their file format as well as possible visualization forms are categorized.

To visualize the core function of this communication system, which includes sending request and receiving feedback, a dialogue panel is created. On the dialogue panel, notification of new message, basic information in request or feedback, and project profile will be presented. Also, a block for free discussion between group members is available on the dialogue panel. In order to spare extra place for presenting content in details, the dialogue panel is designed as foldable (see Figure 6).

According to Gadelhak, Lang and Petzold [14], it is recommended to use a dashboard to display the attached information of the conversation. On one hand, several options can be displayed on different panels of a dashboard. On the other hand, the dashboard gives an overview of all relevant performance aspects of the building and can provide detailed information at the same time if required. The dashboard is therefore in this case particularly applicable for presenting and comparing various options or variants contained in feedback (see Figure 6).

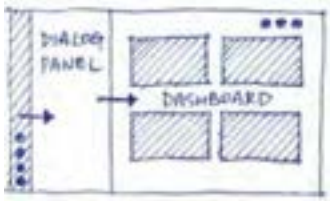

Figure 6. Layout and navigation of platform

4.2.2 Frontend development

In this project the frontend of the web-based application is implemented. There are two types of files to be visualized: the IFC files such as the coordination model and partial model, and the CSV/ JSON files that

		Final report	CSV	List/ Graphics

Figure 7. Various visualization mode for options

Figure 8. Different graphical representations of simulation results

capture the log and problems in the process or final report. The IFC file should first be transferred to the Obj file by data preprocessing such as ifc OpenShell or xbim toolkit. After that it is visualized by ObjLoader.js (provided by three.js) on the web page. Another important file type is the CSV file, which can record the process log, project status, option performance and final report. To visualize the data in several display modes, the libraries of ZingChart and Dygraphs are used specifically. To validate the specific process of implementation we take a three-storey office building of Ferdinand Tausandpfund GmbH & Co. KG [15] in Regensburg, Germany as an example. After the functions are organized and implemented, a web-based application could be developed.

Because all the information of requests and feedbacks is collected on the side of architect, it is meaningful to show the user interface from this view. As Figure 7 and 8 present, various graphical representations are provided. For comparing the options, user can choose floor plan view, bird eye view or inner perspective view (see Figure 7). And for identification of issues in simulation results, user can define a visualization mode from tree chart, pie chart or list (see Figure 8). As mentioned before in 2.4, one important objective of this project is to provide different visualization forms so as to test which one is more preferable for the user and gives the architect more intuitive criteria in decision making [13].

5 Evaluation

Since the implementation of the web-based communication tool is completed, 19 students or practitioners from the AEC industry were invited to participate a user experience study. After experiencing the whole process, more than 60% of the participants consider the platform to be usable in most cases.

It is worth mentioning that in the answer to the question "Which tool do you think is irreplaceable through this platform?" more than a half of users (almost 58%) still consider the face-to-face meeting as irreplaceable. It is very interesting for us because in hypothesis we considered the face-to-face meeting as the most likely replaced media. Some of the reasons given by respondents are:

- The personal meeting is always the most dynamic one and gives the quickest results.
- It can help solving complex problems.
- It is a quick and direct communication way.
- It is real time communication. Whenever you put up a question, there would be an answer immediately.

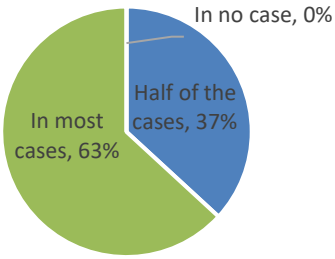

Figure 9. Answer to the question "In how many cases do you think this platform is applicable?"

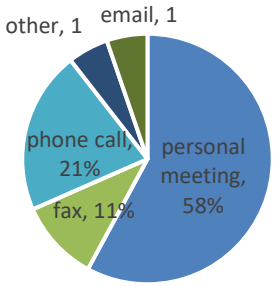

Figure 10. Answer to the question "Which of the following means of communication is irreplaceable by this platform?"

According to the user study, the communication system is helpful especially in illustrating the feedback, and the display of the simulation results. More specifically, most respondents chose bird eye view as best visualization mode for options (50%), and the list as most efficient graphical presentation for issues during simulation (50%) (see Figure 11 & Figure 12). These results for favorite graphical representation can be used later in other corresponding products.

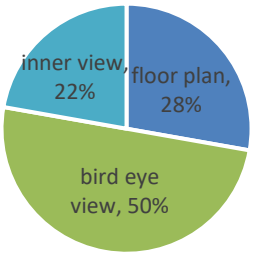

Figure 11. Answer to the question "Which of the visualization mode do you think is most suitable for presenting options?"

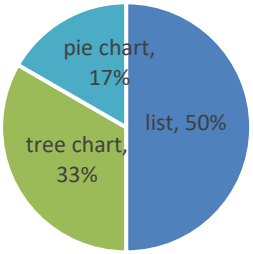

Figure 12. Answer to the question "Which of the graphical presentation do you think is the best for reporting issues in feedback?"

In the end there are also several suggestions for optimizing the communication platform:

- More real time communication in the model would be helpful.
- The authority levels from different users should be distinguished.
- In most of the cases, speedy replies are expected, therefore it would be great if the message notification can be improved and the hint of message priority can be tagged.
- The text should be bigger.

These suggestions are significant indicators for further development of this tool as well as for other similar products.

6 Conclusion

While the market for BIM applications is growing rapidly, there is still no effective working method for architects to propose the variants and discuss with other project participants about design. With the development of adaptive detailing strategies and multi-LOD, it is possible for the domain experts to participate in early design phases and to give suggestions even if there is still missing or vague values in design model. Furthermore, after the literature review on existing BIM based communication tools, the most practical functions, such as the ticket system, are collected and included in this case, whereas the request and feedback functions are embedded as core mechanisms for the communication workflow. Consequently, a BIM based communication platform especially for discussion at early design stages is built based on a specified workflow and in the end validated by a user-study. The result of the user-study shows an overall acceptance of this tool among users, as well as the preferred visualization mode for data in the feedback. These findings could be referred as important hint for further research or for software development in BIM field.

Considering the contribution of this communication platform, it was rewarded in year 2020 as the first prize in the category of Architecture in "Built on IT - Building professions with future" (Auf IT gebaut 2020) federal competition in Germany under the patronage of the Federal Ministry of Economics and Energy [16].

We gratefully acknowledge the support of the German Research Foundation (DFG) for funding the project under grant number FOR2363. We are thankful to the survey participants for their feedback. We thank Ferdinand Tausendpfund GmbH for providing its office building as a sample project.

Abstract -

Construction Site Layout Planning (SLP) is one among the processes that consider decision-making as essential to achieving the desired project performance. In lack of decision support system (DSS), the project planners employ learnings from experience to make decisions that often lead to sub-optimal planning of site, resulting in congestion, safety issues and loss in productivity. Therefore, to mitigate such risks, the SLP targets to identify the temporary facilities (TFs) required to aid the construction and optimally locate these TFs. SLP usually requires all the stakeholders to reach consensus and to aid this a few operations research (OR) models are developed in past studies. While SLP is often viewed as an optimal allocation problem by present research, the decision-making aspect involving multiple stakeholders is understudied. As a result, state-of-art research in modelling and optimal allocation using OR methods are not implemented on site. Therefore, targeting the decision-making in SLP, an approach is demonstrated to enhance the process through efficient exchange of information. This study employs building information modelling (BIM) to make data available for the modelled optimization problem. In addition to this, to foster the decision-making during the SLP task, the study presents an augmented reality (AR) enabled site layout planning decision support system (SLP-DSS) framework to aid the construction practitioners in SLP. The developed DSS with the functionality of AR integrated optimization is designed to make understand the generated solutions to the stakeholders in an efficient manner and targets to ease out the SLP process with a clear perspective exchange.

1 Introduction and Motivation

Construction site layout incorporates positioning of TFs on a construction site. This task is approached at the initial project phase when information related to the project is scarce. To overcome this limitation, the construction practitioners employ the learnings from previous similar projects [1]. Another challenge comes in the form of site topology and to understand it better, the 2D representation of the site in the form of computer-aided drawings (CAD) is employed. This sort of representation of 3D space requires tailoring of plans and elevations from different CAD sheets. Thus, resulting in additional mental exertion in the process of layout planning. The stakeholders involved in the process of planning site layouts sometime does not have enough experience to understand the 2D site representation. This leads to inaccurate information exchange while discussing SLP making the process of decision making cumbersome. SLP task involves stakeholders with individual goals [2] and the limited site space brings them together to plan for efficient space utilization. Thus, requires an efficient method to plan site layouts collaboratively with optimum space utilization. Moreover, to collaborate effectively, the exchange of perspectives in an efficient manner is a must.

In an attempt to release SLP of some obsolete hindrances in efficient decision-making pertaining to the layouts for the construction site, this study utilizes and demonstrates the applicability of technological advancements like BIM and AR. In addition to approach SLP through these advanced technologies, the research highlights optimization-based solution visualized in AR environment to mitigate the psychological efforts in understanding the generated output results. The utilization of BIM is targeted to address the information requirements to plan site layouts. The developed quantitative approach aided with visual aid is expected to enable the stakeholders to make informed and efficient decisions resulting in enhanced site productivity and a safer work environment.

2 Literature Review

Existing research on layout planning has extensively studied the SLP problem as an optimization problem. The quantitative approach to SLP results into numerical based output, requiring manual interpretation of the obtained results. Considering these challenges posed by optimization-based SLP models proposed in earlier research, a few researchers have attempted to consider DSS for SLP. These efforts were because the resulted output of optimization-based models is of no use until verified. In attempts to develop DSS for SLP, approaches like fuzzy-based multi-criteria model was developed and found useful in terms when the required information is imprecise [1]. Another tacit-based approach was developed to plan site layouts. This was approached utilizing a combination of repertory grid technique and interviews of construction professionals [3]. These both research presented examples of quantitative and learnings from the past based methods, respectively. However, the exchange of perspective while planning site layouts is a prime component of decision-making task; this comes out as a limitation to the existing research. Thus, BIM and AR are utilized to address these impediments to efficient SLP. The former provides input data if the models are prepared to the required level of detail (LOD) and the latter augments the optimal solution of the quantitative approach developed in this study for better exchange of perspective among stakeholders.

2.1 BIM for SLP

The utilization of BIM in the construction industry has been profound in the past decade [4]. In existing SLP concerned studies BIM has been adopted as a source of input data and a few researchers have highlighted LOD 300 as the required level of detail [5]. The data related to the materials required for construction and quantity take-off interested researchers to adopt BIM for layout planning. Another research has demonstrated the implementation of BIM integrated AR to establish efficient collaboration among stakeholders [6]. As BIM is data intrinsic model, its utilization can benefit data-centric tasks like SLP in the construction industry.

2.2 AR for SLP

The development of AR was initially conceptualized as a visual enhanced assistance tool to perform certain tasks. Tasks that require instructions delivered or exchange of perspective were primarily targeted to be benefited from this technology [7]. Implementation of AR to visualize and organize construction worksite was approached utilizing marker-based AR to plan rule base site plan [8].

3 Development of Framework for DSS

The study employs BIM to enable data availability following which the inputs to the optimization module of the DSS allows the generation of results. The BIM model developed to demonstrate the working of the developed DSS conforms LOD 300. The model comprises a structural frame for an industrial setup where the site is adequate to accommodate the required temporary facilities. The temporary facilities required to aid the construction are identified from the quantity take-off generated from the BIM model utilizing visual programming tool Dynamo. The developed BIM model enabled the extraction of data pertaining to cost and the distances from the locations identified as possible options to accommodate the required TFs.

Following the task of acquiring inputs, the mathematical model for the site has been modelled as an optimization problem. The objective function is focused to minimize the material transportation cost along with satisfying the constraints related to the positioning of TFs and restriction on locations available to locate the TFs. In order to minimize the transportation cost, the objective function is modelled as a function of decision variable with coefficient as the product of transportation cost per unit distance 'C_{mq}' and the distance 'D_{lq}' between the points of supply 'l' and demand 'q' as shown in (1. The decision variable 'X_{ml}' is modelled as a Boolean variable representing the position of TFs 'm' at a location 'l'.

$$\text{Min} \sum_{l=1}^{L} \sum_{m=1}^{M} \sum_{q=1}^{Q} C_{mq} D_{lq} X_{ml} \qquad (1)$$

The presented optimization model is adopted from existing research [9] presenting a discrete site layout planning problem. To present a better understanding, the following Figure 1 illustrates the points of material supply 'l' and demand 'q'.

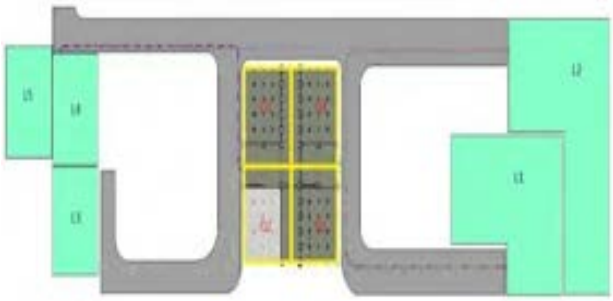

Figure 1. Description of supply and demand points

It indicates that the locations available to accommodate TFs are identified at prior and the continuous site space is divided into isolated areas to position the required TFs. The presented constrain in (2 is modelled to limit each identified location to accommodate a single TF. Similarly, each TF is allowed to occupy a single location on site satisfying the modelled constraint in (3.

$$\sum_{m=1}^{M} X_{ml} = 1 \qquad \text{Where, } \{l=1, 2\ldots L\} \qquad (2)$$

$$\sum_{l=1}^{L} X_{ml} = 1 \qquad \text{Where, } \{m=1, 2\ldots M\} \qquad (3)$$

The modelled optimization model is solved for the optimum value of the decision variable through genetic algorithm (GA). Thus, to obtain the optimum results the crossover and mutation operators are considered in this study. These operators helped in exploring and exploiting the search space in an effort to find the optimal solution. Once the optimal results are achieved, the AR rendering of the solution is generated to visualize the result. This visual aid in the augmented environment is prepared by integrating the code for optimization in the AR development software unity. The following Figure 2 elaborates the steps involved in the development of the AR-BIM enabled decision support system for SLP.

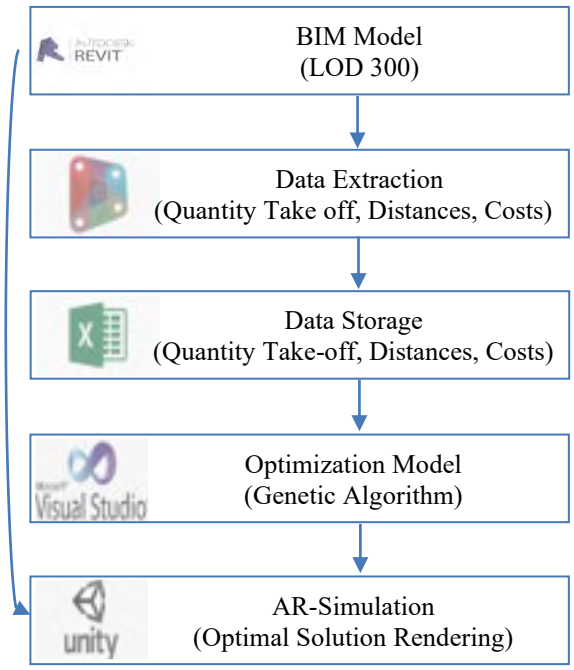

Figure 2. Schematic representation of framework for the proposed DSS

The AR visualization provides a simulation environment to test out the results generated through optimization model. This enhances the effectiveness of the mathematical model by transforming the numerical output of the optimization model to corresponding digital prototypes of the TFs located at the respective obtained locations. Thus, enables the informed decision-making in the process of SLP. A detailed elaboration of the usability of this developed approach is described in the following section.

4 Working of the Developed DSS for SLP

The developed DSS in this study comprises of three key components of any DSS framework i.e. data, model and graphical user interface referred in this research as data, solver and simulation. This section elaborates the approach to obtain efficient results from the developed DSS.

4.1 Data and Solver Component of SLP-DSS

The developed linear flow framework helps in eliminating iterations required for an efficient implementation. This task of developing a support system to aid construction professionals and other stakeholders in making decisions pertaining to SLP could be made as an integral part of the design. If did so, will cater the need of the detailed input data required for the DSS along with providing flexibility to alter certain aspects of design. The presented optimization model in this study targets minimization of the material transportation cost considering actual travel paths on construction site. Thus, for the purpose, the required information related to the materials to be transported, quantities to be handled and the distance travelled by respective material is extracted and stored as input to the optimization model. Table 1 and Table 2 presents the quantity take-off for respective material required for construction and the distance to travel from supply to the demand point on construction site, respectively.

Table 1. Material quantity take-off from BIM

Material	Q_1	Q_2	Q_3	Q_4
M_1 - Reinforcement Steel (Ton)	24.4	24.4	24.4	24.4
M_2 - Quantity of Prefab Steel (Ton)	0	702	0	0
M_3 - Quantity of Concrete (Cubic Meter)	406	405	405	406
M_4 - Quantity of Excavated Soil (Cubic Meter)	287	287	287	287
M_5 - Formwork Material (Ton)	21.5	21.5	21.5	21.5

Table 2. Distance matrix from BIM

	Q_1	Q_2	Q_3	Q_4
L_1	88	108	110	88
L_2	93	114	113	83
L_3	102	82	82	103
L_4	122	100	98	120
L_5	121	101	77	105

Once these inputs to the optimization model are available, a slight modification to the extracted quantities from the BIM model (Table 1) is done to find the required number of trips to be made by the transportation vehicle as shown in Table 3. Following this, the trips are converted to trip cost matrix for unit distance trips and then is multiplied with the distance matrix to obtain the transportation cost. A detailed explanation of the optimization model utilized in this study is available in the existing research [9].

Table 3. Trips required for material transport

Material	Q_1 Trips	Q_2 Trips	Q_3 Trips	Q_4 Trips
M_1	4	4	4	4
M_2	0	88	0	0
M_3	164	164	164	164
M_4	30	30	30	30
M_5	4	4	4	4

Thus, explained the working of the optimization model, the result obtained utilizing genetic algorithm in this research provided a Pareto front to choose a solution. However, the sophisticated approach of mathematical optimization is capable of providing an optimal solution in a reasonable time. The resulted output remains a challenge for the stakeholders discussing site layout if left with the solution as shown in Table 4. The interpretation of the optimal solution would be left upon the mental faculties of the practitioners involved in the task of layout planning. Sometimes these interpretations can be easy as can be perceived in Table 4, but with an increase in the number of materials required or locations available on site can complicate the resultant solution from the optimization model to understand.

Another challenge that is often tackled while planning site layouts is the dynamic nature of construction. This induces relocation of TFs on construction site such that the complexity in planning layouts manifold in multitude.

Table 4. Optimal solution from the optimization model

Optimal Position	Interpretation	Achieved Optimal Cost Unit
$\begin{bmatrix} 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix}$	M_1 at L_2 M_2 at L_4 M_3 at L_3 M_4 at L_1 M_5 at L_5	84,36,400

4.2 Visualization Component in SLP-DSS

SLP is a data-centric task and efficient results are expected through collaborative planning. Thus, it needed an information management tool along with visual management to aid planning for 3D site space utilization. This study is an attempt to furnish the requirements of the primary components of a DSS. The optimization module is supplemented with the functionality of AR to provide a better understanding of the optimal solutions obtained from the optimization model. Improved visualization is expected to help the stakeholders in presenting thoughts in clear and perceivable manner. The stakeholders involved in the task of SLP jointly come together to fulfil individual objectives due to constraint of sharing space common for all on the construction site. The task is subjected to participation from owner representative, project manager of the main contractor, sub-contractor representatives and site supervisors. This diverse participation with different goals to achieve and varying site experience calls for a common mode to experience each other's perspective. Thus, to enable this, the AR-enabled DSS is proposed in this research. The SLP-DSS in this research is developed as an android application that works with marker-less AR. Upon solving for optimal results in the SLP-DSS solver, the results are internally transferred to the unity platform for analyzing the position of respective TFs on the construction site. This internal information handling is achieved by formulating the optimization approach as part of a visualization script used to render the optimal results of optimization.

The application architecture performs in a cyclic manner as shown in Figure 3, enabling the user to initialize the scene and continue (Figure 3A). Once initialized the required TFs are automatically moved in the site space with coordinates at the origin of the scene and marking all the possible locations available for TFs green. The next step renders the site environment in the field of view of the handheld device used for the

purpose (Figure 3B). The application is provided with a user interface to overlay information in the augmented scene required for the user to run the inbuilt optimization algorithm. Once the run is complete the processor renders the optimal solution while placing the TFs at the optimal locations received from the optimization module (Figure 3C). The corresponding cost associated with the rendered solution is displayed to the user on the interface at the handheld device, along with the allowance to the user to move around the scene and verify the implementation possibility of the proposed solution (Figure 3D).

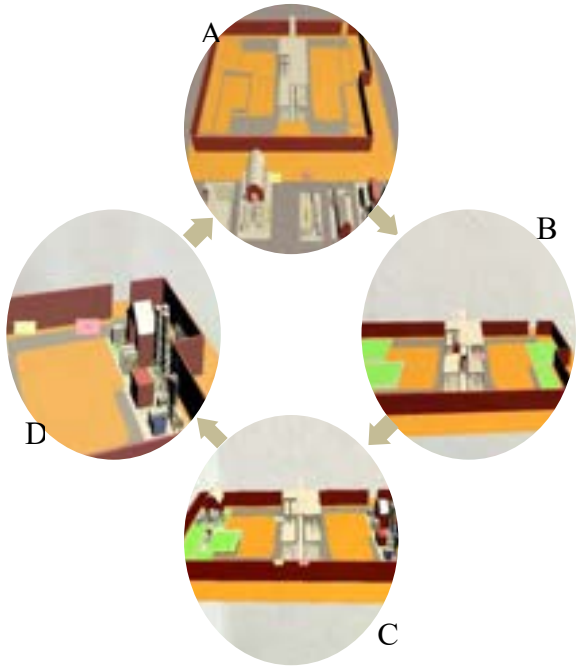

Figure3. Performance of the developed application

If unsatisfied with the results obtained, a rerun is available and the utilization of nature-inspired algorithm GA can be expected to provide another result from the Pareto optimal solutions as shown in Figure 4.

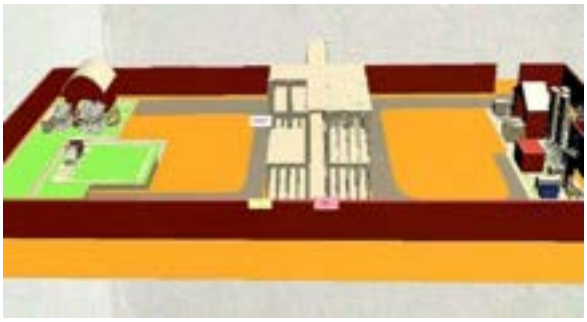

Figure 4. Visual interpretation of the optimal result

5 Limitations

The major limitation to this research comes from the objective function considered as static and discrete site layout example. In order to furnish full functionality of DSS it is proposed to consider other objectives relevant to SLP and the dynamic nature of the site is also needed to be captured. The functionality of the developed application for AR can be distributed among all the stakeholders, where inputs to the augmented scene are possible. This manipulative AR environment will reduce the search space and can provide opportunistic solutions in cases where specific objectives are not modelled as part of the optimization module for SLP-DSS.

6 Conclusion

There exist studies proposing optimization-based approaches to SLP. A few have attempted to come up with a DSS for SLP with a prime focus on the quantitative approach. This study provides a framework of a functional DSS for SLP. The integration of AR for the purpose of visual management is targeted to aid better perspectival exchange among the stakeholders involved in the SLP task. The developed approach illustrates a way forward to make sense of the data available in project designs and the BIM models.

Factors Affecting the Implementation of AI-based Hearing Protection Technology at Construction Workplace

Yongcan Huang[a] and Tuyen Le[a]

[a]Glenn Department of Civil Engineering, Clemson University, USA
E-mail: yongcah@clemson.edu, tuyenl@clemson.edu

Abstract –
Standard hearing protection devices (HPDs) that reduce noise by strictly passive means are mandatory at construction sites. However, standard HPDs have been proved weaken the audibility of safety-critical sounds thus worsen construction workers' auditory situational awareness (ASA). Therefore, a wearable hearing protection technology that uses artificial intelligence (AI) to amplify safety-critical sounds while greatly attenuating ambient noise would be in great demand for construction safety monitoring. However, little to no study has provided clear evidence on understanding acceptance of the AI-based Hearing Protection Device (AI-HPD) since it is still in the early stages of development. To bridge the gap, this research sets out to identify important factors that need to be incorporated in the design consideration of AI-HPD and investigate users' intention of use which concerns us. The preliminary factor table is firstly generated from critical literature reviews on existing technology adoption theories. Expert reviews help to refine the factor table. With all summarized factors integrated, the final questionnaire of main survey is developed and given out. Through the returned report, the study discusses overall results and points out further study. This study enables researchers and professionals to better understand critical design and implementation considerations for the success adoption of AI-HPD technology in the future.

Keywords –
Construction Safety Monitoring; AI Application; Hearing Protection; Influence Factor

1 Introduction

Situational awareness is associated with safety-related perceptions at construction sites, notifying field staff critical information, for example, the safe distance of field workers from onsite equipment [1]. Recent developments in the field of Artificial Intelligence (AI) have led to a revolution in Architecture, Engineering, Construction (AEC) and Facilities Management (FM) domain. In order to increase situational awareness at construction sites, a number of studies have been carried out to solve practical problems with the help of AI. Kim et al. developed augmented-reality-applied system "Proximity Warning system (PWS)", which set out to prevent users from collisions with objects [2]. In Mardonova & Choi's literature review paper on wearable devices and sensors that enhance workers' situational awareness during mining operations, four types of sensors have been classified accordingly: environmental sensor, biosensors, location tracking sensors and others. Based on related research so far, it can be concluded that situational awareness enhancement is getting more and more attention in both industry and academia [3].

A construction site is such an unpleasant workplace since it mixes up many kinds of sounds beyond comfort level. According to a report from University of Washington [4], construction workers are exposed to multi-level noises because of the equipment they regularly use on-site, such as bulldozers and impact drivers. The average intensity of the noises is well above the 85 dBA in general. However, any sound featuring intensity at 85 dBA or higher is believed to cause ear damage and is great enough to be defined as hazardous. With that said, denoising is a significant technical issue in terms of protecting field workers' hearing. On the other hand, safety-critical sounds at construction sites, varying from acoustic safety cues to human speeches, make great contributions to generating situational awareness that further directs workers' behaviors. Therefore, auditory situational awareness (ASA), referred to situational awareness resourced from auditory signals, has been introduced. Despite that, traditional hearing protection solutions for field workers such as earplugs fail to balance preventing from ear damage and promising ASA. A practical example of construction can interpret this scene. When a carpenter installs a sub floor by connecting it to wooden-frame joints and uses impact driver to put nails in the joint through the sub-floor, the

sound of a successful hitting the joint is different from the missed sound and signals the carpenter a well-done job. However, if the carpenter works with earplugs on, he/she is not able to hear the drilling sound clearly thus fails to give a swift inspection. Additionally, wearable devices are popularly applied to improve situational awareness in industries. As a result, a hearing protection technology in design of wearable device that uses AI to amplify safety-critical sounds while greatly attenuating ambient noise would be in great demand for preserving or augmenting the ASA of construction workers.

Audio signal processing for automated detection guarantees the technology of realizing the AI-based hearing protection device (AI-HPD). A variety of audio signal processing methods employing robust machine learning or deep learning models show prosperous successful potentials to quickly detect auditory safety cues and promise the ASA [5][6][7].These computing advances have been adapted to different contexts, ranging from indoor and public environments [8], medical and health care systems, to working environments [9]. However, when it comes to construction safety, it remains a problem to be addressed. Moreover, little to no study, to the best of our knowledge, has provided evidence on understanding the acceptance of AI-HPD because it stays the early stage of development. In view of the industry's infamous nature of resisting innovation, investigating what controls the successful acceptance of AI-HPD will provide useful information to convince practitioners of its viability.

In this paper, based on construction workers' hearing protection demands and current technical foundation, we envisioned a new AI-based hearing protection device. In an effort to explore user's input, concerns, requirements that are critical to the development of such technology in the future, we firstly listed possible factors according to a systematical literature review of social, physiological, and cognitive knowledge under the topics, for example, innovation adoption, technology acceptance. Then, we revised the factors in ways of introducing an expert panel review where experts from both the industry and the academia are invited to evaluate each factor. Subsequently, we proposed a questionnaire that integrates all reasonable factors after expert panel review and spread it to targeted group, practitioners who have working experiences at construction sites. After retrieving the returned questionnaires, we summarized and described the data and clarified our findings on it. At last, we concluded our work at this stage and pointed out future work.

2 METHOD

2.1 Influence Factors

In system/technology-related research, quite a few frequently used success models and adoption theories are applied to set up connections among multiple levels of practitioners on understanding the feasibility and benefits when an emerging system/technology is about to implemented [10]. Existing studies to date reveal that these basic models and theories have been extensively used across many fields in knowing the technology adoption and implementation, varying from financial services, Internet to education. Construction industry is not an exception. Son et al. took an interest in figuring out a mobile computing device's acceptance by construction professionals. They extended Technology Acceptance Model (TAM) [11] to explore determinants of user satisfaction with the device and link between user satisfaction and perceived performance. In order to determine the success or failure of EPR (Enterprises Resource Planning) system implementation in construction industry, Chung et al. generated a success model by adapting TAM model with Delone and McLean's information systems [12] and integrating them with key project management principles [13]. In analyzing what affects individuals' intention to utilize new technology for the sake of better leading a construction business, Sargent et al. practiced the Unified Theory of Acceptance and Use of Technology (UTAUT) model to examine IT adoption in construction management [14]. In previous studies, researchers followed a general workflow in preparation for confirming those factors controlling the success of a certain technology adoption: choose an original success model or theory, for example TAM, moderate the TAM based on the original model constructs and context-related variables, collect data and test the moderated model. Considering AI-HPD is part of innovation, confirming the factors can start from previous success models and adoption theories. In our study, we firstly put the basic constructs or variables of models in our factor table, like TAM, UTAUT, Delone and McLean Information System Success Model, Technology Organization Environment (TOE) Model [15], Theory of Planned Behavior (TPB) [16]. Secondly, we widely collected more technology adoption investigation documents in regard to the construction industry and also consider broader aspects of society, economy, and organization. By doing so, we developed a preliminary factor table for AI-HPD, which is supposed to be reviewed by the expert panel review and modified according to their comments.

2.2 Expert Panel Review

After the preliminary conceptional model comes into being, the content review by an expert panel is advised. Referring to previous study and sample size calculation, five experts including three researchers and two professionals in practice, with an average of 16-year experience in construction management, were suggested to review the preliminary factor table with regard to AI-HPD [17]. Out of getting sound and valid result, the candidate list for the expert review were selected from databases such as Google Scholar, ResearchGate, and LinkedIn by their academic or occupational relevance to the topic and academic influence. Three associate professors with key word tag Construction Management at Google Scholar respectively from the United States, Japan, China were invited to check the factor table via emails. Two USA-based civil engineers with approximate 20 years on-site working experience accepted the invitation. As a result, the final factor table was generated, as shown in Table 1.

Table 1. Factor table after expert review

No.	Factor	Definition or Scope
1	Participants Demographic Background	Age, institution or company, gender, race, annual income, education level, job title, hearing status, exposed-to-noise experience, hearing protection history
2	Perceived Usefulness	The degree to which a person believes that the use of AI-HPD would enhance his or her personal or job performance
3	Perceived Ease of Use	The degree to which a person believes that AI-HPD would be easy to use
4	Subjective Norms	Perception of important (or relevant) others' beliefs about my use of AI-HPD
5	Resistance to Innovation	The extent to which an individual resists new technology
6	Openness to Data Utilization	The extent to which an individual is comfortable with his or her data of job conditions being used and shared by a certain group while using AI-HPD
7	Hearing Health and Safety Consciousness	Awareness and care of hearing health conditions, and the degree to which hearing health concerns are integrated into an individual's regular work
8	Perceived Economic Constraints	Perception of the economic constraints or consideration of using AI-HPD
9	Perceived Organizational Impact	Perception of the organizational and societal constraints or influence of using AI-HPD
10	Attitude	User's general attitudes towards AI-HPD
11	Familiarity with the Use of AI Assistant	The degree to which the user is familiar with AI assistant
12	Trust	The extent to which an individual believes that using AI-HPD is secure, reliable, effective, and poses no privacy threats
13	Perceived Risks	A combination of uncertainty and seriousness of an outcome in relation to performance, safety, psychological or social uncertainties

2.3 Main Survey

The main survey was conducted in the form of a questionnaire, which consists of three primary sections, includes 79 open- and close-form questions. The first

section introduces fundamental know-how of AI-HPD such as working principles, working modes. After reading the product introduction, participants are expected to answer the trap questions that help to filter out unqualified responses. The trap questions follow the prompts of "I read and understood the introduction section about AI-HPD", "How many modes would the AI-HPD operate", "When using the device under mode 1, you will hear every ambient sound". The second section requests demographic-based information from the survey participants. The third section asks the participants to rate the perceived level of importance for each factor using a five-point Likert scale where 1 represents "Totally disagree" and 5 represents "Totally agree." In particular, the questionnaire survey was designed on the platform of an online tool Qualtrics and distributed to elicit responses from the participants about the importance of the identified factors. At the same time, Amazon Mechanical Turk assisted to identify and reach the targeted construction personnel [18].

In our study, the AI-HPD would offer the following two operation modes.

- **Under the mode 1**, the intelligent filter blocks every sound to the user's ears and only send an alert when a hazard event is detected. The user would not hear anything except for warning alerts.
- **Under the mode 2**, the intelligent filter reduces every sound to under a safe level, but amplifies any critical sounds detected and attenuating unimportant sounds. The user would hear every ambient sound along with a warning alert if any.

Additionally, Intention of Use functions as a very important indicator in testing the participants' acceptance; whether AI-HPD would be accepted or not, which mode would be accepted, whether users would like to recommend it to others, should be focused. Therefore, our survey design subdivides the final Intention of Use into four parts in order to fully reflect the participants' acceptance on AI-HPD, which is specified by following questions, "I intend to use AI-HPD if it is provided by my organization", "I would prefer to use AI-HPD under the condition the device is on the mode of blocking all sounds to my ears and sending me an alert if a hazard event is detected, considering that system might miss an important sound or send a wrong alert", "I would prefer to use AI-HPD under the condition the device is on the mode of reducing all sounds to a safe level, but bypasses and amplifies any critical sounds detected, considering that the system might fail to amplify a critical sound or amplify an unimportant sound", "I will encourage field workers who are exposed to hazardous noises to use AI-HPD for hearing protection". Besides, when setting up questions for factor Perceived Economic Constraints, a filter question "Do you work, or have you ever worked as a business leader of a project" is designed for stopping unqualified participants.

3 Data Description

There were 332 completed responses. An additional 68 participants began the survey but failed to complete it either quitting halfway or being filtered out by trap questions, resulting in a dropout rate of 17% (68/400). The median survey completion time was 437 seconds.

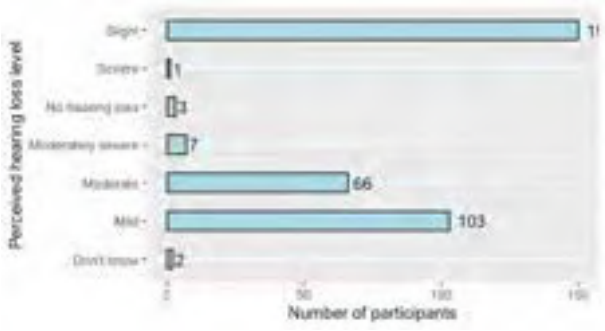

Figure 1. Perceived hearing loss as reported by participants. (N = 332)

3.1 Participant Background Characteristics

Participants ranged from 18 to 69 years old, with median age of 30 (M=32.9, SD=8.9). With all participants positively answering this question, the majority (78.3%) identified as female (N = 260), while 21.7% (N = 72) identified as male. 79.8 % of the participants hold Bachelor or higher degree (N = 265), however, only 1 participant didn't go to high school. Participant' s occupation diverged from business leader to carpenter. Figure 1 shows self-reported level of hearing loss that participants perceived they were suffering, as most participants reported slight or mild hearing loss. Similarly, at least 71.4% (N = 237) of the participants believed they were exposed to noises of different levels during working, as shown in Figure 2. When asked about if they put on hearing protection device whenever there is hazardous noise by Likert scale, the median located at 4 with standard deviation of 1.28, as Figure 3 shows the details. When asked about whether they have heard about any forms of loss caused by the use of hearing protection, the answers were split cleanly between Yes (P = 49.7%, N = 165) and No (P = 50.3%, N = 167), see Figure 4.

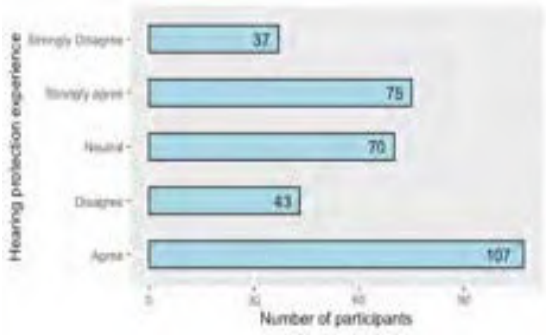

Figure 3. Hearing protection experience as reported by participants. (N = 332)

Figure 4. Heard about any injury case caused by using hearing protection as reported by participants. (N = 332)

3.2 Non-demographic factors and Intention of Use

Responses to non-demographic factors represent participants' attitudes towards AI-HPD under the premise they have understood this technology by browsing the introduction section. On the other hand, these factors, to certain degree, reflect the results of how society, economics, organization shape the way that participants treat such an innovation. Based on this, the data description of non-demographic factors is discussed.

Of Perceived Usefulness, approximate three quarters ("agree" or "strongly agree") of the respondents (P=72.5%, N=241) indicated that AI-HPD would be useful in improving the status-quo of construction sites. Just over 78.2% (N=261) of those who responded agreed that AI-HPD was supposed to be easy to use, concluded from the data of Perceived Ease of Use. In terms of Subjective Norms, 263 of 332 participants believed that people who were meant important to them would suggest them to practice AI-HPD if they got to know about it. As for Resistance to Innovation, different from the whole construction industry which posited a negative attitude towards innovation, almost 72.3% (N=240) of the participants were willing to try new technology. According to the result of Openness to Data Utilization, it's noteworthy that the population (P=61.4%, N=204) of those who positively agreed that job-related data could be used and shared was relatively less, in comparison to other factors. Specifically, only 80 of 332 participants chose "strongly agree" in this case, as shown in Table 2. In regard to Hearing Health and Safety Consciousness, the majority (P=81.3%, N=270) of the questionnaire takers concerned about their health and safety during job. Well under 7% of the participants didn't regard it as a big issue. Three questions were designed to observe Perceived Organizational Impact among the participants. When asked about "the regulations, policies, and procedures on safety in my organization is very strict", at least 241 of 332 believed that safety management was strictly performed in his/her organization. When asked about the hearing protection usage of collogues, by the question "most of my peers working in the field are currently using earplugs or earmuffs whenever required", 205 participants agreed that using earplugs or earmuff for hearing protection normally existed. At this time, the population of those who held neutral attitude rose up to 81 as shown in Table 3, which shows that a certain number of participants didn't have any knowledge about the hearing protection usage of their collogues. In the third question, when asked about "My peers who use earplugs or earmuffs for hearing protection have shown their demand in improving hearing capability", the statistics was very similar to that of the second question, explained by 210 responses of "agree" or "strongly agree" and 75 neutral responses. As for the factor Attitude, over 85.6% (N=284) of participants showed that they liked the idea of AI-HPD. In addition, 237 (P=71.4%) of the participants agreed that AI-HPD would be secure, reliable and efficient in terms of the factor Trust. Moreover, the result of Familiarity with the Use of AI Assistant indicated that most of the participants (P=85.2%, N=283) knew AI assistant well. However, when it came to Perceived Risks, 180 participants perceived that the risks such as misusing personal information, missing important sounds or sending wrong alerts were high. 83 of participants held neutral attitudes, explained by Table 4. This finding revealed that user information management and qualified technology are what concerned users and what we should pay special attention on. Additionally, there were 162 participants recognized as business leaders. More than 80% of them

agreed that their organizations had the funding to afford AI-HPD and 66.7% of them reckoned that the expense of AI-HPD would be high.

Table 2. Openness to Data Utilization as reported by participants. (N = 332)

Openness to Data Utilization	Number of participants	Percent of participants
Strongly disagree	29	8.7%
Disagree	44	13.2%
Neither agree nor disagree	55	16.6%
Agree	124	37.3%
Strongly agree	80	24.1%

Table 3. Perceived peers' hearing protection usage as reported by participants. (N = 332)

Perceived peers' hearing protection usage	Number of participants	Percent of participants
Strongly disagree	15	4.5%
Disagree	30	9.0%
Neither agree nor disagree	81	24.4%
Agree	120	36.1%
Strongly agree	86	25.9%

Table 4. Perceived Risks as reported by participants. (N = 332)

Perceived Risks	Number of participants	Percent of participants
Strongly disagree	14	4.2%
Disagree	55	16.6%
Neither agree nor disagree	83	25.0%
Agree	121	36.4%
Strongly agree	59	17.8%

We examined overall intention of using AI-HPD, and the degree of interest of two modes, and intention of recommending it. Overall intention of use was high, with 79.5% of the participants (N=264) "agree" (scale=4) or "strongly agree" (scale=5) to use AI-HPD. Around 56.6% (scale=4 or 5) of the participants with at least "agree" degree to use mode 1 (users would not hear anything except for warning alerts), while 75% participants show great interest in mode 2 (users would hear every ambient sound along with a warning alert if any), as shown in Figure 5. It was worth noting that participants who rate one mode with high interest may agree or disagree the other mode. However, as far as the acceptance of two modes is concerned, mode 2 seemed to be more popular. The result of intention of recommendation indicated over 83% (N=276, scale=4 or 5) of participants had a strong passion on letting more people know about it.

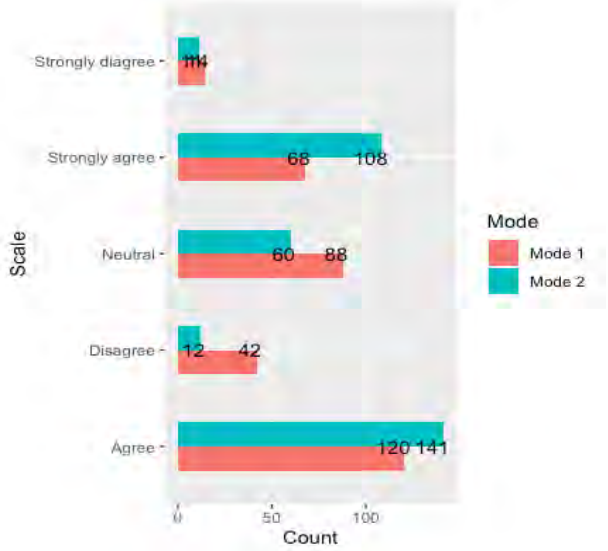

Figure 5. Intention of using Mode 1 and Mode 2

4 Conclusions and Future Work

This paper presents an effort to derive influence factors which control the successful acceptance and implementation of envisioned AI-HPD, a feasible hearing protection technology aiming to improve field worker's operating environments. Significant factors in the realm from social, physiological, economical and construction practice, were confirmed through a review of related literature and expert panel review. In order to further investigate the factors and pre-test workers' intention of using AI-HPD, a survey in the form of a questionnaire was generated, given out and returned with responses. Through describing and discussing the data retrieved, the authors expect this paper to help understand user's input, concerns, requirements that are critical to the development of such technology in the future.

As a result, it can be seen that noises have been an issue to most of the field workers and most of them tried or have been trying to avoid it by taking steps. As for findings from the statistics of non-demographic factors, user information management and qualified technology are what concerned users and where we should pay special attention in post product R&D stage. Quite a few participants believed that organizations they belong to were able to afford the expense of AI-HPD if it was considered; though the expense of AI-HPD was not perceived cheap. This signals us that the economic factors don't need to take up too much consideration when making decisions in the future work. The results of

Intention of Use showed that most people would like to use it; The working mode that enables users hear every ambient sound along with a warning alert if any was more popular, which directs us to focus on amplifying a certain sound in the background of noise in terms of auditory signal processing; large population of them would like to recommend this envisioned technology to their peers.

In future work, there are at least three aspects we should clarify. First, more specific discussions on each identified factor should be practiced. Second, different models or methods are suggested to be applied in analyzing how these factors affect the successful acceptance of AI-HPD and the coefficients of the distinguished factors. Third, the intention of use is made up of three parts, intention of using the technology, intention of choosing mode 1 or 2, intention of recommending the technology. Further data analysis of the subdivisions of intention of use is necessary.

Abstract –

Reusing of the past information and lessons learned helps practitioners in better management of various aspects of construction projects, such as cost estimation, planning, contracting, and design. Measuring the similarity of construction projects improves the efficiency of the existing information systems in retrieval of relevant cases. It was hypothesized that the Work Breakdown Structure (WBS) of projects contains the necessary information to measure the semantic similarity of construction projects; therefore, WBS can be used as a potential representative of the projects. In this research project, a novel method is proposed to assess the semantic similarity of projects by application of natural language processing techniques. In this method, a new project is compared with the documented as-built projects based on their WBS similarity. This method is implemented using two metrics: (1) node similarity that compares the semantics of all nodes in two WBSs; (2) structural similarity which compares the topology of the work breakdown structures. The proposed system calculates a similarity score between 0 and 1 for each metric and the combination of these two scores provides the final similarity score between a pair of WBSs, thus it could rank the similarity of the documented cases to the new project based on their final scores. Experimental results indicated that the structural similarity produced about 15 percent higher degree of retrieval precision than the node similarity.

Keywords –

Project similarity; Construction project; Work breakdown structure; Natural language processing; Knowledge management

1 Introduction

Effective reuse of gained knowledge from past projects helps managers to complete projects in a timely and economical manner, and with a higher quality [1]. In the construction industry, several methods such as knowledge management techniques and case-based reasoning (CBR) have been applied to reuse past information and experiences. A major step in the knowledge retrieval systems is to index stored data based on several attributes in order to find the most relevant document(s).

Knowledge management systems are IT-based systems that aim to improve the organizational process of knowledge creation, storage/retrieval, transfer, and application [2]. The process of knowledge retrieval is difficult and can result in irrelevant documents [3]. A method was proposed to retrieve relevant information in construction projects by keywords, such as project type and title, through a Google-like function [4].

A CBR system can offer a solution for new problems by recalling a similar past situation(s) [5]. CBR methods have been investigated in different areas of construction research, including cost estimation [6,7], safety [8], and planning [9,10]. In CBR systems, the similarity of cases is compared based on predefined nominal or numerical attributes. Finding the appropriate attributes and assigning weights are among the main challenges in these systems.

A quantitative similarity measurement among construction projects provides a comprehensive metric that can improve the process of retrieving related information. Current practices in similarity measurement of construction projects are limited. These methods distinguish construction projects based on generic factors, such as project size and location or specific user defined attributes, such as number of floors, structural system type or keywords, rather than the entire scope of the project The aim of this research is to fill this gap by proposing a method to compare projects using their WBSs.

WBS is one of the main outcomes of the processes in the scope management of projects [11]. The WBS is used in different project management areas such as time and cost management [11]. The proposed system is the first of the kind attempt to use WBS to measure the

similarity of the project scopes. The metrics for this assessment were developed using NLP techniques. NLP was employed to semantically compare the tasks and services within the WBSs.

1.1 Work breakdown structure (WBS)

WBS is s a hierarchical decomposition of the tasks and services to be carried out by the project team to achieve the project objectives [11]. WBS hierarchy begins with the project name at its highest level. The tasks and services in each level of the hierarchy are subdivided into smaller tasks that must be accomplished to satisfy the higher-level packages (samples in Figure 1). This decomposition continues until the tasks cannot be broken down or are no longer meaningful.

1.2 Semantic similarity measurements

The aim of the studies in NLP area is to enable computers to understand natural language text and speech used in human communications [12]. Measuring the similarity between words and sentences is an NLP technique that has been used in different areas, such as text classification, document clustering, and text summarization [13]. Corpus-based [14] and knowledge-based systems are utilized to semantically measure the similarity of words based on their definitions.

In the knowledge-based systems, semantic similarities are measured based on semantic relations among concepts [15]. These relations are embedded in the semantic networks. WordNet, a lexical database of English, is one of the most popular semantic networks [16]. The hierarchical structure of WordNet contains various semantic relations, such as synonymy, autonomy, hyponymy, and membership. These relations are used to calculate semantic similarities [17].

Wu and Palmer method (WUP) is a procedure to measure the semantic similarities between English words based on the WordNet [18]. In this method, the similarity is measured based on the position of concepts c_1 and c_2 and the position of their lowest common subsumer $lso\ (c_1, c_2)$ in the WordNet hierarchy. For example, Equation 1 calculates the similarity of concepts c_1 and c_2 , where the $len(c_1, c_2)$ is the length of the shortest path between concepts c_1 and c_2, and the $depth$ is the length of the path that connects each concept to the root element [18].

$$sim_{WUP}(c_1, c_2) = \frac{2 * depth(lso\ (c_1, c_2))}{len(c_1, c_2) + 2 * depth(lso\ (c_1, c_2))} \quad (1)$$

2 Method

The proposed method quantifies the similarity between two construction projects by two metrics driven from their WBSs: node similarity and structural similarity. These metrics are calculated based on semantic comparisons of tasks within the two compared WBSs. These semantic comparisons include three measurements: the semantic comparison of nodes, parents of the nodes, and siblings of the nodes.

2.1 Semantic measurements

The tasks in a WBS are composed of several words.

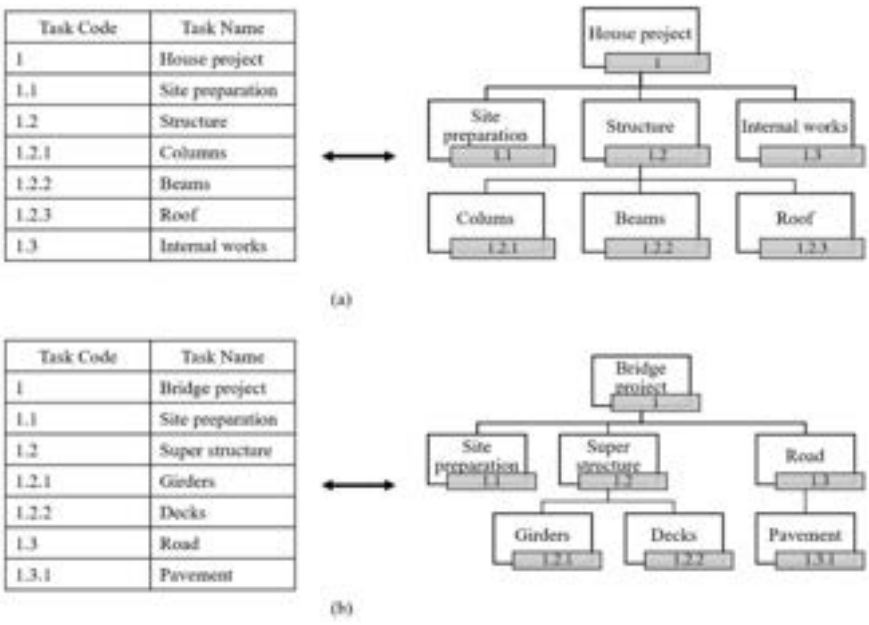

Figure 1. Two simplified work breakdown structures: (a) a House project (b) a Bridge project

The similarity between tasks can be calculated by averaging semantic similarity of their words. This study utilizes Equation 2 [19] to calculate the similarity between $task_i$ and $task_j$. In this equation, the method finds the most similar word for each word (w) in $task_i$ from $task_j$ ($maxSim(w, task_j)_{wup}$) based on Wu and Palmer algorithm [18].

$$sim_{semantic}(task_i, task_j) = \frac{1}{2}\left(\frac{\sum_{w\in\{task_i\}}(maxSim(w, task_j)_{wup})}{\sum_{w\in\{task_i\}} 1} + \frac{\sum_{w\in\{task_j\}}(maxSim(w, task_i)_{wup})}{\sum_{w\in\{task_j\}} 1}\right) \quad (2)$$

2.2 Comparison of nodes

A WBS is made of a hierarchy of nodes containing all the tasks required to complete a project. As shown in Figure 1, each node contains a task name and a task code. The first step in measuring the similarity between two WBSs is to semantically compare the task names. In this study, WBS_N^L represents an entire WBS with N nodes and L levels of hierarchy. Elements of the matrix in Equation 3 represent the semantic similarities between nodes of $WBS_{N_1}^{L_1}$ and $WBS_{N_2}^{L_2}$. In this equation $sim_{semantic}(n_i, m_j)$ equals to the semantic similarity between tasks of nodes n_i and m_j. N_1 and N_2 represent the list of nodes that each WBS contains (N_1: $(n_1, n_2, \dots, n_N)$ and N_2: $(m_1, m_2, \dots, m_M)$).

$$sim_{nodes}(WBS_{N_1}^{L_1}, WBS_{N_2}^{L_2}) = \begin{bmatrix} sim_{semantic}(n_1, m_1) & \cdots & sim_{semantic}(n_1, m_j) \\ \vdots & \ddots & \vdots \\ sim_{semantic}(n_i, m_1) & \cdots & sim_{semantic}(n_N, m_M) \end{bmatrix} \quad (3)$$

2.3 Comparison of node parents

In a WBS, each node is subdivided from an upper-level node which is called the parent of that node. Parent comparison between two nodes measures the semantic similarity of their parents. As shown in Figure 2, each node has a sequence of parents, and the first two parents with a similarity less than a specified threshold are defined as the least similar parents (LSP). The parent similarity, which is calculated using Equation 4, measures the arithmetic mean of semantic similarity of parents which are placed between the intended node and its LSP.

$$sim_{parents}(n_i, m_j) = \frac{\sum_{i=1}^{L_{LSP}-L_n}\left(L_{LSP} - L_{n_i} - (i-1)\right) \times sim_{semantic}(ith\ parents)}{\sum_{i=1}^{L_{LSP}-L_{n_i}}(i)} \quad (4)$$

The matrix in Equation 5 contains the parent similarities between nodes of $WBS_{N_1}^{L_1}$ and $WBS_{N_2}^{L_2}$.

$$sim_{parents}(WBS_{N_1}^{L_1}, WBS_{N_2}^{L_2}) = \begin{bmatrix} sim_{parents}(n_1, m_1) & \cdots & sim_{parents}(n_1, m_j) \\ \vdots & \ddots & \vdots \\ sim_{parents}(n_i, m_1) & \cdots & sim_{parents}(n_N, m_M) \end{bmatrix} \quad (5)$$

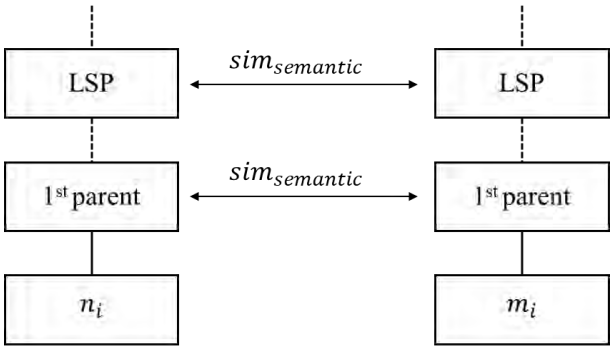

Figure 2. Parent similarity between nodes $\boldsymbol{n_i}$ and $\boldsymbol{m_j}$

2.4 Comparison of node siblings

In a WBS hierarchy, the nodes subdivided from a common parent are called siblings. The sibling similarity between nodes n_i and m_j is calculated by Equation 6 and is the fraction of the number of siblings that were actually matched by the total number of siblings. As shown in Figure 3, any pairs of siblings with a semantic similarity more than a defined threshold are considered matched. The matrix in Equation 7 contains the sibling similarities between nodes of $WBS_{N_1}^{L_1}$ and $WBS_{N_2}^{L_2}$.

$$sim_{siblings}(n_i, m_j) = \frac{|matched_{siblings}(n_i, m_j)|}{|siblings_{n_i}| + |siblings_{m_j}|} \quad (6)$$

$$sim_{siblings}(WBS_{N_1}^{L_1}, WBS_{N_2}^{L_2}) = \begin{bmatrix} sim_{siblings}(n_1, m_1) & \cdots & sim_{siblings}(n_1, m_M) \\ \vdots & \ddots & \vdots \\ sim_{siblings}(n_i, m_1) & \cdots & sim_{siblings}(n_N, m_M) \end{bmatrix} \quad (7)$$

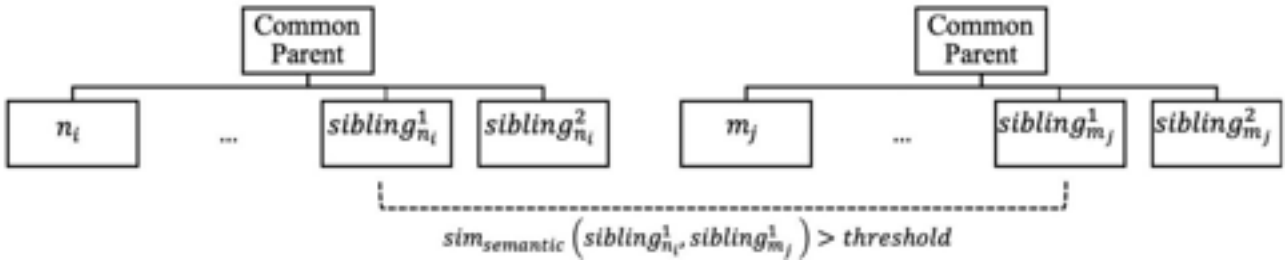

Figure 3. Sibling similarity between nodes $\boldsymbol{n_i}$ and $\boldsymbol{m_j}$

2.5 Mapping of nodes

The average of node, parent, and sibling similarities results in the average similarities (see Equation 8). The matrix in Equation 9 contains the average similarities between nodes of $WBS^{L_1}_{N_1}, WBS^{L_2}_{N_2}$. In this matrix, for instance, the first row includes the similarities between node n_1 from $WBS^{L_1}_{N_1}$, and nodes m_1 to m_M from $WBS^{L_2}_{N_2}$. The node n_1 will be mapped to a node from the second WBS with the highest average similarity. The same procedure will map all the nodes between two WBSs.

Mapped nodes in Equation 10 contain tuples of nodes which are mapped together $(n_i, m_j, sim_{average})$ with their average similarity score (i.e. $sim_{average}$). Mapped nodes and $sim_{average}$ will be used to calculate the similarity scores between two WBSs, as they are utilizied to calculate node similarity and structural similarity scores ($n_i \in N_1$ and $m_j \in N_2$).

$$sim_{average} = \frac{sim_{node} + sim_{parents} + sim_{siblings}}{3} \quad (8)$$

$$sim_{average}\left(WBS^{L_1}_{N_1}, WBS^{L_2}_{N_2}\right) = \begin{bmatrix} sim_{average}(n_1, m_1) & \cdots & sim_{average}(n_1, m_j) \\ \vdots & \ddots & \vdots \\ sim_{average}(n_i, m_1) & \cdots & sim_{average}(n_N, m_M) \end{bmatrix} \quad (9)$$

$$mapped\ nodes = \{(n_i, m_j, sim_{average})\} \quad (10)$$

2.6 Node similarity score

The node similarity score is the arithmetic mean of $sim_{average}$ of the mapped nodes. The node similarity, a score between 0 and 1, is calculated using Equation 11. In this equation, the sum of $sim_{average}$ is divided by the total number of nodes between two work breakdown structures.

$$Node\ similarity\left(WBS^{L_1}_{N_1}, WBS^{L_2}_{N_2}\right) = \frac{2 \times \sum_{(n_i, m_j) \in mapped\ nodes}\left(sim_{avg}(n_i, m_j)\right)}{|N_1| + |N_2|} \quad (11)$$

2.7 Structural similarity score

In the comparison of two WBSs, in addition to the semantic similarity of nodes within the WBS, the structure of hierarchies affects the similarity score as well. The structural similarity [20] was defined based on the graph-edit-distance method [20,21]. Graph-edit-distance is the minimum required operations to alter the structure of one hierarchy to another.

Node deletion and node substitution are two metrics used to derive the graph-edit-distance. In comparison of two WBSs, mapping nodes with a higher degree of similarity requires less effort than mapping nodes with lower similarities. In addition, eliminating the nodes which are not mapped requires an extra effort. Thus, a smaller required effort to change the structures of two WBSs can result in a higher structural similarity. Node deletion measures the required effort to eliminate unmapped nodes. Node substitution is the required effort to link the mapped nodes.

Equations 12 and 13 determine the deletion and substitution efforts between $WBS^{L_1}_{N_1}$ and $WBS^{L_2}_{N_2}$. Equation 12 defines deletion effort (DE) as a ratio of the number of unmapped nodes ($|UN|$) over the total number of nodes. Substitution effort (SE) is calculated in Equation 13 by averaging dissimilarity of the mapped nodes. In other words, a higher degree of similarity between the nodes will result in a lower substitution effort. Arithmetic average of deletion and substitution efforts produces a representative of structural dissimilarity and its complement was determined as a measure of structural similarity as shown in Equation 14.

$$DE\left(WBS^{L_1}_{N_1}, WBS^{L_2}_{N_2}\right) = \frac{|UN|}{|N_1| + |N_2|} \quad (12)$$

$$SE\left(WBS_{N_1}^{L_1}, WBS_{N_2}^{L_2}\right) = \frac{2 * \sum_{(n_i,m_j)\in mapped\ nodes}\left(1 - sim_{average}(n_i, m_j)\right)}{|N_1| + |N_2| - |UN|} \quad (13)$$

$$Structural\ similarity\left(WBS_{N_1}^{L_1}, WBS_{N_2}^{L_2}\right) = 1 - \frac{DE\left(WBS_{N_1}^{L_1}, WBS_{N_2}^{L_2}\right) + SE\left(WBS_{N_1}^{L_1}, WBS_{N_2}^{L_2}\right)}{2} \quad (14)$$

3 Experimental results

Three experts in the project management domain were asked to develop four WBSs for four different construction projects: a bridge construction (steel girder with composite concrete slab), a steel-framed office building, a reinforced concrete-framed residential building, and a road-widening project. Table 1 presents the 12 WBS samples created by these subject matter experts. These samples were utilized to evaluate the performance of the proposed metrics in distinguishing the projects and retrieving the most similar samples.

As was mentioned before, an equal threshold was used in comparison of parents and siblings. To determine the impact of this threshold on the proposed metrics, the results were explored by changing the threshold in the range of 0.5 to 0.8 with 0.05 intervals.

Table 1. Created samples by the experts.

Experts	Developed samples	Represented by
expert 1	$bridge\ construction_1$	B_1
	$concrete\ structure\ building_1$	C_1
	$steel\ structure\ building_1$	S_1
	$road\ maintenance_1$	M_1
expert 2	$bridge\ construction_2$	B_2
	$concrete\ structure\ building_2$	C_2
	$steel\ structure\ building_2$	S_2
	$road\ maintenance_2$	M_2
expert 3	$bridge\ construction_3$	B_3
	$concrete\ structure\ building_3$	C_3
	$steel\ structure\ building_3$	S_3
	$road\ maintenance_3$	M_3

3.1 Retrieval precision and recall

Any retrieved samples resulted from a search process will only fall in one of the following categories: "retrieved and relevant", "retrieved and not relevant", "not retrieved and relevant" or "not retrieved and not relevant" [22]. Recall is the proportion of the retrieved and relevant samples from all the relevant samples [22]. Precision is the proportion of the retrieved and relevant items from all retrieved items [22], as presented in Equation 15.

The samples B_1 , C_1, S_1 and M_1 were chosen to query the database and compute the precision. In each test, one of these samples was compared with all the stored samples in order to retrieve the relevant samples. For instance, the relevant samples to B_1 are B_2 and B_3. In each test, the retrieval process continued until it satisfy the recall score. The results were obtained based on two recall scores of 0.5 and 1. The recall score equals to 0.5 when only one of the two stored relevant samples are retrieved, and it equals to one when both relevant samples are retrieved. For instance, the node similarity scores between B_1 and stored samples are sorted in Table 2. Given that B_1, B_2 and B_3 are developed for the same project, the most relevant sample to B_1 are B_2 and B_3. In this query, assuming recall score is equivalent to 1, all the relevant samples to B_1 (B_2 and B_3) must be retrieved. As a result, the retrieving precision will be equal to 0.67.

$$Retrieving\ precision = \frac{|\{Relevant\ samples\} \cap \{Retrived\ samples\}|}{|\{Retrieved\ samples\}|} \quad (15)$$

Table 2. Comparing B1 with stored samples with a threshold of 0.65

Rank	Query sample	Stored sample	Node similarity score
1	b1	b2	0.64
2	b1	s2	0.56
3	b1	b3	0.48
4	b1	c1	0.47
5	b1	s1	0.40
6	b1	c2	0.39
7	b1	s3	0.35
8	b1	c3	0.34
9	b1	m2	0.13
10	b1	m3	0.13
11	b1	m1	0.05

Figure 4 illustrates the retrieval precision for node similarity and structural similarity scores. It can be concluded that the structural similarity with a threshold between 0.7 to 0.75 results in the highest precision scores.

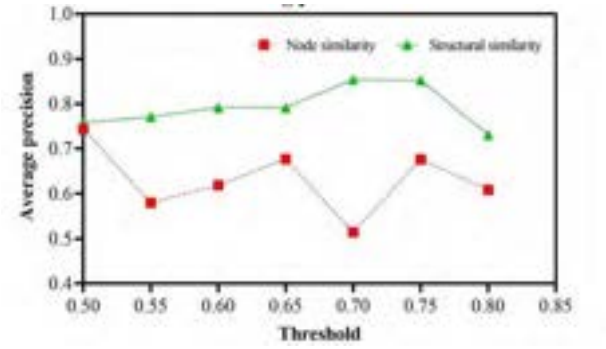

Figure 4. Average precision scores.

3.2 Properties of similarity measures

Symmetry and reflexivity are properties of a similarity measurement [23,24]. A similarity function S: S×S→ [0,1] on a set S, must fulfill two properties that are presented in Equations 16 and 17.

$$Sim(X,Y) = sim(Y,X)\ (Symmetry) \tag{16}$$

$$Sim(X,X) = 1\ (Reflexivity) \quad \forall\, X,Y \in S \tag{17}$$

3.2.1 Symmetry property of work breakdown structure similarity

Symmetry error, calculated using Equation 18, was defined to determine the symmetry fulfillment, in comparing WBS A and B. As illustrated in Figure 5, both node and structural similarity result in low degrees of error of symmetry property, namely the structural similarity error is close to zero.

$$Symmetry\ error = \frac{|sim(A,B) - sim(B,A)|}{average[sim(A,B), sim(B,A)]} \tag{18}$$

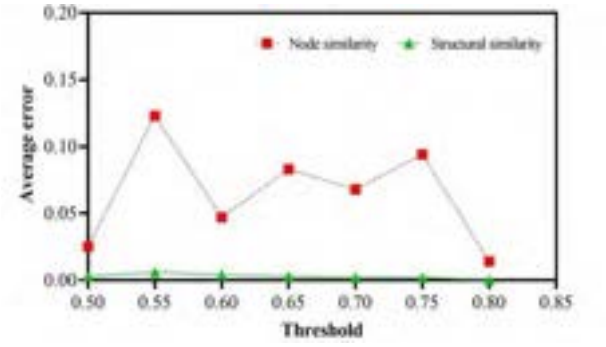

Figure 5. The average of the symmetry errors

3.2.2 Reflexivity property of work breakdown structure similarity

The reflexivity error, calculated using Equation 19, determines the compliance of the node and structural similarities with symmetry property by comparing a WBS to itself. It is evident from Figure 6 that both node and structural similarity result in very low levels of symmetry errors. Specifically, the error for the structural similarity is negligible, indicating better compliance of this metric with the symmetry property.

$$Reflexivity\ error = 1 - sim(A, A) \tag{19}$$

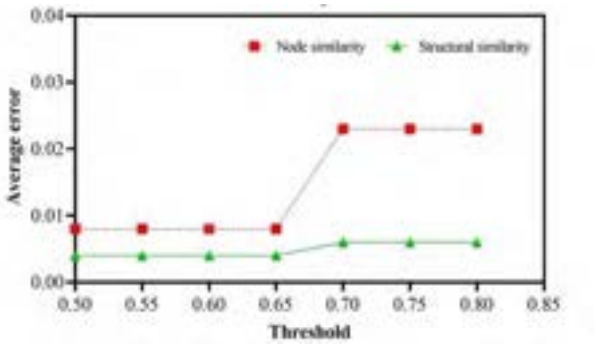

Figure 6. The average of the reflexivity errors

4 Conclusion

A quantitative similarity measurement of construction projects can improve the data retrieval process in knowledge management and case-based reasoning systems. This research utilized the WBS to measure the similarity amongst various construction projects. The WBS theoretically encompasses a significant portion of the tasks and services required to accomplish the project objectives. Thus, the WBS can be used as a comprehensive tool to distinguish constriction projects. The proposed method can be utilized to find the most similar projects and help the project managers use the relevant information and documents of the retrieved projects. This method can also be used as a main metric in exiting knowledge retrieval systems, such as case-based reasoning.

Node and structural similarity metrics were proposed to measure the similarity of construction projects using their WBSs. The results from applying these metrics indicate that the structural similarity performs better than the node similarity in retrieving the relavant samples. Additionally, the results show that the proposed metrics are in compliance with similarity measurement properties.

5 Limitations and future works

To ensure that the work breakdown structures encompass the entire scope of a project, the sample WBSs were developed based on the project management institute guidelines [11]. This approach

might not be fully followed by the practitioners in all construction projects which can limit the performance of the proposed method.

The insufficient number of test samples was another major limitation of this research. The performance of the system can be investigated on a larger sample size. Another limitation of this research was the utilized lexical database, which is WordNet. This is a generic database for English words, in which some of the technical words in the construction domain are not accurately defined. For instance, the word "rebar", which in construction is recognized as reinforcement steel, is not defined in WordNet. This issue can hinder the performance of the metrics in comparing tasks. Thus, there is an opportunity to develop and utilize a semantic network, similar to WordNet, for the construction domain.

Abstract –

Wildfires pose a big threat to human life and property safety. Previous studies on wildfire risk management focused mainly on understanding wildfire behaviour through computer simulations. Effective wildfire risk management also largely depends on the evacuation performance success. Computational tools tend to be the best approach for simulating wildfire evacuation emergencies as well. Therefore, this study proposes a comprehensive simulation framework that integrates Agent-based Modelling (ABM) and Geographical Information Systems (GIS) to efficiently simulate both human behaviour and transportation crowds. In particular, ABM bridges the technical gap between GIS and a multi-agent system (MAS) for simulation design efficiently and effectively. To study the evacuation performance (measured by the number of agents being sheltered or refused to evacuate), our modelling solution enables altering relevant model parameters in wildfire evacuation scenarios. The simulation outputs, as a result, can be used to evaluate the influential factors and further assist in effective evacuation planning. In particular, the following tasks are performed: (1) simulation of the influence of transportation crowds on evacuation performance; (2) evaluation of the effectiveness of public notification on evacuation success; and (3) comparison of the differences among various transportation means as well as their performances during a wildfire emergency. A case study is conducted to verify the simulation framework proposed in this study. The simulation outputs showed that the transportation crowds negatively impact on the evacuation performance, while public notification can enhance resident risk perception, thus assist in the evacuation efficiency. Finally, public vehicles such as public buses have the highest evacuation efficiency compared to other transportation means tested in this study.

Keywords – Wildfire Evacuation Simulation; Agent-based Modeling; Geographical Information Systems

1 Introduction

Wildfires pose a big threat to human life and property safety. The National Interagency Fire Center (NIFC) indicates that, over the past decade, an average of 67,000 wildfires resulted in 7 million acres burned annually [1]. In 2019 alone, there were 4.5 million U.S. homes were identified at high or extreme risk of wildfire, with more than 2 million in California alone [2].

To date, a number of studies have been conducted concerning the simulation of wildfire behavior. Catry et al. [3], for example, studied modeling and mapping the likelihood of wildfire ignition occurrence in Portugal. In [4], Westerling et al. applied statistical approaches to develop models for investigating the wildfire occurrence frequency affected by climate change in California. Linn et al. [5] utilized FIRETEC, a fire growth modeling software, to examine wildfire behavior with regard to different geographical regions. However, modeling wildfire behavior only is insufficient for effective wildfire risk management if both the number of injuries/fatalities and the level of property loss are expected to be minimized.

The success of evacuation performance is a critical factor in wildfire risk management. Due to obvious reasons and ethical concerns, computational simulation tends to be the best approach for studying human evacuation performance and transportation crowds during a wildfire. In addition to fire dynamics, a wildfire evacuation simulation mainly consists of human behavior as well as transportation modules [6]. To that end, this study aims to develop a simulation framework used for simulating both human behavior and transportation crowds simultaneously for wildfire evacuation performance assessment.

The remainder of the paper is organized as follows. Section 2 provides a comprehensive review of the research background. Section 3 details the proposed simulation framework and methodology. The experimental implementation is discussed in Section 4. The final section draws conclusions and offers recommendations for future research.

2 Research Background

A comprehensive review of the relevant literature on wildfire evacuation simulation is provided in this section. Human behavior critical to evacuation performance are also identified.

2.1 ABM and GIS for Evacuation Simulation

In outdoor evacuation scenarios, except for walking, transportation modules typically consist of various transportation means such as bicycles, private or public vehicles. To integrate human behavior and transportation modules into an outdoor evacuation scenario design, Agent-Based Modeling (ABM) technique is commonly used as it provides an environment where agents can be defined as any type of individual simulating their behaviors in mathematical, theoretical, and logical ways [7]. An ABM simulation scenario can reflect agent-to-agent interactions as well as agent-to-environment reactions simultaneously. To date, a number of studies have applied ABM to simulate outdoor emergency scenarios that covered a variety of hazards, including earthquakes [8], tsunamis [9], hurricanes [10], wildfires [11], and so on. Relevant to the study described here, Paveglio and Prato [11] proposed an ABM framework to investigate monetary and non-monetary attributes that influence human behavior and decisions with respect to wildfires. Therefore, it can be concluded that simulating human evacuation reactions and interactions is feasible using an ABM wildfire scenario design.

In addition to simulating human behavior and transportation modules, Geographical Information Systems (GIS) is a tool that can be used for outdoor evacuation simulation as it enables simulating agents' movements and evacuation process by providing the spatial data needed. In [12], Jumadi et al. developed a GIS-ABM simulation model to simulate the volcanic evacuation performance for risk assessment. In this case, ABM bridged the technical gap between the GIS tool and a multi-agent system (MAS) to simulate both human behavior and transportation crowds. Similarly, this study proposes to utilize an integrated ABM - GIS framework to simulate a MAS scenario, and to investigate the influential factors affecting the outdoor evacuation performance during a wildfire.

2.2 Influential Factors Affecting Evacuation Performance

This section provides a review of studies that have assessed wildfire evacuation performance with regard to a variety of human behavior. The following subsections summarize major findings of influential factors affecting human evacuation decisions and related choices in wildfire emergencies.

2.2.1 Public Notification

Public evacuation notification is critical in predicting the decision-making process of evacuees. A telephone questionnaire conducted by Strawderman et al. [13] revealed that, by signal detection theory, reverse 911 warnings had the best performance, and promoted a significantly higher rate of evacuation, compared with other evacuation warning sources. However, evacuees and public safety officials have different perceptions and concerns about the evacuation process [14]. In particular, McLennan et al. reviewed North American research into wildfire evacuation behavior published between 2005 and 2017 and summarized that: (1) even though mandatory evacuation is issued by the police department, many threatened residents are likely to delay evacuating due to the desire to protect their property; (2) some residents who are not on their property may seek to return; (3) warnings that are not sufficiently informative could be another cause for self-delayed evacuation; and (4) residents are likely to engage in information search rather than initiating evacuation actions. Overall, public notification promotes a higher risk-warning efficiency to encourage residents to evacuate. Nevertheless, residents are still likely to refuse to evacuate due to environmental factors and personal factors affecting individual risk perception as well as decision-making that result in evacuation delays.

2.2.2 Risk Perception

Personal factors with regard to risk perception in an emergency are complex and multidisciplinary. Toledo et al. [16] analyzed the influential factors affecting residents' decision-making process during a no-notice wildfire evacuation event that occurred in Haifa, Israel. They found that, in addition to the level of risk that the wildfire event poses to individuals, the influential factors related to household individuals (e.g. initial locations when a wildfire event happened) as well as their relatives (e.g. the number and locations of children or elderly individuals) significantly affect their evacuation decisions and associated movement patterns [16]. Besides, residents' evacuation efficiencies are heavily affected by their knowledge and experience with former wildfires [17], which should be considered in an evacuation scenario design as well.

2.2.3 Risk Mitigation

In addition to risk perception, personal behavior with regard to risk mitigation is another significant factor affecting the decision-making regarding resident evacuation performance. The study by Paveglio et al. [18] revealed that a relatively high proportion of residents are interested in passively defending or sheltering in their homes, with fewer residents favoring evacuation during a wildfire. In particular, resident evacuation preferences

differ significantly due to the forest management strategy. For example, in [11], it was found that in the areas with significantly high rate of forest thinning, the residents chose to stay and actively defend their homes.

In [19, 20], it was found that a higher level of risk mitigation is positively associated with risk perception, including sufficiently informative wildfire information received from local volunteer fire departments, county wildfire specialists, as well as talking with neighbors about the wildfire. To conclude, residents who perceive higher levels of wildfire risk have undertaken higher levels of wildfire-risk mitigation to protect their property. Thus, the relationship between risk perception and risk mitigation undertaken is jointly and mutually represented in our simulation framework design.

2.2.4 Transportation Means

Means of transportation could have a huge impact on evacuation efficiency. In [21], Beloglazov et al. proposed a dynamic modeling approach to simulate the evacuation performance with regard to different evacuation locations. Li et al. [22] investigated the influence of evacuation timing for traffic based on a spatiotemporal GIS approach. In addition to evacuation locations and evacuation timing, movement velocities and loading capacities of various transportation means are significant as well.

Among typical transportation means (e.g. walking, bicycles, private or public vehicles), private or public vehicles account for higher velocities and loading capacities that are meant to have better evacuation performance. Undoubtedly, an efficient transportation network in a wildfire emergency could help residents to evacuate safely. However, frequent occurrence of transportation crowds caused by vehicles occupying the roads could highly impede the evacuation efficiency. Hence, the evacuation efficiency for a variety of transportation means should be further assessed to assist with evacuation strategies and management, and further improve the evacuation success.

2.3 Motivation and Objectives

Understanding the physical and social dynamics imposed by wildfires is fundamental to assessing and mitigating risks for residents [23]. Above all, human evacuation performance is greatly affected by public evacuation warnings, actions, and decisions related to risk perception and risk mitigation, and the variability of transportation means as well as their efficiencies. Those influential factors are critical to evacuation assessment, and pose challenges for modeling an effective wildfire evacuation scenario.

Several studies to date investigated human wildfire evacuation behavior. However, modeling solutions to predict and assess evacuation performance for wildfire scenarios is still at its infancy. Therefore, this paper proposes an evacuation behavior model embedded in an ABM-GIS simulation tool, AnyLogic [24], to simulate and investigate the impact of influential factors summarized in section 2.2. on wildfire evacuation performance.

In particular, (1) the influence of transportation crowds on the evacuation performance is simulated; (2) the effectiveness of public notification on the evacuation success is evaluated; and (3) the differences and efficiencies among various transportation tools during a wildfire emergency are compared. A comprehensive simulation framework, based on the influential factors derived from existing literature on human behavior in wildfires, is introduced to implement the proposed modeling solution. Finally, an experimental case study is conducted to validate the proposed modeling solution using AnyLogic.

2.4 Contribution

The main contribution of this study is a modeling solution for wildfire evacuation simulation in an ABM-GIS simulation framework. To assess evacuation performance (measured by the number of agents being sheltered or refused to evacuate), our modeling solution enables to modify relevant model parameters in wildfire evacuation scenarios. The simulation outputs, as a result, can be used to assess the impacts of influential factors (including the impact of public evacuation warnings, risk perception, risk mitigation, and various transportation means) affecting evacuation performance. Thus, the proposed modeling solution can further assist in safety management and effective evacuation planning for wildfire emergencies. To conclude, this study assesses the evacuation efficiency with regard to human life and transportation crowds in wildfire emergencies, which would ultimately help with wildfire evacuation education and safety strategies.

3 Research Methodology

The proposed simulation framework and modeling solution are introduced in this section. The findings of the recent studies on how to incorporate human wildfire evacuation behavior into an ABM-GIS simulation scenario [13-23] are considered and included in the framework design.

3.1 Simulation Framework

Figure 1 illustrates the simulation framework proposed in this study. The first step is to determine whether there is a wildfire or not. Next, the alert indicator about public evacuation warnings, either positive or negative, divides the scenario into four categories: 1) a true wildfire event and a mandatory evacuation issued by

safety officials (true positive (TP)), 2) a no-notice true wildfire event (true negative (TN)), 3) mandatory evacuation issued for a false wildfire event (false positive (FP)), or 4) neither evacuation alert was issued nor a wildfire occurred (false negative (FN)). These four categories address particular evacuation outcomes, including different evacuation performance for a variety of scenarios.

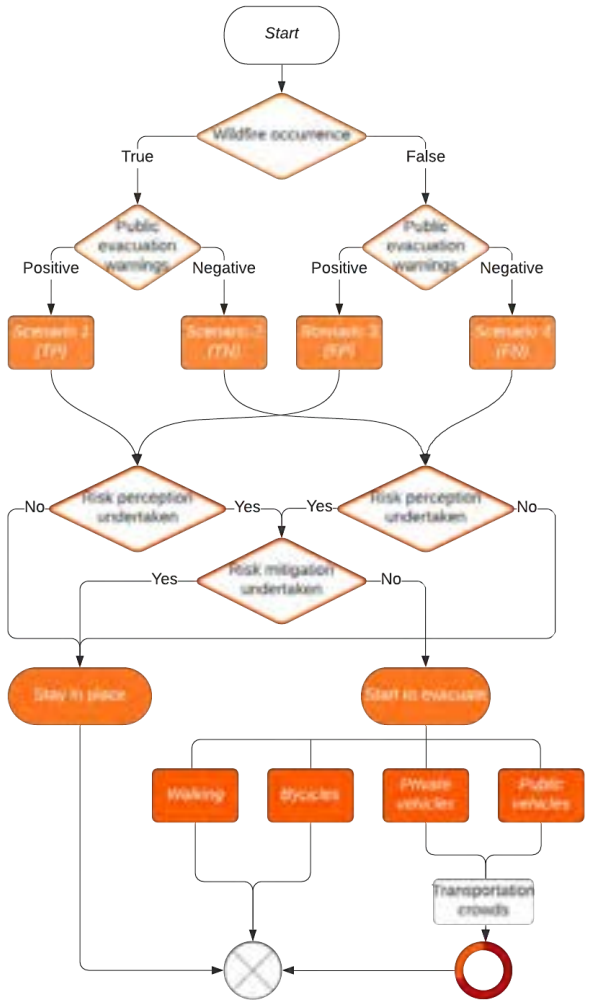

Figure 1. Proposed simulation framework

In the next step, agents' risk perception (true or false) is defined for each scenario. If the agents do not perceive any risk, they will choose to stay in place. The agents who perceive risk will either stay in place to actively defend their homes or start to evacuate. During the evacuation process, vehicles occupying the road may cause transportation crowds. In this case, there will be evacuation delays, which is incorporated in the movement process in our simulation design. The average velocities and capacities of typical transportation means in a wildfire emergency are summarized in Table 1.

Table 1. Designed parameters for various transportation means

	Average velocities (mph)	Common capacities
Walking	3-5	1
Bicycles	12-15	1-2
Public vehicles	30-45	20-50
Private vehicles	40-70	1-5

The final step is to analyze the simulation outputs, which present the number of agents either refusing to evacuate or being sheltered. These numbers can be used to assess agents' evacuation efficiency with regard to the effect of public evacuation warnings, risk perception, risk mitigation, and various means of transportation. Consequently, the impacts of influential factors affecting the evacuation performance are evaluated, which would ultimately help with wildfire evacuation education and safety strategies.

3.2 Modeling Solution

The ABM-GIS wildfire simulation scenario consists of the movement flow module and the geographical module representing the agents' movement process in chosen areas. The modeling software AnyLogic, which embeds the GIS tool, provides a powerful simulation environment, as it enables to simulate agent movement and evacuation process while providing the geographical and spatial data needed.

3.2.1 Modeling Parameters

The movement flow module presents the agent evacuation process. AnyLogic provides users a process modeling library, including various modeling parameters, to define agents' behavior. The agent movement flow in this study is designed based on the simulation framework shown in Figure 1. Hereby, Table 2 introduces several selected modeling parameters including their names, icons, descriptions, and properties of functions.

Table 2. Introduction of modeling parameters [24]

	Description	Function
Source	A starting point of a process flowchart to generate agents.	Define agent location, arrival rate, and quantity, etc.
Select Output	Two output ports to route agents.	Sort agents according to certain criteria.
Select Output5	Five output ports to route agents.	Split the agent flow into different

		transportation means.
Move To	Move agents to a new location.	Define agents' destination and movement speed.
Queue	A queue of agents waiting to be accepted by the next block in the flowchart.	Define the maximum capacity and agent location in a queue.
Sink	An ending point to dispose incoming agents.	Present the number of agents disposed.

3.2.2 The Movement Flow Module

Five agent types are defined in a wildfire scenario, including the residents and four transportation means including walking, bicycles, private vehicles, and public vehicles. By utilizing the process modeling library, the agents' behavior is defined in AnyLogic (Figure 2).

Figure 2. A simplified version of agents' behavior in AnyLogic

At the start of the movement flow, resident agents are sorted based on their judgments about risk perception and risk mitigation undertaken, namely RP and RM. Next, a portion of resident agents, who does not perceive the risk or prefer to self-defend their homes after risk perceived, is disposed to stay in place. The remaining resident agents start to evacuate using one of the four transportation means, which are predefined with different movement velocities and loading capacities summarized in Table 1. It is assumed that transportation crowds (i.e., vehicle flows exceeding the highway capacity) require the agents taking the vehicles to queue to be sheltered. In the meantime, other agents who evacuate by walking or bicycling move toward the shelters identified in the GIS map. AnyLogic allows presenting agents' movements as a 2D/3D animation and counting agents that are disposed by modeling parameters in real-time.

4 Experimental Implementation

To validate the practicality of the proposed modeling solution, an experimental implementation was conducted to simulate a hypothetical wildfire evacuation emergency.

4.1 Experimental Assumptions

4.1.1 Geographical Background

The CampFire in California [25], which occurred in 2018, was used as a geographical background composed of several GIS nodes: (1) the ignition node, namely Creek Camp Road, (2) the shelter node, namely Orland, and (3) four independent scenario nodes, namely Paradise, Oroville, Chico, and Willows, navigated based on their spatial attributes (Figure 3).

Figure 3. Geographical nodes navigated in the GIS tool embedded in AnyLogic

This study assumes the level of wildfire risk for each scenario depending on the spatial distance measured from the ignition node to those scenario nodes. In particular, the town of Paradise is classified as a TP scenario due to its shortest distance to the ignition location, which accounts for the highest level of risk it can be easily detected. Oroville is the second-nearest town that faces a high risk as well, but the risk perceived by residents could be misjudged due to a river close to the node, thus it was classified as a TN scenario. Compared to Oroville, the town of Chico has a lower wildfire risk due to its greater distance from the ignition location, but with higher risk awareness affected by the passing evacuees coming from Paradise. Hence, Chico is chosen to be simulated as a higher possibility for an FP scenario. Finally, the town of Willows is classified as a FN event due to its geographical distance from the ignition location.

4.1.2 Modeling Parameter Setup

For each evacuation scenario, the resident agents are randomly distributed with an arrival rate of one agent per

second and a maximum quantity of 2000 in AnyLogic. The probabilities of select outputs for risk perception and risk mitigation measures undertaken by resident agents vary for different scenarios as shown in Table 3. Besides, this experiment assumes a random distribution for the agent flow split via different transportation means. Furthermore, the traffic flow exceeding a capacity of 100 vehicle agents will trigger transportation crowds, which are represented by agent queues (dashed lines marked in Figure 3).

Table 3. Probabilities of select outputs

	Risk perception undertaken	Risk mitigation undertaken
Scenario 1 (TP)	0.9	0.1
Scenario 2 (TN)	0.1	0.9
Scenario 3 (FP)	0.9	0.9
Scenario 4 (FN)	0.1	0.1

4.2 Simulation Outputs and Analysis

During the simulation, AnyLogic presents the number of agents disposed by modeling parameters in real-time. To evaluate the effectiveness of the proposed modeling solution, test scenarios were developed by adjusting relevant modeling parameters. Hereby, each evacuation scenario was run ten times in order to avoid biased simulation outputs. Simulation outputs with regard to test scenarios are summarized and analyzed in the following subsections.

4.2.1 The Influence of Transportation Crowds

The test scenario was developed with and without the modeling parameter of transportation crowds in order to investigate its influence on agent evacuation efficiency. In particular, the agent evacuation performance is evaluated by the travel time (measured by the modeling time in AnyLogic) for two types of vehicles, i.e., private and public vehicles, in each scenario (Table 4).

Table 4. Travel time (in seconds) for vehicles

	TP	TN	FP	FN
Private vehicles without crowds	2267	1863	2017	1920
Public vehicles without crowds	3983	3189	3463	3301
Private vehicles affected by crowds	7445	6188	7300	6410
Public vehicles affected by crowds	8032	7243	7785	7387

According to the simulation outputs, the evacuation efficiency in each scenario was negatively affected by the transportation crowds due to a longer travel time for both types of vehicles. The queuing time, however, slightly differ among these four scenarios, which have different numbers of vehicles driven through a route as shown in the GIS interface. The simulation outcome, as a result, validate the negative impact of transportation crowds on the evacuation efficiency. In this case, highway capacity must be increased to reduce the occurrence of transportation crowds.

4.2.2 The Effectiveness of Public Notification

To evaluate the effectiveness of public notification, this study used the statistics of disposed agents who stay in place due to not perceiving the risk or perceiving the risk but choosing to stay to defend their homes, as well as the agents who evacuate and reach a shelter using one of the four different transportation means in each scenario (Table 5).

Table 5. Statistics for agents disposed in different scenarios

	TP	TN	FP	FN
Risk not perceived – stay in place	195	1794	174	1825
Risk perceived – stay in place	243	118	1070	27
Walking	120	10	48	11
Bicycles	170	6	80	14
Private vehicles	347	18	165	42
Public vehicles	925	54	463	81

The simulation outputs indicate that public notification has a significant impact on the evacuation decision-making of resident agents. In the scenarios with public notifications (i.e., TP and FP scenarios), the number of agents who perceive the risk is greatly higher compared to the scenarios without notifications (i.e., TN and FN scenarios). Nevertheless, agents in the TP scenario prefer to evacuate after risk perceived and few agents intend to mitigate the risk. Conversely, in the FP scenario, a large portion of agents tend to take actions for risk mitigation instead of evacuating immediately. To conclude, public notification improves resident risk perception, but residents may still refuse to evacuate.

4.2.3 Comparison of Different Transportation Means

In this study, the evacuation efficiency is measured by the evacuation time per agent for different transportation means in each scenario. Several findings are drawn from Table 6: (1) evacuation by walking accounts for the lowest evacuation efficiency; (2) evacuation efficiencies of all transportation means in TP and FP scenarios are greatly higher than the efficiencies in TN and FN scenarios; and (3) evacuation efficiency of

public vehicles is the highest even though their average velocities are slower than private vehicles. One possible explanation is that the loading capacity of public vehicles is the highest, consequently, more agents are loaded and able to approach a shelter at the same time.

Therefore, to improve the evacuation efficiency, it may be helpful to increase the availability of public transportation when evacuating residents in a wildfire emergency.

Table 6. Evacuation efficiency (in %) for different transportation means

	TP	TN	FP	FN
Walking	0.29	0.03	0.12	0.03
Bicycles	1.49	0.05	0.71	0.13
Private vehicles	4.66	0.29	2.26	0.66
(without crowds)	15.31	0.97	8.18	2.19
Public vehicles	11.52	0.75	5.95	1.1
(without crowds)	23.22	1.69	13.37	2.45

5 Conclusions and Future Research

Effective wildfire evacuation planning could help to improve resident evacuation efficiency during a wildfire emergency. Several studies to date focused on studying human behavior and evacuation performance during a wildfire. However, such modeling and simulation solutions to predict and assess evacuation performance in wildfire scenarios are still at their infancy. Therefore, this study proposed a modeling solution, using AnyLogic software, that integrates ABM and GIS to enable simulating and investigating the factors affecting outdoor evacuation performance during a wildfire. To that end, an experimental implementation was conducted to test several wildfire scenarios including: 1) a mandatory evacuation issued by safety officials for a true wildfire event, 2) a no-notice true wildfire event, 3) a mandatory evacuation issued for a false wildfire event, and 4) neither evacuation alert was issued nor a wildfire occurred.

The simulation outputs validated the practicality of our modeling solution. Several major findings are as follows: (1) transportation crowds negatively impact the evacuation performance, (2) public notification can enhance residents' risk perception, thus improve evacuation efficiency, and (3) public vehicles have the highest evacuation efficiency compared to other transportation means evaluated in this study. Several wildfire evacuation management strategies are suggested based on these findings. To conclude, this study assesses evacuation efficiency with regard to human life and transportation crowds in wildfire emergencies, which is expected to help in wildfire evacuation education and safety strategies. The proposed modeling solution provides a novel simulation approach that can used for wildfire safety management and effective evacuation planning for wildfire emergencies.

The proposed simulation framework has several limitations that should be noted. First, human evacuation behavior should be further studied and the modeling solution should be revised by adding or changing relevant modeling parameters to better assess human evacuation performance. Second, AnyLogic software is limited in terms of the number of modeling parameters that can be included in one scenario. Hence, this study fails to add the modeling elements that could simulate those four scenarios simultaneously. Third, due to the limitation of the current ABM modeling technique, this study emphasizes only simulating resident evacuation behavior. However, in reality, wildfire dynamics is a matter that could heavily impact the evacuation performance. To improve the viability of the proposed modeling solution, future studies should: (1) investigate human outdoor evacuation behavior; (2) simulate the interaction between residents living in different geographical regions; and (3) improve the modeling solution to enable simulating the wildfire dynamics and resident evacuation process simultaneously.

Abstract – Three-dimensional (3D) measurement that captures the state of construction sites is key to promoting ICT-supported construction processes. Structure-from-Motion (SfM) and Multi-View Stereo photogrammetry are the best solutions for small and mid-sized construction companies due to their high portability and low cost. However, efficient creation of high-quality 3D dense models using photogrammetry is difficult for site workers because the model quality relies heavily on manually selected camera poses. To address this issue, we propose a photogrammetry process that improves the quality and efficiency of 3D dense model reconstruction to measure construction sites. The proposed process begins with a small initial photo set. Then, a computer-supported best-view guidance system predicts the geometric quality of the dense model, estimates the best target positions for additional photographs using SfM results, and provides workers with that position information. The effectiveness and efficiency of the process and system were evaluated at a real-world construction site. The evaluation demonstrated that the process and system can prevent capturing unnecessary images, improve the efficiency of the on-site photographic work, and generate a dense model with quality assurance. We also found that a smartphone camera is the most suitable device for implementing the process.

Photogrammetry; 3D Modeling; Next-best View; Cloud Service; Smartphone; i-Construction

1 Introduction

In recent years, the "i-Construction" initiative [1], which is intended to improve productivity at construction sites by utilizing ICT, has been promoted at various places in Japan. However, to apply i-Construction initiatives at small and mid-sized construction companies, both the initial and the operating costs of the supporting technologies must be low.

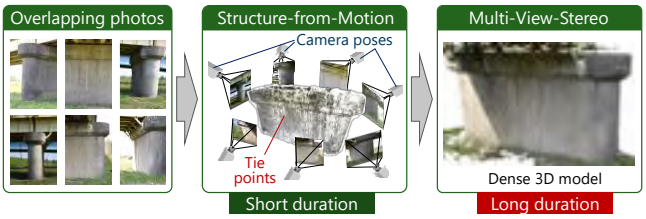

Figure 1. Typical photogrammetry process

Three-dimensional (3D) measurement technology is an essential part of the i-Construction initiative. 3D measurement technology is used to capture the current state of construction sites at various construction stages at high frequency. Currently, terrestrial laser scanners and 3D photogrammetry are used as measurement technologies. Terrestrial laser scanners permit millimeter-accuracy measurements [2]. However, the devices are expensive. In addition, typically, measurement processing is outsourced, which is also expensive. Thus, cost considerations hinder the introduction of laser scanners to small and mid-sized construction companies.

3D photogrammetry [3], shown in Figure 1, is slightly inferior to laser scanners in terms of measurement accuracy. However, it can automatically reconstruct dense 3D models, such as 3D point clouds and textured meshes, from multiple overlapping photos. Photogrammetry can be implemented using UAV-based photography. Consequently, photogrammetry can be

introduced into small and mid-sized construction companies more smoothly than terrestrial laser scanners.

However, introducing photogrammetry and the routine use of high-quality 3D models to monitor construction site activity remains challenging. First, a site worker must take multiple photographs using a heavy, handheld single-lens reflex (SLR) camera. Second, the quality of the dense 3D model reconstructed from the photographs cannot be confirmed on-site because the conventional photogrammetry pipeline requires significant processing time. Moreover, for a given construction site, pre-estimating the camera pose, i.e., the optimal shooting position and orientation, required to capture photographs that can be used to reconstruct a high-quality, dense model is difficult.

To address the various challenges, an innovative photogrammetry process and computer-supported best-view guidance system that can streamline 3D modeling of construction sites is proposed in this paper. The proposed process and the system can be introduced into the everyday activities of small and mid-sized companies by integrating a smartphone, cloud service, and computer-assisted best-view guidance for optimal camera poses. The development of this technology involved both the construction industry and academia, and its effectiveness and efficiency were evaluated experimentally at a real-world construction site.

2 Challenges and Approaches

2.1 Conventional Photogrammetry Process

As shown in Figure 1, the general photogrammetry pipeline to generate a dense 3D model from a set of photographs comprises two steps: Structure-from-Motion (SfM) and Multi-view Stereo (MVS). SfM derives the camera poses and sparse corresponding points, i.e., the so-called "tie points," on real-world objects, and MVS creates a dense 3D model, such as a 3D point cloud or a textured-mesh model, by stereo matching overlapped photographs [3].

SfM processing can be completed in a relatively short time. However, MVS must process all pairs of overlapped photos; therefore, it requires approximately 10 to 50 times more processing time than SfM. For example, for 100 photos, SfM requires only 4 min, while MVS takes 120 min. This example clearly indicates that the MVS step consumes most of the processing time in the photogrammetric 3D model reconstruction process.

As shown in Figure 2, if we attempt to utilize photogrammetry to capture daily progress at a construction sites, the following problems occur.

- The resolution of a 3D model reconstructed by SfM-MVS depends on the resolution of the captured images. Therefore, high-resolution photographs tend to be taken by an SLR camera. However, SLR cameras tend to be large and heavy; carrying and using an SLR camera in complex situations at a construction site, e.g., scaffolding, can be problematic. In addition, with an SLR camera, uploading captured photos via a network is more complicated and less efficient than with a smartphone. Therefore, initially, all captured photos must be stored on the camera's SD memory card. After taking the camera to an office, the 3D model is reconstructed using photogrammetry software. However, this process drops in efficiency because photogrammetry processing cannot be performed during shooting.
- To reconstruct a high-quality, dense model using SfM-MVS, a site worker must carefully consider the importance of capturing overlapping photographs and develop a shooting plan in which the camera poses relative to the object are set appropriately. However, predicting which and how many photos should be taken to reconstruct high-quality models is difficult for the worker. Consequently, defects, such as holes or reduced accuracy in some parts, often appear in the model. To avoid such defects, shooting plans tend to involve a high overlap ratio. However, increasing the number of photographs also increases the MVS processing time.
- To record construction sites using SfM-MVS, it is often necessary to take several hundred to several thousand photographs. With such a large number of photographs, MVS processing can take approximately half a day or even an entire day. Therefore, the quality of the dense model cannot be confirmed on-site immediately after the images are captured. If the model quality is unsatisfactory due

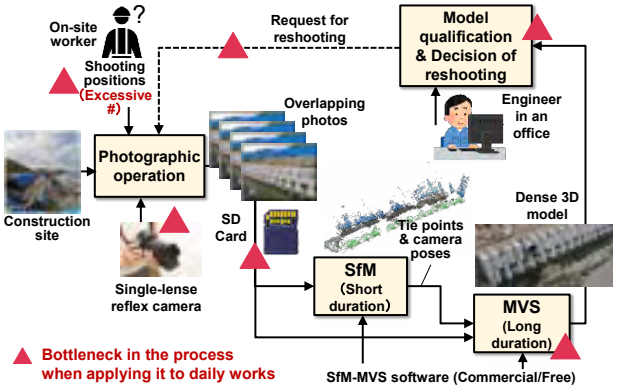

Figure 2. Practical challenges encountered when attempting to apply a conventional photogrammetry process at a construction site

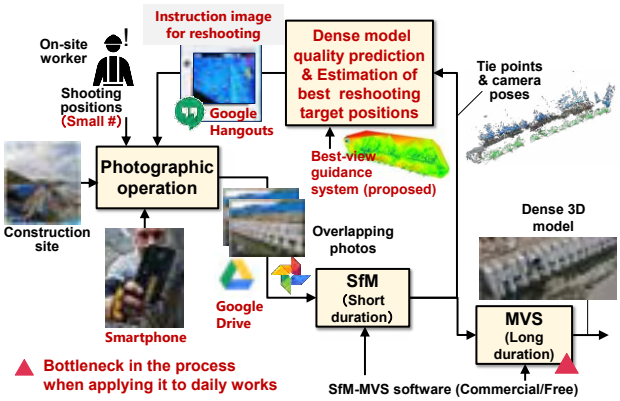

Figure 3. Processing pipeline of the proposed photogrammetry process

to an insufficient number of photographs or unphotographed areas of the site, reshooting will be required, which incurs considerable financial and time costs.

2.2 Proposed Approaches

To address the above problems, the following new photogrammetry process is introduced in this study. The processing pipeline for the proposed process is shown in Figure 3. The process proceeds as follows.

(1) We introduce a smartphone with a high-resolution camera as the device used to capture on-site photographs. Smartphones are lightweight, which makes them suitable for handheld shooting at construction sites. In addition, by utilizing their internet communication function, images can be automatically uploaded to cloud storage (Google Drive) immediately after shooting.

(2) The quality of the dense model that will be reconstructed from the uploaded images is quickly predicted from the SfM results and a computer-supported best-view guidance system. The prediction is based on our developed quality prediction algorithm [4]. The best target positions for additional photo shoots that would improve the quality are estimated in a few minutes by the guidance system connected to the cloud.

(3) The system automatically generates an instruction image in which the marker symbols of these target positions estimated in (2) are superimposed on the photo of the scene saved in the cloud. Furthermore, the instruction image is immediately transmitted to the worker's smartphone at the construction site using a messenger application (Google Hangouts [5]). Then, the worker takes several additional photos according to the target positions on the instruction image and uploads them to the cloud.

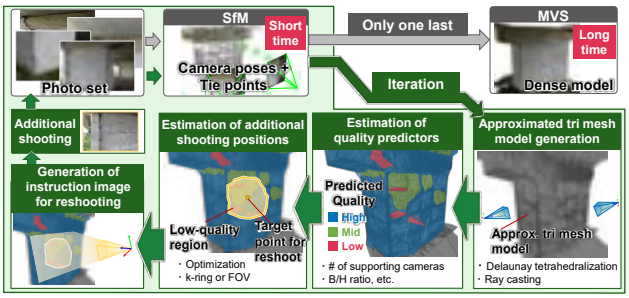

Figure 4. Prediction of the dense model quality and estimation of the best target position for additional shootings

(4) By repeating processes (2) and (3) as often as necessary, a small number of target positions for additional images are estimated only by SfM processing, and additional images are captured according to the target positions. Consequently, the quality of the obtained high-density model is improved successively without requiring multiple MVS processing.

(5) After completing the shooting processes (2)–(4) supported by the best-view guidance system, the time-consuming MVS process is executed only once, and the final dense model is reconstructed. Thus, the MVS process can begin immediately after the required additional images are captured, which improves the overall efficiency of the model reconstruction process.

3 Quality Prediction of Dense Model and Estimation of Additional Shooting Positions

3.1 Approximated Triangular Mesh Model Generation

Figure 4 shows the processing pipeline of the prediction of the dense model quality and estimation of the best target positions to capture additional images. The geometry of the dense model is first approximated by a triangular mesh model generated from the triangulation of tie points created by SfM. The approximation method simplifies a method proposed by Labatut et al. [6] to improve its computational efficiency.

As shown in Figure 5, the triangular mesh generation begins with 3D Delaunay tetrahedralization of 3D tie point set P and creates a set of tetrahedra H. Then, the intersection test is performed between every tetrahedron in P and a set of rays $V_i = \{\boldsymbol{v}_j^i\}\,(\boldsymbol{v}_j^i = \boldsymbol{p}_i - \boldsymbol{c}_j)$ beginning from the projection center of the j-th camera $\boldsymbol{c}_j$ to the i-th visible tie point position $\boldsymbol{p}_i$ $(i \in P)$.

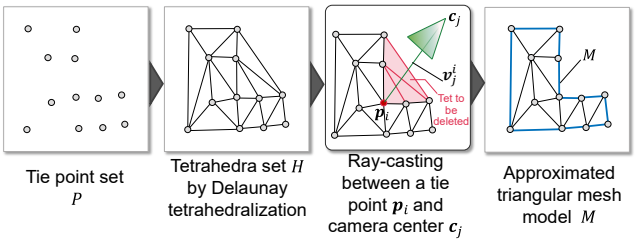

Figure 5. Generation process of the approximated triangular mesh model M

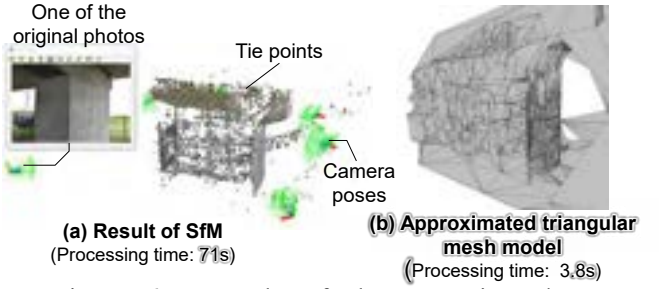

Figure 6. Example of the approximated triangular mesh model M

If a tetrahedron intersects with a ray, it is deleted, and the remaining set of tetrahedra is defined as H'. Finally, we obtain the approximated triangular mesh model M by taking the surface boundary meshes of H'. The algorithm is described in detail in a previous study [4].

Figure 6(a) shows an example of the tie point set P and camera poses generated from 33 original photos of a bridge pier, and Figure 6(b) shows the corresponding approximated triangular mesh model.

3.2 Quality Predictor Estimation

Next, the quality predictors $F_X(i)$ for a dense model are evaluated at a sparse point i ($\in P'$, P': sparce point set) that constitutes the vertex of the approximated triangular mesh model M based on the tie point set P and the camera pose set $E = \{\boldsymbol{e}_j = (\boldsymbol{c}_j, \boldsymbol{\theta}_j)\}$, where $\boldsymbol{\theta}_j (\in R^3)$ is a vector of three Euler angles representing the projection orientation of the j-th camera. The predictor $F_X(i)$ quantifies how accurately the final dense model can be reconstructed around the sparce point $i (\in P')$. The basic idea of the quality predictor was initially proposed by Mauro et al. [7]. Note that we designed different types of predictors based on that study [7].

In the proposed method, the following four quality predictors are evaluated at each sparce point $i (\in P')$.

- **Reliability** $(F_r(i))$. The local geometric quality of the reconstructed dense model around a sparce point i decreases as the n umber of visible cameras $|V_i|$ supporting a point i decreases. Therefore, the *Reliability* predictor of the point i is defined as follows:

$$F_r(i) = |V_i| \tag{1}$$

- **Area** $(F_a(i))$. As the area of a triangle on M enlarges, the reconstruction error of the dense model tends to be large. Therefore, the average area of the triangles on M adjacent to a point i is evaluated as the *Area* predictor defined by as follows:

$$F_a(i) = \frac{1}{|T^i|} \Sigma_{t_j^i \in T^i} area(t_j^i) \tag{2}$$

where T^i denotes a set of triangles adjacent to i.

- **Edge length** $(F_e(i))$. When the object surface to be measured is poorly textured, the edge length of a triangle on M tends to be long and the point clouds generated by SfM become sparce. Thus, the average edge length adjacent to a point i is evaluated as the *Edge length* predictor expressed as follows:

$$F_e(i) = \frac{1}{|D^i|} \Sigma_{j \in D^i} length(e_j^i) \tag{3}$$

where D^i denotes a set of edges connected to i.

- **Baseline and height ratio** $(F_{bh}(i))$. Based on the principle of stereovision, higher-quality reconstruction by MVS is obtained from a correct ratio between the baseline length and height. The baseline length is the distance between two camera positions $\boldsymbol{c}_j$ and $\boldsymbol{c}_k$, and the baseline height is the distance between the space point position $\boldsymbol{p}_i$ and the midpoint of the baseline $\boldsymbol{c'}_{jk}$. It is well known in photogrammetry that the quality of the dense model is related to this ratio [8]. Therefore, the ratio is evaluated as the *Baseline and height ratio* predictor as follows:

$$F_{bh}(i) = \frac{1}{|J_i|} \Sigma_{(j,k) \in J_i} \left(\frac{\|\boldsymbol{c}_j - \boldsymbol{c}_k\|}{\|\boldsymbol{p}_i - \boldsymbol{c'}_{jk}\|} \right) \tag{4}$$

where J_i denotes a set of all possible camera pairs visible from a sparce point i.

The detailed calculation of the indicators is explained in a previous study [4].

To consolidate the four quality predictors into a single indicator representing the degradation of the dense model, first, we converted each of the predictors given by Equations (1–4) to a normalized energy $\in [0,1]$ using the logistic function $L(\,)$ proposed by Mauro et al. [7] and quadratic function $K(\,)$ as follows:

$$E_X(i) = \begin{cases} L(F_X(i) - \mu_X, \sigma_X), & X \in \{a, e\}; \\ 1 - L(F_X(i) - \mu_X, \sigma_X), & X \in \{r\}; \\ 1 - K(F_X(i), \sigma_X), & X \in \{bh\}, \end{cases} \tag{5}$$

where μ_X denotes the average of F_X, σ_X is the standard deviation of F_X, $L(x - \mu, \sigma) = 1/\left(1 + \exp\left(-\frac{2(x-\mu)}{\sigma}\right)\right)$, and $K(x, \sigma) = 1/(1 + (x - 0.5/\sigma)^2)$. In Equation (5), higher energy means that the geometry of the final

(b) Dense model generated from the 33 original photos and 3 additional photos set by MVS

Figure 8. Three target points for additional image capture and the improved dense model obtained used MVS after additional images have been captured

dense model is more degraded.

Finally, the four energy values $E_X(i)$ are aggregated by taking an average to denote a *geometry degradation indicator* at a sparse point i as $E_{GDI}(i)$ as follows.

$$E_{GDI}(i) = \big(E_r(i) + E_a(i) + E_e(i) + E_{bh}(i)\big)/4 \qquad (6)$$

A region with high indicator value $E_{GDI}(i)$ on the approximated triangular mesh model $M^{'}$ indicates that the local region around the sparse point i on the dense model has a more significant possibility of degrading the geometry. It also implies that valid photos are lacking in the region with a high indicator value and that additional image s should be preferentially captured to improve the dense model quality of the region around the point i.

Figure 7(a) shows the distributions of the indicator values $E_{GDI}(i)$ on the approximated mesh model M of the pier shown in Figure 6. The predicted quality of the upper part of the pier is low (red), which suggests that the number of images captured capturing in this area was insufficient. Figure 7(b) shows a dense model generated by MVS from the original 33 photos. In Figure 7(a), the upper parts of the pier shape with high indicator values were not fully reconstructed in the dense model. Thus, it is evident that the quality prediction based on the geometry degradation indicator $E_{GDI}(i)$ is functioning.

3.3 Estimation of Additional Shooting Positions

Low-quality areas on a dense model should be improved by capturing additional images as efficiently as possible. To this end, it is preferable to identify target positions of as many low-quality areas as possible for an additional photo shoot. Therefore, based on the geometry degradation indicator, the target points for the additional photo shoots are selected by an optimization.

First, for every sparce point $i(\in P')$ on the approximated model M, the geometry degradation indicator $E_{GDI}(i)$ value is added as an attribute value w_i. Then, the degree of degradation in the peripheral region of i is estimated both from a target point $j(\in P')$ and from the indicator values of the sparce points i' included in the region near the target point j. A photo shoot to capture additional images should be oriented to cover the areas with the most considerable geometry degradation. Finally, $s$target points for additional photo shoots are derived from the sparce point set P' using the combinatorial optimization and a greedy algorithm. Details of the optimization process are presented in a previous study [4].

Figure 8(a) shows the three low-quality areas and the target points for additional image capture. The areas were derived from the distribution of the geometry degradation indicators in Figure 7(a) with $s = 3$. The indicator values in the areas around the target points are higher than in other areas, and the target points can be placed at the low-quality areas appropriately.

Figure 8(b) shows a dense model reconstructed by MVS from 36 images, including the three additional photos corresponding to the three target points. Compared to the model generated from the 33 initial images in Figure 7(b), the quality of the reconstructed area at the top of the pier increased significantly despite adding only three images. Therefore, the effectiveness of the target point selection algorithm can be confirmed.

4 Case Study

4.1 Evaluation of Reconstruction Qualities

A case study was conducted at a seawall construction site shown in Figure 9 (51 m × 2.4 m) on

Figure 9. Scene of the construction site of wave-dissipating block installations at Toyoura coast

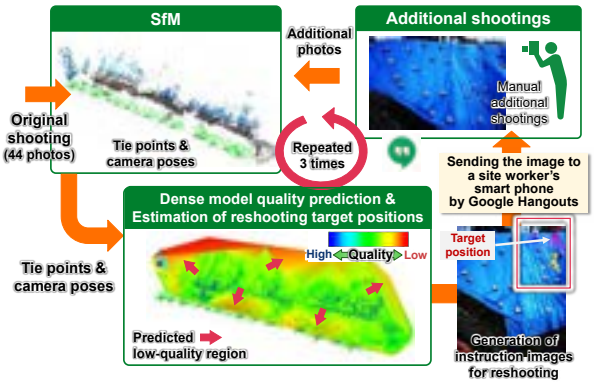

Figure 10. Process flow of the case study

the Toyoura coast in Tomamae-Cho, Hokkaido. The proposed photogrammetry process was performed. The process involved an original photo shoot, dense model quality prediction, on-site best-view guidance, and additional photo shoots to record the installation of wave-dissipating blocks.

To decrease the time required to upload images from a camera to the cloud system, a smartphone (HUAWEI Mate20-Pro) with a built-in high-resolution camera was used. The image resolution was set to 9.7 million pixels to reduce the transfer time, and a wide-angle lens was used. By using a smartphone, captured images could be automatically uploaded to Google Drive immediately. In addition, with this image resolution setting, the upload time could be significantly reduced to within a few seconds per image. Since the SfM and best-view guidance server does not necessarily need to be installed near the construction site, we installed it at the Sapporo campus of Hokkaido University. A high-speed internet connection is available between the university and the construction site on the Toyoura coast.

Figure 10 outlines the process flow of this case study. Forty-four original photos were taken from sparse positions using the smartphone camera by an on-site worker while walking on the top of the wave-dissipating blocks. Next, the next-best target positions to capture additional images were estimated. Then, an instruction image was generated on the server-side and sent to the worker's smart phone. Finally, according to the instruction image, the worker took five to 10 additional photos once and repeated the process of transmitting the images to the server three times. The time required by the process is summarized in Table 1.

Table 1. Processing time in the proposed photogrammetry process

	Total photo # (Additional photo #)	Time for SfM processing	Time for estimating the best target positions	Time for MVS processing
Original	44	**1 min 30 sec**	**3.96 sec**	15 min
1st Addition	49 (5)	**1 min 20 sec**	**4.17 sec**	-
2nd Addition	58 (9)	**1 min 20 sec**	**5.08 sec**	-
3rd addition	68 (10)	**1 min 40 sec**	-	**20 min**

Red Bold： Processing time actually required for the dense model generation using the proposed process

Figure 11 shows the dense model reconstructed by MVS from only the 44 original photos, the estimated best target positions, the corresponding instruction images, and an example of the photos added by the worker. The dense model geometries generated by MVS with those additional images added at each stage are also shown in Figure 11.

As can be seen from Figure 11, it is possible to visually confirm that the 3D model can be generated with relatively good quality even with images captured by the built-in smartphone camera. In addition, using the model quality prediction and estimation of the best target positions to capture additional images, the defects and holes between blocks generated in the model reconstructed from the original images disappeared in the model generated after images were added, and the correct block geometry could be reproduced. The area near the drainage pipes on the upper left of the slope was greatly expanded. As shown in Table 1, estimating the best shooting target position once could be completed in approximately 1.5 min.

From the above results, it is evident that, in a construction site, using a smartphone camera to capture images and as communication device is suitable for 3D photogrammetry measurement in which the model geometry is successively improved. Although the improvement in model quality depends on the number of shots, the result suggested that the proposed process might be able to complete the reconstruction of the dense 3D model on the day that the one-site images were captured.

On the other hand, some areas around the blocks still require additional photo shoots and setting the criteria for terminating these repetitive image capture processes was left as an open problem.

4.2 Estimation of Processing Efficiency

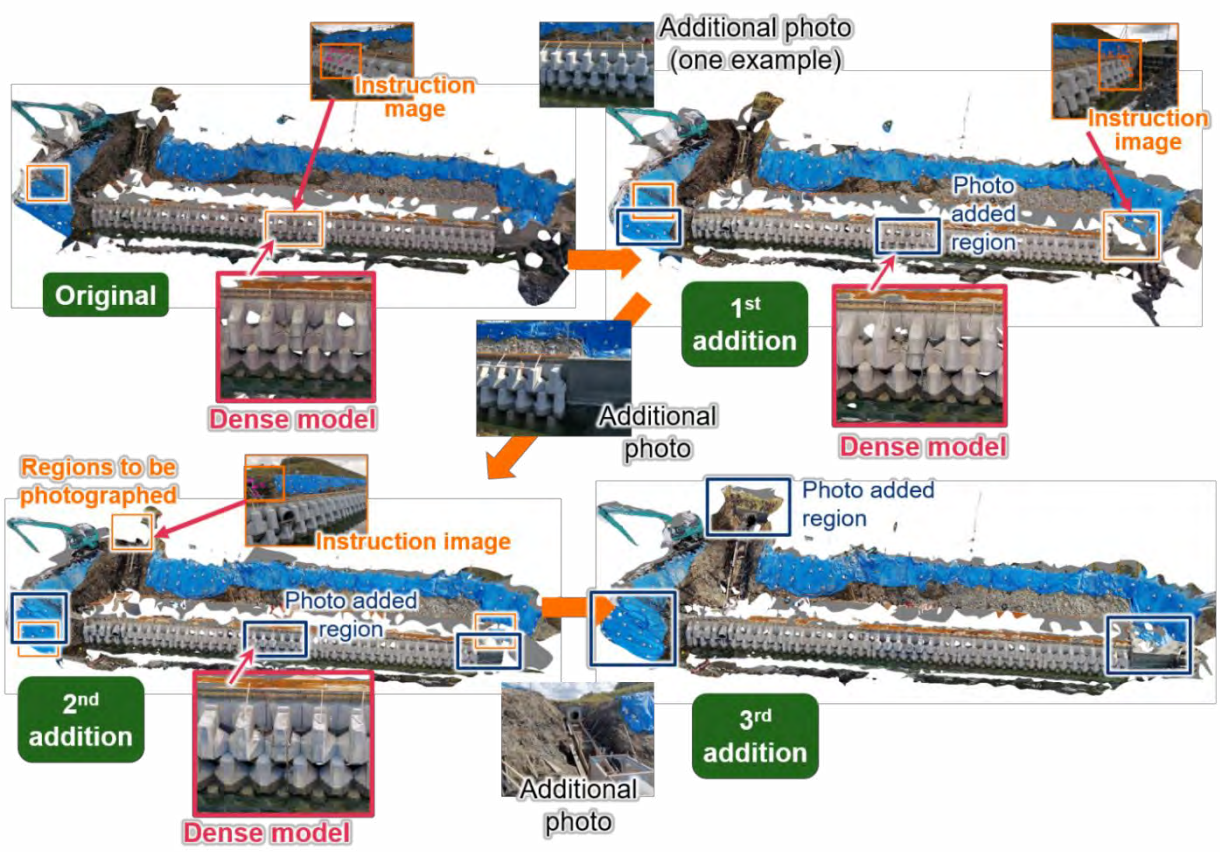

Figure 11. Changes in the dense models by 1st, 2nd, and 3rd addition of images

To quantify how efficient dense model reconstruction using the proposed photogrammetry process is compared to two conventional processes. We compared processing times for the following three approaches.

(1) Conventional photogrammetry with single photo shoot and an excessive number of images. Here, a dense model was reconstructed by performing the SfM-MVS together for approximately 400 images captured at the site.

(2) Conventional photogrammetry with a single additional photo shoot. First, 44 original photos were obtained, and a dense model was generated once by SfM-MVS. Then, the low-quality portions of the dense model were identified manually, and 24 target points for an additional photo shoot were determined. Finally, the SfM-MVS process was re-executed with 68 images to reconstruct a final dense model.

(3) The proposed process. Here, the process started with 44 original images. Then, SfM was performed, target positions to obtain additional images were identified using a computer, and five, nine, and ten photographs were added to the original images. Finally, the dense model was reconstructed by performing MVS only once for the 68 images acquired.

Note, for the processing efficiency comparison, the Toyoura coast construction site was taken as an example (Section 4.1).

The bar chart in Figure 12 shows the comparison results. In estimating the processing time, referring to the values obtained from the construction site of section 4.1, the required shooting time per photograph was estimated to be 15 s. The SfM and MVS processing time per photo was 0.03 and 0.3 min, respectively. Moreover, the time required to estimate the shooting target positions was assumed to be constant at 6 s. Note that the image upload time was included in the shooting time because it was only a few seconds per photo.

As can be seen from the comparison in Fig. 12, process (1) required approximately 3.5 h to reconstruct the dense model from the excessively captured photos. With the proposed process (3), the dense model could be reconstructed in 40 min, which is approximately one-fifth of the time required by process (1).

In addition, since process (1) requires MVS processing of a significant number of images, which takes considerable amount of time, the quality of the dense model cannot be confirmed until the processing is

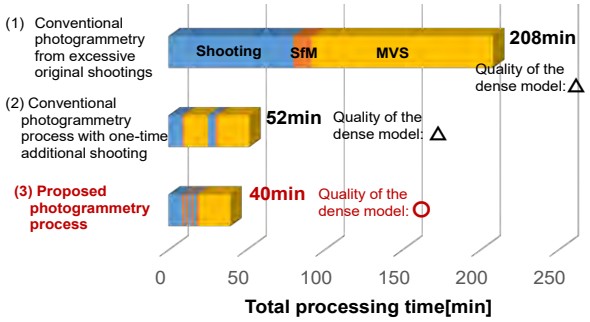

Figure 12. Comparison of the total processing times among (1) conventional photogrammetry process with excessive image capture, (2) conventional photogrammetry process with a single shoot to capture additional images and (3) the proposed photogrammetry process

complete, i.e., approximately 3.5 h after the photo shoot. On the other hand, with the proposed process (3), we estimate that the shooting target positions that reflect the prediction of the dense model quality for the currently captured photos can be fed back to a site worker in approximately 2–3 min after capturing the photo. Thus, it is possible to ensure that all required images are captured and to realize an efficient photo shoot.

Furthermore, in processes (1) and (2), the selection of shooting positions is left to the user; thus, there is no guarantee that the additional photos will improve the reconstructed model's quality. In contrast, with the proposed process (3), since the computer selects the best positions at which additional photos should be taken based on the model quality estimation, it is highly likely that additional images will effectively contribute to the quality improvement of the reconstructed dense model.

5 Conclusion

In this paper, we have proposed a new photogrammetry process that improves the quality and efficiency of dense model reconstruction of construction sites. The proposed process begins with a small original photo set. Then, the computer-supported best-view guidance system predicts the geometric quality of the dense model, estimates the best target positions for additional photo shoots using only SfM results, and feeds back those positions to a site worker. Depending on the number of target positions, the feedback process could complete in 1.5 min. The effectiveness of the proposed process and the system was evaluated at a real-world construction site. As a result, it was found the process and the system could prevent excessive image capture, improve the efficiency of the on-site photo shoots, and generate the dense model with a certain degree of quality assurance. We also found that a smartphone, which can send and receive images to and from the construction site, was the most suitable shooting device for implementing the process.

However, currently, some server-side operations still require manual processing. In the future, we would like to implement fully automated processes that include SfM and best-view guidance on a cloud server.

Acknowledgments

This research was supported by the following grant-in-aid from the Ministry of Land, Infrastructure, Transport, and Tourism in FY2018-19: “Project on the introduction and utilization of innovative technology for dramatically improving the productivity of construction sites: Utilizing data to improve the productivity in construction labor in civil engineering.”

Abstract -

We have been and are doing development and research on construction AI system based on Actor-Critic framework. This paper discusses cyber agents who are computerized agents of mobile entities, which are composed of construction machines, vehicles and workers. Each of the cyber agents would carry with simple function to work together in the Actor-Critic cyberspace. The cyber agents will passively or actively walk through the cyberspace to help for workers to explore and capture critical factors latent in a large amount of information that might go into making decisions. The contents described in this paper might be almost a sublimation of the papers we have submitted to the ISARC for the past decade. This paper is organized as follows. First, this paper describes Actor-Critic framework for construction AI system. Secondly, this paper reports role of cyber agent. Thirdly, this paper explains inference mechanism of abduction reasoning and briefly shows example of inference. Finally, this paper presents further development and research on functions that the cyber agent should carry with in future.

Cyber agent; Humanware; Actor-Critic; Abductive reasoning; SRK model; Subsumption

1 Introduction

We have been and are doing development and research on construction AI system based on Actor-Critic framework (hereinafter called "construction AI") to support workers' decision making for earthworks. Cyber agents are computerized agents of mobile entities, which are composed of construction machines, vehicles and workers (i.e., operators, drivers, foreman, resident engineers, line-manager, and others). Each of the cyber agents would carry with simple function that work together in the actor-critic cyberspace. This cyberspace has three layers structure that consists of knowledge, rule and skill levels (SRK model), and the higher level subsumes lower level with downward commitment and the lower level provokes the higher level with upward activation. The Actor has policy structure to select and take actions, and further the state- or action-value functions to fire signal, sign and symbol. The Critic has functions of edit, calculation and analysis of readings captured by the PoC as explained later.

The cyber-agent will inhabit and passively or actively walk through the cyberspace to help for workers to explore and capture critical factors latent in a large amount of information that might go into making decisions.

The contents described in this paper might be almost a sublimation of the papers we have submitted to the ISARC for the past decade. This paper is organized as follows. First, this paper describes framework of the construction AI system. Secondly, this paper reports role of cyber agent. Thirdly, this paper explains inference mechanism of abduction reasoning and shows example of inference in brief. Finally, this paper reports further development and research on functions that the cyber agent should carry with in future.

2 Framework of Construction AI

Figure 1 shows schematic view of the construction AI system.

Figure 1. Schematic view of construction AI system

The construction AI system consists of the components as described below.

2.1 Points on Construction (PoC)

The PoC takes sensor-based event detection approach to track fleet of construction machines, vehicles and workers which are working together on site. The PoC automatically and real-timely gather a set of readings related to events occurred by the fleet activities [1],[2]. In other words, the PoC looks like a feeler of the cyber agents.

2.2 Geospatial Index based on Space-filling Curve

We use the Hilbert curve that folds one dimensional axis into a 2D space. The Hilbert curve here covers fully minimum bounding box covering working area. A serial number [1, max (number of vertices)] is assigned to each of vertices of the Hilbert curve. The position of the vertices of the Hilbert curve coordinates cell centres of the ground grid, for examples, the position index (i, j) of the corresponding vertex in a 2D array indicates the "i" th vertex in x and the "j" th one in y direction. The serial number might be almost equivalent to zip code in our daily life.

2.3 Database of Readings and Lookup Table of Tuples

Readings are captured by the PoC and then knowledge would be represented by lookup table of tuples. Each of the tuples is composed of code_id, cyber agent name, file name of the readings, proposition, condition, consequent, threshold, effects, belief, w_{ij} and action. The proposition is a parent of conditions and these are organised as a parent - child relationship on a semantic network. In many cases, the condition is expressed as potential cause of failure mode, and the consequent is expressed as potential failure mode in a production rule, which is presented as a disjunction literal and might be a hypothesis.

The threshold is a value above which the condition is true or might take place and below which it is not or might not.

The effect indicates potential effects of failure that forks into two categories "High" and "Hazardous." The former means "Will affect product performance, and some product will have to be scrapped, and rework possible," and the latter means "Will affect workers' safety."

The belief means a posterior probability that is an element of Bayesian Belief Network of the condition and the consequent.

The w_{ij} indicates weight in element [i-th row, j-th column] of Hebbian weight matrix, which represents strength of relationship among the conditions and the consequents or the consequents. The Hebbian weight is defined by the equation (1) [11].

$$w_{ij} = \log \frac{p(y_j, x_i)}{p(y_j) * p(x_i)} \quad (1)$$

In many situations, the consequents might be trouble phenomena happened on site, and otherwise potential failure modes from an action that the cyber agents at the actor component should take as described later.

2.4 Critic Component

Figure 2 shows relationship between the actor component and the critic component. Each of the cyber agents inhabit the critic component, and carries with simple function that could edit, calculate and analyse a set of the readings captured by the PoC. They could set threshold values at the 5% and 95%, or the 1st and the 2nd quantiles of empirical distribution function, and then do quantile processing to convert from the continuous variables to dichotomous ones.

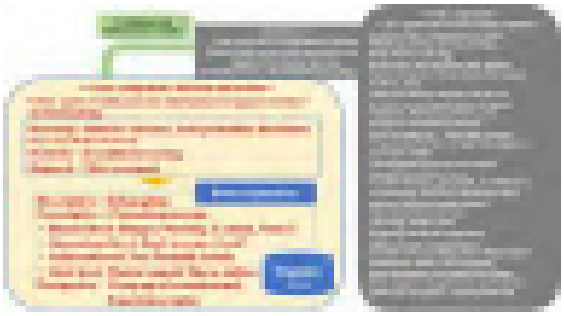

Figure 2. Relationship between actor and critic components

They would hand over their results of calculation and analysis to the cyber agents inhabit the actor component.

2.5 Actor Component

As is shown in Figure 2.4.1, the actor component functions decision and action based on the results received from the critic component. More loosely speaking, the actor component has three mechanisms as follows:

2.5.1 Production rule

Production rule associates a condition or a proposition (if) with the consequent, i.e., a phenomenon or an action (then). Besides, the rule states what cause is most likely to trigger what failure when the consequent might be true.

Strength of production rule indicates firing priority. The production rule is chosen based on the order of

priority predefined by expert experience, or indicated by the calculated Hebbian weight "w_{ij}."

Dichotomous variables received from the critic component would trigger that the cyber agents here would interact with rule-base, that is, listwise production rules and take predetermined action. Besides, each of the cyber agents would carry spatio-temporal analysis model, and functions to generate infographics. The spatio-temporal analysis model would be used to analyse dataset with spatial and temporal property and to visualize a region or points of interest.

2.5.2 Better explanation

The current situation is descriptively depicted by infographics with precaution message might prescriptively be informed as follows:

- Hazard level: Danger, Warning, Caution, Notice,
- Operational level: Bad, Average, Good,
- Achieved level: Not, Partially, Attain, and
- Alert level: Wait or cancel, Take a shelter.

2.5.3 Eligibility trace

The actor produces list-wise infographics with early precautionary messages, and forwards them to the dashboard. Moreover, the visiting of a state or the taking of an action, Hebbian weights are temporary recorded as an eligibility trace. The eligibility trace marks the token (i.e., signal, sign, symbol) associated with the event as eligible for undergoing learning changes. And then, wrap-up of lesson learned would be informed from different person perspectives.

Eligibility trace has two levels: which experiences to store, and which experiences to replay (and how to do so). Here, prioritized experience replay is used to remember and learn from more frequently past experiences [3].

2.6 Dashboard of Remotely Real-time Monitoring System

Figure 3 shows structure of remotely real-time monitoring system.

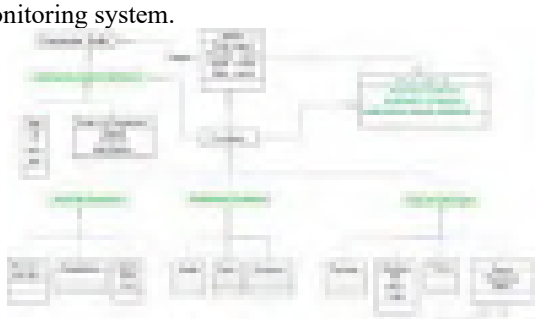

Figure 3. Structure of remotely real-time monitoring system

The dashboard is a visual display on screen of smart phone, PC or other device that are installed at the control or cabin room, and otherwise the operators carry. Information displayed on the dashboard is consolidated and arranged on a single screen so that infographics can be monitored at a glance [2].

2.7 Workers

The workers mean people who are actually working together on site, for examples, operators in cabin room or remote-control room, drivers, foreman, resident engineers, line manager, and others.

3 Role of Cyber Agent

Main role of cyber agents is to pick a set of building block of information at the right level of abstraction and at the right time, and then provide workers with infographics on real time basis. Each of cyber agents with simple functions forms a swarm of them, and interacts with each other. Figure 4 shows schematic view of the cyber agent.

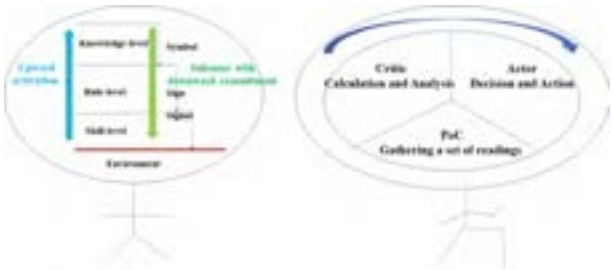

Figure 4. Schematic view of the cyber agent

The actor-critic space, that is, brain of the cyber agent, consists of hierarchy of skill-level. rule-level and knowledge-level （SRK model), and the higher level subsumes lower level with downward commitment and the lower level provokes the higher level with upward activation as shown left in Figure 3.1[4],[5]. At the skill level, signal might distribute from the 1st person point of view. The signal is directly grounded the perception-action coupling with environment. At the rule-level, sign might flow from the 2nd person point of view. The sign is grounded based on social convention, for example, crossing sign "red" means "stop." At the knowledge-level, symbol might propagate from the 3rd person point of view. The symbol has meanings that live in their mind, not in the item itself, for example, flags are symbols for nations. Each of the cyber agents would proceed along cycle of the PoC - the critic - the actor as shown right in Figure 3.1.

Supports for workers' decision making from the 1st, 2nd and 3rd-person point of views are described below.

3.1 The 1st Person Point of View

In general, the 1st person point of view (POV) is used the term that depicts a method to control a radio-controlled machine or vehicle from the operator's or driver's view point. Discussions in this study shall narrow down the eye-hand coordination task regarding to operate construction machine and to drive vehicle from the operator's or driver's view point.

Handling joysticks to operate construction machines or steering wheel in vehicle, either remotely or directly, is an inherently eye-hand coordination task. The eye-hand coordination means to control eye movements with hand movements, and as processing visual representation of the situational views to handle joysticks or to steer control along with the use of proprioception of the hands, or vice versa. In either manned or unmanned operation, the operators' or drivers' performances limited by humanware in their behavioural frameworks, and continuous or intermittent mental workload burden on them. The humanware is defined a function composed of leadership, followership and the reciprocal interaction between the two [6],[7],[8].

Besides, a mechanized earthwork process is separated into several works that are sometime independently and at other time interactively performed by different workers. For examples, road construction includes a series of discretely repetitive operations such as excavating, loading, hauling, dumping, grading, compacting, etc., which are performed by different operators, drivers and other workers, who are belonging to different subcontractors. Consequently, it becomes difficult to gather field data concerning each operation, to grasp their own operations in progress on real time basis, and to understand the "Do's" and "Don'ts" in the whole earthwork process. Here, since workers might reduce their vigilance, they might take physical reactions to startling or unexpected events in the monitors or in front of vehicle, and might not secure the safe, reliable and effective earthwork process.

The cyber agents here would compensate for operator's realistic sensations to enhance spatial awareness by providing workers with physical cues as shown in Figure 5.

It would be significant to provide them with physical cues which would enhance their diagnostic and prognostic capabilities to reflect on their own unsafe behaviour. The information modelling here means a process involving acquisition of field data and feedback of relevant digital representations of physical and functional characteristics of works in progress.

The role of the information modelling is largely grouped in to the followings:
(1) To find signals of overturn, slither, or skid of mobile entity (i.e., machine or vehicle), and then issue alert message. Concretely, the x-, y-, and z-axis acceleration responses are captured and analysed to
- Find signals as to overturn and slither of the mobile entity, and
- Visualize phenomena of rolling, pitching, and vacillation of the mobile entity in order to prognosticate dangerous sections or spots in emergency, and
- Suggest work zone with the driving path to be repaired,
(2) To provide workers with infographics that play role in the following matters:
- Feedback of physical cues related to behaviour of mobile entity, and
- Spatio-temporal visualization of hazards latent in in-situ earthwork process.
(3) To provide oneself with the opportunities to reflect on their own bearings as facing their own works at hand,
(4) To take timely and quickly correct actions based on detailed visibility of appearances and motions of mobile entities in an earthwork process, and accordingly,
(5) To reduce likely mental stress burden on operator and driver in the remote-control or cabin room.

Figure 5. Enhancement of spatial awareness by providing workers with physical cues

3.2 The 2nd Person Point of View

Cyber agents might use push notification service for early precautionary or forced messages to the worker being targeted at, where the use of pronouns: you, your, yours, yourself, yourselves.

The early precautionary messages would hold, referring to ANSI Z535,5 definitions, the levels of early precaution are set as danger, warning, caution, and notice.

The forced message might include changes or stoppage in work order, or evacuation. The forced message could force you to take action in order to prevent undesirable behaviour or events.

3.3 The 3rd Person Point of View

Cyber agents here would pick a set of building block of information at the right level of abstraction, and

produce construction profile at the right time. The construction profile is defined as a set of data to vision characteristics of phenomena being generated along with earthwork in progress and indexes to show their patterns [9],[10]. Figure 6 shows image of cross section and longitudinal analyses. It is expected here to take situational awareness into account in changes and to find any hotspot in spatiotemporal situations.

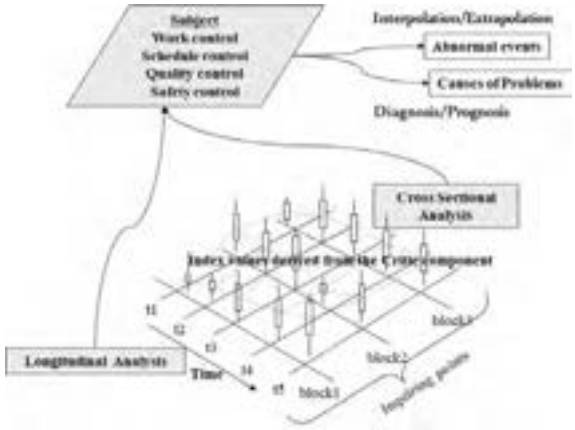

Figure 6. Image of cross section and longitudinal analyses

Based on the above information, the 3rd party people (i.e., resident engineers, line manager and others) would be able to find changes in the situation of work zone or points of interest and to evaluate force account work performed at cross section and toward longitudinal in earthwork progress from the following viewpoints:

- Viewpoint 1: Watch line balance. For example, search unbalance of productive capacity among construction resources;
- Viewpoint 2: Search abnormality in earth work progress. For example, find construction resources that have extra-high production capacity and one in the opposite side;
- Viewpoint 3: Watch state- or action-value of control. For example, find change in mean and variance or shift change in time series, and look at trend of increment or decrement;
- Viewpoint 4: Watch productivity. For example, look at planned versus actual productivity of a work package, and make a comparison between the two. The work package is a group of related tasks within an earthwork process; and
- Viewpoint 5: Look at construction speed based on the following step: first, set base line of earthwork progress; secondly, calculate progress rate in situ, and finally make a comparison between the two.

Infographics could be very helpful for the 3rd people to consider current situation of earthwork in progress from the above viewpoints. The infographics would be displayed on the dashboard of the remotely real-time monitoring system [2].

4 Abduction Reasoning

4.1 Inference Mechanism

The cyber-agent here is a virtual worker who inhabits the cyberspace composed of the actor component and the critic one. The cyber-agent will passively or actively walk through the cyberspace to help workers explore and capture critical factors latent in a large amount of information that might go into making decisions. The cyber agents would utilize abductive reasoning to form threshold value generated by quantile processing of experience probability function, Bayesian Belief Network, Hebbian weight, etc. presented in the tuple, and then inference backwards from consequent to antecedent. The inference is to affirm consequent and then conclude that the condition or the proposition is supposed to be true. In other words, this is inference from the observations to the best explanation, that is, the simplest and most likely conclusion. This inference, however, does not positively verify it.

Figure 7 shows abductive reasoning composition.

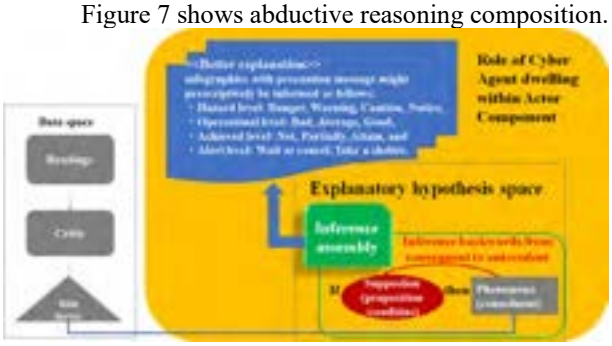

Figure 7. Abductive reasoning composition

4.2 Examples of Abductive Inference

This section shows examples of abductive inference related to dozer operation on highway construction site. First, this section presents a class of the cyber agent. Secondly, composition of tuple is explained. Thirdly, infographics are reported. Finally, Example of abductive inference is briefly shown.

4.2.1 Class of Cyber Agent

The cyber agent is set as a class (ex. R5 in R language). Example of class of dozer is shown below.

```
Bll <- setRefClass(
Class = “dozer ", #character string name for the class.
fields=list(#either a character vector of field names or
a named list of the fields.
maker_name = "character",
model_number = ”integer”,
operating_weight_kg = "numeric",
engine_power _rpm = "numeric",
speed_km/hr = "numeric",
overall_length_mm = "numeric",
```

```
overall_width_mm = "numeric",
overall_height_mm = "numeric",
shoe_width_mm = "numeric",
track_on_ground_mm = "numeric",
ground_contact_area_m2 = "numeric",
ground_pressure_kPa = "numeric",
ground_clearance_mm = "numeric",
),
#named list of function definitions that can be
invoked on objects from this class.
methods =list(
Initialize=function()
  )
)
```

Similarly, each of the required functions is set as a class. A part of the class of the required functions is listed below:

- gg.gauge #progress gauge,
- inflect #Finding local maxima and minima,
- geodetic.distance #distance on the surface of the earth between two points,
- trackDistance #Distance travelled,
- kde2d.weighted #kernel 2D density with weight,
- HampelFilter #median absolute deviation,
- loess (locally weighted scatter plot smooth),
- ses (single exponential smoothing),
- movingAverage,
- LongLatToUTM #Converting lat, long points to UTM meter unit,
- zcr (zero crossing rate),
- PtInPoly #extract points within polygon,
- Hilbert #HilbertCurve,
- force #3-axis acceleration composition value,
- real operational rate of machine by each work-in day,
- body attitude, and
- calculation of polygon area, and so forth.

4.2.2 Composition of Tuple in Lookup Table

As mentioned before, the tuple consists of i code_id, cyber agent name, file name of the readings, proposition, condition, consequent, threshold, effects, belief, w_{ij} and action. This section reports a part of proposition and production rules below.

(1) As for productivity and safety, a part of propositions is listed below.

1. Productivity:
- Reference of productivity per one hour,
- Driving forward or back distance of dozing operation,
- Real operational rate per a day,
- Dumping volume of material per a truck,
- Dozing area performed,
- Performance index (a ratio of the precedent rate to the successive one in each of work cells), Pitch time (time lapsed/production volumne),
- Abnormal observation, and so on.

3. Safety:
- Vehicle uphill/ downhill on a steep slope,
- Jump start; Sudden brake; Sharp turn; Excessive speed,
- Skidding, Overturn,
- Hazards latent in haulage road,
- Proximity Awareness, and so on.

(2) A part of production rules is listed below.

1. Impact and free-fall

Threshold values depends on quantile processing of empirical probability distribution.

If (95% <= the 3-axis acceleration composition value) then it is presumed that strong impact occurred at the longitude and the latitude, and

If (the 3-axis acceleration composition value < 5%) then it is presumed that free-fall occurred at the longitude and the latitude.

2. Dangerous proximity during operating machine when entering into the proximate area of 100 m range from other machine or dangerous spots like those.

3. Dangerous operation:

a) Sudden acceleration or rapid deceleration, when the jerk value of travelling speed gets larger than the predefined threshold value;

b) Turnover risk when finding trend for machine body to lean to crosswise or longitudinal direction and value of rolling or pitching more than 15 degrees; and

c) Defect productivity warning when finding

- Run length of key performance indicator changes in time series more than the threshold "7";

4. Other thresholds are set at the points 5% and 95%, or the 1st and the 3rd quantiles of experience distribution function;

4.2.3 Infographics

Readings in this example are captured by on-board smartphone for dozer. The sampling frequency was one HZ. The array element of the readings consists of [time, longitude, latitude, 3-axis acceleration, 3-axis angular velocity, direction, speed, FB]. The FB is a code that indicates forward, backward, or stopping

Figure 4.2.3.1 shows spatiotemporal trajectory of dozing and compacting In Figure 8, slate blue dashed line means "running trajectory on plane"; Brown dot indicates "spatio-temporal trajectory of running along with the axis of time." It is from Figure 8, we will be able to explore existential changes in spatial and thematic properties of travelling, dozing, and compacting, and also the time lapsed. This trajectory is plotted along with the vertical time axis and with locations on two-dimensional plane of longitude and latitude coordinates. Stopped and/or idling states of machine are dotted vertically along with the time axis. It can be seen from Figure 8 that the stopped and/or idling time is short during dozing and compacting operations. Total distance travelled here was 6030.622 m.

Besides, this infographic can be utilized for a fleet management of several machines, such as backhoes, crawler carriers, dozers, and vibration rollers, and so on. If dotted marks should be plotted at the same time and at the same position, the machine works related to the dotted marks are liable to be interfered with each other.

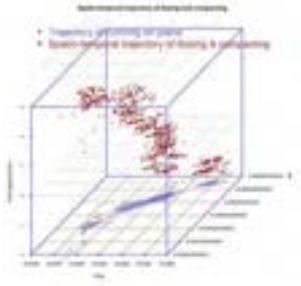

Figure 8. Spatiotemporal trajectory of dozing and compacting

Figure 9 shows index-based Hilbert curve to portray terrain of dozer operation. The Hilbert curve is drawn as following step:
Step 1: Set level=4, then the partition_number=2^leve-1=15; and
Ste 2: Convert longitude and latitude to UTM meter unit; Normalize to range [0,1].

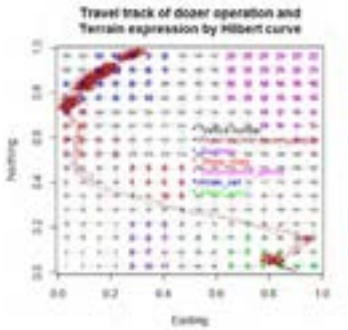

Figure 9. Index-based Hilbert curve

The index-based the Hilbert curve enables us to map multi-dimensional data to one-dimensional sequence values that could be inherently clustered, and then to allow for fast retrieval and storage. As mentioned above, the serial number assigned to the vertices might be equivalent to zip code in our daily life.

4.2.4 Example of abductive inference

The cyber agents could handle many kinds of physical cues to enhance workers' spatial awareness as shown in Figure 5. Due to limitations of space, examples of abduction inference regarding only one part of them are shown below.

Figure 10 and Figure 11 show occurrence spots of sudden acceleration and rapid deceleration while running; and existing of impacts and free-falls on site, respectively.

Some cyber agent might be interested in whether or not impact depends on speed. Here, inference would be proceeded along with the following steps:
Step 1: Set thresholds at the 5% and 95% points of experience distribution function,
Step 2: Generate cross table, that is, contingency table,
Step 3: Do chi-square test,
Step 4: Calculate joint probability and the Hebbian weight.

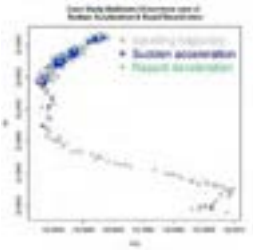

Figure 10. Occurrence spots of sudden acceleration and rapid deceleration while running

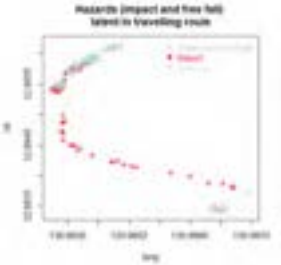

Figure 11. Existing of impacts and free-falls on site.

Figure 12 shows a part of semantic and propagation network related to the issue here.

Figure 12. A part of semantic and propagation network

If the Hebbian weigh might be significant, then the cyber agent would trace upward to the parent node, that is, the hazards latent in haulage road in this case. Otherwise, the cyber agent forgets it. The forget here means “take no-action” but “remember it, in other word, record it.”

The occurrence spots of sudden acceleration and rapid deceleration, and the impact and free-fall are significant, considering the thresholds, respectively, and then the cyber agent would inform workers of that facts, that is, the parent node of them with precaution on the dashboard of the construction AI. The phenomena of sudden acceleration and rapid deceleration is supposed to

be triggered by the dozer operation of "Pushing material" or "Releasing, spreading and compacting material." As for impact and free fall, the workers would investigate the haulage road in situ or review the recorded images of on-board camera for dozer to explore any hazard, for examples, corrugated road surface, pothole, difference in level, cave-in, corrosion, boulder, and so forth, latent in the haulage road.

As for the propagation from sudden acceleration and rapid deceleration to the impact and free-fall, the chi-square test does not show the significance. Moreover, The Hebbian weight values are minus. Consequently, the cyber agent would forget the relationship among the them, that is, "Take no action" but "Remember it."

5 Further Development and Research

The contents described in this paper might be almost a sublimation of the papers we have submitted to the ISARC for the past decade.

Implementation of the cyber agents is yet insufficient and still going on the road. We are required to gain experience of applying the way of thinking about the cyber agents to construction control on site.

For the present, we are scheduled to do further development and research on the following themes:

- Fulfilment of contents built in the tuple, especially, propositions, production rules, belief, Hebbian weights;
- Equipment of existing functions and objects fully with a reference class "setRefClass" in the R language;
- Objectification of abductive inference and to pile up the examples; and
- Experience replay with belief and Hebbian weights propagation.

In closing, we would like to say that any help and suggestions on this study would be heartedly appreciated. We are looking forward to meeting and discussion on the cyber agents with you all at the conference of the ISARC 2021 that will be held in UAE.

Abstract –

For earthwork, whether or not it will be possible to automatically generate a work plan for construction machinery has become the key to realizing autonomous construction of earthworks.

The use of AI is being sought by some researchers for the automatic generation of construction setups. Efforts are being made to utilize the results of construction work plan of construction machinery carried out by skilled engineers as learning data when searching for rules to reproduce construction work plan of construction machinery.

National Institute for Land and Infrastructure Management is considering acquiring work plans of construction machinery data in the MLIT ordering works, and to be going to provide these data. What is required for these data is to reproduce the history of construction progress and explain the reasons for deciding the construction work plan of construction machinery, and to provide those data in a format based on certain rules. We call this approach the examination of data standards for time-series change information at construction sites.

As a starting point, we examined the acquisition method of the topographic shape and the effective display format. We tried the Voxel display as a data format that makes it easy to grasp the amount of construction progress and to add attribute information to each construction point. On the other hand, some experts have pointed out the usefulness of the point cloud data and the surface data generated by connecting the point cloud data in the design of the drainage slope. This paper reports the initiative.

Keywords –

Work plan; Construction machine; earthwork; Learning data; AI

1 Introduction

In Japan, We, the Ministry of Land, Infrastructure, Transport and Tourism (MLIT) has begun to promote the efforts to improve the productivity of construction sites by fully utilizing ICT at construction sites since 2015, under the name "i-Construction" (Figure 1, [1]).

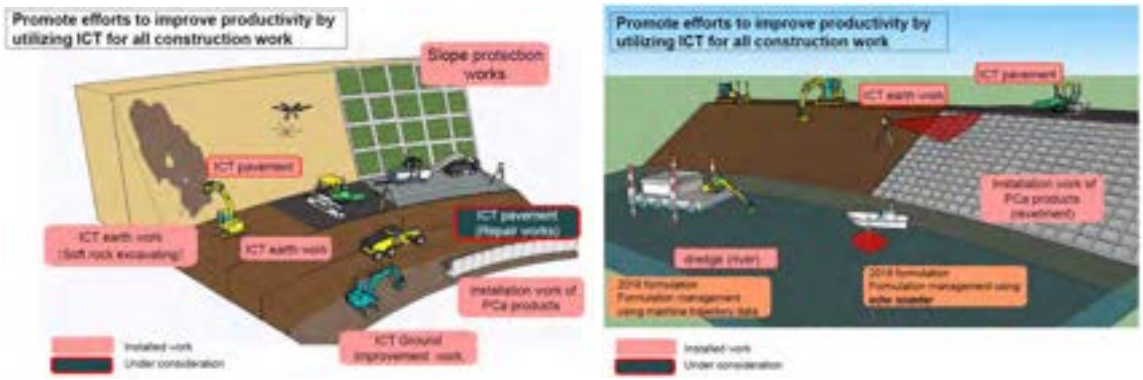

Figure 1. Examples of technologies targeted for introduction [1]

Since then, the following technologies have been utilized in earthwork, paving, dredging, etc.

- Efficient construction survey using ICT.
- A system that provides guidance to construction machine operators about work details.
- Construction machinery that automatically controls the blade edges of buckets and blades such as shovels, graders and bulldozers for shaping slopes and crowns of earthworks.

In the three years up to the end of January 2019, 2,287 cases of ICT utilization work have been carried out in the construction ordered by MLIT [2].

In addition, it is estimated that the amount of work done by humans has been reduced by an average of approximately 30% compared to the past by the full use of ICT in ground surveying, design data correction, construction, work form management/inspection, and electronic delivery [2].

We, National Institute for Land and Infrastructure Management (NILIM; Research department of MLIT) promotes the realization of AI construction machines that can automatically or autonomously construct, and that as a tool for further productivity improvement at construction sites. In order to do so, we started to study the data format for recording the time-series changes at the construction site and providing it in a widely usable form as the learning data for the autonomous construction AI (Figure 2). This paper reports the initiative.

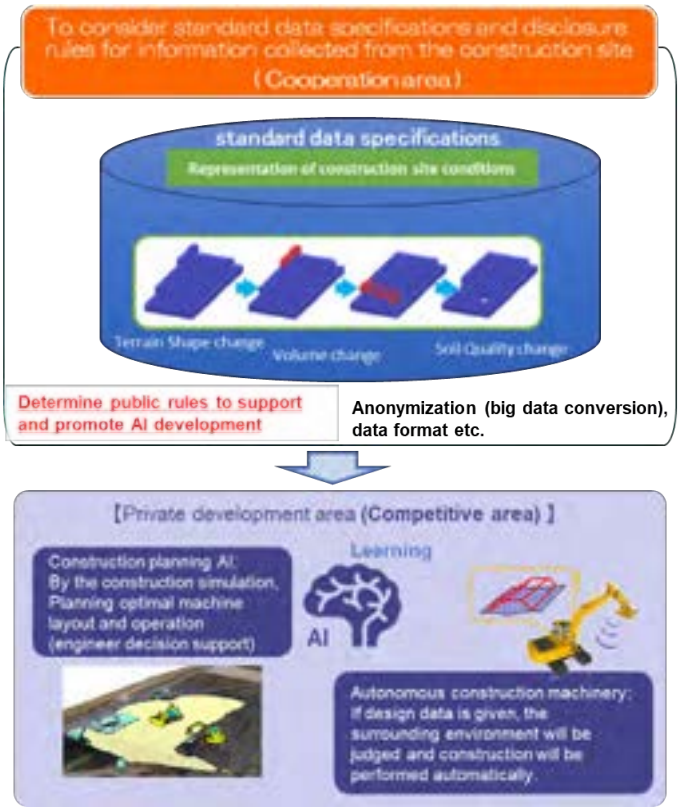

Figure 2. NILIM Project - Overall picture

2 Development status and key to realizing autonomous or automation construction technology

2.1 Current development status

As mentioned above, in earthmoving, semi-automatic control of buckets and blade edges such as shovels, graders and bulldozers has been realized and used for shaping slopes and tops of embankments [3]. Furthermore, some construction companies and construction equipment manufacturers are conducting experiments to operate combined construction of hydraulic excavators, vessel dumps, bulldozers, and vibrating rollers according to a human-defined program. In a closed environment where no one can enter, an excavator scoops up the sand in the sediment storage area, loads it into the dump vessel, moves the dump to the embankment point, dumps it, spreads the bulldozer, and compacts the vibrating roller. A series of work is being attempted [4].

And from a relatively long time ago, automatic calculation of the volume allocation plan has been realized. Compare the current topographic map with the blueprint showing the completed form and calculate the amount of cut and fill at each point. Then, using linear programming or some other method, calculate which embankment is to be filled with which cut so that the transportation cost of the soil is most economical [5].

2.2 The key to realization of autonomous or automatic construction; Development of “automatic generation of construction work plan of construction machinery”

However, based on this volume allocation plan, it is not so easy to calculate where to start and in what order to proceed. In order to move the soil, the difference in the earthmoving machine used (bulldozer, scraper, crawler dump, wheel dump) causes differences in transport efficiency and restrictions on the inclination of the moving path.

In addition, the local procurement costs (rental costs, transportation costs, etc.) of the earthmoving machinery itself to be put into the field will change depending on the site conditions and machine availability information. Many of these constraints exist, and they change depending on conditions such as the weather and economic environment, so if you perform an exact calculation, you will end up with a large-scale model.

When planning these steps with a computer program, it is necessary to examine every possible pattern of the work sequence, evaluate all the patterns, and select the optimum work sequence. This is a so-called "combinatorial optimization problem", and its calculation requires an enormous amount of calculation time compared to the linear programming

method used in soil volume allocation planning. Also, trying to reduce the computational cost of doing so requires a high degree of mathematical manipulation in assigning constraints.

So the bottleneck in automating all earthmoving is the step to achieve the automatic creation of work order plans to execute the volume allocation plan.

(As a program that partially supports work, in the work plan created by humans, the current situation is to calculate the required number of heavy equipment and perform a simulation applying queuing theory.)

3 Study on time series change information of construction site that should be collected as record data of construction execution setup

3.1 Purpose of this study

With the aim of realizing the automatic generation of construction execution setups, which was difficult to achieve with the conventional combination optimization approach, movements aiming for realization using AI are being sought. It is an approach such as using the construction execution setups actually performed by existing humans as learning data, and searching for work rules to reproduce the setups itself.

In order to support this approach, it is necessary to record the actual construction history of the earthwork and collect all the data that would explain the reason for the construction. In addition, it is useful to set certain rules for data collection and data format in order to provide such data in a usable state.

To achieve this, NILIM has begun studying a data standard for time-series change information at construction sites, assuming that this data will be provided.

3.2 Time series change information of construction site to be considered for collection

The most basic information that NILIM considers as time-series information at construction sites (Table 1) is the initial topography and final topography, and the history of changes in topography between them. And, as the constraint information that may have been used when selecting the change process, the ground conditions, usable materials and equipment (size and number of excavators, bulldozers and dumpers, embankment materials, etc.), the maximum number of days allowed for construction, and construction costs.

We will report the results of research and consideration on how to acquire the topographical shape data in Section 3.3, other data in 3.4, and how to link them after 3.5.

Table 1. List of Time series change information of construction site in this paper

	Perspectives of influential elements	Fine details	DATA	Format (unit)	Acquisition timing
Condition of construction machinery	Information for construction machinery management	Machine asset ledger	Construction machinery management records	Text or Numerical value	Annual, renewal
	Position and operating status of construction machinery	Construction machine operation records, location information, location history of work device, etc.	Working time	Date、Time	Secound
			Location log	Latitude/Longitude/ Elevation	Secound
			Operating log	Text or Numerical value	Secound
			Fuel consumption	Numerical value(L)	Day, Hour, Minutes
			Machine sensor log	Text or Numerical value	Secound
	Construction machine maintenance information	Failure code, maintenance history, etc.	Error log	Text or Numerical value	On maintenance or troube occurring
			Maintenance records	Text or Numerical value	On maintenance
	Information for productivity management	Cycle data, payload data, etc.	Construction volume per hour (Calculated by combining other data)		
			Bucket loading capacity	Numerical value(㎥)	On operatiing
Topographical data	Soil volume	Cut volume	Design/Estimation cut volume	Numerical value(㎥)	When starting work
			Actual cut volume	Numerical value(㎥)	On machine operation, UAV surveying
		Fill volume	Design/Estimation fill volume	Numerical value(㎥)	When starting work
			Actual fill volume	Numerical value(㎥)	On machine operation, UAV surveying
	Area	Total area	Design/Estimation area	Numerical value(㎡)	When starting work
			Execution area	Numerical value(㎡)	On machine operation, UAV surveying
		Area for each setting area (construction section)	Design/Estimation area	Numerical value(㎡)	
			Execution area	Numerical value(㎡)	
	Terrain shape	Surface or polygon	Terrain shape or its change	Point cloud、Latitude/Longitude/Elevation	
	Transport distance (outside, inside)	Bull, dump, heavy dump, various scrapers, etc.	Transport distance	Numerical value (km、m)	When starting work
(Geological data)	Soil quality	Clay, silt, sand, gravel, soft rock, hard rock, etc.	Soil type	Text or Index	When measuring
	Rate of change	Loosening rate L, Compaction rate C	Loosening rate	Numerical value(%)	When measuring
			Compaction rate	Numerical value(%)	When measuring
	Specific gravity	1.4～2.1	specific gravity	Numerical	When measuring
	Trafficability	Cone index	Cone index	Numerical	When measuring
	Ripperability	Number of nails	Number of nails	Numerical	When measuring
	Water content	Need for improvement, improvement/aeration yard	Water content	Numerical	When measuring
	Groundwater level	Workability	Presence or absence of groundwater and spring water	0/1	When measuring
(Meteorological and hydrological data)	Considering the number of rainy days and cold regions by region	Area and Weather	Weather	Text or Index	Automatic acquisition/manual input
			AMEDAS data (Regional rainfall information system in japan)	Text or Numerical value	Automatic acquisition
			Cold regions/snowy regions	Text or Index	Automatic acquisition/manual input
	Rainy season/dry season, dry season/normal season		※Present meteorological conditions of the area from past data of AMEDAS		
Construction Site Constraint data	Construction amount limit per day	Cut soil volume (transported soil volume), embankment volume	Cut soil volume (transported soil volume)	Numerical value(㎥)	When starting work or work planning
			embankment volume	Numerical value(㎥)	
	Removal limit of leftover soil	Embankment acceptance conditions and transportation conditions	Limit dump number	Numerical value (number、t)	When starting work or work planning
			Available days/days	Date	
			Available time/number of hours	Time or Time zone	
			Construction volume per hour (Calculated by combining other data)		
	Leveling/adjusting work (cost considerations)	Pile up, landslide, procurable number	Limit machine number	Numerical valeu (Number)	When starting work or work planning
			Available days/days	Date	
			Available time/number of hours	Time or Time zone	
			Construction volume per hour (Calculated by combining other data)		
	Workable time for each area	Securing land, constraints on construction plans	Available days/days	Date	When starting work or work planning
	Workable time constraint	Subdivided according to season, neighborhood, soil disposal conditions, etc.	Available time/number of hours	Time or Time zone	When starting work or work planning
	Secure work space (area)	Separation of heavy equipment that can ensure safety	Machines selected, workload, construction days (process)	Days	When starting work or work planning
			Area of each work area	Area	
	Sky height limit	Overhead line, etc.	Sky height limit	Numerical value(m)、Latitude/Longitude/Elevation	When starting work or work planning
	Construction management standard value data	Quality control, performance control, test/attendance frequency, etc.	Quality control		When starting work or work planning
			Finiish form management		
			test/attendance frequency, etc.		
	Safety management data	Loadable weight of transport machine	Loadable weight of transport machine	Numerical value(%)	When starting work
	Adopting ICT construction equipment construction	3D groundbreaking survey	Organization of construction machinery and surveying equipment to be introduced locally	Text	
		ICT construction machinery		Text	
		3D survey management		Text	
		Others		-	
	Ground improvement	Method	Ground improvement or not	1/0	When confirmed
	Local Soil improvement	Required specifications, materials used, amount added, machinery	Local soil improvement or not	1/0	When confirmed
	Bring-in Soil improvement		Bring-in soil improvement or not	1/0	When confirmed
	Designated construction period		Economic process, last-minute process	Text	
	Limited cost		Limited cost	Text	
	Machines designated for use		Limited Machine for use	Text	

3.3 Survey of technologies for acquisition of basic information (terrain shape data)

The following is the technology for acquiring topographic shapes, which was verified on-site at this time. The description in parentheses at the end is a description of the applied site. The site will be described later.

- UAV photogrammetry (Site A)
- 3D laser scanner (Site B (terrestrial),Site C (with UAV))
- Location history of construction machine work device (Site A, B, C)

These techniques have come to be used for surveys before construction starts and finished work measurements in MLIT ordering work.

The purpose of this survey was to understand the following facts.

- Actual measurement technology that can be used according to site conditions
- Available data area for each measurement technology
- Possibility of extracting topographical shape changes from those data

The field survey was conducted at three sites. The site outline, equipment used, and measurement data are shown.

① Site-A (Figure 3)

At Site A, UAV photogrammetry (about twice a day) and working equipment position history of construction machinery (real time) were used. These are assumed to be the most basic (Figure 4).

The data from the working device position history of the construction machine is, for example, information regarding the history of the blade edge position of the bucket of the hydraulic excavator. The data obtained here is a collection of data on the bottom surface in each range separated by a mesh of a certain size when a series of work is completed at a certain fixed position. In other words, you can acquire and record as data even the breaks for each setup. Utilization of work device position history data seems to be a useful method for grasping work setup.

② Site-B (Figure 5)

From the trial survey at the site A, the usefulness of the working device position history data was confirmed in the scene of utilizing the terrain shape data for grasping the construction execution setup, but at the site B, the problem was also confirmed.

At Site B, it was a site where a steep hill was cut. In order to efficiently carry out the work of loading cut soil into the dump truck to transport the cut soil off-site, the construction company at this site uses the temporarily formed slope for the slope and pushes down the soil to the loading point.

The shape of the pushed-down clod cannot be grasped from the work equipment position history data of construction machinery, so it was necessary to directly measure the terrain

■Site A

Work Type	Embankment widening (River)
Work Outline	Embankment using earth and sand from outside
Machine Configuration	ICT Excavator, ICT Bulldozer, Excavator (normal)
Constructor	Matsuura Construction company (Saitama-pref)
Collaborator	Komatsu Customer Support

Figure 3. Site-A Outline of construction and measure

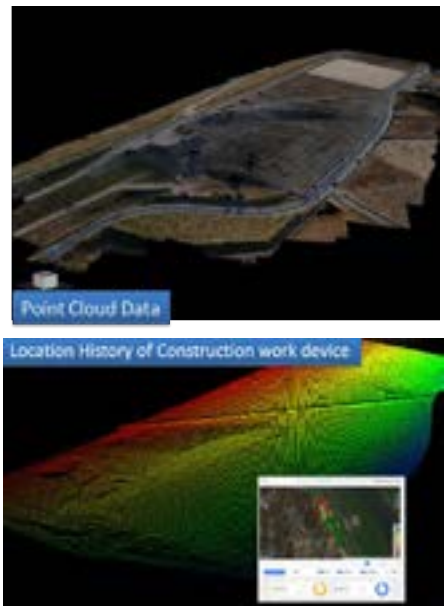

Figure 4. Comparison of point cloud by UAV photogrammetry and Location history of construction work device in Site-A

using UAV photogrammetry or a 3D laser scanner in order to perform this measurement. (Figure 6)

What was even more difficult at this site was the fact that there were roads with heavy traffic in the surroundings and the strong winds made it desirable to refrain from flying UAVs. Therefore, TLS (terrestrial Laser scanner) was used to obtain the topographical shape data.

It took a great deal of effort to change the installation position of the equipment at the site where the height difference was large, and the number of measurements was limited to 4 times per day. (It should be noted that the measurement operators commented that they do not want to carry out such measurements in the future.)

At such sites, it is considered effective to use construction machine-mounted camera images, acquired data from laser scanners, and stationary bird's-eye view camera image data to acquire site conditions.

■Site B

Work Type	Excavation, slope shaping
Work Outline	Excavation of hills, removal of sediment
Machine Configu -ration	ICT Excavator, ICT Bulldozer, Excavator (normal):2
Constru- ctor	Fukuue industry (Kagoshima pref)
Collabor -ator	Sitech Japan, Nippon Caterpillar

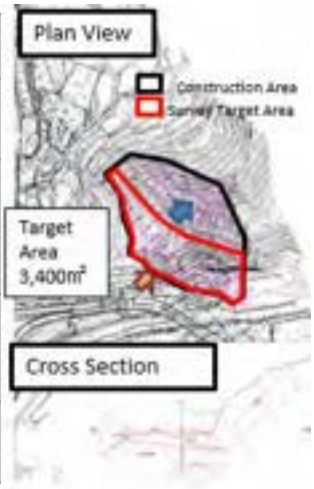

Figure 5. Site-B Outline of construction and measure

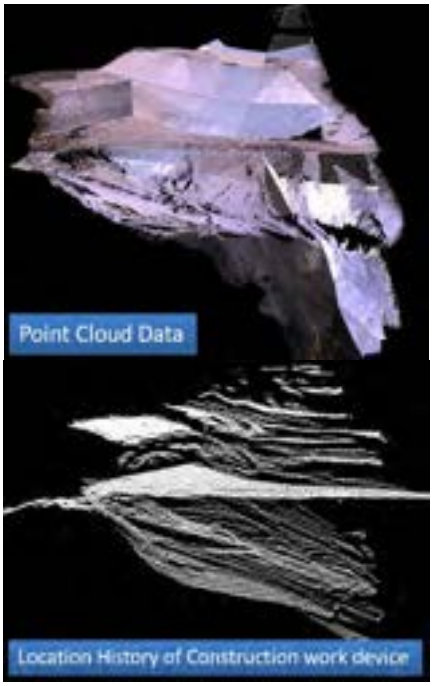

Figure 6. Comparison of point cloud by TLS and Location history of construction work device

③Site-C (Figure 7)

At Site C, we tried to obtain topographical shape data using a 3DLS with UAV. Unlike UAV photogrammetry, it was possible to obtain precise topographical shape data, but it cost about 8 million yen during the survey period. At present, it is difficult to use it from the viewpoint of application of grasping the construction progress. We would like to keep an eye on future technological trends.

Work Type	Road Embankment

Constru- ctor	Choho construction(N agano pref)
Collabor -ator	Kobayashi consultant

Figure 7. Site-C Outlines(upper) and Point cloud by LS with UAV

3.4 Survey on the actual status of data recording the progress of daily construction excluding topographical shape data

In grasping the construction execution setup, we investigated the existence of data that can be utilized to confirm from what viewpoint the site decided the machine selection and construction execution setup.

Although daily construction reports are prepared on site, it was confirmed that most of the sites are managed by handwritten or PC text information (Figure 8).

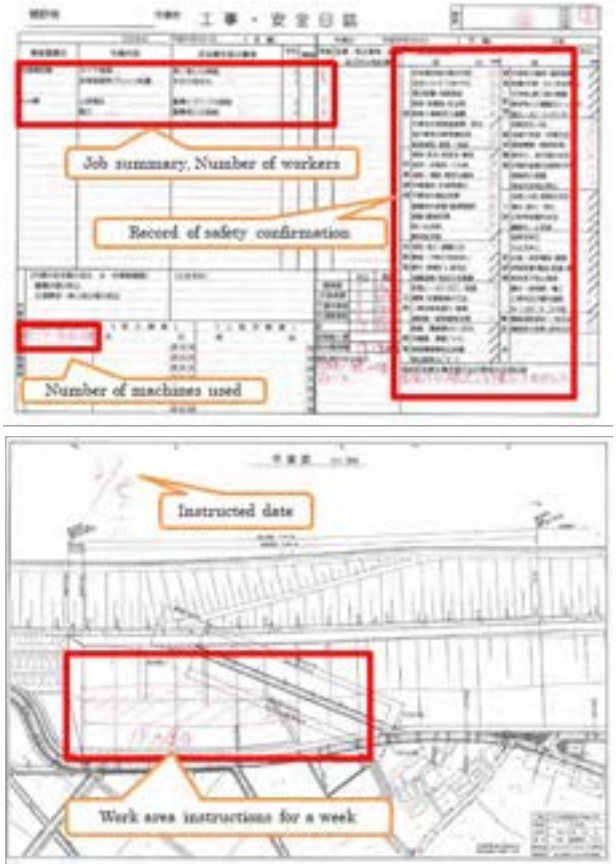

Figure 8. Examples of collected daily reports (upper) and construction instructions (under)

In many cases, the status of safety measures and quality control data are managed by inputting them in files of different styles such as Word and Excel. It is expected to utilize a platform that can handle these data.

System services have been started to centrally provide on-site construction management work, but their use is not yet widespread.

As one of the causes, it is assumed that it is due to the business practice when carrying out the construction work of the construction industry in Japan.

In Japan, the construction contractor, which is the main contractor, works with several companies that do the actual construction work. Also, the combination changes for each individual construction.

As a result, manual data entry can be efficient if different companies use different systems. It is expected that the system side will focus on this point.

3.5 Study on data structure and format of time series change information of construction site collected as record data of construction execution setup

It has been pointed out that the voxel format is useful as a display format of useful topographical shape data in planning the construction execution setup and grasping the progress of the construction.

These papers point out the significance of the following points when performing earthwork with hydraulic excavators and bulldozers [6]-[7].

- Whether the heavy equipment can be moved to the work location
- When planning work, the work volume can be easily grasped by grasping the work in voxel units.
- It is also possible to link quality information such as the material information of the voxel and the degree of compaction.

A further analogy is that when the construction procedure is reproduced later, it is possible to grasp the construction order by associating the starting order of each voxel.

An example of handling data in Voxel is analysis data by CT scan in the medical field. In CT scanning, X-rays are first applied to a fixed human body from various directions, and light is received on the opposite side to obtain transmitted X-ray data. Based on these data, we divide the body into each voxel, construct a simultaneous equation with the transparency of each voxel as a variable, and solve it. In this way, it is a technology that visualizes the internal conditions in three dimensions.

Technology is also being developed to convert the actual patient body data stored in voxel format for the surgery simulator. This has already been used in pre-surgical simulations at medical institutions in Japan [8].

Data retention in Voxel format may contribute to the application of these technologies to the construction side.

It is considered to be useful based on past research and precedents in other fields by converting the acquired topographic shape data into voxels and adding the necessary attributes.

3.6 Trial of data display in voxel display

Using the point cloud data acquired in 3.2, a trial of voxel modeling of the terrain shape was performed.

The voxel model referred to here is a representation of the terrain shape with a set of cubes. Each cube has x, y, z coordinates and is assigned a unique ID. In addition, the side length of a cube can be determined arbitrarily, so it is possible to reproduce terrains of various shapes.

Since this model is created based on the topographic surface data using 3D survey data, it has the feature that a rough ground shape can be visually grasped by the ground model.

Voxels are created by comparing the closest point cloud data with respect to the reference point cloud data and calculating the difference.

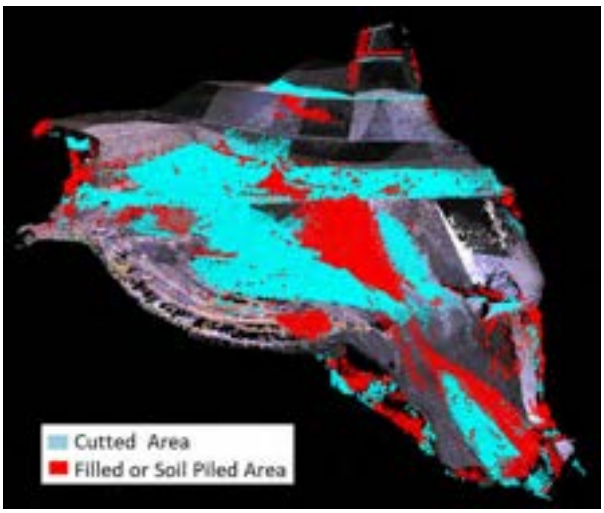

Figure 9. Change amount displayed as voxel on the point cloud data in Site-B

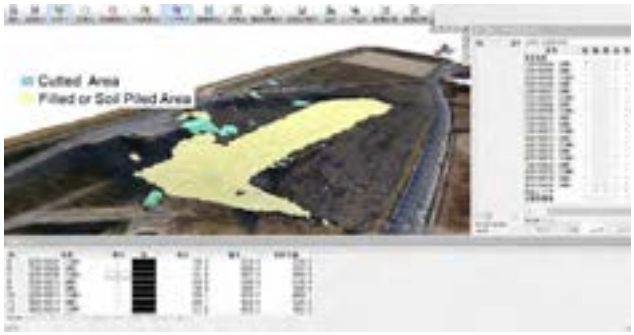

Figure 10. Change amount displayed as voxel on the point cloud data in Site-A

Figure 11. Continuous display of earthwork amount for each day in Site-A

Since software that has the function of changing the mesh width and height of voxels was used, it can be expressed as a cube or a rectangle.

In general, the voxel calculation method can be a one-point method, a four-point average method, a four-point columnar method, a topographic model (TIN) method, or the like. This time, the voxel has a specification that occurs when the difference volume exceeds 1/2 of the voxel volume, and the following method is adopted.

- Mesh width and height: 50 cm Output with voxels on all sides
- Voxel calculation method: 1 point method

By displaying the voxel data overlaid on the point cloud data, it can be seen that the construction part can be effectively extracted (Figure 9, 10).

In addition, the following is displayed separately for each lapse of time (Figure 11).

3.7 Additional discussion on the voxel size and data retention format based on the knowledge obtained from the exchange of opinions with a mechanical earthmoving company for the use of time-series change information at construction sites

Additional discussion on the voxel size and data retention format based on the knowledge obtained from the exchange of opinions with a mechanical earthmoving company for the use of time-series change information at construction sites

We presented these voxel modeled data and asked the construction company that specializes in mechanical earthworks to utilize the time-series change information of construction sites. As a result, the following points were received.

Table 2. Main opinions from earthmoving constructors

	Opinion content
1	I think expressing in voxels is good because attributes can be associated. It is important to consider how the surface water flows. (This is also a provision of MLIT)
2	As earthwork companies, the construction cost is not the best construction plan. In the face of various market constraints, we are planning to make sure that the equipment and human resources that can be arranged will be used without waste. It would be good if we could include things such as constraints.
3	If the construction process can be converted into data, it could be used as a basis for explaining the process to the orderer and for understanding the difficulty of the work.

Among the above points, from the viewpoint of the examination of the voxel model, the point that we should emphasize is that it corresponds to the provision of the inclination angle for drainage regarding the surface finish of earthwork during construction execution setup.

Based on this recognition, the factors affecting the topographical shape were extracted from the precautions for earthwork described in the construction standard specifications, which are applied to the construction ordered by MLIT (Table 3).

Table 3. Main provisions in MLIT specifications related to earthwork topography

Provision Name	Provision Content
1-2-3-3 Embankment	
2. Prevention of embankment sliding	When the embankment is carried out on the ground with the slope steeper than 1: 4, the flat step cutting (minimum width and height are 1.0m and 0.5m) must be carried out, and the embankment and the site board must be closely adhered to prevent the slide, except for the case where the instruction is given.
3. Finished layer thickness	In embankment construction, the finished thickness should be 30 cm or less and compacted flat.
6. Wastewater treatment at the end of work	When the contractor finishes the embankment work or interrupts the work, the contractor must provide a cross slope of about 4% on the surface and compact it evenly to ensure good drainage.

In order to be able to confirm these provisions or regulations with the voxel model, it is necessary to study the size of the voxel. Based on sampling theory, we need to be able to extract less than half the size of the observed object.

It may be necessary to display in a size different from the vertical and horizontal directions, such as 0.5 m or less in the vertical and horizontal directions and 0.15 m or 0.1 m or less in the depth direction, in order to address all of the points pointed out.

When utilizing time series change information at the construction site for accountability to the orderer, it is necessary to consider not only the display format of these data but also the data retention format of the actual voxel model.

Although it is a voxel model, the actual data format may also have a practical idea of having coordinate data of the center point of each voxel and linking the data to it.

The discussion on this point requires further study by grasping the following trends.

- Initiatives for intelligent compaction at FHWA
- Data handling cases in other fields (compared with data capacity from hand rig cases on a computer for large amounts of data)

4 Conclusion

The following findings were obtained in this research.

- Efforts to automate construction work plan of construction machinery will hold the key to the realization of automatic construction in the future.
- To realize the construction work plan of construction machinery support AI, construction history information as learning data is required.
- Construction history information consists of basic time-series data of topographical shape data, quality relations associated with it, and construction constraint data.
- The usefulness of the voxel format as a data display or data storage format.
- Through the trial of voxel display and the exchange of opinions with practitioners based on it, it is necessary to set the voxel size up to 0.5 m in width and height and 0.15 or 0.1 m in height direction along with the effectiveness of the point cloud data.
- Further investigation of data handling precedents in other fields such as consistency with similar efforts in other countries and medical care is effective.

Abstract –

Adaptation of dated residential towers is an urgent issue due to aging housing infrastructure and growing demand for affordable housing. Computational design methodologies have the potential for facilitating optimized design strategies driven by improved energy performance and reduced life-cycle carbon emissions. Modular Construction (MC) can also increase efficiencies in the design and implementation of building adaptation projects and minimize construction waste. The application of MC in the adaptation of existing buildings is gaining interest with improvements to MC technologies and processes, as well as large-scale adoption. There are currently no frameworks for the integration of MC in the adaptation of complex buildings driven by energy performance and Life Cycle Analysis (LCA). To address this gap, a framework is developed for integrating computational design methodologies and design optimization using energy use and LCA for improving overall building adaptation processes. The building adaptation of Ken Soble Tower in Hamilton, Ontario, is used for the functional demonstration. A set of extension modules are considered, and various adaptation scenarios that conform to set design constraints are evaluated for energy use and LCA. The results of this study prove the practicality of using computational design methodologies for the integration of MC in the adaptation of concrete residential towers and can promote the efficiency of improving existing residential infrastructure.

Computational Design; Modular Construction; Life Cycle Analysis; Building Adaptation

1 Introduction

There is a need for the reconsideration of our status-quo linear approach of design and construction with the inevitable end-of-life option of demolition. Adaptation of existing buildings and infrastructure has increased over the past decade as a response to changing environmental conditions, as well as requirements for reducing energy use and production of construction and demolition waste [1]. For a shift to a circular built environment, there is a need to consider building adaptation, including reuse of buildings and materials, with a focus on modularity, disassembly as a means to facilitate continual loops of resources, products and materials in construction [2]. Modular construction facilitates maintenance, repair and reuse during different life cycle stages of a building and minimizes waste generation during construction and deconstruction [3]. Incorporating modular construction strategies in building adaptation projects, specifically modular extensions to existing buildings can improve the condition of an existing building while preparing it for a circular future in which unnecessary demolition is avoided, and the building modules and materials can enter multiple cycles of use.

The success of modular building projects is directly related to appropriate early decision-making due to the planning and coordination focused nature of modular projects. Morphological and modular form generation is improved by environmental performance feedback in an automated design process [4]. Through early design stage optimization, Kiss and Szalay were able to demonstrate

environmental savings of 60-80% compared to traditional design methods. Life Cycle Assessment (LCA) is an essential factor in evaluating the potential environmental impact of buildings. Design option optimization often considers a limited number of options [5], highlighting the need to consider generative design options and evaluation methods for correct optimization of multiple factors simultaneously. An early-stage design optimization tool for modular extension to existing buildings needs to consider energy performance, life cycle analysis, as well as the design considerations of modular building extensions. This research presents a framework for integrating performance optimization in Modular Construction (MC) for the application of building adaptation projects. The critical aspect of the proposed model is the integration of computational design strategies for simultaneous analysis of MC metrics, energy analysis and life cycle analysis. The Ken Soble Tower retrofitting project in Hamilton, Canada is used as a functional demonstration of the proposed framework.

2 Background

In a traditional building adaptive reuse feasibility and early design process, many uncertain factors need to be taken into consideration. The client's inputs, including project requirements, budget and timeline, are taken into account as well as an analysis of the existing conditions of the building, including building geometry, overall status and areas for improvement. The client information and analysis are processed by the design team to develop design options, to be analyzed by consultants, including energy consultants, LCA consultants and cost consultants. Feedback from consultants is looped back to the design team, and design options are revised intermittently and shared with the client for feedback. This cycle may repeat many times over many months to arrive at possible suitable, non-optimized design options at best.

Compared to traditionally constructed concrete buildings, prefabricated modular construction can reduce environmental impacts, increase on-site productivity and construction quality [6]. Jallion et al. (2009) demonstrated that prefabrication in controlled factory environments has been shown to reduce construction waste by 52 % [7], and reported by other researchers to range typically between 10-15% [8]. Effective assembly of prefabricated modular units can also improve on-site construction conditions, including reduced construction pollution, noise and occupant disruptions, making it an ideal strategy for dealing with occupied existing buildings and urban areas [9]. MC integrates modular design with prefabrication and Design for Manufacture and Assembly (DfMA) [10]. A great potential in quality and productivity is in prefabrication and modularization of buildings and their components [11]. There are multiple levels of modular construction identifies including 1) Components and sub-assemblies (i.e. millwork, fixtures, etc.), 2) Panelling Systems (i.e. exterior cladding), 3) Volumetric Pre-fabricated assembly (i.e. kitchen and bathroom pods), and 4) Pre-fabricated modular units, incorporating complex systems of assembly used in combination to form an entire building [3], [12]. This research focuses on the application of modular units as a complete prefabricated unit ready for assembly.

The current strategies for the design of prefabricated buildings are similar in many ways to the design system common in traditional construction. The design of prefabricated buildings is a systematic process, including considerations in design, manufacture and assembly. The design process for conventional construction does not consider methods and principles for addressing the manufacturing process involved in prefabricated buildings [6]. The design process and precisely, decisions made in the first 10% of projects determine up to 80% of the building operation costs after construction [13]. As MC relies heavily on design accuracy due to the coordination focused nature of their process, the success of a modular project is directly related to appropriate early design decision-making.

Environmental design optimization is the process of considering and evaluating alternatives in the design phase that impact the overall performance of a design. Energy use and LCA are important factors in evaluating the success of a design strategy and the potential environmental impacts of a building. They can be considered adequately in the early stages of design. Parametric and generative design environments also enable optimization of building geometry, allowing the designers to test design variation with immediate building performance feedback [4]. The consideration of multiple factors including cost, energy and life-cycle performance has become common in the past decade in early-stage design. Granadeiro et al. integrate early design stage automation of building envelope design with energy simulation using grammars [14]. Yu et al. used genetic algorithms and design structure matrix (DSM) to support automated spatial organization in the early stages of design [15].

Modular construction has proven advantages in terms of LCA and LCC compared to traditional construction and can contribute to more energy-efficient buildings through the improved quality of construction [16]. Form generation is improved by environmental performance feedback in an automated design process [4]. Despite this, there are currently no studies highlighting a framework for the integration of early-stage design optimization of energy use, LCA for MC, specifically for large-scale building adaptation projects. Energy use and LCA

optimization can be applied using a parametric tool with geometry represented mathematically or as topologies [17] in combination with the application of MC design parameters to design building adaptation scenarios that meet the requirements of modular construction, as well as optimization of environmental metrics.

3 Computational Design Framework

The proposed framework is developed in three stages to integrate a computational design methodology as well as energy and life cycle performance optimizations in MC design processes for building adaptation projects: 1) analysis and parametrization of the existing building, 2) design option generation and simulation and 3) result refinement and optimization. Stage one requires manual work and processing from the user and project designers in processing the existing building and defining parameters. Through a step-by-step analysis of the building, development of design constraints and processing of user inputs, precise design constraints and rules are developed for algorithm input. In the second stage, the developed algorithm generates and analyzes design options for energy use and life cycle performance. Design options that meet the set criteria are displayed in stage three. The framework enables the user to input preferences regarding the generated options, beyond which the algorithm will optimize the options for the defined factors. After optimization, the user can parse through the optimized options and select the most suitable. This framework suggests possibilities for the incorporation of external databases and previously analyzed cases for the development of databases of all feasible solutions leading to a predictive model of performance feeding the results, to be investigated at a later stage of this work. The last two stages of the framework are fully automated and can be processed in real-time (Figure 4).

The developed computational framework is differentiated by geometric simplicity, integration of automated processes and simulation tools and processing of direct manual user input in various stages. Existing computational interfaces, plugins and frameworks are being used in the development of a cohesive tool that integrates existing resources and facilitates integration. The generative design tool is programmed using Grasshopper® visual programming interface and plugins are used within the interface for energy use simulations and optimization. One-Click LCA® is used for preliminary life cycle emission calculations. Future development of the framework will involve the incorporation of external databases and analytical cases, creating a database of feasible solutions over time and developing predictive algorithms (Figure 4).

The Ken Soble Tower in Hamilton, Canada, is selected as a functional demonstration and will be used to demonstrate the functionality of the framework in various stages.

3.1 Stage 1 – Analysis and Parametrization of Existing Building

The first stage in the framework is focused on the analysis of the existing building and parameterization, as well as the development of design constraints. The design constraints are developed by processing the existing building information, defining design parameters and determining user inputs and requirements. Design parameters are defined based on analysis of the existing building, existing site conditions, and planning requirements and restrictions. Design input including adaptation strategies to be considered, such as the extension of the building, recladding of the envelope, re-glazing of the windows and enclosing of existing balconies. In this research, the extension strategy is investigated in the functional demonstration of the Ken Soble Tower.

In the first phase of stage 1, the existing building drawings are analyzed, and the geometry of the existing building, including interior spaces and the building envelope, are modelled. The existing structure is analyzed to determine required design parameters, including structural, environmental and spatial shortcomings of the existing building. The existing building is modelled as zones (Breps) and aggregated into topological complexes. The building geometry is further discretized into panels and elements at the discretion of the project designer.

For efficient MC design, the least number of module variants are required. Development of design constraints early in the process, such as a speculative grid for modular design, will limit the dimensionality of the design problem leading to a heuristic approach and increased accuracy of design options generated. For building an extension, recladding and addition, for example, the following steps are required: 1) building parameters defining modular extension parameters; 2) module parameters including spatial configurations, connection parameters, and growth patterns and restrictions; 3) panel parameters including dimensions of panel divisions, the spatial organization of panels and connection details. To acquire this information, the existing building geometry is analyzed in terms of dimensional and spatial constraints for the extension, and the dimensions of a typical module are determined (**Figure 1**). The typical module dimension and the spatial analysis lead to the determination of rules for “growth.” Figure 1 demonstrates the points of “growth”, and the direction of permitted extension determined by the designer. At the level of the determined module size, panels are broken down and analyzed in terms of joining

conditions that include: 1) attachment of new module to the existing building (*e*), 2) connection of two modules together (*c*) and 3) exterior façade (*f*). Through multiple design exercises, the number of required panel divisions for each panel, panels *a* and *b* are determined for each condition of *e*, *c* and *f*. In the case of the Ken Soble Tower project, the variation of module connections lead to 16 different possible configurations of *e*, *c* and *f* for panel *a,* seven different possible configurations of *e*, *c* and *f* for panel *b* as demonstrated in Table 1. The 23 different panel possibilities result in a total of 22 possible module configurations.

As part of the existing building analysis, the LCA of the existing building is determined considering the existing operational energy use standards. After the modules and panels are determined, use the material take-offs and calculate the life cycle impact, not accounting for energy use for each of the modules separately using One-Click LCA. The combination of these modules will be used in the algorithm to determine the LCA of the combined design options in real-time.

A user input interface using Human UI® for GH® takes into account the preferences of the user regarding various aspects, including budget, number of preferred units, unit size variations, balconies and window placements, etc. An integrated user interface allows for changing initial conditions and input values, selecting modes and paradigms of operation, and integration of user selection and manual search for solutions. User interface – using Human UI® depending on the skill level of a prospective user, one can use Human UI® only or start manipulating the GH® scripts that are part of the framework. The user in our framework is defined as the designer, modeller or client evaluating building adaptation strategies. In our framework, the user can input preferences, review and parse through results and to reconfigure preferences based on project data in real-time. The user inputs and requirements include constraints for the extension, number of additional units required, number of bedrooms per unit and unit square footage as well as environmental goals, including energy efficiency and carbon targets. The building analysis results combined with the input parameters are used to feed the developed algorithm for option generation. The building inputs and analysis, as well as design and user inputs, are combined to create a detailed breakdown of the design constraints (B-3) for the development of the algorithm.

3.2 Stage 2 - Option Generation and Simulation

After defining geometry and selecting strategies, a virtual grid of speculative possibilities is computed. The developed algorithm generates adaptive design options by positioning modules and assigning states based on the information stored in the grid, previously determined in stage 1. The design options are generated using the developed algorithm within GH and Topologic is used to track changes in their topological structure.

Topologic® is a software modelling library enabling hierarchical and topological spatial representations through non-manifold topology [18]. Existing geometry is modelled as Breps (directly modelled or extruded from existing drawings) and then fed as input to the module translating Rhino® 3D Brep object to topologic cells, organizing them and forming topologic complexes. The set of options is generated through a brute force search, being finite and relatively small, allowing for computation and comparison of all the possible options. A topological structure with cells governs the distribution of modules and assignment of states. The generated design options will then be analyzed for energy use and life cycle carbon simultaneously.

The net environmental impacts for each building adaptation design option consider the LCA of the existing building and consideration of the extension of life by 60 years through building adaptation. The LCA of modules and the existing building are calculated in line with EN 15978:2011 standards [19] for LCA Modules A1 to Module D. The energy use of each compiled design option is calculated inside GH® in real-time, using the Honeybee® plugin. Honeybee® supports thermodynamic modelling and creates, runs and visualizes the results of energy models using EnergyPlus® and OpenStudio® simulation engines. The number of extension modules is calculated in Grasshopper® in real-time and calculated using the pre-calculated LCA of each module from stage 1 using the following formula (1):

$$E_{total} = E_i[kgCO_2e] + \sum_M n_M\, E_M\, [kgCO_2e] + U_{total}[kWh](U_{factor}[CO_2e/kWh]) \quad (1)$$

Where E_{total} is total carbon emissions including operational energy use, E_i is the carbon emission of the existing building excluding operational energy use, n is the number modules per module type in each design option, M is the type of module used in the design option, E_M is the emission of type M module excluding operational energy use, U_{total} is the total energy use of the building including existing and extension modules, and U_{factor} is the local emission factor.

3.3 Stage 3 – Result Refinement and Optimization

The results of option generation and simulation is visualized using the Human UI® interface in

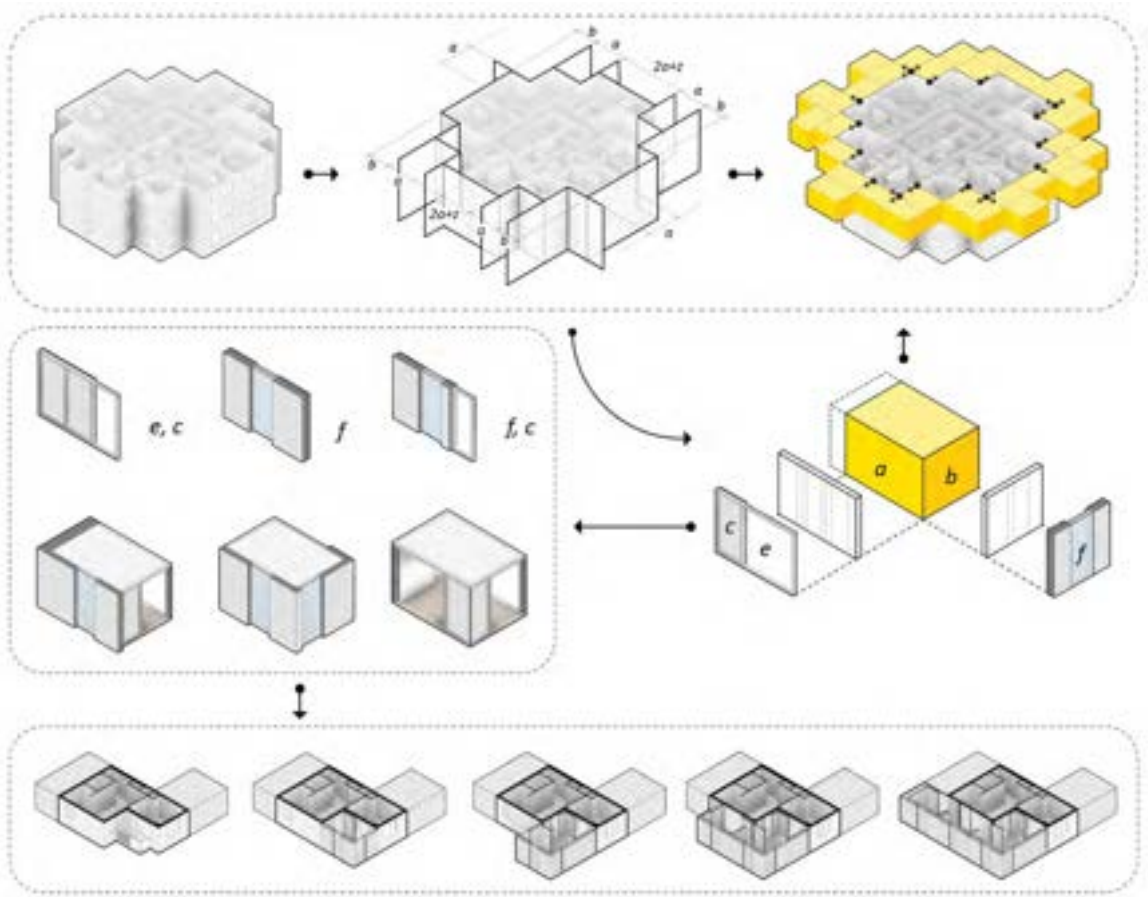

Figure 1. Stage 1 – Parametrization of existing building, determining typical module sizes and panelling configurations, determining possible growth patterns, finalizing module dimensions, and module configurations, determining various module extension options for each existing unit.

Grasshopper®, through which the user can manually review all the generated and evaluated options and refine the search for the most viable option via sliders limiting the scope of the search. After initial refinement user may choose to run a genetic algorithm and optimize further using the selected option as an initial population. The results can be optimized using multi-objective optimization searching for optimal extensions and materials used, based on performance (R-Value), cost or emissions, and refine the distribution of modules.

Octopus®, a multi-objective evolutionary optimization engine, is used within Grasshopper® for optimization of results in stage 3. It allows the search for many goals at once, producing a range of optimized trade-off solutions between the extremes of each target. Octopus® within Grasshopper® is used to optimize material qualities of modules' envelope exploring trade-offs between energy performance and embodied carbon.

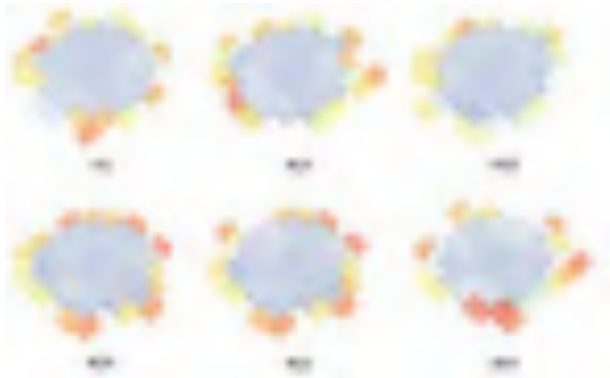

Figure 2. Typical floor plate demonstration of generated design options 1, 14, 16, 97, 24 and 26.

After a predefined amount of iterations of option generations, results are again displayed, and the user can make their final choice and export geometry and data to a predefined format.

From the 100 design option permutations, six designs demonstrate a range of arrangements for a 20-module extension. Figure 2 is a typical floor plate demonstration of the six generated options. Design options 1, 14 and 16 demonstrate similar performance in terms of energy use and LCA. For a 20-module extension, through the generative computational design approach, an 8% saving

of heating energy use and 5% of life cycle carbon emissions was achieved. Design 24 and 26 are similar in overall form. Still, the clustering of modules on one side of option 26, and the resulting reduction in the exposed building envelope, results in option 26 outperforming option 24 by 1,895 kWh of heating energy and 10,619 KgCo2e equivalent of carbon emissions (Figure 3).

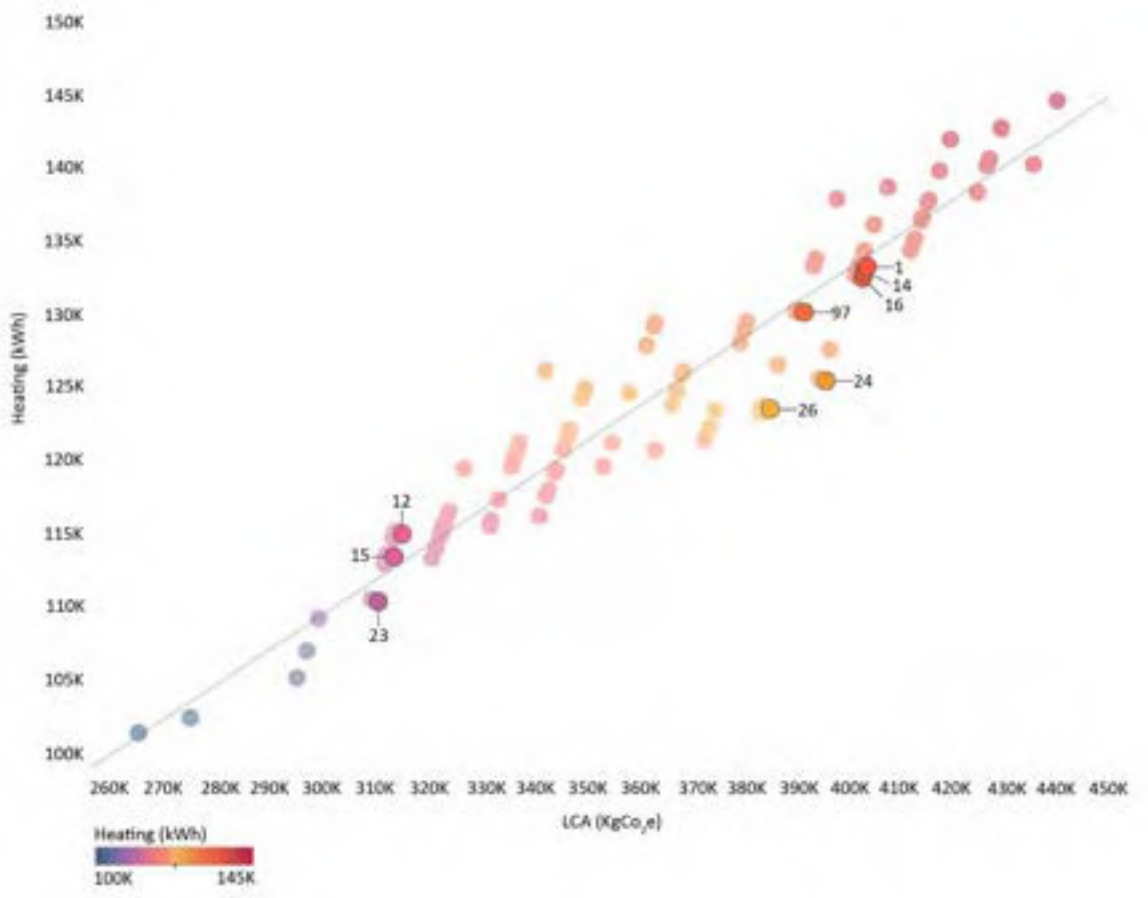

Figure 3. LCA (KgCo2e) and heating energy use (kWh) for 100 design option permutations. Design options are filtered by area of extension – Options 1, 14, 16, 97, 24, 26: 20 module extension (206 m^2) and Options 12, 15, 23: 13 module extension (134 m^2).

4 Conclusion

Adoption of modular construction in building adaptation projects, specifically in extensions to existing buildings, is an essential step in a move to a circular built environment and facilitating the continual use of resources in construction. Parameters and limitations in modular design and the opportunity for design optimization, highlight the importance of incorporating computational design tools in the design of modular buildings. In this paper, a framework is presented for a computational design methodology integrating modular construction in building adaptation projects, while optimizing for energy performance and life cycle impact. The proposed framework is divided into the three stages of analysis and parametrization of the existing building, option generation and simulation and result refinement and optimization. An existing concrete residential building in Hamilton, Canada is used as a functional demonstration of stages one, two and part of stage three of the framework. In stage one, the existing building is analyzed, and a single module size is selected for the extension to the existing building. A grid is developed using rules for module placement, in consideration of the existing building form, interior layouts and required building setbacks. As a result, a growth pattern for the building is determined. The selected module size is broken down into various panelling options that accommodate different module configurations.

An algorithm is developed to generate floor plate module configurations based on the set rules. The energy use and LCA of each design configuration are calculated

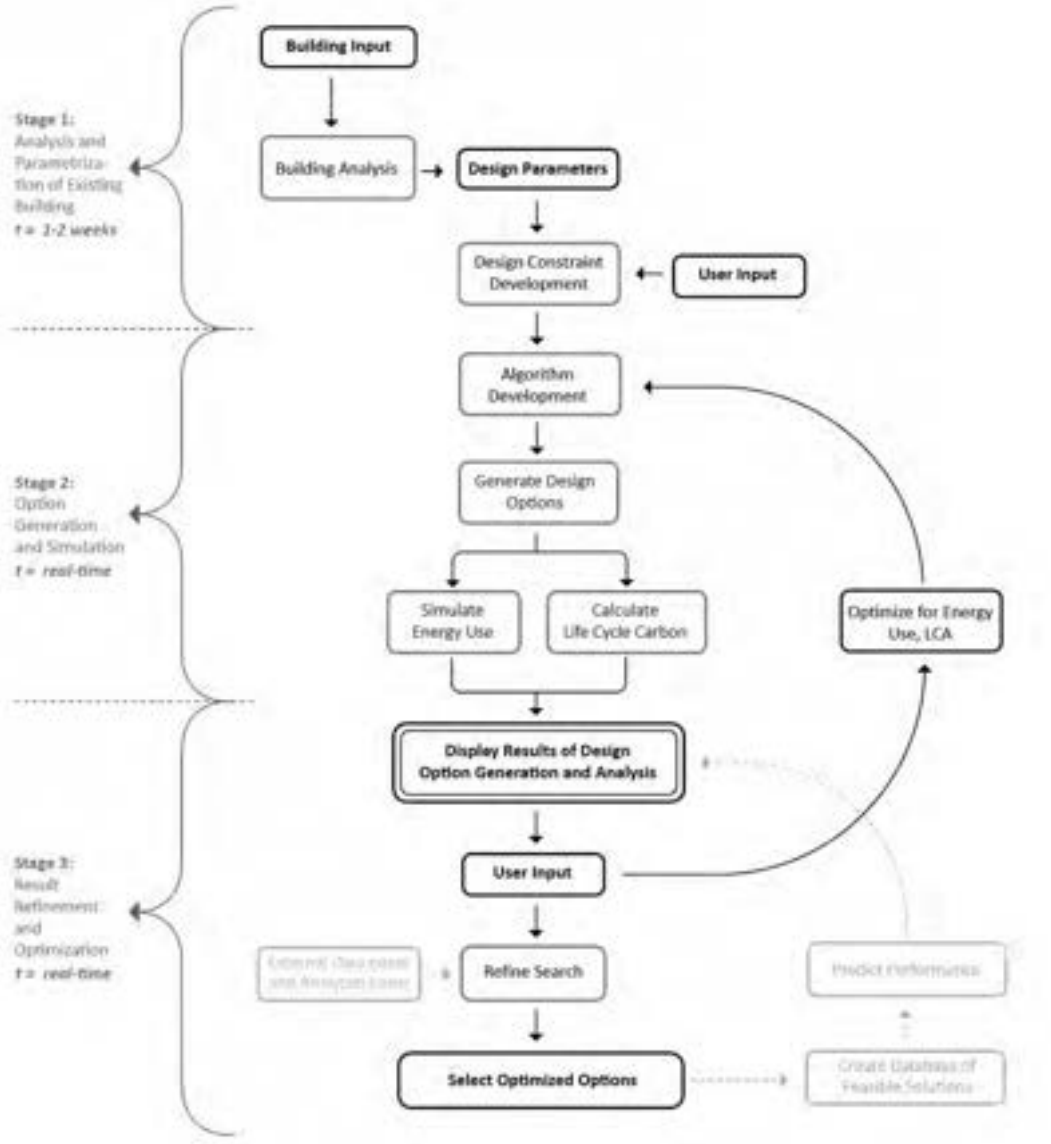

Figure 4. Proposed Computational Design Framework. Framework is separated into the three stages of analysis and parametrization of the existing building, option generation and simulation and result refinement and optimization (the greyed-out portions of the framework are not considered in the functional demonstration and will be pursued in future stages of this work).

simultaneously. A result of 100 permutations ranging from extension of 10 to 20 modules demonstrate the possibility to optimize design option configurations.

The limitations of this research include the exclusion of construction and Life Cycle Cost (LCC) and other environmental factors, such as daylighting, from the optimization model. It is expected that LCC will have a significant impact on design option optimization, and including other environmental factors as part of simulations in stage 2, can increase the quality of generated design options. The design permutations for this research were limited to 100 permutations due to computing limitations. Generating a larger pool of permutations for a single design option will increase the quality and reliability of the design process.

The future of this work will focus on addressing the limitations mentioned and on completing the proposed steps in the framework not investigated in this research. Integration of external databases, linking to other analyzed cases, and the creation of an internal database of feasible solutions will enable the integration of predictive algorithms for enhancing the quality of generated design options.

A View of Construction Science and Robot Technology Implementation

Hiroshi Yamamoto [a]

[a] Komatsu Ltd.，Office of CTO, Japan
E-mail: hiroshi_05_yamamoto@global.komatsu

Abstract –

In this paper, with an aim to contributing to promotion of this field, the author describes his perspective on desirable future situations, and lists his ideas and matters to be taken into consideration in future efforts, focusing on discussions during 2005-2008. Here, the author proposes promotion of design methods in which construction improvement is incorporated in design, and a proposal that machines should be aiming towards substituting human operators in principle.

Keywords –

Construction Science; Construction production engineering; Robot technology,

1 Introduction

In the field of construction production engineering, construction improvements and efforts to utilize robot technology have been continuously ongoing. However, author believes that there is still an urgent demand to make more improvements.

In author's opinion, the basic concept should be to make people working at construction sites happy. For example, currently there are the following challenges in work sites:

1. How can production technology such as those in manufacturing factories be incorporated?
2. A system that allows individual improvements in high-mix, single-item production, "Multi-product one-type construction production technology"; how can they be diverted and reused?
3. Design improvements found from maintenance and construction: how can the result be effectively fed back to design standard?
4. How can we effectively reach the key points of improvement?
5. How can deaths from accidents be reduced?

In this paper, various images, goals, and approaches are proposed, with the aim to promote construction production engineering.

This paper proposes hypotheses that have not yet been verified or is still under verification. This paper does not cover verification of hypotheses.

2 Towards future construction site

If a work method and software can be described, it can be realized. Author's image of desirable future are outlined as follows.

2.1 Image of approach towards future construction site

2.1.1 Pessimistic and optimistic view in work sites

The population in Japan will inevitably decrease; however, the workload demand will not decrease.

A construction site that uses AI and robot technology with a fewer number of people is eagerly sought in work sites. [1]

2.1.2 How to resolve time-consuming and laborious tasks

- "Consistent data sharing from design to maintenance" is one example of good approach There are various types of support to realize this goal.
- By visualizing overall processes, changes in construction plans, adjusting arrangements / procurement for setup changes, and meetings will become much easier.
- Documents are naturally produced as output if the work process is done properly.

2.1.3 Sharing of fundamental concept that "Unsafe condition should not be allowed"

- Humans should not perform hard or dangerous work.
- Machines should do the hard and dangerous work.
- Danger should be avoided in the plan beforehand.
- Danger should be detected by various data on site.

- Eliminating root causes of human errors that may lead to an accident.

2.1.4 To continue PDCA cycle for technology on-site

- Continue improvement and PDCA (Plan, Do, Check, Action Cycle) on site. (Technology itself, human system, work method, etc.)
- The technology system itself to be also spiraled up with PDCA.
- Technology improvement integrated in the construction project (by the government).
- To be used in construction projects, and to be used in the construction field to improve.
- New technology to be supported, and the site does not stop even in case of unfamiliar or trouble occurring

2.1.5 AI support and growth for people together

- To invite input from AI engineers.
- AI will help us to be safer and the job rewarding.
- AI supports and talks, and people will grow together.
- Substitute hard work for people.

"The risk management method using AI" to be prevalently used.

2.1.6 Construction plans to also co-evolve with people and AI

At the construction site, there are many uncertain factors. There are various factors such as weather, soil quality, human factors, utilization of soil generated by other works, circumstances of supervision and suppliers. Therefore, a robust construction plan is required.

Visualization of progress makes it easier to understand how to improve the construction plan. In this case, there is a procurement system environment and an accounting system environment that allow the construction plans to be changed accurately.

The records of changes/improvements in the construction plan are learned, and the number of cases that have been examined in advance increases every year. (The front loading continues to increase.)

The construction plan should prevent accidents caused by people's carelessness and mistakes.

Reduced uncertainties and variability make them more robust, while improving plan optimization and changing flexibility. By utilizing the work robot, the variation in progress is further reduced.

2.1.7 Valuable labor for workers

Key important aspects are: high income, shortened working hours, an environment to easily take vacations, and safe workplace.

Added-value aspects are: motivated working, comfort of workplace, self-fulfillment, social evaluation, good image, etc.

2.2 Image of future construction structure

2.2.1 Easy to construct, operate and maintain

"Ease of operation/maintenance" and "Easy to make" becomes the evaluation criteria, and the learning/feedback mechanism becomes a business process.

If there is a value that has priority over "ease of maintenance" and "ease of making", it will be clearly stated.

" Maintenance" includes operation, inspection, diagnosis, repair, replacement, restoration, renewal, dismantling, disposal, etc.

The idea of "easiness" is consistent and easy to understand.

Constraints in "ease of maintenance" and "ease of making" will decrease every year due to technological improvements.

"Multi-product one-type construction production technology" will improve year by year.

2.2.2 Evaluation throughout the life cycle

There are measurement items that serve as indicators in inspections and diagnoses.

This index is measured during construction, at the time of completion, and is recorded in the electronic history ledger.

Construction/repair and new technology are evaluated for a long time. Where and who did it, and whether the work done was good or bad will be evaluated later.

This can lead to both pride and shame.

A good company will also benefit in the long run.

2.3 Digitization of the real world

The rules for recording underground data for construction excavation, boring, and geophysical exploration are being developed.

3D terrain models are usually measured with good accuracy.

The current digitalization has the following expected cases.

1. The outline can be designed without a new survey.
2. Depending on the accuracy and accumulation, the survey may be omitted.
3. Fewer modifications needed from design to construction.
4. It can be utilized for automatic operation and road maintenance.
5. We can immediately use the pre-disaster data for disaster recovery

3 Hypotheses for problem solving

3.1 Rules and system design for optimization

Since the rapid growth period, vertical and horizontal division of labor has progressed, and the main body of construction site improvement has become unclear. The people involved were forced to stay within partially limited optimization, which was limited to the area where they could improve themselves.

To expand the scope of optimization, it is necessary to make improvements and change rules across multiple parties. For this purpose, the client (owner) and the government are required to have a certain level of involvement and appropriate system design. Institutional design requires everyone to believe that those who have worked hard and made good ideas are fairly evaluated.

3.2 Various hypotheses for problems and solutions

3.2.1 Designed to improve safety and productivity

When improving material manufacturing and on-site construction, it is advisable to review the design if necessary. At this time, it is desirable to be able to review the conditions that constrain the design.

3.2.2 Overall optimization and information utilization suitable for construction production

Information sharing and collaborative operation are important for overall optimization such as modularization of design, linking of orders and procurement/ plant, linking of transportation/ assembly/ construction.

3.2.3 Strategies for effective factory processing

The method of reducing on-site processing, bringing it into the factory after processing, and then assembling on-site may be effective even in a small scale. Especially, it would be desirable to be able to assemble and install by a machine for small scale.

3.2.4 Process control to ensure productive quality

In order to estimate the degree of quality variation in process confirmation, elucidate the relationship when and what should be measured, and incorporate it into the process.

Particularly in the field of civil engineering, it is expected to utilize ICT such as automatic measurement recording/evaluation and remote attendance, which enables flexible process management and setup adjustment.

It is necessary to discuss how to rationalize the involvement of people, such as the centralized management of a wide area by several people.

3.2.5 Optimization of logistics such as soil

It has been said that the bottleneck of earthworks is the uncertainty of the time, amount and quality of soil. Coordination of excess and deficient soil transportation in construction involves many owners in a wide area, and there are cases in which stockyards and soil improvement are used. It may also be a consideration for the government's construction order plan.

Currently, visualization of transportation is being promoted, and we expect that awareness of issues will be shared.

3.2.6 Improvement of quality/quantity confirmation

Level 4 (L4) is a unit of contract modification (MLIT(Ministry of Land, Infrastructure and Transport) estimation standard in Japan), and the quality/quantity confirmation method is determined. It is easy to improve if this is digitized from the time of occurrence and incorporated into the construction process management in a way that requires as few human hands as possible.

3.2.7 Hierarchical structure of construction/work status

The unit of the state of what you are doing now becomes the unit of motion analysis and the unit of learning (preparation unit of teacher data), and has a hierarchical structure.

"Which state can be changed next?" is an internal description of the state transition in the autonomous case.

3.2.8 Command system of instruction and simulation

Even if both remote and autonomous are used, a command system for construction/work instructions from the control is required.

Construction/work instructions are assumed to have a granularity (unit in a hierarchical structure) that is commensurate with the work unit utilizing autonomy.

It is convenient to use this hierarchical command system for construction simulation.

3.2.9 Blasting machines expected to improve work environment

In the case of improving LCC of steel bridges, it is desirable to repaint with high durability at least at the girder end. For this reason, use of blasting as the substrate adjustment is preferred

For that purpose, it is good to use a blast machine system with few scaffolds and enclosures, less scattering of dust and sewage, a light load on workers' protective clothing and dust masks, and high availability.

4 Transformation of safety philosophy

4.1 Safety philosophy

The number of deaths from construction labor in recent years is about four times the average of other industries on a working population basis. From the standpoint of utilizing robot technology, the safety concept that "unsafety condition should not be allowed. People do not do it" should be rigorously pursued.

In example in Photo 1, this person should not be nearby a hydraulic excavator in the first place. He should not measure the depth of the ditch. The depth of the ditch should be measured by hydraulic excavator.

Again, the points of thinking are shown below.

1. Unsafe condition is not allowed. People should not do unsafe operations.
2. The basic idea is to solve by technology.
3. Some extent of human error is always assumed to occur.

Photo. 1. Simulate close work (by PWRI2003)

The technical points to be pursued are as follows.

1. Substitute by machine
2. Machine/person separation
3. AI avoidance, etc.

4.2 Keeping people away from dangerous work

If area near the machine is dangerous (Photo 1), no one should be present. By using MC/MG (machine control/machine guidance), it is possible to assign the measuring task to machine. (Photo. 2) It is no longer necessary for worker to stand a stick in the ditch to measure ditch depth.

In the future, it is expected that in many situations, people will achieve what they do not need do.

Photo. 2. Depth setting MC

5 Towards an object-oriented construction plan

5.1 Object-oriented CAD

3D CAD design data is composed of parts, and the data structure of parts can be object-oriented. (Fig. 1) In recent years, it has been studied in algorithmic design [2] and parametric model design [3]. The image is as follows. [4]

1. Object modules in Library
2. Object modules make up a structure
3. Object modules link Working standards
4. Design with a combination of Object modules (parts and expansion parametric model).
5. Object modules link Design and Analysis tools
6. Object modules (Parts/group) are written with the context of construction.
7. Object modules link Estimates
8. Object modules link Supply chain management

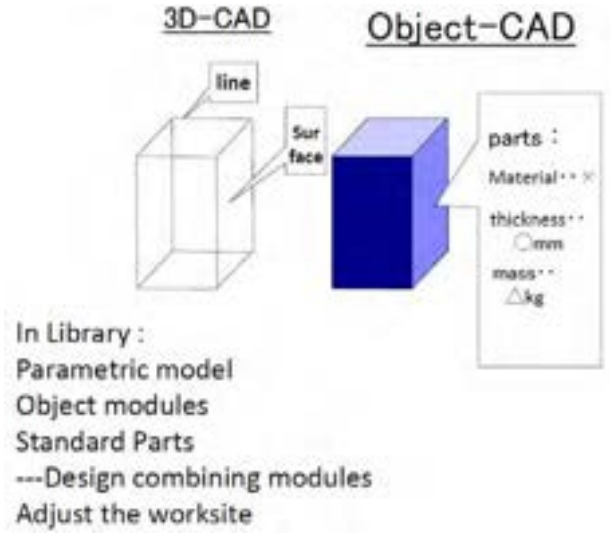

Figure 1. Image of Object oriented CAD

5.2 Expected functional requirements

The evaluation index to be optimized and functions expected from object-oriented CAD are as follows.

1. Object modules in Library
2. Object modules make up a structure
3. Object modules link Working standards
4. It can be solved that construction (/temporary construction) is cheap and quick.
5. It is possible to make a trial design when it consists of only standard parts.
6. It can be solved using environmental evaluation indicators such as energy consumption.
7. Support optimization of setup change
8. Simulation can be performed according to work standard and order.
9. Construction improvement can be described by work standard improvement.
10. Earthwork site rub module can be used.
11. Object modules must Adjust the worksite

6 Conclusion

The author's view on desirable goal and approaches towards the goals was described. In particular, the author presented hypotheses that should be addressed with high priority, with some hypotheses not being discussed for more than 10 years.

This paper lists followings as important aspects to be considered:

1. To share ideas on future construction sites with others.
2. To place high priority and respect on human time, safety and purpose of life.
3. To continue improvement and PDCA on site.
4. To support robust optimization for changes in construction plans and setup changes.
5. Ease of making and ease of maintenance are key indicators in optimization.
6. To set measurement indicators in life cycle
7. To promote digitization in the real world
8. To set rules and system design for optimization
9. To increase production in factory and reduce on-site work
10. Factory products to be handled by machines, not by humans.
11. Monitor process control to ensure productive quality
12. Optimize logistics such as soil
13. Digitization of quantity and quality for each contracted minimum unit
14. To aim for a hierarchical structure of construction/work status
15. To aim for a hierarchical command system of instruction and simulation
16. Unsafe condition should not be allowed.
17. Object-oriented construction plan
18. Object oriented CAD for construction sites
19. How work standard improvements can be diverted and reused

In this paper, author's image, goals, and various hypotheses were presented. It is the author's intention that such information will lead to discussion and promotion in the field of construction production engineering.

The author hopes that further discussions will be deepened and research and development and social implementation will progress toward the future of construction production engineering and robot technology utilization.

Abstract –

Studies have shown that early design finalization is important for projects utilizing Off-site Prefabrication and final assembly on site. Freezing engineering design at an early stage has various advantages such as streamlined manufacturing and timely transportation to site as well as timely deployment of adequate resources on site for assembly. However, it is very important to ensure correct design that can be transported, assembled and erected on site in Brownfield Industrial environments. EPC (Engineering, Procurement and Construction) companies have traditionally adopted a "Suit-to-site" approach, where structural members are largely tailored to fit at the site in order to avoid rework. This approach requires mobilization of a large number of resources to site and consumes a lot of time for the fabrication and installation works. Mixed Reality (MR) systems can be used to ensure correct design which can then ensure accurate fabrication and quick installation of structures. This paper reviews the applicability of different MR systems to the concept of Constructible Design for early design finalization in a brown-field Industrial engineering environment. Structural design review is correlated to different tasks of construction that must be performed on the field. Applicability of different components of MR systems is then evaluated for these tasks. This paper finally concludes with selection of suitable MR systems for deign evaluation based on correlation between construction work tasks and components of MR systems.

Design Validation; Augmented Reality; Design Review; Assembly of Structures; Off-site Prefabrication; Constructability Review; Industrial Structures

1 Introduction

Construction in brownfield industrial environments is largely a complex affair due to the large number of variables presented by a pre-existing industrial facility. The rapid shift in construction technology towards prefabrication and assembly at site requires a shift in focus to early design finalization [1]. Any modifications to design at a later stage cannot be incorporated as such changes will lead to major impacts to schedule or budget or both. This is largely due to the fact that changes to a prefabricated module will result in changes to connected modules. Moreover, making modifications or changes at site is time consuming as well as labour intensive - ultimately a costly exercise. In order to ensure a design, a Mixed Reality system could prove to be instrumental with review of a design before its fabrication.

Mixed Reality is a widely accepted term that was first proposed by Milgram et al. and can be expressed as a spectrum with any form of hybrid combination of Virtual Reality (VR) and Augmented Reality (AR) [2] (Fig. 1). Because of its evolution, MR today not only concentrates on graphics and displays but also incorporates various interactions with users including gesture recognition and spatial registration (interaction with surrounding environment). Owing to rapid development of technology in the past decade, differentiation between AR and MR can often be difficult [3]. For this reason, both AR and Augmented Virtuality (AV) - including use of AV on desktop-based systems, are considered as MR for the purpose of this review and their applicability to Brownfield Industrial Construction.

Construction in Brownfield industrial environment, especially for addition of a new facility, expansion of existing plant or re-purposing the process in an existing plant is described as challenging at best. One of the most critical tasks in such a project is to erect structures suited to site conditions in an existing facility within imposed time constraints. Such activities can be made more accurate, quicker and safer if all the structures related to

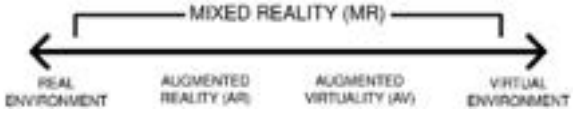

Figure 1. Reality-Virtuality Continuum.
Source: Milgram el al[2]

these activities can be accurately estimated, fabricated off-site and delivered to site for assembly or direct installation.

This paper explores the applicability of Mixed Reality (MR) technologies for early design finalization. The aim of such early design finalization is to arrive at an acceptable level of design accuracy which in turn can facilitate timely fabrication, delivery and installation of tie-in structures thereby avoiding any rework or fabrication work at site. This paper concludes by recognizing See-through Head mounted devices as the most suitable MR systems that can be used to evaluate different work tasks in construction, thereby ensuring a correct design.

2 Review Methodology

For the purpose of review, this paper has been divided into the following sections:

1. Mixed Reality applications
2. Constructability of a Structure and enhancement with MR systems

While discussing the evolution of MR applications, tabulation of features as well as advantages and shortcomings of the more recent and relevant applications has also been done. The purpose of this classification is to then correlate applications with principles of Construction (Work Tasks) in section 4.3. Recommendation of suitable MR systems to reach early design finalization with respect to various facets of design is presented in Section 5.

3 Mixed Reality Applications

3.1 Literature review of work done on Mixed reality in Industrial Construction

Since its conception, Mixed Reality (MR) has been developed to facilitate human-computer interaction. MR has been implemented in devices using various technologies – right from Desktop based applications to Wearable Head Mounted Displays (like the Microsoft Hololens and Google Glass [4] [5]) being used in the Architecture, Engineering, Construction and Owner-operated (AECO) industries.

When it comes to Industrial Construction, Mixed reality has seen applications in areas such as Inspections, Planning and Monitoring of construction work, equipment and material management, training of skilled workers and implementing certain safety management systems. However, MR can also be used to facilitate design reviews of critical structural elements.

Shin et al. reviewed the applicability of Augmented Reality (AR) to various construction tasks in 2008 [6]. The mapping of various construction work tasks and activities to the relevant features of AR systems led to identification of areas where AR can be applied to enhance the performance of activities in their research. Tracking of materials on site for increased efficiency by combining AR with WLAN and GPS information was presented by Behzadan et al. in 2008 [7].

Similarly, Rohani et al. demonstrated the use of Mixed Reality (MR) for development of 4D-CAD based construction management systems [8]. Such systems enable construction managers to visualize the design of a structure along with the reality at a glance and are able to translate this information to provide a powerful management platform for planning and controlling projects. Behzdan et al. explored the use of MR to locate computer-generated graphical information in real world environments [9]. Such information spatially located relative to the user can assist in the performance of various complex engineering tasks.

MR is also being used to train workforce and make some of their tasks easier and/or more efficient. Hou et al. conducted an experiment to analyze the benefits of using AR to train students with no prior experience of piping assembly or using AR [10]. They concluded that AR could increase efficiency, reduce errors as well as optimize cost. Wang et al. conducted research on operating simulation system for tower crane based on VR [11].

Another area where VR has facilitated improvement is engineering reviews - In 2017, Berg et al. reviewed the potency of using VR for early decision making on an industry-based case [12]. The visualization aspect of using VR allowed the design team to make decisions ahead of usual stages and saved them a lot of effort on prototyping. In this aspect, production on assembly lines is akin to that seen in a structural fabrication shop. VR and AR can thus be utilized to foresee and tackle assembly related challenges during design stage rather than do that in field during erection stage. Another research on the same lines by Freeman et al. confirms that use of VR for reviews during design stage can lead to significant improvement in participants ability to understand the geometry of the model correctly, confidently, and quickly, as well as in participants ability to correctly and confidently understand the implications of a proposed design change [13].

These researches are now being applied in field in various areas of construction with the help of new

technological platforms such as Mobile devices (including Mobile Phones and tables), Google Glass, Hololens and Trimble Sitevision [14].

3.2 Understanding MR systems

In order to understand MR systems, it is necessary to understand their components. A recent state-of-the-art review of MR applications in AECO industries by Cheng et al. has a sufficient categorization of components for analysis [3]. The basic categorization of components falls into the following categories – Display, Spatial Registration, User Interaction and Storage.

For the purpose of this review, we will attempt to categorize the components of the following devices:

- Head-mounted See-through displays (likes of Hololens and Google Glass)
- Head-mounted immersive VR displays (like Occulus Rift, Samsung HMD Odyssey Windows Mixed Reality headset)
- Portable Cellphones and Tablets

Table 1 summarizes the categorization of these components. It can be seen from this tabulation that some devices have certain advantages in a particular area that renders them feasible for particular application. For example, Cell phones or Tablets can be used very effectively for outdoor location-based tracking but lack immersive experience which can be crucial when trying to finalize a design and ascertain its feasibility [15]. Similarly, when reviewing a particular structural design which has multiple engineering interfaces involving multiple approving authorities, mobile devices may not make as much sense as use of an immersive display that allows for group interaction - like a Cave display. Another option for group interaction in field would be to use multiple Mixed reality see-through HMD devices like Hololens that can be paired together for group interactions.

3.2.1 Display:

The most important aspect a Mixed Reality system interacts with a user is the way it displays the graphics along with the real-time visuals. Taking into account the devices considered for this review, displays are categorized into the following types:

- ***VR Displays:*** VR displays are usually either Head mounted or immersive CAVE displays connected to a computer and usually used for VR reviews. These displays can be instrumental in remote design reviews also.
- ***Portable Displays:*** Portable displays are actually integrated into portable devices such as Mobile Phones and tablets. These displays employ either LCD or LED displays integrated in the device.
- ***Immersive see-through HMDs:*** Head mounted displays originated back in the early 1980s. The latest development of display technology allows graphic images projected on transparent glass. This gives the user an immersive experience, making virtual graphics seeming as if real, from user's perspective.

3.2.2 Spatial Registration:

Spatial Registration is a feature of MR systems that facilitates "Realistic" experience for the user. The MR system needs to project correct graphics in front of the user's eyes with respect to their motion in real world or in accordance with their commands on a controller device. In order to do this, the device needs to "learn" about its surroundings. This is known as Spatial Registration. The types of spatial registration methods are as follows:

- ***Marker Based:*** Marker-based Spatial registration utilizes a static image also referred to as a trigger photo that a the device scans in order to calibrate its position from the trigger image [16].

Table 1. Categorization of MR System Components

Device Category	Display	Spatial Registration	User Interaction	Storage
See-through HMDs	- Immersive HMD - Immersive Graphic over transparent glass	- Marker Based - Marker-less	- Gestures - Joystick / Controller	- On-board Storage - Cloud storage access
VR Displays	- Immersive HMD	- Marker-less	- Joystick / Controller	- No on-board storage
Portable Cellphones and Tablets	- Portable LCD	- Marker Based - Marker-less - GPS based location tracking	- Touchscreen	- On-board Storage - Cloud storage access

- ***Marker-less:*** Marker-less spatial registration works by accurate measurements of the 6DOF camera pose relative to the real world and matching point features in the current image frame to two spatially separated reference images [17]. This eliminates the necessity for any marker for spatial registration.
- ***GPS Based:*** GPS based spatial registration uses the global position and 3-Dimensional orientation of an MR system in an outdoor environment for calibrating the superimposition of 3D graphics with respect to the real world. This is made possible by use of a GPS tracker and 3DOF orientation tracker in conjunction [9].

3.2.3 User Interaction

In the previous sections we saw how virtual images aligned with the real world. Taking this functionality a step further, MR systems allow the interaction of virtual objects with the real world to simulate real-world collisions, occlusions and interactions [18]. In the context of construction, this interaction can be very helpful when evaluating feasibility of a design or simulating construction or assembly sequences. Modes of interaction available on devices are:

- ***Touch Screen:*** Predominantly used on Mobile MR systems such as Cellphones or Tablets, a Touch Screen allows user to interact by clicking on the projected image on the device. Various gestures such as pinch, pan and rotation can help to interact with the available information.
- ***Joystick or Controller:*** Joysticks or controllers can be used with most MR systems. However, for immersive HMDs, a controller becomes necessary if the display is not transparent (i.e. not see-through) as interactions with real world will not be very intuitive.
- ***Hand Gestures:*** See-through HMDs have a distinct advantage when it comes to user interaction. Combining the marker-less image tracking with the see-through display, the device is able to recognize users' hand gestures and allows interaction of the Virtual Graphics with the real world by executing commands relayed by hand gestures.[4]

3.2.4 Storage

Access to storage on a MR system can enhance its usability in construction industry. This feature enables the device to function independently.

- ***On-board Storage:*** If the device has storage built-in, it is called on-board storage. With on-board storage, virtual models can be directly loaded onto the device and can be accessed in field readily.
- ***Cloud Storage:*** Devices that can access internet via cellular network can use virtual models and other data stored on cloud drives. A clear advantage in this case would be the ability to use a single device on multiple sites as models need not be loaded on to on-board storage or ability to access very large models that are too big for on-board storage drives.

4 Constructability of a Structure and enhancement with MR systems

4.1 Design in a Brownfield Environment

In the context of industrial construction, a brownfield construction site is a site which is either located within an operational facility - such as a capacity expansion project or a new facility being installed to enhance product quality within an operating plant.

The major challenges of a Brownfield Construction Project consist of access through an operational facility, ascertaining location of underground facilities and structures, safety concerns due to an operational facility and schedule related concerns [19]. In order to carry out construction in a safe and timely manner, it makes sense to prefabricate structures off-site and then assemble them with minimum manpower deployment and in minimum possible time.

Also, another issue that arises out of adopting Off-site prefabrication and On-site Assembly is that of customization. Any structure that has been manufactured off-site cannot be modified on site within the scheduled time or budgeted cost [1]. Accuracy of design and fabrication is, therefore, of paramount importance.

4.2 Evaluation of Constructability

Constructability of any structure can be divided into various work tasks that must be completed in order to complete a construction activity [6]. The evaluation of Constructability stems from ability to perform these work tasks as planned and to the design standards. Shin et al. identified work tasks as well as construction activities that can benefit from Augmented Reality based on technology suitability [6]. This study identified the following tasks that benefit from Augmented Reality applications - *Layout, Excavation, Positioning, Inspection, Supervision, Commenting and Strategizing.*

The above mentioned work tasks, in that study, were adopted from J Everett and evaluated against features of AR systems that would enhance the performance of these tasks [20]. Out of the identified tasks, the work tasks that are important for ensuring assembly of prefabricated structures are *Layout, Excavation, Positioning and Strategizing*. Table 2 summarizes the opportunities identified in this study for improvement of work tasks by implementation of MR.

Table 2. Opportunities for evaluating Prefabricated structural design and assembly using Mixed Reality

Work Tasks	Opportunity
Layout and Positioning	Creation of virtual reference points for superimposition on a reviewer's view. This eliminates the need for physical marking the reference points by extensive surveying process to ensure correct location of a structure. This is followed by, projection of a 3D model of prefabricated structure based on reference points. This ensures evaluation of interfaces with existing structures and avoids any last-minute modifications to fit the structure on site (Suit-to-site works)
Excavation	Creation of a 3D reference for superimposition of subsurface structure for a reviewer's view. This will ensure sufficient space for excavation and can ensure constructability of underground structures like foundations.
Strategizing	Projecting 3D image of the complete task can help in visualizing the sequence of various tasks to optimize construction or assembly process and to estimate on-field time of critical machinery.

4.3 Correlation of Work Tasks with MR system features

4.3.1 Layout and Positioning

Fixing layout for the structure being evaluated is largely dependent upon identifying correct reference points on the field and then marking the location of structure with respect to reference points. MR systems can reduce the marking efforts and time required for identifying correct location of a given structure by projecting the virtual image through a MR system. Similarly, Positioning of a virtual 3D image of the structure being evaluated, allows the reviewer to understand its relationship with the surrounding structures and equipment (above ground structures) and also helps to visualize any existing loads that may need to be accommodated into the prefabricated Structure. Refer Table 3 for correlation.

4.3.2 Excavation

In a Brownfield environment with underground structures and facilities, it is very important to be able to visualize the extent of excavation for installation of a structure. Any subsurface structural interfaces that do not come to fore with As-built information can be discovered by an on-site review using an appropriate MR system. This is especially important as foundations need to be ready to receive prefabricated structure for installation. Refer Table 4 for correlation with MR Device Components.

4.3.3 Strategizing

The task of strategizing requires analysis of the actual process of assembly and erection of a prefabricated structure. This process takes into account operations such as logistics, assembly, lifting as well as connecting to any existing interfaces. Strategizing is very different from other work tasks as it is not performed exclusively on site and requires collaboration between different teams. Refer Table 5 for correlation with MR Device Components.

5 Conclusion

Based on Correlation of Work Tasks with MR system features in Section 4.3, we can conclude that see-through HMDs present the best features for reviewing design of prefabricated structure in a brownfield industrial installation. They have the most immersive experience of review - all the while being able to see the real world. They have one of the more accurate spatial registration capabilities which can be further enhanced by use of external attachments to a centimeter level accuracy. User-interaction while using these is very easy and doesn't require any additional device or controller for inputs. These devices can be used for expert reviews as well as collaborative reviews and can help to discover any potential issues for assembly and final installation - thus helping to finalize a structural design much earlier. Another advantage of using these devices for reviewing a critical design is the enhanced customer experience that builds more confidence towards a design firm's capabilities.

Table 3. Correlation of MR System components with work tasks for Layout & Positioning

MR System Components	Work Tasks	Layout & Positioning
Display	VR Display	VR Displays can be used for conducting a Virtual Reality design review or for reviewing any structures remotely when access to a site is restricted [21].
	Portable Display	Device camera is able to produce image of real world on the screen, which is then superimposed with the Virtual image. The only disadvantage with this display is that one hand is occupied with holding the device.
	See-through HMD	These displays have an inherent advantage as the real world is seen through transparent glass and the virtual image is projected on the glass producing an immersive display.
Spatial Registration	Marker-based	A quick and accurate way to calibrate the device camera [22], this technique, however, requires installation of markers on sites. Accordingly, this technique can be adopted for smaller projects.
	Marker-less	Marker-less registration is able to self-calibrate the device to its surroundings by comparing them with pre-captured reference images [17 and thus results in a seamless experience. Also, with marker-less registration, changes to the scene can be detected with the MR system, highlighting any potential clashes.
	GPS-based	GPS based spatial registration on mobile devices has an accuracy of ±10 metres. However, attachments such as Trimble Sitevision are able to enhance the accuracy of measurement and location up to 1 cm [14]. The only disadvantage of using GPS for spatial registration is that it requires clear view of sky and can have issues in tight spaces that experience "Canyon" effect.
User Interaction	Touchscreen	The only disadvantage of using a touchscreen is that it requires use of both hands - one to hold the device and other for interacting with the device.
	Hand Gestures	Identifiable by select MR systems, Hand-gestures can be an excellent way of providing input to a device. Using hand gestures for input also means that both hands are free while not providing any input.
Storage	On-board	On-board storage can be particularly useful when using the device independently and on a remote location devoid of any cellular network or WiFi access. However, this can also be a limiting factor when using large files.
	Cloud	Advantageous when accessing large files and when a single device is used across multiple projects / locations. Needs proper wireless network.

Table 4. Correlation of MR System components with work tasks for Excavation

MR System Components	Work Tasks	Excavation
Display	VR Display	Can only be used for remote reviews. Not suitable to review on-going activity.
	Portable Display	Portable Displays can be used for reviewing interface with subsurface structure but have a narrow field of view since they are small and non-immersive.
	See-through HMD	See through HMDs provide the maximum information in an immersive environment. Reviewing the structural interfaces for excavation using See-through HMDs can help to discover any potential issues [12].
Spatial Registration	Marker-based	Marker-based spatial registration can be effective when reviewing a specific area for interfaces during excavation as it needs pre-installation of markers.

MR System Components	Work Tasks	Excavation
	Marker-less	Marker-less spatial registration would be preferred for evaluation of subsurface structural interfaces as it can identify any changes to the site's surroundings.
	GPS-based	Using GPS-based spatial registration is not particularly accurate to a centimeter level of accuracy. However, if used with enhancements such as Sitevision [14], it can be used to review work done.
User Interaction	Touchscreen	Pinch action on a touchscreen can be used to closely examine a virtual model and may prove to be useful due to limited field of view.
	Joystick / Controller	When reviewing a site remotely, it may be necessary to use keyboard and mouse as controllers to navigate withing the model or recording of the review.
	Hand Gestures	Hand gestures, when coupled with see-through HMDs allow interaction and feedback without use of additional equipment.
Storage	On-board	Particularly useful when using the device independently and on a remote location devoid of any cellular network or WiFi access.
	Cloud	Advantageous when accessing large files and when a single device is used across multiple projects / locations. Needs proper wireless network.

Table 5. Correlation of MR System components with work tasks for Strategizing

MR System Components	Work Tasks	Strategizing
Display	VR Display	Useful for desktop reviews, a VR display like CAVE can be useful in team reviews related to assembly and lifting activities required for erection of a prefabricated modules [12].
	See-through HMD	Some HMDs have collaborative capabilities and can be used for reviewing activities using virtual holograms.
Spatial Registration	Marker-based	Marker-based registration can be used for on-site team reviews.
	Marker-less	Marker-less registration is intuitive and can be used while strategizing. When users are seated around a table, wearing see-through HMDs, the devices can read the table's surface and project holograms for review.
User Interaction	Touchscreen	Large touchscreen displays can be used to convey ideas by marking while carrying out group reviews.
	Joystick / Controller	Keyboard and mice are generally used to navigate within a virtual space. Animations showing performance of important activities may also require user inputs to start, pause and end.
	Hand Gestures	Hand gestures can be useful when carrying out reviews using see-through HMDs. Users can interact with holograms using hand gestures to navigate to different areas of a hologram or to highlight, zoom-in and out of the views.
Storage	On-board	Very important for VR or CAVE reviews as the virtual models require a lot of storage. However, this may not be the apt storage solution for multiple HMDs accessing the same virtual model.
	Cloud	Can be used to ensure currency of the virtual model and also ensures that multiple users can access the same virtual model and review its feasibility.

Abstract –

The advantages of using modular and offsite construction compared with the traditional construction methods are numerous due to its efficiency in delivering shorter schedules, lower cost, higher quality, and better safety. However, one of the biggest challenges facing the prefabrication industry today is the inherent difference between financing traditional construction and the upfront capital requirements for modular and offsite construction. Any solution for this problem should introduce better coordination among developers, banks, financial partners, lending institutions, manufacturers, and general contractors. Financing modular construction is challenging as banks are not familiar with the characteristics of this modern industry, and it is all about risk and return. Financing also helps in reducing risk for developers and allows them to undertake projects without having the upfront capital. However, few studies in literature focused on the financial modeling for modular and offsite construction. This paper is presenting a state-of-the-art literature review for current practices concerning financial modeling for modular and offsite construction. This review discusses current challenges for financing this industry, as well as the introduced initiatives by governments to facilitate financing of modular and offsite construction. Conclusions are presented regarding the current practices for funding the prefabrication industry. Furthermore, recommendations are drawn for encouraging the development of prefabricated housing, and its ability in solving the current shortage of housing in different parts of the world.

1 Introduction

Shortage of affordable housing for low-income renters is affecting every state and metropolitan area in America. The private market is not producing enough affordable new rental housing to these renters, because rents they can afford do not typically cover development and operating costs for rental housing [1], while public supporting subsidy is absent on this regard. Mayors of Philadelphia, New York and San Francisco confirmed that modular construction is a solution to the housing problem in their cities [2] due to its reported advantages. However, many studies investigated barriers of modular construction to increase its market share [3, 4, 5, 6, 7 &8]. These barriers include 1) modular and offsite construction's negative stigma; 2) lack of evidence for successful application of modular and offsite construction; 3) lack of unified building codes and operational standards for modular and offsite construction; 4) traditional procurement systems does not fit practices of modular and offsite construction; 5) conventional financing tools and cash flow structures does not enable the use of modular construction.

Rahman [3], Smith and Rice [4] listed the difficulty in financing, as one of the main barriers to implement offsite construction, because it requires higher initial capital compared to traditional approach. The Canadian construction innovations report [5] highlighted, cash flow challenges for modular and offsite construction when using the traditional cash flow system and outlined the need to restructure project financing for publicly funded projects to enable the application of modular construction. Salama et al. [6, 7 &8] emphasized the need to create financial models that fit the characteristics of modular construction and to create special conferences for lenders to discuss the different nature of financing modular and offsite construction.

The same studies also suggested to create special lending banks and changing policies for financing modular builders as well as convincing insurance

companies to lower insurance rates for modular buildings. Furthermore, they also recommended universities to design cost management methods and lending programs that consider characteristics of modular construction.
This paper presents a literature review for current practices in financing modular and offsite construction and discusses different initiatives that encourage financing modular builders.

2 Challenges

2.1 Large upfront capital requirements

The production and procurement processes for modular construction require material and overhead costs to equal up to 60 percent of a module's total cost. Hence, manufacturers ask for an upfront payment of around 50 percent at the ordering time to procure materials in short period of time to increase efficiency of manufacturing [9]. This large upfront capital requirements from manufacturers can affect bank reserves, so banks and institutional lenders would ask for any collateral to reserve some money on their equity to avoid scrutiny from regulators [10].

2.2 Perception of ownership

During manufacturing, modules are considered personal property of the manufacturer and it does not become real private property until delivery and assembly onsite [10]. Many banks don't release financing instalments until modules are installed onsite to ensure that their money is utilized in real property. However, manufacturers want to get paid before delivery of modules to avoid the transfer of ownership status from personal to private property which can lead to legal complication to future payment disputes [11]. These differences in understanding for perception of ownership of modules complicate financing instalments and the whole financing structure.

2.3 The immature market

Modular construction developers who lack the experience in this industry, face uncertainty in scheduling and pricing which results in risks' inconsistencies. Banks' evaluations for their projects can change and financing costs would increase for developers [12]. Banks are also concerned regarding project completion if a manufacturer becomes bankrupt.
Few American companies can manage high-rise modular projects, and lack of proven manufacturing would make banks request additional contingency funds to satisfy projects' uncertainty [13]. Immature market affect pricing of manufacturers and it would make it unreliable.

2.4 Progress monitoring for manufacturing

Progress monitoring for manufacturing is hard for modules that can be manufactured simultaneously for multiple projects. Materials allocation is crucial for identifying a collateral to get financing from any bank. Securing financing for modular construction can be more difficult than traditional projects because banks would not prefer the increased risk associated with progress monitoring of manufactured modules [12].

2.5 Lack of support from authorities and financial sector

Lack of support from financial sector is a main challenge for offsite construction due to many reasons like the high profitability of lenders who finance traditional housing [14]. Many offsite manufacturers have to internally finance their projects until the end of manufacturing. Hence, only the most successful builders can manage large-scale projects with reasonable cost. Production of modules can begins six months before delivery of first module on site based on size of different projects, while procurement of materials should start 6-7 weeks before manufacturing [15]. This means modular manufacturer has to pay for materials and then pay for labor during manufacturing of modules while banks release construction financing after delivery of modules to construction site. Depending on project size, modular manufacturer may need $16-$20 million before receiving any financing from lenders [15]. Lack of political will from regulatory authorities to motivate lenders to change their policies is also questionable [14].

2.6 High lending rates

Lending rates for offsite construction are higher than its value for traditional construction because it is a relatively new concept and many banks lack the full understanding of it [16]. However, these rates will be changed by time after more research and development initiatives are undertaken, and higher scale of this market is achieved. For example, a two-year traditional construction project can make the developer pay half of the cost up front for the land and the other half is paid throughout the two years of construction. However, for modular construction project with a compressed project time of one year, the whole payment can be due upfront, while financing could be required for only one year instead of two years. If cost of capital is assumed to be 10 percent, then financing costs would be reduced by 5 percent of the total project cost [16].

2.7 Financial impact and considerations

The potential financial impact from utilizing modular and offsite construction should be investigated

and compared to stick-built construction before project can start. Financial impact is different from a state and country to another and many factors should be studied to assess financial impact such as the high labor cost in some countries. Economic situation for housing market, debt situation, and developer capabilities affect also the financial impact which has to be evaluated before taking a decision to utilize offsite construction [11].

2.8 Transportation and storage costs

Transportation and storage costs are essential for modular and off-site construction. However, lending banks may not consider them while providing construction financing [17]. Additional costs may also face developers such as renting trailers for transportation, and wrapping prefabricated modules to protect them from weathering effects and possible damages. These costs are challenging if project site and manufacturing facility exist in different countries.

2.9 Payment certifications for publicly funded projects

If a modular or offsite construction project is publicly funded, then its schedule of values may not fit with a typical schedule of values developed by the American institute of architects (AIA), which determines monthly progress payments. Some publicly funded projects may not permit some payments certifications in a timely manner due to this challenging fact [18].

3 Modular and offsite construction team

For traditional, modular and offsite construction, clients are developers or building owners, who may be individuals, groups, or representatives for owners. They are motivating building projects by providing funding and determining the required delivery method, as well as construction method utilized, whether prefabricated or not, and the level of required prefabrication with the help of the design team [19]. Relationship between developer and project team for traditional construction is shown in Figure 1 where developer may have contracts with different designers and consultants (e.g. Architect, structural, and civil consultants), and another contract with the general contractor who may hire different subcontractors. For modular and offsite construction, the developer may have a contract with the modular builder as shown in Figure 2 who can manage fabrication and may or may not hire a general contractor to establish building foundation and utilities onsite.

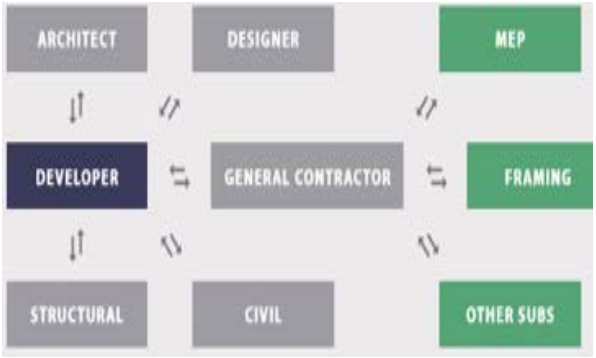

Figure 1. Traditional construction team. Adapted from MBI report [1].

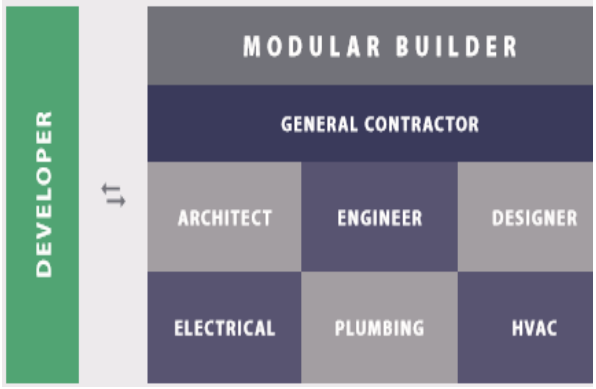

Figure 2. Modular construction team. Adapted from MBI report [1].

4 Financial Modeling

4.1 Financial modeling from developer perspective

Few studies investigated insights of financing offsite construction from developer perspective [11, 20]. Cameron and Carlo [11] conducted a quantitative analysis to assess the impact of utilizing modular construction. Two scenarios were used to measure equity internal rate of return (IRR) – which is the annualized return of investment in any period of time – in a comparison between modular and traditional construction. The first scenario is for a project comprising six buildings constructed as rent development, while the second is for the same project assuming it is constructed for sale. It was concluded that equity IRR increased when utilizing modular construction compared to traditional construction from 35.1% to 47.5% for the first scenario, and from 25.75 % to 27.60 % for the second scenario. Difference between equity IRR of first and second scenarios is attributed to the earned rental income for part of the development. Difference between equity IRR of modular and traditional construction is attributed to flexible phasing of modular construction since for example, two buildings

can be installed onsite to be ready for rental or sale while another building is being manufactured offsite. Shorter schedules of modular construction allows modular developers to reduce interest payments due to the shorter loan period and they can make additional cost savings due to shortened schedules that would reduce the general conditions cost and risk insurance.

Cazemier [20] conducted a comparative financial analysis between a cross laminated timber (CLT) building that utilizes offsite construction technologies, and traditional concrete and steel building in Australia to study economic benefits of using CLT. Feasibility model variables such as sales revenue, land purchase price, construction cost, construction contingency, professional fees, and interest expenses were inputted into EstateMaster software to model their effects on key performance indicators such as development margin, development profit, Return on equity (ROE) – which is the total amount of return receive on original investment –, and IRR. It was concluded that buildings constructed with CLT may result in less development margin, development profit, and ROE, however it will increase equity IRR due to the reduced investment timeline for offsite construction which is the same conclusion of Cameron and Carlo [11]. It was also outlined that any developer will choose between using CLT or traditional buildings based on their investment requirements whether they prefer a greater total amount of return for shareholders on their original investment by the increased ROE, or receive higher annual return of investment by the increase of equity IRR [20]. However, this study is based on using CLT in the Australian market, hence other types of offsite construction such as modular or hybrid construction in other markets like USA or UK might result in different values of ROE and IRR due to the different interest rates, land purchase price, and construction costs in both countries.

4.2 Mortgage financing for consumers

Manufactured housing percentage is nearly 6 % of occupied housing and accounts for much smaller percentage of home loans in the U.S. [21]. Manufactured homes are commonly used in Western and Southern states as shown in Figure 3 [21], and two-thirds of manufactured homes are outside of metropolitan areas in the U.S. Residents of manufactured homes tend to be older and they have lower net worth and incomes compared to residents of traditional homes and they also pay higher loan interest rates than borrowers for traditional homes [21]. Loans for 68 % of manufactured homes are considered “higher-priced mortgage loan” (HPML), which is a definition for loans considered to have high subprime. While only 3% of loans for traditional construction are considered HPMLs [20].

De Mendoza [22] presented a comparison between financial mechanisms for offsite construction in New Zealand and different countries such as USA, Japan, Australia, and Sweden. The main aim of this study is to introduce financial initiatives to encourage offsite construction since New Zealand lacks such financial initiatives where banks do not issue mortgages for manufactured housing.

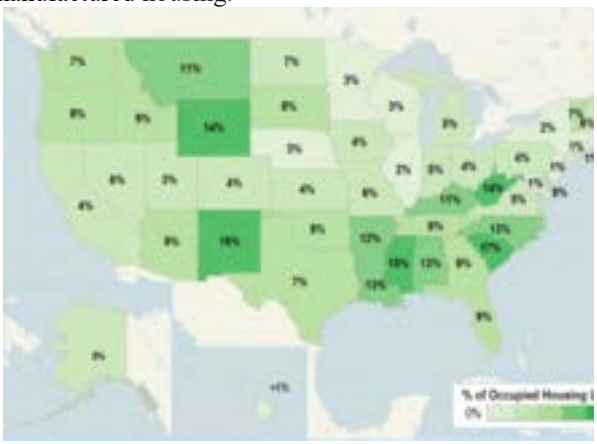

Figure 3. Percentage of manufactured housing of occupied housing units. Adapted from CFPB report [21].

Hence, consumers finance these buildings with chattel/personal loans which are much more expensive than a mortgage. The US consumers’ financing for manufactured homes is based on two types of loans [22]; 1) The chattel loan: which has lower costs at origination, requires more equity for principal payments and it results in higher interest rates and shorter maturities than mortgaging. 2) Manufactured house mortgage: which has lower interest rates than a chattel loan but it would have higher interest rates than traditional construction mortgaging. It has better consumer protections, lower overall costs, and longer maturities. The seven steps for financing modular construction introduced by M&T bank are a good example for manufactured house mortgage [23]. These steps include the creation of a draw disbursement schedule comprising five draws which are disbursed as planned construction milestones are completed. These five draws for construction loan are disbursed for: 1) completion of foundation; 2) delivery of modules onsite; 3) completion of house set; 4) completion of interior /exterior button up and siding; 5) completion of construction. Then, construction loan rollovers to a permanent mortgage when construction is completed. Another innovative financing option is introduced by DIRTT solutions in USA and Canada to lease manufactured homes as leasing cars, where user pays for depreciation of the product during leasing period

[19]. This financial model depends on responsibility of producers/providers for their prefabricated products to be maintained and updated for new leaser after leasing term is expired. While the leaser sets leasing terms with leasing agent as shown in Figure 4.

Manufactured homes in Japan are financed using mortgages which are based on recourse loan contract system [22]. This system is less risky for banks than non-recourse loan system because if borrowers cannot pay for mortgage, they must give up any asset to pay for the loan outstanding, while USA is having a non-recourse loan system in some states, hence borrowers my default on mortgage payments and retain their other assets.

In Australia, banks are conservative in financing manufactured homes [24] because they don't link financing payments to intermediate production stages. Hence, some builders have created other alternatives to ease financing their prefabricated homes. For example, Modscape provides a solution for financing privately the construction, then loan is transferred to consumers using their own bank when project is completed [21]. Other companies established connections with lenders within their group of companies (e.g. TR Homes and Resolve Finance) [22].

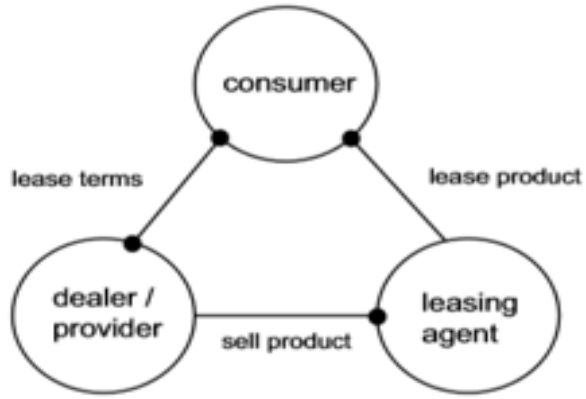

Figure 4. Relationships between providers, leasing agents, and consumers for leasing manufactured housing. Adapted from [19].

5 Recent Advancements

The status of three companies named ZETA factory, Factory OS, and Katerra who worked around the bay area in California illustrate recent developments of modular and offsite construction in USA. The bay area can benefit from offsite and modular construction due to homelessness issues and high prices of real estates in its cities like San Francisco. ZETA factory in Sacramento went out of business in 2016 due to lack of capital after working for 8 years in the market due to issues with ZETA's procurement and ability to deliver projects on schedule [15]. Procurement of materials requires a large upfront capital investment before manufacturing to deliver modules on time. This is challenging for manufacturers, developers and financial partners because each stakeholder has different motivations and constraints. ZETA factory accepted much of its payment after modules were delivered and installed onsite according to the timeline and process of traditional construction. Insufficient capital of ZETA factory led to inability to pay their suppliers in a timely manner and inability to hire personnel for pre-construction activities of the next job. Another developer outlined that many lenders of ZETA factory refused to finance their project, and the lender who agreed at the end needed extensive negotiations and many exceptions to standard bank policies [9]. Hence, the main reasons behind bankruptcy of ZETA factory are the challenges of cash flow management and lack of timely capital [9].

Factory OS and Katerra present a new model an integrated start-ups that develops, designs and builds panelized and modular construction in North America. Both start-ups learned from bankruptcy of ZETA factory and they introduce a recent trend where developers own offsite construction as a response to recent changes in housing market, and both start-ups are supported by venture capital investments from the IT industry in Silicon Valley to solve the homeless problem [2]. Factory OS in Vallejo, California started production in 2018 for a deal required by Google's parent company, Alphabet, to construct 300 apartments with a total value between $25 million and $30 million [25]. Autodesk and Citi bank are also supporting factory floor learning centre at Factory OS which is dedicated to research and education for industrialized construction. This centre is led by Terner centre for housing innovation at UC Berkeley to establish a plan for a new rapid response factory using the best automations to meet demand of quick housing after natural emergencies and disasters. Autodesk is providing software collaboration for design, fabrication and supply chain management, while Citi bank is supporting Factory OS using the initiative of spread products investment technologies (SPRINT) to finance community development projects and affordable housing [26].

Katerra was established in 2015 and built its first manufacturing facility in Phoenix, Arizona after recieving more than $1 billion from the Japanese SoftBank as its major investor, along with other investors such as Foxconn and DFJ, while executives from Amazon and Google joined Katerra's leadership [27]. However, some issues regarding project cost overruns and delayed schedules were reported [27 & 28]. In 2019 Katerra shut down its first factory in Phoenix and laid off 200 workers while some executives were replaced. Then another highly automated manufacturing facility was

built in Tracy, California as a second generation factory for Katerra.

The business models of Factory OS and Katerra as developers and builders follow the business models of Lindbacks in Sweden and Sekisui Heim in Japan who were managing market volatility using their business model for the past 4 decades [2]. Katerra utilized their equipment in Phoenix factory from Sweden's Randek which is nearly identical to the ones used by Lindbacks in Sweden [2] while focusing more in fabrication of panelized construction and Factory OS was focused on volumetric modular construction. Australia's Lend Lease Company is also following the same trend of integrated supply chain to develop, design, and build for multifamily midrise buildings using wood cross-laminated timber (CLT). However, its operations was under review to come up with a new sustainable business model [29].

6 Future Opportunities

Banks are not usually risk-takers and lenders don't consider that offsite construction is affected by both real state and manufacturing risks. Repaying the capital investment of building a manufacturing facility and its ongoing operational expenses affects the business model for offsite construction industry and the expected rate of return. Range of investment cost is based on size of facility and implemented level of automation and it can be between $50 million and $100 million [16]. Cost impact on each project due to this investment can be between 5 % and 15 % of total offsite construction costs [16]. Partnerships and joint ventures are needed with municipalities, general contractors, and IT industry to validate this business model and to reduce any associated risks as well as increasing financing schemes for owners and developers of modular and offsite construction.

In USA, Federal and state funding schemes are introduced to support collaboration between industry and universities to enhance construction productivity for modular and offsite construction [2]. The modular building institute (MBI) is developing a procurement guide for general contractors and modular builders by engaging members of the associated general contractors of America (AGC) to help project teams navigating through lending, bonding, insurance, permitting, and inspection for modular and offsite construction which are different from traditional construction [2].

MBI is also working with an organization named; the housing crisis solutions coalition (HCSC) which believes that federal affordable housing policies, such as low-income housing tax credit (LIHTC) are not efficient. HCSC believes that modular and offsite construction can develop affordable housing quickly to be occupied earlier by low income renters to avoid the need for tax credits. However, some states can offer developers' tax credits as the one presented by State of Virginia for innovative construction processes that develop housing inventory quickly. [1]

A recent action plan was also suggested to the state of Minnesota by industry leaders from around the state to make 10% of multi-family residential developments use offsite construction in Minnesota by 2025 using five steps: 1) Starting multi-sector innovation cohorts to explore challenges and potential of using offsite construction. 2) Promoting learning opportunities to educate lenders, general contractors, and architects about benefits and characteristics of modular and offsite construction. 3) Enhancing local collaboration to fast-track pre-approvals for offsite construction projects. 4) Incentivizing pilot projects using public-private partnership (PPP) which utilize modular and offsite construction. 5) Attracting new modular builders and investors to Minnesota by an economic development campaign [32].

In Australia, the federal government is supporting the advanced manufacturing growth Centre - which is a non-profit advocacy group established in 2015- to issue grants for business development. This centre supports manufacturing companies to increase their capabilities, scope, and scale [2].

In the UK, The housing corporation – which is the non-departmental public organization that funds new affordable housing - started in 2004 to require that 25% of new social housing being funded by the organization should utilize offsite construction. However, government influence on private-sector was limited, and they did not provide direct incentives through planning policy or building regulations [30]. Hence, the housing, communities and local government committee presented a white paper to the parliament in 2017 that recognises the importance of embracing offsite construction to meet UK's plan for building 300,000 homes a year by the mid-2020s [33]. The government response to this white paper was introduced in 2019 outlining many steps to address this issue including their support to financing offsite construction using £236m from the home building fund to support to projects that incorporate offsite construction [34]. As well as establishing an offsite construction working group to address barriers to financing and insurance of offsite construction.

7 Conclusion

This paper presented a literature review for the challenges associated with financing modular and offsite construction, and the current trends in financial modelling from the developer perspective and in mortgage financing for consumers. Recent advancements

in financing modular and offsite construction were also introduced relevant to the new practices of partnering with unconventional financing sources such as venture capitals and IT companies, as well as the cash flow problems incurred by developers. The future opportunities in USA, UK, and Australia were also discussed to present different initiatives developed by organizations and governments to support the use of modular and offsite construction.

It is concluded that a steady demand and support for modular and offsite construction projects could reduce any risks associated with the manufacturing and construction of this industry. Modular and offsite construction projects need to explore new sources of funding and need to develop new sustainable business and financial models.

Abstract –

Modular Integrated Construction (MiC) is an advanced type of modular construction focusing on addressing high-density high-rise buildings and is adopted as a new policy initiative in Hong Kong. Previous studies have examined the potential for using different methods and technologies to support project delivery in offsite and modular construction. However, there is a lack of systematic exploration and a paucity of examination of smart-tech solutions for MiC project delivery. This paper aims to develop a novel methodological framework of smart project delivery of MiC for achieving a better understanding of the complex process of MiC and ensuring the successful delivery of modular projects. This framework systematically structures the science, methods and technologies at four layers: sensor and data capturing, data storage and analysis, data visualization, and decision making. Drawing on the framework, key functions and technologies are explored through a systematic literature review, theoretical analysis and development, and focus group discussion with stakeholders. The framework provides a methodological basis for developing an integrative smart-tech platform for MiC project delivery. The findings of this paper are informative to practitioners and researchers for gaining a better understanding and implementation of MiC smart project delivery. The findings also contribute insights into the scientific methods and techniques of data capturing, analysis, visualization and use for dealing with complex and dynamic processes of modular building in high-density urban contexts.

Keywords –

Modular Construction; Modular Integrated Construction; Smart Technology; Project Delivery

1 Introduction

Modular construction (MC) has been adopted in many countries with demonstrated benefits including enhanced productivity and quality, improved health and safety, and minimized construction waste [1-3]. In Hong Kong, Modular Integrated Construction (MiC), an advanced type of the MC approach, focuses on addressing high-density high-rise buildings and has been developed as a game-changing approach to innovative building project delivery [4]. In MC and MiC, modules are produced in factories and then transported to sites for installation. It is critical to integrate real-time progress information from the factory production, module transportation and module installation on site, so that project delivery can be well monitored and controlled, achieving just-in-time delivery. However, there is still a lack of systematic exploration and a paucity of examination of smart-tech solutions for modular building project delivery.

This paper aims to develop a novel methodological framework of smart project delivery of MiC for achieving a better understanding of the complex process of MiC and ensuring the successful delivery of modular projects. This framework systematically structures the science, methods and technologies at four layers: sensor and data capturing, data storage and analysis, data visualization, and decision making. Drawing on the framework, key functions and technologies are explored through a systematic literature review, theoretical analysis and development, and focus group discussion with relevant academics and practitioners. The framework provides a basis for developing an integrative smart-tech platform for MiC project delivery. The findings of this paper are informative to practitioners and researchers for gaining a better understanding and implementation of MiC smart project delivery. The findings are also insightful in terms of the scientific methods and techniques of data capturing, analysis, visualization and use for dealing with complex and dynamic processes of modular building in high-density urban contexts.

2 Background

2.1 Modular construction in the world

Modular Construction (MC) is a novel approach to

innovate building construction by using the Design for Manufacture and Assembly (DfMA) theory and advanced manufacturing and logistics technologies. A seminal definition of MC was provided by Gibb [5] as the building approach with three-dimensional (3D) units that enclose usable space and form part of the completed building or structure. MC has been adopted in countries including UK, US, Canada, Germany, Australia and Singapore, with demonstrated benefits including accelerated onsite construction, improved health and safety, enhanced productivity and quality, and minimized construction waste [1-3].

However, the adoption of MC has largely been for houses and low-rises, with only a small number of modular high-rises such as one of 44 floors using steel frame modules in London and another of 40 floors using concrete modules in Singapore [see 6]. There is yet little experience in and scarce knowledge of delivering modular tall buildings. For the small number of modular high-rises, reported benefits and challenges co-existed [1-2]. For example, the project Apex House, a 29-floor modular building in London, was found to have achieved the benefits: (1) 12-month saving in construction duration, (2) on-site waste minimized to 2%, (3) the number of on-site workers reduced to 40, but also encountered issues such as the need for (1) more training for workers in factory as well as on site, (2) enhancement of the capability of module supply chain, and (3) early logistics planning [1]. Another example is the 'B2 Tower' project, a 32-floor residential building in New York, which was completed with severe time and cost overrun and broken project partnership. Attributors to the failure were found to include absence of employee training, lack of a comprehensive plan, insufficient quality control, constraints from labor unions and limited supply chain capability [7].

The merits of and challenges to adopting MC for high-rise buildings are not entirely understood by industry and public [3]. The design, production and construction of modules for high-rises face more technical challenges than for low to medium-rises [2]. The challenges are more significant in high-density maritime cities such as Hong Kong, Singapore, London, New York and Sydney where high-rise buildings are constrained by high-density urban environments and challenged by strong monsoons. However, there is a paucity of examination of MC tall buildings in high-density cities.

2.2 Modular integrated construction in Hong Kong

Modular Integrated Construction (MiC) is based on but advances the MC approach, and is first defined by Pan and Hon [4] as "*a game-changing disruptively-innovative approach to transforming fragmented site-based construction of buildings and facilities into integrated value-driven production and assembly of prefinished modules with the opportunity to realize enhanced quality, productivity, safety and sustainability*." It has recently been adopted as a new policy initiative as stated in the Policy Address 2017 of the Hong Kong Government [8].

The MiC initiative in Hong Kong was set in the Policy Address to mainly address two significant issues facing the construction industry: workforce shortage and very high construction cost. There are several ongoing high-rise MiC pilot projects, including two 17-storey blocks of student residence on a 3-storey podium at The University of Hong Kong and one 16-storey block of staff quarter on a 1-storey podium at The Hong Kong Science Park [9]. These projects adopt the MC systems available in the market within the existing planning and design process and practice. The benefits of MC demonstrated in other countries [1-3] are actually highly consistent and associated with time, cost, quality, safety, sustainability and productivity, and thus should also by large be achievable for MiC in Hong Kong. The potential of MiC to have a transformative impact on the construction industry is also recognized [10]. However, there is a lack of empirical evidence to support the advantageousness of MiC and clear knowledge to guide the successful project delivery that could thereby promote the wide uptake of MiC.

2.3 Previous research related to modular building project delivery

Previous studies investigated the challenges facing the delivery of MC building projects. For example, McGraw-Hill Construction [11] surveyed the American construction industry and their report revealed clients' major concerns such as the early commitment to design and engineering work, the higher requirements for transportation, and the constrained number of suppliers. Yang et al. [12] identified that MiC has many new challenges and more stringent requirements in project delivery than conventional construction methods and other types of offsite approaches. For example, onsite works for MiC depend heavily on integrated modules manufactured offsite, which implies that onsite works are especially vulnerable to poor quality control and delivery delays. There are difficulties identified in logistics control, especially when involving complicated and expensive cross-border transportation for overseas module supply [1]. Decisions to support the successful delivery of MiC projects with optimized performance in time, cost, quality and safety require a clear understanding of the complex process of MiC and leveraging of new technologies.

There have been attempts on the use of smart technologies to support project delivery in MC/MiC. Han

et al. [13] integrated simulation models and post-simulation 3D-visualization techniques for MC to support project managers' precise planning of production process and construction operation. Ramaji and Memari [14] developed information delivery framework for standardizing information exchange mechanisms to facilitate Building Information Modeling (BIM) implementation in modular buildings. Li et al. [15] explored the integration of Radio Frequency Identification (RFID) with BIM in the precast concrete factory for scheduling and supply chain management. Niu et al. [16] examined the potential of integrating Geographic Information System (GIS) and BIM for MiC logistics management. These studies and technology applications are promising for tackling different delivery issues in MiC, but there is still a lack of systematic exploration of integrative smart-tech solutions for MiC project delivery.

3 Research Methods

This paper aims to develop a novel methodological framework of smart project delivery of MiC for achieving a better understanding of the complex process of MiC and ensuring the successful delivery of modular building projects.

The framework was developed through an iterative process including literature review, theoretical analysis and development, and focus group discussion with relevant academics and practitioners. The research process is illustrated in Figure 1. First, the 1st round literature review was done on research works regarding MC/MiC, project delivery frameworks, and relevant smart technologies. Second, by integrating literature review results with theoretical analysis, an initial framework of smart project delivery of MiC was developed. Third, drawing on the initial framework, key functions and technologies were explored through a 2nd round literature review, through which the framework was concretized and refined. Fourth, focus group discussion was conducted with relevant academics and practitioners to verify and further refine the methodological framework with embedded functions and technologies. The details of focus group participants are presented in Table 1. Purposeful sampling was used to select focus group participants to cover MiC clients, contractors, suppliers, relevant government departments, as well as academic and professional bodies who have responsibility for MiC research and consultancy.

4 A Methodological Framework of Smart Project Delivery of MiC

Successful delivery of construction projects heavily requires the reliable monitoring and control of project performance in terms of cost, time, quality, safety, and environment to satisfy stakeholder requirements via effective communication [17]. While existing literature [17-19] has addressed decision making issues of what and how performance should be measured, this present paper aims to provide a fundamental exploration of the underlying methods and technologies to support decision making in project delivery intelligently.

The proposed methodological framework of smart project delivery of MiC is illustrated in Figure 2, which systematically structures the science and methods at four layers: sensor and data capturing, data storage and analysis, data visualization, and decision making. The key scientific questions to address include:

- What types of information are needed for MiC smart project delivery?
- How such information can be represented and exchanged in various computing models with accuracy to suit different project stages?
- How such information can be analyzed and visualized for decision support?

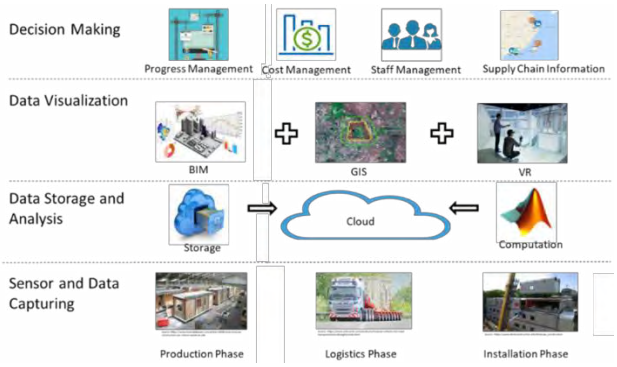

Figure 2. A novel methodological framework of smart project delivery of MiC

Figure 3. Examples of sensors used for MiC smart project delivery in the Greater Bay Area

4.1 Sensor and data capturing

The fundamental layer is sensor and data capturing, which is related to the collection of different types of information during different phases (see Figure 3) to effectively record and track relevant types of information, thereby supporting MiC project delivery.

During the production phase, tagging technologies, such as barcode [20], RFID [20], or Near-field communication (NFC) [21], can be fixed to individual modules for recording production information, e.g. module weight and dimensions, material sources, producers, quality checking and testing records. During the logistics phase, Global Position System (GPS)-based [22] and Bluetooth-based sensors [23] can be used for real-time tracking and tracing of module locations, which can further provide useful information for logistics coordination. During the on-site construction phase, images can be taken by site cameras and drones [24] to capture real-time information on module delivery and installation for efficient site planning and progress monitoring. Besides, different physiological sensors integrated into wearables [25] can be used to monitor fatigue and working conditions of workers for occupational safety and health management, such as electrocardiogram (ECG/EKG) sensors for heart monitoring, electromyography (EMG) sensors for muscle monitoring, and electroencephalography (EEG) sensors for brain monitoring.

Useful insights were obtained through the focus group discussion. Several professionals raised the concern of accuracy requirement (e.g. tracing the module in the factory to the exact on-site location) for selecting suitable sensors. Besides, some participants suggested a life-cycle management perspective that covers the stages from planning through operation and maintenance. In this regard, temperature, humidity, light and pressure sensors can be adopted to monitor the built environment; strain gauges can be used to measure strain on the module structure, thereby monitoring the health condition of the modular building.

4.2 Data storage and analysis

The second layer is data storage and analysis, through which the collected data from using smart sensors can be processed with a cloud-frog-edge computing integrated strategy (see Figure 4).

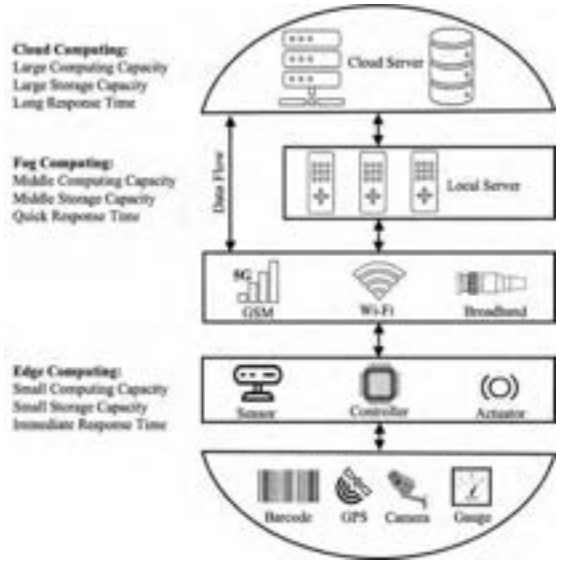

Figure 4. Cloud-frog-edge computing strategy for data storage and analysis

Cloud computing [26], and its extension, fog computing [27] and edge computing [28] can be used for dealing with different data and tasks of MiC. In general, cloud computing [26] is used for tasks that require large computing capacity but allow longer response time; frog computing [26] can be used for tasks that require a middle level of capacity; edge computing [28] is used for tasks that require immediate responses and small computing capacity. For example, in the case of onsite module installation using computer vision to detect the status of the modules, the monitoring task requires immediate responses from video streams and do not require a very large scale of computing compacity, edge computing should therefore be considered. While if the task is like logistic planning that requires large computing compacity on route selection but does not require immediate response, cloud computing should be adopted.

Based on such a data storage and analysis platform, real-time progress monitoring and control function can be developed for MiC projects to achieve just-in-time delivery. Machine learning algorithms can be integrated to predict potential progress delays and risks for better decision making. The concern of platform robustness was also discussed during the focus group meeting, in terms of how to integrate different data sources and extract information for different functions and how to manage and secure big data effectively. It is therefore important to consider information compatibility and design the information exchange schemes.

4.3 Data visualization

The third layer is data visualization, where BIM is the core technique that provides the interface for professionals to access data for project delivery.

The integration of GIS with BIM [16] is recognized as critical in digitalizing the logistics process for logistics planning and decision making. The integration is achievable through building geometry data communication between BIM (e.g. Revit) and GIS (e.g. ArcGIS) platforms for concurrent modelling of buildings. An example is given in Figure 5. Based on the BIM-GIS integration, the transportation and installation status of all modules can be visualized with their location and broader environment information for better logistics management. In addition, augmented reality and virtual reality (AR and VR) [29-31] can be used to enhance BIM for supporting effective execution of construction activities. For example, AR can provide workers with installation details of each type of module in a 3D view, from which workers can easily understand where and how to install a module.

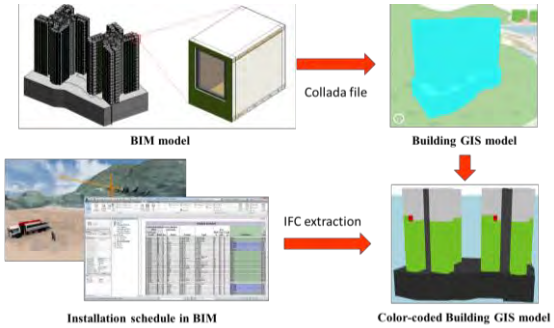

Figure 5. An example of BIM-GIS integration (after [16])

4.4 Decision making

The top layer is decision making, which deals with the managerial issues of how the analyzed and visualized information can be used for data-driven decision support in MiC project delivery. Technically, this layer should involve the design and development of desktop software (e.g. [17]) and mobile application to provide user friendly interfaces for decision making.

From a top-down perspective, identifying key areas of decision making [32, 33] is a preliminary task to support technical design of lower layers. By defining decision criteria and decision making rules, automated monitoring and control can also be achieved.

From a bottom-up view, data visualization can support decision making of stakeholders in an easily understandable manner and provide actionable insights for project delivery. First, decision makers can easily and quickly assess project delivery progress based on visualized data, thereby making timely and informed adjustments. For example, the real-time progress for module delivery can be visualized and compared with the scheduled time to support logistic planning and coordination. Second, different stakeholders can effectively communicate with each other based on data visualization for making joint decisions easier, and also can track the works of other stakeholders to make self-adjustment. Third, alternative plans or different remedial actions for identified issues can be clearly evaluated through data visualization to support decision making.

5 Discussions

The successful delivery of MiC building projects requires accurate and reliable monitoring and control to unleash the full benefits of this “factory assembly followed by on-site installation” [7] construction method for achieving its advantageousness. There are a variety of intelligent methods and technologies available to support MiC smart project delivery. However, how to effectively integrate various methods and technologies to provide

different functions and fulfill stakeholder requirements is still a challenging issue. The developed methodological framework in this paper should address this knowledge gap by providing a systematic approach for understanding many methods and technologies and establishing technical plans for MiC smart project delivery. Table 2 summarizes the examples of methods and technologies with different functions for achieving MiC smart project delivery.

MiC is a very new concept and its feasibility of adoption for high-rise buildings still remains unclear [1]. More research is needed to discover the full potential of MiC and how successful implementation can be achieved. In this regard, the developed methodological framework should support the exploration and examination of best practice for the successful delivery of MiC projects. It provides a benchmarking tool for analyzing different technologies and their integrations to best orchestrate the complex process of MiC project delivery.

From a practical perspective, the developed methodological framework should support the establishment of a workable platform, which could allow optimization for achieving MiC smart project delivery and visualization of the whole process to project stakeholders for better engagement and continuous improvement.

Table 2. Examples of methods and technologies for MiC smart project delivery

Layer	Method and technology	Function
Sensor and data capturing	Barcode, RFID, NFC	Record production information
	GPS, BLE	Track module location
	Camera	Track onsite installation progress
	Physiological sensors	Monitor fatigue and working conditions of workers
	Temperature, humidity, light and pressure sensors	Monitor the built environment
Data storage and analysis	Cloud computing, frog computing, edge computing	Preprocess raw data, match computation tasks with suitable computing capacity, and data storage
Data visualization	BIM	Data manage and exchange center
	GIS	Provide intuitive logistic information
	AR/VR	Assist construction activities
Decision making	Desktop Software, Mobile Application	Interfaces for decision making

6 Conclusions

Modular Integrated Construction (MiC) is an advanced modular construction approach by particularly addressing complex and dynamic high-rise building in high-density urban contexts. It has shown a great potential for the betterment of building construction, but there is still a lack of systematic exploration of how successful project delivery of MiC can be achieved. This paper has developed a novel methodological framework of smart project delivery of MiC. The developed framework systematically structures the science, methods and technologies at four layers: sensor and data capturing, data storage and analysis, data visualization, and decision making. Drawing on the framework, key functions and technologies were explored through a systematic literature review, theoretical analysis and development, and focus group discussion.

The framework provides a basis for understanding different technologies and methods for MiC project delivery. The findings contribute insights into the scientific methods and techniques of data capturing, analysis, visualization and use for dealing with the complex and dynamic processes of modular building in high-density urban contexts. Future study will establish an integrative smart-tech platform based on the developed framework to support project delivery of MiC using real-life projects.

Abstract –

Remicon, an important material constituting the structure of a building, needs an efficient quality management system throughout the entire process from production to delivery, including production management, shipment-transport management, and delivery management, to ensure the required performance by the contractor. Nowadays Remicon factories becoming smart factories and automated form for systematic and accurate management throughout the entire process from production to delivery, including product management, manufacturing facility management, transportation management and quality management based on advanced IT technology and computerization. However, data generated from sensor technology, big data processing technology, and SCM system, which are currently applied to the Remicon factory, are managed through single server management system. A single server has a high possibility of forgery and loss of data, which makes it less reliable for quality management of Remicon.

In this study, we propose a Remicon quality management system based on the hyper-ledger fabric, a private block chain. This is a system that can digitally generate information that needs to be verified by the quality manager to secure the quality of Remicon at each stage of 'mixing-transport-delivery' and share it to all nodes participating in the block chain network to guarantee data reliability. In addition, the Dapp (distributed application) of each node has different ledger access rights. So Remicon manufacturers belonging to different channels do not share sensitive information, but contractors and government can view the status of all Remicon quality management at the construction site.

Keywords –

BlockChain; Remicon; Ready mixed concrete; Quality Management; Concrete

1 Introduction

Ready-mixed concrete (Remicon), which is composed of raw materials, is manufactured by mixing materials according to the pre-designed mixing ratio at the factory. Unconsolidated, flexible concrete, which is Remicon, transported to the construction site within a regulated time and then subjected to a quality evaluation for constructability and durability through quality tests. Remicon, an important material constituting the structure of a building, needs an efficient quality management system in all processes from production to delivery, including production management, shipment-transport management, and delivery management, to ensure the required quality. The general Remicon quality management system manages mixing ratio reports, shipment-entry times, and field test reports based on paper documents. Most of the time, documents are accumulated for a period of time and then batched together and sent to the top, which takes considerable time and energy to organize and computerize the information [1]. This conventional quality management of Remicon can cause various problems. For instance, it is very difficult to informatize the data of the Remicon because when production period, mixing ratio management is completely dependent on the factory. Therefore, the contractor cannot accurately evaluate the Remicon quality [2]. In addition, Remicon has the characteristics of 'Just in Time', so the value as a product is lost after more than 90 minutes, so the supplier must send it to the site according to the date and time requested by the orderer [3]. However, there is no way to determine whether the specified time has been observed [4]. On the other hand, the quality test information is not shared in real time due to insufficient computerization of the quality test of the Remicon. Therefore, even if the one Remicon truck is judged carrying defective product, the defective Remicon continues to produce, and the defective Remicon continuously deliver in the field [2]. Also, it is difficult to check if the quality test inspection report issued by the quality management inspection agency is forged at the construction site, and even if the test report is kept, there is no basis to judge whether the test and inspection

were done if there is no raw data. [5].

Recently, research has been conducted on how to simplify the work by automatically computerizing the quality management data produced by the Remicon to increase the efficiency of the Remicon quality management and share data in real time [1][5][6][7]. For example, a Reimicon production system using an internet network, real-time Remicon delivery-transport management through a location tracking device, and a quality test management system through a mobile device. However, existing information systems are managed through a central server and use a method of storing data in a central database. Centralized servers can operate as a single point of failure (SPoF) vulnerable to security, accessibility and availability [8]. These shortcomings, like Remicon's paper invoice documents, have the potential for concealment and manipulation. In addition, when a concrete defect problem occurs, there is a risk that it is difficult to determine the responsibility of the Remicon factory and contractor [9] through artificial intervention. With this solution, a new way is needed for quality managers to figure out the quality of Remicon without skepticism about the authenticity of Remicon based on reliable quality management data.

2 Related Works

○ General Remicon quality management process

Currently, the Remicon industry is implementing quality management based on paper documents. In general, there are a large number of record registers for document management, which complicates the description and classification, and errors and loss of information occur during documentation. In addition, due to the excessive amount of documents, the documenting work through the manual of the quality manager is burdensome, and the lack of quality management technique makes it difficult to establish history management and evidence data [6].

○ Digitalized Remicon quality management process

In order to solve these problems, large-sized Remicon companies such as Eugene, Sampyo, and Aju have recently built a service model to apply advanced technologies such as information and communication technology (ICT) and artificial intelligence (AI) to the Remicon industry.

Eugene Company has applied Air (Artificial Intelligence for the Remicon industry), a Remicon manufacturing/management system, to domestic plants. It aims to strengthen the competitiveness of autonomous production by improving production efficiency using sensor technology and optimizing logistics using AI.

Aju is building a service model applied with information and communication technologies such as machine learning, chatbots, and robot process automation. The quality manager can automatically check the aggregate usage and check the incoming and outgoing of the Remicon truck by mobile. In addition, it is possible to determine whether quantitative supply between aggregate suppliers is made by replacing paper invoices with electronic invoices.

Sampyo developed a chatbot to check the necessary information such as the Remicon shipment volume, delivery specifications, order quantity, and truck allocation interval in real time. In addition, by establishing an ‘integrated operation system′ that applies ICT technology, it is planning to integrate and manage individual shipments of 26 Remicon factories across the country into 5 regions.

Daewoo E&C introduced the concrete quality management mobile app 'Baroque' to all sites so that the site quality manager can digitize and track the concrete quality test work with the app. Concrete test log

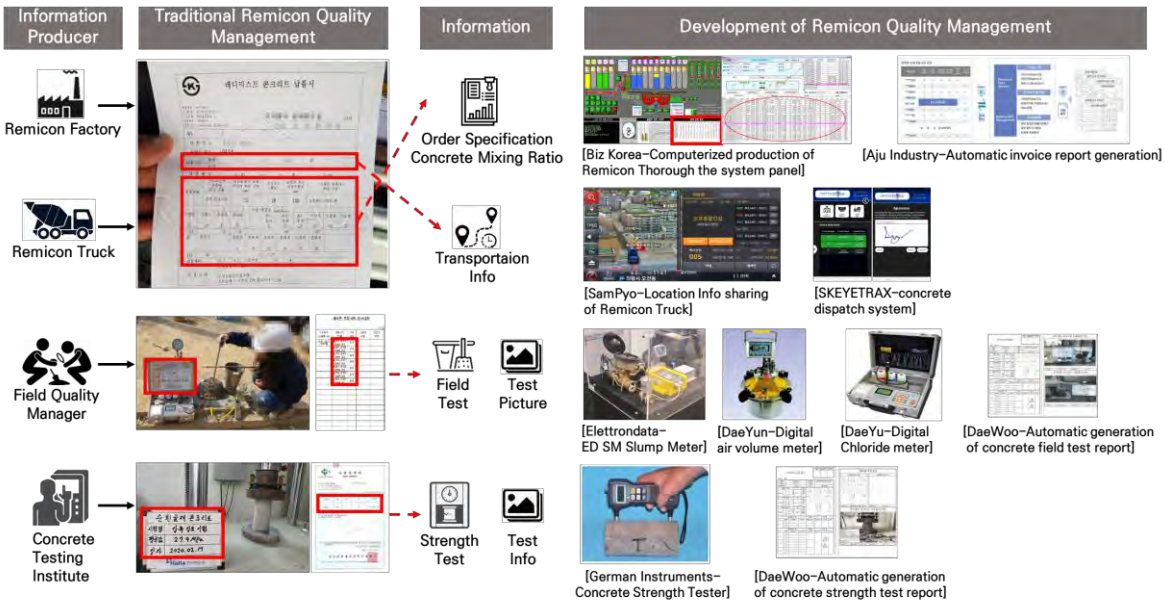

Figure 1. Remicon Quality Management Trend

includes construction site, concrete specification, concrete supplier, slump, air volume, chloride content, compressive strength of 7 and 28 days and test photo.

Biz Korea built their own Remicon quality management system to check material consumption in conjunction with panel and shipment management. In addition, it is possible to check whether the Remicon products are matched by automatically producing the shipping invoice. then, check the weighing error of the panel to manage whether it was produced according to the specifications.

○ limits of Improved Remicon quality management system

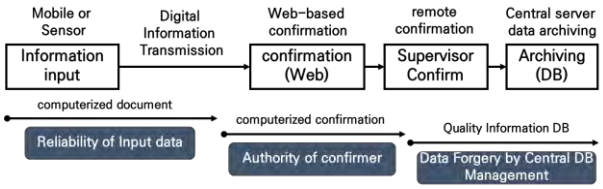

Figure 2. Limits of Improved Remicon Quality Management

Currently, Remicon's quality management is being researched by applying various technologies. It mainly deals with mixing ratio management, delivery management, and on-site quality testing to improve the efficiency of quality management that can occur during the mixing-transport-delivery process. However, the part regarding securing reliability of quality management data generated during the supply chain process of Remicon was found to be insufficient.

The management supervisory authority was keen on whether or not the quality managment of Remicon has been carried out, and in April 2018, the Ministry of Trade, Industry and Energy conducted a “Survey on Eradication of Poor Remicon” to investigate whether the cement content was insufficient or the mixing ratio was manipulated. In addition, in August 2018, the Ministry of Land, Infrastructure and Transport inspected the status of quality management in 779 Remicon factory nationwide to intensively check whether the mixing ratio of Remicon materials was false, and also confirmed whether a quality test was conducted. As such, the emphasis is placed on the reliability of the quality management of Remicon.

○ Research for securing supply chain reliability

Wang, et al studied the transparency and real-time information sharing of PC quality data for each procurement step by utilizing blockchain in the PC (Precast Concrete) Supply Chain section [9].

Abeyratne, S.A conducted a study on the Ready Manufacturing supply chain using blockchain technology to strengthen the reliability of each participants and also mentioned the need to combine blockchain technology with IT technology [10].

A Lanko researched on the efficiency of quality management of procured construction materials by introducing blockchain technology to minimize human intrusion using RFID technology in the procurement process of construction materials and to strengthen the reliability of information [11].

The Mediledger Project was developed by LinkLab and Chronicled to help manage the supply chain of medicines, including transportation of medicines that must comply with trajectory and tracking regulations [12].

N. Nizamuddin applied a blockchain technology to document management to study a system in which various stakeholders can verify and approve documents through a decentralized environment [13].

○ Theoretical considerations

Blockchain-based SCM (Supply Chain Management) is already applied to various industrial groups [14] and researched and proved that it can be sufficiently used in Remicon quality management through use-case. It is not difficult to implement an SCM system for efficient management by connecting individual quality management system at specific stages of mixing, transportation and delivery of the above-mentioned Remicon in one process [15]. Securing the reliability of quality management data using blockchain can be sufficiently approached by collecting and managing computerized data produced by the individual systems mentioned above. This prevents forgery and integrative management of data at the mixing-transport-delivery stage by integrating blockchain data storage with an existing Remicon quality management system rather than creating a new system.

3 Research Scope and Method

Blockchain technology meets the goals of this study with the advantage of sharing data using distributed ledger technology and securing the reliability of stored data. Therefore, this study intends to present a Remicon quality management system using blockchain technology.

In order to ensure the quality of Remicon, the information required by the quality manager is digitally generated and stored in the blockchain distributed ledger. Through this, the framework of the Remicon quality management system that can guarantee the reliability of data will be described.

It analyzes important quality-related data in the remicon production system using the currently developed Internet network, real-time remicon transport time management through location tracking device, and quality test management system through mobile devices.

In addition, it analyzes the data flow that distributes and stores the necessary information through the chaincode running on the blockchain.

4 BlockChain Overview

○ Blockchain

Blockchain is a distributed data storage technology. This structure ensures data integrity, reliability, and cannot be forgery by disclosing and sharing transaction details to all nodes participating in the transaction in a P2P manner without keeping transaction records on a centralized server. There are two main types of blockchain. There is a type (permissionless blockchain) where anyone participates in and verifies transactions, while there is a distributed ledger system where only predetermined participants can access the network (permissioned blockchain)

	Public	Private
Access	Open read/write	Permissioned read and/or write
speed	Slower	Faster
Security	Proof-of-Work/ Proof-of-stake	Pre-approved participants
Identity	Anonymous/pseudonymous	Known identities
Asset	Native assets	Any asset

Figure 3. Difference between Public and Private Blockchain

The permissionless blockchain has the advantage that anyone can participate in transactions and verifications, but does not meet the purpose of this study in that all nodes participating in the network can view the information uploaded to the ledger. The purpose of this study is that the permissioned blockchain that allows only a predetermined participant to access the network (view data) is required in order to set the node authority so that only those concerned with Remicon quality managment can access and input data [16].

○ Hyperledger Fabric

Hyperledger Fabric provides a permissioned network and security by keeping transactions confidential. In addition, it is possible to automate business processes using chaincode and verify the identity of network participants with the MSP function. Therefore, it is possible to clarify the responsibility and network configuration with reliable nodes. In addition, through the Channeling function, the ledger can be released only to authorized participants, thereby preventing indiscriminate data access.

5 BlockChain based Remicon Quality Management System

This chapter describes the development of a Remicon quality management system based on blockchain technology to increase the reliability of stored data. The developed system constructs a Permissioned-Private network using Hyperledger Fabric blockchain technology. Therefore, the important information produced at each stage of the quality management of the Remicon can be distributed and stored so that the quality manager can access the information.

○ system architecture

This system divides the chaincode function according to the type of information produced in each process of mixing-transportation-delivery and distributes the individual information on the quality management of Remicon.

The chain code consists of an insert data function

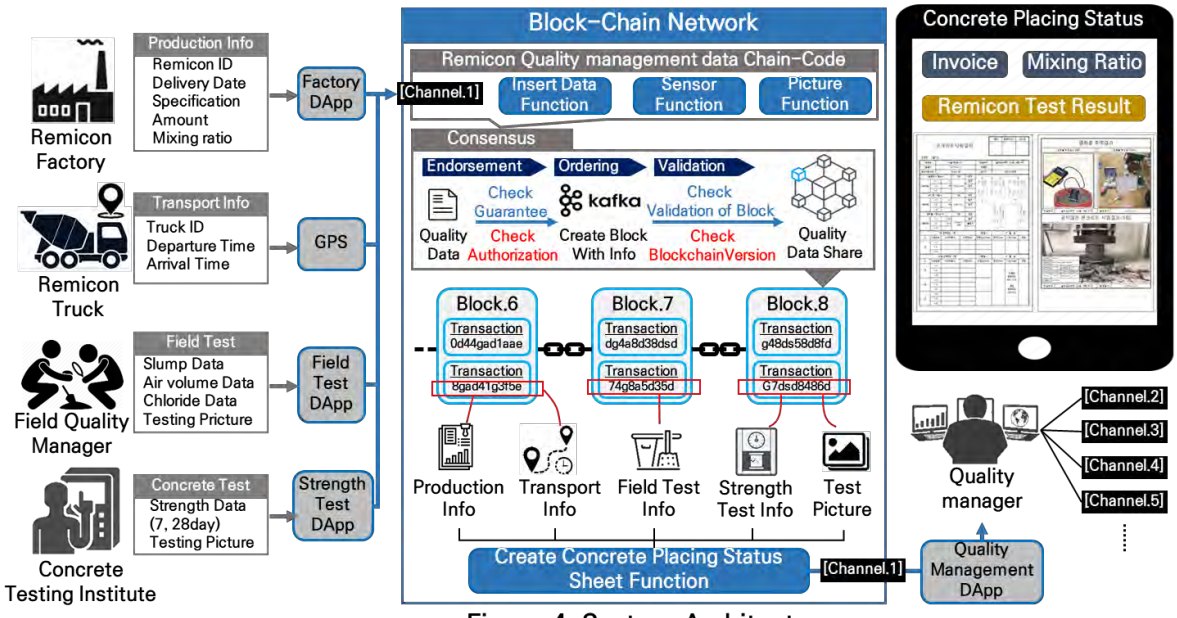

Figure 4. System Architecture

that stores the values input from the Remicon factory, a sensor function that stores GPS data of the Remicon truck and test data, and a picture function that stores pictures of the test process. It is composed of create concrete placing status sheet function for convenient reading by quality manager by reconfiguring mixing ratio information, transportation information, and test information.

Distributed client applications that operate on this blockchain-based Remicon quality management system are divided into Remicon factory, field quality managers, concrete testing institute, and quality manager according to the user's role. In order to use these applications separately for each user, Hyperledger's Membership Service Provide (MSP) function manages the necessary authority (account) to call each function of the chaincode for each user. The authorized user sends data through the application with the corresponding account. The transferred data is verified again through the process of identification and signature verification in the consensus process to verify the reliability of the data produced by the user(quality management data producer).

The Remicon quality management data of each step is called a create concrete placing status sheet function as an application for quality managers after a step of checking an account at the request of the quality manager. Therefore, the stored data is arranged in a certain form and the quality management of the Remicon is provided to the quality manager.

In addition, through the channel MSP, producers of Remicon quality management data can access the corresponding ledger, but not the data of other ledgers. For example, Remicon A factory can judge whether their Remicon has been properly delivered to the ordered site and tested, but cannot see the order history of Remicon B factory belonging to other ledgers. In this way, the quality manager can read the quality managment contents of the Remicon in all ledgers, but it is designed not to share sensitive information among the Remicon factories.

○ Smart Contract architecture

The essence of the transaction is the invoking of a smart contract (chaincode), deployed into the blockchain network to enable interaction with the shared ledger.

Fig 5 illustrated the interaction flow with the chaincode. The client inputs the function name and arguments to initialize the truncation and peers access or modify the ledger via chaincode based on multiple application. Generally, two operations are involved in chaincode: the “init” and “invoke” functions. The “init” function is called when initializing or upgrading chaincode; “invoke” is used in response to transaction proposals to query or update the ledger. In this system, the “invoke” function is composed of eight specific functions: InsertDB, UpdateTransportationTime, UpdateSlump-Test, UpdateAirTest, UpdatePressureTest, Update-Picture and QueryDB.

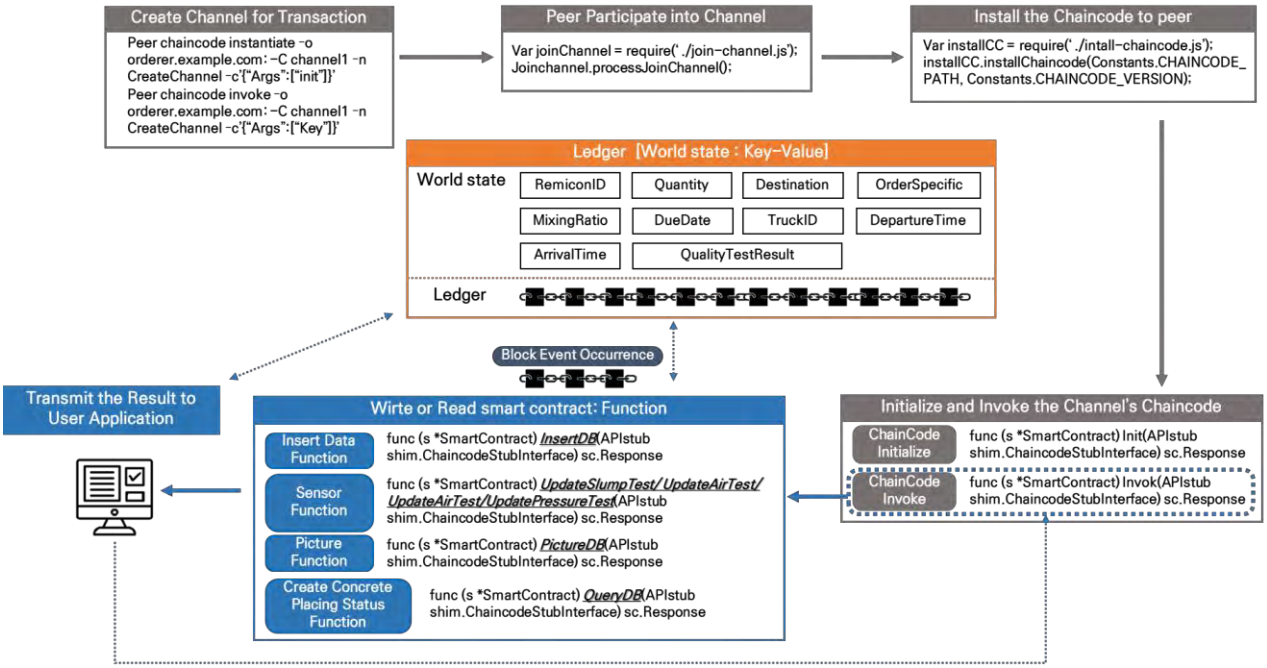

Figure 5. Architecture of Chaincode

Fucntion Name	Invoke Authority	Explaination
InsertDB	Remicon Factory	Input the mixing ratio value into the Remicon mixing control panel
UpdateTransportationTime	Remicon Truck	Input departure and arrival times based on the GPS data of the Remicon Truck
UpdateSlumpTest	Field Quality Manager	Input sensor-based slump data
UpdateAirTest	Field Quality Manager	Input sensor-based Air Volume data
UpdateChlorideTest	Field Quality Manager	Input sensor-based Chloride data
UpdatePressureTest	Concrete Testing Institute	Input sensor-based Compressive Strength of Specimen data
UpdatePicture	Field Quality Manager/ Concrete Testing Institute	Uploade the picture of while tesing Remicon Quality
QueryDB	Quality Manager (Contractor/ Government/ Factory Quality Manager)	All Remicon quality data can be invoked and created in a certain form to be viewed as an application for quality manager.

Figure 6. Explanation of functions

○ Function

The functions and calling authority for storing or viewing Remicon quality management data through the client application are as follows Fig 6.

"QueryDB" function is used to obtain the Remicon quality management data and attributes value. The last seven functions are invoked when Remicon is produced, transported, and delivered, respectively.

6 Features of the Developed Remicon Quality Management System

In general, Remicon quality management checks whether the performance required by the contractor is secured on a document basis. It is difficult to judge the existence of improper quality management records that can be forged. In contrast, the developed blockchain-based Remicon quality management system used computerization and sensors as a way to minimize human intervention when storing mixing ratio reports produced at the mixing stage, compliance with time regulations during transportation, and test data after delivery. Therefore, it reduced human-error and allowed quality manager to view the reliable quality management data in real time.

○ Mixing process

Data for preparing shipping invoices are received from the Remicon panel, which is a system that automatically calculates the mix ratio of Remicon according to the order specifications of the construction company and automatically weighs raw materials. Input RemiconID, Quantity, Destination, Order-Specification, Mixing Ratio, Due date data into Remicon Invoice Info table in charge of Remicon production information in Production Process.

○ Transport process

Departure Time and Arrival Time are recorded in the Transportation Info table in charge of managing transport time information in the transport process by analyzing the GPS data attached to the Remicon.

○ Site Test process

The sensor corresponding to the test info table in charge of the Remicon quality test data put into the delivery process by receiving the slump value, air volume, and chloride content of the Remicon through sensorization of the on-site test equipment. In addition, pictures for each test are transmitted.

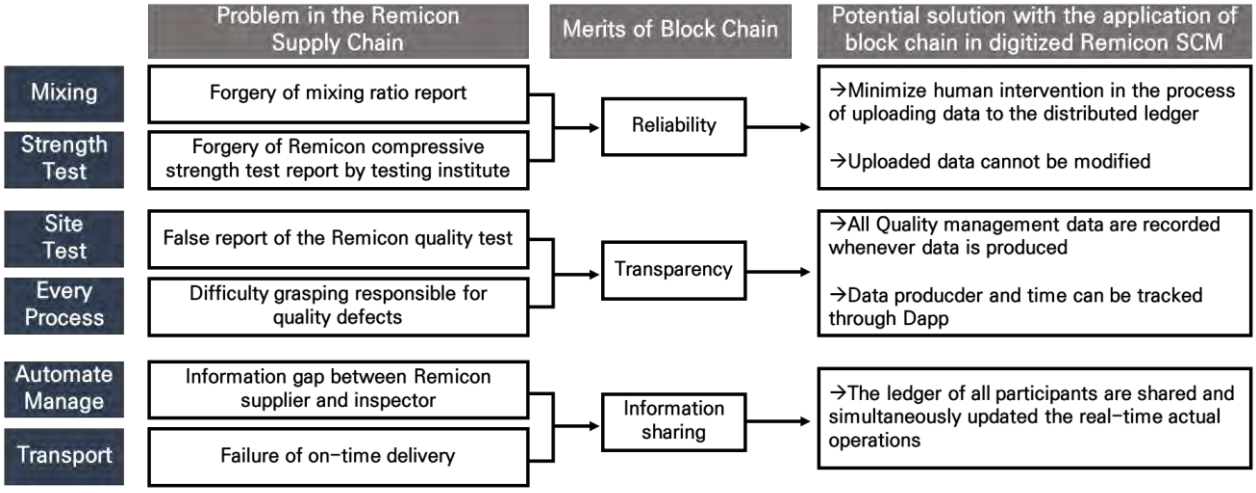

Figure 7. Advantages of System Utilizing Blockchain

○ quality test institution process

The strength of the specimen on the 7th and 28th is measured by the in-house quality testing laboratory or the external quality testing institution. After receiving the data through the strength measurement sensor, record the compressive strength of 7 and 28 days in the Test Info table in charge of the Remicon quality test data in the delivery process. Also, pictures for each test are transmitted.

○ Automation of Remicon quality management documents

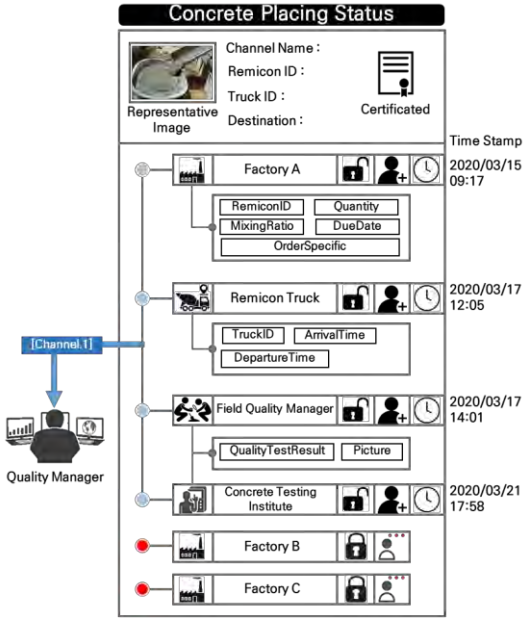

Figure 8. Data Produce Structure

The quality manager (Contractor, Government, Factory Quality Manager) can easily comprehend the status of the quality management of the Remicon by automatically filling in the digital document of the concrete placing status sheet in a certain form by calling all stored Remicon quality management data.

○ Data Base

Fig 9 show indicate what kind of data would be stored in blockchain. Remicon Invoice Info, Transportation Info, and Test Info data produced by each quality management data producer accessing the application with the corresponding account during the quality management process are as follows. The data to be registered in the block chain is Remion ID, quantity, Destination for Remicon, order specification from contractor, mixing ratio of Remicon, due date for delivery, Remicon truck ID, truck Departure-Arrival time, test result(slump, air, chloride, strength) and picture of test. This information is continuously recorded through a step-by-step process, and each data can know who and when stored the information and the account who generates the action. The action execution result is stored in the blockchain in the form of a transaction. By checking the transaction history, it is possible to grasp at what stage there is data forgery, and finally, to ensure the reliability of the Remicon quality management information producing. In addition, the quality manager can view reliable Remicon quality management data.

7 Conclusion

In this study, we proposed to form a trust protocol for quality management through transparent disclosure of quality management details among data producers by utilizing blockchain technology.

The proposed system can prevent the generation of false results by accessing the distributed application used by the producers of Remicon quality managment data at each stage through the corresponding account. In addition, it is meaningful in that it is possible to perform the quality managment of Remicon with integrity, confidentiality and reliability. This ensures transparency through the transaction history of which data is inputted and when data is stored according to the process, and makes it possible to clarify the responsibility even if a concrete defect occurs. since both the contractor and the Remicon factory can share the quality data, the factory can read the field test contents and have confidence in the quality of their product. In addition, the access rights of each blockchain network participant node's ledgers are different, so that remicon factory belonging to different channels do not share sensitive information like how much be ordered or payed, but contractors or national supervisory authorities, etc. can view the status of all remicon quality management at the construction site. it is expected that the national supervisory authority will be able to solve the problem of document forgery/falsification in the process of inspecting whether

Figure 9. DataBase Structure in Blockchain

the quality managment of concrete at the site has been properly performed by reading the concrete placing status sheet of digital document based on trusted data.

In this study, in order to solve the Oracle problem (If information is posted on the blockchain, it is almost impossible to correct it, and forgery is impossible, so if incorrect information is uploaded from the beginning, the information cannot be trusted) when computerizing the Remicon quality management data produced at each stage, it was designed to minimize human intervention. This presupposes the direct transmission and reception of computerized quality management data generated from sensor technology, data processing technology, and SCM systems currently applied to the Remicon industry. In order to connect with the data transmission part of the computerized Remicon quality management system, it is necessary to open and interwork with the system API of the corresponding company, and optimization to meet compatibility is expected. In addition, due to the nature of the blockchain, all quality management data are disclosed, and sensitive concerns that each company's core technology is leaked out should be adjusted.

Abstract –

Lending inspiration from the manufacturing industry, industrialized house-builders have adopted some of its characteristics such as high standardization of configurable products and manufacturing processes. Standardization of product and information flow within industrialized house-building has shown to beneficially increase offsite manufacturing efficiency. They have however not been able to transfer the increase in efficiency to onsite construction, leading to it being one of the key issues resulting in delays. For offsite manufacturing, previous research has suggested Bill of Material (BOM) as a structure to define information for in manufacturing phases. However, due to the variation in workflow between offsite manufacturing and onsite construction, the structure of a BOM for offsite manufacturing cannot be reused in onsite construction, ultimately resulting in increased data redundancy and recreation.

A conceptual model of a BOM for onsite construction has been developed inspired by Bill of Materials (BOM), Work Breakdown Structure (WBS), Location Breakdown Structure (LBS), Standard Operating Procedure (SOP) and Work Instructions (WI). The conceptual model utilizes space structure LBS to link spaces with SOPs. Furthermore, it also utilizes WBS to link SOPs with WIs.

The BOM for onsite construction is generated by a transformation from offsite manufacturing P-BOM. Streamlining the information flow and transformation between manufacturing and construction phases open the possibility to develop IT-solutions for industrialized house-builders. By developing existing IT-systems to reduce data redundancy, the fragmentation between offsite manufacturing and construction sites could be utilized by reusing existing data. The conceptual model supports multiple information views and allows for information filtering determined by the performed work and project.

1 Introduction

Industrialized house-building (IHB) has been considered as one of possible solutions to achieve the desired increase in effectiveness and efficiency of the construction sector [1]. It has therefore been a major research area in Sweden, where the Swedish construction sector has been a driving force in achieving a substantial development of industrial house-building. IHB has been characterized by high standardization in platforms for basic house types, configurations as well as offsite manufacturing [2]. It has shown several benefits within the construction sector, including assurance of product quality, higher productivity, improved control over manufacturing processes and even improved storage management within onsite construction [3]. IHB has led to an increase in the amount of information produced, handled and gathered around a project [4]. Usage and distribution of information within offsite manufacturing have drastically improved in recent years through a highly integrated offsite engineering, design and manufacturing process [2,3].

IHB could potentially improve the efficiency of onsite logistics, material handling, progress tracking and other onsite activities [3]. To achieve that, its management system must be well integrated with the already existing offsite manufacturing systems. This is however far from reality, where onsite construction is wasting resources searching, sharing or recreating of data,

indicating a clear information flow detachment between prefabrication, assembly and construction site [5].

The degree of redefinition is based on the needed level of flexibility to achieve the desired customer value from the product [6]. Therefore, it is important for the information structure to be flexible according to company needs and clients demands.

Inspired by the manufacturing industry, some companies in the industrialized construction sector have adopted information structures relying on the Bill of Materials (BOM). BOM has the potential to describe the breakdown of a product for IT systems, with the intention of organizing information in a form that makes it usable to visualize multiple information views as well as different phases of a product's life cycle [7,8]. For this, BOM structures need to be integrated with the existing manufacturing systems [3].

The purpose of this study is two-folded. First, explore how BOM could be extended to onsite construction. Secondly, analyze how the extended BOM for onsite construction could reduce data redundancy as well as fragmentation between offsite manufacturing and onsite construction.

2 Research Approach

The study uses Hevner's design science (DS) approach [9], focusing on data collection from five case studies consisting of unstructured interviews, observations and supplemented by a literature review. DS is utilized to research and explore models for onsite BOM, by combining unstructured interviews and observations from case studies to identify practices and structures of construction sites.

Three companies have been observed in the study, two IHB companies (A and B) and one traditional construction company (C). In total these make up five study product cases, two with company A, one with company B and two with company C. A and B have been chosen due to them being the leading IHB companies in Sweden and have during the latter years focused on their processes and information flows, thus represented the leading edge of digitalization of the industry. C is one of the five biggest contractors in Sweden and focuses on construction site digitalization.

The literature review has been an iterative process; each phase of the research has yielded concepts that have been further reviewed and incorporated into the paper, which also has led to further unstructured interviews and discussions. The literature review started out with basic concepts such as the status of Information structures, BOM, Building information modelling (BIM) and Information filtering.

3 Theory

3.1 Information structure & Bill of Materials

A major limitation in current Building Information modelling (BIM) practices is the prevailing activity-based focus of the construction industry, rather than information-centric [10]. Information structures, attributes as well as multiple information views are important for an IT-system to be able to support a variety of construction processes under the life cycle of a building [11]. A way to handle this is through standardization in the form of BOM. Creation of a common information structure and a basis for information flow provides the opportunity for IHB to integrate their products into IT-systems and therefore simplify communication not only within the company itself but also with other companies [7]. BOM can be used to describe the structural breakdown of a product and its relationship with sub-assembly, parts and materials. The BOM has the intention of organizing information so that it can be used in IT-systems under multiple different phases of its life cycle and for a variety of cases by using different information views optimized for each specific task [7,12,13].

When it comes to BOMs in construction, more specifically in IHB, research has exemplified definitions created for design and offsite production phases, there is however little published research on onsite construction within the context of IHB.

Within design and offsite manufacturing, research focuses mainly on Engineering BOM (E-BOM), Manufacturing BOM (M-BOM) and Process BOM (P-BOM) as well as their transformations, see Figure 1. Transformation between these BOM types occurs by modifying the information structure hierarchy, adding or even deleting data from the parent BOM [8]. E-BOM often works as the essential source of information for all other types of BOMs, meaning that all other forms of BOMs are subtypes of an E-BOM [8]. Therefore, it is important to keep E-BOM as the foundation of BOM structure when a transformation occurs.

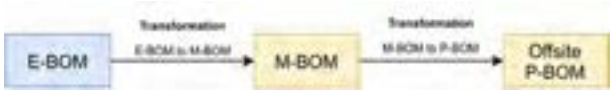

Figure 1. BOM Transformation [7].

Research defines E-BOM as a BOM utilized by designers with the intention to represent the product structure from an engineering viewpoint and is often produced by CAD/BIM systems [14]. M-BOM represents the manufacturing assembly sequence of a product. Its structure is perceived as a series of hierarchical groups and is generated from an E-BOM

transformation, in which additional information of manufacturing sequence is added to the structure [14]. P-BOM is utilized in offsite manufacturing and is generated from an M-BOM transformation with inclusion of detailed process information for assembly of modules and its components [8].

3.2 Location Breakdown Structure

Location Breakdown Structure (LBS), see Figure 2, is a hierarchical structure of spaces that can be used within a project [15,16]. LBS is intended to decompose spaces into smaller units, where each descending level has higher detail of space definition, resulting in a more usable and manageable LBS. Space is a geometrical volume which contains information describing a specific portion of the construction site as well as its relation to other spaces. Different detail levels can be used depending on the needs of each task. Detail planning and finishing related tasks is often preferred to be conducted at the highest level of detail [17]. The highest level in the LBS hierarchy usually represents the construction site of the project, and the lowest level often is represented by apartments. However, it is also possible to have each individual room in the apartment at the lowest level.

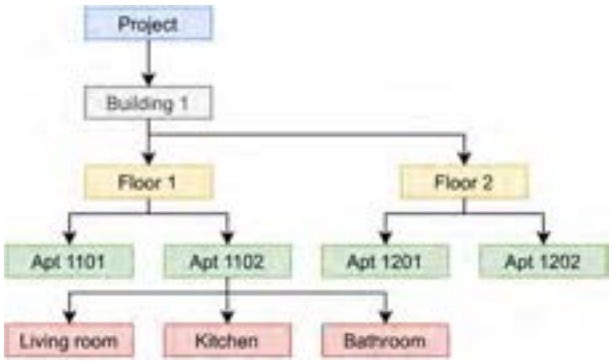

Figure 2. LBS example for a construction project.

3.3 Work Breakdown Structure

Work Breakdown Structure (WBS), see Figure 3, is a project breakdown from the perspective of construction tasks, where the completion of the project is related to the tasks being done [18,19]. WBS is intended to decompose the tasks into smaller tasks that are more manageable by creating a hierarchical structure of tasks [20,21]. Each descending level in the WBS hierarchy represents the subdivision of tasks and an increase in detail of task definition. Usually, the highest level represents the entire project and the lowest level being work packages. It is at work package level that tasks can be assigned to individuals, teams or even contractors [20,22]. WBS must be used with an appropriate level of task detail, as unneeded decomposing will end up requiring additional management efforts and higher cost [20]. Using WBS can improve process management, process definition, scheduling, risk analysis, cost estimation and project organization [21,23].

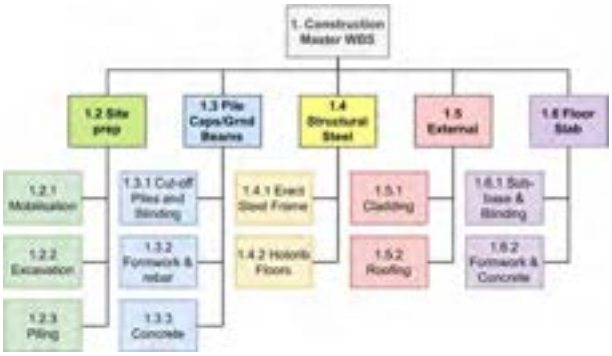

Figure 3. WBS example for a construction project [24].

3.4 Standard Operating Procedure & Work Instruction in construction

Standard Operating Procedure (SOP) is a documented manual of a company's established practices [25]. According to Nakagawa, a well-documented SOP utilizing companies' experience is essential to reach increased construction quality and consistency as well as reduction of scheduling waste, environmental impacts and safety risks [26]. To achieve its goals, a SOP needs to contain information about construction methods, assembly sequence, activity duration, safety instructions and preparatory work [25,26].

Work instruction (WI) is a documented manual of a company's construction methods [27,28]. Traditionally, it is created as text documents containing a list of instructional tasks to guide the assembly process of a building project, it can include shop drawings, 3D models, animations and pictures [29]. A WI includes sequenced instructional description of tasks, safety information as well as a list of resources such as tools and materials [28,29]. To avoid assembly process errors, delays and damaging the credibility of WIs, it is of utmost importance to ensure that WIs are updated in a quick manner [29,30].

4 Conceptual Model Development

The current information structure according to studied cases of offsite P-BOM cannot be reused for onsite construction, with the main reason being the variation in workflow. The industrialized offsite manufacturing and assembly process is done in a factory single assembly line. Components and parts are being assembled while the semi-finished modules are being moved from one workstation to another. Meaning that the factory defines specific workstations in which specific tasks and resources are being used. This enables optimization of tasks and resource management within the factory as well as minimizing the resource usage. Due to spaces being the non-movable components in onsite construction. Instead, it is now the workers and resources that are being moved. While the construction is ongoing, unlike assembly line production, new spaces are becoming available, leading to a more complex and dynamic relation between spaces that needs to be taken into consideration.

This paper proposes the creation of a new BOM for onsite construction, called **onsite BOM**. Onsite BOM aims to improve data sharing by streamlining the information flow process and reducing data redundancy. For that, an onsite BOM is defined, its transformation as well as its dependencies.

4.1 Transformation of BOM

Generally, all forms of BOM transformation are derived from either E-BOM or M-BOM [8]. However, due to the existence of reusable information within offsite manufacturing, and to achieve the aim of reducing data redundancy as well as information recreation, the concept is instead based around a transformation of offsite P-BOM to onsite BOM, see Figure 4. This transformation gives access to information that before was unavailable to the construction site and had to be recreated or modified. From E-BOM, it gets access to information about module types, properties, location of modules as well as components within modules. It even gets access to space data from E-BOM, information used to identify room types, room properties while simultaneously identifying module relations as well as space requirements and limitations. Sequence of module assembly for onsite construction is available from the M-BOM and can be used to identify delivery order of modules, assembly order of modules as well as delivery date estimation to construction site.

Offsite leftover tasks are leftover tasks allocated to onsite construction from offsite manufacturing and the information is available to access from P-BOM to identify additional work instructions required for project completion. Reuse of its data can result in data redundancy reduction as currently this data is manually recreated by site managers as well as skilled workers.

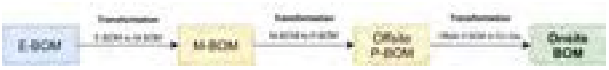

Figure 4. Concept of BOM Transformation from offsite P-BOM to onsite BOM.

4.2 Location Breakdown Structure

To manage and utilize generated spaces within onsite construction a concept of LBS for IHB has been developed from the case study, in which variations of space types and their relation are identified according to needs of IHB.

- The highest level in the LBS hierarchy embodies the whole space that the construction site will occupy, called Product or Project.
- The first descending level in LBS is Buildings, this hierarchy embodies the separate buildings within the product to create a distinction between the building volumes as well as maintain information independently between them.
- The second descending level in LBS is Levels, in which spaces are hierarchically organized with a higher level of detail according to their floor level in the building.
- The third descending level creates a distinction between apartments and stairwells, in which all apartments and stairwells are identified.
- For apartments, the fourth descending level in the hierarchy maintains information about the room, including its room type.
- The lowest descending level in LBS is Modules, it defines the bounding space of modules manufactured offsite and is derived from either Room or Stairwell.

This structure of LBS gives an identified module relation with other modules by identifying which modules create which rooms or stairwell, see Figure 5.

In the concept, Modules have been put as the most detailed level of the space, while they arguably could have been placed under Buildings or even under Levels. Information on Modules are often only required in early stages of onsite construction with exception to offsite leftover tasks, while Levels and Apartments are used from the beginning until completion of construction. Therefore, having the highest level of detail results in it not being required as often when performing construction tasks and can therefore be more often filtered from the information view.

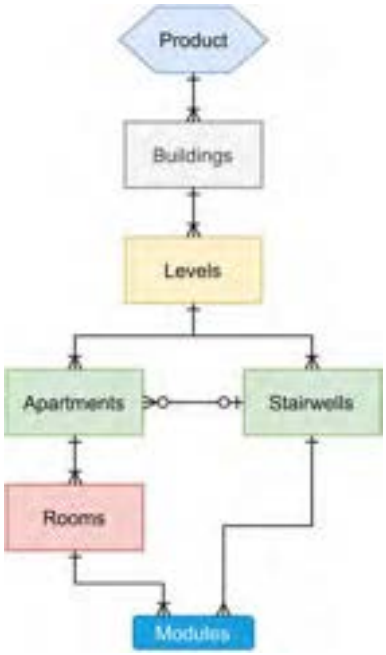

Figure 5. Concept of LBS for IHB projects.

4.3 Relations of BOM for onsite construction

The concept, Figure 6, utilizes the structure of LBS to link spaces with SOPs to create a relation between construction tasks and associated spaces. Each work instruction within a SOP contains information of what spaces it needs to be performed on, with what resources as well as what its space restrictions and requirements are. To put in context, see Figure 6, a SOP is performed for replacement of a window due to a leftover task. It includes two WIs, one for removal of the window and one for its installation, due to it being a leftover task, the SOP is linked to the Module, the highest level of detail, and therefore accessing the available information about the module from offsite P-BOM, including type, dimensions and other specifications of the window.

The concept has spaces as the sole carriers of construction status to establish a communication hub with all other SOPs. The links between WI, SOP as well as LBS ensures a consistent information interoperability between them under all levels of detail. Information interoperability is essential to dynamically modify the sequence of WI and SOPs to adjust according to construction sites continuously changing demands. It is

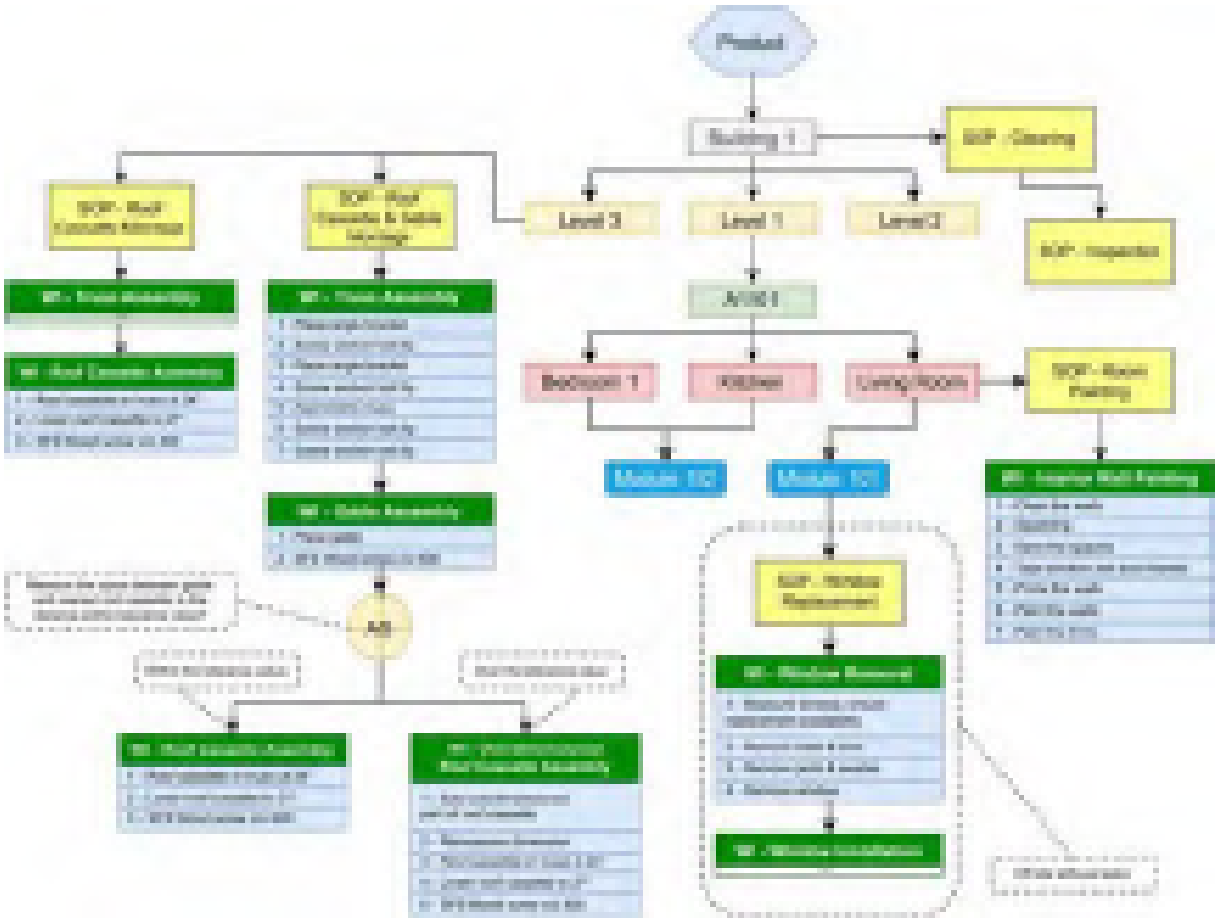

Figure 6. Concept of onsite BOM for IHB projects linking LBS with SOPs, WIs, AS and instructions.

also essential, when looking for an information structure that supports information filtering, as in showing the right amount and type of information to the right target group in information views. Information needs to be interoperable in the information structure for it to be synchronized and filtered to the correct target group. The breakdown structure of information makes filtration possible as it specifies all the existing relations under all levels of detail for the system, therefore showing the ones needed as well as the ones that can be filtered out. The existing types of relation in the concept are: Space – Space, Space – SOP, SOP – WI, SOP – Alternative sequence, Alternative sequence – WI, WI – WI and WI - Instructions.

Alternative sequences (AS), see Figure 6, are alternate WI arrangements within a SOP that can be triggered for foreseeable changes or issues that can be required to conduct a SOP correctly. The study shows that AS changes the sequence of WI within a specific SOP. A SOP has therefore accessibility to information available within its WI sequence and AS. AS consists of a ruleset describing its intentions, multiple alternative WIs and a description of said WIs. It reduces the managerial demands for when modifications are necessary, for example due to weather or construction tolerance related issues that occur commonly. In addition to that, it decreases data redundancy by reducing the need for modification of construction sequence as well as recreation of WI specific for special cases.

The conceptual BOM is built to ensure that SOPs can be assigned to any space independent of its level of detail. This is done by ensuring that available and required information within spaces stay consistent independent of spaces level of detail. Inspired by the hierarchical structure of the decomposed task structure of WBS, a hierarchical structure of SOP, WI and instructions have been developed and later been integrated with LBS. To put in context, see Figure 6, a SOP was developed for roof cassette montage, it has been broken down into two WIs and further into seven and three instructions, respectively.

A SOP is linked to a space either directly or through one of the SOPs it is linked to in a sequence. In cases where a previous SOP exists, that SOP must be fully completed, or as an exception for it to be moved to the next SOP in the sequence. According to theories, a SOP has the requirements of containing a title, description of its usage and step-by-step instructions, known by WIs.

To secure quality of work and safe work procedures, foremen and site managers can use lists of predefined WIs. According to theories and interviews a WIs for onsite construction needs to include an instructional description of itself, safety notes, list of tools, machinery, components, materials, instruction durations, space requirements, space restrictions, number of required skilled workers as well as their work qualifications.

In addition, the study has shown the need to link SOPs to spaces for identification of task locations. AS is required to quickly be able to adjust to constant construction demands and changes. SOPs correlation with WI is designed with intention to reduce data redundancy as well as the need for recreation of said data as the occurring data sharing between SOP and WI.

The concept may achieve this by ensuring that no data redundancy exists between SOP and WI, and that data only exists in a single place with a single owner. Additionally, it aims to ensure that a SOP gets access to all data within its WIs and therefore be able to further generate additional information such as a dynamic list of resources to a changing construction site such as when delays or shortages occur.

5 Discussion & Conclusion

The adopted characteristics of the manufacturing industry, in which most of its engineering and manufacturing is done offsite, this study highlights some major issues with IHB. The existing need of conducting a certain amount of work at the construction site has been a bottleneck, the non-structured information flow has led to data redundancy and fragmentation between offsite manufacturing and onsite construction, further increasing the issues. By usage of BOM structure, this concept aims to improve data integration, reduce fragmentation by streamlining the information flow. Additionally, identifying information types and possible transformation sources of the information to the construction site could ensure that data redundancy can be minimized.

Based on observations, onsite construction in IHB mostly utilizes shop drawings, Excel sheets and to some extent even cloud storage with none of them promoting data integration. Resulting in data redundancy, information is recreated into separate documentation with no bi-directional connections.

A real-time information view opens the possibility of optimizing the construction site and its sequence, by filtering the information and showing only the necessary information to the user. Concept hierarchical structure of level of details opens the possibility to filter information based on a variety of parameters, such as locations, number of skilled workers, their qualifications, etc. Making it possible to generate information views, as an example, a view for a painter, in which the painter gets access to information displaying SOPs and WIs associated with tasks they are qualified to and is ready to be performed.

Leftover tasks were a common occurrence that worsened the situation for construction sites by increasing the demand for communication between

onsite and offsite. Non-standardization of the tasks and information availability has resulted in site manager's not being able to optimize the workflow or assign teams for conducting these tasks, ordering of replacement components and parts has been a demanding process. Therefore, we believe that transformation of BOM to onsite BOM would facilitate the work of the site manager, since the factory can potentially utilize the transformation to allocate leftover tasks with SOPs and resources, thus reducing data redundancy and data fragmentation between offsite and onsite. Furthermore, transparency of SOP and WI communication has the possibility of reducing the risk of construction errors.

Onsite BOM has the potential to simplify the process of maintaining and updating SOPs as well as WIs within a construction. This is done through standardizing of information flow and information requirements between offsite manufacturing and onsite construction as well as the whole company in general. A combination of the information structures of WBS, LBS, SOPs and WIs has shown the potential to manage the information flow by BOM for onsite production.

6 Acknowledgement

This research study was made in the research project Connected Building Site funded by the Swedish Governmental Agency for Innovation (VINNOVA). Connected Building site is a testbed on digitization of construction with a focus on site planning, production and supply. We thank interviewees as well as construction companies for their incentive and effort.

Abstract –

With a focus on mechanical earthworks, automation of limited operations is progressing with regard to driving operations such as hydraulic excavators, bulldozers, and compaction rollers. The Ministry of Land, Infrastructure, Transport and Tourism is promoting public works that positively utilizes automated construction equipment and the like for the purpose of improving productivity at construction sites.

In the future, it is expected that the scope of automation of construction machinery will expand due to further technological advances such as AI and IoT. In that discussion, it is instructive to note that the classification of automation driving in automobiles serves as the basis for discussion of technology diffusion. Regarding automated construction machinery as well, in considering the promotion of the introduction of this technology into society, we believe that it is useful to formulate a concept at the autonomous construction level.

In this paper, while referring to cases such as classification of automation driving in automobiles, while paying attention to the differences between automatic running of vehicles and autonomous construction of construction machines, a conceptual draft of the level of autonomous construction by construction machines is proposed. In addition to showing the results of the study, the additional study issues that became clear in the study process are shown.

Keywords –

Autonomous; Construction; Level concept; Construction machine

1 Present situation for ICT in mechanized construction field and necessity of roadmap or concept of level for realization of automatic construction

1.1 Short history of introducing construction machinery and Machine control.

Mechanization of construction work has progressed in crane work and earthwork. After the Meiji Restoration, electric shovels were developed in Japan in the 1940s and were mainly used in large-scale earthwork sites [1].

In Japan, the mechanization of construction work has been rapidly promoted since the Second World War. In order to improve the supply capacity for the enormous demand for infrastructure, the construction machinery used by the United States during the war were paid off to japan government and construction industry, and then and then through technical cooperation with overseas companies, domestic construction machinery manufacturing took place again. Nowadays, several construction machinery manufacturers in Japan are competing to contribute to mechanization of construction sites in the world (Figure 1, [1]) [2],[3].

Since the 1980s, in the midst of rapid anxiety about the aging of the working population, automation and autonomy were sought for earthwork, which was the

Kobe Steel (1930) Komatsu(1943) SCM(1961) Hitachi(1965))

Figure 1. Example of construction machinery manufactured by a Japanese manufacturer [1]

most mechanized construction field.

Around 1990, hydraulic excavator manufacturers developed and commercialized semi-automatic hydraulic excavators. Operating a hydraulic excavator is a difficult operation in which the operating levers of the boom, arm, and bucket are moved simultaneously. However, with this semi-automatic product, the system automatically assists the hydraulic valve by the operator only operating the arm operation lever, and the bucket blade edge moves linearly for shaping.

Unfortunately, the economic downturn caused a recession and many workers returned to the construction site, so these did not lead to large sales.

Then, taking advantage of the spread of GNSS technology, an information presentation technology was developed that assists construction machine operators to visually confirm the difference between the cutting edge and the topographical design information. In the 2000s, these were called machine guidance systems in Japan and have been introduced in hydraulic excavators and bulldozers. (In Europe, this is called "Machine Control".)

Nowadays, semi-automated technology and its combination are used to provide hydraulic excavators and bulldozers that assist shaping operations at any place in the construction site using 3D design information and real-time position information. In Japan, this is called 3D machine control [4]-[7].

Figure 2. Concept of future vision for construction work [9]

Also, within a limited environment, trials have been made to automatically construct embankments by operating a plurality of such construction machines programmatically [8].

The Ministry of Land, Infrastructure, Transport and Tourism of Japan has set a future vision of realizing automatic construction in order to increase the production per worker in the construction field amid the rapid aging of the population (Figure 2, [9]).

1.2 Present situation for ICT in mechanized construction field and necessity of roadmap or concept of level for realization of automatic construction.

On the other hand, there are some differences in the understanding and evaluation of the actual situation of the developed semi-automated level among the parties concerned. Both the overestimation and the underestimation have caused cases in which the introduction of users is hindered and the policy making of the administrative agencies promoting the utilization becomes difficult.

The public works orderer wants to utilize these technologies to facilitate the supervision and inspection work such as step confirmation during construction. However, there are concerns that such misunderstandings will cause difficulties.

Please note that the content presented in this paper is not the official view of the Japanese government at this point, but is a report at the stage of consideration as a national research institute.

2 Investigation study on roadmap and technical level concept classification of automation driving

First, we reviewed the progress of the study on the roadmap for realizing automation driving in Japan (Figure 3, [10])

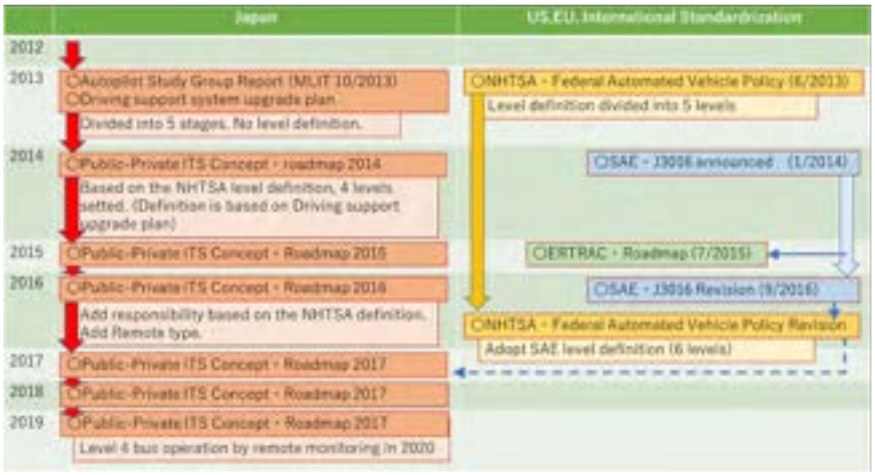

Figure 3. Movement around definition of autonomous driving level [10]

In Japan, the "Autopilot Study Group" established by the Ministry of Land, Infrastructure, Transport and Tourism held discussions and compiled the "Driver Assistance System Advancement Plan" in 2013. After that, with the Cabinet Secretariat as the secretariat, the Prime Minister's top meeting: Advanced Information and Communication Network Society Promotion Strategy Headquarters was launched, and at that meeting the roadmap for realizing automation driving is being

discussed. At that meeting, the first version of the "Public-Private ITS Concept/Roadmap" was formulated in 2014.

In the discussion there, the definition by the US Department of Transportation NHTSA and the discussion on the ERTRAC/Roadmap were investigated, and the definition of automation driving was referenced. With the aim of defining the concept of level classification and refining the scope of the roadmap, representatives of automobile manufacturers, government officials, and other parties continue to hold discussions and update the roadmap every year. Discussions and revisions were also held in response to the drastic revision of SAE/J3016 in 2016.9.

In Japan, a system that automatically stops the traveling vehicle by detecting people or objects was introduced due to the technological development of several manufacturers. For that reason, the terms "safe driving support system" and "automation driving system" existed before. The discussion of correspondence and consistency between those terms and the terms defined in the discussions such as NHTSA was an important issue.

In addition, a service was offered to reduce automobile insurance costs in response to the introduction of these systems. For this reason, the concept of responsible relationship between the driver and the safe driving support system installed in the automobile was also discussed.

In automation driving, what role the driver and self-driving car should share, and how to organize the components of the task of driving were important subjects of the discussion.

In the 2016 revision of SAE/J3016, these issues were organized as DDT, OEDR, DDT fallback, ODD, etc.

The roadmap for automation driving in Japan also follows this concept.

These conceptual arrangements have contributed greatly to clarifying the evaluation of technical contents as well as the definition of automation driving (Table.1, [11]).

Based on these discussions, revisions to the concept and roadmap of automation driving in Japan have been made. This has led to deepening of discussions and progress of work mainly in the following points.

- Clarification of manufacturers' priority development products and enhancement of management strategies
- Discussion from the perspective of how automation driving can help solve social issues
- Clarification of use cases that should be preceded
  (* Mobile services in depopulated areas (Level 4 bus operation by remote monitoring, etc.)
- Discussion on how much resources the government should devote to the social introduction of self-driving cars.
  (*Positioning of advanced driving systems for safe driving, etc.)
- Revision of relevant laws and regulations by the government
  (*Revision of technical standards for automobiles and consideration of new formulation)
- Adjustment of existing laws and regulations for experiments in real environments
  (* Clarification of necessity of road use permission rules by police, review to enable experiments of remote monitoring vehicles)

Table 1. Elements Concept [11]

Element		Definition or Meaning
DDT	Sustained lateral and vehicle motion control	Sustained lateral and vehicle motion control
	OEDR (Object and Event Detection and Response)	The subtasks of the DDT (dynamic driving task) that include monitoring the driving environment (detecting, recognizing, and classifying objects and events and preparing to respond as needed) and executing an appropriate response to such objects and events (i.e., as needed to complete the DDT and/or DDT fallback
DDT fallback		Complete action or Response to when DDT operation is difficult to continue (i.e. Transiton to Minimal Risk condition)
ODD (Operational Design Domain)		The specific operating domains in which the ADS (Automated driving systems) is designed to function.

3 Conceptual study of autonomous construction level in construction machinery that is becoming more automated

3.1 Arrangement of element concepts that are the basis of level division

-The survey and consideration in the previous section confirmed that the role played by the roadmap is effectively useful for the social introduction of technology. In addition, useful points were confirmed regarding the roadmap and level conceptual studies for the automation of construction work.

In particular, it is effective to sort out the concepts of DDT, Vehicle control motion, OEDR, Fallback, and ODD, and we took steps to sort out this point of view regarding automation of construction work.

Table 2. Elements Concept of Automation construction and comparison with Automation driving one

Automation driving		Automation construction		
Element		Element name		Definition or Meaning
DDT	Sustained lateral and vehicle motion control	TASK	Control work device	Control of work device of construction machine (including movement of construction machine)
DDT	OEDR (Object and Event Detection and Response)	TASK	OEDR	Detection of the changes of work objects and terrain shapes and procedure changes due to changes in them
DDT fallback		Task fallback		What to do if the construction machine system cannot control the task (Site Condition change, Changes in soil quality etc)
—		Work area setting / Task allocation		Construction execution planning or setup
ODD (Operational Design Domain)		ODD		(Site Condition change, Changes in soil quality etc)

Table.2 is the corresponding concept that we have examined (Table.2).

Here, as a new element, we propose to add "Work area setting/Task allocation" separately from “DDT”.

It is because that we define automatic construction in mechanical earthworks as changing the existing terrain to the terrain shape shown in the design drawing of the area without human intervention.

If you think in that way, the construction setup will emerge as the next necessary element after the above Task (corresponding to DDT) and fallback.

For example, if the automatic excavator digs the ground all the way to the surface of the design shape, the dump may create a slope that cannot carry the soil. In order for the work to proceed properly, it is necessary to determine the order of the excavation work positions of the excavator and the depth at which each is to be excavated in stages.

In addition, when performing construction with a bulldozer, just because the ground at that point needs to be excavated, the construction does not proceed simply by pushing down the cutting edge. If you do not set up a plan for where to push the soil and carry it, that is, the traveling route, the work will not proceed.

From this perspective, we added the construction setup as the adding new element.

However, we recognize that there is room for further discussion on these points. For example, an already developed car navigation system is responsible for searching for the movement from the current position to the destination in automation driving. And this car navigation is outside the scope of the roadmap (Figure 4, [12]).

Considering the current location as the current topography and the destination as the design drawing, considering how to reach it is equivalent to route selection, so there may be a way of thinking that the construction setup is outside the roadmap.

Since the proposals in this paper are tentative, we expect many opinions.

3.2 Tentative plan of level division concept in automatic or autonomous construction

Based on the above concept of functional elements and whether they are shared by people or systematization, we propose the level divisions concept (Table.3).

The outline of the six levels and the descriptive definition of each level follows the table of automobiles. Of course, this division depends on the combination of the realization of each element, so the level division also changes depending on how the element is considered.

In addition, between level2 and level3, we set level2.9 as the realization of automation with a single construction machine among the components of level3.

It is level 3 after level 2 when it is classified as a commercial level. However, among the development factors required before reaching Level 3, automatic excavation of hydraulic excavators is being realized in research. We think that it is necessary to realize Level 3 after Level 2 in order to have a significant meaning in practical use. However, level 2.9 may also be useful as a practical category when performing embankment compaction as a single task.

In addition, referring to the discussion on the roadmap for automation driving in Japan, we described the technologies that have already been realized and the technologies that are expected in the future at each level.

In Japan, the semi-automatic control of the shovel is called MC, and please note that it is different from Europe. In Japan, a system that gives guidance to operators is called MG.

The automatic embankment construction system at the dam site realized at Kajima corporation was set to level 3, but this may be a point of discussion.

Furthermore, similar to the discussion on the roadmap for automation driving in Japan, the safety equipment introduced to prevent accidents where construction machinery comes into contact with people on-site was not included in the table. This is an area where it seems to be highly effective as a utilization destination of AI for image analysis based on deep learning, which has undergone remarkable technological innovation these days. However, this is because the highest level was

organized from the viewpoint of a realization route to autonomous construction that does not involve people on-site.

We think that this point is also subject to debate, depending on how to utilize the roadmap and considering the possibility of human intervention at the site of autonomous construction.

Table 3. Level Concepts of Automation or Autonomous Construction

Level	Name or Narrative Definition	Task		Task fallback	Work area setting / Task allocation	ODD	Product
		Control work device	OEDR				
0	Non automation The work area of each operator is determined by the instruction of the foreman, and each operator controls construction machine in the allocated area, using finishing stake as a guide.	Operator	Operator	Operator	Foreman/ On-Site Agent	n/a	
1	Work Support The foreman (or on-site agent) divides the work range, and in that work range, each operator controls construction machine based on work device position information obtained from sensor and inputted 3D design digital data.	Operator (with position information support)	Operator	Operator	Foreman/ On-Site Agent	Limited	Machine Control In Japan, called "Machine Guidance"
2	Work Device Control Assistance The foreman (or on-site agent) divides the work range, and in that work range, the operator controls construction machine basically, the control system assist its control based on work device position information obtained from sensor and inputted 3D design data .	Operator and System	Operator	Operator	Foreman/ On-Site Agent	Limited	"Semi-auto" In Japan, called "Machine control" [4]-[7]
2.9	Work Device Control Automation The foreman (or on-site agent) divides the work range, and in that work range, control system controls construction machine to work based on work device position and current terrain information obtained from sensor and the inputed 3D design digital data. When the work is completed, it is in a standby state automatically.	System	System (Monitored by Operator)	Fallback-ready Operator	Foreman/ On-Site Agent	Limited	Multiple realization cases at the research stage. (Hydraulic Excavator, Wheel Loader) [13],[14]
3	Semi-auto combination construction The foreman (or on-site agent) divides the work range basically, and system assist. And in that each work range, the control system controls construction machine to work, the operator supervise those machines. Automatic stop when it is difficult to continue appropriate work.	System	System (Monitored by Operator)	Fallback-ready Operator	Foreman / On-Site Agent and System	Limited	KAJIMA corporation "A^{4}CSEL" called "Quad accel" [8]
4	Conditional automatic construction The system is used to perform work plans from the planned completion (design drawings) and work division to each construction machine in the work that consists of only specific conditions and specific work types. Each construction machine carries out work autonomously and autonomously.	System	System	System	System	Limited	
5	Automatic construction Automation of construction in all case.	System	System	System	System	Un-limited	

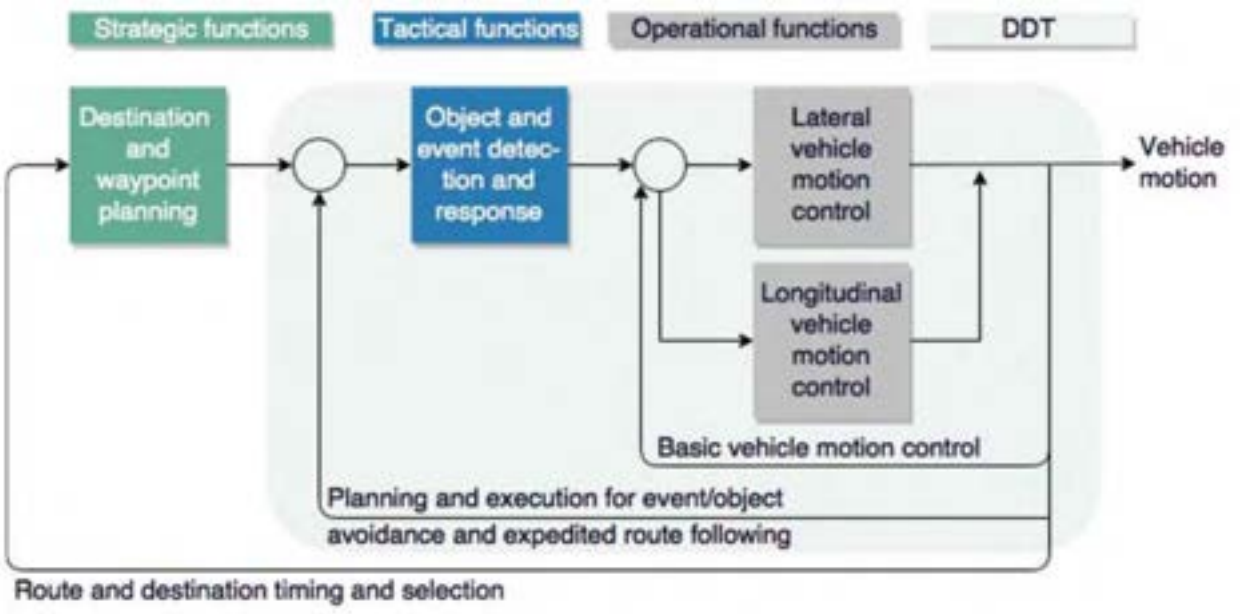

Figure 4. Functional component classification according to SAE J 3016 [12]

4 Additional study issues clarified in this study process

4.1 Need for automatic generation system of construction execution setup (Between Level2 and Level3)

At the construction site, the person in charge of the construction and the work team leader who receives the work instructions from the person in charge of the construction decide the work place and work goals for the day and work plans. Further, in many cases, detailed work preparation is left to the operator himself, and his know-how has not been formalized. It became clear that a solution to this point was required.

Note that a large amount of learning data is required when it is assumed that this problem will be solved by AI.

NILIM is considering the need for an approach by AI as a system to realize this function. In addition, we are conducting activities to collect on-site data as learning data for construction setup creation support AI. This will be announced in another paper (Figure 5).

4.2 Necessity of roadmap composition with "improvement of safety at construction site" as policy objective

The goal of the autonomous construction movement in Japan is to let the machines do what they can do, as a countermeasure for labor shortages in the construction industry.

However, the cause of the labor shortage in the construction industry is that the construction industry is dangerous. Further, in order to realize a completely safe machine earthwork, it is beneficial to construct an on-site environment where people do not mix with heavy equipment. This final goal matches the definition of automatic construction set above.

Also, by setting a roadmap with safety as the main goal, it is possible to put the technology of safety measures at the time of contact between people and construction machinery on the roadmap.

The above-mentioned person detection technology will be required when a third party enters the construction site even if autonomous construction is realized in which workers and construction machinery do not coexist in the future.

Due to these advantages, it is useful to construct a roadmap that aims to realize safety in order to realize automatic construction.

4.3 Necessity of refining the level concept when assuming development

In this level conceptual study, autonomous construction of machine earthworks was assumed, and it was expanded to other types of work in level 5. However, in addition to this positioning, the work of earthmoving also differs depending on the type of machine adopted, so it is necessary to make detailed the level classification that assumes them.

To this end, it may be useful to proceed with the discussion from the perspective of developing the hierarchy of ideas that correspond to the original ODD in more detail, based on the correspondence relationship of DDT.

(*We are aware that the Public Works Research Institute of the National Research and Development Agency is working on this point, and we are exchanging opinions. I would like to ask you to continue your studies.)

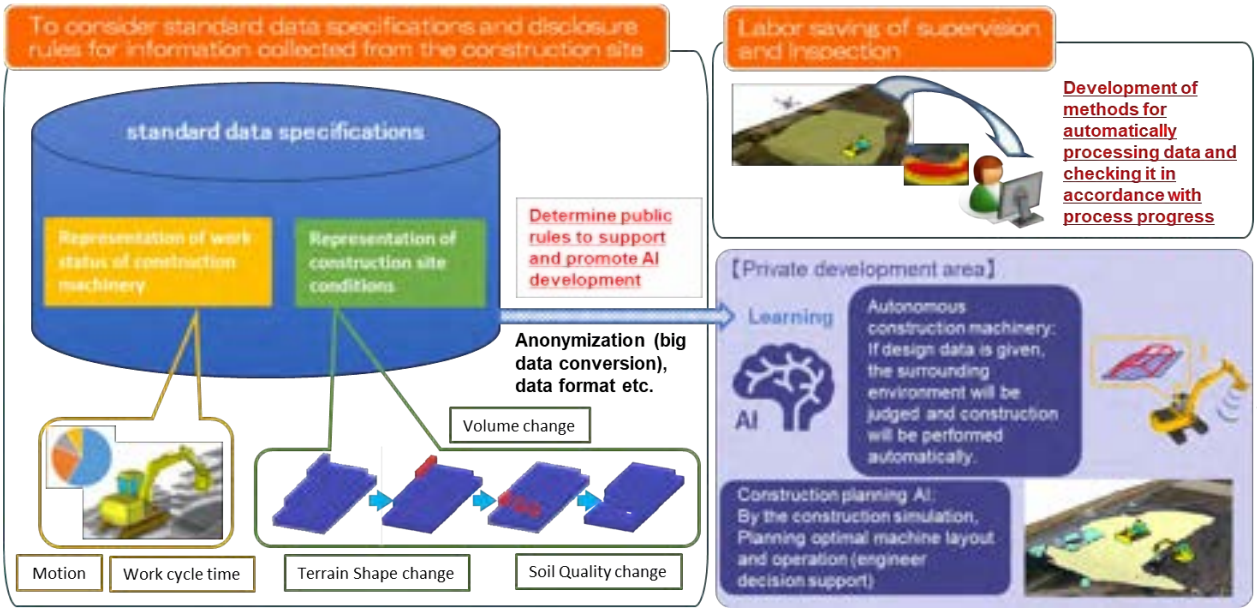

Figure 5. NILIM project outline

4.4 International terminology issues

In addition, there are some confusions among Japanese stakeholders due to differences in terms such as MC in Europe and Japan.

In the future, when broadly discussing the roadmap and the concept of level, it is necessary to make efforts to organize the term definitions between countries.

However, it may be difficult to make a complete agreement because there are differences in the construction sites and backgrounds of construction in each country.

5 Conclusion

① The following effects were confirmed as the roles of the automation driving realization roadmap.

1) Clarification of manufacturers' priority development products and enhancement of management strategies
2) ・Discussion from the perspective of how automation driving can help solve social issues
3) Clarification of use cases that should be preceded
4) (* Mobile services in depopulated areas (Level 4 bus operation by remote monitoring, etc.)
5) Discussion on how much resources the government should devote to the social introduction of self-driving cars.
6) Revision of relevant laws and regulations by the government
7) Adjustment of existing laws and regulations for experiments in real environments

② Based on the discussion on automatic operation, we created a draft of Level classification based on the concept of functional elements in automatic construction and the current technical situation. As a concept of functional elements, the category of 3) is newly added.

1) Task (Concepts corresponding to "DDT")
   ① Control work device
   ② OEDR (Object and Event Detection and Response)
2) Task fallback
3) Work area setting / Task allocation : Construction execution planning or setup (Additional element candidates not in automation driving)
4) ODD (Operational Design Domain)

③ Based on the concept of functional elements of Automation Driving and the current state of technology, a draft for Level Concept was created.

④ The following additional considerations were confirmed from these processes.

1) Need for developing construction execution setup setup generation system. (Between Level2 and Level3)
2) Necessity of roadmap composition with "improvement of safety at construction site" as policy objective.
3) Necessity of refining the level concept when assuming development
4) International terminology issues

The definition of automatic construction, functional elements, and level conceptual divisions shown in this paper are all in the trial stage. Opinions from interested parties are

welcome. In response to those, further discussion will be deepened in the future.

Abstract –

In the construction industry, there is often a need to identify and localize assets and activities on the jobsite to assess and improve the performance of their associated processes. Traditional methods for monitoring construction activities are costly and time-consuming. Excavators and dump trucks are among the most common assets used in the construction industry. Consequently, accurately monitoring their activities can reduce time and increase the efficiency of progress monitoring.

With the presence of cameras on jobsites and the advancement of methods based on artificial intelligence and computer vision, progress monitoring activities can be automated. Furthermore, by using techniques such as deep learning, a wider range of data resources can be processed, and oftentimes more accurate results can be produced for the purpose of object detection.

This research proposes a computer-vision approach that utilizes a Mask Region Based Convolutional Neural Network (Mask-RCNN) to detect excavators and dump trucks in a construction site. This research investigates an innovative technique to achieve high accuracy object detection using relatively small datasets. To overcome the problem of overfitting and improve generalization, a pre-trained model based on a Microsoft COCO dataset is used as a network that presumably has already been trained to distinguish basic features. Finally, the model is further fine-tuned to minimize validation loss.

Computer Vision; Artificial Intelligence; Deep Learning; Mask R-CNN; Construction Monitoring; Progress Management

1 Introduction

An efficient and effective workforce improves the time and cost performance of construction projects [1, 2]. Accurate progress monitoring, safety management, and quality control activities require skilled labor with adequate supervision, which in turn increases time and project costs.

With the advancement of methods based on artificial-intelligence, computer vision and deep learning, the abovementioned activities could be automated, leading to time and cost reductions. Specifically, there is a growing trend to use computer vision approaches to detect construction machinery from video outputs. These technologies could help project managers to access more accurate data in order to monitor construction assets, facilitate progress management and manage site safety.

To address this need, a region-based deep learning architecture called Mask R-CNN is utilized in this study to detect and segment excavators and dump trucks in the images from jobsites using a relatively small dataset.

The main objective of this research is to develop an improved deep-learning-based network to enhance the accuracy of predictions and decrease the processing time. The study's sub-objectives are to:

1. Develop a network for automatic detection of machinery (i.e. excavators and dump trucks) on construction sites from captured videos based on machine learning algorithms.
2. Train and validate the network on a small dataset.
3. Fine-tune the network's parameters to further increase its performance.

2 Related Works

AI techniques can assist project managers in monitoring and analyzing job site activities [2, 3, 4, 5, 6, 7]. Furthermore, AI approaches can be used for safety management to monitor and reduce risks [8, 9, 10, 11, 12].

Machine learning techniques can be deployed to detect construction machinery on jobsites. Project managers can utilize the information about these assets to increase the efficiency and safety of the projects.

Deploying an Unmanned Aerial Vehicle (UAV), Kim et al. [13] presented a visual monitoring method that

could automatically measure proximities among construction vehicles and workers. They localized objects using a deep neural network, YOLOv3, and developed an image rectification method that facilitates the measurement of actual distances from a 2D image. Struck-by hazards around workers could be detected with this method, making timely intervention possible. YOLOv3 provides bounding boxes for detected objects, but it is unable to generate pixel-level masks.

In another study, Kim et al. [14] developed a vision-based method to classify equipment operations in video data. The framework consists of four stages: equipment tracking, individual action recognition, interaction analysis and post-processing. The hybrid detector used in this study consists of ferns and a random forest classification algorithm, which uses a sliding window to propose bounding boxes and cannot provide shape data.

To detect dense multiple vehicles from UAV, Guo et al. [15] presents a deep learning approach that uses a single-stage detection (SSD) algorithm with orientation-awareness and integrates it with a developed feature fusion module. Similar to YOLOv3, the SSD algorithm is unable to provide pixel-level mask data for the detected objects.

3 Methodology

In this research, two common classes of construction vehicles, namely excavators and dump trucks, are studied. Due to the unavailability of open datasets, a dataset of 341 annotated images of excavators and dump trucks is created to train the proposed network. In order to develop a high-quality dataset of these heavy machineries in construction sites, public domain images were gathered through Google Image® and Flicker®. Some 269 images are used for the network training, while 72 images are assigned to the evaluation process. VGG Image Annotator (VIA) [16] is used to annotate the images of the dataset to provide the ground truth for the training process (Figure 1).

Figure 1. Data annotation using VIA [16]

Since the size of the dataset is relatively small, pre-trained weights for the MS COCO dataset are used as a transfer learning technique to overcome overfitting problem and increase the accuracy.

3.1 Instance Segmentation

In this study, an instance segmentation technique called Mask R-CNN is used, which can provide pixel-level boundaries for each detected object. Mask R-CNN has a new ability to segment objects in addition to classification and detection, compared with its predecessor Faster R-CNN [17].

As illustrated in Figure 2, first, the feature map of the entire image is extracted using a ResNet-101 architecture as a convolutional backbone. Then, a Region Proposal Network (RPN) analyzes the developed feature map and proposes candidates for object bounding boxes. To resolve Faster R-CNN's problem regarding the pixel-to-pixel misalignment between network inputs and outputs, a quantization-free layer called Region of Interest (RoI) Align is utilized, which preserves spatial locations. After fixing the misalignment problem of the bounding-box candidates, using fully connected (FC) layers, the network can classify objects and recognize bounding boxes and in parallel, a convolutional layer unit predicts masks that are applied separately to each RoI [17].

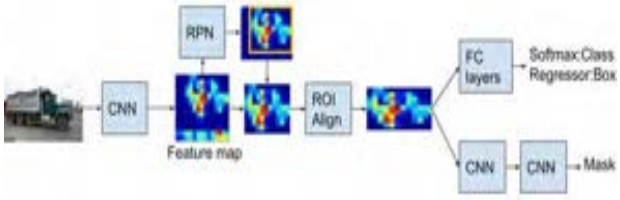

Figure 2. Mask R-CNN architecture

3.1.1 Loss Function

A multi-task loss is defined on each RoI as the sum of the classification loss (L_{cls}), the bounding-box loss (L_{box}), and the mask loss (L_{mask}) [17].

$$L = L_{cls} + L_{box} + L_{mask} \quad (1)$$

3.2 Training Method

As shown in Table 1, the hardware setting is Laptop ROG Strix GL502VS with a NVIDIA GTX 1070 8GB GPU. It has an Intel Core i7 7700HQ as CPU processor and 16GB of RAM. Concerning the limitation of GPU memory, we use 1 image per GPU for each mini-batch and each epoch consists of 100 steps.

Table 1. Hardware setting

ROG Strix GL502VS	
CPU	Intel Core i7 7700HQ

GPU	NVIDIA GTX 1070 8GB
RAM	16GB

Matterport's implementation [18] of Mask R-CNN on Python 3, Keras, and TensorFlow is used. The backbone of our network is ResNet-101 and we utilize only one class of data augmentation in our training phase, which consists of horizontally flipping 50 percent of the images. As described in section 3, pre-trained weights on MS COCO are used as our initial network weights. We adapted a multi-phase training strategy to fine-tune our results. In the first phase (first 5 epochs), only the top layer (heads) of our developed network was trained with the learning rate (lr) of 0.001. Next, for epoch 6 to 15, ResNet stage 4 and up were trained with lr of 0.001, while the rest of the layers are frozen. In the third step, for epoch 16 to 30, ResNet stage 3 and up were trained and lr decreased to 0.0001. In the final phase (epoch 31 to 40), all layers of ResNet were trained with lr of 0.00001. Table 2 presents the specifications of the developed multi-phase training.

Table 2. Multi-phase training specification

Phase	Epochs	Training layers	lr
I	1-5	Only top layer	0.001
II	6-15	ResNet stage 4 and up	0.001
III	16-30	ResNet stage 3 and up	0.0001
IV	31-40	ResNet all layers	0.00001

3.3 Metrics for Evaluating Performance

The network's performance is evaluated and quantized using two metrics: Average precision (AP) and inference time, which is the amount of time the network requires to do the prediction.

3.3.1 Average precision (AP)

According to the definition of Pascal VOC 2010 [19], for a specific value of Intersection over Union (IoU), the AP measures the precision/recall curve at recall values (r_1, r_2, etc.) when the maximum precision value drops. The AP is then computed as the area under the curve by numerical integration [20].

$$AP = \sum (r_{n+1} - r_n)\, p_{interp}(r_{n+1})$$
$$p_{interp}(r_{n+1}) = \max_{\tilde{r} \geq r_{n+1}} p(\tilde{r}) \quad (2)$$

The metric mAP is the average of AP over a range of IoU from 0.5 to 0.95 at intervals of 0.05 (AP@ [.5:.95]) [20].

3.3.2 Detecting Threshold

To eliminate network predictions having a low confidence score, only detected instances above the threshold level of 0.9 are considered in the final results.

4 Results

Over the 40 epochs of training the network, the minimum validation loss function took place at epoch 38 with a value of 0.1889. Figure 3 illustrates the loss function of the network at each epoch. As shown in Table 3, the total training time was 68 minutes on 1 GPU.

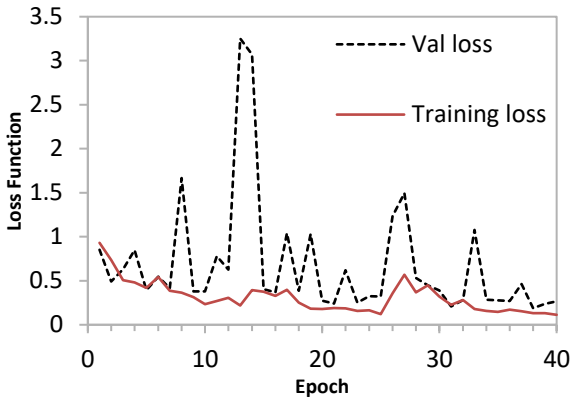

Figure 3. Loss function at each epoch

Table 3. Training time

Phase	Training time
I	7 min
II	24 min
III	48 min
IV	68 min

4.1 Metrics Results

The results of the average precision of the network predictions are reported in Table 4.

Table 4. Average precision results

Average precision	
AP_{50}	0.8792
AP_{75}	0.7438
mAP	0.5984

The inference time is calculated by averaging the time required to segment 10 images, which amounted to 3173 ms with the current hardware setting.

4.2 Examples of network predictions

As illustrated in Figure 4 and Figure 5, the network's performance was excellent for the classification task with a confidence score nearly equal to 1, while keeping a reasonably high-performance level on segmentation with

an IoU measured above 0.85.

Figure 4. Excavator example (Confidence score/IoU), network prediction (red line) vs. ground truth (green line)

Figure 5. Truck example (Confidence score/IoU), network prediction (red line) vs. ground truth (green line)

Although the developed network performs with a good level of accuracy on most testing images, there are some situations in which the network segments the instances weakly. For example, if there is an occlusion in the image, as illustrated in Figure 6, the network has difficulty recognizing the proper boundaries of the occluded objects. For example, in the case of Figure 6, the IoU for the excavator was as low as 0.485.

Another condition that dramatically affects the network's performance is low illumination. As shown in Figure 7, the overall lighting in the image is low. The network confidence score associated with the truck was consequently below the detecting threshold of 0.90, which means the truck cannot be detected by the network.

Figure 6. Example of Occlusion (Confidence score/IoU), network prediction (red line) vs. ground truth (green line)

Figure 7. Poor illumination example

5 Discussion

A deep learning model is developed to segment excavators and trucks utilizing a relatively small dataset of public domain images.

By using a small dataset, complications arise in the training process as the network faces challenges such as overfitting. Transfer learning, data augmentation, and fine-tuning techniques were used to decrease the effect of overfitting and increase the accuracy of results.

To deal with the challenges associated with occlusion and low lighting, it is proposed that a larger training dataset should be created to enhance the network's performance. In this study, the use of data augmentation is limited to flipping, yet the use of a conclusive data augmentation that deals with occlusion and lighting should be considered in future studies.

With the current hardware setting, the inference time was measured as 3173 ms, which is high for real-time applications. By using a more powerful hardware setting, the inference time could be decreased. Additionally, other implementations of Mask R-CNN should be tested to avoid slow performance related to weak network implementation.

6 Conclusion

In this study, a deep learning model was developed to accurately detect and segment two types of construction machineries. The network's performance resulted in an average precision of 0.8792 and inference time of 3173 ms, using a relatively small dataset and a transfer learning technique.

The pixel-level segmentation approach can provide the spatial information about objects. Compared with the previous approach relying on bounding boxes to measure proximities between vehicles, the generated pixel-level masks increase the accuracy of the proximity calculations related to safety control and decrease false safety alarms.

The number of vehicle classes in the proposed model could be increased to include a broader range of machineries and could be used to efficiently manage construction assets and monitor safety on jobsites.

The network performs poorly when objects are occluded or poorly lit. In future studies, it is proposed that a larger and more diverse dataset be used to overcome problems such as occlusion and poor lighting. Further work is also needed to study the effect of data augmentation on the network performance when it faces occlusion or illumination challenges.

Abstract –

The construction industry has insufficient utilization of standard work and workload. Generally, scheduling for construction projects follows the common sense of the industry. The sequencing of activity and its duration estimation is highly dependent on the experience of the experts who are assigning them to the project, and it is a considerable barrier for automating scheduling process.

To overcome this challenge, the FP-Growth algorithm, which is an automated unsupervised learning tool, applied to create a platform for the acquisition of knowledge from actual construction schedules which are the outcome of experienced experts. The main advantage of this method in comparison to supervised learning models is the fact that it can generate contractor-specific rules from a given schedule and also identify a variety of potential path when it is applied for multiple projects which are similar to each other. The main contribution of FP-Growth Algorithm to this research is in finding association rules between sets of activities and identifying recurrent patterns in the sequence of activities, their duration, logical relationship (FF, SS, SF, FS) and specifications in different sections of construction projects.

The model applied on schedules of two case studies with different occupational function and structural material. The model substantiated to be capable of learning and identifying various rules including activity durations, predecessor activity and logical relationship and lead times that can happen in between two related activities.

Keywords –

Unsupervised Learning; Construction Scheduling; Rule Learning; Machine Learning; Association rules; FP-Growth Algorithm

1 Introduction

Construction project schedules are heavily replying to schedulers' expertise and corporate scheduling approaches.

Also the construction industry always faces delays and change orders.[1] Poor planning, lack of flexibility during change orders and inconsistent resource allocation are the leading causes of delay, which are instigated directly by deficiencies in scheduling practice. The main goal in scheduling is to set a baseline for activity relationships and their duration while considering optimized tradeoffs between time, cost and resources. The scheduling process mostly based on personal experience of planners and lacks standardized sets of work items. The complex nature of the scheduling process with the presence of logical and resource-based constraints makes it difficult for project planners to generate the optimum schedule persistently [2]. Hence, construction management practice needs more dynamic and integrated schedules.

Previous works on the issue mainly focus on small and partial sets of activity for projects and try to find a mathematical solution to optimize time while meeting all the resource and cost restraints of projects [3]. The common shortcoming for all of these studies is that they applied in large scale and real-life projects. The main approach to overcome this gap and simplify the scheduling problems could be binding sets of activities together and assign single values of constraint to them [4]. Another way is generating association rules based on the sequence of activities and use them as constants while generating a schedule based on mathematical models. While the majority of the solutions for automating schedules focus on supervised learning which has to establish probabilistic hypothesis to generate a single solution for similar scheduling, this research implements the Frequent Pattern Algorithm(FP-Growth algorithm) to absorb different possibilities and sequences that can be performed to create a schedule. FP-Growth Algorithm identifies association rules among activities which can be different from project to project and instead of having a model with given premises, the model learns contractor specific rules. The main benefit of using FP-Growth over other pattern finding methods is the fact that it is compatible with confined groups of datasets which

would be the case for current research [5]. After shaping the constants for the schedule genetic algorithm would be implemented to optimize time for the rest of the project based on its tradeoff with resource and cost.

2 Related Researches

Time overrun is one of the significant barriers to project success. There are a plethora of factors contributing to the intensification of this problem. Some studies investigated the factors which are instigating delays and their importance to tackle the negative effects of them on schedules. According to Zidane and Andersen [1] who implemented a broad literature review on the issue, poor planning and scheduling, resource shortage and poor decision making in change orders are the most repeated factors in altering construction project time globally. Different strategies had been applied to improve each problem.

In addressing resource-constrained scheduling, many scholarly works focused basically on using mathematical optimization tools. Adeli [6] defines an optimization function for minimizing direct cost based on the maximum acceptable time for a transportation project and applies artificial neural networks to generate a solution for the target function. Toklu [7] uses sets of concrete-related activities for applying Genetic Algorithm as the time minimization tool which sets on the stage for other papers to implement a genetic algorithm for scheduling problems. Dawood and Sriprasert [8] had continued the path adding time-space confliction alongside the resource constraint as a variable to the mathematical model of optimizing time according to cost. In another significant approach to the problem, Birjandi and Mousavi [4] differentiated between a set of activities that can be bind together and other activities in the schedule in modelling and formulating their target function for optimization. There has been plenty of similar researches conducted based on optimizing cost time relation through the application of some alterations using Genetic Algorithm and stochastics [9-16].

Koo, et al. [17] concentrate on rescheduling practice by developing an anthological hierarchy for categorizing critical path activities based on the level of effect they got from resource constraint during the project and also their effect on their successor activities. Building information modelling also applied as a tool to automate data generating in some of the recent works where tasks which are driven from BIM models are subject to optimization to reach the time-cost-efficient solution.

Faghihi, et al. [3] focused on sequencing activities for a limited set of activities in the steel structure model while Chen, et al. [18] developed a comprehensive module to generate a full schedule of the project through linking it with resource and cost data.

Reviewed works are containing valuable solutions to address scheduling problems, but they all share a common gap. They generate a single solution for a dynamic problem of creating schedules and using stochastic models for considering uncertainties to run their model. This is due to the complexity of calculations for mathematical models when they engage with a plethora of activities and their intensified logical relations. Alongside that, they put aside the current practice by trying to generate schedules with any kind of input from historical data from contractors. Hence, the schedules generated in this manner are not expandable to complex projects in commercial, residential sections of the construction industry. Figure1 summarizes the problems and gaps that have been identified in this research.

Figure1.

The construction scheduling automation literature

FP-Growth algorithm has the potential to ease both problems. By extracting rules from current schedules and apply them as constants, uncertainty and thus, the complexity of mathematical models can decrease. Furthermore, the FP-Growth algorithm has the potential to mine project-specific rules schedule by schedule and integrate the knowledge of experts with generated results.

The current study focuses on generating knowledge from real-life project schedules. Identifying patterns in a sequence of activities as association rules inside a project and assessing the significance of them could be the missing step in generating automated schedules.

3 Research methodology and Data preparation

As discussed, the scheduling practice in the construction industry lacks consistency and flexibility, and both problems could be alleviated through automation. Automation can be considered as sequencing activities or allocating resources. The current article aims

to reduce the complexity of automation in generating schedules, by suggesting rules which are driven through investigating contractor schedules and reduce variables and give more certainty to optimizing models. Unsupervised learning has the ability to capture underlying knowledge), which is specific to each schedule. To be more specific FP-Growth algorithm as an unsupervised learning tool is capable of mining durations and relationships of activities in a project-specific manner.

FP-Growth's main contribution to the research was it is ability in Finding frequency among features and attribute relationships which were both needed in finding a chain of activities that would be repeated in each floor or work sections.

The research uses two construction schedules as the case studies to examine the possibility of extracting association rules from them which draw a certain and meaningful sequence of activities. The first project was a multi-story hotel building with a concrete structure (CASE 1), and the second one was a 3-story commercial building with steel structure (CASE 2).

For extracting association rules and their significance, there are multiple options in the unsupervised machine learning realm. The FP-Growth Algorithm selected as the data available were confined. While the FP-Growth Algorithm works with nominal variables, it fits with the type of data that can be extracted from schedules.

3.1 Preparing data for the FP-Growth algorithm

The next step was transforming the available schedule into a decent input for FP-Growth Algorithm. The schedules included activities identification number (ID), description, start date, finish date, predecessor activity or activities and duration. Furthermore, logical relationships and sequences like Finish-to-Start (FS), Start-to-Start (SS), Start-to-Finish (SF), Finish-to-Finish (FF) gathered to be mined and provide more practical rules.

While the FP-Growth Algorithm works with nominal variables, it fits with most of the attributes except duration, which is a continuous value. By rounding all times into an integer, this problem solved as well. The main challenge here was to identify the type of activities from the description section.

3.1.1 Attribute extraction from descriptions

Each project had a specific routine in the description section. For CASE 1 schedule, the description part had a systemic approach. The operational part separated into three main parts. The building had 14 stories above ground and description was based on the level of the building, the activity, and the section of work on that level which can be extracted in excel and put into three different attributes. The predecessor for each activity also located and expanded in the same row. Table1 shows attributes extracted from CASE 1 and their range.

For CASE 2 dataset available had an attribute as activity types like contracts, procurement, structure, foundations, interior, paving and etc. In each group of activities with the same type, the extraction of attributes of section, level and type from the description part was the challenging part due to inconsistency in naming activities. So, as an instance in the foundation to extract attributes from activities, the tags created based on possible foundation types. The first step was to know what is the foundation type and how it is named description section. Tags such as Drill, Drilled, Pier, Shaft, Caisson, Mat, Grade, Grade Beam, Slab on grade, footing, strip, spread checked on data set and the results showed that the building uses drilled piers and grade beams for the foundation. Here due to lack of enough datasets, general knowledge of construction work played a role in guessing tags. By having more datasets, text mining can come to help in not only in generating tags but also in creating trees of activities which are connected based on tags. Table2 shows attribute extracted from activities with foundation type and their variety and range in CASE 2.

Table 1. Attributes extracted from CASE 1

Attribute	Range
Activity	
Duration	Integer (weeks)
Activity/ PRE-Requisite	
Type	MB(Mobilization), EX (Excavation), C.R. (Crane), SG (Slab on grade), CS(Concrete) R.B.(Rebar), FR (Framing)
Section	1,2,3, ALL
Level	B2-L14
Spec	PR (pouring), FT (footing) FR (framing) SC (stress cable)
Logic	Finish-to-Start (FS) Start-to-Start (SS) Start-to-Finish (SF) Finish-to-Finish (FF)

PRE-Requisite	
Level Difference(D)	Integer
Lag	Integer (hours)

Table 2. Attributes extracted from CASE 1

Attribute	Range
Activity	
Duration	Integer (weeks)
Activity/ PRE-Requisite	
Element/area of Work	Piers Grade beams Elevator Slab on Grade Under Slab
Section	1,2,3, ALL
Level	N/A for foundation
Spec	Pour Cure Forms(edge) Forms (Carton) Waterproof Electrical Plumbing Reinforcing Strip/lift Excavation Backfill
Logic	Finish-to-Start (FS) Start-to-Start (SS) Start-to-Finish (SF) Finish-to-Finish (FF)
PRE-Requisite	
Level Difference(D)	Integer
Lag	Integer(hours)

3.1.2 Attribute extraction from sequences

For each activity, there might be a predecessor or successor activities in a given schedule. So, extracting attributes from predecessor or successor has already done except the possible connection between predecessor or successor and the activity itself. The logic of connection (i.e., Finish-to-Start, Start-to-Start, Finish-to-Finish and Start-to-Finish) and lags were ones which already provided in the schedules. Furthermore, there are some locational dependencies which can happen between activities. So, to consider that, Level (i.e., floor) difference (i.e., Level D) attribute defined as subtraction of level in which activity takes place, and the level predecessor needs to be done. To monitor sections, section-relation attribute defined. As there are only three of them in each CASE, all six possible connections considered as a different value of the attribute.

Hence, for a given activity, attributes extracted for itself and also for its predecessor shape a row of feature for it. If activities have multiple predecessors, a new row of feature would be considered for the attributes of the same activity and the other predecessor. So, for example for and activity with four predecessors there would be four rows of features in the dataset which is subject to be analyzed by the FP-Growth algorithm. It is evident that while covering activities and their predecessors, its precisely the same job in the reverse direction if the study would focus on the activities and their successors. Hence, to eliminate the unnecessary data and keep dataset consistent only the predecessor relations considered as the basis.

3.2 Implementation of FP-Growth Algorithm

In the previous section, the activities and each of their predecessor analyzed and expanded into a row of features. FP-Growth algorithm implemented to figure out if there is a significant pattern among the rows of features, While all the attributes could get finite values (either it is integer or string), an operator used to transfer or nominal variables into binominal. Dummy encoding used to separate columns for each value of a single attribute to make it more flexible to use in the FP-Growth model. Furthermore, the model applied to sets of activities with the same attribute of type in both CASE 1 and CASE 2 to give more realistic results. The process of data preparation and modelling has done in RapidMiner Studio®. The overall process has shown in Figure 2.

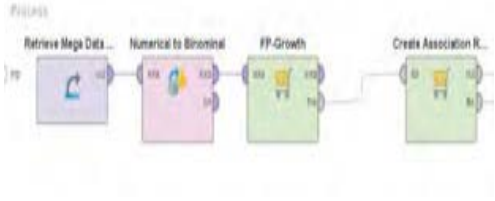

Figure2.

Process of implementing FP-Growth in Rapid mining

The association rules which are driven from the FP-Growth Algorithm are containing premises and conclusions. Premises are the constant parts that we would always have in our datasets. Conclusions are that might vary when the data changes. In this case activity, spec and detail are the constant part, and the parts that are needed to get defined as conclusions are the duration of activity and its predecessor logic, type, Level D. So, the rule generation followed the same logic by separating different activity types.

This process repeated for all the sections of both projects and CASE 1 concrete pouring and framing generated some rules and in CASE 2 foundation and structure came out with some rules that will be discussed in section 4.

4 Data Analysis

The first group of activities that generated meaningful association rules were framings in CASE 1. The main reason for that was the fact that the framing activities repeated in 14 levels without any sectional consideration. The first step was applying FP-Growth to all row of features with framing (i.e., FR) as their activity type. Here the main output is not all the created rules but just identification of most repetitive values in each attribute. The most repetitive values were as below:

As it is discussed in section 3 section, specification and type of activity (i.e., Activity Section, Activity Spec, Activity Type) and also the type, section and specification of predecessor and its logical relationship (i.e., SS/FS/FF/SF PRE Requisite Spec, SS/FS/FF/SF PRE Requisite Section, SS/FS/FF/SF PRE Requisite Type) alongside the Lag (i.e., SS/FS/FF/SF PRE Requisite lag) would be components of one rows of attributes in the dataset generated from the schedule.

Activity Section = ALL,
Activity Spec = IN,
Activity Type = FR,
SS PRE Requisite Lag = 0,
SS PRE Requisite Level D = -5,
SS PRE Requisite Section = 2,
SS PRE Requisite Spec = PR
SS PRE Requisite Type = CS
FS PRE-Requisite Lag = 14 days,
FS PRE-Requisite Level D = 1,
FS PRE-Requisite Section = ALL,
FS PRE-Requisite Spec = IN,
FS PRE-Requisite Type = F.R.
Duration = 3(weeks)

Before reporting rules resulted from the implementation of the FP-Growth algorithm, it is necessary to mention that the association rules are frequent if-then patterns which can be found through a data set and significance of them in identifying recurrent patterns are related to *support* and *confidence criteria.* Support is an indication of how frequently the items appear in the data. Confidence indicates the number of times the if-then statements are found true.

As the first endeavour for finding association rules, the search was for the attributes that could be bind together in the framing section. To make that happen the attributes connections with FR (framing) attribute evaluated. Initial interpretation for the outputs was the fact that the framing had taken place without any further section separation inside each level. It had happened at the same time for a single level. (Activity sec=All).

Premise:
Activity Type = FR
Conclusion:
Activity Section = ALL, Activity Spec = IN
(Confidence:1, Support:1)

So, for any given activity with FR (framing) type, its section and spec would be as of ALL and IN (interior). While doing more detailed rule mining, these three attributes could be considered as one for framing related rows of features and bind together as the general premise in the next steps.

Further looking there are two frequent predecessors for Framing activities in CASE 1. The first one has a Start-to-Start logic and is among pouring activities from the floors above. Second, framing activities from lower floors which has a Finish-to-Start logical sequence with the desired activity. While the framing activities take place in similar square feet in most levels, the duration could also be mined as three weeks (Duration=3) which is not a rule but a valuable taking for indicating the rate crews would work on that.

Premise:
Activity type= FR,
Activity Section = ALL,
Activity Spec = IN
Conclusion:
Duration=3weeks
(Confidence:1, Support:0.923)

After figuring out which attributes are the most frequent in framing rows of feature, a more specific FP-Growth algorithm had performed separately on the row of features in framing with FS predecessor and also SS predecessor. Given rows with FR. as the type and SS as

the logic of relation and putting them in the premise section of creating association rules, the first significant rule was as below:

Premise:
Activity type= FR,
Activity Section = ALL,
Activity Spec = IN
Conclusion:
FS PRE-Requisite Lag = 14 days,
FS PRE-Requisite Level D = 1,
FS PRE-Requisite Type = F.R.
(Confidence:.0.8, Support:0.923)

Given rows with FR as the type and FS as the logic of relation and putting them in premise section of creating association rules the first significant rule was as below:

Premise:
Activity type= FR,
Activity Section = ALL,
Activity Spec = IN
Conclusion:
SS PRE Requisite Lag = 0,
SS PRE Requisite Level D = -5,
SS PRE Requisite Section = 2,
SS PRE-Requisite Type = CS
(Confidence 0.9, support:0.583)

Based on the analysis on this section for any given framing activity that would be inside and will not be done on sections in each level. Furthermore, for nearly most of the FR activity, there is the FR predecessor with the Finish-to-Start relationship in one level lower. There would be a 2-week lag between predecessor and successor in this case

Finally, for nearly half of framing activities (support=0.583) there is CS (concrete for structure) predecessor with Start-to-Start logic which happens in Section two and six-level higher than the level that activity takes place, without any lags.

The second part of CASE 1, which generated meaningful rules was pouring concrete, and the schedule was gathered all the related tasks (forming, reinforcing and pouring) into one single item.The process which has applied for the framing section utilized here as well. First, the most repetitive attributes identified from applying the FP-Growth algorithm to all rows of features in CS (concrete of structure) section.

Activity Spec = PR
Activity Type = CS
FS PRE-Requisite Lag = 0
SS PRE Requisite Level D = 0
Duration = 2weeks
FS PRE-Requisite Level D = 1
FS PRE-Requisite Spec = PR
FS PRE-Requisite Type = CS
SS PRE-Requisite Lag = 0
SS PRE-Requisite Level = NA
SS PRE-Requisite Logic = NA
SS PRE-Requisite Section = 0
SS PRE-Requisite Spec = NA
SS PRE-Requisite Type = NA

Before starting any further analysis, the frequent attributes show that there is not any Start-to-Start predecessor for pouring activities while all the extracted frequent values for that are showing NA (not applicable). Hence, the main focus here remains with Finish-to-Start predecessors.

The first part was searching attributes that could be bind with activity type (CS). Implementing FP-Growth here gave us the following results.

Premise:
Activity Type = CS
Conclusion:
Activity Spec = PR
(Confidence:1, Support:1)

The duration of activities proved to be minable in the CS section while the pouring parts were in equal square feet and setup.

Premise:
Activity Type = CS
Activity Spec = PR
Conclusion:
Duration = 2
(Confidence:0.8, support:0.972)

The level difference and Lag and also type predecessor and the support rate of them also evaluated by putting them in the conclusion section of FP-Growth algorithm while considering Activity type (CS) and specs (PR) as the premises.

Premise:
Activity Type = CS
Activity Spec = PR
Conclusion:
FS PRE-Requisite Level D = 1
FS PRE-Requisite Type = CS
SS PRE-Requisite Lag = 0
(Confidence:0.9, support:0.889)

This indicates that for nearly most of CS activity, there is a CS predecessor with the Finish-to-Start relationship in one level lower. There would be no lag between predecessor and successor in this case. All the CS activities have PR (pouring) specification, which directly relates with the setup that schedule uses in gathering all forming, reinforcing and pouring as one

activity.

CASE 2 undergone the same process FP-Growth Algorithm and for foundation section, main rules were as below:

Premise:
Element= Piers,
Type= Pour,
Logic = FS,
Conclusion:
Element P=Pre1-Cage
(Confidence: 1.000, support: 0.375)

Here our model identified for any pier pouring activity there would be predecessor containing pier cage with Finish-to-Start relation to that. The reason for the decrease in support ratio is the fact that in CASE2, the four kinds of logic between activities put in separated rows of features. So, the initial ratio divided into each logic. For example, the support rate for the appearance of Element=Piers and Logic = FS is 0.625.

For the grade beams, the model came up with association rules as below:

Premise
Element=Grade Beams
Conclusion
Element P=Pre1-Grade Beams
(Confidence:1.000, support: 0.890)

Premise:
Element=Grade Beams,
Element P=Pre1-Pour
Conclusion:
Logic = FS
(Confidence: 0.917, support: 0.890)

5 Findings and conclusion

Implementation of the FP-Growth algorithm for CASE1 and CASE2 had a variety of notable findings. In CASE1 due to abbreviations in the work description and consistent way of naming activities make data mining relatively easy comparing CASE2, which had more descriptive titles as its activities' names.

Furthermore, unlike the successful experience of extracting duration for activities in CASE1, the model experienced lower confidence rates in extracting durations in CASE2. The main reason for that was more repetitive and typical activities in CASE1 with the sequence of activities remaining the same in each floor. For buildings with a lower number of floors, the only possible way is gathering group of similar projects and create full rows of features for them to mine duration.

In learning the logical relationship between activities and their Lag, the model performed well in both cases and generated meaningful rules. Start-to-Start and Finish-to-Start relationships between activities were identified as the most informative rules because they were addressing the connection between varying types and specifications in most cases which could be the cornerstone in shaping a masterplan. For example, FP-Growth algorithm learned SS relationship between framing and pouring five floors away from each other in the CASE1, which could be a significant barrier if it has not been put into consideration in master and detailed planning.

The model was performing better over CASE2 in identifying the sequence of activities ending in a specific element. The main reason for that could be the detailed description of each activity in their name column. The rules were found showed the pier cage as the predecessor of pouring for the pier. Also, pouring the pier was a predecessor for grade beam related activities with excavation specification. The reason for that was the broad details provided in naming each activity. The rules generated from CASE2 could be used to complete in between any two milestones which are identified for masterplans with activities.

To conclude, the research shows the possibility of generating rules in micro and macro scale from historical data and real-life schedules. Generated rules could minimize the uncertainty of mathematical models for scheduling as they can function as constant features in them. Also, by having hundreds of similar schedules, the standardization of construction work can happen through generated rules from more descriptive schedules. The results also have the capability to be used in generating alternative schedules Further uses of the results of current research could be in reducing uncertainties in scheduling process which can help to optimize the projects' cost-time tradeoffs which are highly dependent on the mathematical model. By having more learned rules that their frequency and certainty had been evaluated, the initial schedule could be set up and the allocation of resource with the goal of optimizing time-cost function happen for remaining activities.

Abstract –

The growing number of bridges and their deteriorated conditions on one hand and the budget squeeze for their repair and rehabilitation on the other call for automated detection of defects and smart methods for condition rating of these bridges. This paper presents a newly-developed standalone computer application for automated detection and evaluation of spalling severities in reinforced concrete bridges. The application is coded in C#.net and makes use of an early developed model for detection of surface defects. The method is applied in two tiers, in the first tier, a single-objective particle swarm optimization model is developed for detection of spalling based on Tsallis entropy function. The second tier is devised for evaluation of spalling severities. It generates a comprehensive representation of the bridge deck image using Daubechies discrete wavelet transform feature description algorithm. The second tier also encompasses a hybrid artificial neural network-particle swarm optimization model for accurate prediction of spalling area; circumventing the drawbacks of the gradient descent algorithm. The developed method was tested using 60 images from three bridge decks in Montreal and Laval in Quebec, Canada. Results indicate significant superiority in area prediction accuracies; achieving mean absolute percentage error, mean absolute error and relative absolute error of 6.12%, 56.407 and 0.393, respectively. The developed method is expected to assist transportation agencies in performing more accurate condition assessment of concrete bridge decks and accordingly assist them in developing optimum maintenance plans.

1 Introduction

Bridges are viral elements in infrastructure systems. Meanwhile, they are vulnerable to severe deterioration agents such as freeze-thaw cycles, excessive distress loads due to traffic overload, sulfates, alkali-silica reaction, poor construction practices, etc. It was reported that 26% of the bridges in Canada are experiencing medium to very poor severity levels. They are expected to suffer a further degradation in their condition ratings resulting from the increase of backlog of intervention actions [1-2]. There are two main reasons for the significant deterioration of bridges which are: the decrease in the public investment, and the high age of bridges. The investment in bridges is below the required level to maintain the age of bridges constant, whereas the age of bridges increased by 3.2 years from 21.3 years in 1985 to 24.5 years in 2007. Bridges in Quebec have the highest average age followed by Nova Scotia. Conversely, Prince Edward Island's bridges have the lowest average age. In this context, the average age of bridges on Quebec, Nova Scotia, and Prince Edward Island are 31, 24.5, and 15.6, respectively [3].

In the light of forgoing, it is essential to assess the structural condition ratings of bridges in order to maintain them within acceptable performance levels. The use of machine vision technologies has emerged in the last few years because they enable more efficient and cost effective assessment of structural components than visual inspection. Spalling is an important surface defect that is larger and deeper than scaling. It is created as a result of corrosion of steel reinforcement and it affects the durability and structural integrity of reinforced concrete bridges [4]. In this regard, the present study proposes a novel method for the evaluation spalling in reinforced concrete bridges. It is expected that the developed method will enable decision makers in improving accuracy, reducing cost and minimizing the inherent subjectivity of the visual

inspection process of reinforced concrete bridges.

2 Literature Review

Several machine vision-based methods were developed for the purpose of evaluating of surface defects in bridges. Ho et al. [5] developed a method for surface damage detection in cable-stayed bridges. In the developed method, median filter and histogram equalization were applied to improve the quality of captured images. The captured images were then projected onto principal component analysis sub-space. Mahalanobis square distance was then utilized to detect the existence of defects through computing the distance between the projection of input image and all the trained images. Noh et al. [6] proposed a method for the detection of cracks using fuzzy C-means clustering. In it, a set of morphological operations were employed to better reveal the characteristics of cracks and remove noise from the background. This encompassed dilation operation, manually-tuned masks and connected-component labelling. It was highlighted that the developed method could achieve higher recall and precision when compared against other edge detection-based methods.

Mohammed Abdelkader et al. [7] introduced a two-stage multi-objective optimization-based method for the sake of detection of crack images in reinforced concrete bridges. In it, invasive weed optimization algorithm was employed to find the optimum thresholds capitalizing on Kapur entropy function and Renyi entropy function. It was found that the developed method could achieve mean-squared error, peak signal to noise ratio and structural similarity index of 0.0784, 11.4831 and 0.9921, respectively. Talab et al. [8] proposed an approach for the detection of cracks in images based on a combination of edge-detection and histogram-based algorithms. Sobel filter was first applied to detect the edges of crack. Then, Otsu algorithm was utilized to classify the image into cracking pixels and background. It was deduced that the proposed approach could achieve clear and accurate identification of cracks with no noise.

Otero et al. [9] introduced five-stage algorithm for the detection of cracks. Anisotropic diffusion filter was applied to smooth the image while preserving cracking details. Sobel algorithm was utilized to extract cracking edges from the image. The resulted images from Sobel algorithm were processed using active contours technique for the segmentation of cracks. A group of morphological operations were then applied to remove noise blobs. It was highlighted that the developed algorithm could deal with transversal, longitudinal and alligator cracks. Liu et al. [10] presented a method for the detection of cracks in concrete structures capitalizing on multi-scale enhancement and visual features. Multi-scale enhancement algorithm supervised by gradient information was utilized to filter out noise from the images. A combination of Sobel operator and adaptive threshold segmentation was used to binarize the enhanced images. Closing and small area removal morphological operations were then used to integrate the fragmented cracks and remove the noises. It was found that the developed method could eventually achieve higher true positive rate when compared against Otsu and morphology-based algorithm in addition to percolation model-based algorithm.

Wang et al. [11] introduced an algorithm for crack detection of concrete bridges. In it, adaptive filter o size 3×3 was employed multiple times to remove any superimposed noises. Then, contrast enhancement was applied to the processed images to retain detailed information of the target crack as much as possible. An integration of Otsu threshold segmentation and modified Sobel operator were used to detect cracking pixels present in the image. It was inferred that the developed algorithm could achieve absolute error of 0.02 mm in the detection of cracking width. Pavithra et al. [12] developed an image processing-based method for the detection of cracks in concrete structures. Median filter was employed to remove salt and pepper noise that corrupts the images. Threshold segmentation was applied to separate the cracking pixels from the background. Erosion and dilation morphological operations with manually tuned structuring elements were applied to better detection the details of cracks. The outputs from Grey-level co-occurrence matrix alongside statistical features of the images were used as an input to the cascaded random forest classifier for cracking detection. The developed method was able to achieve a detection accuracy of 98%.

Shehata et al. [13] developed two models for the estimation of cracking width using feed and cascade forward back propagation artificial neural network models. Each crack was divided into segments and the maximum width of each segment was computed. It was reported that feed forward back propagation artificial neural network provided higher prediction accuracies achieving mean absolute testing error of 10.3%. Andrushia et al. [14] presented a method for structural concrete crack detection using a combination of image processing algorithms. Anisotropic diffusion filter was first employed to smooth the input images. The filtered images were then fed into the six sigma statistical method to separate the foreground cracking pixels from the background. The developed method outperformed some state of the art methods accomplishing mean squared error, peak signal to noise ratio and mean structural similarity of 62.41, 35.63 and 0.923, respectively. Jain and Sharma [15] proposed an

automatic system for the detection of severity levels of cracks. After applying histogram equalization and contrast enhancement, the processed images were segmented using K-means clustering algorithm. Different settings of K-means clustering were investigated, whereas it was found that random initialization with Euclidean distance provided better results. A fuzzy inference system was then devised for crack risk prediction based on aggregated score.

3 Proposed Method

The primary objective of the present study is to develop a computerized platform for the automated detection and severity assessment of spalling in reinforced concrete bridges. This research study extends on a method earlier developed by the authors for the recognition of surface defect type in the image [16]. The flowchart of the proposed method is depicted in Figure 1. In this context, the framework houses five main modules, namely data prep-processing, automated detection, feature extraction, automated evaluation and method validation. It should be mentioned that the spalling detection and assessment of its severities are described and validated separately. In the first module, the input true-color image RGB is transformed to the grayscale image to accelerate the computational process, whereas the intensity values of the gray level image are varying from 0 to 255. The images are resized to 200×200 to better capture the details and characteristics of spalling present in the images.

The performance of machine vision algorithms depends on the quality of the input images which may be corrupted with noise during acquisition and transmission phases. Noise is undesirable random fluctuations in the color and brightness of the image. In this context, the proposed method utilizes Frost filter to remove noises from the input images while retaining the fine details and edges of the object of interest. Frost is an exponentially weighted average filter that employs local statistics to reduce separate and multiplicative noises. It is based on computing an image coefficient of variation which is equal to the ratio of local standard deviation to the local mean of the noisy filter. Frost filter can be mathematically expressed as follows [17-18].

$$R\hat{}(\tau) = \sum_{n\times n} K\alpha e^{-\alpha|t|} \quad (1)$$

Such that;

$$\alpha = \frac{4}{n\sigma\hat{}^2} \times \frac{\sigma^2}{I^2} \quad (2)$$

$$t = |X - X_o| + |Y - Y_o| \quad (3)$$

Where;

K denotes a normalizing constant. $\sigma\hat{}^2$ stands for the image coefficient of variation. σ^2 denotes the local variance. n represents the moving kernel size. I represents the local mean.

Processing of defects images in reinforced concrete bridges is a challenging task because of their complexity, low contrast, color distortion and non-uniform illumination. In this regard, the proposed method utilizes min-max gray level discrimination approach for the sake of improving the contrast of images. This is accomplished through increasing the gray level intensities of the spalling pixels meanwhile decreasing the intensities of the non-spalling pixels [19].

The second module is designated for automated detection of spalling. Image segmentation is one of the basic and critical operations used to analyze the retrieved images in pattern recognition applications. It is the process of dividing the image into non-overlapping multiple segments based on some attributes such as color, intensity and texture. In this regard, optimization-based method proved their efficiency in dealing with complex image segmentation problems in various applications [7]. In the present study, bi-level thresholding is applied to segment the spalling images by designing a single-objective particle swarm optimization model that aims at maximizing Tsallis entropy of the image. The output of this module is a single threshold T that classifies the image pixels into two classes: the spalling (foreground) and surface (background).

The third module is the feature extraction of the captured images. It comprises the use of Daubechies discrete wavelet transform. It decomposes the input original image into four sub-images via high-pass and low-pass filters. The four quadrant sub-bands are called HH_n, LL_n, HL_n and LH_n. For instance, LL_n is generated through employing low-pass filter for both rows and columns. LH_n is generated through employing low-pass filter for rows and high-pass filter for columns [20-21]. The fourth module is the automated assessment of spalling severities. The proposed method ($ANN - PSO$) utilizes particle swarm optimization algorithm for both parametric and structural training of back propagation artificial neural network. This involves autonomous optimizing the weights of artificial neural network and its best possible architecture. In this context, artificial neural network is trained through formulating a variable-length single-objective optimization problem which encompasses a fitness function of minimization of mean absolute percentage error of spalling area. The optimized artificial neural network is then appended and adopted to simulate the testing dataset for its performance evaluation. Particle swarm optimization algorithm is a widely-recognized meta-heuristic that proved its efficiency in dealing with complex and

diverse optimization problems such as allocation of irrigation water [22], resource-constrained project scheduling [23] and damage detection using vibrational data [24].

The automated detection model is validated through comparison against Otsu algorithm. It is an unsupervised algorithm that is used to segment an image by maximizing the variance between the segmented classes [25]. The performance of the automated assessment model is evaluated against the back propagation artificial neural network for its validation.

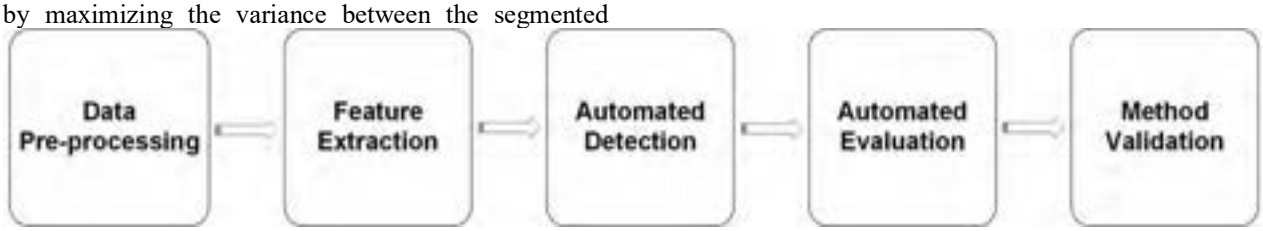

Figure 1. Main modules of the developed spalling detection model

4 Method Development

This section describes the basic computational procedures of Tsallis entropy algorithm and particle swarm optimization algorithm.

4.1 Tsallis Entropy

Assume an image I that contains L gray-levels $\{0, 1, 2, 3, \dots \dots . L-1\}$. Tsallis entropy can be defined using Equation (4) [26-27].

$$S_q = \frac{1 - \sum_1^k (P_i)^q}{q - 1} \quad (4)$$

Where;

k represents the total number of possibilities in the system. q denotes Tsallis entropy or entropic index.

Tsallis entropy of a whole system can be described based on the pseudo additive entropic rule as shown in Equation (5).

$$S_q^{A+B} = S_q^A + S_q^B + (1-q) S_q^A S_q^B \quad (5)$$

Tsallis entropy of the two classes C1 and C2 can be computed using Equations (6) and (7), respectively. Tsallis entropy is computed based on the calculation of the probabilities of occurrence of the gray levels P_i, whereas $\sum_{i=0}^{L-1} P_i = 1$

$$S_q^{C1}(T) = \frac{1 - \sum_{i=0}^{T-1} \left(\frac{P_i}{P^{C1}}\right)^q}{q-1}, P^{C1} = \sum_{i=0}^{T-1} P_i \quad (6)$$

$$S_q^{C2}(T) = \frac{1 - \sum_{i=T}^{L-1} \left(\frac{P_i}{P^{C2}}\right)^q}{q-1}, P^{C2} = \sum_{i=T}^{L-1} P_i \quad (7)$$

Where;

$S_q^{C1}(T)$ and $S_q^{C2}(T)$ represent Tsallis entropy of the two classes C1 and C2, respectively.

Thus, the objective of the optimization problem is to find the gray threshold T , which maximizes Tsallis entropy of the segmented classes as per Equation (8).

$$F(T) = \max \left(S_q^A + S_q^B + (1-q) S_q^A S_q^B\right) \quad (8)$$

4.2 Particle Swarm Optimization

Particle swarm optimization is a population-based meta-heuristic that was first introduced by Eberhart and Kennedy. The basic computational stages of particle swarm optimization algorithm are depicted in Figure 2 [28-29]. It is inspired by the social behaviour of migrating flock of birds. Each candidate solution is called "particle" and a population of randomly positioned particles in the search space is called "swarm". Each particle in the multi-dimensional solution space is characterized by its position and velocity. During each iteration in the evolution process, each particle monitors its current position, the best position it achieved and its own flying velocity. The position and velocity of each particle is updated according to its own best flying experience and the best position achieved by the entire swarm. In this regard, the position of the best particle in the swarm is obtained based on the pre-defined fitness function(s). The computational procedures of particle swarm optimization algorithm combines local and global search which helps in providing a proper balance between exploration and exploitation. The positions and velocities of the swarm of particles in the trajectory are updated as follows.

$$v_i(t+1) = w \times v_i(t) + c_1 \times r_1 \times (pbest_i(t) - x_i(t)) + c_2 \times r_2 \times (gbest(t) - x_i(t)) \quad (9)$$

$$x_i(t+1) = x_i(t) + v_i(t+1) \quad (10)$$

Where;

$x_i(t)$ and $x_i(t+1)$ denote the position of the i-th particle in iteration t and $t+1$, respectively. $v_i(t)$ and $v_i(t+1)$ represent the velocity of the i-th particle in iteration t and $t+$, respectively. $pbest_i$ is the individual local best position that particle i achieved so far. gbest stands for the global best position achieved by the entire swarm. c_1 and c_2 are two acceleration coefficients that denote cognitive learning, and social parameters, respectively. They enable controlling the global and local guides. r_1 and r_2 represent two uniformly distributed random numbers searching search for better solutions along the direction towards the personal best and global best. w refers to the inertia weight. It is advised to start with a large inertia factor and then it decreases within the evolution process to enable both global and local explorations.

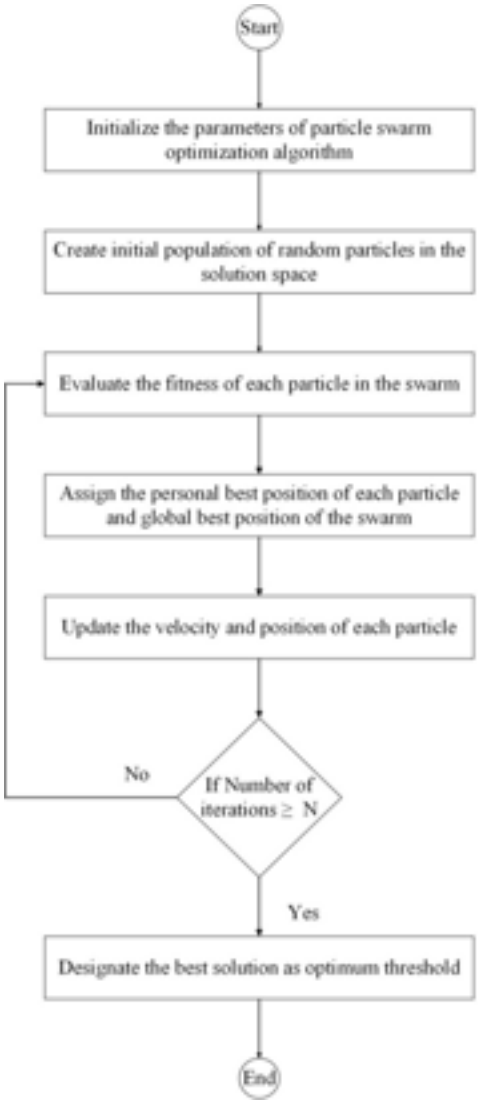

Figure 2. Flowchart of particle swarm optimization algorithm

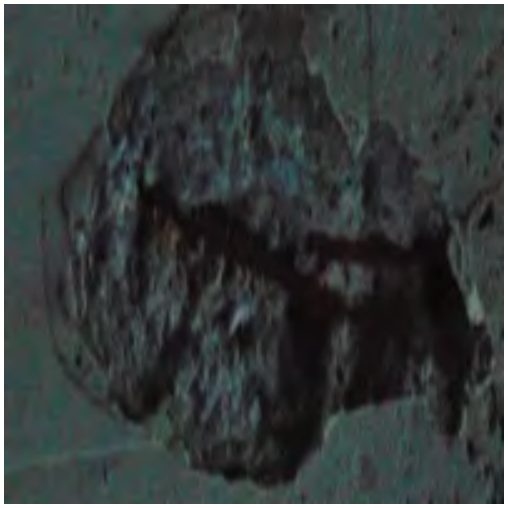
5 Method Implementation

A dataset comprising of 60 real-world images are used as an input to experiment the proposed method such that 50 images are used for training while the remaining 10 images are used for testing. These images are captured from bridge decks in Montreal and Laval, Canada using Sony DSC-H300 digital camera of 20.1 megapixel resolution. All the calculations and optimization algorithms took place on a laptop with an Intel Core i7 CPU, 2.2 GHz and 16 GB of memory. Sample of the spalling images used is presented in Figure 3.

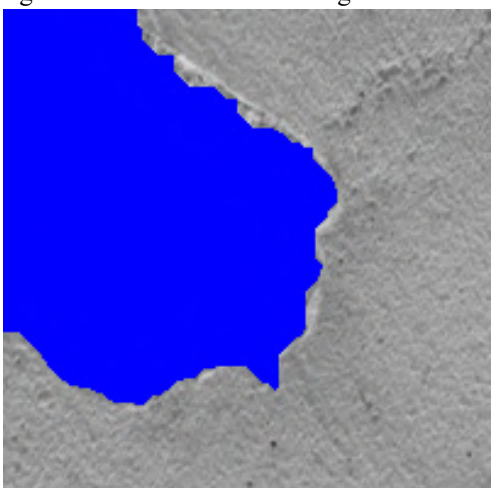


(a) Image "A"

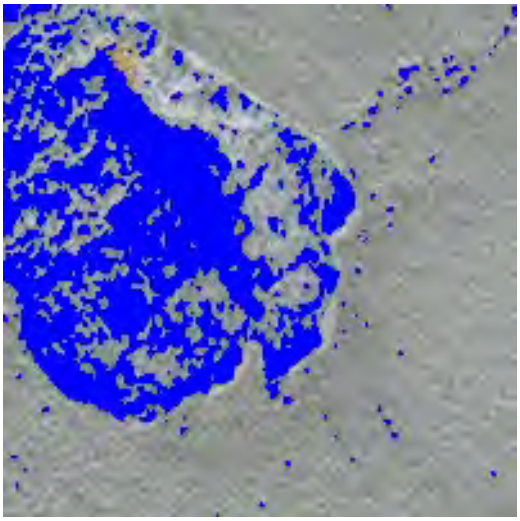
(b) Image "B"

Figure 3. Sample of the spalling images

In the automated spalling detection model, Tsallis entropy index is assumed 0.5. With respect to the particle swarm algorithm in this model, the number of iterations and the initial population size are assumed 30 and 10, respectively. The cognitive learning and social parameters are assumed 2 while the inertia factor is assumed 0.5. Figure 4 demonstrates the segmented image of spalling after the application of the single objective particle swam optimization-based segmentation method alongside the segmented image after the implementation of Otsu algorithm. As can be seen, the developed detection model successfully recognized the spalling. However, Otsu algorithm failed to discriminate the spalling pixels from the background causing a lot of distortion in the image.



(a) Segmented image using the developed detection model



(b) Segmented image using Otsu algorithm

Figure 4. Visual representation of spalling detection models

At the level of spalling evaluation, the ANN – PSO model is composed of one output neuron for the prediction of spalling area. The optimization parameters of the developed ANN – PSO model are recorded in Table 1. It is found that the optimum numbers of hidden layers and hidden neurons are one and two, respectively. Tangent sigmoid is the optimum transfer function. A comparative analysis between the ANN – PSO model and the back propagation artificial neural network is presented in Table 2. The comparison is carried out using mean absolute percentage error (MAPE), mean absolute error (MAE) and relative absolute error (RAE). It can be inferred that the developed assessment model substantially outperformed the conventional artificial neural network through reducing MAPE, MAE and RAE by 76.65%, 71.47% and 71.43%, respectively.

Table 1. Optimization parameters of the developed **ANN – PSO** model

Parameter	Corresponding value
Minimum number of hidden layers	1
Minimum number of hidden neurons	1
Maximum number of hidden layers	10
Maximum number of hidden neurons	10
Initial population size	200
Number of iterations	400
Cognitive learning	2
Social parameter	2
Inertia weight	0.5

Table 2. Performance comparison between the spalling evaluation models

Model	MAPE	MAE	RAE
ANN – PSO	6.12%	56.407	0.393
Artificial neural network	26.21%	197.756	1.376

6 Conclusion

Routine visual inspections are mandatory to build condition assessment models. Nevertheless, they are prone to subjective judgments. This can lead to inaccurate deterioration models and intervention actions. In this context the present study introduces a novel two-tier method for the automated detection and evaluation of spalling in reinforced concrete bridges.

Results obtained from the visual comparison demonstrated superiority of the spalling segmentation model of the developed method. It was able to establish

well-separated thresholds as well as more compact and homogenous clusters. On the other hand, Otsu algorithm failed to detection spalling pixels in the image. With regard to the spalling evaluation, it was concluded that the developed spalling evaluation model managed to reduce of the prediction error by values ranging from 71.43% to 76.65% with reference to the artificial neural network. Accordingly, the developed method can be deployed as an efficient tool to provide safer, productive and more reliable inspection of reinforced concrete bridges.

Abstract –

The construction industry has been forever blighted by delay and disruption. To address this problem, this study proposes the Fitzsimmons Method (FM method) to improve the scheduling performance of activities on the Critical Path before the project execution. The proposed FM method integrates Bayesian Networks to estimate the conditional probability of activity delay given its predecessor and Support Vector Machines to estimate the time delay. The FM method was trained on 302 completed infrastructure construction projects and validated on a £40 million completed road construction project. Compared with traditional Monte Carlo Simulation results, the proposed FM method is 52% more accurate in predicting the projects' time delay. The proposed FM method contributes to leveraging the vast quantities of data available to improve the estimation of time risk on infrastructure and construction projects.

Keywords –

Construction Schedule; Machine Learning; Project Delay; Critical Path Method

1 Introduction

At present, around £100bn is spent in the UK each year on infrastructure investments [1], making the delivery of infrastructure 70% of the total spending on the National Health Service. By 2030 it is estimated that around £19bn a year will be wasted on the avoidable costs generated by poorly delivered infrastructure projects [2]. This is a worrying trend in an age where populations are aging and productivity in the UK economy has stagnated [3]. Experts estimate that for every £1 invested in infrastructure, the benefit to the economy is £2.841 [4]; the money wasted on poorly delivered infrastructure would equate to as much as £35bn per year in unrealised economic benefit. The cost to the global economy would be $620bn each year, if the trend were extrapolated worldwide [5], with around $1.1tn of potential loss. While delays are only part of the picture, it has been argued that they are among the most significant culprits in undermining the successful completion of infrastructure investment [6,7].

Recent research used machine learning methods to predict project delay, including naïve Bayesian [8], Bayesian Belief Network [9] and logistic regression [10]. In practice, some software packages (e.g. Deltek Acumen Fuse) enable users to pre-define delay factors and its correlations while modelling risk. However, the analysis of these packages is still inarticulate and does not have a strong evidentiary basis.

This research aims to create a more objective and evidence-based framework for schedule risk analysis, given the theoretical limits and incompatible software in risk analysis. The proposed solution – the FM Method simulates risks on the critical path and predict project delay. Hence, the proposed method can provide the project manager and schedulers insights about the potential risks of their planning before execution, thus enable effective planning.

This paper starts with reviewing literature ineffective planning and project duration prediction, followed by the proposed FM method, analysis results of FM method and a discussion of analysis results. The conclusion is summarised at the end.

2 Literature Review

This section provides a comprehensive review in construction project delay estimation. This section starts with a review in schedule quality, followed by commonly used methods in predicting construction delay. Research gaps and questions are summarised at the end.

2.1 Schedule Quality

Late project delivery is affected by many factors either internally or externally, from engineering design to project management [11]. External factors including weather [12,13] and macroeconomic conditions [14] being unpredictable and uncontrollable. Whereas addressing internal factors, and in particular schedule quality [15], can significantly reduce the chance of late delivery [16]. A quality schedule uses expected outputs,

resource and space constraints, and technical expertise to determine an optimal and achievable schedule of activities. Subjectivity and uncertainty hinder the production of quality schedules.

Schedulers estimate time-risk on construction projects and allocate time contingency for high-risk activities to minimise the possibility of project delay in common practice. However, the estimation of time-risk on construction projects is done subjectively, largely by experience, and the penetration of academic concepts into the realm of common practice is negligible [17,18]. Including time continency is one of the trickiest areas of project planning, as it deals with a level of uncertainty which can be challenging to calculate and understand without detailed knowledge of historical records [19].

2.2 Predicting construction delay

The most traditional way to detect project delay in the practice is the Critical Path Method (CPM) [17,20]. CPM connects a series of construction tasks with defined dependency links to create a directed acyclic graph (DAG) network. Programme Evaluation and Review Technique (PERT) is a variant of CPM that accounts uncertainty with Beta distribution [21,22]. Azaron et al. [23] look at refining the bounds of the project duration risk by introducing the concept of a dynamic Markov PERT model. The approach estimates societal factors such as war, strikes and inflation to make activity durations non-static over time. However, it is an untested model, but it begins to link external factors, deterministic CPM, PERT, and correlation together in an interesting way.

To add covariance and correlation effects to PERT and MCS, Ökmen et al. [24] construct a system called Correlated Schedule Risk Analysis (CSRAM), which uses simple subjective inputs on a range of project risks including weather, soil conditions, labour productivity, and material/resource availability factors. However, CSRAM does not address the crucial problem of subjectivity and opinion-based analysis, a factor commonly associated with disputes in contracts [25,26]. Furthermore, the empirical evidence that this technique is scalable and works across a range of projects types is lacking.

Recent researchers predict project delay using machine learning methods (e.g. Artificial Neural Network (ANN)) based on influencing factors (including the project manager's experience). Kog et al. [27] create a neural network for determining schedule performance from extraneous project factors, including project manager's experience and monetary incentive to the designer. Attal [28] used the overall duration and cost of highways projects to train a series of ANN to determine the key project features to be used in a duration prediction model. Hola et al. [29] take a more specific approach, using ANN to predict earthworks durations. Similarly, Bhokha et al. [30] predicted the duration of building construction using ANN.

A promising solution to the problem of co-variance and project uncertainty is the Bayesian Network (BN) approach. A BN is a probabilistic DAG network, with nodes representing outcomes and arcs, or links, representing the conditional relationships between the nodes [31]. In this respect, they are very similar to construction schedules, where each task could be considered a node and each logic link a conditional dependence relationship. BN has been successfully used in several fields, including medical diagnoses [32] and modelling of complex interactions including operational risk [33], environment [34], and road traffic accidents [35]. Consequently, several recent studies have proposed a framework for using BNs to enhance schedule risk analysis [36–38].

2.3 Research gaps and questions

Three research gaps are identified through extensive literature: (1) it is not known how well the subjective risk analysis studies scale up to large infrastructure projects – they either set out an untested framework or use small sample projects to demonstrate accuracy; (2) the studies which use data have done so at a macro level, which does not allow risk simulation and assessment of a baseline schedule to be undertaken; (3) natural language processing techniques have not yet been optimised for construction industry language. In essence, the research problem left unsolved is that there is no unified approach which seeks to model uncertainty in project schedules using historical data to validate all of the inputs into the process.

This study aims to answer the following research questions: (1) What techniques can be employed to prepare historical construction schedule data for prediction model training? (2) What effect will the application of these techniques, combined with prediction modelling have on the accuracy of time-risk simulation models?

3 Proposed Method

This section provides the proposed method. It starts with an overview of the methods. This study proposes a framework - Fitzsimmons (FM) Method for simulating schedule risk which combines the strengths of Bayesian Networks, Support Vector Machines and Monte Carlo Simulation to simulate project outcomes. Figure 1 presents an overview of the proposed FM method. This study targets an analysis risk of the critical path statically, not dynamically. Therefore, the change of critical path is not evaluated in this model. The following subsections explain the proposed FM methods

in detail.

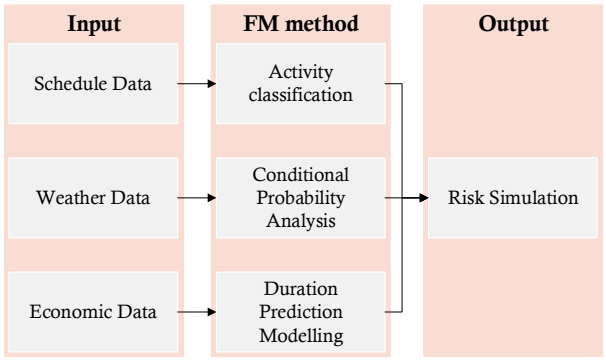

Figure 1. Overview of the proposed method

3.1 Word Embedding

Word embedding (Word2Vec) was used to add semantic meaning to the words in each task description. The two neural network architectures identified for this purpose were Skip-gram and Continuous bag-of-words (CBOW) embeddings. CBOW and Skip-gram are recent methods that learn word embedding representation and predict target words from context [39], but work inversely [40]. CBOW predicts target words from source text words; while, Skip-gram predicts source text words from target words [40].

It is unavoidable that there are similar activities, in terms of its functionality; for example, 'pour concrete for ring beam' and 'concrete ring beam'. Since distinguishing the semantic differences between activities remains challenging, this study clustered activities into topics using Gaussian Mixture Modelling (GMM). GMM is a probabilistic model for representing normally distributed subpopulations within an overall population [41]. The most common and well-used topic modelling methods are Latent Dirichlet Allocation (LDA) [42] and Latent Semantic Analysis (LSA) [43]. These models have been shown to work well for large corpora and documents, where keywords may appear several times [44]. Whereas, the average construction task description length is 5-10 words, rendering LDA/LSA largely ineffective. Hence, this study employed GMM to cluster construction activities. The optimal number of clusters was determined by using topic coherence as a reference. After several iterations of the test, it was difficult to determine a precise optimum number of topics.

3.2 Bayesian Probability

This study measures activity duration deviation, rather than activity delayed duration, to simulate the project duration. Early finished activity may also lead to project duration variation. Activity duration deviation is estimated as follows:

$$Duration\ deviation = \left(\frac{Actual\ duration}{Original\ duration} - 1\right) \times 100\% \quad \text{Eq. (1)}$$

In this study, BN is used to estimate the probability that each activity duration will deviate based on its characteristics and position within the CPM network in this study. The probability of activity duration deviation derived will be used as input in the next step. Figure 2 presents a simplified BN that estimates the probability of activity duration deviation.

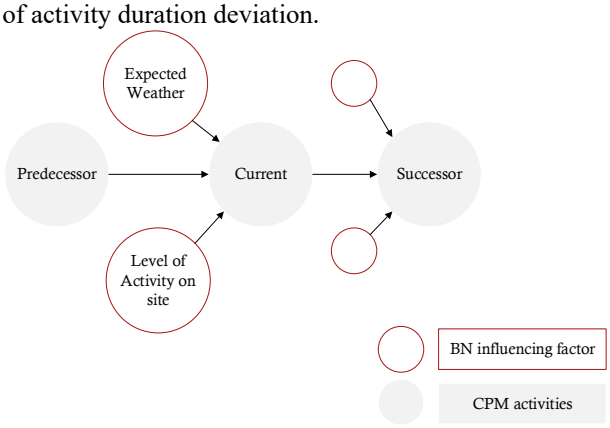

Figure 2. Simplified BN

3.3 Support Vector Machines

Support Vector Machines (SVM) is a classification method which distinguishes classes via solving a constrained quadratic programming problem and inserting a hyperplane [45]. SVM is used to predict the duration growth percentage of activity. Different from BN, SVM estimates the duration deviation of the current activity. Except for the probability of duration deviation derived above, SVM inputs also include the level of concurrent activity, estimated duration, and previous activity duration deviation. The dataset was split into train and test subset with a ratio of 80/20%, to avoid overfitting, to train an accurate SVM.

SVM, in this study, predicts the duration growth percentage of activity, as highlighted earlier. A task of 200 days and a task of 2 days could both find a prediction of 400% duration increase, but with different levels of impact to project delay. Therefore, this study calibrates duration growth percentage into a relative number as compared to the activity's duration. Eq. (2) explains the duration growth percentage calibration:

$$\tilde{Y} = (2 \times \hat{Y} \times \delta \times \mu)/(2 \times \delta \times \mu + \hat{Y} \times \delta \times ED) \quad \textit{Eq. (2)}$$

Where $\tilde{Y}$ is the calibrated duration growth of a given activity,

$\hat{Y}$ is the predicted duration growth of a given activity by SVM,

δ is the standard deviation of all durations in the project being simulated,

μ is the mean activity duration for the project being simulated,

ED is the estimated duration of the given activity.

3.4 Risk simulation

The simulation algorithm intended to calculate the average finishing position of each task over a nominal number of simulation iterations. This gives a time-distributed profile of tasks that can be used as the output of the risk analysis simulation. It is conceptually based on the Monte Carlo Simulation algorithm but with uncertainty and SVM to predict the deviation parameters. A beta distribution is used to determine the final duration deviation factor, to ensure that the duration uncertainty parameters change from one simulation iteration to the next. This distribution is parameterised by the SVM model prediction. The author chose this method to capture the strengths of MCS and PERT in modelling duration uncertainty. This model can be described as truly dynamic. With each iteration, the SVM input values will change and the duration deviation estimate will change with them, giving a broader range of possible values for the duration of each task.

4 Data Collection and Analysis Results

4.1 Data Collection and Pre-processing

The schedule data was collected from two construction and engineering firms. One of the organisations is a tier one contractor who directly delivers large infrastructure projects on behalf of public and private sector clients. The other is a schedule management consultancy that provides services to clients and contractors in several engineering disciplines. Both were requested to provide as-built schedules and initial baseline schedules for infrastructure projects regardless of the project outcome. The files were provided in the software-native Primavera P6 '.XER' format.

In total 560 project files were collected, of which 302 were valid. Some were invalid due to corrupt native files or a lack of 'actual versus planned' information. Figure 3 below shows the split by project discipline, with a relatively broad range of projects included. In total 444,173 tasks were added to the dataset, using an algorithm which interrogated the native schedule files and extracted any useful information into a large data file in '.txt' format. For context, a simple analysis of 'task count vs. project value' suggests that every 1,000 tasks represent £20m in project value. This indicates that the database may be equivalent to as much as £8.9bn in completed infrastructure.

This study pre-processed activity names to secure accuracy, before feeding activity names into analysis models. Pre-processing steps include tokenisation, lemmatisation, stemming and removing stop words. Tokenisation is a process that transforms text into tokens which are readable in a computer language [46]. Lemmatisation and stemming are used to reduce the effects of inflectional form and words' morphology [47]. Stop words (e.g. 'and', the') and punctuation was removed, to get eliminate the unmeaningful words.

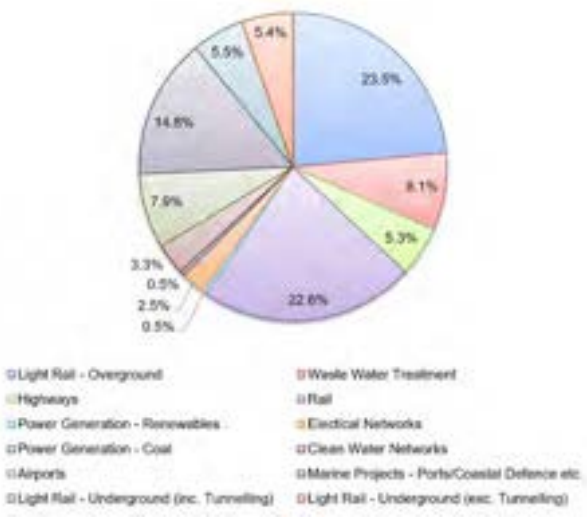

Figure 3. Data Distribution

4.2 Analysis Results

After pre-processing, data were fed into the proposed FM method. The following subsections summarise analysis results of each step from word embedding to simulation results.

4.2.1 Word Embedding

The first step in the proposed FM method represents construction activities' names with word vectors and clusters similar activities into topics. This study used Word2Vec to represent construction activities names with word vectors, as highlighted in Section 3.1. The hyperparameters of the Word2Vec model are the number of training iterations, the context window length, and the vector size [48]. A range of 5, to 50 iterations was tested with no significant improvement in performance, so the default value of 5 iterations was used. The context window of 8 was selected based on the average concatenated task description and section heading length. The default vector size of 100 was used, which is suggested by literature [49,50]. In total 5,496 unique words were used in the embedding process, training across a raw dataset of 3.1 million co-occurring words.

Following that, similar activities are clustered into topics using word vectors as input. Topic modelling is an unsupervised learning method and determining the number of clusters is challenging. This study used the coherence score to determine the optimal number of

clusters. It is found that the score settles between 10 and 25 topics, with higher scores towards 20 by plotting the coherence score. Intuitively, this feels appropriate. The design manual for roads and bridges [51] has 16 volumes; if more topics are allowed for procurement, rail and mechanical & electrical trades, then 20 is reasonable.

4.2.2 Activity Duration Deviation

The SVM kernel selected was the radial basis function (RBF), which enables the SVM to perform well with high-dimensional non-linear data. The results of the activity duration growth percentage are summarised in Figure 4. The mean value of activity duration growth percentage is 114% with a standard deviation of 631%. The result indicates that on average, activities are delayed for 114%, as compared with its original duration.

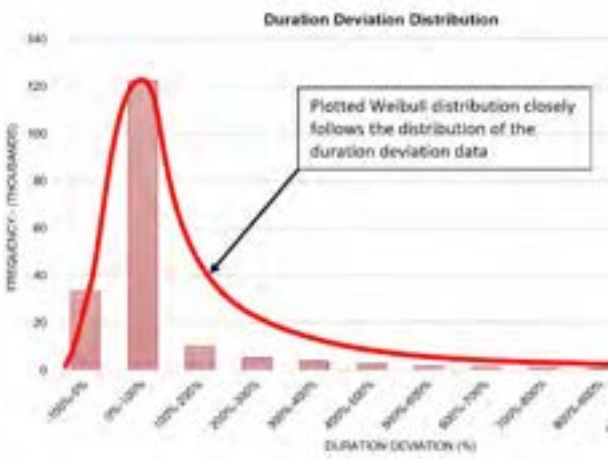

Figure 4. Distribution of Duration Deviation

Using variations about the mean is not the optimum way to simulate activity by activity variance, as shown in Figure 4. The value is heavily skewed by a few extremely high variance numbers, which in normal circumstances might be considered outliers. The issue with treating this as a normal distribution problem is that the data will never be normally distributed. Schedule duration growth works such that most samples sit around the 0% growth point – the 'quicker than planned' activities are bounded at -100%, whereas increased durations have no upper boundary. This makes deciding what constitutes an outlier a particularly difficult activity as normal conventions, involving excluding data over a certain standard deviation (σ) threshold, cannot be meaningfully applied to datasets with large right-skewed distribution tails. The activity duration deviations appear to more closely represent a Weibull distribution as discussed by [52]. Perhaps an approach to modelling duration risk which instead selects duration deviation from a Weibull rather than a normal distribution would be a more appropriate methodology.

Significantly, the high variability was smoothed to give estimates with an average variance of around +68% against the original duration estimate, when using SVM with a radial basis function kernel to predict the variance in an activity. The SVM results predict that some activities could finish earlier, and some activities could be late for 1,500%, which is more than enough to raise a red flag to those looking for significant risks.

The accuracy of SVM results is 80% in predicting whether an activity is delayed, on time or early on the test set. The SVM model predicts a standard prediction error of 122% of activity duration. This may seem extreme, but in a very random training set with a standard deviation of 870%, this is remarkably accurate.

4.2.3 Risk Simulation

The last step is the risk simulation. The case study used was selected randomly and excluded from model training. The selected case study is a port renovation work with a contract value at £40M in the UK. This project finished 26 weeks later than its originally estimated duration. The key risks in this project were that the piling on the existing dock – the ground conditions and existing substructure - were unknown, as well as the condition of the existing aging structures. These were additionally subject to tidal working constraints, which exacerbated the delays experienced because of the realisation of the above risks.

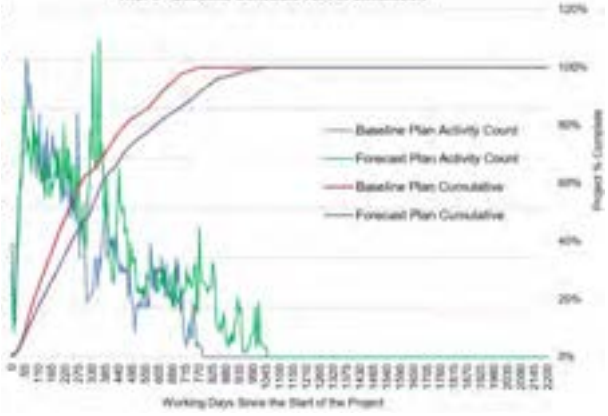

Figure 5. Baseline schedule vs FM simulation

MCS was run first, using inarticulate risk parameters derived from the literature review (best case = 90%, most likely = estimated duration, worst case = 130%). Following that, the proposed FM method was run to estimate the project finishing time and compare results with the MCS results. The MCS results suggested that the project will delay for 1 week; whereas results of the FM method suggested that the project will delay for 38 weeks, which is 52% more accurate than MCS results.

Figure 5 shows a comparison of the baseline schedule and the FM simulation over project completion. In addition, the FM method output has succeeded in assigning large time delays to the piling works and tidal interface works, so in this case study it can be considered a relative success.

4.3 Results Interpretation

The case studies and hypothesis test indicate that the proposed FM risk simulation methodology is significantly more accurate than the state of practice – Monte Carlo Simulation. The standard prediction error was 35 weeks for MCS and 12 weeks for the FM. This suggests that the FM could be 52% more accurate than a standard MCS model. Despite these promising results, the error for the simulation of 12 weeks is still very high and the SVM model prediction standard error is also very high at 122% of the activity duration. There is ample scope to improve on the predictive accuracy of this model, although it may require a good deal more high-quality data than what has been gathered in this research.

It is also apparent from the case study that the risk simulation methodology is unable to detect some of the most significant reasons for project delay; namely: changes to scope, problems with land access, and unexpected existing site conditions. It is difficult to see from the available literature how this might change in the future, but the mitigating factor for contractors is that the time and costs associated with much of those types of delays should be recoverable through standard out-of-court contractual claim mechanisms. This would remain a highly significant problem for project promoters. The evidence is also compelling that construction activities experience delays greater than those commonly allowed for in schedule risk analysis practice.

5 Discussion

This study proposed an FM method which integrates BN and SVM to predict project completion time under uncertainty. This study focuses on analysing activities on the critical path to predict project duration. A domain-specific task classification model for construction schedule data has been demonstrated. This is an approach which combines unsupervised machine learning – word embedding – with Gaussian mixture models and has been adapted from methods intended to topic model social media, revealing promising if imprecise results. Bayesian Networks are used to calculate the conditional probabilities associated with the independent and duration deviation variables. Using tables of these conditional probabilities the problem is turned into a simpler Naïve Bayes or converging Bayesian Network to calculate the probability of a task changing from its original estimated duration. MCS results suggest that the project will delay for 1 week; whereas results of FM method suggest that the project will delay for 38 weeks, which is 52% more accurate than MCS results.

In summary, there is no single technique that can be applied to the complex task of measuring risk in a noisy sequence of construction operations, using only the data contained within a Gantt chart schedule. Understanding how multiple techniques can be employed to add meaning to a construction schedule dataset, however, is a useful contribution towards leveraging the vast quantities of data available to improve the estimation of time risk on infrastructure and construction projects. Using these techniques, machines can learn about highly complex construction projects without being explicitly programmed, which presents some exciting opportunities for construction practice.

The topic modelling techniques proposed in this research could be used for a range of other purposes including automatic schedule alignment of costs and 3D objects in 5D modelling. Similar natural language techniques could also be used to monitor sentiment across a company's portfolio of projects, delivering a contemporaneous health check. Construction schedules are possibly the most up-to-date and comprehensive records on large construction projects; harnessing the value of the data they contain is a significant area of opportunity.

6 Conclusion

This research presents a new framework for construction schedule risk analysis. It represents the first approach to use machine learning to pre-process noisy construction schedules for a novel hybrid application of Bayesian Networks (BN) and Support Vector Machines (SVM). The proposed solution (the Fitzsimmons Method) was trained and tested on large infrastructure projects. The FM method looks at the delay risks before project execution and simulates the delay risks on the critical path. Hence, the proposed method provides the project manager and schedulers insights about the potential risks of their planning. The method is built on the work of several studies describing how machine learning can be used to approach the problem of understanding construction schedules. It has been shown that using large datasets to train prediction models can lead to superior simulation results on a limited sample, doing so with a technique eminently scalable to larger datasets and higher numbers of test projects. In tackling the problems associated with construction schedule data, some valuable contributions have been made to research around applied artificial

intelligence. The proposed method is limited to predict the delay of critical path statically. Future research can investigate the incorporation of dynamic modelling to facilitate a real-time project delay prediction.

Abstract

Recently, Off-Site Construction (OSC) is being actively applied to improve productivity by efficient factory-based production method rather than on-site production.

In OSC-based construction process, problem is the accurate quality inspection for the members produced in the factory is carried out but the quality inspection for the members shipped from the factory and brought to the site is not performed properly. The existing problem in OSC-based Precast Concrete member site detection is on-site workers have to check the members directly, which is very time-consuming and expensive, and the detection accuracy is low. In addition, quality inspection is performed only in the unit of sample, not all members

This study classifies the major detection items of PC members by analyzing the importance of all the detection items of PC members based on the PC member quality checklist that workers have used for on-site detection of PC members.

The items that can automatically detect the damage of PC members are derived, and the types of damage necessary for the detection of each member such as deformation, crack, and wear are classified.

Then, in order to apply the automatic detection technique, the data according to the damage type is collected respectively, and the damaged part is automatically detected through the machine learning. The detected damaged area is reclassified according to the degree of damage. Finally, based on the degree of damage, the status of the member is automatically identified and automatically reported to the checklist.

1 Introduction

1.1 Background and objectives of the research

Recently, the construction industry has introduced "Off-Site Construction (OSC)", which is a factory-based production method, rather than an existing site-oriented production method, to increase productivity and efficiency of work and to enhance the competitiveness of the construction industry. OSC is a method in which members, parts, and pre-assembled parts are produced in advance in a factory, and then transported to a site where such construction materials will be assembled and building will be constructed. In the process of OSC-based construction, accurate quality inspection is performed on parts produced in factories. However, the exact quality test has not been performed on the members that have been transported from the factory and brought into the field. The existing problem in OSC-based PC member field test is that it takes a lot of time and money and the test accuracy is poor because workers have to test the members brought into the field after being checked with the naked eye. In addition, due to the lack of manpower in the field, only the sample units are being tested. Members shipped from the

factory may be damaged or get defected during transportation to the site. Therefore, it is essential to test the quality of the imported material in the field. In order to detect the breakage or defect of the member, recently, studies on image-based defect detection, such as concrete cracking and surface defect detection of electronic components, have been actively conducted using one of deep learning technologies, the Convolutional Neural Network (CNN). In addition, several researches have been conducted on quality inspection automation support systems using mobile devices such as Smart phones and tablet PC to support efficient quality inspection and management of construction and buildings by field workers. Therefore, in this paper, research was conducted to support more efficient and accurate test of field workers on PC members brought into the site. The main concepts of the automatic quality test & reporting system presented in this study are as follows. First, it prevents errors that may occur due to the manual writing of the PC member test checklist that workers are using during the existing inspection. Second, it prevents the loss of the test checklist and the detection by the subjective judgment of the worker. Third, the test results are automatically recorded and saved in a quality checklist through a mobile device-based quality test system. Finally, it assists field workers to figure out the quality status of PC members according to damage criteria.

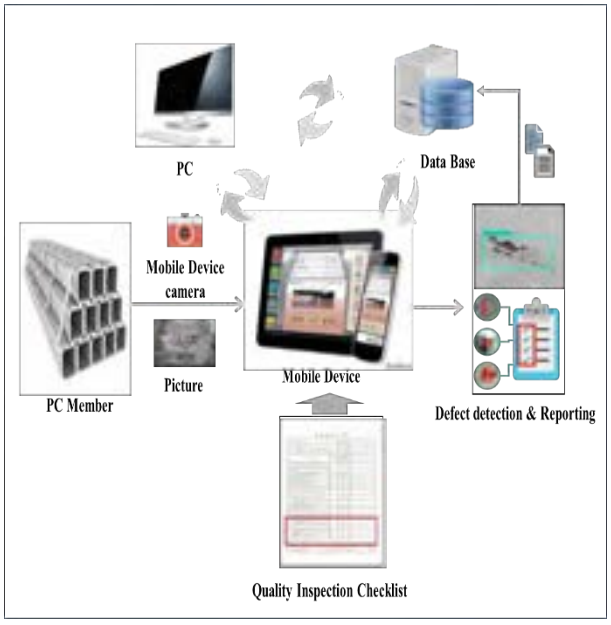

Figure 1. Conceptual diagram of automatic quality inspection reporting system

1.2 Study method and procedure

This study was conducted by the following procedures. First, the quality test automation support system using mobile devices such as Smart phones and tablet PC to support defect detection through AI technology-based image learning and efficient quality inspection and management of construction and buildings by field workers. Second, all test items in the collected PC member test checklist were analyzed to classify the main test items to be tested in the field. Third, when A.I technology is applied based on the main test items classified above, items that can be tested for member damage are automatically reclassified. In addition, the member's damage types such as breakage and cracks were classified to enable automatic defect testing of the member. Fourth, in order to apply AI-based automatic test technology, data according to the type of damage was collected and the member's damaged area was automatically detected through deep learning. In order to classify the detected damage sites in more detail, damage criteria according to the degree of damage were established. Lastly, the quality of the member is found according to the damage criteria, and a configuration diagram of an automatic quality test system based on a mobile device capable of automatic reporting is presented.

2 Analysis of previous studies

2.1 Automatic quality defect detection using A.I technology

In the past, quality test of structures or members has been performed by the operator's eyes. The quality test by the operator's naked eye takes a lot of work time and manpower, and the subjective judgment of the worker can be involved, so there is a problem of objectivity and reliability. Recently, to solve this problem, deep learning technology has been applied to perform more efficient and accurate quality tests on various objects such as concrete structures such as buildings, roads, bridges, tunnels, and electronic products. In order to perform such an automatic quality defect test, research on image-based defect detection using a convolutional neural network (CNN), one of deep learning technologies, has been actively conducted.

Kim[1] carried out a study to detect cracks in concrete ground structures by applying deep learning and image processing techniques.

Lee[3] re-learned Inception-v3, one of the deep learning neural network models, using concrete crack photography, and carried out a study to recognize and visualize cracks in concrete photography using the retrained model.

Jung[5] applied deep learning and image processing technologies to recognize cracks in concrete and conducted research on algorithms that testers can check for crack width and length information.

In Kim's research[2], deep learning models that are actively used in recent image analysis fields for image-based concrete crack detection are classified into four types (image classification model, object detection model, shape refinement model, and instance refinement model). This study compared and analyzed the performance of crack detection of representative models of ResNet-101, Faster R-CNN, DeepLab, and Mask R-CNN.

Choi[4] carried out a study on the detection of defects on the surface of electronic components by using a convolutional neural network (CNN) for the inspection of surface defects of electronic components with high detection difficulty and insufficient learning data.

As a result of analyzing the previous studies, most of the studies that automatically recognize or detect the presence or absence of a concrete surface defect on the existing structure or member have been actively carried out, but researches on automatic quality defect detection for quality testing of members are still insufficient.

Table 1. A.I-based automatic quality defect detection related research

Research area	Research subjects
CNN- based crack detection	Crack detection of concrete ground structures using deep learning and image processing techniques
	Visualization of information on the width and length of cracks in concrete using deep learning and image processing technology
CNN-based crack detection	Comparison and analysis of crack detection performance of deep learning models (ResNet-101, Faster R-CNN, DeepLab, Mask R-CNN)
CNN-based damage detection and classification	Detection of surface defects in electronic components using a convolutional neural network (CNN)
	Damage detection and classification of damage in sewer pipes using a convolutional neural network (CNN)

2.2 Automated quality inspection using IT technology

During test activities such as quality inspection, safety inspection, etc. for construction work or buildings, field workers should be familiar with various test information such as design drawings, specifications, and inspection items. They write the completed items directly on the checklist, and write a report after the test activity. In order to solve the inefficiency and inconvenience caused by the repetitive work of these workers, in recent years, workers in the field use a mobile device such as a Smartphone or a tablet PC during the test activity. For more efficient and accurate test quality test automation, several studies have been conducted.

Yoon[7] has established and prototyped a quality inspection system for the temporary construction, which is the basis for the development of an electronic work support system based on the construction test information, so that the quality of the construction work can be improved by accessibility of necessary information and the systematic inspection is performed through automation of inspection work. Research was conducted to develop the type.

In order to improve the efficiency of quality inspection, Choi[10] carried out a study on the development of a quality inspection system for a temporary construction in connection with BIM that can automate related tasks and systematically store and manage various quality inspection information.

In order to enable mobile devices to be used for safety during building safety inspection, Ko[6] carried out a research to develop a prototype for regular inspection of buildings by deriving the existing safety

inspection practical problems and core required functions.

Oh[8] carried out a study to collect information on the quality inspection and defect management of apartments in real time using PDA and the web, and through this, it is an apartment quality inspection and defect management system that enables efficient business processing among related actors and support for generational history management.

Seo[9] carried out a study on the 'automated levitation railroad facility automatic inspection system'. to improve the maintenance efficiency and advancement of the magnetic levitation railway using the vision system, check the main inspection items of the track facilities, and automatically analyze the data to detect abnormal points and provide the user with location information of abnormal points.

As a result of analyzing the previous studies, the researcher found that several studies have been conducted on the quality inspection automation for the ongoing construction or completed facilities, but studies on the automation of the quality test to check the quality of the member to be assembled before construction starts, such as OSC-based PC construction are still insufficient.

Table 2. Automated quality detection using IT technology

Research area	Research subjects
Automated construction information management	Prototype research for development of electronic work support system based on construction inspection information
	Development of quality inspection system based on rule-based temporary construction in connection with BIM
Automated defect inspection	Development of prototype for periodic inspection application using mobile devices
	Development of PDA and web-based apartment housing quality inspection and defect management system
Automated Safety inspection	Development of Vision-based magnetic levitation railroad facility automatic inspection system

3 Analysis of PC Member Quality Checklist

3.1 Derivation of main inspection items for PC Member

In this study, a PC member test checklist was collected from a PC member specialist to develop automatic PC member quality test reporting technology.

The quality test of the PC member produced in the factory is based on the test checklist items as shown below. After the test is over, members with no abnormalities are brought to the construction site by a transport vehicle by attaching a test checklist. As the members brought into the site are likely to have been damaged or damaged during loading or transportation, so the field workers perform a quality test on the members one again. Workers carry check construction name, member code, manufacturing year, month, date, product inspection mark, crack,

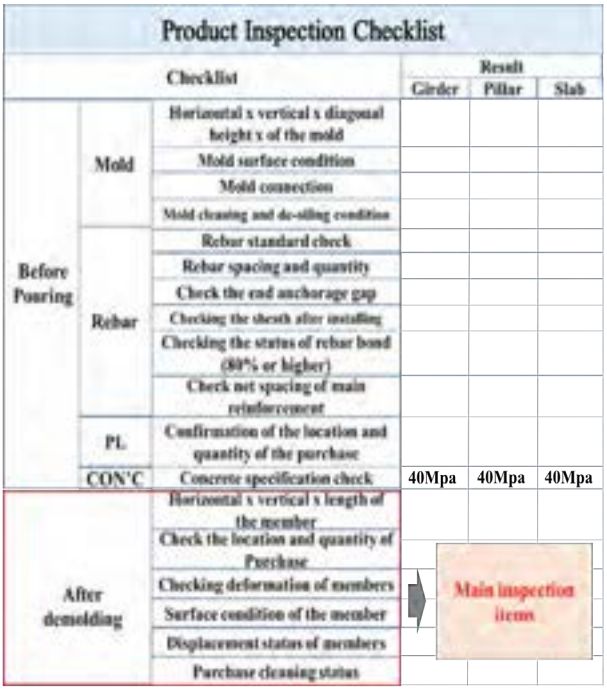

Figure 2. PC member quality inspection checklist

breakage, deformation, etc. in accordance with the PC Construction Standard Specification. Therefore, the main items to be tested in the field according to the specifications of the PC construction standard specification were classified as shown in the following figure2.

3.2 Deriving inspection items that can be measured using A.I technology

In order to support more efficient and accurate quality testing by on-site quality test workers, items that can be automatically tested for quality among the main items of the quality checklist derived above were classified as the following table3.

Table 3. Inspection items by A.I

Checklist	Check items
After demolding	Horizontal x vertical x length of the member
	Surface condition of the member
	Displacement status of members

4 Automatic quality inspection based on A.I

4.1 Classification of damage types and establishment of damage criteria

In this study, in order to check the surface condition of a member among testable items by applying deep learning technology, the member's damage type was classified into cracking and breaking. Later, in order to train the CNN model, which is one of the deep learning techniques, each image data of cracks and fractures was collected. The image data was secured through photographs of Google images and concrete cracks existing on the inside and outside walls, floors, and road surfaces of buildings. In addition, in the case of damage criteria for the quality condition of PC members, if the crack width exceeds 0.3mm based on the contents specified in the PC construction standard specification, it was classified as Class 1 crack, if 0.2~0.3mm, classified as Class 2 crack, and if 0.2mm or less, such fine cracks, it was classified as Class 3 crack. In the case of damage, the damage criteria was established by classifying the damage to the 1st class damage if the joint part was damaged by 200mm or more, the second class damage if the edge of the base plate was damaged, and the third class damages for other damages.

Table 4. Damage types and criteria

Damage Type	Rating	Rating criteria
Crack	Class 1	Crack width exceeds 0.3mm
	Class 2	Crack width 0.2~0.3mm
	Class 3	Crack width 0.2mm or less
Breakage	Class 1	Damage to joints over 200mm
	Class 2	Breakage of the edge of the bottom plate
	Class 3	Damage other than Class 1 and 2

4.2 CNN-based image learning and defect detection

After collecting the image data for each type of damage, the image was modified by resizing and labeling each image to enable image learning through CNN. Afterwards, image learning was performed using Faster R-CNN model, which has high test accuracy and high detection speed, among several CNN models. 500 images were used for training image data and 100 images were used for test image data. As a result of learning and testing of Faster R-CNN, it was identified that cracking and fracture recognition and detection are possible as follows. In addition, a study was carried out to enable detailed visualization of defects by applying an algorithm to visualize numerical values for the width and length of the crack.

The deep learning algorithm for automatic member defect test is largely divided into a stage of learning the damage image, a stage of extracting the damage feature (length and width of the crack), and a stage of visualizing the damage information. Defect detection is visualized through the calculation of the

pixel for the damaged part and the damage type detection through the Canny Edge Detector in the damage feature extraction step. Based on this, member quality test results are output along with the check of the test checklist items.

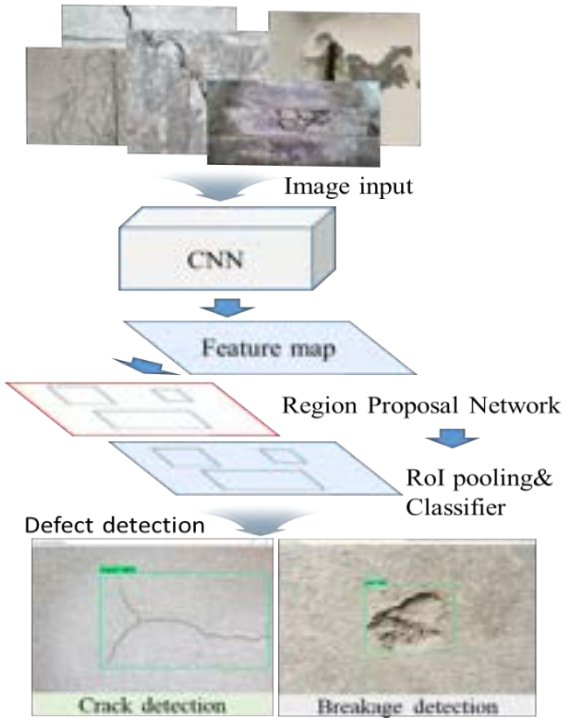

Figure 3. Automatic crack and breakage detection

5 Automatic quality inspection reporting system

The configuration of the automatic quality test reporting system is as follows. First, set the member to be tested. Second, run the camera App mounted on the tester's mobile device to take an image of the target member. Third, defects are detected and visualized through image analysis. Fourth, after a

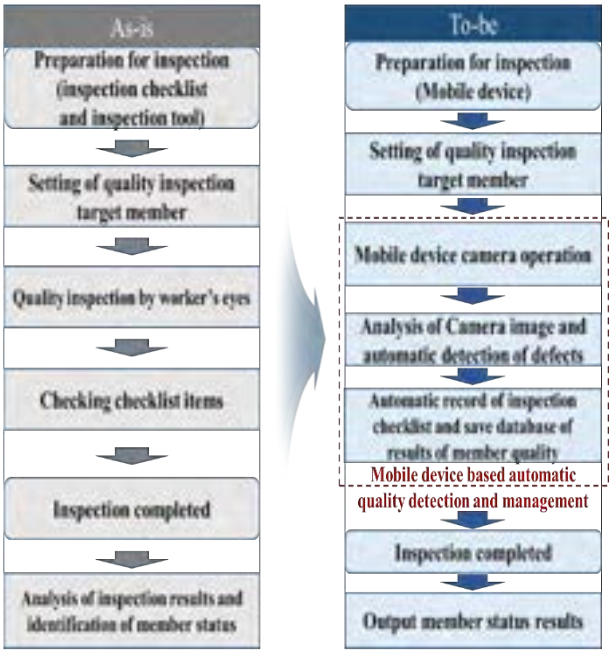

Figure 5. As is – To be Process of Quality Inspection Work

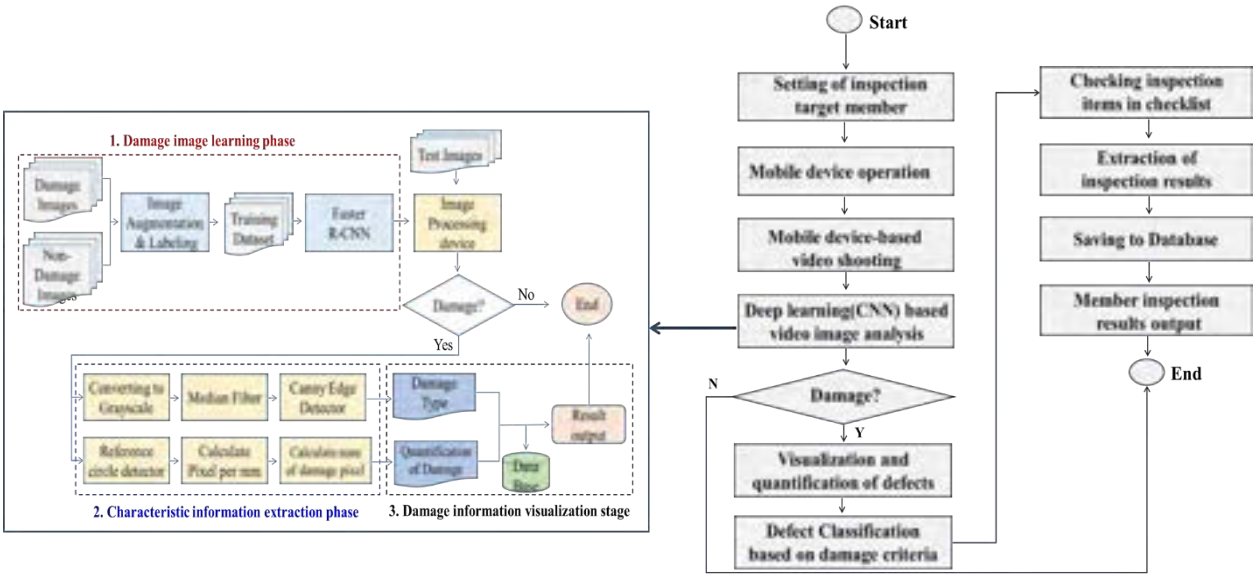

Figure 4. Member defect automatic detection algorithm

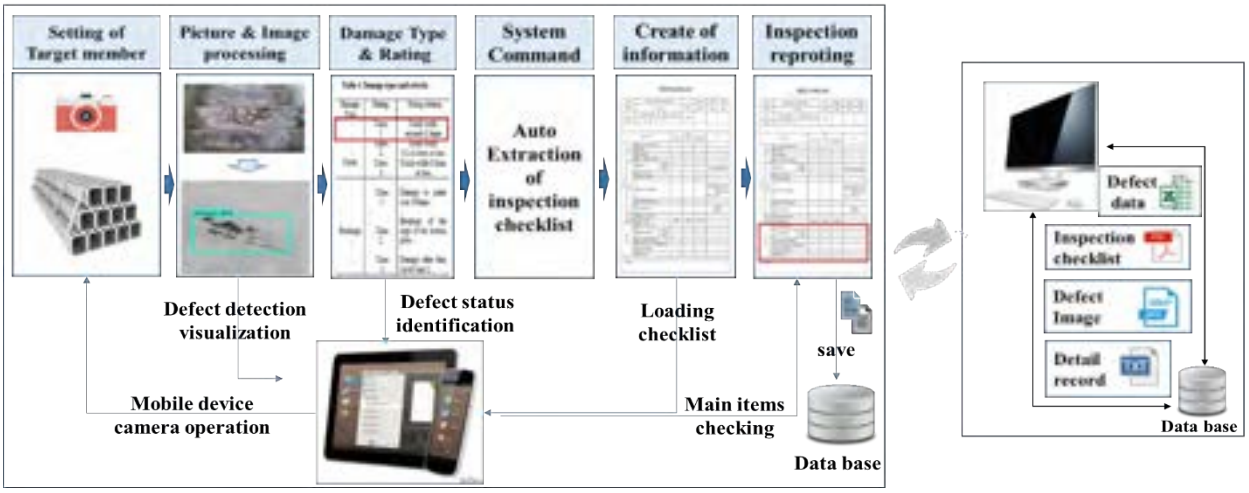

Figure 6. Automatic quality inspection reporting system

defect is detected, a test checklist is automatically loaded in the mobile device system. Finally, the main items in the checklist are checked. After the check is completed, the test checklist file is saved in the database. Test related data can be converted into file formats such as xls, pdf, jpg, txt, etc., and shared and stored in the worker PC.

Therefore, it is possible to automate member damage detection and test checklist inspection through a mobile device-based automatic quality test reporting system.

6 Conclusions

In this study, the researchers proposed an automatic quality test reporting technology to increase the test efficiency and accuracy of field quality testers for OSC-based PC members. In order to implement the automatic quality test technology, the damage type of the PC member was classified into cracks and breaks, and image learning was conducted using the deep learning model Faster R-CNN. In addition, damage criteria were established based on the PC construction standard specifications to figure out the quality status of PC members. Through the automatic quality test reporting technology of this study, on-site testers can more easily detect damages such as cracks and breakages of PC members, and finally identify the member status according to the damage criteria.

In the future, in order to complete the automatic quality test reporting technology suggested in this study, it is necessary to add a process of technology verification and feedback with workers through practical system development and field application. In addition, since this study only discovered cracks and breaks on the member surface when applying A.I technology, it is expected that the quality test method for the deformation of the member itself, such as bending or warping of the member, can be completed through further study.

Abstract –

Although execution is generally the phase during which challenges faced by the construction industry become apparent, it only represents the tip of the iceberg. Execution depends on the effectiveness of construction planning and control – an area identified by researchers as in need of improvement. Production Strategy is a fundamental step and a critical component of production planning and control where decisions are collectively made to properly allocate and deploy resources to achieve project objectives. The Production Strategy Process (PSP) involves a massive information transfer and requires a high level of communication between the project team members. The increased complexity and sophistication of construction projects along with the rapid advances in emerging technologies has fueled construction companies' interest in technology as a source of innovation. One technology that has gained great interest in recent years is Augmented Reality (AR). AR, a pillar of the fourth industrial revolution, offers powerful capabilities to enable the next generation of PSP and provides companies significant opportunities to maintain their vitality and competitive edge. This research investigated the integration of AR with PSP and the impact that AR can have on the process. An AR-enabled PSP prototype was developed for the Microsoft HoloLens headset and was validated on an ongoing construction project. The results showed that AR has the highest impact on PSP in three areas, namely analytical, tracking, and informational.

1 Introduction

While the importance of the construction industry as a main contributor to the prosperity of nations has been well documented, volumes have been written about the long-standing challenges facing this industry. The daunting decline in productivity, cost and schedule overruns, costs of rework and waste, loss of information when design documents are translated into construction documents, and inability to execute according to the plan are, to name a few, some of the major challenges that researchers have been investigating [1].

One common trait with the above-mentioned problems is that they all occur during execution, which depends on the effectiveness of production planning and control systems – an area identified by researchers as in need for improvement [2].

Construction researchers noted that major issues in production planning and control are caused by the 1) inadequacy of traditional project management theory and 2) improper applications of information technologies (IT) [3]–[5], [2], [6]. Inspired by innovations in manufacturing, the application of Lean Production and the advancements in Information and Communication Technologies (ICT) have been at the core of addressing the deficiencies in the traditional planning and control system. New innovative production planning and control systems such as the Last Planner® System (LPS) emerged and were empowered with the integration of Building Information Modeling (BIM) [7]. While the implementation of LPS results in a more predictable workflow, a greater degree of team-building, respect, and reliable delivery of tasks, the system does not presuppose any specific work structure [8]. Researchers have investigated a location-based work structure, namely Takt-Time Planning. Takt is a German word that means 'beat' or 'rhythm' and is a Lean concept used to establish flow [9].

The complementary nature of Takt-Time Planning and LPS was investigated and studied by various researchers. The concepts of Takt-Time Planning were then added to the LPS in the form of a new stage, named Production Strategy [10].

Production Strategy is an integral part of production

planning and control and is essential to developing a reliable and balanced production plan [11]. [1] noted that The Production Strategy Process (PSP) involves a massive information transfer and requires a high level of communication between the project team members.

The increased complexity and sophistication of construction projects along with the rapid advances in emerging technologies has fueled construction companies' interest in technology as a source of innovation [12]–[15]. One technology that has gained great interest in recent years is Augmented Reality (AR). AR, a pillar of the fourth industrial revolution, is described as both an aggregator of information and an information publishing platform which allows users a spectrum of capabilities to 1) passively view displayed information, 2) actively engage and interact with published content, and 3) collaborate with others in real-time from remote locations [1]. AR offers powerful capabilities to enable the next generation of PSP and provides companies significant opportunities to maintain their vitality and competitive edge. This paper builds on the work of [1], which proposed an AR-enabled PSP future state.

2 Research Objective and Methodology

This research investigated the integration of AR into PSP and the impact AR can have on the process. The methodology employed to achieve the research objective consists of 1) reviewing the current state of PSP and its challenges, 2) exploring the capabilities of AR, 3) identifying how the AR capabilities can address PSP challenges, 4) developing an AR-enabled PSP prototype for the Microsoft HoloLens headset, and 5) validating the prototype on an ongoing construction project through a survey and analyzing the impact of AR on PSP.

3 Production Strategy Process

3.1 Current State

[8], who noted that LPS does not presuppose any specific work structure, indicated that work structuring happened before project control – i.e., before lookahead planning could occur. [10] introduced PSP as the third step of LPS. Therefore, Production Strategy is implemented after the project team has set the expectations for the project in Master Schedule level (step 1) and has broken down the project into phases (such as overhead, exterior) and identified the activities to be carried out in each phase in the Phase Scheduling level (step 2). The Production Strategy level is where the project teams collectively develop a production plan for each phase. [7], [1] interviewed subject matter experts on PSP and provided a detailed explanation of the process. The authors explained that PSP consists of a prerequisite step and five other principal steps.

The prerequisite step highlights the importance of collaboration among the project team which consists of the General Contractor and Trade Partners (also known as Subcontractors). PSP is, thus, best implemented on an Integrated Project Delivery (IPD) project. The five steps consist of:

- Step 1 – Perform sequence and flow analysis of a phase: Project team reviews 2D construction drawings for a certain phase and agree on the sequence of construction activities and identify the direction of the flow.
- Step 2 – Gather information: The General Contractor conducts one-on-one meetings with the last planners of individual Trade Partners and ask them to 1) highlight on the 2D construction drawings how much work they can perform in one day (daily production), and 2) to group the highlighted daily productions into production areas with five days' worth of work.
- Step 3 – Develop Common Areas: The General Contractors collect the documents produced in Step 2 from each last planner, overlays them, and attempts to identify common production areas.
- Step 4 – Define Production Areas: The General Contractor works with each last planner to ensure that the scope of work within the developed common areas can be completed within five days. Depending on the situation, the last planner might need to adjust their production information or the General Contractor might need to adjust the common areas.
- Step 5 – Validate the Production Strategy: The General Contractor shares the initial production plan with all Trade Partners and solicit their feedback. The production plan is then revised and updated.

3.2 Current Challenges

[7] noted that PSP is information-dense, lengthy, and iterative and identified 11 challenges associated with the current process, namely:

- Collaboration: The lack of effective visual rendering in the traditional 2D drawings does not support collaboration.
- Communication: 2D drawings, unlike 3D models, do not embed detailed information on building components, which can result in misunderstanding and miscommunication among different stakeholders, leading to inefficiencies in the PSP.
- Decision-making: Specific information needs to be extracted from these drawings and processed to

formulate the necessary knowledge for making decisions and taking actions. The nature of the existing PSP does not support the rapid and right decision-making.

- Detection of Errors: 2D drawings do not allow for efficient design coordination, which can lead to inaccurate production input.
- Documentation: The documentation of the current PSP is decentralized where necessary data is often stored in various forms across different devices or locations.
- Efficiency: The one-on-one meetings with the last planners of each activity and the iterative process to develop common production areas and balance the workflow are time-consuming.
- Information Access: A variety of information and data is needed to feed the production plan. Project Participants often need to review multiple documents and software to access the needed information. For example, while 2D drawings are useful to illustrate the spatial arrangement of a project, numerical information is often not represented.
- Information Flow (Navigation): 2D drawings and paper-based information storage that planners rely on often hinder information flow.
- Input Accuracy: Some information depicted on the 2D drawings may not be current or consistent, which complicates the decision-making process of PSP participants. Therefore, when last planners highlight their daily production capacity, they are not provided with the actual quantity of their daily production.
- Interpretation of Plans (Spatial Cognition): 2D drawings present an individual view that is subject to individual interpretation.
- Safety: It is not easy for engineers to discuss and identify construction safety problems and considerations based on 2D drawings.

4 Opportunities to integrate AR

4.1 AR Capabilities

[16] explained that opportunities for supporting a process with Information technology (IT) fall into nine categories. The opportunities to integrate AR – an emerging and promising technology in the realm of IT – into PSP can be also grouped into those nine categories, defining the capabilities of AR, as explained (in alphabetical order) below:

- Analytical: Data analytics and AR build off one another. AR can provide real-time in-situ information visualization of multi-dimensional data [17]. AR brings a new dimension to present and visualize and interact with big data. The technology also offers a new medium that supports users in analyzing data [18]. AR enhances the perception of the user which leads to a better cognition and an enhanced understanding of the environment. Better cognition results in more processed information, wider understanding, and more effective learning leading to more successful and accurate decisions. AR supports the decision-making process by displaying the needed information and enhancing collaboration between those involved in the process [19].
- Automation: AR systems allow the automation of processes. Information can be automatically generated in real-time and displayed onto the real environment [20].
- Disintermediating: With the transition to the digital era, technologies such as AR has the potential to disrupt industries and intermediate and disintermediate processes [21]. AR overcomes the big hurdles of data capture, storage, processing, and integration and therefore creates a new kind of disintermediation.
- Geographical: One of the greatest potentials of AR is the development of new types of collaborative interfaces. AR can be employed to enhance face-to-face and remote collaboration where remote participants can be added to the real world. AR enables a more natural co-located collaboration by blending the physical and virtual worlds to increase shared understanding. Researchers identified five key features of collaborative AR environments: 1) Virtuality – objects that don't exist in the real world can be viewed and examined; 2) Augmentation – real objects can be augmented by virtual annotations; 3) Cooperation – multiple users can see each other and cooperate naturally; 4) Interdependence – each user controls their own independent viewpoints; and 5) Individuality – Displayed data can be different for each viewer [22].
- Informational: AR overlays digital content and contextual information onto real scenes which increases the perception the user has of reality. Furthermore, information can be captured from the user and saved for later analysis [23].
- Integrative: AR is a new source of context-rich data that allows the user to connect the dots between cross-functional teams [24].
- Intellectual: AR supports tacit knowledge exchange. A remote expert can transfer their tacit knowledge through AR via demonstration. Graphics, audio, and video could be used to effectively transfer tacit expert knowledge through AR [25].

- Sequential: AR systems support the performance of activities/tasks in parallel. This is also enabled with the remote collaboration feature that AR provides [20].
- Tracking: AR can visualize BIM data along with the real world of each construction activity and therefore, the status of the activity (complete, in progress, delayed) can be monitored and tracked, allowing the generation of an automatic report to check the progress of an activity [26].

4.2 Matrix of AR capabilities and PSP Challenges

Once the capabilities of AR have been identified, ways of integrating AR to overcome the challenges of the current PSP listed in the previous section are discussed. The nine impact areas laid the foundation for exploring opportunities to address the challenges encountered in the current process. A matrix was created to identify how each challenge will be addressed using the AR impact areas (as shown in Table 1). A detailed description of how AR can address each challenge is provided as follows:

- Collaboration: AR can be used to create a unique collaborative experience. Co-located users can see shared virtual objects (3D and 2D) that they can interact with. AR has the potential to augment the face-to-face (local) collaborative experience and to enable remotely stationed people to feel that they are virtually co-located [27]. AR allows multiple users to be actively engaged in the PSP.
- Communication: [28] reported that AR facilitates communication and discussion of engineering processes in real-time. AR supports the broadcasting of the user's view into a different screen allowing other users to freely exchange information.
- Efficiency: [29] showed that AR can improve performance time and mental effort in collaborative design review. AR can be a proactive approach that enables efficient re-planning [26].
- Decision-Making: [30] stated that using AR can result in better planning by reducing wastes of overproduction, waiting, unnecessary movement, and unnecessary inventory. AR can be used to make a well-informed decision on resource allocation and dynamic adjustment. AR has the capability to process real-time graphics which allows the user to process data faster and more effectively [31].
- Detection of errors: [30] mentioned that the integration of AR and BIM allows subcontractors to immediately recognize the interdependencies between activities. BIM provides the capabilities to identify activities and their interdependencies, and AR serves a visualization tool that provides a context for the work that needs to be performed in the field. AR also displays singular and integrated views in real-scale, context, and time and allows the planners to accurately recognize design errors, which can, therefore, minimize repeated work.
- Information Access: While BIM aims to consolidate and archive all relevant information related to the project, the merge of AR with BIM improves the information search and access. Users can also filter the 3D model by enabling and disabling different construction phases, levels, activities, and components. Users can also select elements in the 3D model and extract information corresponding to that element. Furthermore, an AR system can be connected to other databases that contain other planning and relevant information that the user can search for and extract.
- Information flow: Replacing 2D drawings and paper-based information storage with data-rich 3D models projected using AR facilitates a seamless flow of information from one stage to the other, providing planners with the needed information at the right time.
- Input Accuracy: AR allows the last planners to better recognize inter-relationships and links between activities. Furthermore, information can be associated with each element, and the user can select a certain component and visualize and read its corresponding information (such as properties, the material used, geometry, etc.). BIM can identify the interdependencies between the various activities, and AR offers a powerful visualization tool to supply such information to the last planner who is directly involved in the execution phase. AR can make the interdependencies between activities more explicit [26].
- Interpretation of Plans: AR can display any chosen single view or integrated view into the real view of the user. The challenge to construct a mental model can be alleviated with AR because 3D models are visualized [26].

5 Prototype Development and Implementation

Developing a prototype is a way to simulate and test the operations of the new process [16]. Instead of describing the new process, prototyping allows the user to visualize and experience it. The prototype developed in this research is a small-scale, quasi-operational version of the AR-enabled PSP.

The AR-enabled PSP prototype is developed for the HoloLens, one of the most widely anticipated display devices for the AR market. Additionally, a study conducted by [32] surveyed 128 construction professionals and showed that Microsoft HoloLens is the device that is most commonly used in construction.

The cross-platform Unity 3D game engine was used to build a proof-of-concept of the AR-enabled PSP. Developing for the Microsoft HoloLens requires the use of the Universal Windows Platforms (UWP) to create 3D (holographic) applications. Such applications use Windows Holographic Application Program Interface (API). Therefore, Microsoft recommends the use of Unity to create 3D applications for the HoloLens.

The 3D model used for the prototype was a Navisworks model of an ongoing healthcare project that was acquired from a construction company. The model had a Level of Devolvement (LOD) 350. From the moment the 3D model was acquired to the time when the validation phase would take place, it was anticipated that the construction team would be developing the production strategy of the overhead to the third floor of the project. Therefore, a series of selection sets were created in Navisworks to only show the overhead work of the third floor. Figure 1 shows the first view that is displayed to the user and consists of the user menu and the section of the 3D model that was used.

Figure 1. User's First View of the menu and the 3D model

6 Prototype Validation

Once the prototype was fully developed and implemented, it was validated on the ongoing healthcare project. A short presentation was delivered to participants to introduce them to the research topic, review the steps of the PSP, explain the technology (AR), outline the research objective, and provide an overview of the demonstration software. Participants were also provided with short tutorial videos that demonstrated the functionalities of the prototypes and asked to familiarize themselves with the software and its capabilities. In addition, the means of interacting with

the prototype (gaze and air-tap, and tap and hold gestures) were explained and demonstrated to the participants.

Participants were first asked to test the prototype and were then asked to complete a survey to capture their feedback. Physical and digital copies of the survey were distributed and a total of 20 surveys were obtained.

6.1 Participants Information

Participants were asked to select their age category. 45% of participants were between 18 and 34 years, 35% between 35 and 44 years, 15% between 45 and 54, and the remaining 5% between 55 and 64. Participants were also asked to specify their current job title. 5 out of the 20 participants are Project Managers and 3 participants are Field Engineer. Single responses were collected from participants with the following titles: Project Engineer, Project Technology, Virtual Design and Construction (VDC) Specialist, Project Manager/BIM Manager, Steamfitter Foreman, Foreman, Mechanical/Electrical/Plumbing (MEP) Coordinator, Senior Project Manager, Director of Production Planning and Innovation, Production Engineer, BIM Coordinator, Member of the Performance and Innovation Resources Team.

The respondents' expertise in construction ranged from 2 years to 27 years, with average expertise of over 13 years. Collectively, the respondents totaled 248 years of experience in construction. During their years of experience in the construction industry, the number of projects that the participants worked on ranged from 2 to over 100 projects. Out of these projects, participants were asked to identify the number of projects on which they have been involved in PSP. The respondents' experience with PSP ranged from 1 project to over 20 projects.

6.2 Technology (AR) Evaluation

The survey included two sets of questions to solicit participants' opinions and feedback regarding the capabilities of AR as a promising technology in PSP. The first set of questions asked participants about their level of agreement with four statements using a five-point scale of strongly disagree (1), disagree (2), undecided (3), agree (4), and strongly agree (5). The results displayed in Figure 2 show that, on average, respondents agree that AR enhances their cognitive understanding of the process, facilitates the decision-making process, provides the user with the needed and desired type of information, and allows for a natural way to interact with the displayed information.

The second set of questions asked participants to rate the impact of the nine AR capabilities on PSP using a five-point Likert scale of very low (1), low (2), moderate (3), high (4), and very high (5). The results are reported in Table 2.

k-means cluster analysis was then performed to identify the capabilities that have the highest impact on PSP. Cluster analysis is a statistical method used to group data by comparing each candidate AR capability, for example, to the other AR capability already in the cluster. If the difference between the candidate AR capability and the other AR capability already in the cluster is significant, then the candidate AR capability is assigned to a different cluster.

The cluster analysis grouped the nine AR capabilities into three clusters based on the participants' average impact, with each cluster encompassing three areas. The three areas of Cluster 1 are the areas where AR has the highest impact on PSP and are as follows: Analytical (3.95), Tracking (3.79), and Informational (3.74).

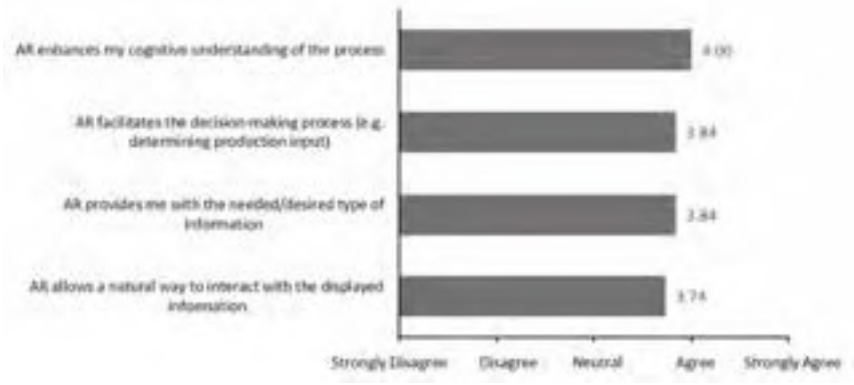

Figure 2. Technology (AR) Evaluation Criteria

Table 2. Clustered Table of the impact of AR Capabilities on PSP

AR Capability	Explanation	Average Impact	Clusters
Analytical	Improving the analysis of information and decision making	3.95	
Tracking	Closely monitoring process status and objects	3.79	Cluster 1
Informational	Capturing process innovation for purposes of understanding	3.74	
Geographical	Coordinating process across distances	3.63	
Integrative	Coordinating between tasks and processes	3.58	Cluster 2
Sequential	Changing process sequence or enabling parallelization	3.47	
Automation	Reducing human labor from a process	3.16	
Disintermediating	Eliminating intermediaries from a process	3.16	Cluster 3
Intellectual	Capturing and distributing intellectual assets	3.05	

6.3 User Experience

Another question in this section asked respondents to describe their experience using the AR-Enabled PSP. Figure 3 shows that participants saw this experience as engaging, interesting, innovative, fun, and easy.

Figure 3. User Experience (generated with WordItOut)

7 Conclusions

As interest in AR continues to grow, this paper explored the impact of AR on PSP – an information-intensive process. The current state of PSP and its challenges were first reviewed. Then, nine AR capabilities were discussed and a matrix was developed to explain how these capabilities can address the PSP challenges. Next, an AR-enabled PSP prototype was developed for the HoloLens and validated on an ongoing healthcare project. Twenty construction practitioners were asked to test the prototype first and then completed a short survey. Survey results showed that participants agreed on average that AR enhances their cognitive understanding of the process, facilitates the decision-making process, provides them with the needed and desired type of information, and allows for a natural way to interact with the displayed information. According to participants, the average impact of the AR capabilities varies between high and moderate with Analytical, Tracking, and Informational being the areas with the highest impact (cluster 1). Overall, participants saw this experience as engaging, interesting, innovative, fun, and easy and recognized the value AR can add to the PSP.

While this paper focused on integrating AR into the production planner process, further studies can build upon this work and study the integration of AR throughout the entire production planning and control system.

8 Acknowledgments

The authors would like to thank The Boldt Company for their continuous support throughout this research effort and for partially funding this project. The authors would also like to thank Parker Schroeder for helping in implementing the AR-enabled PSP.

Abstract –

Recently, the demand for base-isolated structures has been increasing, especially in Japan. For reliable construction of seismic isolation devices, contractors must ensure that the area ratio of the air bubbles occupying the backside of the base plate does not cross the threshold, which is decided by the structural designer. However, the backside of the base plate can include larger and more air bubbles than ordinary concrete surfaces as it is difficult to pour concrete into the foundation properly. Additionally, the inspection process includes many time-consuming tasks. Therefore, it normally takes about one week or longer after concrete work to perform the inspection.

We present a method to automate the tasks relating to inspection, including image preprocessing, air bubble extraction, and calculation of the area ratio of the air bubbles, using conventional image processing and a convolutional neural network (CNN) to speed up the inspection.

While CNN normally requires a significant amount of training data to achieve high performance, it is generally difficult to collect such a large amount of high-quality data. We have conducted thorough accuracy inspections to evaluate the appropriate amount of training data required. Additionally, we have verified the effect of data augmentation and compared the performance of certain typical CNN architectures.

As a result, our method has obtained results that are close to those of manual inspection by a skilled inspector. We can conclude that our method can reduce the overall inspection time by 50% compared to conventional methods.

1 Introduction

The demand for seismic base isolation has increased due to the number of earthquakes experienced across the world, especially in Japan. Seismic isolation devices are installed at specific levels of the building in a base-isolated structure to reduce the tremble caused by earthquakes. As shown in Figure 1, seismic isolation devices are installed on the base plate, which is set on the base-isolated foundation. To integrate the base plate into the foundation correctly, it is necessary to pour concrete with the base plate in place, as shown in Figure 2. This pouring process could lead to the formation of air bubbles underneath the base plate, which should be avoided. As these bubbles negatively affect adhesion, their area ratio should be decreased to increase the adhesion force. However, the removal of the base plate is not allowed during the construction phase to check for the presence of air bubbles. Therefore, a full-scale construction field test is required before the base-isolated foundation work.

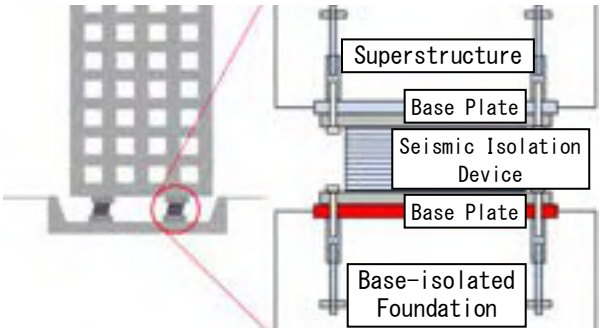

Figure 1. Cross-section of base-isolated foundation

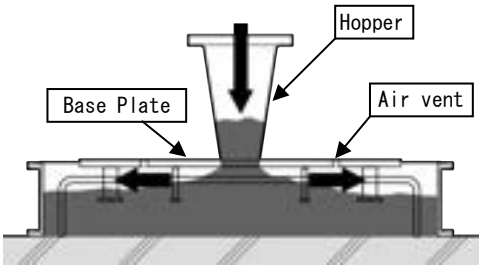

Figure 2. Methodology to cast concrete underneath a baseplate

A field test is conducted to inspect whether the ratio of the area of the air bubbles to that of the concrete surface satisfies the criteria that are generally set by structural designers. According to [1], the criteria for the ratio of the area of air bubbles is defined as less than 10%, which differs for each project. We need to locate air bubbles and measure each bubble's maximum diameter and area to calculate the area ratio. As there can sometimes be over 1000 air bubbles, the entire inspection process is time consuming and work intensive.

The purpose of the field test is to confirm whether the planned workflow of the base-isolated foundation is appropriate. Base-isolated foundation work can begin when the result of the field test is verified. However, if the field test does not pass the criteria, the concrete placement plan must be reconsidered. Naturally, the field test must also be repeated.

This study introduces a method to automate the entire inspection process in the field test using conventional image processing and a convolutional neural network (CNN). Additionally, we have conducted many accuracy inspections to evaluate the appropriate amount of training data and to determine which architecture is suitable for the considered purpose. The remainder of this paper is organized as follows: related works are reviewed in Section 2, the conventional inspection method is presented in Section 3, the proposed method is introduced in Section 4, the experiments and results at the actual site are described in Section 5, and the conclusions are presented in Section 6.

2 Related Work

Many technologies have been developed to improve productivity in concrete work [2]. Their scope is not restricted to construction as they can be applied to inspection. Visual inspection is one of the important examinations in concrete work. Prasanna et al. [3] developed an automated crack detection algorithm for robot inspection.

As in the present study, previous research has used CNN and other machine learning approaches to tackle this issue. Cha et al. [4] developed a crack damage detection method based on a CNN architecture. They mentioned that CNN is more robust than conventional approaches, such as the Canny and Sobel edge detection methods. Gang et al. [5] tested certain typical CNN architectures for tunnel crack detection. As listed here, many studies have focused on automatic crack detection systems.

However, certain studies have also focused on automatic air bubble detection on the concrete surface. Yoshitake et al. [6] developed a method for tunnel lining. Gang et al. [7] developed a CNN-based method and compared it to Otsu's thresholding method and Laplacian of Gaussian (LoG) algorithm. They concluded that their method was more robust against various light conditions. Fujia et al. [8] tested a popular CNN architecture for semantic segmentation, which is a major field in computer vision. The goal of semantic segmentation is to classify the class labels at the pixel level.

In contrast to prior studies, this study specifically focuses on the concrete surface of the backside of the base plate in base-isolated structures, rather than the concrete surfaces on more classical architectural elements, such as walls and columns. The backside of the base plate normally includes more air bubbles than the surfaces of other architectural elements, as it is difficult to vent the air from the bottom of the base plate properly. Additionally, it is not possible to check how the concrete is being filled during the construction owing to the base plate structure. Therefore, the bottom of the base plate can include many air bubbles, of sizes larger than those on ordinary concrete surfaces. In a report focusing on the detection of air bubbles at the bottom of the base plate, Mitani [9] and Katoh [10] evaluated the accuracy of their method, which connected 2 CNN architectures that were used for object detection and semantic segmentation. However, the main targets of most object detection methods based on CNN are the objects, which are along the XY coordinates. This is due to the manner in which object detection methods are trained. In the training process, they normally evaluate if they properly detect the target objects by using bounding boxes that are along the XY coordinates. In contrast, air bubbles are multi-oriented objects. Therefore, they can be impediments in the training process as their bounding boxes can cover a wide area of the concrete surface and may intersect with other air bubbles.

In contrast, as semantic segmentation methods generally do not depend on the axes on which target objects are based. Thus, we only used a CNN architecture for semantic segmentation to deal with various types of air bubbles. Additionally, this paper presents a method to automate the entire inspection and air bubble detection processes. Here, we employ conventional image preprocessing approaches, followed by semantic segmentation with a CNN structure, to detect air bubbles accurately. Each of these processes will be explained in Section 3.

3 Conventional Inspection Method

In the field test, according to the construction plan, concrete work is conducted at the beginning, after which the base plate is removed. Marking work is then

completed as a preparation for the area ratio calculation (Figure 3). If the area ratio satisfies the criteria, the construction site can proceed to the actual construction phase. The area ratio calculation in conventional inspection is composed of the following steps.

1. Color the air bubbles red by hand using markers. (Figure 4)
2. Take a picture of each grid.
3. Preprocess pictures, through keystone correction, cropping, and resizing of each picture using an image processing software.
4. Color the areas that are not on the backside of the base plate, as this is outside the scope areas of the inspection. (Figure 4)
5. Automatically extract the colored air bubbles identified in step 1 using the software. If necessary, correct the extracted results manually.
6. Exclude the air bubbles that are less than the specified diameter. (Figure 4)
7. Repeat steps 3 to 6 for each grid.
8. Automatically calculate the area ratio of the air bubbles against the area of the concrete surface.

It is important to note that certain tasks need to be carried out carefully. To perform accurate automatic extraction in step 5, it is necessary to color the air bubbles accurately in Step 1, and then take a picture from the front of the concrete surface as much as possible in Step 2. Although keystone correction in Step 3 is necessary irrespective of how carefully the pictures are taken, the lower the distortion, the higher the obtained image quality. The areas identified as out of scope in Step 5 indicate locations that can be ignored. These not only include the outside of the backside of the base plate but also on bolts, air vent holes, and pressure inlets. As shown in Figure 4, these areas are colored using different colors so that they are ignored during the color extraction process in Step 8. Additionally, a negligible minimum diameter is normally set for this inspection. The air bubbles that are smaller than the minimum diameter need to be colored in Step 6 (colored black in Figure 4). After all the grids are processed completely from Steps 1 to 6, the area ratio can be automatically calculated by using the color extraction method.

The conventional inspection method involves a lot of manual work. Additionally, the number of pictures to be processed can reach up to 100 per specimen. Further, if the construction site has multiple design types of base-isolated foundations, the field test must be conducted for each design. Thus, the tests need to be performed by a skilled inspector to hasten the entire process. However, despite having a skilled inspector for the field test, the process takes about a week after the completion of concrete work to obtain the test results when using the conventional inspection method.

Figure 3. Concrete specimen and marking work

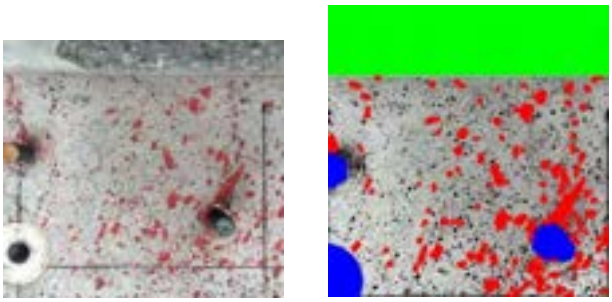

Figure 4. Before preprocessing (Left), result of preprocessing (Right)

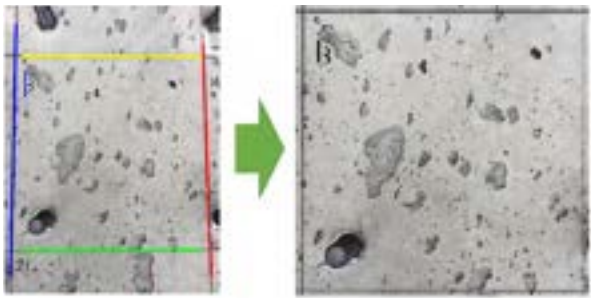

Figure 5. Example of processed marking recognition, keystone correction, and cropping

4 Methodology

4.1 Automation of preprocessing using a conventional image processing method

The preprocessing described in Step 3 in the previous section includes keystone correction, cropping, and resizing. This is necessary to calculate the area ratio in the real scale from a photograph. The preprocessing is performed manually using an image processing

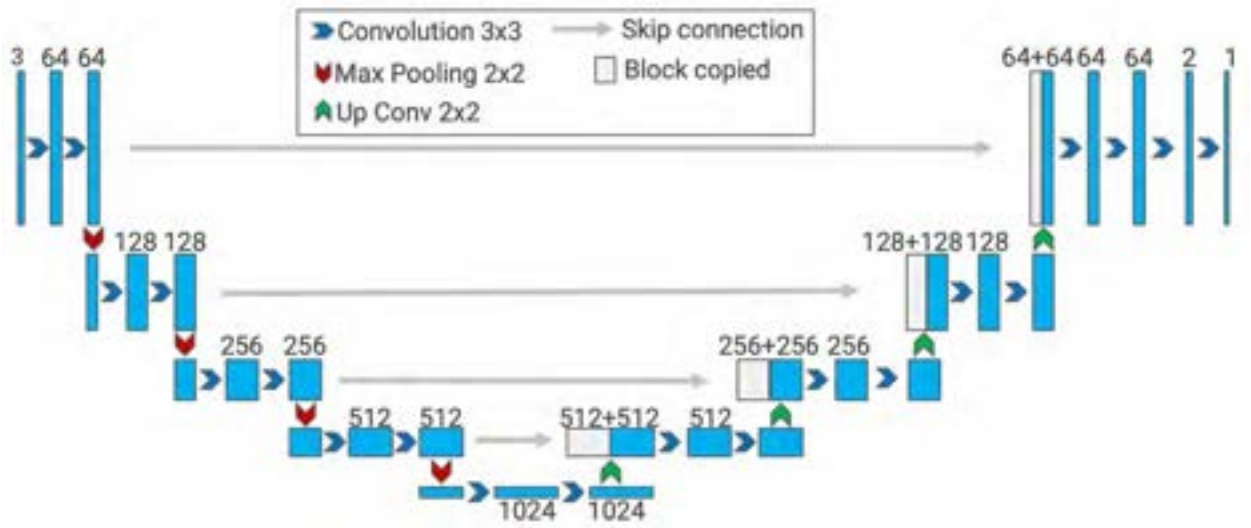

Figure 6. Network architecture based on U-Net. Each number describes the number of channels in each convolutional layer.

software. This process takes about one day, even for a skilled inspector.

To automate the keystone correction process, it is first necessary to recognize the marked grids automatically. In this study, we use a template-matching algorithm to achieve this. The template-matching algorithm can detect the areas in the image that have a pattern similar to the pattern of the input template. We prepared simple vertical and horizontal templates to detect the grids. As a result, the algorithm can detect the grid lines as four different colored lines, as shown on the left side in Figure 5.

Keystone correction utilizes the results of template matching. It needs to calculate the conversion matrix from a perspective image to an orthogonal image. It uses the four corner points detected by template matching for this. As a result, we obtain a square image that does not contain the perspective distortions, as shown on the right side in Figure 5.

The image is then resized to the specified resolution. This process clarifies the relationship between the pixels and the real scale. The resolution used in this study was set to 2000 px.

4.2 Automation of air bubble detection using a CNN

In this study, a U-Net-based architecture is utilized for automatic bubble detection. The U-Net was designed for semantic segmentation, which won the International Symposium on Biomedical Imaging (ISBC) cell tracking challenge in 2015 [11]. Semantic segmentation is a typical task in the machine learning field and is performed to classify images in pixel units.

As shown in Figure 6, the U-Net is mainly composed of two symmetry paths for encoding and decoding, where each path is composed of multiple layers of CNN blocks. Each layer has a connection from the encoding path to the decoding path. The connections contribute to maintaining a wide context in each focus area. The U-Net was originally designed for biomedical image segmentation, but its simple architecture can be utilized for many purposes, including air bubble detection. Therefore, we adopt the U-Net as the base architecture of our method.

CNN is a type of neural network that normally consists of many convolutional layers. Each layer has many filters, and each filter can be trained to extract various types of image features. In contrast to CNN and recent learning-based algorithms, conventional image processing algorithms are not robust in diverse environments. Several studies referenced in Section 2 report that CNN is more robust to changes in the light environment than conventional image processing algorithms.

Although CNN is more accurate and robust, its

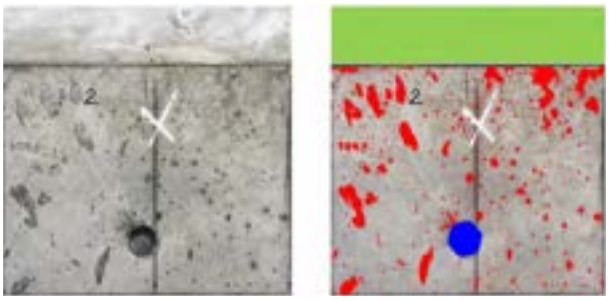

Figure 7. Sample pair of training data

training process needs a large amount of training data. Additionally, U-Net belongs to a supervised training algorithm, indicating that the training dataset needs to have not only images but also labels that describe the classes to which each pixel in the image belongs. Therefore, we collected a large amount of data, as shown in Figure 7.

While a learning-based algorithm is used for air bubble detection, the postprocessing, including calculation of each air bubble's maximum diameter and area, uses the thresholding and contour extraction method. As mentioned in Section 3, small air bubbles that have maximum diameters less than the specified length are ignored in the inspection. In Section 5.2, the negligible diameter is set to 5 mm.

5 Experiments

5.1 Basic Experiments

We evaluated different combinations of datasets to identify a suitable amount of training data to obtain a high-performance trained model. We collected 452 images from 4 construction sites, with varying characteristics and light environments. Additionally, four images from each construction site were used as test data. Therefore, in total, 436 training data points and 16 test data points were considered. Each image was divided into smaller images, as processing high-resolution images requires a large GPU memory. Thus, the resolution was set to 512 px.

Precision, recall, intersection over union (IoU), and F1 scores were used as metrics to evaluate each result. Equations (1), (2), (3), and (4) define these metrics. Figure 8 describes each value of the equations, such as true positive (TP), true negative (TN), false positive (FP), and false negative (FN). In this study, we assign

$$Precision = \frac{TP}{TP + FP} \quad (1)$$

$$Recall = \frac{TP}{TP + FN} \quad (2)$$

$$IoU = \frac{TP}{TP + FP + FN} \quad (3)$$

$$F1\ Score = \frac{2Precision * Recall}{(Precision + Recall)} \quad (4)$$

		Actual	
		Positive	Negative
Predicted	Positive	True Positive (TP)	False Positive (FP)
	Negative	False Negative (FN)	True Negative (TN)

Figure 8. Confusion matrix used for the evaluation

Table 1. Training Dataset

Dataset	Site 1	Site 2	Site 3	Site 4	Total
S1	10	10	10	10	40
S2	30	30	30	30	120
S3	60	60	59	60	239
S4	223	94	59	60	436

Table 2. Results of Each Dataset (N = 16)

Dataset	Precision	IoU	Recall	F1 Score
S1	0.803	0.687	0.835	0.812
S2	0.874	**0.769**	0.869	**0.868**
S3	**0.888**	**0.769**	0.856	**0.868**
S4	0.839	0.763	**0.897**	0.863
Otsu	0.686	0.563	0.786	0.712

the greatest importance to the F1 score, as it can evaluate not only precision but also recall.

We prepared four datasets, as shown in Table 1, to evaluate the effect of the amount of training data. Table 2 presents the results obtained using the datasets. According to the results, the result of S2 was almost the same as that of S3 and slightly better than that of S4. The result indicates that 30 images from a construction site can contain most of the patterns in the construction site. Additionally, we evaluated Otsu's automatic image thresholding [12] as a baseline result of conventional image processing. The result is shown at the bottom of Table 2. The result is lower in all metrics compared to the results of our method, even if the dataset is as small as S1. This means that air bubbles are not always darker than concrete surfaces and have various characteristics.

To improve the results, we additionally conducted a study using data augmentation (DA). DA is known as the general technique to improve the results of machine learning algorithms. It includes a wide variety of manipulations, but we used only simple image processing methods, such as rotation, mirroring, expansion, contraction, color channel shifting, brightness, and random crop. The results are shown in Table 3. It increased the F1 score by 0.024. The result shows that DA can work well in our domain as well as in the other domains.

Table 3. Results of Data Augmentation (N = 16)

Dataset	Precision	IoU	Recall	F1 Score
S4	0.839	0.763	**0.897**	0.863
S4+DA	**0.885**	**0.800**	0.895	**0.887**

5.2 Additional Experiments

In addition to the experiments presented in the previous section, we conducted several experiments to identify the generalization of the trained model and

prepared additional datasets, as shown in Table 4.

S4 was the same as the dataset used in the previous section. S5 included the data from S4 in addition to the data from Site 5, 6, 7, and 8, and S6 included data from S5 in addition to data from Site 9.

Table 4. Training dataset for generalization test

Dataset	Site 1–4	Site 5–8	Site 9	Total
S4	436	0	0	436
S5	436	494	0	960
S6	436	494	32	992

In this test, four images from Site 9 were used as the test data. Site 9 was not included in S4 and S5 and was included only in S6. To clarify the results, we used a simpler DA approach, such as slight rotation, expansion, contraction, mirroring, and random crop, in this test.

As shown in the result in Table 5, the higher the number of training data points, the more accurate the result. However, while S5 had almost the same number of training data points as S6, the result was not at the same level. This means that obtaining good results requires more diverse data or data from the construction site where our method was planned to be use.

Table 5. Results against test data from Site 9 (N=4)

Dataset	Precision	IoU	Recall	F1 Score
S4	0.726	0.615	0.792	0.756
S5	0.724	0.684	**0.927**	0.809
S6	**0.913**	**0.823**	0.894	**0.902**

Additionally, to evaluate the capabilities of different architectures, PSPNet [13] and DeepLabv3+ [14] were compared to the U-Net-based architecture. Both PSPNet and DeepLabv3+ are known for their well-designed architectures that enable them to exploit a broad image context. In this study, ResNet-101 [15] was used as the backbone architecture for PSPNet and DeepLabv3+.

We used the S6 dataset to train all the architectures during the test. Additionally, four images from 8 construction sites were used as test data, totaling 32 data points for the test. We also used a simple DA, similar to that used in the previous test.

As shown in Table 6, our U-Net-based architecture obtained the highest F1 score. This was almost the same as the results for S2, S3, and S4, as described in Table 2.

Table 6. Results of Architecture Comparison Including Negligible Air Bubbles (N = 32)

	Including negligible air bubbles			
Architecture	Precision	IoU	Recall	F1 Score
U-Net based	0.873	**0.768**	**0.869**	**0.865**
PSPNet	0.885	0.643	0.698	0.774
DeepLabv3+	**0.916**	0.704	0.754	0.821

Table 7. Results of Architecture Comparison Ignoring Negligible Air Bubbles (N = 32)

	Ignore negligible air bubbles			
Architecture	Precision	IoU	Recall	F1 Score
U-Net based	0.864	0.687	0.770	0.803
PSPNet	0.860	0.710	**0.805**	0.819
DeepLabv3+	**0.909**	**0.715**	0.770	**0.821**

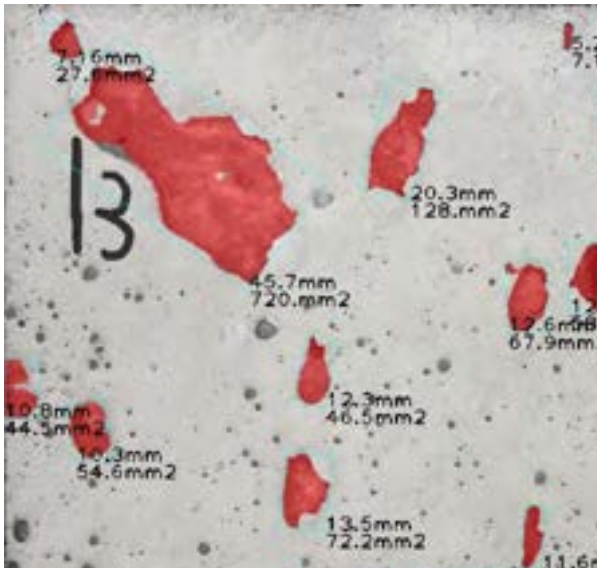

Figure 9. Result of the proposed method

However, while our U-Net-based architecture can detect almost all the smaller air bubbles, we found that it sometimes did not work well against larger air bubbles. Therefore, we reevaluated the results while ignoring the negligible air bubbles. As mentioned earlier, the negligible length was set to 5 mm. Table 7 shows the results, and Figure 9 shows the predicted result.

It can be seen that when the negligible length is ignored, the results change significantly. The recall of PSPNet was increased by 0.097, indicating that it was good at detecting larger air bubbles but not smaller ones. However, the recall of our U-Net-based architecture declined by 0.139. This reveals how well this architecture worked against small air bubbles. Additionally, Table 7 shows that our U-Net-based architecture maintained a comparative F1 score in this study.

From these results, we found that the dataset used in this paper needs not only the capability of detecting details, but also the capability of wide perception. For future work, continuous exploration of CNN architectures will be required to achieve higher performance.

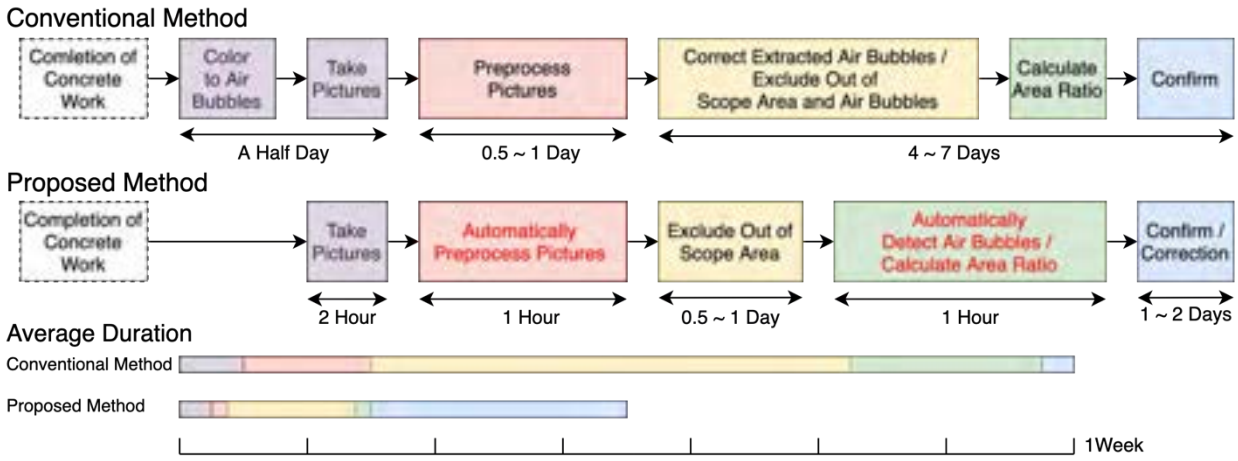

Figure 10. Workload Comparison between Conventional Method and Proposed Method, assuming that 100 pictures have to be processed.

5.3 Workload Comparison between the Conventional Method and Our Method

In this section, the workload between the conventional method and the proposed method is compared to evaluate the effect of the proposed method. The best-performing model in Section 5.1 was used for air bubble detection.

Figure 10 shows the workflow and workload of the conventional method and the proposed method. As shown here, the conventional method generally took approximately one week. The main tasks in the conventional method included preprocessing images and coloring of the air bubbles by hand. However, these manual steps were avoided in our method. At this moment, the predicted results still contain some false detections. However, as mentioned earlier, the U-Net based architecture works well against smaller air bubbles.

Therefore, in this comparison, the inspector did not have to care about the smaller air bubbles. The area ratio was obtained with a high degree of accuracy by correcting the oversight of large air bubbles. The surface of the base-isolated foundation used in this comparison has 64 grids. Considering these grids, the area ratio obtained manually was 6.19%, and that calculated by our method, with oversight correction, was 6.56%. Additionally, the oversight correction took less than 2 hours since the inspector only focused on correcting the oversight of large air bubbles.

Although the performance of our method needs to be improved, we have confirmed that it is effective in reducing the overall inspection time. Additionally, regarding the automation of preprocessing, we found that it worked almost perfectly for the expected situation where the grid was marked. Although it sometimes does not work well when including traces of the base plate's boundary, we conclude that it contributes to improving the speed of the preprocessing step.

From the above results, we conclude that our method can reduce the overall inspection time by 50%.

6 Conclusion

In this study, we developed a method to automate concrete surface inspection of a base-isolated structure. This paper presented a method that uses conventional image processing algorithms and a learning-based algorithm. Conventional image processing algorithms, such as template matching, thresholding, and contour extraction, were used for preprocessing and postprocessing of the images. For the learning-based algorithm, we used a U-Net-based architecture for automatic air bubble detection.

In the experiments, we evaluated the performance of our method, recording a best F1 score of 0.887. When the salient false detections are corrected by hand, the difference between the area ratio calculated using our method and the area ratio calculated manually by a skilled inspector was 0.37%. Furthermore, the workload between the conventional method and our method was compared. As a result, although the results predicted using our method needed to be corrected by hand, our method can reduce the overall inspection time by 50%.

In conclusion, this paper demonstrates the promising performance of the proposed method. While there is still room for improvement in terms of performance, this paper shows that our approach can automate the entire inspection process. There are many other promising CNN architectures and techniques available to improve

the performance. Accordingly, future work should focus on exploring better architectures and correcting more training data.

Abstract –

A majority of safety accidents in construction workplaces stem from workers' unsafe behaviors. Such unsafe behaviors are often caused by "risk habituation," the tendency to underestimate a risk after previous repeated exposure to similar hazardous situations. Understanding the risk habituation process in construction is critical for intervening and preventing the unsafe behaviors that it causes, but the approaches adopted in previous studies, which are retrospective and self-evaluative, pose challenges to gaining an unbiased understanding of the factors affecting this habituation process. In this context, this study exploits virtual reality (VR) as an experimental tool to examine the risk habituation process in construction and demonstrates the validity of the approach. A VR model that engages a subject in a road reconstruction project is designed and developed, and then is used to repeatedly expose subjects to struck-by hazards and warning signals for such hazards. The results from the pilot experiment indicate that the developed VR model is effective in replicating and accelerating the risk habituation process, thereby allowing researchers to more expeditiously study the factors influencing risk habituation process.

Keywords –

Construction safety; Risk habituation; Virtual reality; Unsafe behavior; Safety training

1 Introduction

"Habituation" is the decline of a response to a repetitive stimulus [1]. Similarly, the capability of a stimulus to elicit a response can be diminished when the stimulus occurs repeatedly [2]. Such habituation can result in workers being less cautious about stimuli associated with hazards in workplaces when the stimuli present, and therefore to workers engaging in unsafe behaviors [3]. This problem is relevant to the construction industry, where workers have been found to be prone to becoming habituated to hazards after exposure to repeated hazardous situations [4] at construction sites. Workers who are habituated to hazards tend to underestimate risks and put themselves at jeopardy of being in an accident [5]. This behavioral phenomenon is called "risk habituation" [6], and is considered one of the main causes of workers' unsafe behavior. Many researchers and practitioners are dedicated to understanding why and how workers underestimate risk and engage in unsafe behaviors, but previous studies have mostly relied on the capability of subjects to recall when they were in hazardous situations. Consequently, the results can be biased and cannot clearly explain the developmental process of risk habituation [7–11]. Furthermore, it is extremely difficult to control moderating and influencing factors in risk habituation in field experiments, due to their potential to harm subjects [12]. In this context, this study aims to design and evaluate the validity of a virtual reality (VR) model as an experimental tool to examine an individual worker's risk habituation process.

2 Background

Around 80–90% of all workplace accidents are caused by workers' unsafe behavior [9,13,14]. Previous studies have shown that an individual's risk perception significantly affects his/her unsafe behaviors at construction sites. Repeated exposure to hazards in the workplace can cause a bias to form in workers' risk perception [15]. Even if workers properly identify hazards, they may engage in risky behavior due to improper perception and evaluation of risk [16]. Irizarry and Abraham [17] examined the factors influencing the risk perception of ironworkers, and their results indicate that long tenure in working experience at workplaces is correlated with unsafe behavior caused by bias in workers' risk perception. Majekodunmi and Farrow [4] investigated the risk perception of lift truck operators. Their results indicate that repeated exposures cause workers to become accustomed to the hazards related to their tasks. While these studies indicate that risk

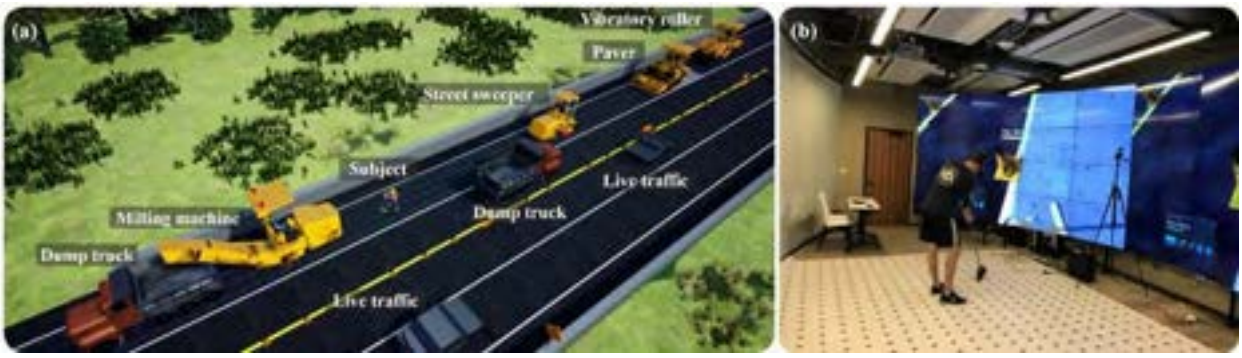

Figure 1. Experimental environment: (a) the landscape of the immersive virtual road construction environment, (b) the Building Information Modeling-Computer Aided Virtual Environment (BIM-CAVE)

habituation is one of the factors causing unsafe behaviors, a knowledge gap still exists as to which specific personal and situational factors critically influence the development process of risk habituation and how this development process can be intervened in, due to the methodological limitations of the approaches adopted in the previous studies, which were uniformly retrospective and self-evaluative.

With the recent development of virtual reality (VR) technologies, VR has emerged as an experimental tool for examining workers' unsafe behaviors. VR-based safety interventions in previous studies have enabled researchers to expose subjects to virtually replicated hazardous situations without any actual risk. Albert et al. [18] showed that as a safety intervention platform, VR can provide close-to-reality simulations. Thus, workers can evaluate the risks of hazard very similarly in the VR environment as in a real environment. Moreover, VR enables researchers to analyze workers' behaviors in near real-time. Many researchers have therefore utilized VR to investigate construction workers' behavior in dangerous situations. For instance, Hasanzadeh et al. [19] attempted to observe a roofer's risk-taking behavior in the virtual environment (VE) and demonstrated that a group of roofers with more safety protection took more risks than other groups in the VE. Shi et al. [20] utilized a VR model as an experimental tool in order to show the effect of accident experiences on workers' fall risk behavior. To this end, this study exploits VR as an experimental tool to address uncertainty in construction workers' risk habituation processes. An immersive VE for road construction is developed to expose workers to repetitive hazardous situations. Leveraging data acquired from subjects' physical responses to hazards in the VE, this paper demonstrates the approach's validity as an experimental tool to examine an individual worker's risk habituation.

3 Methodology

The objective of this study has been accomplished in three phases. An immersive virtual road construction environment was built and a cyber-physical interactive system that synchronizes the actual movement of a subject with a virtual movement in the VE was developed. A pilot experiment was then conducted to observe and evaluate how the risk habituation process in the VE develops. The data from the pilot experiment was analyzed to identify the relationship between repeated exposures to hazards and subjects' responses to repetitive hazards in the VE.

3.1 Designing the Scenario

A road maintenance workplace in which subjects would be part of an asphalt milling crew was selected for the VE development scenario (Figure 1-a), as such a scenario is high-risk and likely to cause risk habituation in the VE. Road construction and maintenance work repeatedly exposes workers to struck-by hazards such as working adjacent to live traffic and heavy construction equipment; 532 workers were killed at road construction work zones between 2011 and 2016 in the United States [21]. The proposed VR model focuses specifically on the construction equipment risk, with a subject at risk of being struck by a dump truck, street sweeper, or other piece of heavy construction machinery.

A normal asphalt removing, and paving work process was modeled in the VE. As the first step of the process, a milling machine removes the surface asphalt of a highway and loads the millings onto a fleet of dump trucks to haul off-site. As part of the cleaning crew, a subject then follows closely behind the milling machine and carefully sweeps the surface to remove debris. Behind the subject, a street sweeper moves back and forth

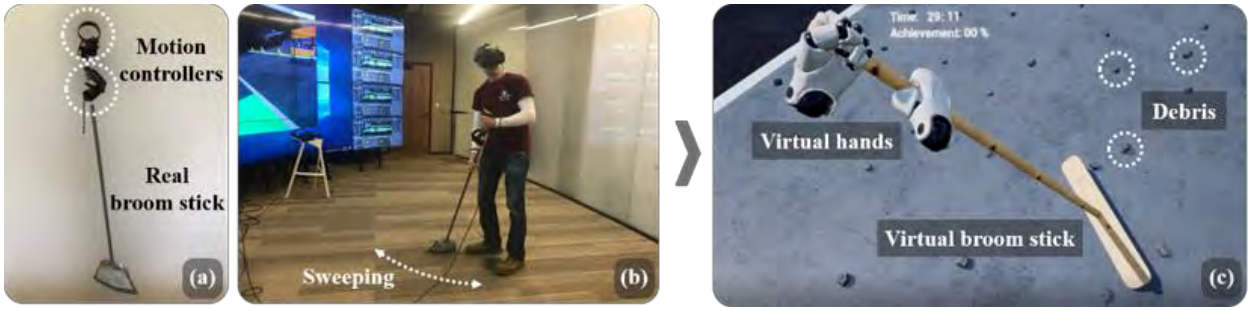

Figure 2. Cyber-physical interactive system for hand-movement synchronization; (a) Motion controllers on real the broomstick, (b) sweeping in the real world, (c) debris on the surface in the VE

continuously. After that, the paver will lay down asphalt, and a vibratory roller will move forward. Next to the lane where the asphalt maintenance takes place, a fleet of dump trucks intermittently moves to supply materials. Live commuter traffic takes place also within the construction work area. In this VE, the various pieces of road construction equipment (e.g., the milling machine, roller, and other machinery) expose each subject to the risk of a struck-by accident and allow researchers to observe subjects' responses to repeated hazards.

3.1.1 Immersive Virtual Road Construction Environment Modeling

Unreal Engine 4 (UE4) was adopted to develop an immersive virtual road construction environment. UE4 offers various project templates, allowing researchers to rapidly develop a VE. All models used in this study are drawn using Maya and 3dStudioMax. Then, all aspects of an immersive virtual environment were created using UE4 with a graphical user interface in order to induce risk habituation in subjects while working in close proximity to live traffic and heavy equipment in the VE.

3.1.2 Hazards and Non-Player Characters (NPC) Setup

Life-threatening hazards in highway construction sites (e.g., adjacent live traffic, heavy construction equipment, and a fleet of dump trucks moving near workers) were simulated in the VE. All the interactive components in the VE respond to behaviors of a subject. Behind a subject, the street sweeper moves back and forth at a constant speed. An alarm sounds as the street sweeper moves forward in order to notify its proximity to a subject. The movement of the sweeper is subject to the distance between a subject and the street sweeper, and repeatedly endangers a subject to struck-by accident. Next to the lane where the road maintenance takes place, dump trucks intermittently pass by very close to the subject, with accompanying warning alarms. These movement cycles of the sweeper and dump trucks will continue while the subject performs the task.

3.1.3 Cyber-physical Interactive System

The level of immersiveness in any VE plays a crucial role in VR-based safety training [22]. Feeling the VE as a real working environment is an important factor in VR-based safety training [23]. To achieve the necessary high level of immersiveness, a cyber-physical interactive system was applied. Motion controllers for a Head Mounted Display (HMD) were attached to a real broomstick (Figure 2-a), and the movements made by a subject sweeping in the real world is then linked to the broomstick in the VE (Figure 2-b). This physical interaction addresses the limitations of previous VR-based safety research that did not consider the influence of actual human body movements in a VE [8]. Moreover, in order to realize a high level of fidelity, around 1,000 pieces of debris were placed on the road in the VE. This debris is responsive to each subject's sweeping movements in the VE. The goal of the subject is to remove all debris and clean the entire surface of the road by sweeping with the broomstick (Figure 2-c).

3.2 Risk Habituation Measurement

In this study, habituation is defined as the decline of a subject's hazard-checking behavior and the increase of the number of deviations in the working lane. For the purpose of observing the risk habituation development process, this model monitors hazard-checking behaviors of a subject and documents the distance to the hazard when a subject undertakes a hazard-checking action as a precautionary action. Hazard-checking behaviors are defined as any movement the subject makes to look for hazards (Figure 3-a); the measurement system that detects subjects' hazard-checking behavior is validated by comparison with video recordings of the experiments. The system documents the distance between the subject and the sweeper when such checking behavior is sensed. In addition, the system records the movement trajectory of subjects in order to detect the moment when a subject deviates from the working lane, regardless of the risk of being struck by the truck. The analysis of the movement

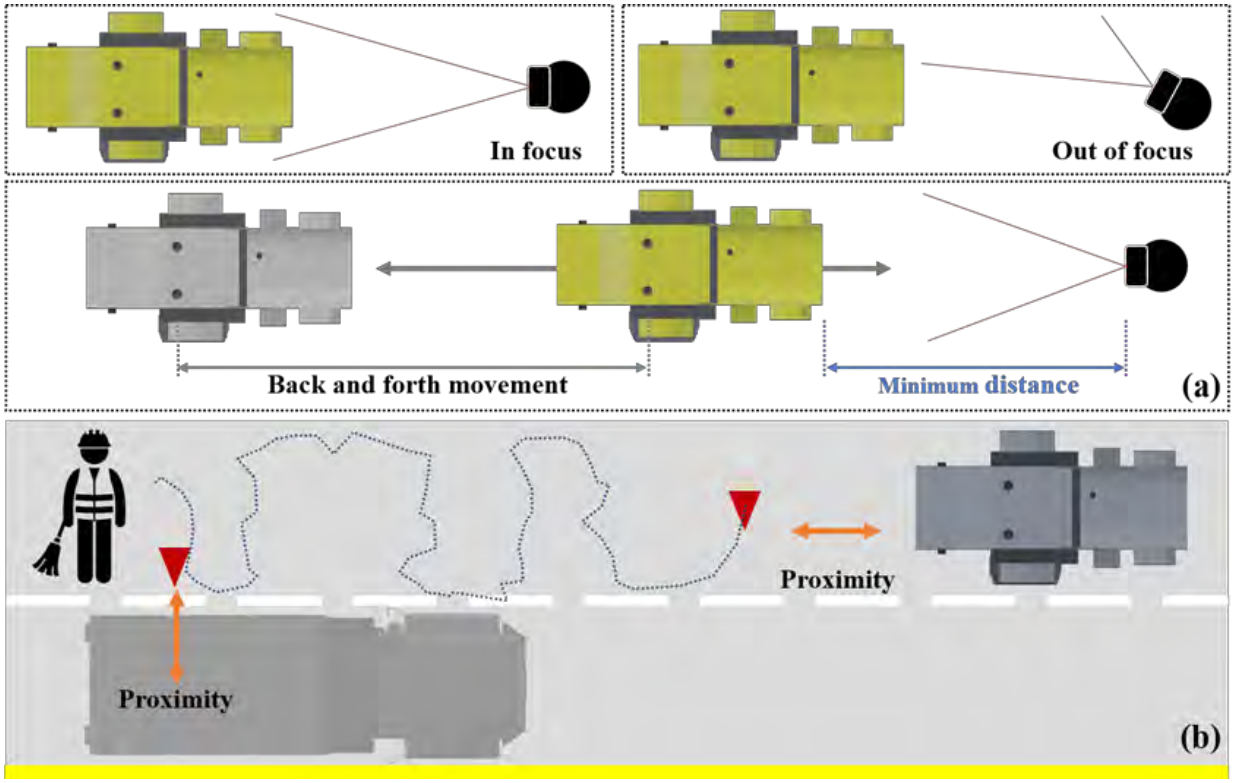

Figure 3. Unsafe behavior measurement system; (a) detecting the hazard-checking behavior, (b) recording the movement trajectory of a subject

trajectory allows researchers to identify when and how a subject becomes habituated to the risk of being struck by accident (Figure 3-b). The location of a subject is collected with a peak frequency of 30 Hz.

3.3 Pilot Experiment Conditions and Procedures

A pilot experiment was performed in the Building Information Modeling-Computer Aided Virtual Environment (BIM-CAVE) at Texas A&M University (Figure 1-b). Three subjects who are graduate students in the department of construction science were recruited for a pilot experiment; none of the subjects had any prior hands-on experience with road construction maintenance work. The following instructions were given: 1) the subjects should follow the milling machine, 2) the subjects should sweep away all the debris from the working lane, and 3) the subjects should pay attention to approaching equipment and warning signals for safety purposes. Completing the overall task in the VE took around 20 minutes, and once a subject ignored the hazards more than 10 times, the experiment was discontinued since this was perceived as a signal that the subject had become habituated to the risk in the VE. A follow-up interview on the perceived immersiveness of the environment was conducted after the experiment.

4 Results and Findings

By analyzing the data directly acquired from the subjects' hazard-checking behaviors, the process of subjects' risk habituation in the VE was observed. Figure 5 demonstrates a relationship between the number of cycles and checking distances of the respective subjects, and the distance between the sweeper and a subject at the moment when s/he undertook an action to check the approaching sweeper at each cycle. The dashed blue lines indicate the designed minimum distance between the sweeper and a subject. If the subject didn't check the sweeper's position until the minimum distance was reached, this was regarded as unsafe behavior. The data points marked with black in the graphs indicate subjects' unsafe behaviors. The highlighted parts of each graph represent the moment where the subjects' unsafe behaviors rapidly increased and give an opportunity to identify which subjects became accustomed to the hazard more quickly than the others. All distances were measured employing Unreal units, the default measure of length within the Unreal Engine environment; one Unreal unit equals one centimeter.

Table 1. Analysis of subjects' hazard checking behaviors in the VE

Subject #	Mean distance	F	p-value	Slope of the line	Correlation coefficient
Subject #1	984.356	10.106	0.003	- 10.023 ± 2.024	-0.459
Subject #2	939.512	32.628	< 0.001	- 14.345 ± 2.021	-0.670
Subject #3	1096.837	44.628	< 0.001	- 54.176± 2.074	-0.818

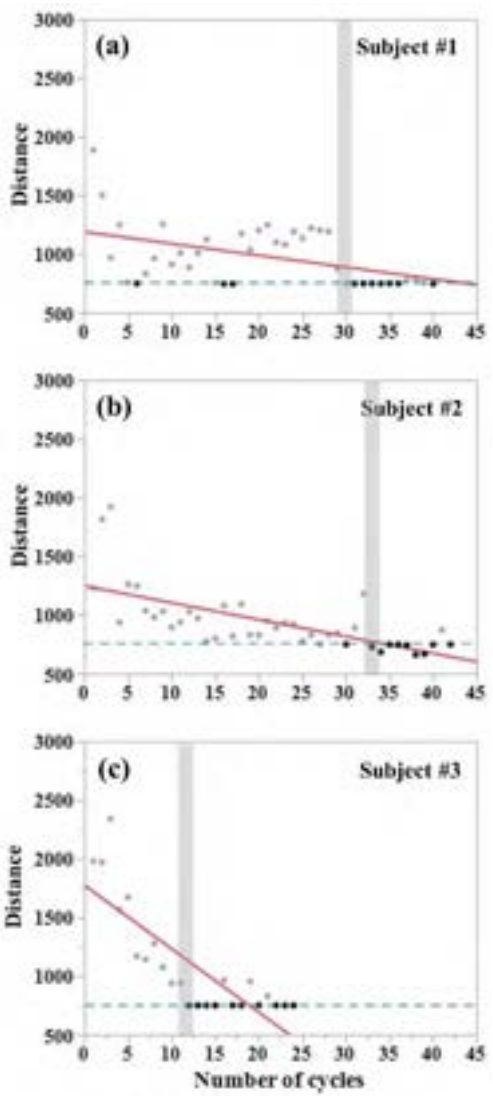

Figure 4. The distance to the street sweeper when subjects checked the proximity of the equipment

To measure the strength and direction of the linear relationship between two variables, the Pearson correlation coefficient, referred to as Pearson's r, was employed. Table 1 shows that there is a statistically significant correlation between checking distances and the number of exposures to the hazard. The checking distance and the number of exposures are moderately negatively correlated in the data from Subject #1 ($r(39) = -.46$, $p = .003$) and Subject #2 ($r(41) = -.67$, $p < .001$), and strongly negatively correlated in the data from Subject #3 ($r(22) = -.82$, $p < .001$). At the beginning of experiment, all subjects immediately responded to the warning sounds and looked back to check the source of warning alarm. However, as the number of cycles (i.e., the number of exposures to the hazard) increased, subjects responded more slowly, and the checking distances gradually decreased in all three subjects. The correlation coefficient and slope of the line of Subject #3 show the strongest negative linear relationship among three subjects. Subject #3 ignored the hazard 10 times out of 22 times. This indicates that Subject #3 became habituated to the hazard more quickly than other subjects (Figure 4). After the experiment, the subjects reported how they felt and why they ignored the hazard. Subjects answered that they no longer paid attention to the hazards and began to act dangerously from the moment when they focused on the completion of the task and started to This debris is responsive to each subject's sweeping movements in the VE believe the surrounding hazards would not hurt them. Interestingly, Subject #1 relayed that he totally ceased to hear the alarm sound of the sweeper when he felt time pressure and started to think about how to finish the task more quickly.

The movement trajectories of subjects were plotted (Figure 5) in order to examine how close the subject moved to the truck when the truck was passing by in the neighboring lane. The highlighted points are the moments where the subject crossed over the lane regardless of the risk of being hit by the truck. Subject #1 relayed the fact that although at the beginning of the experiment he had been thinking about the hazard related to trucks, he unconsciously crossed the lane to sweep debris on the road. This result showed that analyzing the movement trajectory can help in detecting unconscious unsafe behaviors of subjects in the VE. Although the sample size was small and further studies are necessary to confirm these findings, the results of the experiment indicate that repeated exposure to hazards in a VE can lead to subjects' risk habituation, highlighting the utility of VR as an experimental tool in examining safety behaviors.

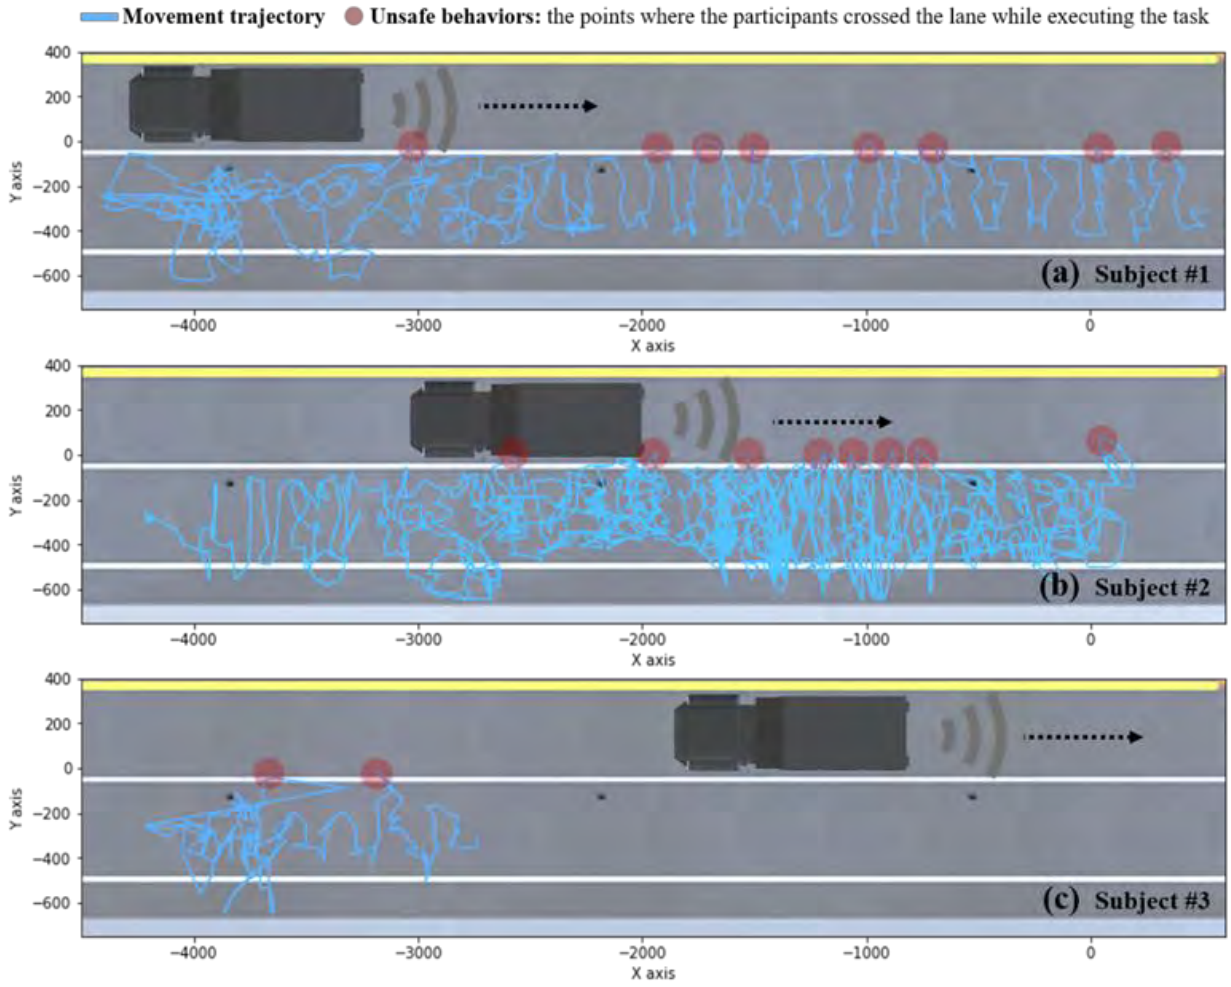

Figure 5. Movement trajectory analysis

5 Conclusion

The results of the experiment indicate that the designed VR model is capable of observing an individual's risk habituation process. Although there were individual differences, all subjects became habituated to repeated hazards in the virtual road construction environment. After a certain period of time, subjects began to ignore the proximity of the construction equipment behind of them and began to cross the lane in pursuit of finishing their cleaning task, regardless of the risk of being struck by the truck. This highlights the opportunities available in analyzing behavioral responses of construction workers to hazards in an immersive virtual construction environment. For example, a similar such VR model could provide a chance to investigate which personal factors (e.g., working experiences, injury experiences, and personalities) and situational factors (e.g., safety rules, the behavior of other personnel in working groups) affect workers' unsafe behavior in construction. Future work will also examine VR-based intervention mechanisms to prevent construction workers from becoming habituated to hazards and engaging in unsafe behaviors that might cause life-threatening accidents at construction sites.

Towards a Computational Approach to Quantify Human Experience in Urban Design: A Data Collection Platform

Keundeok Park and Semiha Ergan

Tandon School of Engineering, New York University, the USA
E-mail: kp2393@nyu.edu, semiha@nyu.edu

Abstract –

Design features that form urban settings such as greenery, height of buildings, and variation in the building façade (materials, color, and proportion) are known to have effects on how people experience environments. As the urban population grows and shifts to urban settings for living (e.g., 82% of people live in cities in the US), understanding the impact of urban environments on human experience becomes more essential. Previous studies to capture human experience in urban settings have been limited due to the labor-intensive and manual process of data collection (i.e., field surveys). Due to limited quantified data on urban design features, previous methodologies were constrained to a few neighborhoods, hence lacked generalizability across regions. Advancements in technologies such as GIS, computer vision, and data-driven methodologies and accessibility to large image sets on urban settings provide opportunities to eliminate the labor-intensive process of data collection. With the help of technologies, it is possible to quantify how people experience cities. This study leverages such advancements and aims to develop an automated approach for quantifying human experience toward built environments regarding their restorative impact on citizens. Towards this aim, within the context of this paper, we provide the details of a web-based crowdsourcing platform developed for the data collection at urban scale. We combine Geographic Information System (GIS), Google Street View (GSV), and JavaScript libraries to build the platform to capture the responses of participants on the restorative impact of the environments displayed to them as images. Based on the geolocation information obtained from GIS, we collected high resolution 360° GSV images within New York City (NYC) and used them to collect responses of citizens on structured questions tailored to the scope of the study. The crowdsourcing platform enables participants to evaluate the overall restorative impact of environments given in a 360° image, and to specify areas and design features influencing their evaluation. To quantify the influential design features on responses, we use semantic segmentation, and perform statistical analysis on the dataset to examine the impact of each urban design feature on the overall restorative impact. The approach will be presented for researchers to integrate GIS, Google API, and libraries to pull massive urban data for research study necessitating a good representation of the built environment as inputs. The outcomes will guide practitioners in urban redevelopment projects about urban design features that are influential.

Urban design; Restorative environments; Computer vision; Semantic Segmentation; Crowdsourcing; GIS; Google Street View

1 Introduction

The indoor and outdoor built environment has a strong association with restorativeness, which directly impacts mental fatigue, stress indicators, and quality of life of individuals [1-5]. As the urban population grows (82% of Northern American people are living in cities), the stress level of the urban residents has increased because of reduced space and overcrowding accompanied with urbanization [6]. With the aim to improve the quality of life, many researchers have been focusing on studying the impact of the built environment on human perception, including the restorativeness of the environment on people [7-9]. Various studies under this umbrella evaluated the relationship between the built environment and people's experience (e.g., preference, feeling of safety, stress/anxiety) and behavioral changes (e.g., reduction/increase in physical activities) in urban settings [1-6,10]. Their studies evaluate the built environment at micro and macro scales, including understanding the effect of various urban design elements, such as buildings, streets, and urban design blend as a whole. Majority of such empirical studies utilized Geographic Information System as a tool to quantify properties of such elements in the built environment (e.g., urban density, building height),

resulting in many street level design elements (such as the presence of street furniture, type of building façade) being omitted due to the hardship of data collection and representation format in existing data sources, mostly being shapefiles. In order to reflect street level elements as impacting factors on human experience, more recently, few studies have utilized urban street imagery and machine learning algorithm. These studies used urban street images that are prelabeled by people indicating how they feel about the environment in the images to predict people's perception (e.g., safety, excitement) about a given environment [11-15]. However, previous studies used non-panoramic and low-resolution images, which lacked rich visual information to give realistic experience of streets. In addition, what lacked in those approaches are the assessment of individual contributors of the type and amount of urban design elements on the resulting influence. Such information is essential for urban designers/practitioners to shape the urban settings with clear knowledge on how they will positively influence people's experience in an area.

Hence, in this work, we propose the details of a data collection platform that will enable (a) capturing rich geometric and visual information from multiple perspectives in a given area, and (b) correlating the overall experience of people in that area with the type and quantified properties of urban design elements that make up that area.

2 Literature review

This study is at the intersection of (a) previous studies that evaluated urban design elements on their restorative impacts on people, (b) metrics defined for measuring restorative capability of an environment, (c) data collection methods to measure impact of urban settings on people, and (d) contemporary and large image sets from urban settings.

2.1 Urban design elements and their impact on human experience

This work focuses on the restorativeness impact of the built environment on human experience, which is defined as the potential to recover and increase cognitive, physical, and mental capacity of people [27,34]. The effects of restorative environments on physical, social, and mental well-being has been examined extensively by studies in environmental psychology domain [3, 33].

Kaplan & Kaplan (1989) established the attention restoration theory and the value of nature on psychological restoration [27]. Based on that, studies in environmental psychology domain have empirically proved that not only the natural environment but also the presence of certain elements in the built environment have restorativeness effect on people. Examples of these urban design elements are provided in Table 1. Due to the high population density of cities, this potential of restorative environments in urban settings is significant.

Table 1. Urban design elements that were studied for restorative impact of the built environment

	Urban design elements	Reference
Built environment	Height of buildings	[4,5,28]
	Presence of socialization places such as cafés and restaurants	[25,26]
	Width of streets	[28]
	Visual complexity (e.g., the number of signages, dis/continuity of building façade style)	[23]
	Presence of landmarks and historical buildings	[24,27]
Natural environ-ment	Presence and amount of water bodies around	[23,25]
	Presence and amount of vegetation (e.g., trees, flowers, plants) around	[4,5,16-18]

2.2 Metrics defined for measuring restorative capability of an environment

One of the first studies that aim at measuring restorative impact of an environment is by Hartig et al. (1997). Perceived Restorativeness Scale (PRS) suggested by that study has been used to capture restorative quality of environments in environmental psychology studies. PRS was designed to measure the restorative quality of environments by capturing four psychological aspects - which are Being-away (being away from daily concerns), Fascination (capacity to drag people's attention), Coherence (clear order of the physical arrangement of design elements), and Compatibility (match between people's goals and availability of required activity in the place). The original version of PRS composes of 11 scale (0-10) and 26 questions. After Hartig et al. (1997) suggested PRS, several researches have made efforts to make shorter versions of PRS questionnaire and prove the usability of new versions of questionnaires [5,11,21,22]. In this study, to adopt a user-friendly and a shorter version, we adopted PRS questionnaires as used in Lindal & Hartig (2013) to capture being-away and fascination of built environments in urban settings. Due to characteristics of an online crowdsourcing platform, the shorter version of questionnaire is more appropriate for the participants' convenience and the reliability of the collected information.

2.3 Data collection methods utilized in literature

Previous studies are mainly empirical studies that aim to define the urban design elements that affect the restorative impact of a neighborhood. Such studies examine the direct and indirect effects of physical urban design elements (e.g., building height, presence of greenery and vegetation, bench) on streets on restorativeness, measured through a combination of metrics such as the feeling of openness, being away, fascination, compatibility, and complexity [4,16-18]. The data collection efforts that provide the required inputs for these studies can be mainly grouped under three categories: (1) field experiments, which include taking trips to areas of interest and conducting interviews with participants [19,20]; (2) image auditing, which includes using static street images with varying context (e.g., commercial area vs. historical place, residential area vs. parks and recreational areas) and comparing people's responses [21,24]; and (3) 3D modeling, which includes generating digital replica of an urban location with controlled objects in a scene and asking questions to participants regarding their perception of the area [4,16].

Each one of the described categories has specific limitations: field experiments are labor intensive, image auditing is manual for quantitative analysis of each urban design element on a scene, and 3D modeling is time-consuming to get realistic representation in virtual worlds. Besides the limitations that are specific to each category, they share a common limitation that hinders the extension and generalization of research outcomes, because of the fact that they could only focus on a specific urban area in these labor-intensive data collection processes. Hence, to alleviate the limitations in the existing data collection processes and enable collection of massive and rich data on urban settings, we describe a data collection platform that can merge several data sources, slice, and extract geometric and location information of areas with rich contextual data.

2.4 Contemporary and large image datasets that are generated to measure human experience in urban settings

A few recent studies focused on understanding human perception on the aesthetic preferences of people in urban settings using images and data-driven methods [29-31]. Although these studies differ in the urban evaluations, they are worth mentioning here because of the large datasets generated for similar purposes. Being one of them, the Aesthetic Visual Analysis (AVA) dataset has 250,000 images with semantic annotation (e.g., cityscape, landscape, architecture, etc. already labeled) and ratings of people on the images about how aesthetic they find [29]. Using the AVA dataset, some of the studies examined the possibility of machines mimicking human perception toward the selection of places (represented as images) with high aesthetic appeals [30,31]. Beyond this dataset, a few research studies have generated image sets on human perception in street level urban environments [11-15,32]. Place Pulse project by MIT Media Lab collected human perception regarding safety, wealth, boring, beauty, depressing, and livability using 100,000 images from 56 cities by comparing two street images and selecting better image in terms of being safer, wealthier, less boring, more beautiful, less depressing, and more livable [11,12]. The image ratings are through pairwise comparison of two static images, which show the place only from one viewpoint and without disaggregating the images into influential urban design elements on human perception The data platform presented in this paper eliminates these limitations by enabling (a) capturing high-resolution 360° panorama images of locations of interests, and (b) annotations on images for defining the influential objects in assigned ratings by participants.

The results of previous studies that utilize such image datasets to predict human perception indicate that visual representations captured in images are reflective of human perception and are promising to study urban design through leveraging image datasets. Previous studies also provide a point of departure about the strong indication that a machine can mimic human perception in an urban environment if presented with structured and large data. With the overall aim to have an empirical study on quantifying human restorativeness on urban environments, this paper provides the data collection platform developed to provide the required input of well-structured and large datasets for such studies. The structure of data is maintained through disaggregation of captured images to primitive urban design elements and quantifying their influence on the overall human experience.

3 Urban-scale data collection platform

In this section, we provide the details of the platform by introducing the major components of this platform and how they function and interact with each other. Major components of the platform are explained based on their roles in forming the image database (part 1 in Figure 1) and in capturing participants input in the crowdsourcing phase of the data collection (part 2 in Figure 1).

3.1 Overview

An overview of this platform is provided in Figure 1. First, the urban image database for images from areas of interests should be captured, which includes Geographic

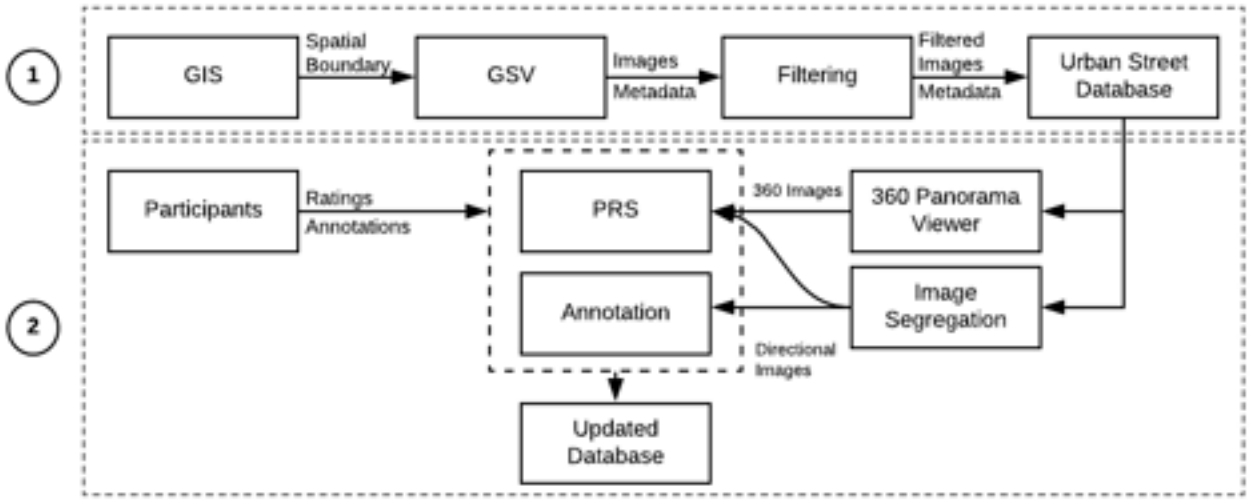

Figure 1. Components of the data collection platform and their interactions.

Information Systems (GIS) and Google Street View (GSV) APIs. The images are stored for locations represented with global latitude and longitude information of a specific location in Google's database and retrieved by a point by point request through Google API. Therefore, to request images through Google API, we need to (1) set the spatial boundary of interest using GIS, (2) generate a large number of points within the boundary in GIS, and (3) request the images and metadata (i.e., panoID, geographic coordinate) through Google API. During this request, all types of images from GSV including the ones about indoor environments are also retrieved. Therefore, a filtering component has been integrated in the platform that use semantic segmentation and unsupervised learning to eliminate images that are irrelevant (as detailed in section 3.4).

The images that stand out after the filtering are stored in our database and ready for use in part 2 of the platform (labeled with #2 in Figure 1). This part deals with capturing and storing response of citizens, who participate in the crowdsourcing based data collection. The data to be collected includes the ratings of people on restorative impact of the environment displayed on a set of randomly assigned 360˚ images and the associated unidirectional images (i.e., an image from front, back, left, right of a selected field of view) along with the annotations on images that define sections that were influential in participant ratings (see details in section 3.3). Ratings are captured through a 1-5 Likert on the perceived restorativeness scale (PRS) (detailed in section 2.2). In summary, the data collection platform enables to capture: (1) GSV image, (2) segmentation output of the image, (3) crowdsourced ratings on 360˚ and each directional image, and (4) annotations of influential urban design elements present in an image (Figure 2).

The following subsections provide further details of these components and their functions over the example implementation in New York City.

3.2 Populating the Urban Street Image Database

GSV is an open data source that provides street imagery and its metadata, which can be requested by a panoID or geographic coordinate. In the platform presented here, 360˚ panorama images are captured from Google Street View (GSV) in equirectangular projection, which is a 360˚ panorama image representation format providing a 360˚ horizontally and 180˚ vertically stitched image (Figure 4). Extracting the related images for a

Figure 2. Data captured and stored through the platform for one image.

neighborhood of interest, first a spatial boundary is defined in GIS. An example boundary (near Washington Square Park, NYC) is provided in Figure 3. We generate a number of points in GIS (represented as latitude and longitude) within this boundary and request GSV images

and their metadata for each point generated. As a result, generated points within the specified boundary are matched with available GSV data as shown in Figure 3. As part of the metadata, there is "panoID" which is the unique key representing a street view image. Using "panoID", 360˚ panorama GSV images are retrieved in this platform.

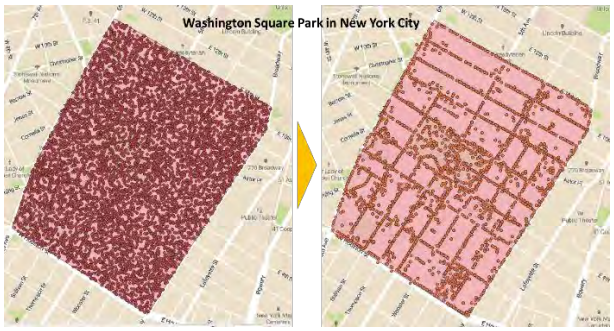

Figure 3. Illustration of a spatial boundary selection and mapping of GSV metadata within the boundary. Left: generated points by GIS; Right: obtained images.

Using this process, it is possible to populate a large image dataset for a neighborhood of interest without the need for time consuming manual image collection. The image resolution we obtained is 8192 × 4096, which is the same quality of 4K 360˚ camera and 4K content in VR device, surpassing the problems in previous data collection efforts resulting in low resolution images (640x640) and lack of visual details. For testing of this platform, we captured 2,628 images from NYC Washington Square Park area.

3.3 Projecting images and annotation

Equirectangular image is a popular format to store and convey 360˚ panorama images. However, the image is not intuitive to human perspective because it is projected as a single flat image with 360˚ horizontal and 180˚ vertical coordinate in the image (Figure 4). Therefore, to use the equirectangular image in the platform, the image needs to be converted to a perspective projection image.

Figure 4. Equirectangular image

Firstly, to capture entire human experience in the place at the first page, we used a 360˚ panorama viewer. We used open source panorama viewer Pannellum, which is built using web programming language (Figure 5). Next, we extracted unidirectional images from equirectangular images (Figure 6). The selected field of view are looking front, right, left, back and up along the street.

Figure 5. Equirectangular image projected in a 360˚ panorama viewer.

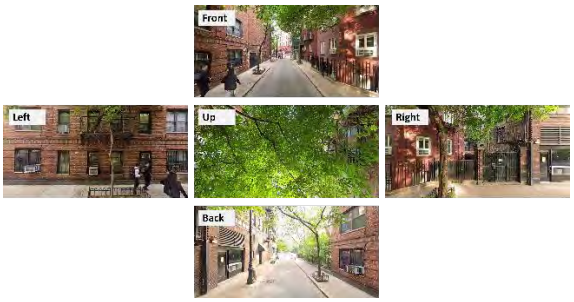

Figure 6. Unidirectional images (Front, left, up, right, bottom along the street) extracted from the equirectangular image shown in Figure 5.

To facilitate capturing parts of an image that were influential to a participant's ratings on restorative impact of that image, we set HTML canvas that allow users to draw rectangles on sections in images (Figure 7). The rectangular shapes on canvas are stored as images during the data collection process, which will be segmented further in the data analysis phase for quantifying urban design elements.

Figure 7. Annotation capability in the platform.

3.4 Filtering out irrelevant images

The automated population of images from GSV in a spatial boundary could result in extracting images that are stored in GSV but not representing street views. To eliminate such irrelevant images from the image database, this data collection platform has a filtering component that utilize semantic segmentation and unsupervised learning to classify indoor and outdoor images. During the initial step of populating the urban image dataset, points generated could match to images that are representing indoor environments. In order to exclude the images related to indoor environments, we used semantic segmentation and unsupervised learning. Semantic segmentation enables us to parse images and assign a class label (i.e., flower, tree, building, car) by pixel level and unsupervised learning facilitates clustering based on the segmentation output (objects in the image). Since the indoor environment has distinct object compositions from outdoors, one of the clusters represents the indoor images. For semantic segmentation, we utilized the HRNetV2 model, which is a neural network based model developed by Sun et al. (2019) as a segmentation model [35]. Since the objects appearing in indoor and outdoor images are distinguished (i.e., indoor: chairs, floor, ceiling, refrigerator, as shown in Figure 8; outdoor: cars, trees, sky, buildings, as shown in Figure 9), the unsupervised learning algorithm can learn the difference between indoor and outdoor images based on the information from the output of semantic segmentation of the image without label. Figure 8 and 9 show segmentation results for images captured indoors and outdoors, respectively.

Figure 8. Sematic segmentation of an image from indoors. Top: original image; Bottom: segmented image, where each colour represents a different category of objects.

The performance of the filtering process has been tested using the images captured in Washington Square Park boundary as a testbed. For the testbed we generated,

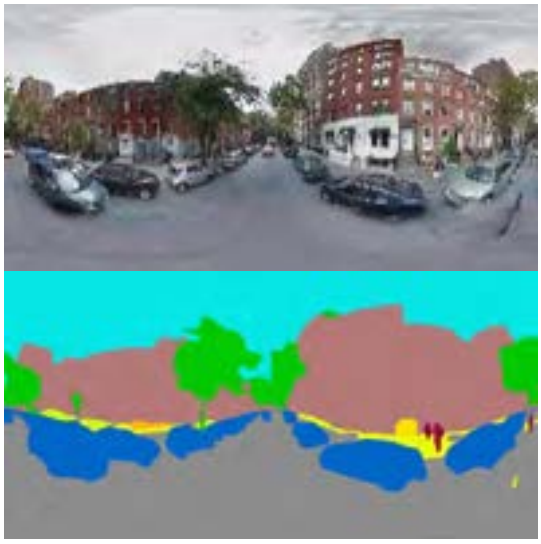

Figure 9. Semantic segmentation of an image from outdoors. Top: Original image; Bottom: Segmented image, where each color represents a different group of objects.

We eliminated 406 images from the original urban street image set from Washington Square Park. The overall accuracy of the model to classify indoor/outdoor images was 99.23% and the only error was on Type I (i.e., outdoor predicted as indoor) as 5% (Table 2).

Table 2. Accuracy of indoor/outdoor classification model.

Actual class / Prediction	**Indoor**	**Outdoor**
Indoor	**386**	20
Outdoor	0	**2,222**
Accuracy	**99.23%**	

3.5 Crowdsourcing to capture citizen ratings

PRS to measure restorativeness impact of a location and 360˚ panorama GSV images were integrated and implemented as part of a questionnaire in a crowdsourcing platform to capture the restorative quality of places in urban settings. The crowdsourcing platform was developed by utilizing JavaScript and SurveyJS for generating the survey forms and integrates to the urban street database generated. The questionnaire composes of six pages, where each page has the same PRS questions (Figure 10). A participant will be given a 360˚ panorama image (same as a GSV in Google Maps) on the first page, and the rest of the pages will show the unidirectional images (along the street: front, right, left, back, up). The reason for collecting responses for each disaggregated image is since the PRS ratings of the 360˚ panorama image includes contributions of each disaggregated image. Additionally, in each unidirectional view of the

location (e.g., front), participants are asked to select areas that were influential in their ratings of that location's restorative capacity as annotations on the image.

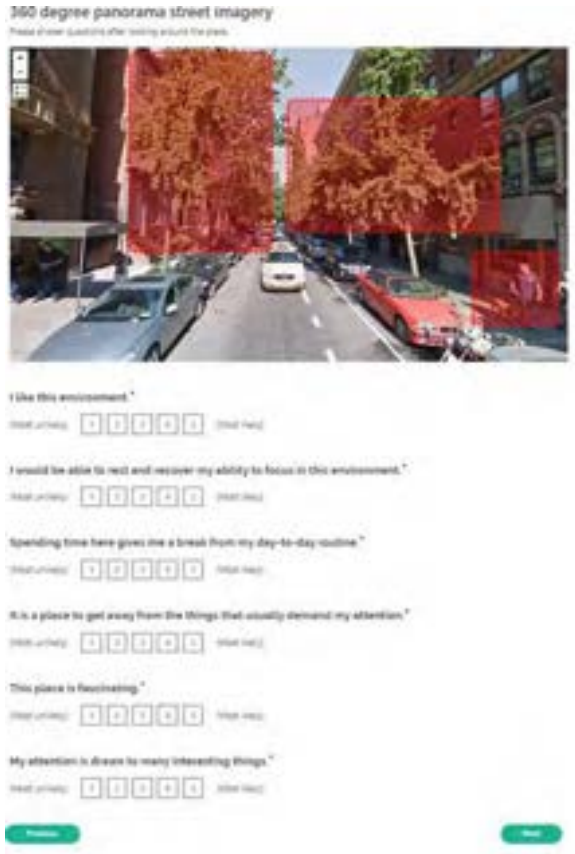

Figure 10. Crowdsourcing part of the platform.

This information is captured and used to update the images stored in the filtered database. Figure 11 shows examples of images stored in the urban image dataset through the utilization of the platform.

Figure 11. Examples of collected 360˚ panorama images

4 Conclusion and Future Work

We developed a data collection platform that integrates GIS, GSV, and a crowdsourcing module to enable capturing of massive and high-resolution urban scale image sets that are rich in visual information. The platform also enables marking urban design elements present in images and relating them to citizen ratings captured through the crowdsourcing component. We implemented this platform and developed measurement tools to capture a sense of restorativeness towards urban street images. The platform uses semantic segmentation and unsupervised learning to classify images to exclude indoor images retrieved from GSV.

The collected data is anticipated to be used to identify the urban street elements affecting perceived restorativeness as a future work. Finally, we expect that this platform will be utilized in other interdisciplinary studies since the database and platform have the potential to be extended to capture other aspects relevant to urban studies possibly expanding with other GIS data such as census data, land use data, and building data as needed.

Abstract -

Productivity and safety are in a trade-off relationship, and the improvement of the safety management system of construction sites is a pressing issue. Therefore, it is important to know and analyze information about incidents at real construction sites. However, it is difficult to gather information about these incidents from workers' self-reports. Therefore, in this research, we take an approach to view the workers as the sensors distributed in construction site and detect these incidents with the reaction of the workers. Biological signals such as heart rate, sweating, and muscle activity are the signals generally used to detect an emotional reaction; however, requiring workers to attach electrodes to their body during work is not suitable. Thus, we focused on blinks since they can be detected without electrodes attached to the skin. This study aims to investigate changes that occur in human blinks during an incident at a construction site. For safety purposes, this study used VR technology to simulate an incident at a construction site. During the simulation, an image of the subject's eyes was taken by the camera installed in the head-mounted display. The results of this study suggest that humans who face an incident have lower blink rates because they gaze at the cause of the incident.

1 Introduction

Focusing on current industrial accidents in Japan, the number of fatalities in the construction industry accounts for more than 30% of fatal accidents in all industries. The number of fatalities due to accidents in construction industries has been on a downward trend; however, the decline has stagnated over the last decade. This shows that ensuring the safety of workers at construction sites is an important and urgent theme. On the other hand, improvement in labor productivity is also an urgent challenge. In many situations, productivity and safety are in a trade-off relationship. For instance, the areas, where workers and construction machines are active, are often separated for safety reasons in construction sites. However, restricting movable ranges too narrowly for safety reasons would adversely affect work efficiency. This means development of technologies for improving safety without lowering efficiency is necessary.

Figure 1. Concept of the final goal

To improve safety without lowering efficiency, identifying when danger occurs at the construction site is of utmost importance. It is also generally said that there are many "incidents" behind the serious accidents that cause fatalities. Thus, the motivation for our study is to collect information on these incidents. At many construction sites, these incidents are currently collected through reports from workers. However, these are uncertain methods because they are subjective on the worker's memory.

There are two possible methods for detecting incidents from construction sites. One is by observing the entire construction site using cameras or LiDAR, and the other is through the measurement of workers. In this study, we focused on the latter method.

A previous study detected incidents through the measurement of workers via heart rate variability. This method is also actively conducted, especially for detecting stress [1], sleepiness and fatigue[2], and the feeling of "traffic near-miss" (surprising)[3, 4] among car driver subjects using heart rate and other indicators. Heart rate is related to a person's mental state. During tension, the sympathetic nervous system is more dominant resulting to higher heart rates. However, it is generally known that the heart rate increases not only during mental tension but also during exercise and work. Furthermore, attaching many electrodes to field workers is not considered as a suitable method. Therefore, we focused on the element of eye blinks.

Blinking is associated with various factors such as prevention of corneal dryness, eye purification, eyelid muscle refreshment, and mental conditions such as anxiety and tension/attention[5]. A study relates blinking to stress in driving and using a personal computer[6, 7]. Blinking is not only measured by electrodes attached to the skin, but a method has also been developed for measuring it from images, which is suitable for this study since it is a non-contact procedure.

The aim of this study is to detect incidents that occur at construction sites. We aim to detect them by measuring blinks of workers when faced with dangerous incidents. Figure 1 shows our concept. As the first step, it is necessary to investigate what kind of changes human blink shows when human experiences a dangerous incident. This study uses VR technology as a safety precaution during the simulation of such incidents.

2 Method

VR technology was used to simulate the incident. Specifically, the subject wore a head-mounted display while viewing the VR image. A small camera was also installed in the head-mounted display to observe the state of blinking during the experiment.

Simple image processing was performed to detect the state of blinking. Since the camera was fixed to the head-mounted display, the position of the eyes can be easily specified manually. First, the brightness and contrast were adjusted for the obtained image, including the eye region. Next, the edges of the upper and lower eyelids were clearly visualized by bilateral smoothing and adaptive binarization. After image processing, the number of blinks was counted visually. Similarly, the high-speed opening and closing of the eyelids that occurred during 100-200 ms was considered to be a "blink". Figure 2 shows an example of this simple image processing.

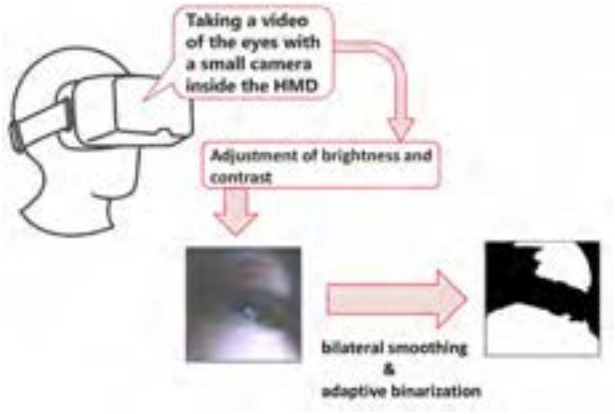

Figure 2. Simple image processing to blink detection

For comparison, we calculated the blink rate, which represent the number of blinks per minute. We compared the blink rate both when the incident is occurring and not occurring.

3 VR Experiment

3.1 Outline of Experiment

In this experiment, participants watched the simulation environment of the construction site through a VR video. During the simulation, an image of the subject's eyes was taken by the camera installed in the head-mounted display. In order to know the scene where the subject perceived danger, a gamepad was used and the subject was instructed to press a button during a dangerous scene.

3.2 VR video

The videos shown to the subject in the VR experiment must reproduce the incident. We focused on incidents related to collision of construction machines and humans, which is a very common accident at construction sites. To prepare videos that are impressive to the subjects, we used reverse playback. We carefully brought the construction machine and the 360-degree camera close to each other and shot a video of the construction machine moving away from the high-speed 360-degree camera.

We prepared the following four types of incident VR videos:

- Two types of incident videos in which the hydraulic excavator goes backwards without noticing the presence of the worker and almost comes into contact with the worker. There are two types of stop positions: (i) long-distance backward and (ii) short-distance backward.
- Two types of incident videos in which the hydraulic excavator turns unaware of the presence of the worker, and the tip of the bucket almost comes into contact with the worker. There are two types of distances to the excavator: (i) Long-distance turning and (ii) Short-distance turning.

For that incident VR video, we compared the blink rate before and after the incident occurs. However, discrepancies may arise when subjects expect that an incident will occur.

Therefore, we prepared four types of VR videos where incidents do not occur.

- One type of non-incident scene where the hydraulic excavator is stationary at a sufficient distance from the worker (stand by).

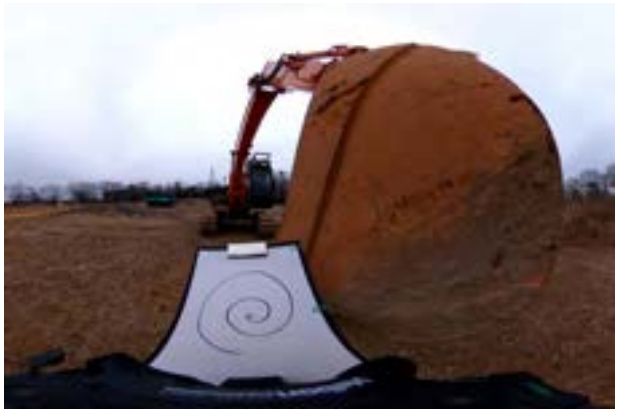

Figure 3. Sample Scene of a VR Video

Figure 4. Two cameras installed inside the head-mounted display

- One type of non-incident scene where the hydraulic excavator turns in the opposite direction from the worker (non-accidental turning).
- One type of non-incident scene where the hydraulic excavator moves forward and away from the worker (forward).
- One type of non-incident scene where the hydraulic excavator crosses at a distance far enough from the worker (crossing).

In addition, we prepared the videos so that the subject could see the paper near the subject's hand. This replicates a scene where the subject is working at the site while looking at the paper, such as progress schedule charts. The subjects were instructed in advance to look at the paper in front of them while paying attention to the construction machines as if they were in a construction site. These eight types of images were about one-minute long each and presented to the subjects in random order. An example scene of the prepared VR videos is shown in Fig. 3.

All these VR videos were shot at the Public Works Research Institute. We used Theta V from Richo and ZAXIS120 from Hitachi Construction Machinery as the 360-degree camera and hydraulic excavator, respectively.

3.3 Experimental Equipment

The head-mounted display used in the experiment was Vive COSMOS from HTC. This included headphones for the audio output of the virtual environment.

The two small cameras installed inside the head-mounted display were Raspberry Pi Camera Module V2. To capture a wider area inside the head-mounted display, the lens of the cameras was replaced with a 195 属 wide-angle lens. Two cameras were controlled by the Raspberry Pi 3B with a frame rate of 30 fps. This frame rate was selected since blinks are generally captured between 150 and 200 ms. To synchronize the VR video presentation and camera control, an integrated experimental environment was constructed using Unity.

The inside of the head-mounted display is shown in Fig. 4 where the two red circles are the cameras. Since the inside of the head-mounted display is sufficiently dark, the camera does not interfere with the subject's VR watching.

3.4 Participants

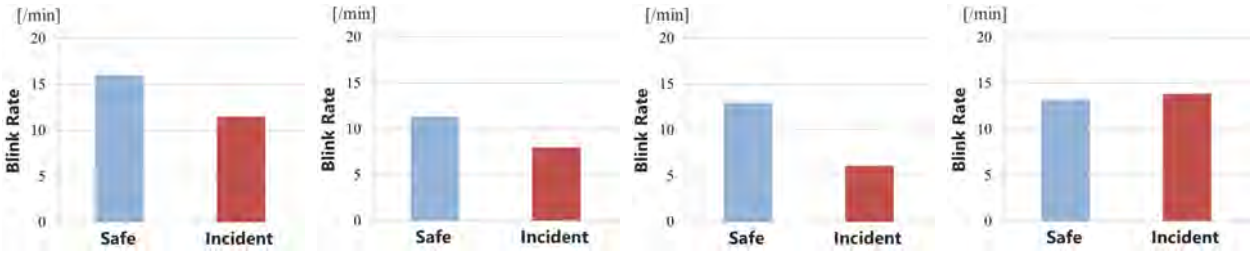
Three healthy male volunteers took part in the experiment and supplied informed consent. This study was approved by the research ethics committee of the University of Tokyo.

4 Results and Discussion

The results of the VR experiment are shown in Fig. 5. The blue bar stands for the average of subjects' blink rate before the incident occurs, while the red bar stands for the average of subjects' blink rate during the incident. The timing of the incident was determined from the video once the heavy equipment started to move.

Three results excluding short-distance backward revealed that the blink rate during the incident tended to be lower than that in the safe state. First, we must consider the reason why the blink rate did not decrease in Short-distance backward. Interestingly, the blinks that seemed to be voluntary were concentrated in the results of one subject which shows the higher blink rate. This is considered to be the reason for the higher average of blink rate in Short-distance backward. Voluntary blinks caused by some reasons unrelated to VR incidents such as eye itching become noise in this experiment. Hence, increasing the number of subjects and performing statistical processing are recommended to potentially eliminate noise unrelated to VR incidents.

Next, we discuss the decreasing tendency observed in



(a) Long-distance turning (b) Short-distance turning (c) Long-distance backward (d) Short-distance backward

Figure 5. Blink rate during incident and safe time

the three graphs. The first possibility is that the blink rate gradually decreases while watching a VR video for one minute. In other words, the blink rate is high until subjects adjust to the brightness of the VR image, and it decreases as they adjusted to it. Therefore, we calculated the blink rate in the "stand-by" condition where subject is farthest from the incident by dividing one minute into 10 seconds each (0-10 s, 10-20 s, 20-30 s, 30-40 s, 40-50 s, and 50-60 s). According to the results of the calculation, the blink rate under the stand-by condition remained almost constant. Therefore, this consideration was excluded. From this, it was considered that the decrease in the blink rate shown in the three graphs is related to the incident.

Another possible cause for the decreasing trend is that the subjects gazed at the cause of the incident (excavator). It is well known that the blink rate of a person who is gazing at something decreases, and this can explain the decreasing trend properly. The purpose of this study was to examine changes that occur in human blinks when humans experience an incident at a construction site. The results of this research suggest that humans during an incident have lower blink rates because they gaze at the cause of the incident.

During application of this approach for incident detection at construction sites, it is necessary to make a distinction between blink rate reduction due to incidents from those due to gaze irrelevant to incidents. In this case, a combination of saccades and facial expressions is considered effective.

5 Conclusion

In this study, we investigated the changes that occur in human blinks when humans experience an incident at a construction site. The VR experiment was performed using a VR video simulating an incident scene. Our results suggest that humans during an incident have lower blink rates because they gaze at the cause of the incident. However, increasing the number of subjects is recommended to further verify the suggestions obtained in this study.

Abstract –

An Unmanned Aerial Vehicle (UAV), equipped with a Light Detection And Ranging (LiDAR) scanner, can collect high-accuracy point cloud data of facilities in cluttered indoor environment. Recent developments in aerial robotics have demonstrated navigation through designated waypoints, yet little has been investigated on the trajectory to complete a full scan of the environment. This study develops an automated approach to integrate scan planning and trajectory generation of a LiDAR-carrying UAV. The proposed approach converts an as-designed Building Information Model (BIM) into an occupancy map, where a set of waypoints are generated with a greedy algorithm. The shortest collision-free path to traverse all the waypoints is computed with the A* algorithm and Genetic Algorithm (GA). After that, the straight-line segments are transformed into a minimum snap trajectory formed of piecewise polynomials. The planned trajectory is validated with both a MATLAB numerical solver and a Hardware-In-the-Loop (HIL) simulation in the Unreal Engine 4.

1 Introduction

Terrestrial Laser Scanning (TLS) is commonly used in the Architecture, Engineering, Construction and Facility Management (AEC/FM) industry for site inspection, progress tracking and model generation. Traditional ways of TLS involve selection of scanner locations and registration of multiple point clouds. This process is usually conducted manually by surveyors, which is time-consuming and subject to coverage issues [1]. A wise approach is to integrate a Light Detection And Ranging (LiDAR) scanner with a ground or aerial robot, making it a versatile and efficient tool for Mobile Laser Scanning (MLS). An Unmanned Aerial Vehicle (UAV), owing to its autonomy and flexibility, is a good choice for the platform, especially in cluttered environments where the walkability is poor. In recent years, research in LiDAR-carrying UAVs has demonstrated robustness in Simultaneous Localization And Mapping (SLAM), as well as autonomous navigation in unknown environments [2]. However, most existing methods focus on navigation through a sequence of designated waypoints, while it is difficult to achieve an autonomous flight. The missing segment is planning for the essential waypoints to explore the environment and complete a full scan. This problem can be effectively addressed when prior knowledge of the environment is available, such as the design information of buildings and facilities.

This study is proposed to close the loop of scan planning and UAV path finding, with the aim of facilitating a fully autonomous flight for LiDAR-carrying UAVs. It starts from an as-designed Building Information Model (BIM), which retains the geometric and semantic information of a facility and is compatible with various data formats [3]. The sensor model is constructed based on an existing product [4] to represent the perception range, Field of View (FOV), and Level of Detail (LOD). A greedy algorithm is designed to iteratively maximize the coverage of the planned waypoints, followed by a Traveling Salesman Problem (TSP) to solve for an optimal path that consists of straight-line segments. This serves as a guiding path, which is transformed into a minimum snap trajectory with Quadratic Programming (QP).

The planned trajectory is validated first with a MATLAB numerical solver, before conducting a Hardware-In-the-Loop (HIL) simulation with the Robot Operation System (ROS) [5] and Unreal Engine 4 (UE4) [6]. The HIL simulation builds on our previous work [7] with an extension of automated control input. The intended scene is a cluttered indoor environment filled with Mechanical, Electrical and Plumbing (MEP) components.

This paper is organized as follows: section 2 provides a comprehensive review of the related studies

on LiDAR-carrying UAVs. Section 3 illustrates the proposed methodology on scan planning and trajectory generation, followed by the simulation environments and results in section 4. In closing, the conclusion and future work will be presented in section 5.

2 Literature Review

2.1 Scan Planning

The purpose of scan planning is to ensure coverage of the target objects while minimizing the cost of time or energy. Compared with traditional TLS, a mobile LiDAR scanner automatically enforces overlapping between consecutive scans for registration. However, similar techniques can be applied for visibility analysis and occlusion handling. For example, Argüelles-Fraga et al. [8] developed a method to parametrize the influencing factors of scan accuracy, based on a circular cross-section tunnel. Biswas et al. [1] proposed a BIM-oriented approach to determine optimal scanner locations that maximize the covered surfaces while considering occlusions between components. Wang et al. [9] presented a greedy algorithm to iteratively generate scanner locations around concrete specimens. While the above-mentioned studies aim at planning for fixed scanner locations, an integrated framework was proposed in [10] to generate waypoints of LiDAR-carrying UAVs and connect them with the shortest path. This study provides a clear outline to plan for scanning paths, yet little has been discussed on trajectory generation and flight control for detailed implementation.

2.2 Localization and Mapping

Localization is a critical issue for UAVs in an indoor environment, where GPS signals are not available. It is often combined with mapping to form a SLAM problem. The objective of localization is to obtain the 6-DoF (Degrees of Freedom) state estimation, including 3 positions (x, y, z) and 3 orientations (yaw, pitch, roll). This can be achieved with internal sensor suites, including Inertial Measurement Units (IMUs), LiDAR scanners, monocular and stereo cameras. IMUs are easily accessible, lightweight sensors that measure acceleration and angular velocity at high frequency. They are usually fused with other sensory data to produce odometry. LiDAR-based solutions, such as LOAM [11], outperform vision-based methods in terms of cumulative drifts. However, the demand for payload limits their application in Micro Aerial Vehicles (MAVs). There are also methods that take advantage of both types, such as V-LOAM [12], which is ranking the top on the KITTI odometry benchmark [13].

SLAM problems can be solved with filter-based algorithms, such as the commonly used Extended Kalman Filter (EKF), Unscented Kalman Filter (UKF) [14] that deals with highly nonlinear models and particle filter [15] that can handle non-Gaussian distributions. In recent years, it is a growing trend to switch from filters to graph optimization, integrated with loop closure to reduce cumulative drifts. Such examples include ORB-SLAM [16] and VINS [17].

2.3 Motion Planning

In UAV motion planning, the term “path” and “trajectory” are often used interchangeably. According to [18], a path can be a continuous curve or discrete line segments connecting two positions, while a trajectory refers to a path parametrized with time *t*. In this paper, we use “path” to denote straight-line segments connecting waypoints, and “trajectory” for high-degree polynomials to be followed by a UAV.

The objective of UAV path planning is to determine the shortest collision-free path that connects the take-off position, a sequence of waypoints, and the landing position. Path planning problems can be solved efficiently with sampling-based methods, which generate random samples and connect to a search graph. Examples include Probabilistic Road Map (PRM), Rapid-exploring Random Tree (RRT), and RRT* [19] which converges to optimality as samples increase. Search-based methods, such as Dijkstra’s algorithm and A* algorithm, are also frequently used to find the optimal path from a search graph. A* is an extension of Dijkstra’s algorithm that evaluates each search node with a heuristic function before accessing it. As shown in [20], search algorithms can be combined with sampling methods to enable real-time processing.

To transform a path into a trajectory, the simplest approach is to solve for the polynomial parameters with respect to *t*, by setting waypoint constraints. However, a UAV trajectory is supposed to be safe and feasible, at least twice differentiable to produce velocity and acceleration. Mellinger and Kumar [21] formulated the trajectory as an optimization problem to minimize energy consumption and solved with Quadratic Programming (QP). Richter et al. [19] extended their work to an unconstrained QP and ensured safety by adding intermediate waypoints. A different technique was proposed by Chen et al. [22] that generates flight corridors formed by safe regions, and constrain the trajectory within it.

3 Methodology

This section describes the proposed methods and implementation. An overview of the framework is illustrated in Figure 1. The planning phase consists of four steps: (1) map construction, (2) waypoint

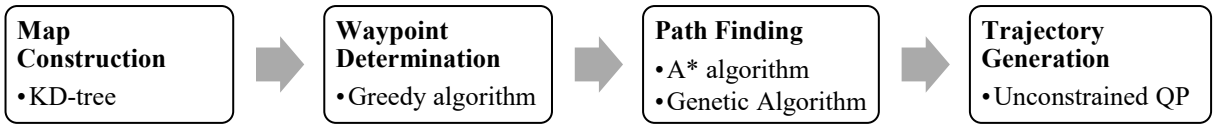

Figure 1. Workflow of the planning phase

determination, (3) path finding and (4) trajectory generation, which are detailed in 3.1-3.4, respectively. The target facility is a water treatment plant located in Tai Po, Hong Kong SAR. It is a cluttered indoor area filled with MEP components, such as pipelines and valves. One set of the pipelines, which is part of the duplicated layouts, is extracted as the test area. The planning phase is implemented in MATLAB, followed by the simulations in section 4.

3.1 Map Construction

The UAV motion planning is performed on an occupancy grid map, where each cell is attached with a label, indicating obstacles or free space. The map is constructed based on an as-designed BIM of the target object, as shown in Figure 2. The model is exported as an OBJ file with an add-in [23] of Revit, and meshed in CloudCompare [24] to produce a reference point cloud, displayed in Figure 3. The reference point cloud consists of evenly distributed points, covering the surface of the objects. It is represented with the KD-tree data structure, which enables fast K-Nearest Neighbor (KNN) search for computing safe distance. An empty voxel grid is created with resolution s, and a KNN search is applied between the grid points and the reference point cloud. Depending on the nearest neighbor distance d, and the safe threshold θ_d, each cell in the voxel grid is labeled as obstacle ($d < 0.5s$), safe region ($d > \theta_d$), or buffer zone. Considering the scale of the facility, s and θ_d are determined as 0.5m and 1m, respectively. This completes the construction of the occupancy grid map.

Figure 2. The as-designed BIM of the target components in Revit

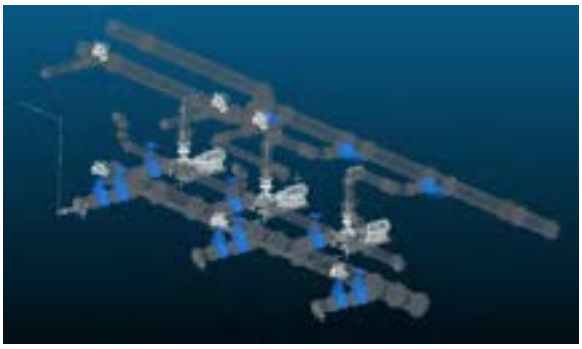

Figure 3. The meshed point cloud in CloudCompare. Surface density = 1000. RGB entries are obtained from the texture.

3.2 Waypoint Determination

The objective of waypoint determination is to bridge the problem of traditional TLS with that of LiDAR-carrying UAVs. A greedy algorithm was proposed in [9] that maximizes the number of covered surfaces at each selection. However, this method is not model-based and works only for concrete specimens. In this study, we adopt a similar idea that tries to achieve the local optimum when generating each waypoint and iterate until the requirements are satisfied. Besides, we describe the coverage based on the LiDAR model and consider occlusion handling.

3.2.1 LiDAR Model

The sensor model in this paper is constructed based on an existing product, RS-LiDAR-32 [4], of which the specifications are listed in Table 1. Geometrically, the sensor coverage can be described as the volume between two conic surfaces, bounded by the sphere of perception range (Figure 4). Given the LOD requirement δ and angular resolution θ, the perception range L should be reduced according to Equation (1):

$$L = \delta/\theta \quad (1)$$

In this case, the smallest element has a diameter of 5cm. Considering the typical measurement error of ±2cm and the worst-case resolution 0.4°, the perception range is determined as 4m to ensure detection of the pipes. As for the FOV, UAVs will not stay horizontal during the flight because the pitch, roll angles change according to the x-y motion. Therefore, the vertical FOV can be reduced to account for the inclination. In this study, the

reduction is taken as 10%.

Table 1. RS-LiDAR-32 specifications

Horizontal FOV	360°
Vertical FOV	–25° ~ +15°
Horizontal Resolution	0.1°/ 0.2°/ 0.4°
Vertical Resolution	≥ 0.33°
Range	200m
Range accuracy (typical)	±2cm

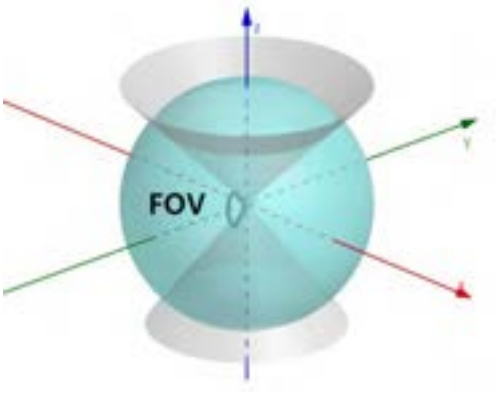

Figure 4. Coverage of the LiDAR model. The donut shape bounded by two conic surfaces (FOV) and a sphere (perception range)

3.2.2 Greedy Algorithm

The greedy algorithm is designed to generate a set of waypoints by maximizing the number of newly covered cells at each iteration, until the stopping criteria are met. The algorithm takes all the occupied cells (i.e. obstacles) as the target to be covered, and the safe regions as potential waypoints. A greedy search is applied to determine the safe cell with maximum coverage and add to the waypoint list. Detailed procedures are illustrated in Algorithm 1. The coverage examination is explained as follows.

For each safe cell, the range search is applied to return all the target cells within the sphere of perception range. This is also achieved with the KD-tree structure. After that, the sphere is reduced according to the FOV with Equation (2), where γ is the angle between the vector **u** from the safe cell to the target cell, and the body frame z-axis **z**. This represents the volume sandwiched between two conic surfaces from the vertical FOV, as illustrated in Figure 4.

$$\gamma = \cos^{-1}\left(\frac{\boldsymbol{u}\cdot\boldsymbol{z}}{\|\boldsymbol{u}\|\|\boldsymbol{z}\|}\right) \in \frac{\pi}{2} - FOV \tag{2}$$

The occlusion handling is realized with similar techniques. The vector **l**, which connects the safe cell with an obstacle cell, is checked against **u**. When Equation (3) and (4) are both satisfied, the ray to the target cell is considered as occluded by the obstacle. These equations indicate the cylindrical volume centered around **u**, with radius 1/2 of the grid size. An illustration is available in Figure 5. The occlusion check is applied for the obstacle cells within the spherical range. When all the obstacles return false, the target cell is considered as within the coverage.

$$h = \frac{\|\boldsymbol{l}\times\boldsymbol{u}\|}{\|\boldsymbol{u}\|} < \frac{1}{2}s \tag{3}$$

$$p = \frac{\|\boldsymbol{l}\cdot\boldsymbol{u}\|}{\|\boldsymbol{u}\|} \in (0, \|\boldsymbol{u}\|) \tag{4}$$

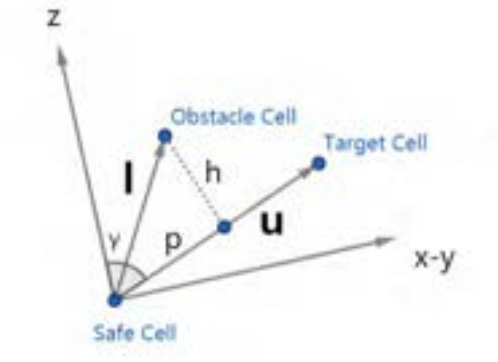

Figure 5. Illustration of Equation (2), (3) and (4). γ is the angle between **u** and **z**, h is the point-to-line distance and p is the projection of **l** on **u**

3.3 Path Finding

After a set of waypoints are determined, the problem is to compute an optimal path to traverse all of them. According to [10], this can be formulated as a TSP and solved efficiently with Genetic Algorithm (GA). We adopt similar techniques to solve for a collision-free path that ensures the shortest summed Euclidean distance. However, this path contains straight-line segments and sharp turns that are unsuitable for flight control. Therefore, it serves as the waypoint constraints for trajectory generation.

To form the TSP, a cost matrix is required to represent the pairwise path cost between the nodes. In this problem, it is constructed with the A* algorithm, which is applied on every pair of the waypoints. The occupancy map is treated as a search graph, where the successors of a cell are generated from the 26 adjacent cells. The heuristic function is taken as the Euclidean distance to the goal, which is guaranteed to be admissible.

After the cost matrix is obtained, the GA is implemented as follows:

1. The initial population is generated with random permutation of the waypoints, in bit arrays.
2. The tournament selection is applied to obtain a set of parents based on the fitness function, which is the summed path cost of the ordered sequence.
3. Three operations are applied to produce the next generation: (1) copy: select a member and copy directly to the next generation. (2) crossover: select two parents to produce offspring. Here, the order crossover operator is used, which takes a subset from parent 1, and arrange the remaining bits according to their order in parent 2. (3) mutation: select a member and randomly switch two bits in it.
4. Iterate from step 2, until N generations.

For this study, a population size of 1000 is applied on a set of 10 waypoints. The rate of copy, crossover and mutation are 9%, 90% and 1%, respectively. The optimal solution first appeared after 9 generations.

3.4 Trajectory Generation

The UAV trajectories are usually represented as piecewise polynomials parametrized with time *t*, in three dimensions, respectively. To ensure kinodynamic feasibility, the trajectory is subject to the derivative constraints which come from the specified end derivatives, and the continuity constraints which ensures smoothness. The expression in one dimension is shown in Equation (5) and (6), where the trajectory is an N-degree polynomial with M pieces:

$$f(t) = \begin{cases} f_1(t) = \sum_{i=1}^{N} p_{1,i}(t-T_0)^i & T_0 \le t \le T_1 \\ f_2(t) = \sum_{i=1}^{N} p_{2,i}(t-T_1)^i & T_1 \le t \le T_2 \\ \vdots & \\ f_M(t) = \sum_{i=1}^{N} p_{M,i}(t-T_{M-1})^i & T_{M-1} \le t \le T_M \end{cases} \quad (5)$$

$$\text{s.t.} \quad \begin{cases} f_j^{(k)}(T_j) = x_{T,j}^{(k)} \\ f_j^{(k)}(T_j) = f_{j+1}^{(k)}(T_j) \end{cases} \quad (6)$$

To solve for the polynomial parameters $p_{j,i}$, we refer to the method in [21], which formulates the trajectory as an optimization problem: the objective is to minimize the fourth order derivative (i.e. snap) of the trajectory, subject to the continuity constraints and derivative constraints. Equation (7) and (8) illustrate the problem definition in vector form, where **p** is the collection of polynomial parameters and **Q** is the Hessian matrix, $\mathbf{A_{eq}}$ and $\mathbf{d_{eq}}$ are the collection of constraints. The minimum snap trajectory is a seventh degree (N=7) piecewise polynomial, which optimizes the least energy consumption. The variable **p** can be solved with QP.

$$\begin{aligned} \text{min.} \quad & J = \int_o^T \left(f^{(4)}(x)\right)^2 dx \\ & = \begin{bmatrix} \boldsymbol{p_1} \\ \vdots \\ \boldsymbol{p_M} \end{bmatrix} \begin{bmatrix} \boldsymbol{Q_1}(T_1) & & \\ & \ddots & \\ & & \boldsymbol{Q_M}(T_M) \end{bmatrix} \begin{bmatrix} \boldsymbol{p_1} \\ \vdots \\ \boldsymbol{p_M} \end{bmatrix}^T \\ & = \boldsymbol{p^T Q p} \end{aligned} \quad (7)$$

$$\text{s.t.} \quad \boldsymbol{A_{eq}} \begin{bmatrix} \boldsymbol{p_1} \\ \vdots \\ \boldsymbol{p_M} \end{bmatrix} = \boldsymbol{d_{eq}} \quad (8)$$

However, direct optimization of polynomial parameters is numerically unstable, because the values are usually very small as time *t* increases. Therefore, we adopt the method in [19] to reformulate the problem as an unconstrained QP. A mapping matrix **M** is constructed to transform the variable from polynomial parameters **p** into the end derivatives **d**. Additionally, a binary selection matrix **C** containing 1s and 0s is constructed to separate the fixed derivatives $\mathbf{d_F}$ and free derivatives $\mathbf{d_P}$. The derivative constraints and continuity constraints are automatically enforced by the selection matrix. In this way, the problem is transformed into an unconstrained QP. The composition matrix in the middle can be further split according to the size of $\mathbf{d_F}$ and $\mathbf{d_P}$, as shown in Equation (9) and the close-form solution is obtained with Equation (10). The optimized end derivatives are transformed back to polynomial parameters to compute the trajectory.

$$J = \begin{bmatrix} \boldsymbol{d_1} \\ \vdots \\ \boldsymbol{d_M} \end{bmatrix} \boldsymbol{M^{-T} Q M^{-1}} \begin{bmatrix} \boldsymbol{d_1} \\ \vdots \\ \boldsymbol{d_M} \end{bmatrix}^T = \begin{bmatrix} \boldsymbol{d_F} \\ \boldsymbol{d_P} \end{bmatrix}^T \boldsymbol{C M^{-T} Q M^{-1} C^T} \begin{bmatrix} \boldsymbol{d_F} \\ \boldsymbol{d_P} \end{bmatrix} = \begin{bmatrix} \boldsymbol{d_F} \\ \boldsymbol{d_P} \end{bmatrix}^T \begin{bmatrix} \boldsymbol{R_{FF}} & \boldsymbol{R_{FP}} \\ \boldsymbol{R_{PF}} & \boldsymbol{R_{PP}} \end{bmatrix} \begin{bmatrix} \boldsymbol{d_F} \\ \boldsymbol{d_P} \end{bmatrix} \quad (9)$$

$$\boldsymbol{d_P^*} = -\boldsymbol{R_{PP}^{-1} R_{FP}^T d_F} \quad (10)$$

To construct the Hessian matrix **Q** and mapping matrix **M**, the time duration T_i for each segment is required. In this study, the time is allocated according to the Euclidean path cost, based on the predefined average velocity at 1m/s. Another critical issue in trajectory generation is that the piecewise polynomial may deviate from the collision-free guiding path. To reinforce safety, collision check is performed along the trajectory with KNN search. The positions at each timestamp are checked against the nearest obstacle cell. The midpoint of guiding path segments will be added as an intermediate waypoint if collision is detected.

4 Validation

This section describes two separate experiments to validate the planned trajectory. The first one is performed in MATLAB with the numerical solver ode45. A simple PID controller is implemented to realize the motion control. The second experiment is an HIL simulation in the UE4 environment, where a physical flight controller is employed to communicate with the simulator. Details are explained in 4.1 and 4.2, respectively.

4.1 MATLAB simulation

The UAV trajectories are executed with a flight controller, which takes in the desired states and true states of the UAV at each moment to produce the desired motor output. The planned trajectory is published in a stream of state vectors $[x, y, z, v_x, v_y, v_z, \psi, \theta, \varphi, \omega_x, \omega_y, \omega_z]^T \in R^{12}$, with a fixed frequency. It was demonstrated in [21] that the full state vector can be reduced to the 3D position and yaw angle $[x, y, z, \psi]^T$, due to the differential flatness property. For this study, only the 3D position is enforced while the yaw planning is left as future work. A PID controller is constructed following the nested loops in [25], where the position control lies in the outer loop and influence the attitude control in the inner loop. The governing equation is shown in Equation (11), where **e**(t) is the error between the desired state and true state. The control output **u**(t) is

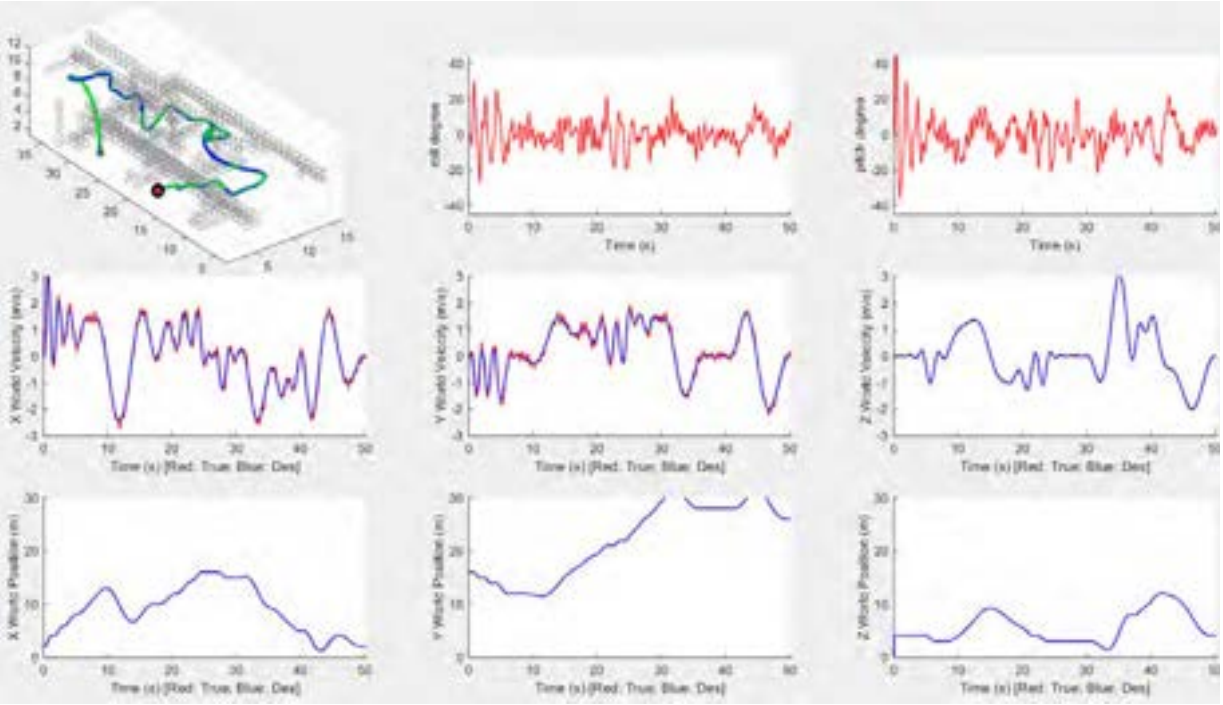

Figure 6. Simulation results in MATLAB. In subplot (1), the planned trajectory and the ground truth trajectory are plotted with green and blue curves, respectively. The grey cells indicate the obstacles. In (2)-(9), the desired states and the true states are plotted with blue and red curves, respectively. For the roll and pitch angle, the desired values are not commanded, but determined by the horizontal motion, instead.

related to the Force and Moment with the Newton-Euler equations, as shown in Equation (12) and (13). The weight *mg* and moment of inertia matrix **I** are determined according to the UAV model in [26]. The gain parameters K_p and K_d are tuned manually, while the Integral term is omitted for simplicity. During the simulation, the desired states are the input from the trajectory generator, while the true state is computed with the ode45 solver, based on rigid body dynamics.

$$\boldsymbol{u}(t) = \ddot{\boldsymbol{x}}^{\boldsymbol{des}}(t) + K_d\dot{\boldsymbol{e}}(t) + K_p\boldsymbol{e}(t) \tag{11}$$

$$m\ddot{\boldsymbol{p}} = \begin{bmatrix} 0 \\ 0 \\ -mg \end{bmatrix} + \boldsymbol{R} \cdot \begin{bmatrix} 0 \\ 0 \\ \Sigma F_i \end{bmatrix} \tag{12}$$

$$\boldsymbol{I} \cdot \begin{bmatrix} \ddot{\Phi} \\ \ddot{\theta} \\ \ddot{\psi} \end{bmatrix} + \begin{bmatrix} \omega_x \\ \omega_y \\ \omega_z \end{bmatrix} \times \boldsymbol{I} \cdot \begin{bmatrix} \omega_x \\ \omega_y \\ \omega_z \end{bmatrix} = \begin{bmatrix} \Sigma M_x \\ \Sigma M_y \\ \Sigma M_z \end{bmatrix} \tag{13}$$

The simulation result is plotted in Figure 6, where subplot (1) is a 3D view of the trajectory and (2)-(9) are the UAV states against time.

4.2 HIL simulation

The UE4 is an advanced game engine that provides highly realistic virtual environment. Besides, it enables a wide range of robotics applications, such as navigation, computer vision, deep learning, etc. This is the main reason why it is selected as the platform for experiment. The HIL simulation is carried out based on our previous work [7], in which a software pipeline was developed to integrate UE4 with ROS. The former provides the physics engine and high-quality sensor data, while the latter contains abundant packages for robotics perception and odometry. The communication between them is realized with the ROS master.

In this simulation, the as-designed BIM of the target facility is exported in FBX format and then imported into UE4 to create a scene, as shown in Figure 7. The planned trajectory is coded into a script as a stream of messages with timestamp, position and orientation. The script is passed into the UE4 server through an API layer, AirSim [27]. The trajectory is executed with a hardware flight controller, Pixhawk 4 [28], which subscribes desired states and ground truth states from the UE4 environment and publish motor outputs to the UAV model. A screenshot during the simulation is displayed in Figure 8.

5 Conclusion and Future Work

This paper presents an integrated framework to bridge the robotics problem of UAV navigation with the civil engineering application of as-built point cloud generation. The framework comprises BIM-aided map construction, waypoint-based scan planning, static path planning, and dynamic trajectory generation. These techniques are verified with a numerical simulation and a highly realistic HIL simulation. The results demonstrated that the motion planning algorithms can deal with complex environments with MEP components.

The proposed framework can be improved in several aspects. First, the yaw planning for trajectory can be completed, which is critical for vision-based odometry and navigation. Secondly, the quality of scanning is not evaluated. This can be addressed by setting a LiDAR sensor model into the UE4 environment to perform a virtual scan. Furthermore, it is promising if the framework can run in parallel with ROS to achieve real-time application. This is possible with the MATLAB ROS Bridge and it is expected to conduct a real-world experiment in future.

Abstract –

The purpose of this research is to use digital technology to streamline operations and improve construction when using non-uniform building materials with discrete and differing forms, such as those used in traditional wooden buildings. Taking irregular timber procurement as a model use case, we formulated a method of utilizing 3D scanning technology to facilitate inspection and processing considerations.

Keywords –

Traditional building; Wood; BIM; 3D laser scanner; Point cloud

1 Introduction

Recent years have seen the wider construction industry in Japan look to the use of cutting-edge technologies in construction work as a possible means of increasing productivity. For example, the Ministry of Land, Infrastructure, Transport and Tourism has begun a set of initiatives, called "i-Construction," to promote the use of digital technologies. At the same time, given the growing problem of the declining number of construction workers with advanced skills, new construction methods are needed to mitigate the loss of human resources and these advanced skills. Some examples exist of research into construction management or processing building materials method utilizing digital technology. One is a research project by Kano et al., who are exploring a method to automatically ascertain the progress of PCa projects using 3D laser scanners during the construction stages [1]. In terms of research into the machining of building materials, Takabayashi et al. have reported on a method of generating machining paths for regular, uniform timber using robotic arms [2]. One of the key points proposed in these research projects is a technology to measure the shape of the PCa member and the lumber processed accurately. The authors have focused herein on digitizing material geometry accurately as one technical issue commonly found in the above research and other initiatives to refine craftsmanship and manufacturing through digital technology. Construction is the process of assembling building materials to match design information. By digitizing the shape of the building material accurately throughout each phase of the production process, this technique should allow for using complex simulations and automated control of machinery during subsequent construction steps.

The focus in this research is on renovation projects involving traditional wooden buildings as the most suitable use case. This is because the parts used are not mechanically machined such as those seen in industrial products, but those in which the processing steps must accommodate the unique geometry and form of each tree. Shrines, temples, castles and other ancient structures were built in Japan long ago, with many such traditional buildings remaining in existence and of high value today. While wooden buildings today generally use machined timber such as laminated wood and CLT, traditional Japanese wooden buildings tend to, for instance, employ a single timber log for columns or beams and exceptional skills are required throughout the entire production process, from procurement to processing and assembly.

Accordingly, we chose to treat the procurement phase, which marks the start of the manufacturing process, as a case study and propose a method to assist inspection work. This method employs 3D scanning technology to

digitize the timber geometry during the inspection phase. We also propose a method of converting the data into a lightweight and general-purpose format, reflecting the assumption that the shape data would be used when considering how to process the timber in subsequent work phases.

2 Current Workflow

We begin by enumerating some of the aspects of the procurement and processing process in traditional Japanese wooden building conservation and renovation projects.

In terms of the procurement process, the timber supply chain is very unique and since the timber used in traditional wooden structures is generally a single piece from a single tree, the materials involved tend to be large. Many of these pieces of timber are over 5m long and weigh upwards of 1 ton. Construction companies lack the commercial flow and know-how to purchase large pieces of timber within a short time, making it difficult for construction companies to purchase materials directly from timber owners. Consequently, construction companies must themselves purchase from specialist wood suppliers. The construction company communicates the design specifications to the suppliers and the suppliers collect pieces of timber that meet these specifications on the contractor's behalf. Timber obtained from the supplier in line with the above is generally rough, with only the bark removed and processed into square or round shapes. Since the cross-sectional dimension and curvature of this timber is unique in each case, construction companies inspect the merchandise at the warehouse to determine its fitness for a specific portion of the architectural design, ultimately purchasing only those pieces that pass this check. The current inspection covers points like shape, such as length and cross-sectional dimensions; aesthetics, such as color and scratches; and physical properties, such as Young's modulus. For shape inspections, 1:1 scale printed drawings are laid under the timber to check the size and the details are checked via tape measure, while aesthetic inspections are conducted visually by the design supervisor. In many cases, special measuring instruments are used to ascertain the physical properties. In addition, the inspector also relies on visual particularities, such as the shape, knots, barks caught inside and rots to infer the internal condition of the wood and determine whether it is fit for use. Given the considerably advanced skills and timber processing experience this entails, construction companies sometimes assign carpenters to handle inspections. The construction company asks the carpenter to cut the timber down to match the desired dimensions and cut the surface to ensure a consistent cross-sectional shape. Any pieces that are intended to connect to other parts must be further processed in detail.

The process by which the shape of the timber changes is shown in Figure 1.

3 Creation of Inspection Assistance and Data Conversion Methods

Two methods, to facilitate inspection work and convert the data into a lightweight and general-purpose format are explained in detail.

3.1 Inspection Assistance Methods

The timber shape is digitized accurately in advance and automatically screened by the program, so the inspection itself takes place minimizing the number of people involved and with maximum accuracy. The technical requirements for implementing our proposed method are as follows:

3.1.1 Digitization of Timber Shapes

First, a 3D laser scanner is used to digitize the timber geometry accurately as shown in Figure 2. This is because it is a machine that can measure the shape of objects very precisely, rendering them as a collection of points with three-dimensional coordinates. Many commercially available products of this type can measure target objects up to ten meters away with error tolerance to within 2 to 3 mm, making it sufficiently accurate to facilitate timber inspection and processing. The data obtained is a collection of point data described by seven

Trees in the forest | Timbers after felling | Timber at inspection | Timber after processing

Figure 1. Process by which the shape of a timber changes

text strings: three-dimensional coordinates (x, y, z), laser reflection (intensity) and color information (R, G, B). This is generally referred to as a point cloud. Next, two data processing schemes are implemented to generalize the point cloud data and perform registration such that it is converted into a general-purpose format for editing by common programs using most commercially available software.

3.1.2 Automation Program for Inspections

Next, we developed a new program used to automate the inspection of timber geometry. To replace conventional inspection work with programmatic processing, the main functions required are: (1) automatic generation of the required dimensions, (2) superimposition (overlaying) of design blueprints. We developed a program to meet the following requirements to utilize timber point cloud data for the purposes described above:

a) Ability to read point cloud data

b) Point cloud data display function

Most pass/fail criteria are expressed numerically, such as dimensions and the position of the dimensions to be measured is determined in a horizontal or vertical projection plane relative to the timber. We opted to display the point cloud data in three two-dimensional perspectives, rather than three-dimensional views, namely: plan, elevation and cross-section.

c) Automatic sorting and alignment of point cloud data

The timber orientation is crucial. Cross-sectional cut surfaces, which always includes two sections, are referred to as the "koguchi," or cut end, with the root side referred to as the "motokuchi," and the other, the "suekuchi." A lot of pine timber is bent as a characteristic of the material and when using wood, the curvature generally faces upward, as a building material to the extent possible the area closest to the "motokuchi". Accordingly, the location of the "motokuchi," "suekuchi," and bend must be determined, even when measuring the dimensions. The program we developed is designed to automatically arrange the timber rendering in the above desired orientation when importing the cloud point data. This process involves first generating a 3D bounding box for the cloud point data and arranging it on the plan view such that the long side of this rectangular solid is horizontal. Next, we compare the two point cloud sections closest to the two faces on the short side and determine that the larger and smaller areas correspond to the "motokuchi" and "suekuchi" respectively, arranging them such that the "motokuchi" is on the right side in the plan view. Finally, all point clouds in the bounding box are compared to the point clouds for the cut ends and the point clouds in the bounding box are positioned so as to appear higher up in the plan view.

d) Automatic display of dimension lines and figures

We referred to the inspection sheets used in actual inspections and discussions with designers, contractors and shrine carpenters, to indicate which dimensions should be used to determine a pass or fail. We used this insight to develop the program such that it automatically generates the exterior dimensions and those implicated in downstream processing, to facilitate timber inspection. The processing dimensions indicate where the timber (in its raw state during inspection) should be cut to obtain the desired piece. This cutting process is referred to as "kidori." The bend is a key criterion during assembly and calculated based on the shape obtained after the "kidori" process. When viewing the external timber lines in a plan view, the two long sides form the arcs of a curved line and represent the "mukuri," calculated as the largest vertical distance from the straight line obtained by connecting both ends. The names and dimensions of each part of the timber are shown in Figure 3.

・Outer dimensions of the timber: width and height of both cut ends, length of timber

・Timber dimensions: length from the "motokuchi" and "suekuchi" sides to the location of the "kidori," length of timber after "kidori" cutting (design length), camber value after "kidori," and the width and height of both cut ends after "kidori"

e) Overlaid display of blueprint data

For items for which determining the dimensional values is difficult, the system superimposes the cloud point data with cross-sectional lines from the blueprint when displayed in plan view and these cross-sectional lines indicate the sections on which other cut materials

Figure 2. 3D laser scanner

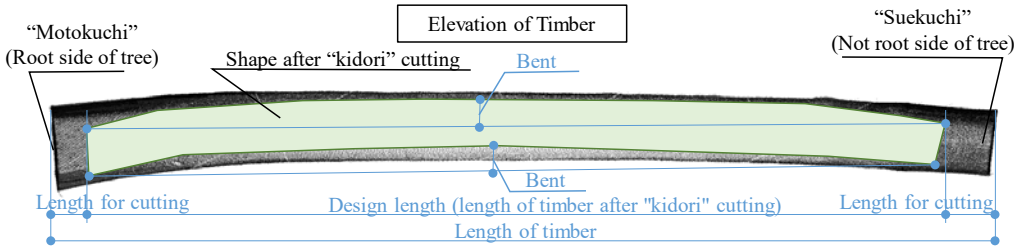

Figure 3. Names and dimensions of each part in timber

intersect. Given that timber does not comprise perfectly straight lines or curves, it must be checked prior to assembly to verify whether it will properly intersect and connect with other pieces.

3.2 Data Compaction and Generalization Method for 3D Scan Data

We propose a method of converting point cloud data into a lightweight, general-purpose format such that the geometry data of the timber obtained in Section 3.1 can continue to be used in subsequent processes.

We focused on using this solution in the context of considering how to process wood after it is procured. This process presumes the use of the tool to simulate, using a CAD program, how timber would be processed and machined for subsequent use. The cloud point data is converted into a more lightweight polygon mesh.

To that end, we employed both the following algorithms to convert the data to meet those requirements:

3.2.1 Culling Point Clouds Using Octrees

When generating polygon mesh data from point cloud data, we first mechanically generate triangles using the point clouds as vertices. Therefore, creating lightweight polygon mesh data requires culling points to a more even approximation. However, point cloud data is a collection of points measured by laser radially around a 3D laser scanner, which means even the same piece of timber can exhibit considerable variation in point density depending on the scan location. Accordingly, an even thinning method using octrees is used to simplify the non-uniform point cloud data. Octrees are a representational method of dividing a target space evenly on a grid; we believed that leaving single point data within the cells of a subdivided space would help us obtain evenly culled cloud point data as shown in Figure 4.

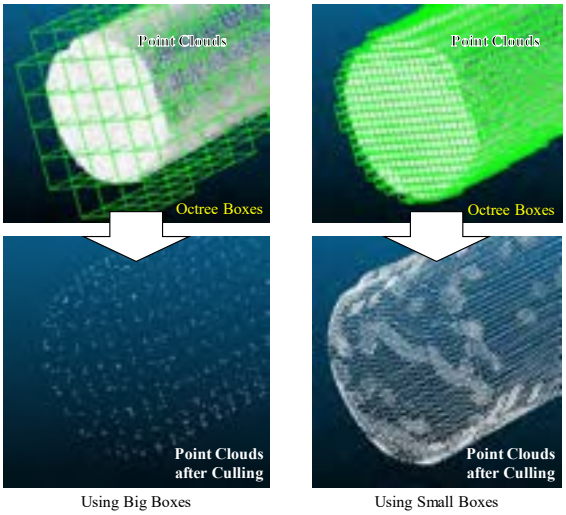

Figure 4. Examples of culling points by octrees

3.2.2 Smoothing Using Poisson's Equation

When creating a polygon mesh using the culled point cloud, one issue is noise within the point clouds, which is then calculated as part of the vertices, resulting in irregularities that differ from the actual shape. The laser scanning process functions by estimating the distance from time and phase differences caused by laser reflection, which implies that some noise is inevitable due to airborne dust or dirt on the equipment. Therefore, we allowed for the generation of polygon mesh containing some noise, then minimized its impact by smoothing the mesh. Specifically, we adopted a smoothing algorithm using Poisson's equation, as announced by Kazhdan et al. [3]. This is the process of calculating the average plane of the neighboring faces, preventing sharp irregularities and smoothing the entire surface as shown in Figure 5. We believe that this step allows for generating a polygon mesh that is minimally affected by mechanical noise. The resulting polygon mesh is archived in STL format. We opted to use STL because it is a universal intermediate file format commonly used in 3D CAD software in architectural systems and simulation and analysis software in other fields.

In this research, we tested the effectiveness of these methods in actual projects, the outcomes of which re detailed in the next section.

4 Application to the Project

4.1 Project Overview

An actual project to restore a traditional wooden building is adopted in this paper as its theme.

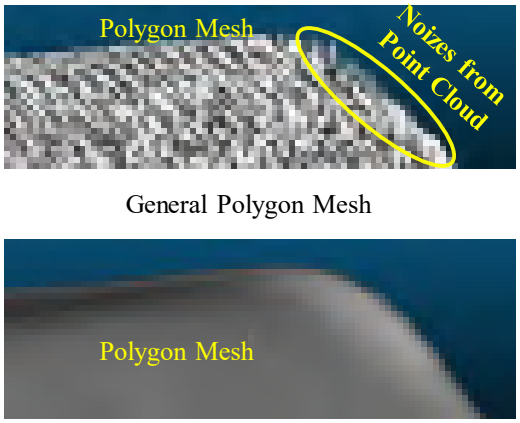

Figure 5. Smoothing polygon mesh

About 2,323 trees covering a volume of about 2,000 ㎥ were used as the materials for the mainframes; mainly Hinoki cypress and pine and square and round pieces of timber depending on the part. These were then processed into materials by carving out one column or beam from each tree.

The following is an explanation of the inspection tasks to serve as the model case for inspection. First, the timber to be inspected was laid on the ground in the direction for which its warp is parallel. The exposed parts in this state, which specifically constitutes both ends of the cut section comprising roughly 3/4 of the sides of the timber, are subject to inspection. In this instance, a blueprint of the designed cross-section with the original dimensions was laid between the timber and ground as necessary to compare the shapes. This process was carried out for all the timber and to move it and turn it over smoothly, the timber to be inspected was laid out on the ground by the day before the inspection, whereupon the timber that had already been inspected was moved and stacked in the stockyard in order. The new methods were then applied as part of this workflow.

4.2 Ways of Applying the Proposed Methods

4.2.1 Objectives

The first objective involved automatically executing inspections related to shape beforehand. The second objective involved archiving the point cloud data obtained as light and general data to be utilized in post-inspection processes.

4.2.2 Targets of Application

The targets were about 500 poles of round pine timber to be used as material for the main frame. This is because they had the most complex and unique shapes among the materials to be used, presenting the most significant potential impact of consequently applying the proposed methods.

4.2.3 Application Period and Location

The application took place between January 2019 and March 2020 in Iwate Prefecture, Japan.

4.2.4 Equipment Used

・3D laser scanner (FARO Focus 3D S120)
・Point cloud editing software (FARO SCENE)
・Developed inspection assistance program
・A software package to execute algorithms to cull and generalize point clouds: Cloud Compare (free software)

4.2.5 Ways of Application to the Project

1. Inspection Assistance Methods

Each timber block had its shape 3D scanned twice. The first was when the timber was laid out the day before the inspection and the second was when the timber was turned over after the inspection and moved to the stock-yard. To avoid missing any measurements, each timber block was scanned from two to four positions and the state of the timber pieces the day before the inspection is shown in Figure 6. There were two reasons for scanning the timber twice. The first was to scan the surface as a minimum requirement for automatic inspection prior to human inspection. Even if this is done beforehand, there are not enough surfaces exposed when pieces of timber are stacked and it was considered feasible to inspect the shapes when the timber is laid out on the ground. The second reason was to avoid adding steps to the usual procedures. To utilize the data from the scans in later processes, data is required for all the timber surfaces. However, the considerable effort would be needed to do so before the inspection, as a forklift would be needed to move and rotate the timber. Therefore, the second scan was carried out when the remaining surfaces would be exposed during the usual workflow.

The point cloud data scanned from multiple directions was registered using dedicated auxiliary software and converted to point cloud data in PTS format, which is a

Figure 6. Statement of timbers the day before inspection

general intermediate file format, after being separated into files for each timber block.

Subsequently, the inspection assistance program was used on the point cloud data for each timber block to automatically generate the following dimensions while also overlapping the designed cross-section data.

・Outer dimensions of the timber: The width and height of the cross-section at both ends and the length of the timber

・Dimensions after processing: The design length and the distance between both ends of the materials carved out of the timber, the warp of the materials and the width and height of the cross-sections at both ends of the materials

To add, regarding the length between both ends when carving out the materials from the timber, the initial value was 250mm from the root side of the timber, which was set as a standard rule for the project because the pieces of timber ordered are 500 mm longer than the design.

2. Data Compaction and Generalization Method

The process of simulation the processing shape of the timber by the construction department on a post-process using polygon mesh data, using the popular computational design software programs Rhinoceros and Grasshopper. The processing flow was set up to first apply the processing rules written in the programming language to the 3D timber data before processing and then automatically generating the log shape after processing. To implement this processing flow, the 3D data to be input should be general-purpose surface data and the file size must be 10 MB or less. Since the point cloud data obtained do not meet this requirement, we attempted to transform the data obtained with the method proposed in the previous section.

As the target polygon mesh data specifications, the vertices of the triangular meshes comprising the data were set at intervals of about 10 mm. The reason is that after interviewing a designer who is considering machining and a carpenter, when considering machining with characteristic distortions and scratches on the timber surface in mind, the data suffices provided irregularities of 10 mm or more are expressed, because the conclusion has been obtained.

Specifically, since timber used in traditional wooden construction is often around 7,000 mm long, point cloud data at 9.6 mm intervals can be obtained by dividing with $9^3 = 729$ grids.

Then, a polygon mesh was generated using this point cloud as its apex and the surface was smoothed using Poisson's equation. These processes were carried out by combining multiple features available in the free software package CloudCompare.

The results of applying the above processes are explained in the following chapter.

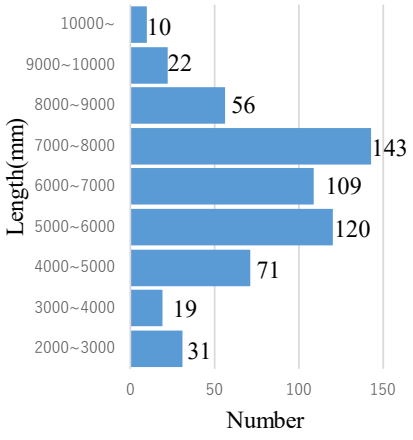

Figure 7. Statement of timbers the day before inspection

5 Results and Discussion of Applying the Proposed Method

First, we will describe the results of 3D scanning of timber. We accompanied timber inspections to apply this method during a 32-day period between January 2019 and March 2020 and performed 3D scans of all 581 logs of round timber including re-inspection. The number of logs by length is shown in Figure 7. The shortest log was 2,350 mm and the longest was 16,968 mm, with a median length of 6,800 mm. The results of the inspection assistance method using these data and of the data compaction and generalization method are described and discussed in the following section.

5.1 Results and Discussion of Applying the Inspection Assistance Method

First, we will describe the results of testing this method on one representative timber log. A timber log 7,130 mm long, which is close to the overall median length and shaped similarly to many other logs, was selected as the test log and will hereinafter be referred to as the sample log. The first 3D scan was performed a day before the inspection, with the sample log laid out on the floor next to four other logs. The 3D scan was performed from seven positions around the five logs to reduce shielding as much as possible. The equipment positioning during the measurement is shown below. Four plastic balls, 145 mm in diameter, were placed around the log to serve as benchmarks during the registration process and laser scanning was performed at a resolution of 5,120pt/360°. This density corresponds to intervals of about 4 mm at a distance of 10 meters. Next, the data for the sample log were

extracted from the obtained point cloud data with point cloud editing software and saved in PTS format. Then, the inspection assistance program we developed was used to automatically generate the dimensional values required for inspection. The specific inspection items and dimensional values generated with the program are shown below. Inspection items: Length of 6,800 mm or more, W×H of the cross-section on the root side of the log of 550 x 550 mm or more and warpage within 150 mm ± 30 mm. The automatically calculated values included a length of 7,044 mm, a cross-section of 728 x 663 mm and warpage of 139 mm, which met the acceptance criteria. In addition, a cross-sectional layout view was superimposed on the point cloud data, so that one inspector could make a preliminary evaluation, even for shapes that could not be expressed numerically. Consequently, the conventional process of comparing the log with a full-sized paper diagram placed under the timber log at inspection could be omitted for this sample log. The preliminary inspection using this program is shown in Figure 8.

We will discuss the results of using this inspection assistance method by assessing the required man-hours. 20 minutes per log are required for the usual inspection. The inspection time is shortened by 10 minutes by omitting any comparison to a full-sized drawing paper. Conversely, the 3D scanning and data processing carried out by a single engineer requires about 30 minutes per log. The above approach shortened 50 man-minutes out of 160, or about 31%.

In addition, the use of this method created added value that were inexpressible numerically. At the request of a highly skilled craftsman, we were able to confirm dimensions and shapes that were not assessable when inspecting the actual timber log in advance. There are two specific points, the first of which is warpage. The inspection items include confirming the parts that can be measured on the outside of the log. Using the point cloud data, we could measure warpage from the inside of the timber to the top, which is more important for construction. The second point is the cross-sectional shape of the timber when processed. In this case, we could assess the virtual cutting surface using the point cloud data, which demonstrates how a highly skilled craftsman can perform more sophisticated work when using this digital technology.

5.2 Results and Discussion of Applying Data Compaction and Generalization Method

We will describe the results of testing this method on the sample log. The point cloud data obtained in (1) are described as a text array of (x, y, z, intensity, R, G, B). The point cloud data of the sample log comprised 1,097,310 data points of heterogeneous density with a file size of 67 MB. As a first step, a three-dimensional octree

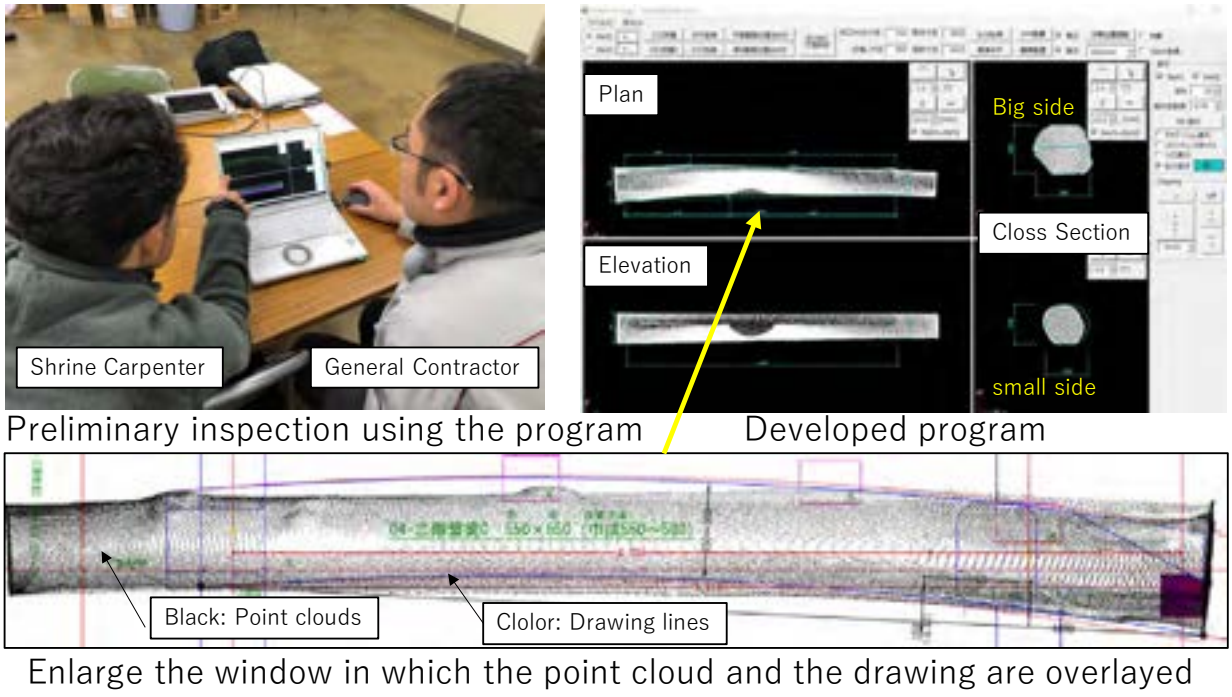

Figure 8. Statement of timbers the day before inspection

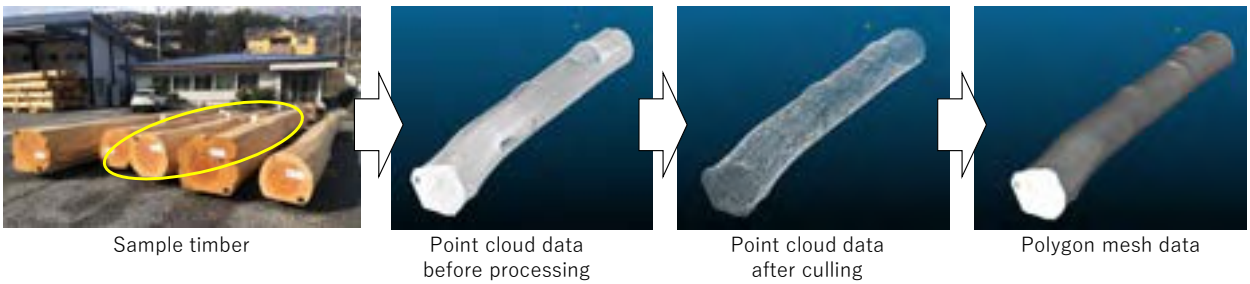

Figure 9. Procedure of data conversion for sample timber

was generated by dividing the data into 93 areas and only one point was left in the center of each area, reducing the data evenly to a density of about 10 mm intervals. Next, a polygon mesh comprising triangles and with each of these points as vertices was mechanically generated and the surfaces smoothed using Poisson's equation to produce polygon mesh data of the desired quality. When the data was saved in the STL format, the file size could be reduced by 88.4% to 7.6 MB. The data conversion procedure is shown in Figure 9.

The data created by the above procedure could be used for processing simulation, as shown in Figure 10. Specifically, the cross-sectional shape is defined as a regular hexagon inscribed in a circle of diameter 550 mm and timber is cut along the center line in the long axis direction. Usually, simulations are done with a simple BIM model for design purposes, but with our method, the real shape of the timber log could be used to plan more precise processing and extract potential issues. This demonstrates that compacting and generalizing the data obtained in (1) can enable more sophisticated work, including in later work stages.

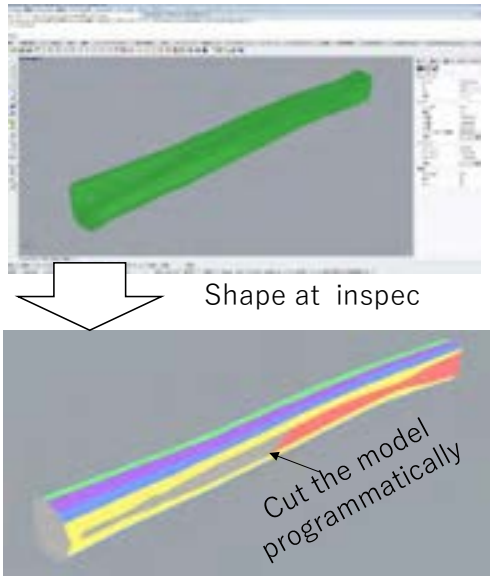

Figure 10. Processing simulation after inspection

6 Conclusion

In this study, we proposed a method to assist inspection using 3D scans of building material shapes and a data compaction and generalization method to facilitate use of these data in subsequent work stages. We also verified the effectiveness of these methods by applying them to a traditional wooden castle restoration project. Our results showed that the method helped save about 4,000 man-hours involved in inspecting building materials and that converting the obtained data into polygon mesh data about 90% smaller in size made them amenable for use in subsequent processing simulations. Our results also suggested the feasibility of a highly skilled craftsman using this digital technology to perform more sophisticated work than with conventional methods.

In future, we aim to investigate ways to efficiently manage the relationship between these data to use data obtained with such digital technologies more efficiently in the overall architectural workflow and improve construction.

Abstract –

In order to monitor the state of large-scale infrastructures, image acquisition by autonomous flight drones is efficient for stable angle and high-quality images. Supervised learning requires a large dataset consisting of images and annotation labels. It takes a long time to accumulate images, including identifying the damaged regions of interest (ROIs). In recent years, unsupervised deep learning approaches such as generative adversarial networks (GANs) for anomaly detection algorithms have progressed. When a damaged image is a generator input, it tends to reverse from the damaged state to the healthy state generated image. Using the distance of distribution between the real damaged image and the generated reverse aging healthy state fake image, it is possible to detect the concrete damage automatically from unsupervised learning. This paper proposes an anomaly detection method using unpaired image-to-image translation mapping from damaged images to reverse aging fakes that approximates healthy conditions. We apply our method to field studies, and we examine the usefulness of our method for health monitoring of concrete damage.

1 Introduction

1.1 Related Works

Starting from a climbing robot for inspection in 2000 [1], there has been much research on autonomous robotics for infrastructure inspection [2];for example, bridge crack detection [3] using unmanned aerial vehicles (UAVs), and so forth. After the deep learning revolution in 2014 [4], vision-based infrastructure inspection techniques have been researched using deep learning algorithms [5]. UAVs as autonomous robotics and vision-based deep learning techniques have been combined for powerful inspection applications [6]-[9].

In the field of infrastructure inspection, there are useful algorithms to detect damages such as object detection tasks and semantic segmentation. However, from a supervised learning standpoint, the damaged class is a rare event and the dataset including such events is always imbalanced, and hence, the number of rare class images is very small. When deteriorations are more progressed, the less events that occurred to enable image collection. Because of this scarcity of damaged data, it is difficult to improve the accuracy of supervised learning in infrastructure inspection. This is one of the hurdles to overcome our underlying problems for infrastructure aging detection for data mining from supervised learning approaches. Instead, this paper proposes an unsupervised deep learning method for aging detection.

Since 2014, the original generative adversarial network (GAN) paper has been cited more than 21,400 times to date (August 14, 2020). Starting from GAN's invention in 2014, the field of GAN has been growing exponentially. Over 500 papers have been published on the topic [10]. GANs may be used for many applications: not just fighting breast cancer or generating human faces, but also 62 other medical GAN applications published until the end of July 2018 [11].

Furthermore, unsupervised deep learning approaches such as the generative adversarial network for anomaly detection algorithms have progressed [12]. When a damaged image is a generator input, it tends to reverse from the damaged state to the health-like state image. Using the distance of distribution between the real damaged image and the generated reverse aging health-like image, it is possible to detect the concrete damage automatically from unsupervised learning.

In the field of infrastructure, there are synthetic augmentation studies to map from the structure edge label to damaged images such as concrete crack and rebar exposure [13]. Here, the conditional GAN framework pix2pix [14] is one of the most successful one that uses paired images, but the image-to-image relationship, i.e., the one-to-one relationship, is a strong constraint for dataset preparation. In particular, we could not collect any unseen damaged image not yet experienced.

In contrast, the CycleGAN framework is flexible for the case of mapping unpaired images from domain-A to domain-B. Even if each number of domain images is different, the CycleGAN framework enables the optimization of end-to-end unsupervised learning. This paper proposes an anomaly detection method using the unpaired image-to-image translation framework CycleGAN, mapping from damaged raw images to reverse aging images as a fake that approximates health conditions. We apply our method to field studies conducted on two dams in Japan.

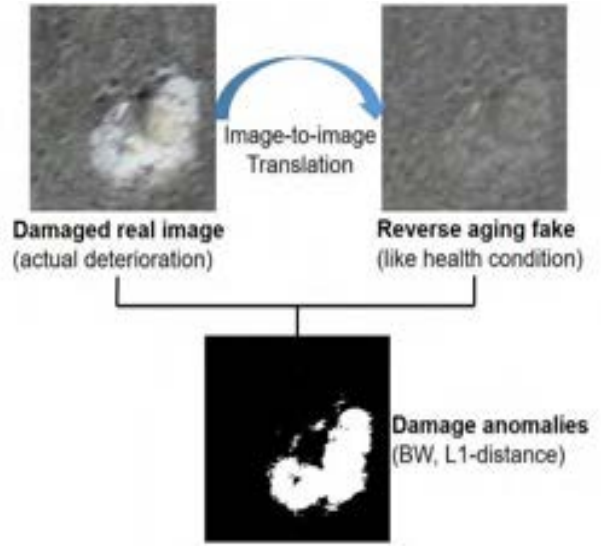

Figure 1. A proposed method using unsupervised generative learning and L1-distance detection.

1.2 Unsupervised Aging Detection Workflow

Figure 1 shows an overview of our method using unsupervised generative learning and L1-distance anomaly detection. This method consists of three mainly workflow so as to detect aging infrastructures.

1. Prepare unpaired images dataset: extract from drone images into unit size images and divide two subgroups with damaged and healthy conditions.
2. Train generators and discriminators to optimize the objective function of CycleGAN network mapping functions reverse aging (forward) and deterioration (backward), and cycle consistency.
3. The damage anomalies are visualized by adapting the noise threshold to compute the L1-distance between the real damaged image and the fake output that approximates the health condition using the reverse aging generator.

2 Generative Damage Learning Method

2.1 Unpaired Dataset Preparation

Auto-flight images captured by a drone have 43 images with a pixel size of 6,000 × 3,000 at the upper left side of dam-1 in the Kanto region. In this study, we set the unit size to 256 × 256. Without loss of resolution, we are able to resize the original size to 5,888 × 2,816 because the resized width is 256 multiplied by 23 and the resized height is 256 multiplied by 11, without any remaining surplus. This method of preparation results in 10,879 unit images.

Second, we classified two groups: a damaged group with damaged regions of interest (ROIs) made up of 4,549 unit images, and a health condition group without any damage made up of 6,325 unit images. Furthermore, we classified four groups 1) health condition without damage (3,852), 2) damaged image (279), 3) blurred (353), and 4) repaired region image (69).

Thus, we create an unpaired image dataset based on the minimum number 222 that contains domain-D (damaged) and domain-H (healthy). The domain-D contains pixel elements of both ROIs and background. Similarly, regarding dam-2 in Tohoku region, the auto-flight drone image has a size of 6,000 × 4,000 pixels, from which we extracted 12,600 unit images of size 256 × 256. This leads to another unpaired image dataset of 237 images.

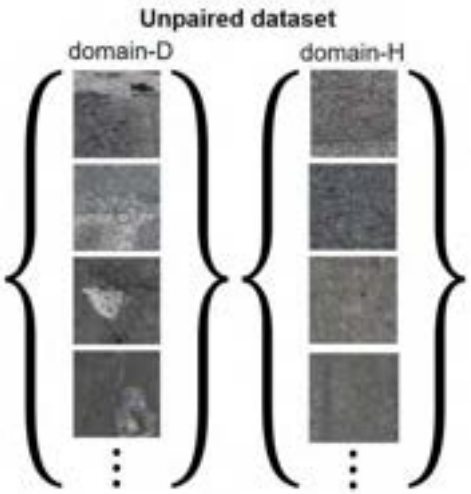

Figure 2. Unpaired images dataset: domain-D (damaged) to domain-H (healthy) translation using CycleGAN.

2.2 Damaged-to-Normal Image Translation: Reverse Aging via CycleGAN

Figure 3 shows an overview of our applied CycleGAN framework mapping the “reverse aging” (forward) function R : D →H and the “deteriorated aging” (backward) function F : H →D.

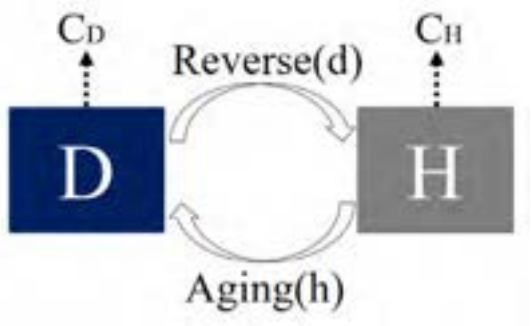

Figure 3. Our applied CycleGAN model mapping functions R : D →H and F : H →D. Discriminator function C_D classifies whether the image is a real damaged image or a generated fake one, and C_H discriminates whether it is a real health condition image or a fake output image.

As Equation (1) shows, for each image d from domain D, the image translation cycle should be able to return d to the original damaged image. This is reverse aging (forward) cycle consistency.

$$d \to R(d) \to A\big(R(d)\big) \approx d. \quad (1)$$

Similarly, as Equation (2) shows, for each image h from domain-H, both translation cycles R and A should also satisfy aging (backward) cycle consistency.

$$h \to A(h) \to R\big(A(h)\big) \approx h. \quad (2)$$

Equation (3) represents the full objective function that consists of the reverse aging adversarial loss mapping R : D →H and discriminator C_H ; the aging adversarial loss mapping F : H →D and the discriminator C_D , and the cycle consistency loss to prevent learned mappings R and A from contradicting each other as follows:

$$\mathcal{L}(R, A, C_D, C_H) = \mathcal{L}_{GAN}(R, C_H, D, H) + \mathcal{L}_{GAN}(A, C_D, D, H) + \lambda\, \mathcal{L}_{cyc}(R, A), \quad (3)$$

where λ controls the relative importance. More detailed numerical representation and network architectures of the generator and discriminator are shown as references [16].

2.3 De-noise Anomaly Detection L1-distance

Using the prediction output (health conditions as a fake output) and the input real damaged image, we propose an anomaly detection based on L1-distance. In order to detect damage anomalies as a ROI signal (large difference), another background noise (small difference) is reduced using the background noise threshold ϵ as a hyper parameter. A larger difference means the deteriorated damage, in contrast a small difference stands for the background noise, such as stain and moss-grown concrete surface. Furthermore, we try to perform blob analysis, such as area open, dilate image, and clear border analysis. This paper computes the next seven steps of image processing as follows:

1. Predict reverse aging output (healthy as a fake prediction) using a trained generator
2. Transform RGB into grayscale of real and fake
3. Centralize the median and set the absolute value
4. Visualize damage anomalies more than the background noise threshold ϵ , which is the maximum peak vector, exceeds the median
5. Area open to delete four connected elements less than 0.3ϵ (background noise threshold)
6. Dilate image with structural element “octagon”
7. Clear image border where the regions are more blight than neighbors with eight connected

3 Applied Results

3.1 Dataset of Auto-flight images

Table 1 shows the case study field of two dams in Japan from which we collected images of the concrete surface via an auto-flight drone. Dam-1 took 20 years at an early deterioration stage on the public service timeline. In contrast, Dam-2 is located in one of the snowfall regions of Japan, and consequently, 62 years passed so that several large damages have occurred in appearance.

Table 1. Dam field profile to data collect by Auto-flight

Profile	Dam-1	Dam-2
Form	Gravity Concrete dam	Arch Concrete dam
Height	156.0 m	94.5 m
Length of Levee	375.0 m	215.0 m
Service years	20 years	62 years
Region	Kanto	Tohoku

3.2 Early Damage Study: 20 years

3.2.1 Training Damaged-to-health Image Reverse Aging Translation

Figure 4 shows the training process of discriminator loss using the CycleGAN framework in the Kanto region, where the loss values are transformed into the moving average within an interval of 300 iterations and plots after skipping every 10 iterations. This discriminator classifies whether an image is the real image in the domain-H (health condition) or if it is a predicted fake output. At approximately 15,000 iterations, the discriminator recognizes the generated fake image, but after 40,000 iterations, the fake image often fools the discriminator because the generated image approaches the real health condition. This testing took 17 hours.

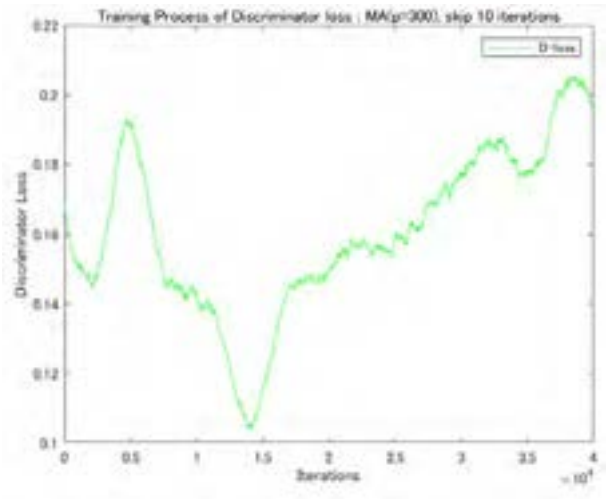

Figure 4. Training process of discriminator loss using CycleGAN framework in the Kanto region.

Figure 5 shows the training process of generator loss using the CycleGAN framework in the Kanto region. This generator transforms from domain-D (damaged) into domain-H (health condition). After 40,000 iterations, the generator approaches a minimum level.

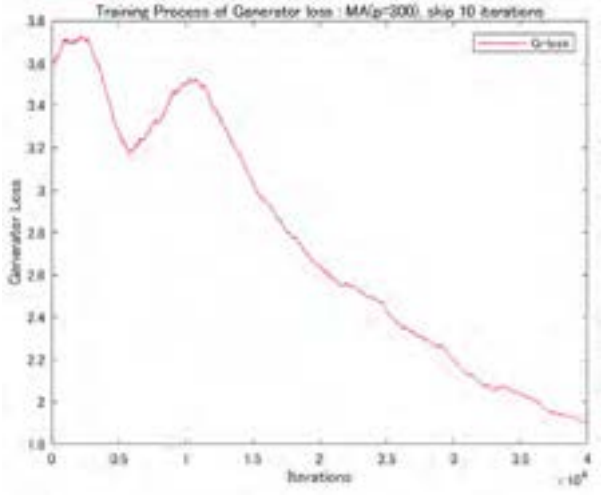

Figure 5. Training process of generator loss using CycleGAN framework in the Kanto region.

3.2.2 Anomaly aging detection using L1-distance between raw image and predicted fake

Figures 6 to 9 show the output results of dam-1, such as damaged image (upper-left) and reverse aging "health condition fake" (upper-right) that were translated using trained generator mapping from damaged to health conditions. Both the real damaged and reverse aging fake output are subtracted into a gray-scaled L1-distance mask output (bottom). Although a small noise level remains, our method can detect phenomena such as exfoliation, isolated stone, and sand leak. In particular, Figure 9 shows that sand leak damage is not yet recognized.

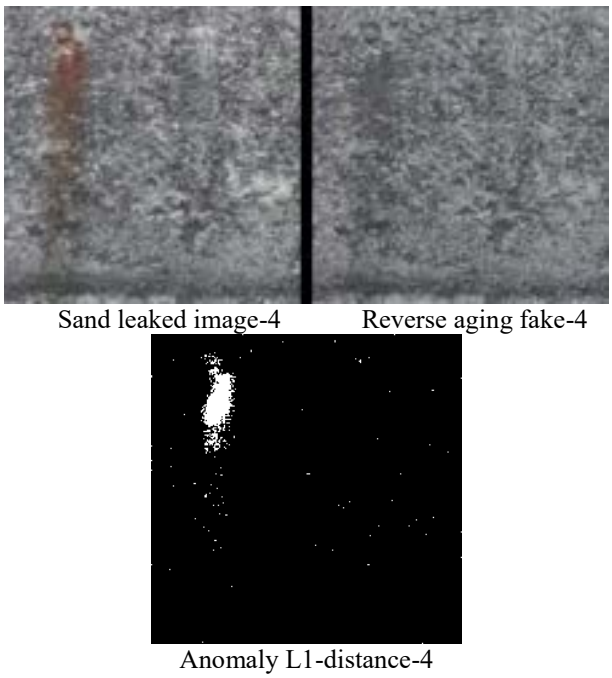
Anomaly L1-distance-3

Figure 8. Pre-cause pop-out isolated stone image (upper-left) and reverse aging "health condition fake" (upper-right) translated using trained generator mapping from damaged to normal image. Grayscale L1-distance mask output (bottom).



Sand leaked image-4 Reverse aging fake-4

Anomaly L1-distance-4

Figure 9. Sand leak image (upper-left) and reverse aging "health condition fake" (upper-right) translated using trained generator mapping from damaged to normal image. Grayscale L1-distance mask output (bottom).

We learn a lesson from this dam-1 case that was 20 years old. Even if the inspection target class is a rare event, by using "reverse aging" generator, any damage anomalies could be detected. In studying a dam over a period of 20 years, our method is useful for "rip care" on the early deterioration stage, such as sand leak and exfoliation, so as to avoid subsequent progressive damage at the prognosis of concrete structures.

3.3 Cold Damage Study: 62 years

3.3.1 Training Damaged-to-health Image Reverse Aging Translation

Figure 10 shows the training process of discriminator loss using the CycleGAN framework in the Tohoku region, where the loss values are transformed into the moving average within an interval of 300 iterations and plots after skipping every 10 iterations computing. This discriminator classifies whether it is a real image in the domain-H (health condition) or if it is a predicted fake output image. After 20,000 iterations, the discriminator repeats to fool the output image because the generated image approaches the real health condition. It took 17 hours to complete this training process.

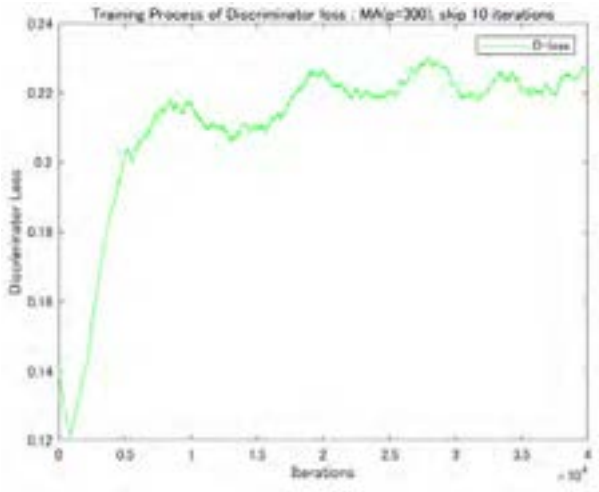


Figure 10. Training process of discriminator loss using CycleGAN framework in the Tohoku region.

Figure 11 shows the training process of generator loss using the CycleGAN framework in the Tohoku region. This generator maps from domain-D (damaged) into domain-H (health condition). After 30,000 iterations, the generator approaches a stable level.

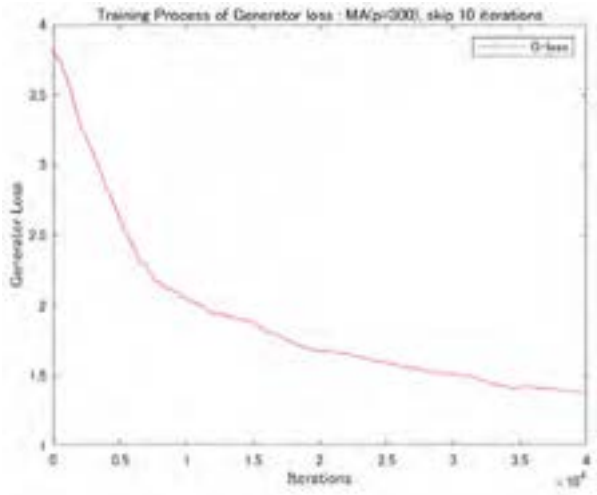

Figure 11. Training process of generator loss using CycleGAN framework in the field of Tohoku region.

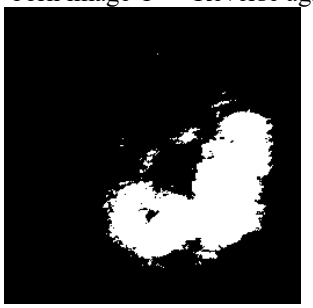
3.3.2 Anomaly aging detection using L1-distance between raw image and predicted fake

Figures 12 – 15 show the detection studies conducted on dam-2, similar to those on dam-1; the damaged image (upper-left) and reverse aging "healthy fake" output (upper-right) were translated using trained generator mapping from damaged to health condition image. Both the real damaged and healthy fake output are subtracted into a gray-scaled L1-distance mask output (bottom).

Pop-out crater-born image-1 Reverse aging fake-1



Anomaly L1-distance-1

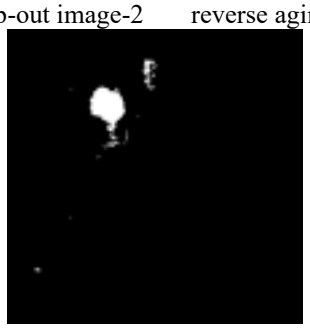
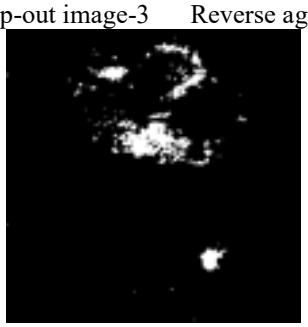
Soft stone pop-out image-2 reverse aging fake-2



Anomaly L1-distance-2

Figure 13. Soft stone pop-out image (upper-left) and reverse aging "health condition fake" (upper-right) translated using trained generator mapping from damaged to normal image. Grayscale L1-distance mask output (bottom).

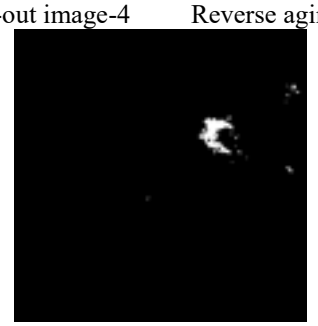
Crater-like pop-out image-3 Reverse aging fake-3



Anomaly L1-distance-3

Figure 14. Crater-shape pop-out image (upper-left) and reverse aging "health condition fake" (upper-right) translated using trained generator mapping from damaged to normal image. Grayscale L1-distance mask output (bottom).

Small pop-out image-4 Reverse aging fake-4



Anomaly L1-distance-4

Figure 15. Small pop-out image (upper-left) and reverse aging "health condition fake" (upper-right) translated using trained generator mapping from damaged to normal image. Grayscale L1-distance mask output (bottom).

4 Concluding Remarks

4.1 Contributions and Lessons

This paper proposed an anomaly detection method using the unpaired image-to-image translation framework CycleGAN, mapping from damaged raw images to reverse aging predicted fake output as healthy conditions. We apply our method to field studies conducted on two dams, one at its early stages and aged 20 years on the public service, and another one aged 62 years, which is located in a cold region. The CycleGAN framework is flexible because this input only requires an unpaired image dataset such as raw images including a damaged ROI and health raw images without damage. This is a data-mining merit instead of the paired image algorithm, such as that of pix2pix.

In addition to the merit of more flexible dataset, our generative unsupervised approach does not require annotation works supervised for any classes, such as damaged ROIs and background. After we prepare to extract a unit size image and divide a damaged group with another health group, we can use unsupervised deep learning to perform end-to-end training to create an image-to-image translator mapping from the damaged domain to the health (normal) domain. Even if the inspection target class is a rare event, using a "reverse aging" generator, any damage anomalies could be detected. Based on our case studies, in a dam deteriorating over 20 years, our method is useful for "rip care" on the early deterioration stage on the public service of concrete structures, such as sand leak and exfoliation, so as to delay the later progressive damage.

4.2 Future Works

It is necessary to optimize a background noise threshold for visualizing the target signal of damage anomalies, and for computing the L1-distance between a damaged image and predicted fake output that approximates healthy condition. This study only considered two case studies of concrete structures. In the future, we will gain further experience with another service periods (e.g. 40 years), much moisture damp locations, steel materials, and another infrastructures such as bridges and tunnels. We will create damage anomaly scores using the L1-distance based on the generator of GAN, in addition to featurematching based on the discriminator. We will also attempt to build another framework that contains a parallel encoder for more efficient damage detection.

Acknowledgments We would like to thank Shinich Kuramoto and Takuji Fukumoto for providing practical deep learning MATLAB resources.

Evaluation of Drainage Gradient using Three-dimensional Measurement Data and Physics Engine

Kosei Ishida[a]

[a]Department of Architecture, Assistant Professor, Doctor of Engineering, Waseda University, Tokyo, Japan
E-mail: k_ishida@waseda.jp

Abstract –

The shape of a building can be recorded through various technologies, such as three-dimensional (3D) laser scanners and photogrammetry. The 3D measurement technology facilitates the mensuration of unevenness of a reinforced concrete structure, horizontality of the floor, and drainage gradient. In particular, measuring devices with a tilt sensor (e.g., 3D laser scanners) allow the evaluation of the horizontality of buildings using point cloud data. In this study, a method is introduced to evaluate the drainage gradient using 3D polygon data and a physics engine. The point cloud data were acquired via a 3D laser scanner and converted into polygon data. The polygon data were imported into a virtual space through the physics engine. Subsequently, the drainage capacity was evaluated by placing water particles on the polygon data and observing their movement according to the physics engine. The aim of this procedure is to evaluate the inclination angle of all parts of a building (e.g., rooftop) and develop a method for identifying the locations where puddles can frequently occur. Our simulation software was created using Unity and NVIDIA FleX. In this research, a simulation was conducted in which the polygon data were imported into the developed software, and the drainage situation was predicted.

1 Introduction

1.1 Background and Related Work

Point cloud data are composed of a set of points containing information related to three-dimensional (3D) coordinates and colors. However, because the data are only composed of points, they are usually converted into 3D models and building information modeling (BIM) data. Alternatively, data analysis is applied to point cloud data, for example, comparing the horizontal plane information with the point cloud data to analyze floor flatness. Accordingly, several researchers have examined evaluation methods using 3D point clouds, shape recognition of point clouds, and automatic conversion of point clouds into BIM data.

In the construction industry, approximately half of the studies on the application of point cloud data are based on 3D model reconstruction [1], and a quarter involve geometry quality inspection [1].

The automatic segmentation of point cloud data into building parts (e.g., walls and columns) acquired by a laser scanner has been investigated [2]. Research on reconstructing point cloud data into a 3D model has been performed by creating BIM data for buildings [3] and other civil engineering structures, such as tunnels [4]. Studies on creating BIM data according to the level of development (LOD) specification using point cloud data have also been explored [5]. In some studies, point cloud data and parametric modeling are combined [6]. For example, one study performed a dimensional quality assessment of the rebar of a reinforced concrete element based on point cloud data. [7]. In recent years, methods for directly performing structural calculations from point cloud data have been explored [8]. A system implemented for floor flatness compliance control given a set of point clouds and a 3D BIM model has also been proposed [9].

1.2 Research Aim

Point cloud data contain considerable amounts of information. For example, surface dirt and deterioration of buildings can be observed based on point cloud data. Furthermore, because the accuracy of 3D laser scanners has improved, it is possible to analyze the drainage gradient using the data acquired by the scanner. A 3D laser scanner can measure even the slightest unevenness in an actual building.

In several recent studies, methods for automatically converting point cloud data into a 3D model or BIM data have been investigated. The general BIM data exhibit a smooth shape of walls and floors. Therefore, the 3D shape information of the building included in the point cloud data is typically lost after conversion into BIM data. Point cloud data contain the exact shape and color

information in the real world; hence, these data include richer information than the BIM data of the LOD 500 level.

The purpose of this study is to utilize the shape information contained in point cloud data. Our research aims to devise a mechanism to evaluate drainage performance by combining a 3D surface converted from point cloud data and a physics engine.

The objectives of this study are summarized as follows:

(1) Devise a procedure to create a 3D model for analyzing drainage capacity
(2) Verify water particle movement on a 3D surface model using the physics engine
(3) Conduct validation of the drainage capacity analysis results by comparing against actual measurement data

2 Drainage gradient evaluation method using 3D measurement data and physics engine

2.1 Drainage Gradient Evaluation Procedure Using Point Cloud Data and Physics Engine

The evaluation method for the drainage gradient using point cloud data and the physics engine involves the following three steps:

(1) Measurement using a 3D laser scanner
(2) Creation of a simulation model based on point cloud data
(3) Evaluation of the drainage gradient using a physics engine

The point cloud data of a building that are obtained using a 3D laser scanner cannot be employed for simulation that uses a physics engine. Accordingly, we have formulated a procedure for converting point cloud data into information that can be applied to such a simulation.

The procedure for converting point cloud data is shown in Fig. 1. Two 3D models are used to evaluate the drainage gradient using point cloud data and a physics engine. The first type of 3D model is a surface model converted from point cloud data; the second is a 3D model of a sewer created from point cloud data and field surveys.

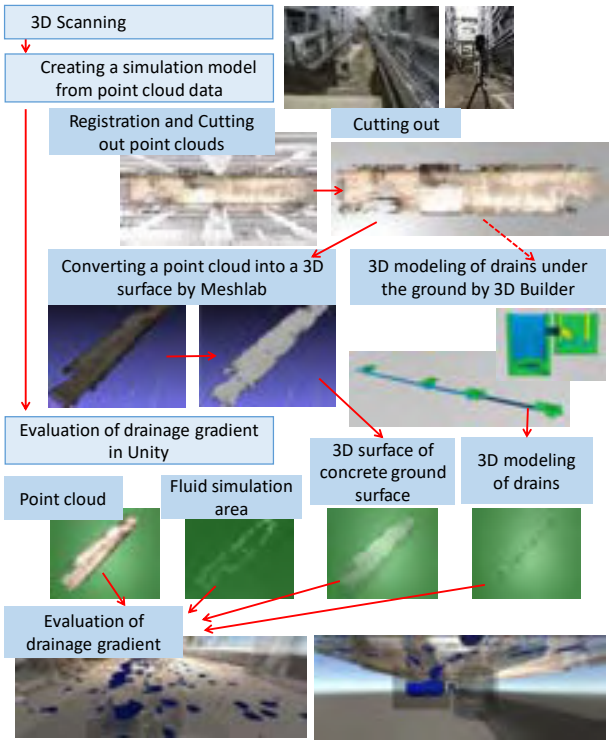

Figure 1. Evaluation procedure of drainage gradient using 3D measurement data and physics engine

2.2 Level of graphical information acquired from point cloud data

Point cloud data contain rich information; to utilize this information, the data are usually analyzed and converted into another data format. In this study, we categorized the level of graphical information acquired from point cloud data. This classification is summarized in Table 1.

A point cloud is composed of 3D coordinates, color, and brightness. We can observe the shape and color of a building as well as the stains and wet spots on its surface based on the color of the point cloud.

The data containing the information extracted from the point cloud data for analysis are derived by examining the 3D coordinates of the point cloud data. For example, there are certain amounts of data containing information on the distance of a point from a horizontal plane that represent this distance in terms of color.

The 3D surface is composed of data obtained by converting point cloud data into polygon data. In this study, objects in motion were used based on the physics engine.

The simulation model is a 3D model that implements various simulations. It is composed of a 3D surface converted from point cloud data, a simulation area, point cloud data, and 3D models. The simulation model is employed to estimate the drainage capacity using actual measurement data.

Table 1. Level of graphical information acquired from point cloud data

2.3 Creation of the Simulation Model from Point Cloud Data

2.3.1 Procedure for Creating a Simulation Model from Point Cloud Data

To create a model for simulation, we organized three types of 3D data by analyzing and converting point cloud data. These three types consist of "point cloud data analyzed to extract information" and "3D surface," as summarized in Table 1. Additionally, we created "a 3D model of drains under the ground." However, underground drains cannot be measured using a 3D laser scanner. Therefore, after examining the point cloud, we estimated the position of these drains and created a 3D model to represent them.

Four positions were scanned with the 3D laser scanner; Fig. 2 presents a photograph of these measurements. The acquired point cloud data of the campus building are shown in Fig. 3. These data were used to create the simulation model employed in this study.

The procedure for creating a 3D surface from the point cloud data is detailed below:

(1) Register several scanning data
(2) Cut out the point cloud data on the floor
(3) Convert the point cloud data into a 3D surface model

Figure 2. Measurement scheme in experiment

Figure 3. Acquired point cloud data of campus buildings

2.3.2 Registering and Cutting Out Point Clouds

We registered the point cloud data and removed the floor point cloud data to convert them into a 3D surface model; the cutoff point cloud data are depicted in Fig. 4. The installation positions of the 3D laser scanner are denoted as A, B, C, and D. The point cloud data captured from these four positions are illustrated in Fig. 5. The data were classified into four colors (i.e., red, blue, yellow, and green) corresponding to the point cloud data acquired from these four locations.

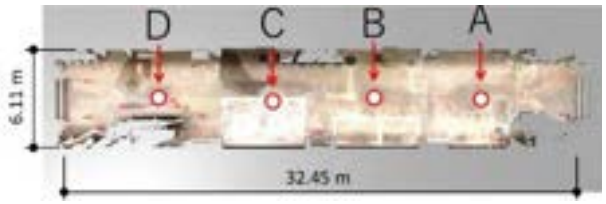

Figure 4. Installation positions of 3D laser scanner

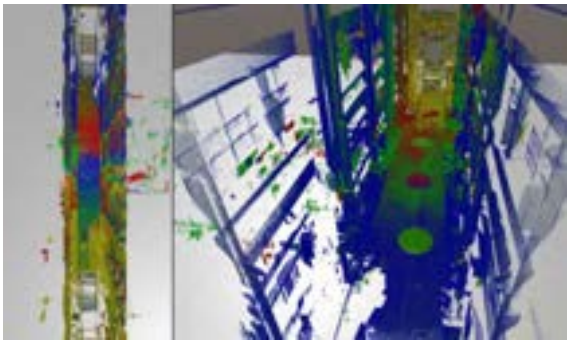

Figure 5. Point cloud data captured from four measurement positions

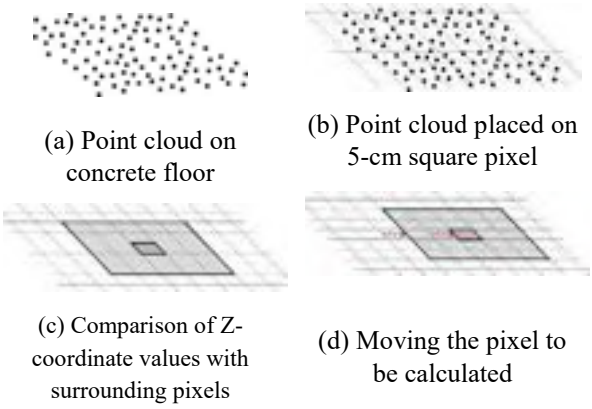
2.3.3 Measurement of Concrete Floor Flatness Using a 3D Point Cloud

The slope of the concrete slab is obtained from the point cloud data, and the location of the local minimum point is then analyzed, as presented in this section. Water accumulates in locations with low elevation. Therefore, it is essential to analyze the position of the local minimum point to compare the Z-coordinate values with the surroundings.

The analysis of the position of this minimum point was performed according to the procedure shown in Fig. 6. First, as shown in Fig. 6(a), the point cloud on the floor is extracted. The point cloud is placed on the XY plane in a 5-cm square grid, and the average value of the Z coordinate of the point cloud in the grid is calculated. Next, one grid is selected, as shown in Fig. 6(c), and the elevation based on the Z coordinate is compared with the surrounding grids of 11 × 11 cells. If the Z coordinate of the selected grid has the smallest value in the 11 × 11 cells, then that position is defined as the local minimum point.



(a) Point cloud on concrete floor

(b) Point cloud placed on 5-cm square pixel

(c) Comparison of Z-coordinate values with surrounding pixels

(d) Moving the pixel to be calculated

Figure 6. Calculation procedure of local minimum point position on concrete slab surface by point cloud data

The analysis results of the flatness of the concrete floor slab are presented in Fig. 7, which illustrates the inclination of the concrete slab towards the four drain covers. The positions and elevations of the local minimum point on the concrete slab are shown in Fig. 8.

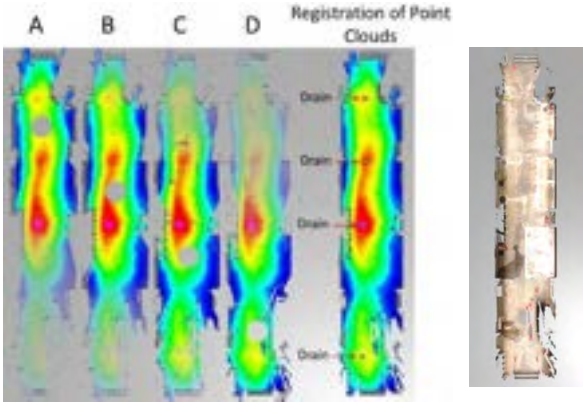


Figure 7. Measurement of concrete floor flatness using 3D point cloud data

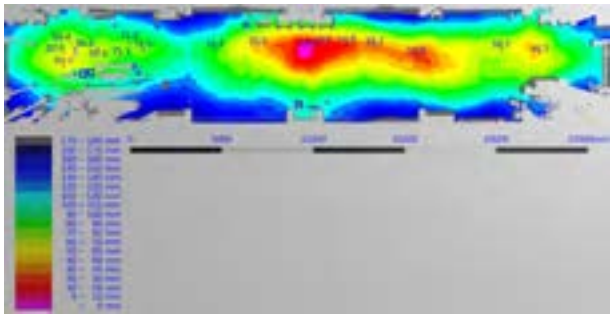

Figure 8. Positions and elevations of local minimum points on concrete slab extracted by point cloud data analysis

2.3.4 Point cloud data conversion into 3D surface model

The point cloud data shown in Fig. 4 were used to convert the point cloud into a 3D surface model through MeshLab [10]. The point cloud data consist of 6.67 million points, which were reduced to a density of point clouds at intervals of 2 cm. Thereafter, the point cloud data contained 525,000 points. Subsequently, the point cloud data were converted into mesh data. Furthermore, hole filling was performed using mesh data. Finally, the data compression process was conducted until the number of faces in the mesh data was 50,000.

2.3.5 3D Modeling of Underground Drains

We were unable to measure the shape of the drainage and sewer under the concrete slab using a 3D laser scanner. Therefore, the drain cover position from the point cloud data was extracted, and the shape of the drainage and sewer was estimated. Subsequently, a 3D model of the drainage and sewer was created using “Microsoft 3D Builder,” as shown in Fig. 9.

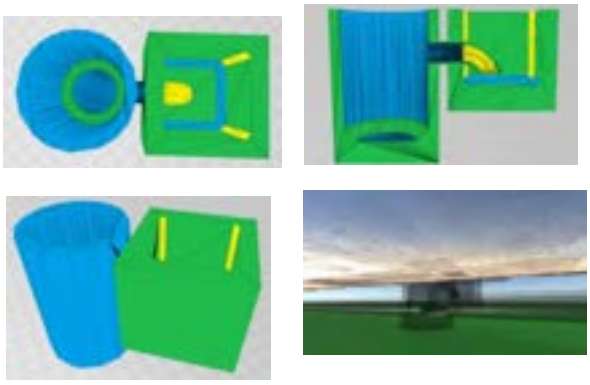

Figure 9. 3D modeling of underground drains by 3D Builder

2.3.6 Simulation Model for Analyzing Drainage Capacity

We created a 3D model and a simulation model to evaluate the drainage capacity. The 3D model contains four types of 3D shape data, as shown in Fig. 10.

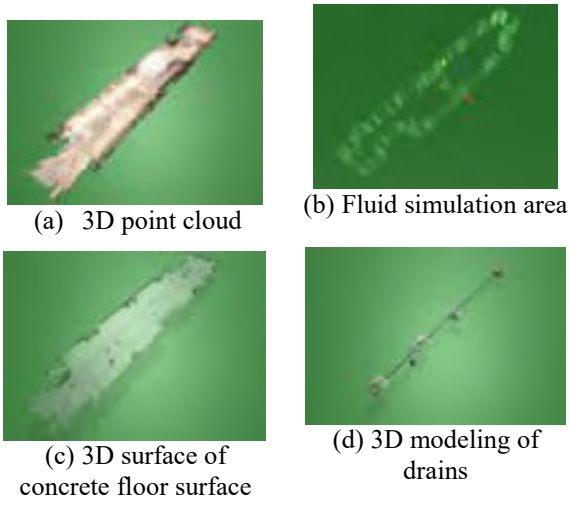
(1) color point cloud
(2) fluid simulation area
(3) 3D surface of concrete floor surface
(4) 3D model of underground drains

In this study, fluid flow simulations were performed using the NVIDIA FleX for Unity [11]. Therefore, a 3D object, which can engage with the fluid "particles", was used to convert the point cloud on the concrete floor into a 3D surface.

The 3D model of the drain was placed below the 3D surface of the concrete floor. Four holes on the 3D surface were created according to the position of the drain cover. Water particles flow through the holes in the drain cover into the 3D surface and move inside the 3D model of the drain.

The fluid simulation area is defined as a wall-shaped object. A 3D model with the wall-shaped object of the fluid simulation area is presented in Fig. 11. This area can prevent the flow of water particles from the periphery of the 3D surface.

In addition, a colored point cloud was employed to observe the dirt and water wet spots on the concrete floor.



(a) 3D point cloud (b) Fluid simulation area

(c) 3D surface of concrete floor surface (d) 3D modeling of drains

Figure 10. Four types of 3D shape data for evaluating water flow

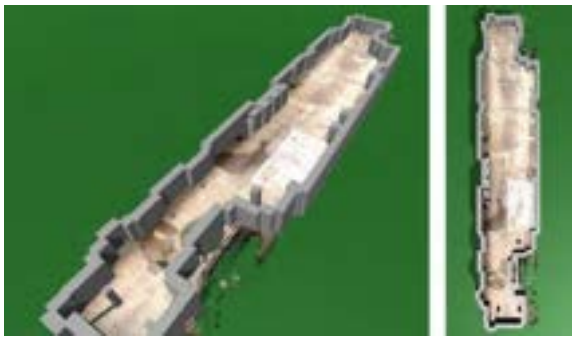


Figure 11. 3D shape data for analyzing drainage capacity

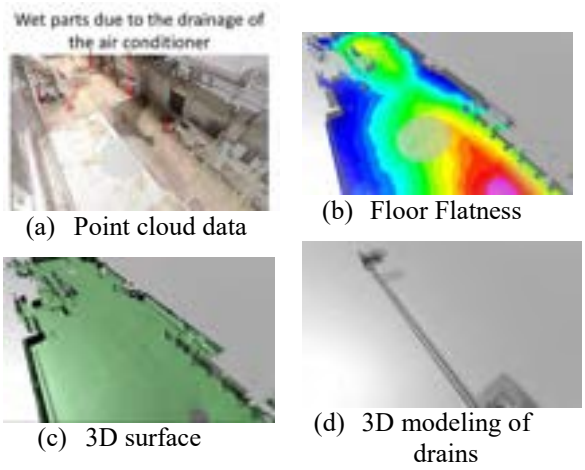
2.4 Verification of water particle movement on 3D surface model using a physics engine

The simulation model demonstrated in Fig. 11 was used to evaluate whether the water particles moved according to the principles of the physics engine. A part of the concrete slab measured in this study was wet due to water draining from the air conditioner, as illustrated in Fig. 12 (a). The water particles were generated according to the positions of the drainage of the air conditioner, thereby evaluating the water particle movement.



(a) Point cloud data (b) Floor Flatness

(c) 3D surface (d) 3D modeling of drains

Figure 12. Simulation model for verification of water particles movement using physics engine

The simulation was performed in Unity, and NVIDIA FleX was used to achieve water movement. The simulation for generating water particles in Unity and moving them onto the 3D surface is shown in Fig. 13. The water particles created by NVIDIA FleX for Unity in the 3D measurement model are shown in Fig. 14. The diameter of the simulated water particles is 0.03 m.

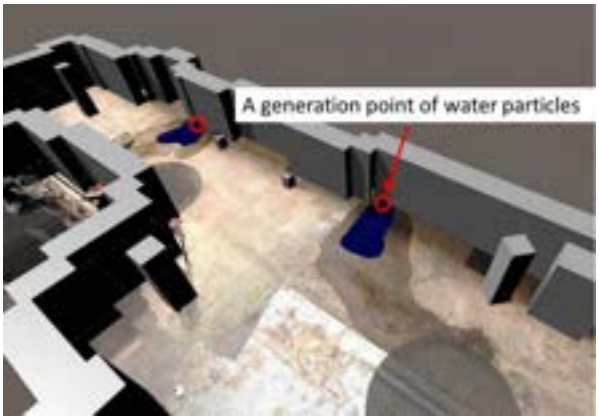


Figure 13. Simulation for predicting drainage flow

Figure 14. Water particles generation by NVIDIA FleX for Unity on 3D measurement model

The evaluation results of the drainage gradient using 3D measurement data and the physics engine are presented in Fig. 15. We confirmed that the water objects flowed on the wet parts of the concrete floor. Using the visualization data that analyzed the distance of each point from the horizontal plane and represented the distance in color, we confirmed that the water objects were flowing along the low positions of the concrete floor rather than on the surrounding area.

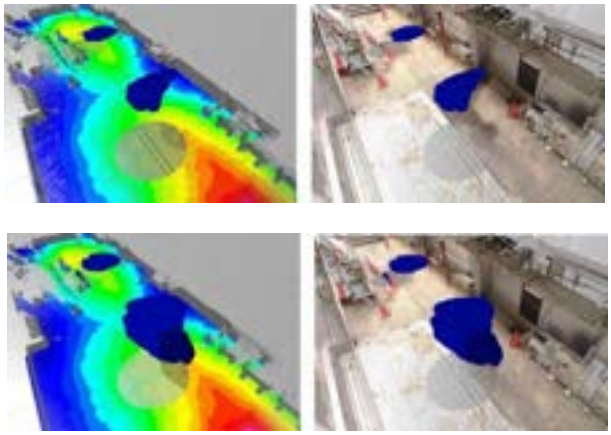

Figure 15. Drainage gradient evaluation result using 3D measurement data and physics engine

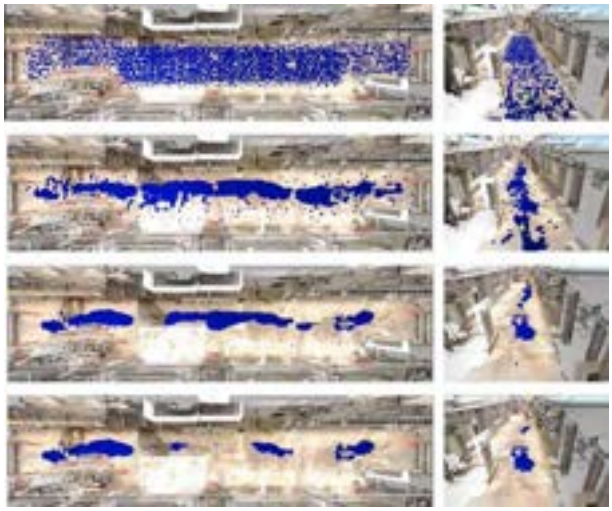
3 Results and Discussion

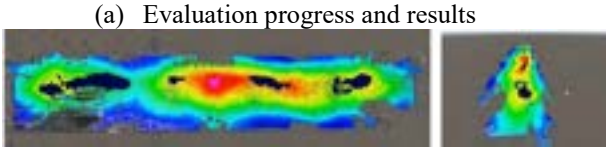
3.1 Evaluation of drainage capacity when water is uniformly generated.

A 3D measurement model was used to evaluate the drainage capacity. The results are presented based on a uniform distribution of water particles. Water particles with a diameter of 0.03 m are uniformly generated on the upper surface of the simulation model. The movement of these particles, according to gravity and their flow from the drain, was observed. The image in Fig. 16 (a) indicates that our system uniformly generated water particles.

These uniformly generated water particles on the concrete floor moved to a location with a lower elevation than the surrounding area. Thereafter, the water dropped into the drainage channel, reducing the amount of water on the floor. However, some water particles did not drain and instead remained on the concrete floor. The image in Fig. 16 (b) illustrates the accumulated water particles in the section where the gradient is low.



(a) Evaluation progress and results



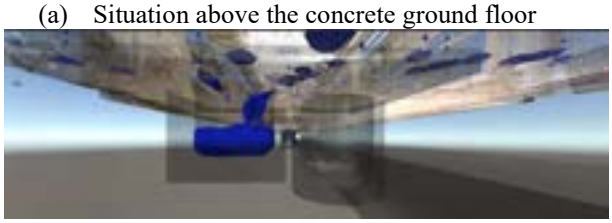
(b) Evaluation results and concrete floor flatness

Figure 16. Evaluation of drainage capacity when water is uniformly generated

3.2 Situation of drains and sewers under concrete floor slab

In the simulation (Fig. 16), it was observed that water particles flowed into the drain and through the sewer. As shown in Fig. 17 (a), the water particles flowed to the drain located above the concrete ground floor. Moreover, Fig. 17 (b) shows that the water particles flowed into the drain and sewer under the concrete floor slab.

(a) Situation above the concrete ground floor



(b) Situation of water particles flowing through drains and sewers under concrete floor slab

Figure 17. Water objects falling into drain

As shown in Fig. 18, the water particles were stored in a storm drain consisting of a catch basin and sand traps. It was confirmed that the water particles flowed into the sewer through the outlet trap when the catch basin was full.

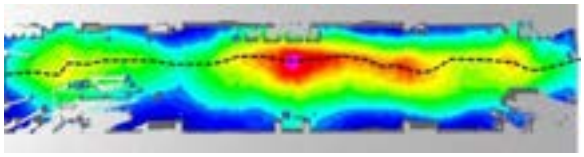
Figure 18. Water particles accumulating in drainage drain and flowing into sewer pipe

3.3 Verification of Drainage Capacity Analysis Results Using Actual Measurement Data

The simulation results of the drainage gradient were investigated using 3D measurement data and a physics engine. These were compared with the actual situation of floor drainage. First, the locations of the remaining water objects were compared with the unevenness of the concrete floor. The dotted line in the image in Fig. 19 (a) denotes the position of the valley line on the concrete floor. The figure shows that the water objects remain near the valley line of the concrete floor with a small slope value.

The locations of the minimum point elevation on the concrete slab are shown in Fig. 20. If the elevation is minimum at a 55 × 55 cm area, then this can be defined as the minimum elevation point. Considering the results shown in Figs. 19 and 20, it can be observed that water tends to remain at a point relatively lower than the surroundings.

(a) Drainage gradient evaluation results with point cloud data



(b) Concrete floor flatness and position of the valley line

Figure 19. Location of remaining water objects and valley line of concrete floor

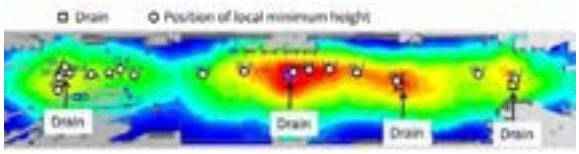


Figure 20. Position of local minimum elevation

The image on the left side of Fig. 21 depicts the condition of the actual concrete floor after the rain. The image on the right side represents the condition of the virtual concrete floor after the water particles have been drained. In observing the concrete floor state after the rain in the actual world, and based on the simulation results, it can be confirmed that water accumulates along the valley line portion, as shown in Fig. 19.

From Fig. 21, it was confirmed that the simulation results based on the measurement data were accurately analyzed to a certain extent.

Figure 21. Conditions of concrete floor after rain in actual world and after water particles are drained in virtual world

4 Conclusion

In this study, a 3D surface was created from the data obtained by converting point cloud data. The data representing the concrete floor contained 6.67 million points. However, the use of 3D surfaces reduced the number of faces to 50,000. The size of the concrete floor measured by the 3D laser scanner was 32.45 × 6.11 m, as depicted in Fig. 4. We reproduced the concrete floor, of an area of approximately 200 m², with a 3D surface composed of 50,000 faces. This 3D surface with a reduced data size was used to verify that the drainage gradients could be evaluated.

Furthermore, we reproduced the drainage and sewage channel under the concrete slab using a 3D model, which was used in combination with the 3D surface in the drainage simulation. It was confirmed that the water particles properly flowed inside the drains and sewers.

Ultimately, this study verified that the drainage gradient could be evaluated using a 3D measurement model and physics engine.

Stakeholder Perspectives on the Adoption of Drones in Construction Projects

V.P.C. Charlesraj and N. Rakshith

RICS School of Built Environment, Delhi NCR 201313 India
E-mail: vpcharlesraj@ricssbe.edu.in, rakshithn.mc18n@ricssbe.edu.in

Abstract –

Drones or Unmanned Aerial Vehicle (UAV) and services based on them have been used globally in various sectors including but not limited to construction, real estate, e-commerce, agriculture, utilities & energy, financial services, and media & entertainment. Use of such robots have a potential to reduce the cost & time and increase safety & productivity among other benefits. The use of drones is increasing in India and the UAV market is expected to grow at a CAGR of 18% during 2017-2023 in terms of revenue. While the use of drones is primarily in defence sector compared to commercial use, it has been reported that drone-based solutions are being explored in agriculture, energy & utilities, insurance, infrastructure, media & entertainment and mining in India. Hence, there exists a need to investigate the level of awareness, application, benefits and barriers of using drones in Indian construction.

The primary objective of this study is to investigate the level of awareness and the application of drones among the key stakeholders in Indian construction through questionnaire survey-based quantitative research among key stakeholders. The study revealed there is high level of awareness of drones and low level of usage in Indian construction. The overall pattern in the data revealed that the respondents have rated most of the indicators highly important. Following are the top-rated attributes: Drones must be experimented before using it in the construction projects (relevance); Surveying (application); Drones provide real time updates from the site (benefit); Weather related issues (barrier) and Health and Safety (KPI). It has been observed that there is statistically significant difference in perception among contractors, consultants and clients with respect to relevance & application of drones and not so for benefits, barriers & impact on KPI.

Awareness; Drones; Indian construction; Unmanned Aerial Vehicle (UAV)

1 Introduction

The construction industry globally is worth 10 Trillion Dollars per annum. The countries around the world spend around 9-15% of the Gross Domestic Product on the construction sector. But the construction industry is very fragmented and unorganized. The construction industry is facing huge challenges compared to other sectors. There is a serious performance outfall observed over the decades in the construction industry [1].

The challenges such as lack of performance, low productivity of labours, lack of data collection and documentation, cost over runs of the project, lack of adoption of technology, delays in project completion, safety issues on site, lack of quality, lack of innovation, high expenses and management issues are observed in the construction industry [2]. The industry suffers with severe shortage of labours, lack of adoption of new technology, lack of performance due to decreased productivity [3]. Disasters such as one created by COVID-19 pandemic demand change in working conditions in addition to unavailability of resources.

One of the ways to overcome these challenges in construction operations is to implement automation and robotics to improve the performance [4]. Construction industry is labour dependent and robotics & automation has shown potential improvement in the productivity and quality of the construction projects [5]. The emerging technologies such as Building Information Modelling (BIM), Internet of Things (IOT), Light Detection and Ranging (LIDAR) and robots like bricklaying machine, glazing machine, Unmanned Aerial Vehicle or drones, autonomous ground vehicles, robotic 3d printing can be used to increase the productivity, reduce the cost over-runs and delays in the project. So there is need for adopting the innovative technologies for the development of the construction industry [4,6].

Drones or Unmanned Aerial Vehicles (UAV) can be adopted as potential solution to the challenges faced by the construction industry. While the use of drones in India is primarily in defence sector compared to commercial use, it has been reported that drone-based solutions are being explored in agriculture, energy &

utilities, insurance, infrastructure, media & entertainment and mining in India. The regulation on the use of drones in India has been released very recently. Adoption of drone technology is in its formative stage in Indian construction. Hence there is a need to investigate the adoption of drones in Indian construction. It has been attempted to study the level of awareness & adoption of drones in Indian construction and assess the perspectives of various key stakeholders.

2 Literature Review

2.1 Drones

Drones or UAVs also known as Remotely Piloted Aircraft (RPA) are the aircrafts which operates without the requirement of onboard human pilot and are controlled by remotes [7]. Drones vary in the sizes and can be equipped with various accessories. The various parts of drones include frame for supporting the components of drone, propeller and engine which constitutes propulsion system for lift off, battery which acts as power source, electronic and communication system which is used to control drone [8] . The drones are attached with sensors which are used for the alignment and positioning. Manual interference of the pilot is not required due to these sensors[9].

2.2 Types of Drones

Based on the vehicle mass principle the drones can be classified as "heavier than air" drones in which the drone uses aerodynamics and propulsive thrust, "Lighter than air" drones in which the drones which uses the principle of buoyancy. Wing type and rotor type come under the "Heavier than Air" drones. Wing and rotor are further divided as wing type multirotor, fixed-wing, flapping wing, single-rotor and fixed wing hybrid[10]. Based on take-off and landing it is further divided into two types as horizontal take-off and landing(HTOL) and vertical take-off and landing(VTOL)[11].

The classification of drones based on total weight including payload in India is shown in Table 1 [12]:

Table 1. Types of Drones

Sl. No	Type	Payload
1	Nano	≤250 Grams
2	Micro	>250 Grams and ≤ 2Kg
3	Small	>2 kg and ≤ 25 Kg
4	Medium	>25 Kg and ≤ 150 Kg
5	Large	> 150 Kg

2.3 Regulations on Drones in India

The Director General of Civil Aviation (DGCA) has released a policy on regulation of drones on 27th August and came into effect on 1st December 2018 in India [12]. The policy briefs about the classification and restriction on drones. The operators must obtain license Unique Identification number and Unmanned Aircraft Operation permit.

Any drones imported to India have to obtain Equipment Type Approval (ETA) from Department of Telecommunication. Except Nano drone all the other drone categories should apply for DGCA clearance

Unique Identification Number (UIN)

All the drones except Nano Drones must obtain the Unique Identification Number (UIN) from the DGCA.

Unmanned Aircraft Operator Permit (UAOP)

The civil drone operators must obtain the permit from the DGCA. The DGCA should provide the permit within seven days of the application submitted date. The validity of the permit is for five years from the date of issue and should not be transferred.

Drones owned by government institutions are not required to get a permit. Nano drones operating below 50 ft and micro drones operating below 200 feet are exempted from taking permit and Micro drones. All the drones must be within the Visual Line of Sight of the Operator. The maximum height allowed for the drones for various categories is as follows: Nano drone-50 ft, Micro drone-200 ft, Small, Medium, Large drones-400 ft above ground level.

2.4 Application of Drones in Construction

It has been reported that drones have been used in various activities such as damage assessment and building maintenance [13], land surveying [9,14], Safety inspection [15-17], 3-D modelling [18-20], building inspection [21], drone assembly [22,23], monitoring of progress [24], site inspection and management [25], facility management [26,27], and 3-D printing [28].

2.5 Benefits and Barriers

A study of benefits of using drones in construction sites reported that *safety inspection* and *accessibility to inaccessible location* are the top benefits [29]. Some of the critical barriers to the use of drones are *limited battery life* and *weather-related issues* [30].

2.6 Summary

The "Global Construction 2030" states that the construction industry will grow by 85% by 2030. Construction industry is purely dependent on labour,

work and materials involved in construction change. Use of robots in construction can have advantages such as higher safety by deploying machines for dangerous jobs, high quality, increased productivity, and reduction in costs [31].

The technology adoption rate in the construction industry is lagging compared to other industries and usage of these technologies is proving challenging for the management [15,17]. The traditional techniques are replaced by drones and they provide enhanced performance and early accomplishment of tasks [32]. The drones are needed in various aspects for the development of the industry [6]. With limited literature on drones in Indian construction and the potential application is humongous, there is a need to investigate the adoption of drones in Indian construction. Hence, this study is aimed at assessing the awareness of the drone technology in and analyse the perceptions of key stakeholders on the relevance, application, benefits, barriers of using drones in construction and the impact of the same on the Key Performance Indicators (KPI) of projects. The scope of this study is limited to Indian construction and the stakeholders involved are Clients, Contractors and Consultants.

3 Research Methodology

The primary research methods used to achieve the intended objectives are literature review and questionnaire survey-based quantitative study. An in-depth literature review in the field of drones in construction has been attempted to identify the variables of study (relevance, application, benefits, barriers and KPI) and the indicators as presented in Figure 1.

3.1 Experimental Design

A questionnaire instrument has been designed for the quantitative study and deployed online. The questionnaire contained seven sections with questions related to the respondent's profile, awareness, relevance, application, benefits, barriers and KPI. Five-point Likert scales (of agreement and value) are used to measure the indicators of the variables identified. The questionnaire also had a cover note and two informative short videos for clarity and benefit of the respondents.

Target population for this study are clients, contractors and consultants in Indian construction industry. Stratified sampling is used.

Descriptive statistics is used for data analysis. *Relative Importance Index (RII)* is used to rank the indicators to understand the relative importance as perceived by the stakeholders. *ANOVA analysis* is used to check the statistical significance of the perceived differences between clients, contractors and consultants. Cronbach Alpha is used for internal consistency and data reliability for analysis.

3.2 Data Collection

The questionnaire instrument is deployed on Google Forms and the enquiries are sent to over 100 prospective Indian respondents (clients, contractors & consultants) through Email, LinkedIn, and over phone. There are 75 valid responses received, which includes coincidentally 25 each from the three stakeholder groups after continuous follow-up in a span of 4 weeks.

4 Data Analysis, Results and Discussion

The data collected is screened and codified for further analysis.

4.1 Data Analysis

Cronbach Alpha is used to evaluate the internal consistency of the instrument and reliability of the data collected for further analysis. The calculated Cronbach Alpha values are presented in Table 2. It is observed that all the values are greater than 0.8 (except for KPI), which is very good, and the data collected is reliable for further analysis.

Descriptive data analysis is conducted to understand the profile of the respondents and awareness levels. *Relative Import Index (RII)* is computed for all the indicators and ranked overall and within stakeholder groups for observation. *ANOVA* test have been conducted to check for statistical significance in difference in opinion of respondent groups.

4.2 Results

Among the 75 respondents 88% belonged to private sector and rest to public sector. Majority of the respondents (~70%) are from large organisations base on turnover (>INR2500M) and number of employees (>250). It has been observed that 12, 32 & 56% of respondents represent top, middle & operations management in their respective organisation. It is also interesting to note that most of the respondents (76%) less than 5 years of experience and 15 & 8% of respondents having an experience of 5-10 & 10-20 years respectively (Figure 2). A little fraction of them have more than 20 years of experience.

4.2.1 Awareness and Use of Drones

The results of the analysis on the awareness and use of drones are shown in Figure 3 and 4. The results show that 83% of the respondents were aware of drone and 17 % of them were unaware. Among the respondents who are aware of drones, 85% of them have not used drones and 15% of them have used drones in various operations.

Code	Relevance of drones [R]
R1	Drone is an emerging robot in the field of construction
R2	Automation and robotics have an impact on construction industry
R3	Drones have potential uses in the construction industry
R4	It is simple for me to use the existing drone technology
R5	Drone are compatible to the construction industry
R6	Drones are still in inception stage in implementing when it comes to construction
R7	Drones must be experimented before using it in the construction projects
R8	Drones are difficult to handle and require a skilled personnel to handle it

Code	Application [A]
A1	Surveying
A2	Inspection
A3	3-D Modelling
A4	3-D Printing
A5	Drone Construction
A6	Progress Reporting
A7	Safety Monitoring
A8	Facility Management
A9	Logistic and Tracking
A10	Emergency Response and Accessibility
A11	Advertising and Marketing

Codes	Benefits of drones [B]
B1	Drones provide real time updates from the site
B2	Drones can fly to inaccessible areas and hazardous areas
B3	Drones decrease the cost of projects
B4	Drones can carry out the work faster
B5	Drones provide easier access to data to professionals of different department
B6	Drones create new job opportunities and add value to construction
B7	Drones help in accurate and enhanced data collection
B8	Drones help in effective communication
B9	Drones reduce the safety risks
B10	Drones improve the productivity
B11	User friendliness and Eco

Codes	Barriers of drones [BA]
BA1	Loss of Data and Signal
BA2	Limited Payload and Battery life
BA3	Weather related issues
BA4	Acquisition and maintenance cost
BA5	Owner and Management support
BA6	Accidents and interference in sites
BA7	Air traffic restriction and regulation
BA8	Requirement of skilled professional
BA9	Privacy Issues

Codes	Key Performance Indicators [K]
K1	Cost
K2	Time
K3	Quality
K4	Health and Safety
K5	Stakeholder Satisfaction

Figure 1. Indicators of Relevance, Application, Benefits, Barriers and KPI

Table 2. Cronbach Alpha

Variable	Questions	Cronbach Alpha
Relevance	Q1-Q8	0.87
Application	Q9-Q19	0.90
Benefits	Q20-Q30	0.88
Barriers	Q31-Q39	0.79
KPI	Q40-Q44	0.57
Overall	Q1-Q44	0.94

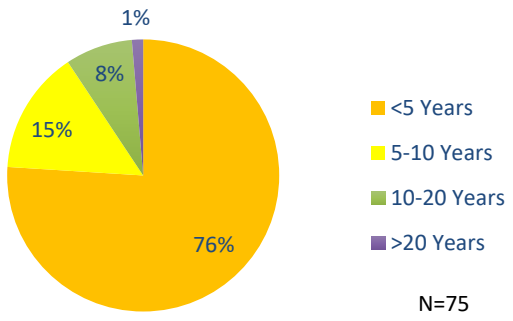

Figure 2. Experience of Respondents

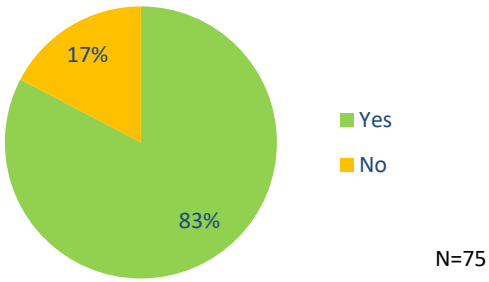

Figure 3. Awareness on Drones

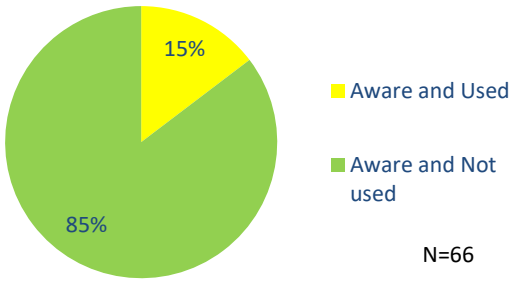

Figure 4. Awareness and Usage Chart

4.2.2 Relative Importance of Indicators (Overall)

RII has been calculated for all the indicators of chosen variables (Figure 1) using the data from all the respondents. RII along with the frequency distribution of individual ratings of indicators is presented variable-wise in Figure 5. The overall pattern in the data and RII revealed that the respondents have rated most of the indicators highly important. The top-rated indicators within the chosen variables are presented in Figure 6.

4.2.3 Relative Importance of Indicators (within stakeholder groups)

Indicators of the chosen variables are ranked using RII that is calculated based on the responses from three difference stakeholder groups (C1-Contractors, C2-Consultants and C3-Clients) in order to compare the perspectives of these groups on the relative importance. The results are presented in Table 3(a-e). The pattern in the results indicate there are differences in the relative importance of the indicators.

Table 3. Relative importance of indicators (within stakeholder groups)

a) Relevance

	C1	Rank	C2	Rank	C3	Rank
R1	**0.73**	**2**	**0.77**	**2**	**0.70**	**2**
R2	0.70	4	**0.74**	**3**	0.63	5
R3	**0.72**	**3**	0.67	7	0.66	4
R4	0.70	4	0.63	8	0.62	6
R5	0.70	4	0.71	5	**0.70**	**1**
R6	**0.74**	**1**	0.70	6	0.66	4
R7	**0.73**	**2**	**0.78**	**1**	**0.69**	**3**

BA7	**0.77**	**3**	0.70	5	0.70	5
BA8	**0.78**	**2**	**0.74**	**2**	**0.72**	**3**
BA9	0.71	9	0.70	5	**0.72**	**3**

e) Impact on KPI

	C1	Rank	C2	Rank	C3	Rank
K1	0.70	4	0.72	3	**0.72**	**3**
K2	0.67	5	0.68	5	0.64	5
K3	**0.72**	**3**	**0.74**	**2**	**0.75**	**1**
K4	**0.76**	**2**	**0.75**	**1**	**0.74**	**2**
K5	**0.82**	**1**	**0.72**	**3**	0.66	4

C1-Contractors C2- Consultants C3-Clients

4.2.4 ANOVA Analysis

It has been attempted to test this difference in perceived relative importance among Contractors, Consultants and Clients is by chance or statistically significant using ANOVA analysis at 5% significance level. The test results are shown in Table 4.

Table 4. ANOVA Analysis

Variables	F	p-value	F-crit
Relevance (R)	4.553	**0.011**	3.011
Application (A)	3.134	**0.044**	3.007
Benefits (B)	2.075	0.126	3.007
Barriers (BA)	2.948	0.053	3.009
KPI (K)	1.379	0.253	3.020

It can be noted that p-value is less than 0.05 for variables Relevance (R) and Application (A) that implies that there is statistically significant difference in perception among C1, C2 & C3. There is no significant difference with respect to other three variables.

4.3 Discussion

While high level of awareness is a welcome sign, low levels of actual usage must be looked in to by promoting the benefits/drivers and addressing the barriers. It is also supported in the higher ratings for relative importance for various indicators. Top rated relevance *Drones must be experimented before using it in the construction projects* (R7) implies that there is a need to demonstrate the use/benefits of drone through use cases. The most relevant applications for drones are *Surveying* (A1), *Emergency Response and Accessibility* (A10) and *Safety Monitoring* (A7). Necessary action plans may be drawn

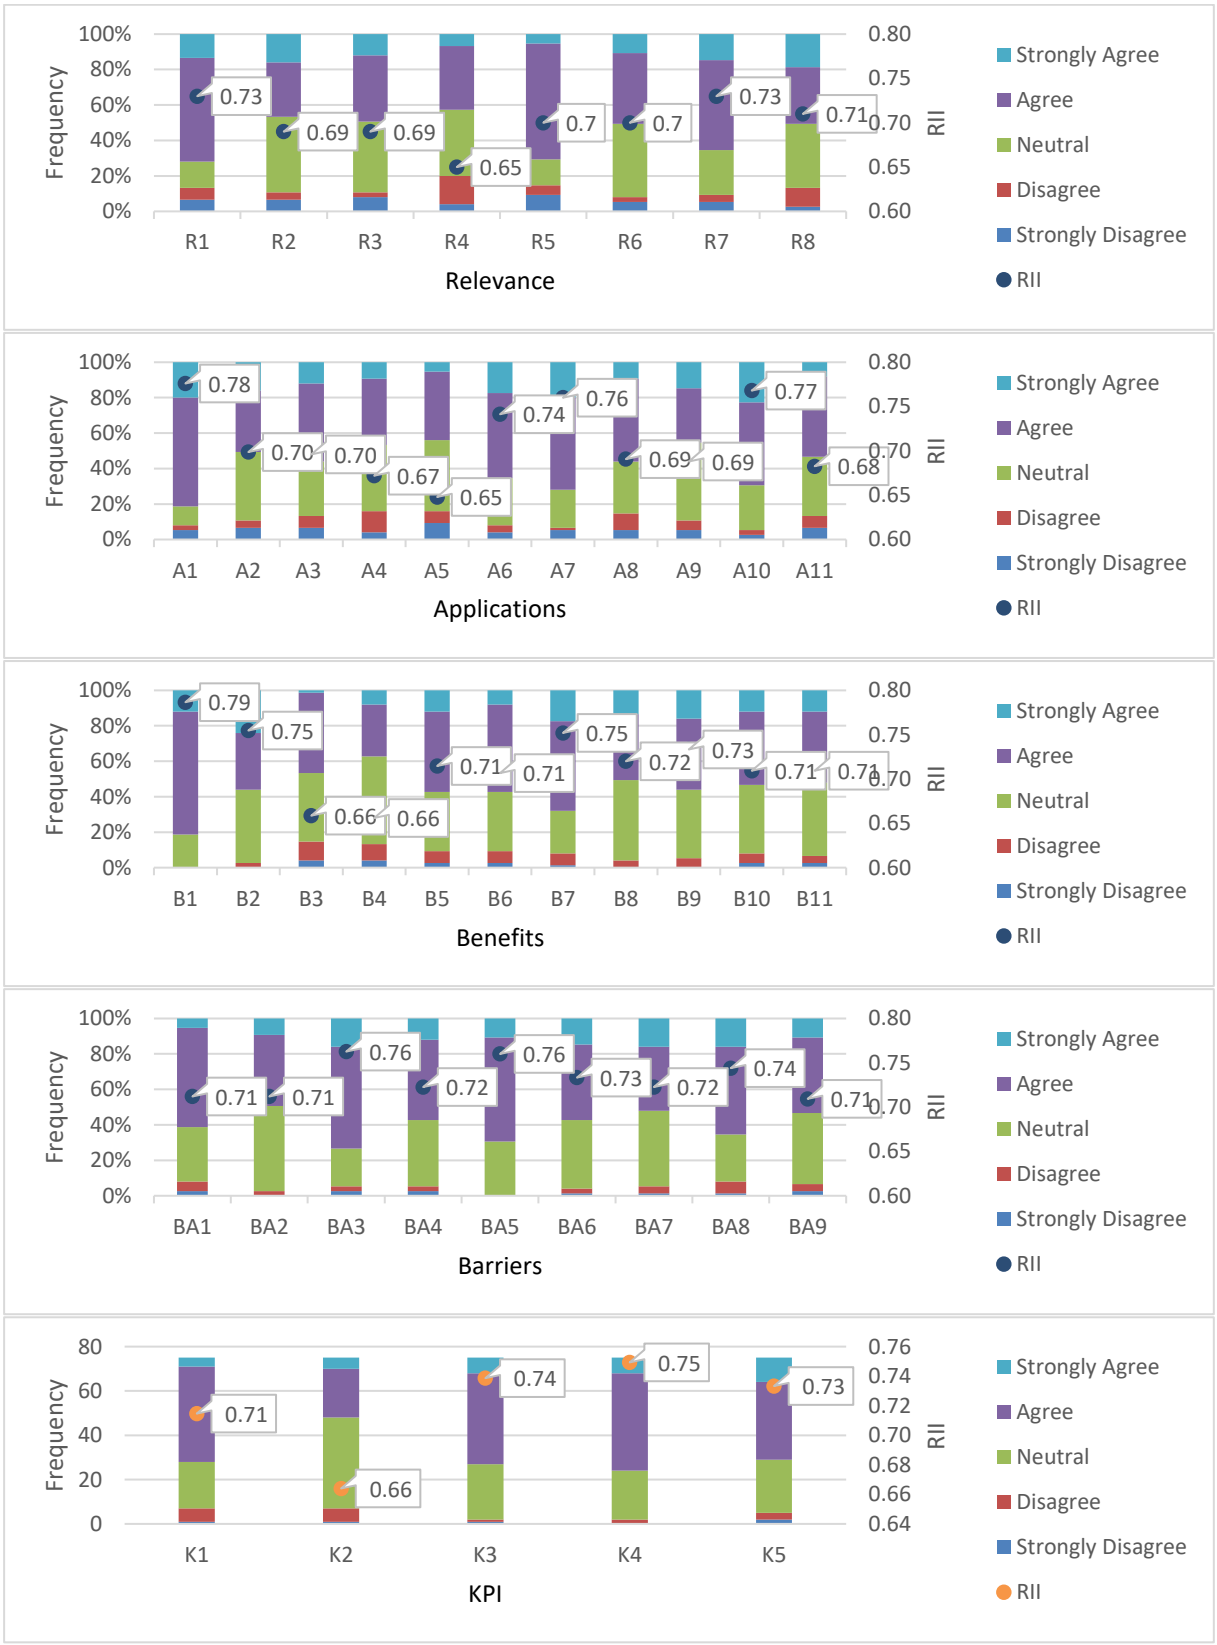

Figure 5. Frequency distribution & RII of indicators (overall)

Code	Variables/Indicators	RII	Rank
	Relevance		
R7	Drones must be experimented before using it in the construction projects	0.73	1
R1	Drone is an emerging robot in the field of construction	0.73	1
R8	Drones are difficult to handle and require a skilled personnel to handle it	0.71	2
	Application		
A1	Surveying	0.78	1
A10	Emergency Response and Accessibility	0.77	2
A7	Safety Monitoring	0.76	3
	Benefits		
B1	Drones provide real time updates from the site (through video)	0.79	1
B2	Drones can fly to inaccessible areas and hazardous areas	0.75	2
B7	Drones help in accurate and enhanced data collection	0.75	2
	Barriers		
BA3	Weather related issues	0.76	1
BA5	Owner and Management support	0.76	1
BA8	Requirement of skilled professional	0.74	2
	Key Performance Indicators		
K4	Health and Safety	0.75	1
K3	Quality	0.74	2
K5	Stakeholder Satisfaction	0.73	3

Figure 6. Top rated indicators based on RII (overall)

by the professional organisations & educational institutions to instil the skills required. The highly rated benefits are *Drones provide real time updates from the site* (B1), *Drones can fly to inaccessible areas and hazardous areas* (B2) and *Drones help in accurate and enhanced data collection* (B7). This information may be of great value for the construction contractors and drone operators. The key barriers for the adoption of drones in Indian construction are: *Weather related issues* (BA3), *Owner and Management support* (BA5) and *Requirement of skilled professional* (BA8). The project managers and drone manufacturers/operators may find this information useful to plan their business/project objectives. *Health and Safety* (K4), *Quality* (K3) and *Stakeholder Satisfaction* (K5) are the most important KPIs impacted by the use of drones. These are in line with the demands of changing business environment.

5 Summary and Conclusions

Efficient project delivery is a continuous challenge in construction. With growing complexity and uncertainty in project environments, it more prudent to promote innovate solutions to overcome the challenges and create value for the stakeholders involved. Automation and robotics have been promising in efficient and safer construction projects. However, the uptake of robot technology such as drones/UAV is slow in Indian construction. It has been attempted to study the level of awareness & use of drones as well as benefits, barriers & impact on the KPIs.

It has been observed that there is high level of awareness of drones and low level of usage in Indian construction. The overall pattern in the data revealed that the respondents have rated most of the indicators highly important. Following are the top-rated attributes: *Drones must be experimented before using it in the construction projects* (relevance); *Surveying* (application); *Drones provide real time updates from the site* (benefit); *Weather related issues* (barrier) and *Health and Safety* (KPI). ANOVA analysis revealed that there is statistically significant difference in perception among contractors, consultants and clients with respect to relevance & application of drones and not so for benefits, barriers & impact on KPI.

The sample size of the groups is limited in this study and a larger sample size may unfold results that can be generalised with much more confidence. It is worth investigating the relationship between the application, benefits, barriers an KPIs for more insight. Also, a detailed study among public & private clients shall be useful in formulating strategies for greater adoption of drones.

Abstract –

Many of Japan's bridges built during the period of high economic growth are deteriorating and require proper maintenance. However, due to the shortage of specialist in the field of civil engineering as well as the declining birthrate and aging population, the current bridge periodic inspection the proximity visual inspection and the preparation of inspection reports require a lot of work by each inspection engineer. To promote bridge inspection using robots such as UAVs, we have been improving efficiency in on-site inspection and the documentation of inspection results. The current challenges in this effort are the management of a vast number of images, image analysis and damage detection, and the accurate recording of damage locations. In this report, we present the results of the accuracy test of 3D bridge data generated by Structure from Motion (SfM) and explain the management of images using 3D data.

1 Introduction

Many Japanese bridges constructed during the period of high economic growth are aging and require proper maintenance. Due to the shortage of specialist in the field of civil engineering as well as the declining birthrate and aging population, realization of more efficient bridge inspection is an urgent issue for proper maintenance of bridges.

Bridge periodic inspections every five years in Japan require a lot of labor, time and cost, and for on-site visual inspection and preparation of inspection reports. MLIT (Ministry of Land, Infrastructure, Transport and Tourism) which manages bridges, has published Guidelines For Using New Technology for the purpose of streamlining bridge inspections, and is actively promoting the use of inspection robots.

In that case, it is necessary to efficiently perform, Managing the tremendous amount of images acquired from robots, Recognizing degradation in image, and Accurate recording of degradation position.

In recent years, UAVs and computer vision have been utilized in various fields of civil engineering.[1] Among these technologies, we focused on SfM, which automatically estimates the shooting position and shooting direction of images shot continuously in 3D space, generates 3D data of the shooting target.

In this paper, in order to improve efficiency the field work and record creation work of the bridge periodic inspection, we report the status of the examination up to now regarding bridge inspection using 3D data.

2 Research Content

In order to verify the possibility of bridge inspection using robots and 3D data, we examine the following three processes for the South Loop Bridge on the site of PWRI(Public Works Research Institute).

1. Efficient image shooting by a bridge inspection robot
2. Generation of 3D data of bridge by SfM
3. Image management method using 3D data

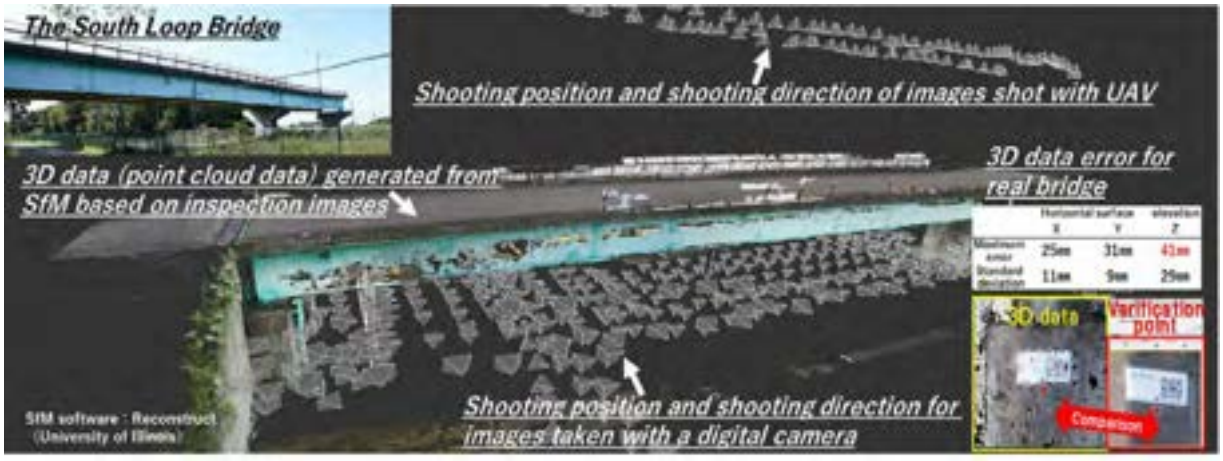

Figure 1. 3D data of South Loop Bridge generated from SfM

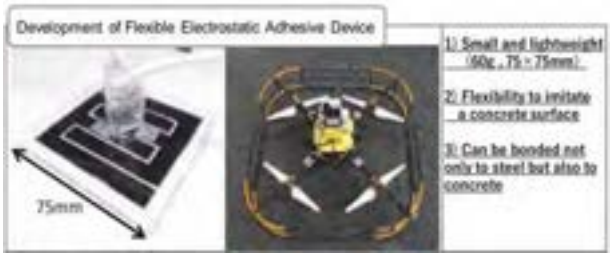
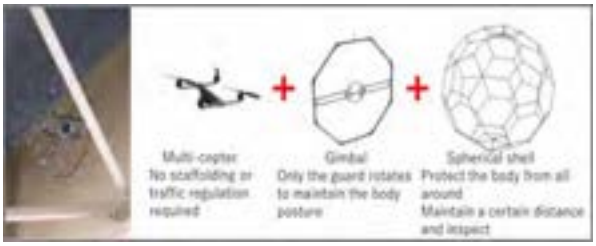


a) Development of infrastructure inspection system using semi-autonomous multi-copter equipped with flexible electrostatic adhesive device



b) Development of UAV for Observing and Hammering Aged Bridges at Short Range

Figure 2. Example of bridge inspection robot developed by SIP[3]

3 Generation of 3D Data and Image Management Using Images of Bridge Inspection Robots (UAVs, etc.)

3.1 Accuracy Verification of Generated 3D Data

In this paper, the bridge was shoot with a UAV (Phantom4Pro made by DJI) and a digital camera (α7R2 made by SONY). It was confirmed that the 3D data of the bridge can be generated by SfM from the shooting image and that the position and direction of the captured image can be expressed in the 3D space. 'Figure 1'

The coordinates of the verification points on the actual bridge obtained from the survey criteria and the coordinates of the verification points on the 3D data were compared. The error of all verification points was within 5 cm, which satisfied the quality control standard defined by MLIT. 'Figure 1' [2]

3.2 Applicability to Bridge Inspection Robot

Figure 1 shows 3D data generated from images of general UAVs and digital cameras. Furthermore, by utilizing the robots specialized for advanced bridge inspection developed by the Cabinet Office's SIP (Cross-ministerial Strategic Innovation Promotion Program), more detailed bridge photography can be performed. 'Figure 2' [3]

By generating 3D data from the images taken by such a bridge inspection robot, it becomes possible to manage images taken of the damage conditions inside members and girders.

3.3 Management Example of Image Shooting Position Using 3D Data

3.3.1 Bearing

As shown in 'Figure 3 a)', the area around the bearing is often complicated due to abutments, floor slabs, main girders, and various piping. This area is generated as 3D data by SfM, and the shooting

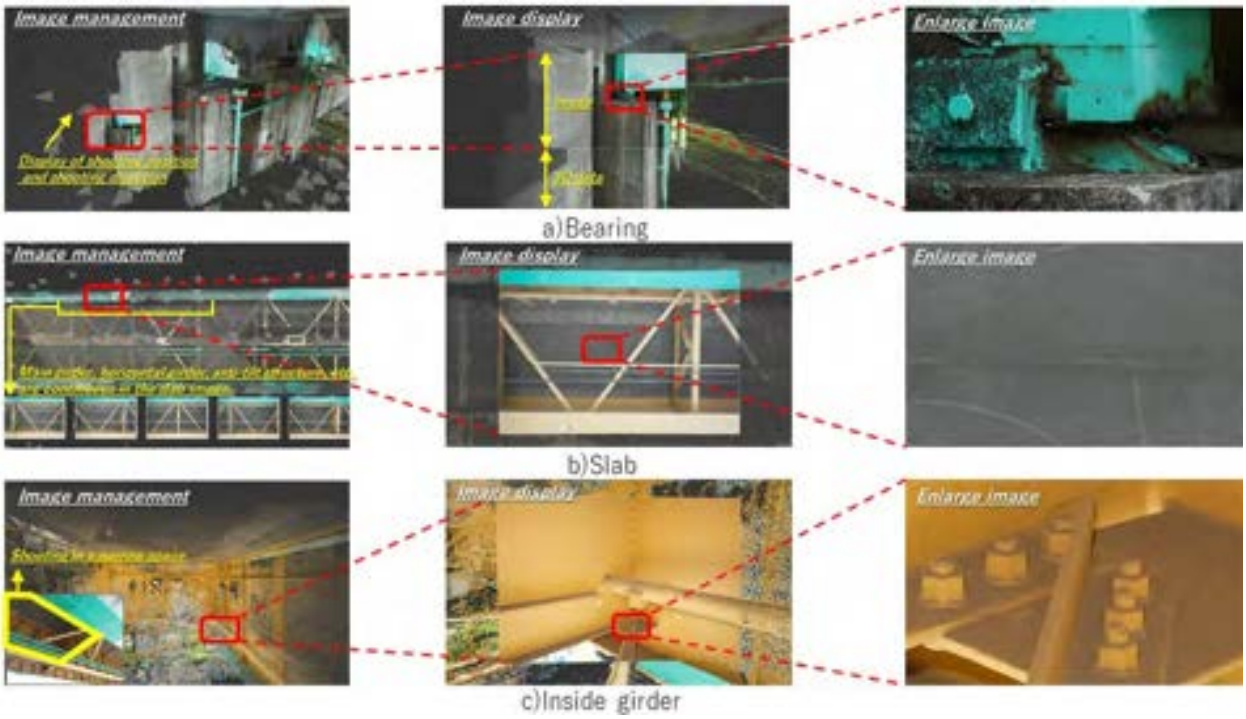


Figure 3. Image management example using 3D data

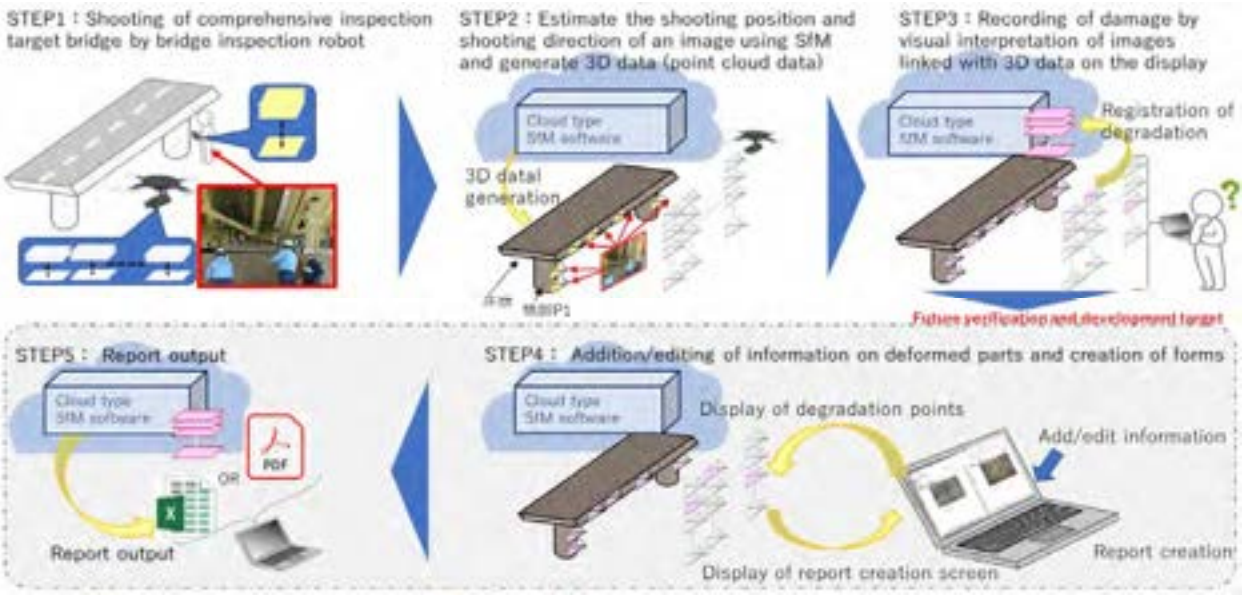

Figure 4. Bridge periodic inspection method utilizing 3D data

position and direction of the image can be expressed as a quadrangular pyramid in 3D space.

When the image of the bearing is displayed, it is displayed so as to match the 3D data, and the accuracy of the automatically estimated shooting position and shooting direction can be confirmed.

3.3.2 Slab

As shown in 'Figure 3 b)', the inspection results of slab in the current bridge inspection are managed by span. When the slab is continuously and comprehensively photographed, slab, main girders, horizontal girders, and the like are repeated, so a large number of images with the same contents are stored,

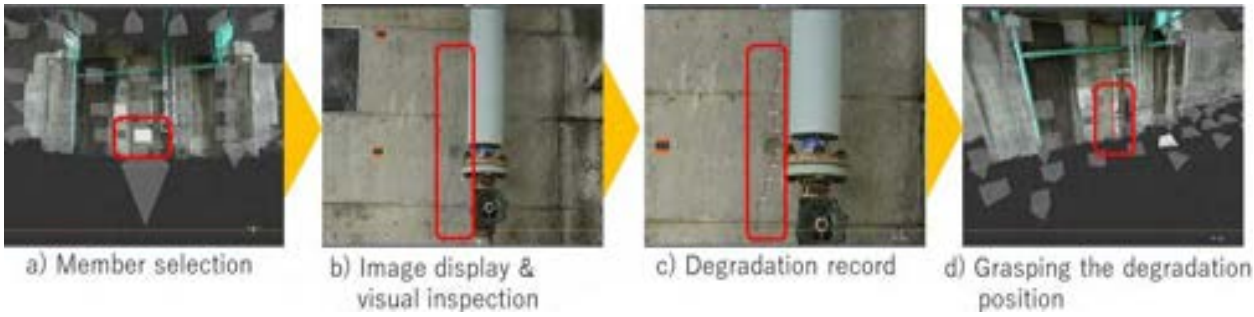

Figure 5. Visual confirmation of image degradation and recording example

and it becomes difficult to estimate the shooting positions of them later.

However, SfM's automatic image shooting position estimation and automatic association of 3D data with images can improve the efficiency of such continuous-image management.

3.3.3 Inside Girder

As shown in 'Figure 3 c)', It is difficult to manually record the image inside girder in the image shooting direction. The reason is that the shooting is focused on checking the condition of slab, the main girder, the anti-tilt structure, etc., and that the shooting is performed in a narrow space surrounded by the main girder and the horizontal girder.

By automatically estimating the shooting direction of the image with SfM, it is possible to manage the image of only the local part such as the bolt inside the girder and the corrosion condition of the anti-tilt structure.

4 Bridge Periodic Inspection Utilizing 3D Data

4.1 Proposal of Bridge Periodic Inspection Method Utilizing 3D Data

Based on the examination results to date, we propose a bridge periodic inspection method that uses 3D data generated by SfM as a solution to the problem which are Efficiency of inspection work, recording accuracy of deformed position of bridge inspection. 'Figure 4' This study does not limit the generation of 3D data, the estimation of the shooting position, direction of images to SfM in consideration of future technological development and development of this inspection method.

Since this inspection method generates 3D data by SfM, it is premised and important that robots shoot a comprehensive image of the bridge. After that, the inspection engineer will visually inspect only the areas where the degradation can be confirmed from the images taken by the bridge inspection robot and the areas where it was difficult to take images. The characteristics of the inspection method are as follows.

4.1.1 Efficiency Improvement of Visual Inspection for Actual Bridge

When the degradation of the member is confirmed on the image, the position of it can be grasped by referring to 3D data. In addition, an engineer will visually inspect the actual bridge depending on the condition of the degradation.

Therefore, it is possible to narrow down the scope of visual inspection on-site by the engineer in advance in the office.

4.1.2 Enhancing the Record of Changes in Visual Inspections by Engineers

The scope of visual inspection by the engineer is narrowed down, and more detailed degradation inspection can be performed on the degradation, so the contents of the recording of the degradation status are enriched.

4.1.3 Upgrading of Degradation Management by Utilizing 3D Data

By managing images and degradations by associating them with the three-dimensional data of the bridge, the shooting position and shooting direction will become clear, and it will be possible to guide the degradation shooting with the same angle of view in later years. In addition, by comparing images having the same shooting angle of view, it is possible to contribute to highly accurate progress grasp of aged deterioration.

4.2 Degradation Recording Example on Image

One of the merits of utilizing 3D data in bridge inspection is the possible to check and record the state of degradation on images managed in association with 3D data.

After 3D data is generated from the image by SfM,

the image of the member to be confirmed is displayed, and the content of the degradation is recorded on the image for which the degradation can be confirmed. ‘Figure 3 a)~c)’ The degradation is recorded in association with the 3D data, and the position of the degradation can be grasped on 3D data even when the image is not displayed. ‘Figure 3 d)’

5 Summary

This paper reported the research results on the method of utilizing 3D data for the purpose of improving the efficiency of periodical bridge inspection. As a concrete content, the basic verification result of the 3D data accuracy of the bridge generated by SfM was shown, and the image management method using the 3D data was proposed. This paper is summarized as follows;

1. We proposed a bridge periodic inspection method using 3D data as a solution to the problems of bridge inspection (many image management, accurate recording of degradation position) when using robots.
2. It was shown that the 3D data of bridges generated by SfM from the images taken continuously and automatically by UAV satisfy the quality control standards set by MLIT.
3. We proposed an image management method and a degradation confirmation method using 3D data. The feasibility of periodical bridge inspection using 3D data was also shown by introducing application examples.

The information generated by the proposed method in this paper, such as a set of image angles and perspectives and 3d structure by SfM, has not been applied in bridge inspection phase. Utilizing those infomation to improve the whole management cycle, which is not limited to the inspection, will contribute to improvement of the productivity in the entire construction field. Future research contents assume points listed below;

1. Confirmed to the bridge manager and the inspection engineer "Recording method for image degradation and expression method on 3D data" and "Delivery standard and management method for products of bridge periodical inspection utilizing 3D data" To do. Based on the results, we will study the workflow, functional requirements and related standards for social implementation.
2. It takes a great deal of effort to grasp the degradation on the image because the engineer performs visual inspection. Therefore, we will study support technologies that can efficiently detect degradations from images (automatic extraction of degradations by AI, emphasis on degradations by image processing).
3. By managing the images at the time of completion using this method, we will examine the utility of this method during emergency inspections such as grasping the displacement and degradation of the bridge structure after an earthquake.

Abstract –

This study developed a system that generates video from a view following a robot, using composition CG of the present position of the robot using deliberately delayed video on the robot for displaying the current position and orientation of the robot. The proposed view generation method overcomes the disadvantage of conventional methods because it always has a close-up view, and has the advantage of the video making it easy to understand the area around the robot. In this study, we verified the advantage of this method experimentally using a crawler carrier and the robot, and addressed some problems.

Past image; Remote control; Bird's-eye view

1 Introduction

When a disaster occurs, unmanned construction is used for recovery and investigation using a construction machine in a safe area. In general remote-control and unmanned construction, the pilot controls using the subjective view sent to the pilot's terminal by a camera on a construction machine, or a third-person view sent by a camera installed in the surroundings. Subjective view has the advantage that it can be seen in front of the construction machine at all times, and third-person view has the advantage that it is easy to determine when the construction machine is about to hit obstacles. However, subjective view and bird's-eye view videos have parts that cannot be seen or are difficult to see. The purpose of this research was to develop a system that generates video from a view behind the robot by composition CG of the present position of the robot, using deliberately delayed video from the robot.

2 Related research

2.1 Classification and advantage of camera view

In remote control, camera images are used to understand the environment of the construction machine.

Here, we classify the installation positions of the cameras and the obtained images, and describe the advantages and disadvantages thereof.

- Subjective view

Generally, the camera is installed in the driver's seat of the construction machine, and a subjective image is taken as if the operator is looking forward from the driver's seat. A typical obtained image is shown in Figure 1.

Subjective images are realistic and easy for the operator to imagine, and the device is simple and fully contained in the construction machine; thus, the usage cost is low. However, the general camera can only retrieve limited information because its viewing angle is narrower than the human viewing angle. Thus, there are cases where multiple cameras are installed or a fisheye camera with a wider viewing angle is used [1].

Figure 1. Example of subjective view

- Swingable subjective view

In a previous study, the attachment of a swing mechanism was attached to the camera to allow the operator to check the sides and back to overcome the narrow viewing angle of subjective images [2]. However, it is not possible to change the large view such as leaning forward to check the rear like in a manned vehicle, and the viewing angle is limited. In addition, the swing mechanism is operated separately; VR technology can be used to simplify this[3].

- Fixed third-person view

In unmanned construction, the condition of the construction site and the positional relationship of the construction machine therein are important. Thus, it is common to install cameras on pipe scaffolding or prefabricated scaffolding for a broad third-person view. An image from a typical fixed third-person-view video is shown in Figure 2. The third-person-view video may have a sensational discrepancy between the operation and the movement of the construction machine, because it does not always face the same direction as the construction machine; therefore, it requires skill to operate. For example, the right crawler must be moved to turn the construction machine in Figure 2 to the left. In addition, when the distance between the camera and the construction machine is large, the construction machine in the image may appear small, or another object may appear between the two, hiding the construction machine. Furthermore, the installation cost of the camera is high, and installation of the camera itself may be impossible immediately after a disaster.

Figure 2. Representative fixed third-person view video

- Third-person view from mobile robotsthird-person view

In some disaster response robots, a rod is extended backward on the robot and a camera is installed in a high position on the tip of the rod to obtain a third-person-view video of the robot surroundings. A typical image is shown in Figure 3. In this case, the orientation of the robot and the position and orientation of the camera always match, and it is easy to grasp the surroundings subjectively. Toda et al. obtained a bird's-eye view from the top in real time by mooring a balloon on the robot instead of a stick, and looking down at the robot from the camera installed on the balloon [4]. Nagatani and others also moored a drone on a construction machine [5]. These methods increase the total height, which includes that of the camera. Moreover, they limit the usable environment because it is necessary to physically separate the camera from the center of the robot. Further, there is the drawback that the image is very shaky owing to the effects of rotation, vibration, and wind of the construction machine because the robot moves away from the center of rotation.

The technology of artificially generating a bird's-eye view image by synthesizing a plurality of camera images mounted on a robot on a plane has been applied practically by automobile manufacturers. An example of the one put into practical use is the around view monitor of Nissan Motor Co., Ltd [6]. Sato et al. applied this method to unmanned construction equipment [7]. Shimizu et al. applied this method and made it possible to move the view [8].

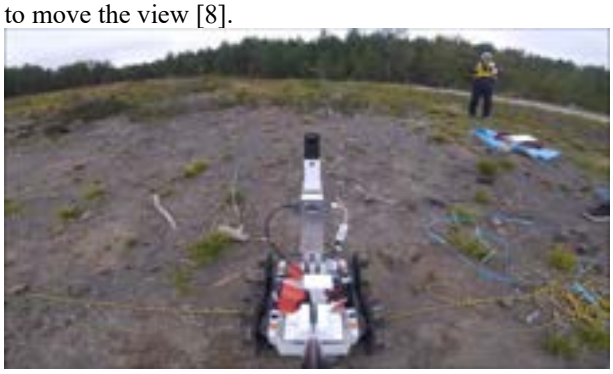

Figure 3. Representative moving third-person view video

2.2 Fixed third-person view using past image method

Shiroma et al. saved a still image acquired by a camera mounted on a robot, and synthesized a CG that matched the position of the robot in the still image in the save history to view the robot from the position where the still image was acquired; they proposed a method to generate an imaginary bird's-eye view [9]. In addition, Kinoshita et al. eliminated the narrow viewing angle by shooting still images using an omni-directional camera [10]. Figure 4 shows the outline and Figure 5 shows the generated third-person-view image.

The fixed third-person-view generation method using previous images involves obtaining the fixed third-person-view view by using previous still images captured by the robot. That is, if the only moving object in the image is the robot, the still image once taken is used as the background, and the moving robot draws the CG according to the position and orientation

information. This method has the merit that the amount of communication and the associated communication delay can be reduced because moving image transfer is not required.

In contrast, the image obtained by this method has a fixed third-person-view, and thus there is the problem that the size of the image decreases as the robot moves away. To solve this, it is necessary to retake a still image when a certain distance is reached. In addition, moving objects such as humans and other robots are perceived as stationary, because moving objects other than robots are not assumed.

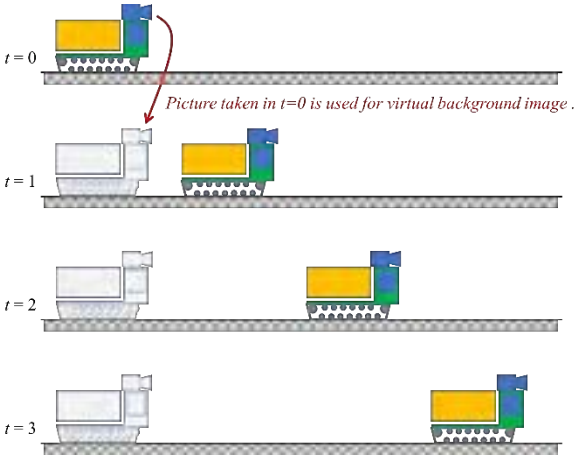

Figure 4. Overview of past image method

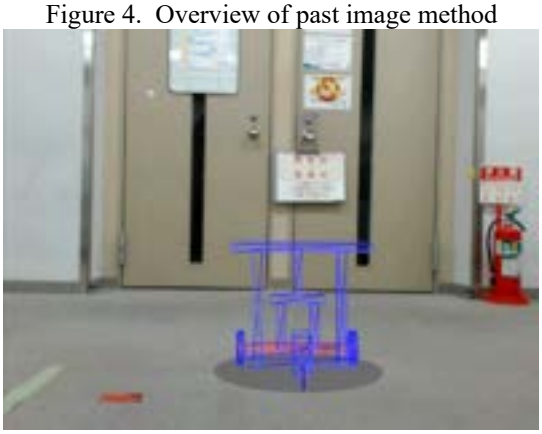

Figure 5. Third-person view image by past image method

3 Tracking third-person view video method

3.1 Proposal of tracking third-person video method

We extended the idea of the fixed third-person-view generation method using past images from an omni-directional camera developed by Kinoshita et al. We used a moving image instead of a still image, and intentionally delaying this to create a CG image at the robot's current position. We proposed a method of generating a moving view in which a camera positioned behind a robot is followed by continuous drawing [11]. Figure 6 shows the outline. In this paper, this is called a tracking bird's-eye view view. In the case of the fixed bird's-eye view image described above, the drawing position of the robot and its size change. However, in this method, it is always drawn in a fixed size in the center of the screen; thus, it has the advantage of being easily drivable. In contrast, in the proposed method, the amount of communication is not reduced because moving images are used. Although the moving object is reflected, it is a delayed moving image and does not correctly reflect the movement of the object.

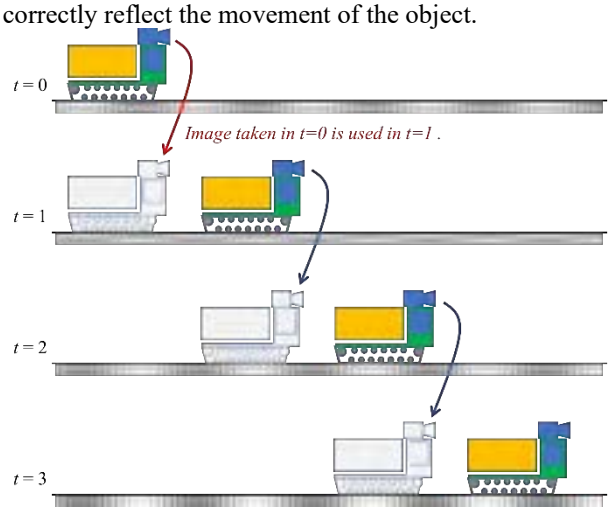

Figure 6. Overview of tracking third-person view method

3.2 Generation method of tracking third-person view video method

The generation procedure of this method is shown as follows.

1. The robot saves the current time and the position and orientation of the robot along with the moving image.
2. A moving image and robot position and orientation that meet the conditions are selected. There are two possible conditions to select.
   A) Fixed time delay—Selection of the latest moving image where the difference between the current time and the shooting time of the image is more than a certain value.
   B) Fixed distance delay—Selection of the latest moving image where the distance between the current position and the shooting position of the image is a certain distance or more.
3. The robot sends the current position/orientation of the robot, the selected moving image, and the position and orientation at the time of image capture to the operator terminal.

4. The CG reflecting the current position and orientation of the robot is superimposed on the moving image received by the operator side, and displayed on the screen. The current direction of the robot is cut from the moving image when drawing so that the CG of the robot is always centered.

3.3 System configuration

Figure 7 shows the system configuration of this research. The upper left side of the dotted line shows the processing performed by the robot side, and the upper right side shows the processing performed by the operator side. These are the contents of the software. The lower part of the dotted line shows the required hardware. The system on the operator side calculates the relative position and orientation from the shooting point from the current position and orientation received from the system on the robot side and the position and orientation at the time of shooting the moving image, and synthesizes the CG of the robot with the moving image. The positional relationship between the self-position estimation sensor, the omni-directional camera, and the robot must be obtained before the experiment. The position where CG is combined with the moving image is calculated as follows. Figure 8 shows an example of robot behavior. Position/posture P_{pc} of the camera at the time of shooting when the position/orientation of the robot center at the time of shooting is the origin, position/posture P_{pr} of the robot center at the time of shooting, sensor position/posture P_{ps} at the time of shooting, current position/posture P_{nr} of the robot center, The current position/orientation P_{ns} of the sensor is defined as follows.

$$P_{pc} = (x_{pc}, y_{pc}, z_{pc}, yaw_p, pitch_p, roll_p)$$
$$P_{pr} = (x_{pr}, y_{pr}, z_{pr}, yaw_p, pitch_p, roll_p)$$
$$P_{ps} = (x_{ps}, y_{ps}, z_{ps}, yaw_p, pitch_p, roll_p)$$
$$P_{nr} = (x_{nr}, y_{nr}, z_{nr}, yaw_n, pitch_n, roll_n)$$
$$P_{ns} = (x_{ns}, y_{ns}, z_{ns}, yaw_n, pitch_n, roll_n)$$

The relative position of the position and orientation of the camera, the position and orientation of the robot center, and the position and orientation of the sensor are fixed because they are fixed to the robot. Also, assuming that the directions of the camera, sensor, and robot are the same, the yaw, pitch, and roll values are the same. Therefore, the position and orientation P_{rs} of the sensor viewed from the center of the robot and the position and orientation P_{sc} of the camera viewed from the sensor are defined as follows.

$$P_{rs} = (x_{rs}, y_{rs}, z_{rs}, 0,0,0)$$
$$P_{sc} = (x_{sc}, y_{sc}, z_{sc}, 0,0,0)$$

When the robot moves as shown in Fig. 8, the vector from the camera at the time of shooting to the center of the robot after the movement is obtained by the following procedure.

1. Obtain the position and orientation of the camera during shooting from the position and orientation of the sensor during shooting

$$P_{pc} = P_{ps} + P_{sc}$$

2. Obtain the coordinates of the current robot center from the current sensor position and orientation and the sensor position and orientation seen from the robot center

$$P_{nr} = P_{ns} - R_y R_p R_r P_{rs}$$

However, $R_y R_p R_r$ is the following formula.

$$R_y = \begin{bmatrix} \cos(yaw_n - yaw_p) & -\sin(yaw_n - yaw_p) & 0 & 0 & 0 & 0 \\ \sin(yaw_n - yaw_p) & \cos(yaw_n - yaw_p) & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix}$$

$$R_p = \begin{bmatrix} \cos(pitch_n - pitch_p) & 0 & \sin(pitch_n - pitch_p) & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ -\sin(pitch_n - pitch_p) & 0 & \cos(pitch_n - pitch_p) & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix}$$

$$R_r = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & \cos(roll_n - roll_p) & -\sin(roll_n - roll_p) & 0 & 0 & 0 \\ 0 & \sin(roll_n - roll_p) & \cos(roll_n - roll_p) & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix}$$

3. Obtain the current position/orientation P_{pcns} of the robot center with the position/orientation of the camera as the origin

$$P_{pcns} = P_{ns} - P_{pc}$$

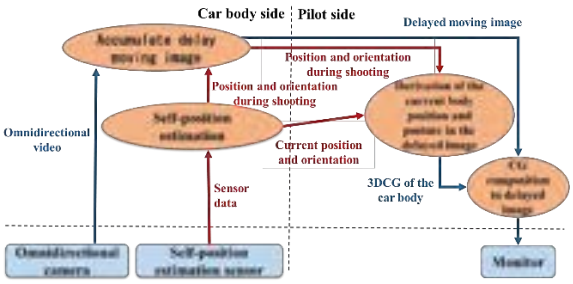

Figure 7. System Configuration

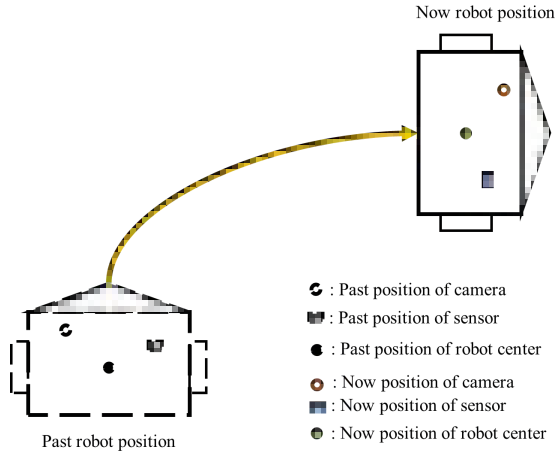

4 Figure 8. An example of robot behavior Experiment of generating a third-person view video

4.1 Video generation experiment using construction machinery

4.1.1 Purpose

Using the proposed method, we attempted to generate a tracking third-person-view image from the moving image of the omni-directional camera acquired while traveled the crawler carrier equipped with the implemented robot side system and the information of RTK positioning.

4.1.2 Data acquisition robot side system

Figure 9 shows the robot system used to acquire the data. The installed camera is the omni-directional camera which name is " RICOH THETA V ".

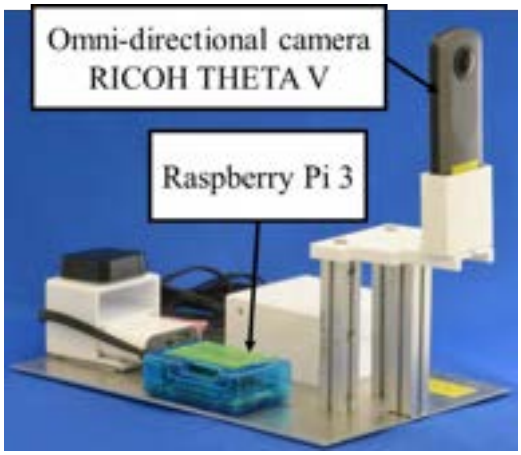

Figure 9. Data acquisition robot side system

4.1.3 Content

The robot side system shown in Figure 10 was installed in a crawler carrier IC 120 manufactured by KATO WORKS. Figure 10 shows the dimensions of the crawler carrier, and Figure 11 shows the camera installation position. The position of the crawler carrier was determined using the data of RTK positioning.position In this experiment, only the position of the crawler carrier and the moving image of the omni-directional camera were acquired during operation, and the video was generated offline. The condition for moving image selection during image generation was the fixed time delay described in 2(a) in section 3.2.

Figure 10. IC120 dimensions

Figure 11. Camera's position

4.1.4 Results and discussion

The video in Figure 12 was generated offline from the data acquired during the experiment. The video is available at https://youtu.be/HMjuIucaNg4. The

generated image confirms that the rough movement of the CG of the construction machine matches the movement of the actual construction machine, and that the view follows the CG. As a result, we demonstrated that it is possible to generate a third-person view image from the image of the vehicle-mounted camera. There was a problem in that the view sometimes caught up with CG when the construction machine speed decreased. This is probably because the delay time was constant and the distance to the camera changed depending on the speed of the crawler carrier. There was a further problem that the CG skidded and oscillated. It is considered that this is because the shooting time of the moving image and the acquisition time of the position and orientation were not correctly synchronized.

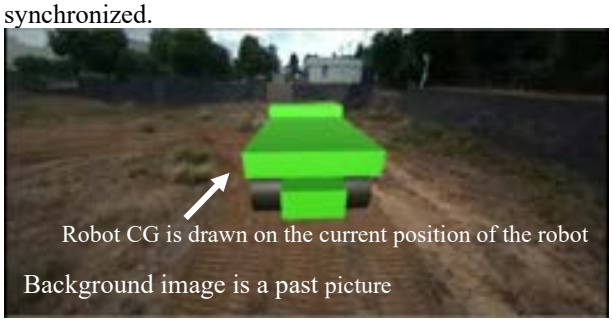

Figure 12. Video generated in an experiment using a crawler carrier

4.2 Video generation experiment using a small dolly

4.2.1 Purpose

Based on the experiment detailed in the previous section, we attempted to solve the problem by improving the system. The video was generated in real time to check for practical problems.

4.2.2 Implementation on a robot for running experiments

We implemented the system on Beego, a small indoor vehicle shown in Figure 13. The installed camera is the omni-directional camera which name is " RICOH THETA S ".The odometry obtained from the number of tire rotations was used to acquire the position and orientation of Beego.

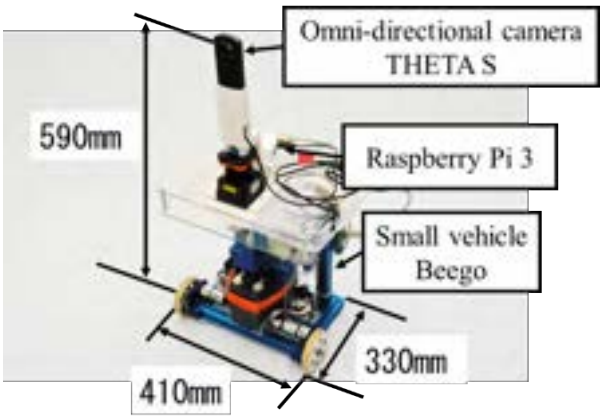

Figure 13. Mounted small vehicle

4.2.3 Content

We generated a tracking third-person-view image with the improved system. In the experiment, the vehicle traveled from the position shown in Figure 14 along a 2-m square perimeter, drawn as a dashed black line. The turns were made on the spot or without stopping. The image selection condition for moving image generation was the constant distance delay (75 cm) described in Procedure 2(a) in Section 3.2.

Figure 14. Indoor experimental environment

4.2.4 Results and discussion

An image from the video generated in real time while driving is shown in Figure 15; the video is available at https://youtu.be/GBiFHKc6bh0. From the generated image shows that the camera position changed according to the robot's moving and stopping, we confirm that the position change of the camera also changed with the speed and stopping of the robot. From this, we succeeded in keeping the distance between the robot and the camera constant. However, the CG was drawn at a different position to the actual position. When the CG bent inward from the actual robot position, especially when it turned smoothly without stopping, it was inflated and drawn outside. A visual check confirmed that the actual robot position and the CG position were shifted by a maximum of approximately 106 cm. And, the stop position was offset by about 5 cm

in the direction of travel. It is considered that this is because the operation of the program is slow, and the delay of the program is unintentionally added to the intentional delay.

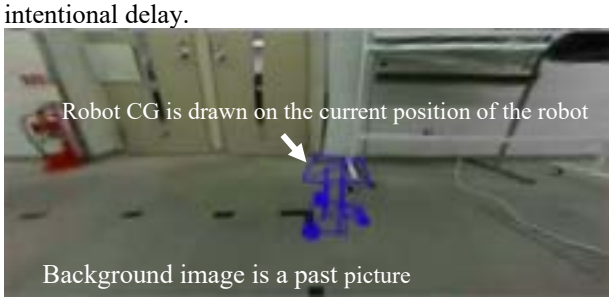

Figure 15. Video generated in an experiment using a small vehicle

5 Summary and outlook

This paper described a method to generate a video that follows the robot from the back, using the camera on the robot, by intentionally superimposing the CG of the robot on the delayed video. We implemented a tracking view generation method. We conducted experiments using two types of robots—a construction machine and a small vehicle—and confirmed the basic operation. From the experimental results, we prove that the third-person view image can be generated from the image of the camera on the robot according to the theory, and it was confirmed that the distance between the robot and the camera can be fixed. A mounting problem caused a phenomenon in which the actual position of the robot and the position of the CG caused an error and the CG skid. As a result, in addition to the intentionally generated delay, there was an unintentional delay in the program.

In the future, we plan to reduce the delay in the system to more accurately superimpose CG. In addition, we aim to demonstrate the superiority of this research by performing a subject experiment using the generated tracking bird's-eye-view image and other images.

Abstract –

Lean construction (LC) and Building Information Modeling (BIM) support an integrated vision for short cycle plan-do-check-act cycles of planning and control in construction. However, operations control tasks, such as delivery of design information to the field, monitoring, progress evaluation and error detection are still largely manual and thus time-consuming, costly and error-prone. Innovations in construction technologies can be applied to reduce cycle time, waste, construction errors and the rework that necessarily follows. In this context, we propose application of a projection and scanning technology to provide workers with real-time information and feedback regarding the quality and accuracy of their handiwork. The goal is to achieve proper quality in the first iteration, with fully automated inspection, and no rework.

As a proof-of-concept, we demonstrate the system using an example of wall plastering. The result of plaster application is difficult to measure in conventional means, and errors are difficult to detect. Our system monitors the progress of the procedure (Field-to-BIM), evaluates the surface flatness and projects corrections onto the surface itself, after optimizing with respect to industry standards and tolerances (BIM-to-Field). We demonstrate the concept in an experimental setup using a Trimble™ TX8 laser scanner and an angled adjustable projector. The results show high precision detection of wall flatness deviations, of up to 2 mm accuracy.

1 Introduction

Lean construction (LC) and Building Information Modelling (BIM) support an integrated vision for short cycle plan-do-check-act cycles of planning and control in construction [1]. LC aims to maximize the value and eliminate the wastes in the construction process while BIM supports closer collaboration among project teams during the design and construction phases. Yet thorough implementation of the potential remains elusive because manual methods of information delivery from BIM-to-field *(a process to automatically transfer product and/or process information from BIM environment to construction field)*, and of monitoring operations in the field and reporting the data to the Information Technology (IT) systems (Field-to-BIM: *a process to automatically collect/collate raw data from construction field, to interpret the data and store situational awareness information in BIM environment*), are costly, time-consuming and error prone.

IT, BIM and other construction technologies (3D scanners, sensors and cameras, etc.) can be applied to automate these information delivery and collection tasks. Especially noticeable is three-dimensional laser scanning technology which is widely used around the construction industry in tasks like mapping buildings and creating detailed as-built models, deterioration tracking, quality assurance and progress monitoring. Laser scanners provide fast, extremely detailed, easily manageable information about their surroundings in the form of point clouds. These data can then be processed for useful as-built information to be recorded and organized. Point cloud processing is possible using proprietary software tools but unfortunately, their abilities are limited and sometimes not accurate enough. Where the use of laser scanners is task-specific, the algorithmic support must be tailored to meet the unique requirements.

In this paper we demonstrate the use of terrestrial laser scanning technology and image projection as a proof-of-concept for parallel, short cycle time control of a construction operation. Figure 1 summarizes the flow of the presented proof-of-concept demonstration. The specific use-case is a wall plastering operation, and the demonstration includes monitoring and quality assessment. We implement our algorithmic approach to track the progress of construction while detecting errors and suggesting corrections, all in near to real-time. We showcase the positive effect of information transfer from site to BIM using laser scanners and data processing, and from BIM-to-field by projecting our results, in the form of images, using standard projectors. We demonstrate our results with a small-scale experiment, performed in a rectangular room, defining one of its walls as our target wall.

2 Related Work

The following sub-sections discuss the implementation of construction tech and computer vision for on-site data collection, monitoring, and information projection.

2.1 Construction Technology Integration for Automated Site Monitoring Systems (Field-To-BIM Data Gathering)

The construction industry, to date, has many construction technologies innovations. Many research papers have discussed a variety of technologies with potential for improving operation control. Lee and Choi presented a study of combination between laser scanning and imagery for building reconstruction purposes [2]. Shih and Wang reported a laser scanning system for controlling the dimensional compliance of finished walls [3]. Gordon, Lichti et al. discussed the results of using the laser scanning for structural health monitoring [4]. Biddiscombe discussed the uses of laser scanning for controlling as-built dimensions [5].

Akinci, Boukamp et al. used spatial raw data gathering from the construction field, integrated the collected data into the project models, and developed a formalism for pro-active QA/QC construction for defect detection [6]. Ordóñez, Arias et al. proposed an image-based approach for controlling dimensions of flat elements, but it requires significant human input [7]. Bhatla, Choe et al. used a 3D laser scanner to capture and record the site progress data. The results were proven as more accurate than traditional site progress tracking [8].

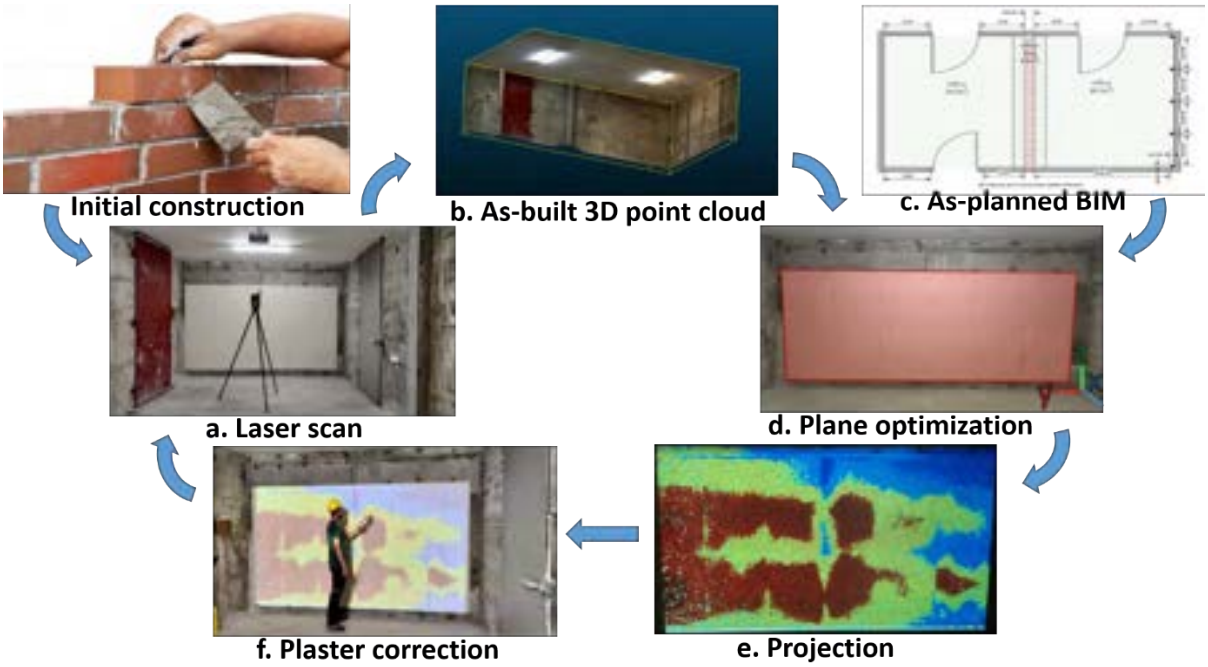

Figure 1. Flow of proof-of-concept demonstration. (a) Begin by scanning for progress detection, (b) obtain high accuracy as-built point cloud, (c) compare to the as-planned BIM data and detect errors, (d) cost optimization, (e) output projection, (f) correction of errors in accordance with image projection on the wall. Repeat scanning for updating status and next flow iteration until reaching termination at satisfactory conditions.

Braun, Tuttas et al. presented a test case of on-site progress tracking and recording. The presented work discussed ways to transfer collected raw progress data to BIM workspace using point cloud technology for construction control purposes [9].

Pučko, Šuman et al. presented a method where site works are constantly monitored, instead of scanning of a whole building under construction from time to time [10]. As a result, the as-built BIM model is continuously updated during the construction cycle. The presented method depends on low precision 3D scanning devices which are small enough to fix on workers' helmets and on the active machinery as well. The 3D scanning devices allow workers to capture the workspace and work that has been done, inside and outside of the building, in real-time. The recorded data include workers' locations and capturing time. The captured point-clouds were imported to 4D as-built BIM models. Then, the comparison between 4D as-built model with 4D as-planned model enabled identification of the differences between both models and the deviations from the time schedule as well.

Current approaches to control surface flatness are inefficient. Bosché and Guenet proposed an automatic surface flatness control process using laser scanning and BIM [11]. Their approach applied straightedge and F-Numbers methods. Their experiments demonstrated the suitability of laser scanning for standard dimensional controls and validated its quality and efficiency benefits vis-à-vis traditional measurement approaches. Valero, Forster et al. presented a method for automated defect detection and classification in ashlar masonry walls using laser scanning and machine learning [12]. The algorithm they developed identifies material defects and discoloration. Neither of these methods included in-situ feedback to the workers, as our system does.

Clearly, laser scanning technology is one of the leading methods for spatial data gathering. Past success encouraged us to choose this technology for our experiments.

2.2 BIM and Construction Technology Integration for Information Management

BIM and construction technology integrated applications are still not very common. Alizadehsalehi and Yitmen [13] and Patraucean et al. [14] discussed the impact of the combination of data capturing techniques with BIM in construction companies; both discussed the point cloud based method for creating as-built BIM models. The results show that site surveying for work done on site could be prepared in less time and more accurately by overlaying as-designed BIM models with 3D as-built captured BIM models, than by manual surveying.

Bosché, Ahmed et al. discussed the value of integrating Scan-to-BIM and Scan-vs-BIM techniques for construction monitoring [15]. They used laser scanning and BIM in a unified approach for automated mapping of as-built vs. as-planned MEP works to monitor earned value (work done), and to assist in delivering as-built BIM models from as-designed ones (performance measurement). Among the incremental improvements of their approach: (1) recognition and identification of objects not built at their as-planned locations; and (2) consideration of pipe completeness in the pipe recognition and identification metric.

Kim, Chen et al. presented a navigation and object recognition method that was implemented and tested with a custom-designed mobile robot platform, which uses multiple laser scanners and a camera to sense and build a 3D environment map [16]. The study shows that the 3D colour-mapped point clouds of construction sites generated were of sufficient quality to be used for many construction control applications such as construction progress monitoring, safety hazard identification, and defect detection.

Kopsida and Brilakis have evaluated different methods for reality augmentation by BIM model information and came to the conclusion that sparse 3D data leads to the most robust results when as-built and as-planned information overlay is requested for progress management [17].

2.3 Construction Technology Integration for Product and Process Information Transfer (BIM-To-Field)

To date, Augmented Reality (AR) has rarely been applied to construction control. However, it has the potential to improve the efficiency and quality of construction work by providing digital content on top of physical surface views to assist teams in the field [18]. Different approaches to integration of BIM and AR in construction have been proposed. Yang and Ergan discussed integration of BIM and AR, showing how semantic information can be transferred from a BIM platform to an AR system to improve the user visualization interface [19]. Williams, Gheisari et al. proposed an approach for BIM model translation to be used in a mobile AR application, which improves the direct use of BIM information through AR on-site [20].

Degani et al. presented an integrated BIM-Robot-AR system with self-localization method using data from distance sensors to find the probable pose (position and orientation) of system in an identified space [18]. The study showed the accuracy of self-localization and the system's feasibility for accurate projection of BIM model data directly onto physical surfaces in the field. In this work, we extend the capability of that system, focusing on two-way communication of information, from BIM-to-field and from field-to-BIM.

3 Methodology and Algorithms

3.1 Initial Assumptions

To reduce extra effort for unlikely scenarios, a few assumptions were made. The main assumption, regarding the operational area, is a rectangular shaped room. The room is assumed to have four walls, a ceiling and a floor, six planes in total, all perpendicular (or parallel) to each other. The origin of the coordinate system is assumed to lie within the room, in the geometric center. It is also assumed to be almost empty, without furniture or clutter. These assumptions help organize the initial conditions and partially assure consistency in the point clouds received after scanning the operational area. In previous work, we have demonstrated the ability to localize a moving AR projector using Markov localization [18]. In this work, we simplify by assuming a static projector in a known location.

3.2 Laser Scan Pre-Processing

To achieve satisfactory conditions for working with the point cloud recorded by the laser scanner, each scan needed to be pre-processed. Each scan was acquired from two scanning stations and registered manually. The use of two scanning stations enhanced the overall accuracy of the scanned data. The stations were located opposite one another, one on each side of the operation room. Combining two scans roughly evens out the point density of the entire cloud, since the point spacing grows linearly with the distance between the scanned object and the laser scanner. Using Trimble Realworks™, the point clouds of the two stations were manually registered together and aligned with the X, Y and Z axes. Later, the alignment is manually refined as discussed in the next section. The point cloud was down-sampled by a factor of 10, yielding a dataset that was easy to work with without compromising accuracy. A RANSAC algorithm was applied on the points and a normal was estimated for each point based on 10 of its nearest neighbors [21]. This normal represents the plane on which the point is assumed to lie. Finally, the point cloud's center of mass was calculated by averaging all the X, Y and Z coordinates of the points. With two stations, each with its own deviations, we could refine the alignment between the two. In the next section, we will describe the process of wall detection. This is needed for two reasons: first, we impose no requirements or constraints on the position and orientation of the laser scanner during the scans; second, as we are capturing the status of the operation at partial progress, with possible errors already present on site, we can use the as-planned information only as reference while making sure the detection of walls, errors and progress status are correct.

3.3 Wall Detection

Once the point cloud had been pre-processed, the walls were detected, and a specific target wall was identified. The walls, or planes, of the point cloud were detected using a clustering algorithm, K-means [22]. The clustering algorithm receives the normals of the points as input. The points were then divided into six clusters. Each cluster represented one of the walls, the floor, or the ceiling. The algorithm also assigns a center of mass (COM) to each group, which is not necessarily a member of the cluster. This COM was then validated by averaging all X, Y and Z arguments of the normal of the points related to each cluster. The central normal of each cloud, at this stage, has slight deviations from the absolute Cartesian axes. This can be fixed effortlessly by calculating a transformation between the absolute axes and the current plane normals. This transformation was then applied to the entire point cloud, aligning it with the absolute coordinate system of the as-planned information. For simplicity's sake, the experiment focused on a single, randomly chosen wall called the 'target wall'. The wall was identified by its ID output of the k-means algorithm and separated from the point cloud. At this stage, all elements of the room are known and identified. Any construction progress made with respect to previous scans can be updated and registered. The process is detailed in algorithm 1.

Algorithm 1: Wall Detection

Input:
- Scan of the room [PCL file]
- Target wall normal vector [float vector]

Output: Target wall point cloud aligned to wanted vector

Constants:
- NUM_OF_WALLS
- WALL_NORMALS

```
Mean_PCL = avg{ PCL (x), PCL (y), PCL (z)}
Displacement = -1* Mean_PCL
Normals = find_normals(PCL)
Normals = rotate normals towards Mean_PCL
Walls = cluster(Normals, num_of_walls)
for wall_index :=1 to num_of_walls:
   normal := avg{ Normals (x), Normals (y), Normals (z)}
Rotation = angle(normal(1), const_normal(1))
PCL = translate and rotate(Displacement, Rotation)
for wall_idx := 1 to num_of_walls:
   if wall_normal == target wall normal
      target_wall_idx = wall_idx
target_wall_ PCL = PCL (wall_idx)
rotate (target_wall_PCL [0,0,1])
```

3.4 Plane Optimization

Two main features of our proposed system are error detection and correction. After detecting the error, a cost assessment must be performed for the repair operation. To estimate this cost, we must know how different the current state is from the desired, optimal one, i.e. how

severe the detected errors are. Note that the optimal result does not necessarily conform to the originally designed state defined in the BIM model. In certain situations, considering underlying deviations from the original design, such as deviations in the concrete or block face, an optimal result may be one that can be achieved economically while still satisfying design performance conditions (such as planarity, verticality). The decision needs to be made simultaneously with the construction operation. As part of our proof-of-concept experiment, we are dealing with monitoring and correcting plaster application. Our goal is to supply real time improvement suggestions and we want it to be optimal in terms of cost. A tight constraint we face is the fact that the wall must be perpendicular to the floor. In 3D terms, we are left with two degrees of freedom for plane adjustments, keeping the plane's normal parallel to the floor. Figure 2 shows in top view, the exaggerated features of the wall surface with a blue line and the red line is the optimal plane.

As can be seen in Figure 2a, one option is to move the plane along its normal, basically controlling the "d" parameter of the plane equation. The equation of a plane in the three-dimensional space is:

$$ax + by + cz + d = 0 \qquad (1)$$

In Figure 2b and Figure 2c the second degree of freedom is presented – rotating the plane about the Z axis. Each one of the two described changes in the plane's location results in a different topography of protrusions and depressions. Figure 2d shows the grid of cost calculation. The calculations are demonstrated in algorithm 2.

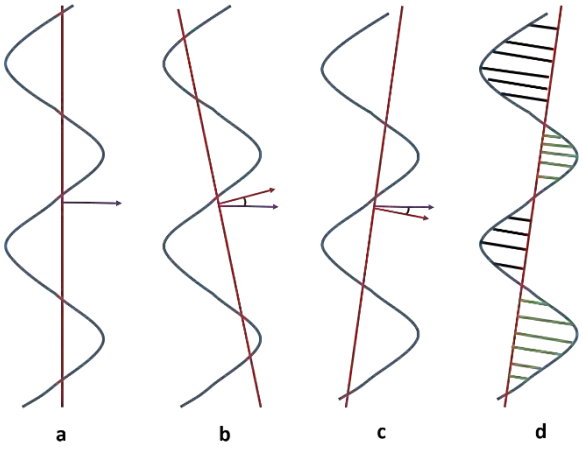

Figure 2. Surface flatness optimization. (a) Nominal plane, (b) rotated plane to positive angle limit, (c) rotated plane to negative angle limit, (d) visualization of grid for cost calculations.

Algorithm 2: Cost Optimization

Input:
- Target wall point cloud [PCL file]
- Nominal plane [plane parameters]
- Filling up cost [float number]-FU_cost
- Shaving off cost [float number]-SO_cost

Output: optimal plane [plane parameters]
Constants:
- Target wall absolute normal vector-TWANV
- Industry tolerance-IT
- Design constraints-DC

```
DC_vec := [0:0.001:DC]
IT_vec := [-IT:0.001:IT]
Optimal_plane := Nominal_plane
Fill_up_cost := 0
Shave_off_cost := 0
Cost_TOT = max(FU_cost,SO_cost)*num_of_ PCL _pts
for D in DC_vec:
   for Angle in IT_vec:
      Curr_plane := [Angle, D]
      Fill_TOT = (num_wall_points > curr_plane)*FU_cost
      Shave_TOT = (num_wall_points< curr_plane)*SO_cost
      Curr_cost := Fill_up_cost_TOT + Shave_off_cost_TOT
      If Curr_cost < Cost_TOT:
         Cost_TOT = Curr_cost
         Optimal_plane = Curr_plane
```

4 Experiment

4.1 Experimental Setup

The experimental setup includes a rectangular, 32 m^2 room (8 m x 4 m), a laser scanner (Trimble™ TX8) and a standard projector. As can be seen in Figure 3, the room has bare, unfinished walls, a convenient state for benchmarking the accuracy of the laser scanner. The room is rectangular, and all of its parameters are in accordance with the initial assumptions given in section 3.1. The purpose of the experimental setup is to construct a proof-of-concept system that can monitor, assess, and evaluate a wall plastering operation. The system is required to perform in near real-time and provide a complete start-to-end solution. System demands include progress monitoring and surface quality assessment by error detection and optimal error correction. Three visual steps of the flow can be seen in Figure 4.

4.1.1 Indistinguishable Discrepancies

A reasonable assumption is that errors of plaster application are difficult to notice with the naked eye. Imperfections will usually be due to gradual straying from a desired plane, without rough changes or noticeable edges.

Figure 3. Experimental room

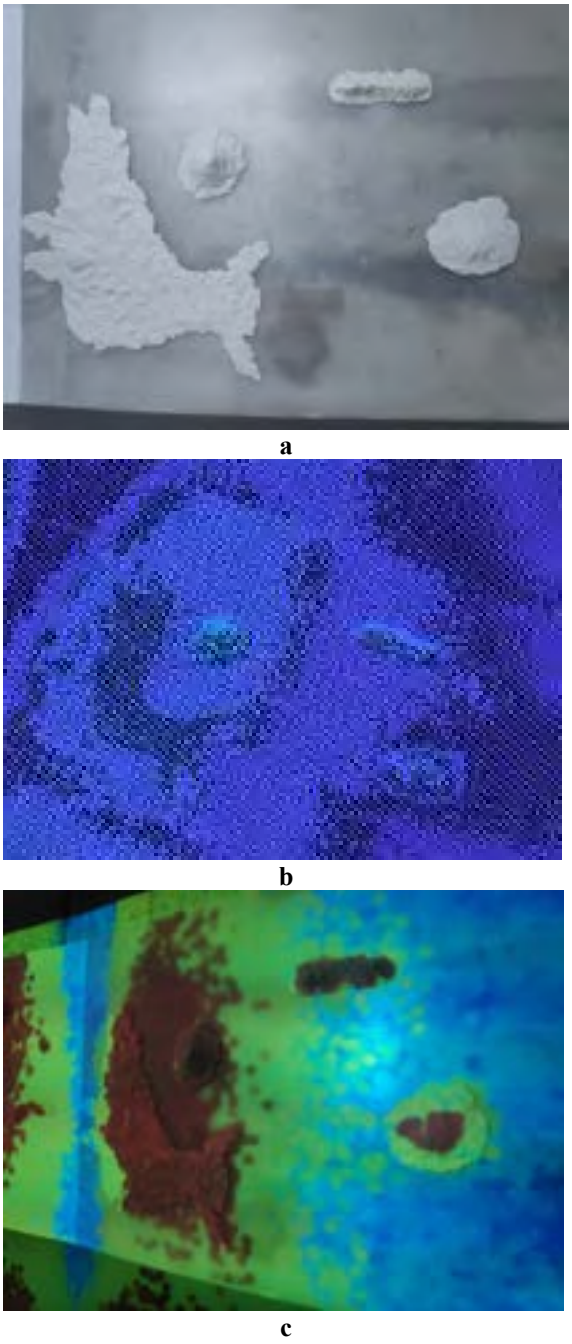
In these cases, our system is most useful, which was the motivation of this experiment. This experiment is performed in the same room, but with a target wall with thin cardboard sheets attached to it as shown in Figure 5a. The sheets are fixed adjacent to one other and cover most of the surface of the wall. The main purpose of the setup was to simulate a gradual drift of the plaster surface instead of rough, highly visible discrepancies. The target wall imperfections were also taken into consideration, but their effect was negligible as the optimal plane placement is fixed with respect to absolute X, Y and Z global coordinates.

4.2 Experimental Flow

The experiment is used to show the full extent of the construction operation. The main target of our proof-of-concept experiment was to demonstrate the cycle of construction work monitoring, error detection, error correction and status update. The experiment comprised a few stages, which are discussed in the next subsections.

4.2.1 First Scan

The first scan was performed to calibrate and prepare the system. Two scanning locations ("stations") were used as described in section 3.2. Each scan was performed with highest accuracy setup of the laser scanner. For the Trimble™ TX8, used in this work, the point spacing at 30 m is 5.7 mm. Each scan took about 10 minutes. Both stations were registered using a proprietary software tool that receives manual input – the user needs to mark three pairs of locations on both scans. The same scan setup was performed twice, both in an illuminated environment and in complete darkness. The scans were compared, and the results were similar - both point clouds met the requirements of section 3.2 and had equal errors. In accordance with sections 4.1.1 and 4.1.2, a wall was chosen for demonstration purposes and two types of plaster lookalikes were applied.



a

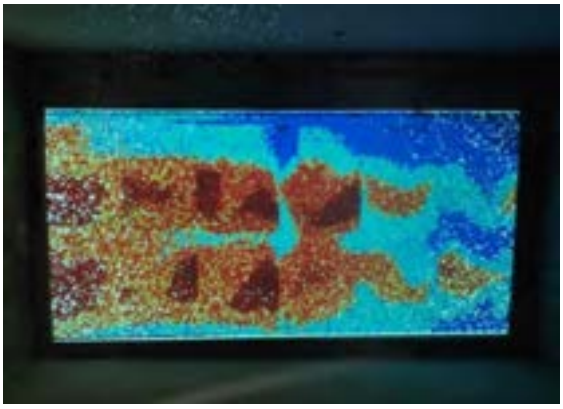
b

c

Figure 4. Using modelling clay to simulate discrepancies in the wall. (a) Hand sculptured modelling clay, (b) point cloud of the target wall, (c) projection on the target wall.

The cardboard sheets were placed on the wall to simulate low frequency plaster irregularities and the play dough was placed to simulate rough inaccuracies and to benchmark the laser scanner accuracy. People find it difficult to identify small inaccuracies in a plastered wall. This is why the cardboard setup was chosen for the rest of the experiment.

a



b

Figure 5. (a) Using cardboard sheets attached to a target wall to simulate minor discrepancies in the wall, (b) error correction projection on target wall.

4.2.2 Data Processing

Data processing was performed as described in sections 3.2 and 3.3. After extracting all the points of the working wall, a mean normal was calculated and a plane was fitted by this normal. This was the nominal plane that identified the current baseline target wall from which the optimization calculations could start.

4.2.3 Optimization

After making sure that the nominal plane was perpendicular to the plane of the floor, an optimization process was initiated. With the current state of the target wall, an optimal plane was derived from the optimization process. In some areas the optimal plane was "submerged" in the target wall and in others – raised above it. This was evident in the projected image as different areas had different colors.

4.2.4 Projection

A topographic map was produced, relative to the direction of the optimal plane normal. A manual calibration of the projector's location was done in order to project the image on the wall with the correct perspective. We have previously demonstrated the ability to localize a projector based on an image captured by a camera in a known location [18]. As can be seen in Figure 5b all areas on the target wall that needed to be shaved off were colored in shades of red and the ones that needed to be filled up with plaster were colored in blue. The color map helped with visualizing 3D data in a 2D image. The gradient of colors was equally spread between the "highest top" and the "lowest bottom". All the high contrast areas that can be seen in Figure 5b are edges between sheets of cardboard or between a sheet of cardboard and the wall itself.

4.2.5 Additional Iterations

The cardboard sheets were flattened to simulate a flattening procedure in accordance with the projection. The room was then scanned once again, with identical parameters as the previous time. The second cycle was about finer detail correction, in comparison to the first one. The scan was similarly processed, and another complete flow cycle was carried out, resulting in a new heat map. The heat map was projected using the same static projector and both iterations included high precision projection accuracy with offsets no more than 1 cm. Within the projected image, the measured errors had a mean of 2 mm. The projection process was not optimized and can be improved in future executions. This procedure can be repeated as often as needed, terminating once the work complies with some predetermined accuracy threshold.

5 Conclusion

In this work we have successfully demonstrated practical implementation of a conceptual short cycle of construction control composed of progress monitoring, error detection and optimal error correction. We have planned and carried out a small-scale experimental setup dealing with wall plastering assessment.

The experiment indicated that maximal accuracy is within reach and is restricted only by the capabilities of the hardware in use, i.e. laser scanner. In our model and scan setup we were able to achieve 2 mm accuracy of scan that was reflected on the measured results. We have iterated over two complete cycles of the flow, improving the plastering quality with every iteration. In each cycle we measured the distance between the projected elements and the real ones before mending the work.

We assume that the principles demonstrated by our proof-of-concept experiment can be applied to other

construction operations, and that our bi-directional workflow can help automate operations. We stress that from a technological perspective, each task must be treated in a different manner with appropriate algorithms. The robustness of the specific implementation is restricted to the task at hand and cannot be easily transferred to other construction tasks. We plan to integrate automated localization for the projector in future work.

E-mail: lin611@tsinghua.edu.cn

Abstract –

Due to limited funds, road authorities around the world are facing challenges related to bridge management and the escalating maintenance requirements of large infrastructure assets. Nowadays, many government organizations have published a variety of data to enable transparency, foster applications, and to satisfy legal obligations. Open governments data like bridge data, weather data would help to better assess the condition of bridges for maintenance purpose and allocation of funds. However, these data sets are fragmented in different systems or formats, and their value in bridge management are not fully explored. This paper proposes a graph-based bridge information modeling framework to integrate open government data for bridge management. The framework represents bridge inventory data as a labeled property graph model and extends the model with weather data. Implementation of the framework employs python scripts for data processing, and neo4j database for data management. The framework is demonstrated using data from national bridge inventory (NBI) and national oceanic and atmosphere administration (NOAA). The results show that the proposed framework can potentially facilitate the integration and retrieval of public government data, and effectively support and provide services to bridge management. Scripts and used data are also shared on GitHub to foster future explorations.

Keywords –

Bridge management; Open government data; Bridge information modeling; Graph database; Data retrieval; Knowledge.

1 Introduction

As essential infrastructures for transportation, bridges are widely seen in both cities and rural areas. Since most of the bridges have been built for decades, the deterioration of structural assets and more specifically, deficiencies related to ageing bridges have become a common problem throughout the world[1]. Given that theirs conditions are getting worse year by year, there is a huge demand for resources and funds to maintain bridges every year. For instance, UK has more 160,000 bridges and it will cost about £180 m to maintain or repair bridges in England only according to previous research[2].

Due to limited funds, it is hard to fulfill the escalating maintenance requirements, and the road authorities have to make decisions wisely to avoid potential structural failures. Thus, structural condition assessment and rating are always utilized to choose bridges that with the worst conditions[1, 3]. This calls for a national bridge database[2] as well as bridge management systems, to estimate costs of bridge maintenance accurately. Thus, National Bridge Inventory is established as a unified database to analyze bridges and judge their conditions, for safety and management purposes[2] in the United States since 1968. And similar databases are later created in other countries.

Usually, typical bridge maintenance scenarios like risk evaluation or condition rating require not only structural characteristics, inspections but also other factors such as environmental parameters[4]. However, environmental parameters such as temperature, precipitation are not included in the national bridge databases like NBI. And environmental data are still missing in most of the bridge management systems[2] such as Pontis[5] in the United States, DANBRO in Denmark. Lack of environmental data will lead to inaccurate assessment of bridge conditions and impact the decision-making process.

Recently, many government organizations have published a variety of data to enable transparency, foster applications. For example, the public sector information directive in Europe, the open data initiative in 2009 in the United States, are proposed and open government data portals such data.gov.uk, data.gov, and data.gov.sg are provided for citizens and stakeholders[6]. The Federal

Highway Administration (FHWA) of the U.S. Department of Transportation has opened the NBI database for public access[7]. While there are also quite a few datasets related to environmental data available from national oceanic and atmosphere administration (NOAA)[8]. Integration of all these datasets will bring new opportunities for bridge management and maintenance.

However, to the best knowledge of the author, few attentions have been paid to integration of open government data for bridge maintenance. Therefore, this research explores how to integrate open government data and how to use them for bridge management purpose. First of all, research methodology and framework are proposed in section 2. Then, a labeled property graph model is introduced to model bridge inventory data and environmental data in section 3, procedures and scripts for integration of open government data to create the graph model are also explained in this section. While section 4 demonstrates how to use the established graph model in various data retrieval scenarios related to bridge management. Finally, benefits of the proposed method and potential future works are concluded and discussed in section 5.

2 Framework

As mentioned above, various government data have been opened for public access, and more open data will be accessible in the future. However, these data are usually represented in different formats. To integrate heterogeneous data from different sources, graph based data model are preferred than relational data model according previous investigations[9].

Thus, this research utilized a similar approach based on labeled property graph. As shown in Figure 1, the proposed framework consists of five steps, namely, data collection, graph modeling, graph creation, model extension and application, which are explained in detail as follows.

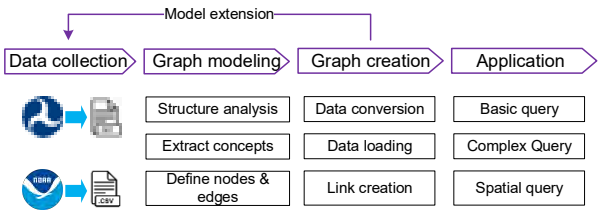

Figure 1. Workflow of the proposed framework

1. **Data collection:** first of all, bridge information from opened bridge databases like the NBI database[7] are downloaded as text files similar to csv format, and environmental data is also obtained from the website such as the NOAA[8] as csv files.
2. **Graph modeling:** considering that the data types, property names and values are encoded and represented with different rules, for instance, NBI database is recorded and encoded following this guide[10], structure of the collected data are analyzed. Then, key concepts as well as their properties are extracted by analyzing corresponding guides on data formatting. At last, key concepts are modeled as nodes of a graph, with their names or classes attached as labels, and relationships between concepts are represented as edges.
3. **Graph creation:** to create the defined graph model in the previous step, a data conversion process is firstly implemented based on python scripts. Then, all data are loaded into a graph database called neo4j, and links between datasets from different sources with neo4j cypher scripts if needed.
4. **Model extension**: since more open data could be accessed, they could be integrated in the graph model through model extension. Generally, engineers or developers could follow the same way as the above-mentioned 3 steps, and the same concepts used in different models and links between different concepts should be identified to merge different data sources and connect different concepts together.
5. **Application**: finally, the created graph is demonstrated with different data retrieval scenarios. In this research, basic query showing the capacity of graph database, complex query for finding bridges linking two states, and spatial query to get environmental data from nearest weather stations of a bridge are provided.

3 Graph-based Modeling of Bridge and Environmental Information

3.1 Concept Graph Model

Following the above-mentioned framework, a concept graph model in Figure 2 is first established for bridge management purpose.

In the middle of Figure 2, concept Bridge is used to represent basic information of a bridge. Structure type, year built, length, and a few other properties defined in NBI database are included in Bridge. Instead of taken all data related to a bridge into a single row as NBI database did, Route, Feature, Traffic, Navigation, Inspection, SpecialInspection, and Improvement are introduced as new concepts. Route stands for a road a bridge carries, and Features are rivers, creeks, etc., that a bridge intersects. Traffic and Navigation capture properties related to traffic loads (i.e., cars, trucks, buses) and navigation control on waterway. Within these two concepts, average daily traffic, vertical and horizontal

clearance of navigation are usually considered properties. Meanwhile, Inspection and SpecialInspection are also introduced to model data related to bridge inspections. Date of inspection, inspection frequency as well as category of special inspections like underwater inspection, fractural inspection is considered in the data model. Finally, improvements made to a bridge are also modeled as Improvement in the proposed model. Cost, date and other properties of improvements are considered.

Moreover, the concepts State, County, and Agency are also introduced to represent state, county a bridge locates in and the agency which the bridge belongs to. According to the NBI database, states are also responsible for the maintenance of bridges, and thus a relationship ResponsibleFor is defined.

To better illustrate the proposed graph model, an exemplary graph of bridge inventory which shows most of the previously mentioned concepts and relationships are provided in Figure 3.

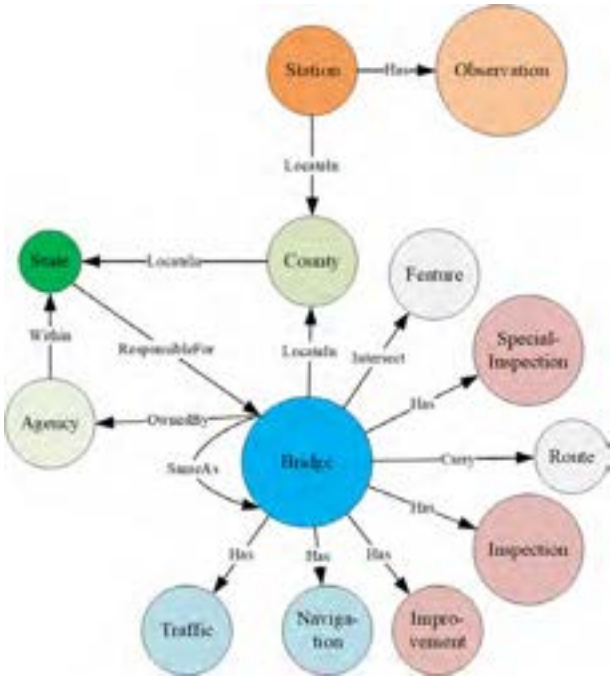

Figure 2. Concept graph model for bridge management

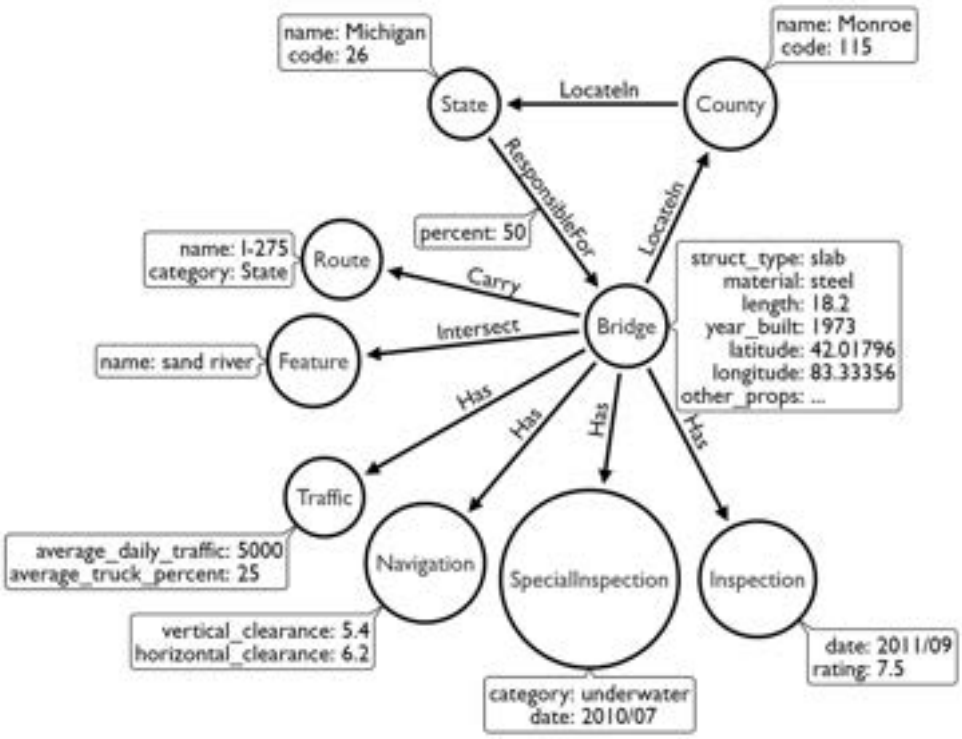

Figure 3. Exemplary Graph of Bridge Inventory

At the top of Figure 2, two concepts, Station, and Observation, are introduced to model environmental from NOAA. Station captures the ID, name, latitude, longitude, and elevation of a weather station, while Observation represents a few environmental features such as temperature, precipitation, wind, observed at a curtained time. And a Has relationship is used to model the relationship between Station and Observation. In this way, an exemplary graph model as shown in Figure 4 could obtained based on raw data from NOAA website.

Note that the Has relationship defined in the graph model is not only used to link bridges and inspections, features, navigations, but also used to connect weather stations and their observations. This is where graph model shows its power. Another benefit of labeled graph model is that relationships can also have properties, as ResponsibleFor relationship does in Figure 3, which is quite straightforward for engineers.

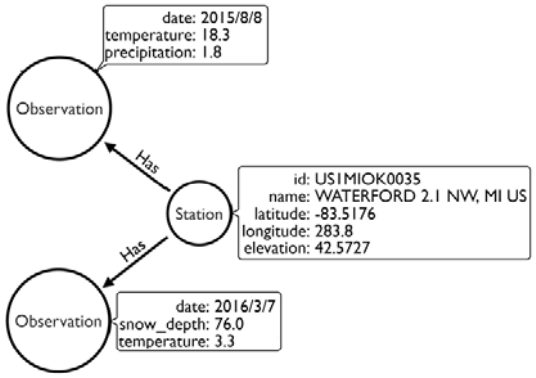

Figure 4. Exemplary Graph of Climate Data

3.2 Data Integration and Graph Creation

To convert multiple source data into the proposed graph model, a data integration and graph creation method is adopted in this research.

Firstly, to transform a data row containing all data related to bridges into different concepts, data mapping rules are defined based on python scripts. Figure 5 shows how to map NBI data tables to Bridge concept and ResponsibleFor relationship of the graph model. According to the upper part of Figure 5, label of the Bridge concept followed by NBI properties used to generated its ID are firstly provided. Then, how to map each column of the NBI data table to properties of the Bridge concept is then defined. Similarly, label and property mapping configurations of relationship ResponsibleFor are defined at the bottom part of Figure 5. Meanwhile, labels as well as NBI properties used to created IDs of source and target concepts are also provided, which links between different concepts can be further created.

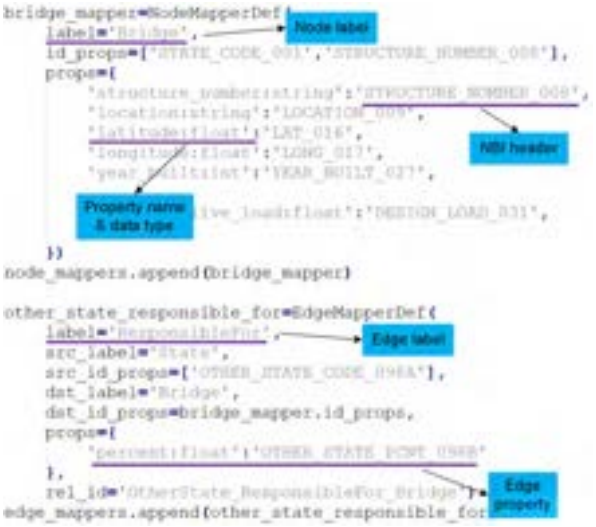

Figure 5. Mapping scripts to create graph model

In addition, since data values of the NBI database are encoded following specific rules, python scripts to decode and convert the data are also needed. For example, latitude and longitude are encoded as a string with 6 digits in the NBI database, and degree, minute, second are represented by the first two digits, the middle two digits, and the last two digits respectively. In this way, python scrips to convert the string to a float number representing the latitude and longitude in radian is provided in Figure 6. Another example shown in Figure 6 is the python script used to convert the year information represented with a two digits string in the NBI database.

```
def get_latlong(raw_val):
    degree=float(raw_val[:-6])
    minute=float(raw_val[-6:-4])
    second=float(raw_val[-4:])/100.0
    return degree+minute/60.0+second/3600.0

def get_date(raw_val):
    month=int(raw_val[:-2])
    year_str=raw_val[-2:]
    if int(year_str[0])<3:
        year=int('20'+year_str)
    else:
        year=int('19'+year_str)
    return datetime.datetime(year,month,1)
```

Figure 6. Scripts to convert NBI properties

Therefore, with defined mapping rules and data conversion scripts, bridge information of the NBI database are converted to different csv files, each of which persists data of a concept or a relationship of the proposed graph model.

Then, the generated csv files could be loaded in neo4j database and the graph is established. As shown in Figure 7, bridge information could be imported with the csv

loading script of neo4j, and nodes representing bridges are automatically created.

```
LOAD CSV WITH HEADERS FROM
"file:///Bridge.csv" AS row merge
(n:Bridge{id:row.id}) on match set
n+=row on create set n=row;

LOAD CSV WITH HEADERS FROM
"file:///State_To_Bridge.csv" AS row
match (s:State{id:row.src_id}),
(d:Bridge{id:row.dst_id}) merge (s)-
[r:ResponsibleFor]→(d) on match set
r+={percent:row.percent} on create
set r={percent:row.percent};
```

Figure 7. Data loading scripts

Furthermore, once nodes representing bridges and states are created, the ResponsibleFor relationship can also be created by loading corresponding csv files with script provided in Figure 7.

Following the same way, data tables obtained from the NOAA website could also be converted and imported into neo4j database, thereby creating data nodes and relationships related to environmental data.

If connections exist between data nodes generated with different datasets, extra rules could be defined based on neo4j script. For example, if ID of concept ConceptA from a dataset equals a property PropB of concept ConceptB generated by another dataset, then the following script in Figure 8 could be used to create the relationship RelAtoB.

```
match (a:ConceptA),(b:conceptB) where
a.ID=b.PropB create (a)-[:RelAtoB]→(b)
```

Figure 8. Data script to create relationships

4 Demonstration

Following the previously mentioned workflow, this research build a graph model based on data retrieved from the NBI and NOAA website. Specifically, NBI data of Michigan state from 2011 to 2016 and Wisconsin state in 2016 as well as environmental data in Michigan and Ohio state from 2015/1/1 to 2016/12/31 are utilized. In addition, codes and names of all states and counties are also included when creating the graph. At last, there are 190, 525 nodes with 13 labels and 283, 616 relationships with 8 labels created in total. Details of nodes and relationships are listed in Table 1.

According to Table 1, it is concluded that there are 25, 410 bridge inventories carrying 1, 509 routes and intersecting with 6, 955 features in total. While 30, 737 inspections, 1, 506 special inspections as well as 3, 879 improvements were made from 2011 to 2015. In other words, about 1.27 inspections were made for each bridge on average and only 15.26% of them were improved during this period, reflecting that there is a huge demand of funds for bridge maintenance.

Table 1. Number of Nodes and Relationships in Generated Graph Model

Category	Label	Amount
Node	State	52
Node	County	3, 228
Node	Agency	26
Node	Bridge	25, 410
Node	Route	1, 509
Node	Feature	6, 955
Node	Traffic	25, 747
Node	Navigation	15, 952
Node	Improvement	3, 879
Node	Inspection	30, 737
Node	SpecialInspection	1, 506
Node	Station	179
Node	Observation	75, 345
Relationship	LocateIn	28, 628
Relationship	OwnedBy	25, 411
Relationship	Within	26
Relationship	ResponsibleFor	25, 513
Relationship	Carry	25, 413
Relationship	Intersect	25, 438
Relationship	Has	153, 166
Relationship	SameAs	21

To further illustrate how the established graph could be used for various data retrieval scenarios. Due to limited content of this paper, three scenarios are chosen to show basic query, complex query and spatial query capacity of the neo4j graph database.

4.1 Scenario 1: Query Data Related to Bridges

Top of Figure 9 shows a basic query retrieving bridges and all nodes they direct to. In the query, putting noting in the square brackets means matching all relationships, and the arrow implies that only relationships directing from bridges to other nodes are considered. To limit the results within 25, graph shown at the middle of Figure 9 is obtained.

Figure 9. Query bridges and its connected data

It is found that there are 3 bridges built in the year of 1932, 1980, and 2000 respectively, and two of them carry the same route. Meanwhile, a special inspection considering fracture critical details is also conducted when inspecting the bridge built in 1932. In this scenario, it is quite easier to retrieve all information related to a bridge with a simple query. It is also possible to match certain nodes connected with a specific relationship by specifying the relationship's label in the square brackets.

4.2 Scenario 2: Query Bridges Linking Two States

Furthermore, it is also possible to retrieve bridges linking two states. Query shown at the top of Figure 10 generates a small graph at the bottom of Figure 10.

As illustrated in Figure 10, two bridges connecting Michigan state and Wisconsin state are identified with the query. Since the NBI database assigns different unique numbers to bridges located in different states, there are two bridge nodes representing the same bridge in Figure 10. It is also illustrated in Figure 10 that the bridges are maintained together by the two states.

In this way, it is possible to query bridges carrying the same route, intersecting with the same feature, or owned by the same agency.

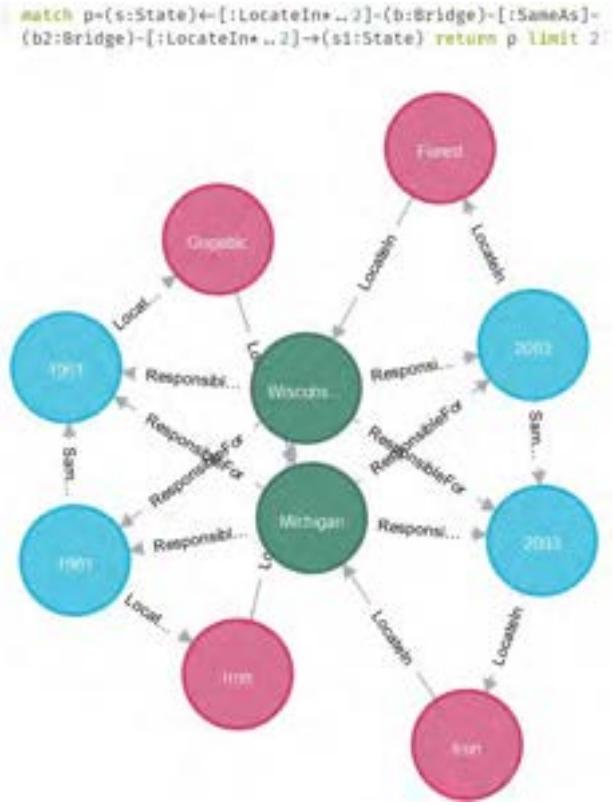

Figure 10. Bridges linking two states

4.3 Scenario 3: Query Nearby Environmental Data of Bridges

At last, given that longitude and latitude of bridges and weather stations are available in the created graph database, it is also possible to retrieve nearby environmental data of a bridge. For example, Figure 11 shows a query retrieving temperature and precipitation observed by nearby weather stations of a bridge for underwater inspection purpose. And part of the results of the query are listed in Table 2

```
match p=(b:Bridge)-[:Has]→
(ins:SpecialInspection{category:'underwater inspection'}),
q=(s:Station)-[:Has]→(o:Observation) where ins.date>o.date
and o.precipitation>0 and exists(o.temperature) return
b.structure_number,ins.date,o.temperature,o.precipitation,di
stance(b.loc_point,s.loc_point)/1000 as distance order by
distance limit 5
```

Figure 11. Query nearby environmental data of bridges for special inspection

It is found that underwater inspection of bridge No. 000000000011328 is conducted on 2015/4/1 and the temperature and precipitation observed by the nearest weather station (about 5.92 km away) at the same day are 1.7℃ and 0.3mm respectively. While similar results could be also obtained for the other two bridges.

In this way, researchers, engineers, and road authorities could extract environmental data from weather stations, thereby developing better model for condition evaluation and making wise decisions for bridge maintenance.

Table 2. Nearby environmental data of bridges for special inspection

Bridge No.	Date	Temperature/℃	Precipitation/mm	Distance/km
000000000011328	2015/4/1	1.7	0.3	5.92
B27007400000000	2015/11/1	6.1	3.8	24.05
000000000011884	2015/4/1	-2.2	0.3	27.90

5 Discussion

In this work, a framework integrating multi-source open data for bridge management and maintenance is proposed and demonstrated in a few scenarios.

The framework is validated with data collected from the NBI database and the NOAA website, since they are the public available and could be accesses easily. Despite this, it is possible and easy to adapt the proposed framework for integrating other bridge databases and data sources. For example, bridge database of the UK could be accessed from data.gov.uk, then the same workflow proposed in Figure 1 can be directly used to create a graph model for bridge management and maintenance. Similarly, open weather data could also be integrated with the same way. Moreover, except for bridge data and environmental data, as other open data is published, it is also possible to further extend the established graph model and continuously integrate more data sources.

With the proposed framework and graph model, it is possible for the managers to query related bridge information, environmental data as well as their connections for bridge management purpose. In this way, decision-makers could take open government data as a supplement of their private data to further improve bridge maintenance process. For example, a manager could take a target bridge operated by the agency he/she belongs to, query bridges that have similar states and environmental conditions with the target bridge from the graph database, and by comparing the retrieved bridges with the target bridge, he/she could get insights on how to improve the inspection and maintenance decisions.

However, when conducting this research, it is also found that the quality and richness of open government data still need further improvements. Detailed inspection information, other factors such as geotechnical stability, subsurface conditions are still not available from open data sources. Thus, it is recommended that the governments as well as other data providers should open more data if possible, and an approach that integrating both open data and private data for bridge maintenance are suggested.

6 Conclusions

As the government keeps opening data for public access, there is a trend in integrating multisource open data to foster applications and innovations in different areas. However, though bridges are essential for delivering goods and people around the urban and rural ear and there is a huge demand of funds for bridge maintenance, value of open government data for bridge management has not been explored yet.

This research investigates how to integrate the bridge information and the environmental data opened by the government based on graph modeling for bridge maintenance. A labeled graph model and python scripts for data conversion and integration are proposed. Demonstration in different scenarios show the flexibility and feasibility of the proposed framework. With the proposed method, it is possible to query various data related to bridges and retrieve environmental data nearby bridges, which are valuable for flood risk assessment, vulnerability, damage modeling [5] and decision-making, etc.

In the future, stakeholders are encouraged to open more data, such as data of highway network, traffic data collected by mobiles or sensors, which could be integrated and innovative application in bridge management would emerge quickly. In addition, it is also recommended to integrate both open data and private data as they could complement each other, thus bridge managers could make better decisions for bridge maintenance purpose.

What's more, to foster more explorations and applications, scripts used for data conversion and graph creation as well as a few exemplary graph queries are shared through GitHub:

https://github.com/smartaec/OpenBridgeGraph. Other researchers could access and modify the scripts for their further works.

Abstract –

Building information modeling (BIM) is a rapidly developing technology used in the construction industry. Many construction companies have implemented BIM into their construction processes for executing various construction management tasks, including four-dimensional (4D) progress simulation and cost control. However, 4D progress simulation has not been simultaneously integrated and compared with cost control thus far. With the execution of this simultaneous task, the relationship among project progress, construction cost, and project components can be explored. Moreover, currently, when conducting a cost review, discretionary adjustments cannot be performed based on an actual site implementation. To this end, in this study, first, the quantities of each of the cost items are calculated using BIM and are matched with the corresponding construction progress. The quantities of each of the cost items can, therefore, be included in each construction progress report. Next, BIM is integrated with the construction cost and the project schedule to generate an S curve concurrently with the 4D simulation. By using the S curve, cost control can be performed according to construction progress. In addition, the proposed model can be presented clearly by using virtual reality (VR).

Finally, this study explore the feasibility of the proposed model by applying it to a bridge construction project. The results indicate that the cost of each stage can be clearly determined using the proposed model. When a cost item is unclear, it can be compared with the simulated construction progress. Coordination and management can be performed, and any gaps therein can be filled early to increase the efficiency of the management process.

Keywords –

Building Information modeling; Virtual Reality; Five-dimensional Simulation

1 Introduction

Building information modeling (BIM) is a rapidly advancing technology in the construction industry. Numerous manufacturers use BIM to manage operations during construction, such as four-dimensional (4D)[1,2] progress simulations and cost control. Progress schedules are linked with BIM components by using 4D progress simulations. Accordingly, BIM models are progressively developed according to the progress schedules, which enable examinations of crucial matters and management items during each operation. Cost estimation entails quantity calculations using BIM models, which link the unit price of each work item and distribute the cost of items to corresponding operations[3]. This allows users to determine the daily costs incurred from various operations and plot a cumulative cost curve (S-curve) [4].

Despite the prevalent use of 4D progress simulations and cost control in construction companies, they have yet to be integrated together to simultaneously determine the relationships between progress, costs, and building components. Thus, when conducting cost reviews, construction companies cannot account for actual situations at the construction site or make adjustments accordingly. Therefore, this study integrated each cost item and its corresponding BIM model into 4D simulation task lists and integrated construction costs and schedules to generate S-curves. This enabled real-time simulation of construction progress by using the models and control costs by using S-curves. In addition, virtual reality (VR) was used to clearly present the models.

2 Literature Review

2.1 BIM 4D Progress Simulations

Generally, 4D simulations are effective auxiliary tools for construction planning and monitoring and help convey construction-related information. Early detection of conflicting construction items and process problems can help construction companies save considerable

money. Communication during meetings can help clarify problems, discuss issues related to construction interfaces, facilitate the attribution of responsibility, save communication time, and reduce wasted time resulting from misunderstandings. 4D simulations offer visual information to no construction personnel, and BIM provide easy-to-understand information that allows them to solve problems during preconstruction, diminish construction risks, control progress, and plan and review the planning of building interfaces and circulation. By using 4D simulation visual technology, construction companies can quickly understand relevant situations, which allows them to save communication time, reduce construction errors, enhance efficiency, and lower costs [5].

2.2 BIM-based Five-Dimensional Cost Control

Replacing traditional two-dimensional (2D) design processes with those that involved the integration and visualization of three-dimensional (3D) parameters and objects substantially reduces the number of drawings used. Moreover, this reduces the amount of work overseen by entry-level staff, which effectively integrates human resources and streamlines manpower costs. Construction schedules and costs are closely related, and 4D schedule planning enables managers to accurately monitor construction quality and progress, thereby controlling construction costs. Although effective in many respects, traditional 2D drawings are ineffective in presenting the number and areas of 3D space in houses. Five-dimensional (5D) cost estimates can be employed to perform detailed estimation of areas and material costs by using drawings. Specifically, this approach considers construction companies' budgets and material unit prices, accurately estimates construction costs, and reduces material estimation costs [6].

2.3 BIM and VR Integration

Intrgrating BIM and VR is a revolutionary breakthrough in the construction industry. BIM enhances authenticity, motion capture precision with VR plugins, and display resolution. BIM+VR has been promoted in the construction and construction marketing fields and enable the integration of BIM and VR systems. Such system integration prevalently used in the construction design industry. Promoting BIM+VR is possible because of advances in computer and Internet technology, which offer the construction industry enhanced computing power and effective software–hardware connections. Applying a BIM+VR system in construction projects and construction marketing is the result of increased investments in relevant systems by the construction industry and the public's improved consumption power [7].

3 5D Simulation of BIM+VR-Based Bridge Construction

3.1 BIM Model Building

This study entered various building dimensions from 2D drawings into Revit to generate 3D models. In general, each building component is separated during the drawing process to allow users to click on the building components separately during component scheduling (i.e., when selecting components and their corresponding operations) and design (Figure 1).

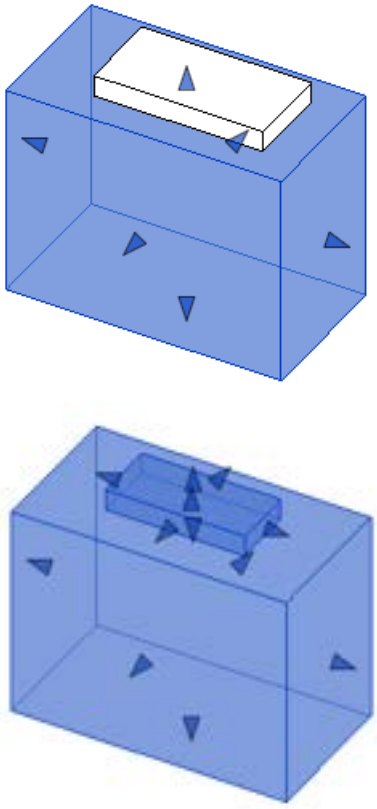

Figure 1. Difference between models with and without separated components

3.2 Number of Various Components and Cost Calculations

The concrete cost is determined by calculating the concrete required using the BIM model and multiplying

this number by the concrete unit price. The template cost is determined by calculating the surface area (using the BIM model) and multiplying this number by the concrete formwork unit price.

Because rebars are not drawn when building the models, the rebar cost is determined by calculating their lengths by using the rebar distribution diagram, multiplying these numbers by their corresponding unit weights, and multiplying the total weight by the unit price. The same calculation method are employed to determine the costs of other materials.

3.3 BIM Models Integrated with Construction Schedules: 4D Simulations

In this study, work items that needed to be completed in the progress schedule network diagram were first identified because numerous work items were completed prior to actual construction. Because this study only investigated the actual construction, work items that were completed before and after the construction process were removed. According to the progress schedules, work items and their corresponding components were integrated into a task list to adjust parameters such as construction time, animation speeds, animation effects, and illumination level to ensure that the 4D simulations ran smoothly.

3.4 3.4. Costs Integrated with 4D Simulations: 5D Simulations

The cost of each component previously calculated is entered into each progress schedule item. This allows users to know the total work item costs when performing 4D simulations. The users learn of these costs by selecting the construction shapes desired and examining the cost curves generated. The construction schedule–cost integration process is described as follows:

(1) The construction schedules and costs are integrated into an Excel sheet.
(2) The costs are entered as the material costs in actual construction schedules.
(3) The construction shapes in the left column of the 4D simulations are selected to generate cost curves.

3.5 VR and 5D Cost Control Integration

For managers to oversee the construction of a building as if they have participated in the construction process in person and review the construction progress, this study displayed the 5D simulation results in VR environments. By using the VR function of Fuzor along with external hardware devices, handles, and a VR head-mounted display, users can observe 4D VR simulation models to simulate authentic construction processes.

External drive equipment that connects the built-in VR functions of Fuzor with external VR drivers (e.g., STEAMVR.GeForce) include Sony PlayStation, Sony VR, and HTC Vive head-mounted displays. Users who do not have this equipment at their disposal could have used a smartphone with easily accessible VR glasses to enjoy the VR experience.

4 Case Study

4.1 Case Descripting

This study use a cable-stayed bridge as a case project. The cable-stayed bridge investigated is near the National Freeway 1 Daya Interchange, spanned Provincial Highway 74, and connected to Shuinan Economic and Trade Park in Taiwan. The sketchup model of case project is shown in Figure 2.

Figure 2. The sketchup model of case project

4.2 BIM Model Construction

The bridge was drawn in four stages: the drawing of the pier foundation, bridge roads, main tower, and steel cables. When drawing the bridge, the Revit group was turned on, and the computer-aided design drawings of each component were imported. Subsequently, the extrusion function was used to draw the bridge according to the construction shapes desired and elevations set. All components had to be drawn separately when drawing the bridge.

The bridge roads drawn were divided into six segments, and the components were drawn using the cross-sections of the roads. Because the bridge was not straight but curved, this study developed bridge roads through the sweeping method in Revit.

The main tower comprised 14 steel components that were drawn separately before being put together. The left and right sides each had seven components,. Similar to the bridge roads, the components were developed using the sweeping method. The main tower model is shown in Figure 3.

Figure 3. The BIM model of the main tower

Steel cables were found on all four sides of the bridge. Each side of the bridge contained 24 steel cables for a total of 96 steel cables. The steel cables were drawn using built-in components of Revit. Because some road surfaces were tilted or had turns and because steel cables in different sections varied in length, the cables on the four sides were drawn individually, and the cable lengths and locations had to be adjusted. Finally, the pier foundation, bridge roads, main tower, and steel cables were integrated, as presented in Figure 4.

Figure 4. The BIM model of the integrated model

4.3 Number of Each Component and Cost Calculations

The bridge was built using steel and reinforced concrete, and the upper and lower parts were constructed using steel and reinforced concrete, respectively. Calculations revealed that the quantities of concrete, rebars, concrete formwork, road steel plates, and main tower steel plates used were 15,722.3 m^3, 2,081,987.6 kg, 3,882.2 m^2, 844,062.3 kg, and 945,862.2 kg, respectively.

Revit was used to calculate the volume of the building components, from which the quantity could be determined. The components calculated included full-casing foundation piles, foundations (e.g., precast and self-filling concrete), piers, top beams, steel roads, parapets, asphalt concrete, the steel main tower, and the concrete formwork.

4.4 Costs of Performing Calculations Through BIM

After obtaining the quantity of each component by using these calculations, this study searched for the unit price of each component by using the unit price database prepared by the Public Construction Commission. The two variables were multiplied to derive the costs. The costs of concrete, rebars, the concrete formwork, road steel plates, and the main tower steel plates were NT$33,803,035, NT$41,639,753, NT$1,071,484, NT$145,321,869, and NT$28,375,866, respectively.

4.5 BIM Models Integrated with Construction Schedules: 4D Simulations

To clearly grasp the overall construction progress on the dates specified by construction companies, the construction progress schedules shown in the network diagram can be viewed. This enables users to learn about the schedules, float time, and progress of each work item and facilitate subsequent 4D simulations, as displayed in Figure 5.

Figure 5. Parts of the schedule of the case project

After displaying the overall construction progress by using Project, users are required to enter the names and durations of the construction work items in the BIM model by using the Fuzor 4D model task creation menu. Next, 4D simulations are generated (Figure 6), which allows overall construction progress to be observed visually. After entering the schedules for all models, users can preview 4D simulation results in advance and produce smoother 4D simulation animations by adjusting parameters such as the animation speed and illumination level. 4D simulation animations are produced using Fuzor through the following three steps:

(1) Add simulation items: Select the function “4D simulation model” in the menu and turn on the function “4D simulation.” Then, add new items for subsequent scheduling.
(2) Set construction dates: Set the overall construction start and completion dates. For instance, in this study, the “start date” and “completion date” were set as “September 23, 2017” and “October 19, 2019,”

respectively.

(3) Add model parameters: After importing the model into Fuzor, click on the models to be scheduled and set the work items and construction dates to facilitate 4D simulations for each work item according to their schedules.

Figure 6. 4D simulation

4.6 Costs Integrated with 4D Simulations: 5D Cost Control

Costs are integrated with 4D simulations to produce BIM 5D simulations. The cost of each work item is incorporated into 4D simulations to form cost curves, which allows them to be generated when each work item was implemented, and corresponding costs are simulated. 5D simulations are performed using Fuzor through the following two steps:

(1) Enter work item costs:When entering costs in 4D simulations, the costs of the component are used as the material cost of the work items. For example, the cost of hoisting the steel bridge in this study was 28,375,866. Work item costs could also be entered using Project or Excel, as shown in Figure 7.

(2) Display cost curves: After entering costs in 4D simulations, select the function “construction shape” to generate cost curves. Cost curves are also displayed during 4D simulations, as illustrated in Figure 8.

Figure 7. Work item costs

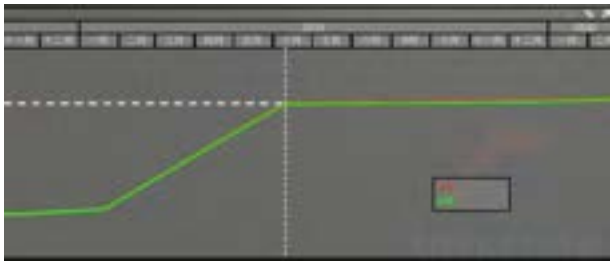

Figure 8. Progress curves of cumulative cost

4.7 5D Simulations Displayed as VR

In this study, mobile phones were placed in VR Boxes, and joysticks were used to move around in the VR environment and present the results of integrating VR and 5D simulations. In general, 5D simulations are displayed through VR through the following three steps:

(1) Initiate connection: Connect to a mobile phone by using Riftcat2.0 and turn on VRidge in the phone to connect it to a computer, as shown in Figure 9.

(2) Place a mobile in a VR Box (as shown in Figure 10) and click the option “connect” in Riftcat2.0 to connect it to VR.

(3) After opening Fuzor Project, use the VR button to connect the VR environment to the VR Box for viewing, as shown in Figures 11 and Figure 12.

Figure 9. Link the phone and the computer

Figure 10. VR Box

Figure 11. VR environment on the computer screen.

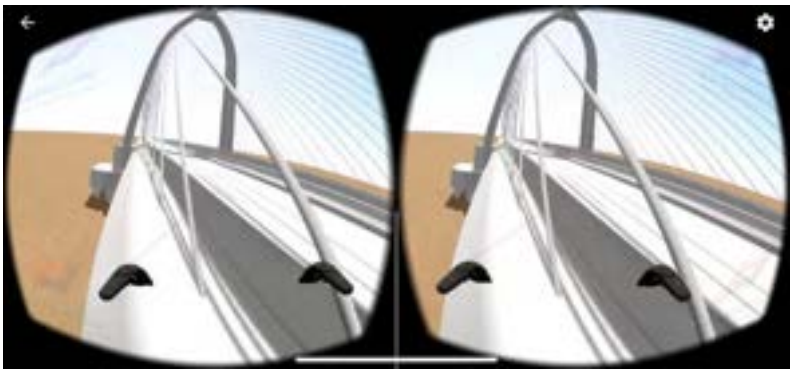

Figure 12. VR environment on the mobile screen.

5 Conclusion

5.1 Benefits of Applying Cost Curves

This study combined 4D simulations and costs to display 5D simulations. 4D simulations enable constructions to be viewed as animations, and construction progress costs are viewed as cost curves. Comparing the simulated cost curves with actual cost curves allows identifying actual construction progress and construction costs. This enabls construction companies to determine whether they are ahead or behind schedule on the basis of the discussions and revisions made to elevate construction quality.

5.2 5D Animation Simulations Integrated with VR

Although the group method can be adopted to create bridge models by using Revit and incorporated the models into projects, 4D simulations exhibit the following problem: Only one 4D simulation can be performed for identical components in different work items. Therefore, different component groups must be created for different work items to enable 4D simulations for all work items.

In addition, although higher-standard VR equipment (such as HTC Vive) can produce superior and immersive experiences, it requires using VR sensors, head-mounted devices, and a computer connection, rendering it unfeasible in specific locations. By contrast, this study used VR Box, connected it to a laptop computer and mobile phone, and placed the mobile phone in a VR Box to display the VR, which effectively elevated the applicability of VR displays.

Digital Twinning of Railway Overhead Line Equipment from Airborne LiDAR Data

M.R.M.F. Ariyachandra[a] and Ioannis Brilakis[a]

[a] Department of Engineering, University of Cambridge, United Kingdom
E-mail: mfa47@cam.ac.uk, ib340@cam.ac.uk

Abstract –

The automated generation of geometry-only digital twins of Overhead Line Equipment (OLE) system in existing railways from point clouds is an unsolved problem. Currently, this process is highly reliant upon manual inputs, needing 10 times more labour hours than scanning the physical asset. The resulting modelling cost counteracts the expected benefits of the digital twin. We tackle this challenge using a novel model-driven method that exploits the highly regulated and standardised nature of railways. It starts by restricting the search for OLE elements relative to point clusters of the railway masts. The resulting point clusters of the OLE elements are then converged with various parametric models of different catenary configurations to verify the presence of OLE elements and to find the best possible fit. The method outputs a geometry-only digital twin of the OLE system in Industry Foundation Classes (IFC) format. The method was tested on an 18 km railway point cloud and achieves overall detection rates of 93.2% F1 score for OLE cables and 98.1% F1 score for other OLE elements. The accuracy of the generated model is evaluated using distance-based metrics between the ground truth model and the automated model. The average modelling distance is 3.82 cm Root Mean Square Error (RMSE) for all 18 km data.

1 Introduction

Cost overruns are a worldwide phenomenon for railway projects, irrespective of the size and the contract value. The average cost overruns account for 29% projects' engineer estimates for rail and road projects in Europe and the United Kingdom (UK) [1], [2]. For example, the London Docklands Light Rail project is currently overrunning by over £1 billion in costs and three years [3] in duration. These cost and time overruns are common partly due to the absence of Information and communications technology (ICT) sector-level data management for construction/upgrade and maintenance of railways. Specifically, the absence of any form of a digital representation of railways caused by the extensive time required for collecting and processing raw data into working models makes it challenging to upgrade railways.

We argue that the need to create and maintain up-to-date digital twins of railways is an opportunity that should not be missed. Digital twins are expected to bring significant benefits to time, cost and quality parameters of railway projects [4]. These benefits include an 80% reduction in time, 10% through clash detection and 40% elimination of unbudgeted change [5], [6]. Yet, the current cost of creating and maintaining the digital twins greatly counteracts the perceived benefits of the digital twin. The non-canonical shapes in railways require 95% of the total modelling hours for manual shape customisation and fitting processes [7]. The automation of the twinning process will reduce the modelling time and ultimately save costs. We presented a method for generating railway masts as a first step to tackling this challenge [8], which also presented a method for removing the majority of the vegetation and other noise data from the input Point Cloud Data (PCD). The current paper addresses the next step; a method to automatically generate Geometric Digital Twin (gDT)s of railway Overhead Line Equipment (OLE) systems from airborne LiDAR data.

2 Overhead Line Equipment (OLE)

We define the following components as OLE elements (Figure 1).

- Connecting beam - Connects two masts of the same pair together.
- Contact cable - Transmits power to the train by a pantograph. They lie in the lowest height among all overhead cables and shall not be placed less than 5.8 m from the ground [9]. The contact cable runs in a zig-zag path above the track to avoid wearing a

groove in the pantograph. The zigzag known as the 'stagger' - is generally achieved using 'pull-off' arms attached to the support structures.

- Auxiliary cable – Placed between the catenary and contact cables, functions as a buffer and reduces the fluctuation of the cables.
- Catenary cable - Supports the contact cable and located immediately above auxiliary cables.
- Cantilever - Consists of horizontal and vertical metal tubes, connects catenary cables to masts. It supports the catenary projecting from a single mast on one side of the track.

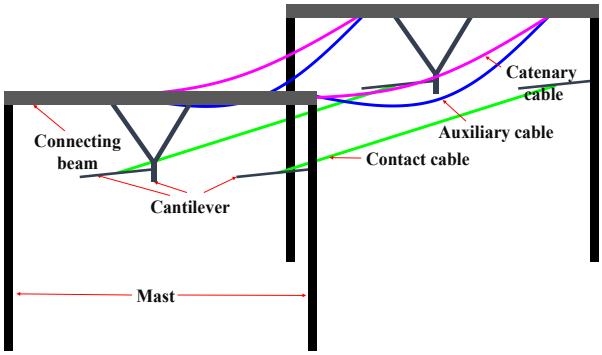

Figure 1. OLE elements

3 Research Background

3.1 Contact, Auxiliary and Catenary Cables

The process of converting PCD into gDTs of cables involves three steps: (1) Extraction of cable points, (2) Clustering single cable points, and (3) 3D cable fitting. Methods for cable extraction and clustering include: (1) Statistical analysis of PCDs based on height, density or number of pulses, etc. [10]–[14] (2) Hough transform and clustering based on two-dimensional (2D) image processing [11], [15], [16] (3) Supervised classification based on metrical and distribution features between points [13], [17]–[19]. Verification of detected cables is performed using a simplified model to fit into detected cables in the planar horizontal view [20] or by the usage of the Random Sample Consensus (RANSAC) algorithm combined with intensity values [21] or a polynomial function to fit the model [22]. We review each of these for cables in both railways and roads.

3.1.1 Statistical Analysis of PCDs Based on Height, Density or Number of Pulses

Jwa and Sohn [23] converted the cloud into voxels and detected cables using the linearity of the element. The method also used point density and segmentation analysis to differentiate roof edges, fences and other linear assets from cables and to group the points into catenary and contact cables. However, their method highly depended on the point density and the size of the voxel. The method did not work well when the cloud had data gaps, vegetation encroachment, and bundled cables. Cheng et al. [10] used a similar approach following KD trees and a polynomial function for clustering and 3D model fitting. The main limitation was they ignored the sagging posture of cables. Also, the method was influenced by frequent occlusions by trees or buildings, ambient conditions such as the temperature and the ageing of spans. The high detection and clustering accuracies were also attributed to the high point density of the data.

Zhu and Hyyppa [11] used statistical analysis considering height, point density and histogram thresholds and image processing methods to extract cables considering geometric properties. However, the thresholds highly relied on the point density and their dataset had a clear cut-off edge between cables and trees. In the majority of cases, OLE cables are not located at a distance away from the surrounding trees and other pole-like objects. A similar approach was used in Guan et al [14] to differentiate road and off-road points and to extract power-transmission cables/power tower points from the latter, followed by the extraction of individual power-transmission cables via Hough transform and Euclidean distance clustering. Finally, a 3D object fitting was done using linear and hyperbolic cosine functions. However, the method was sensitive to the point density of their PCD and did not work well for a different point cloud. Following previous methods, Cserép et al. [13] used height analysis to filter ground points and then used intervals along a selected axis with a point counter assigned to each interval to remove outliers. Finally, the method extracted cable points using using a density analysis and 3D voxels. Yet, their method could not reconstruct those cables into 3D models as the density algorithms removed some cable points as well.

3.1.2 Hough Transform, and Clustering Based on 2D Image Processing

Liu et al. [15] used statistical analysis and an improved Hough transform [24], to segment and to detect cable points. However, the thresholds were sensitive to the point density of the PCD and further work is needed to map the detection results to original 3D data and fit the curves to cable points. The method used in Sohn, Jwa and Kim [16] segmented cable points using Markov Random Field (MRF) classifier, which classifies power cables from other linear assets. The locations of pylons were used to detect cable span, within which cables are modelled with catenary curve models in 3D using the piecewise model growing. Yet this method assumed that the cables were parallel.

3.1.3 Supervised Classification Based on Metrical and Distribution Features between Points

Kim and Sohn [17] used Random Forests classifier as a supervised classification method to detect five key object classes which include cables, pylons, building, vegetation and low objects. They used 2D Hough Transform to 2D points of cables obtained by projecting 3D points onto a horizontal plane. A similar approach has been used in Wang et al. [19] by filtering cables using the height relative to the other objects. Then, the multi-scale spherical neighbourhoods are used to capture the anisotropy and details of cable topology structure. Next, metrical and distribution features were used to enhance classification accuracy. Finally, using Support Vector Machine (SVM) they classified cable points. However, both methods were unable to perform well when cables become the only object of interest as all the feature-based classifiers were highly attributed to the five class objects they considered. Furthermore, these methods only classified but not reconstructed 3D models of any of the class objects.

Following the same classification process, Guo et al. [18] used an improved RANSAC algorithm that includes similarity detection. A powerline between a span was segmented into neighbourhood cubes. Then the points within the cubes were projected onto planes to detect the similarities amongst the planes. At last, they detected cables using the inliers selected by RANSAC. However, the accuracy of the method was sensitive to the sparseness of the data and did not work well for a different point cloud. For instance, if there are few or no points on the cables, data are classified as vegetation by default. Also, cables were split into several pieces or categorised as false negatives when parts of the cables are being obscured by vegetation or when there were few points along a section of the line.

3.2 Cantilevers and Connecting beams

There are only two methods exist that detect cantilevers from PCD in Pastucha [25] and Rodríguez et al. [26] and no methods exist that detect connecting beams. In Pastucha [25], the method used the pattern of the points; a cross above the track to indicate the presence of cantilevers using RANSAC algorithm. All model points are classified as the catenary system in the case of positive authentication. Yet, the high detection rates were attributed to the trajectory of the mobile scanner and the density of the PCD. Besides, all the geometrical distances and properties of the objects should be manually entered by the end-user. Rodríguez et al. [26] detected points of cantilevers using a range search algorithm to filter the highest set of points relative to the points on the catenary cable. However, they could not validate the method since the data set was too small, so it only contained one cantilever.

3.3 Gaps in Knowledge

Cable scene complexity including data gaps, vegetation encroachment [11], [18], and bundled cables affected the accuracy of the results of the existing OLE elements detection methods [10], [23], [26]. Majority of methods were sensitive to the size of the voxels used [23], the setting of thresholds, point density [10], [11], [14], [15], [18] and to ambient conditions such as the temperature and the ageing of spans [10]. A few studies disregarded the sagging of the cables [10], while some assumed cables as a set of small straight-line segments [13], [23] and that cables are always parallel [16]. These methods were unable to distinguish cables from other straight lines such as building roof edges, fences and tree stems [23]. Also, these methods did not perform well when reconstructing 3D models of OLE elements as the initial filtering removed some of the OLE elements points as well [13]. Finally, one of the methods used to detect cantilevers considered a very small dataset which only contains one cantilever and the method did not contain any validation process [26]. OLE elements are very thin, hence often represented with few or no points. The detection of OLE elements is a very hard problem also due to the presence of vegetation. These factors render the methods discussed for OLE elements detection ineffective. Also, the gDT generation for OLE systems in existing railways is almost missing in the literature.

4 Proposed Solution

4.1 Scope

Our method focuses on typical double-track railways that represent 70% of the existing and under construction railways in the UK [27]. Railways are a linear asset type; therefore, their geometric relations remain roughly unchanged often over very long distances. Close inspection of railway PCD validates this effect, with repeating geometrical features such as; (1) the special relations between masts, cables and the rails remain fairly unchanged along the railway [9], (2) the connections between masts and the cables are placed in regular intervals (roughly 50-70m intervals), (3) the main axis of the masts (Z-axis) is roughly perpendicular to the track direction (X-axis) (error tolerance is 11° [9]) and (4) masts are always positioned as pairs throughout the rail track.

4.2 Overview

It is often the case that there are few to no points on the OLE elements in a railways PCD due to the small

size of the cables compared to the size of the asset. This is expected and likely to occur no matter what scanning technology is used. This creates obstacles that hinder the robustness of OLE elements reconstruction. We argue that the strengths of model-driven strategies (providing fast geometrical models without visual deformations [28]) are strong in the scenarios with very low point densities meaning the model-driven methods can create the gDTs of OLE elements despite poor densities and sparseness of the PCD. Hence, our method proposed a fitting of pre-defined parametric assemblies to the point segments obtained using previously sorted mast position coordinates [8]. This proposed method is a re-iterative method throughout the track; it exploits the railway geometric relations mentioned in section 4.1 and railway topology as key factors. The workflow of the proposed method is illustrated in Figure 2.

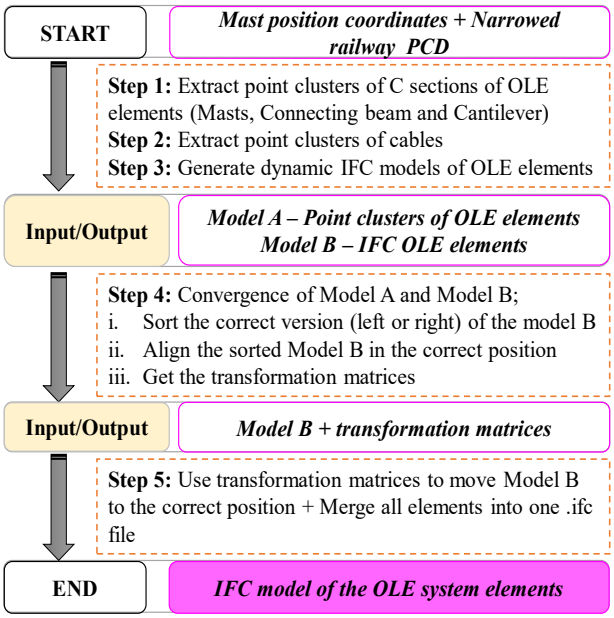

Figure 2. The workflow of the proposed method

4.3 Extract Point Clusters of OLE Elements – Model A

4.3.1 Point Clusters of Other OLE Elements – C Sections

Initially, we extract point clusters of the OLE system includes two railway masts, the connecting beam and the cantilever. This unit is hereafter known as 'C section'. We use a crop box filter to extract the point segment of the C section. The crop box filter automatically extracts all the data inside of a given box, by removing any points that lie outside the specified range along the specified field.

In our proposed method we have set three fields, which refer to intervals along the X, Y and Z directions. The limits are defined relative to the mast coordinates so that the filter extracts any points according to the given direction and the limits. Specifically, the X range is experimentally set to 1.0 m in the direction along the track length. This range has been set relative to the X coordinates of masts to include the width of the mast allowing 0.7 m of a buffer window. The Y range is the distance between two masts of the same pair, calculated using Y coordinates of the two masts and the experimentally set buffer window of 0.6 m, in the direction along the track width. The Z range is experimentally set to 9.5 m (height of the mast) in the direction along the mast. We have experimentally eliminated 0.23 m from the ground plane to remove ground points as it would suffice to extract the C section without shortening the mast. In this paper, we haven't illustrated the graphs representing calculations for these parameters due to limited space. This finally gives resulting point segments of C sections along the track.

4.3.2 Point Clusters of Cables

We use an improved RANSAC algorithm to extract point clusters of cables. The method starts by determining Bounding Boxes (BB) using mast position coordinates along the track to crop the input PCD such that the resulting pieces are relatively straight enough for any further processing. The general RANSAC could not detect cables as lines due to few or no points on the cables.

Hence, we initially up-sampled the points on cables to improve line detection. The up-sampling was done along the track direction (Figure 3) with defined intervals along either side of the actual points. The track direction is not constant along a particular direction due to the varying horizontal and vertical elevations along the track. To determine the track direction prior to up-sampling, we calculate the range between minimum and maximum of X and Y values of each BB and sort the general track direction along the X-axis if the X range > Y range and vice versa (Figure 4).

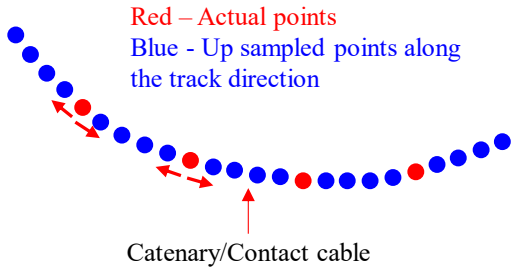

Figure 3. Upsampling along the track direction

Next, we use two pre-processing steps prior to the RANSAC algorithm to improve line detection and to reduce the computational cost.

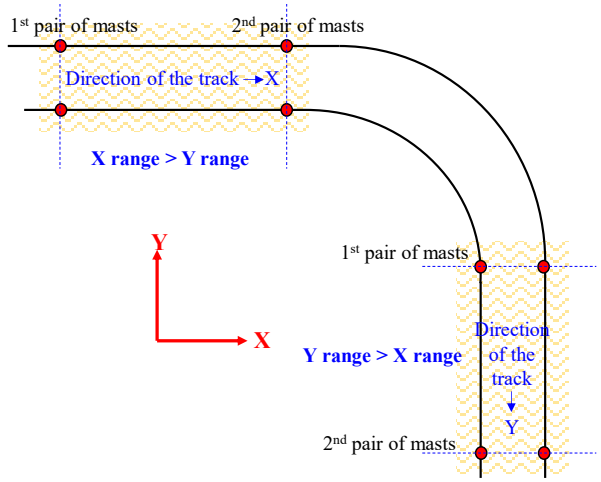

Figure 4. Determining general track direction

Firstly, we remove the ground plane to eliminate all ground points. This ensures all points on the ground are removed prior to further calculations. This significantly reduces the points for faster computational performance and reduces the number of false positives that would be caused by the lines on the ground. Secondly, we get the XY projection of the cloud. This allows projecting the catenary shapes of the catenary and auxiliary cables into straight lines so that RANSAC can detect those cables despite its curved shape. We then detect cables as lines using RANSAC and classify cables based on the heights of the lines relative to the track structure. The detected cables along with the previously extracted C sections are hereafter known as 'Model A'.

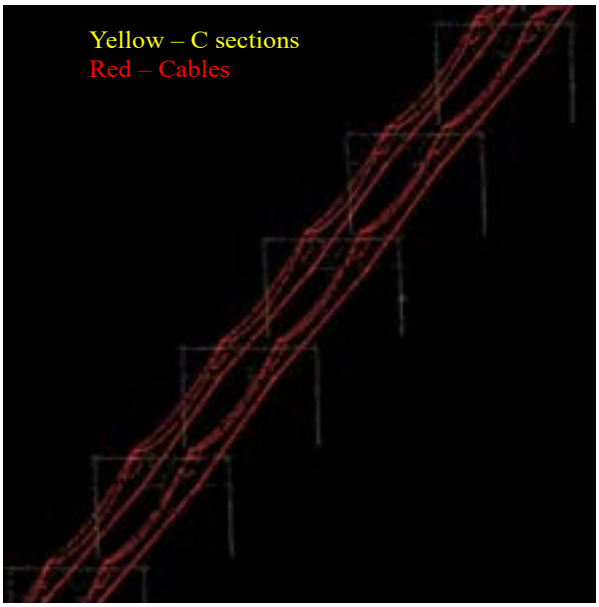

Figure 5. Point clusters of OLE elements – Model A

4.4 Generate Dynamic IFC Models of the OLE System

We design a parametric OLE system model; hereafter known as 'Model B' using standard railway electrification guidelines [9] to represent the geometry of the real OLE elements. This model preserves geometrical properties of the elements, such as angles between the different elements, relative distances compared to each element of the system. The model developed during this research is much simpler compared to the real OLE system as the model is limited only for the elements defined at the beginning of this paper. This limited number of elements simplifies the task of adjusting the model while the resulting model is still suitable to reconstruct the geometric shape of the OLE system.

The orientation of Model B constantly changes from left to right along the track due to the stagger occur in the OLE system. However, this alignment might change if the track is not perfectly straight so that we cannot assume the orientation of the model. Hence, we have created 10 variations of Model B, compatible with the left and right versions of the 5 types of the OLE configurations exist in UK railways [9]. Figure 6 illustrates only one of those configurations due to the limited space. Note that on the actual model, two of these configurations (from the same type) are connected with cables.

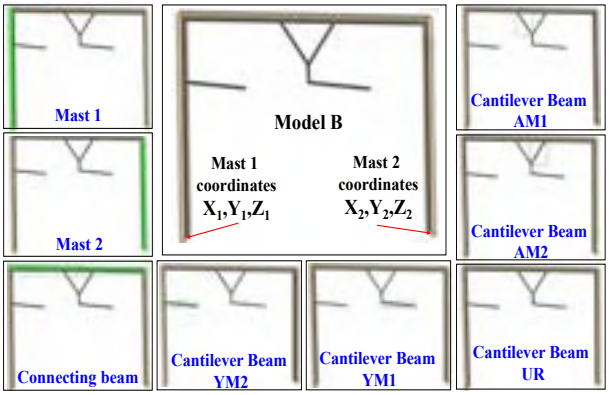

Figure 6. The left-to-right orientation of one of the OLE configurations

We define each of the OLE elements using extruded area solid definition in IFC format. We use the standard cross-sectional dimensions given on Network Rail standards [9] to define the 2D area profile for each element. The extruded area solid defined the extrusion of a 2D area; here defined as the section profile, by two attributes. One is the extruded direction, defining the direction in which the profile is to be swept. The other attribute is the distance over which the profile is to be swept. For each OLE element, we define these distances using either standard height (for masts) or length (for

every other OLE element). The extruded direction and relative angles are derived considering the position and the orientation of each element relative to mast positions.

4.5 Convergence of Model A and Model B

Iterative closest point (ICP) algorithm aims to find the transformation between a point cloud and its reference cloud, by minimizing the square errors between the corresponding entities. We use this algorithm to converge Model B to Model A. Initially, we set Model A as the reference cloud; is kept fixed while the left and right orientations of Model B are source clouds. We first convert Model B into .pcd files and then these source clouds are transformed to find the best match with the reference – Model A. The ICP iteratively revises the transformation of Model B to minimize the distance to the Model A, such as the sum of squared differences between the coordinates of the matched pairs. Hence, by using ICP we first sort the correct orientation (left or right) of OLE configuration as the correct orientation ideally has the minimum sum of squared differences between the coordinates of the target and reference clouds. Once we sorted the correct orientation, our method then converges the sorted model on to the correct position and finally gives transformation matrix which provides the corresponding translation vector and rotation matrix of the Model B (model) relative to Model A (point cluster). Finally, we moved .ifc format of the Model B to the correct position using the resulting transformation matrices of the previous step and finally merged all units (including two C sections and cables) into one file to get the final IFC model of the OLE elements.

Figure 7. The convergence of Model A and Model B

5 Experiments

5.1 Ground Truth Data and Results

We used the rail track located in-between 's-Hertogenbosch and Nijmegen in the Netherlands and specifically a piece of the railroad track that is approximately 18 km long, to test our proposed method. The size of this file was over 100 GB hence too large to process with the machines available in terms of processor and memory capacity. We address this challenge by splitting the data file into three sub PCDs as D1, D2 and D3 each length around 6 km. We also manually generated two sets of Ground Truth (GT) datasets consist of three sub-datasets each per one railway PCD;

GT A: This set is created by manually extracting point clusters of C sections and cables along the rail track. They are used to compare against the automatically detected point clusters of OLE elements.

GT B: The set is created by manually creating the OLE systems models. They are used to compare against automatically generated gDTs of OLE elements.

We implemented the solution with the Point Cloud Library (PCL) version 1.8.0 using C++ on Visual Studio 2017, in a laptop (Intel Core i7-8550U 1.8GHz CPU, 16 GB RAM, Samsung 256GB SSD).

Table 1 illustrates the results of the point cluster extraction and Figure 8 demonstrates the results of the automated gDTs compared to GT B. The detection of OLE elements needed an average of 35 seconds per km. Generation of dynamic IFC models and conversions took 16 seconds per km, while the convergence required 51 seconds per km. Finally, the transformation only took 0.2 seconds per km. Hence, the processing time of the proposed method was on average 103 seconds/km.

6 Evaluation

6.1 Evaluation of point cluster extraction

We used performance metrics; precision (Pr) and recall (R) and F1 score (F1) as; True Positive (TP) - OLE elements were correctly detected as OLE elements, False negatives (FN) - OLE elements were not detected as OLE elements and False Positives (FP) - other objects were detected as OLE elements, to measure the performance step 1 and 2. The average detection accuracy for C sections was 98.1% F1 score and for cables 93.2% F1 score (Table 1).

6.2 Evaluation of the OLE system gDTs

We used cloud-to-cloud (C2C) distance evaluation to detect changes between GT B and the automated ones. Initially we converted the GT B and the automated gDTs into .pcd files. Then we computed the Root Mean Square Error (RMSE) between each unit of automated gDT of OLE elements (consists of two C sections and cables) and corresponding GT B model (Figure 8). The average model distance between the two for all 18 km was 3.82 cm RMSE.

Table 1. Performance metrics for OLE elements point cluster extraction

	Performance metrics for C section extraction						Performance metrics for cables extraction					
Dataset	TP	FP	FN	Pr	R	F1	TP	FP	FN	Pr	R	F1
D1	104	0	2	100%	98.1%	99.0%	101	1	4	99.0%	96.2%	97.6%
D2	86	0	4	100%	95.6%	97.7%	77	8	12	90.6%	86.5%	88.5%
D3	90	0	5	100%	94.7%	97.3%	84	3	10	96.6%	89.4%	92.8%
Average				*100%*	*96.2%*	*98.1%*				*95.6%*	*91%*	*93.2%*

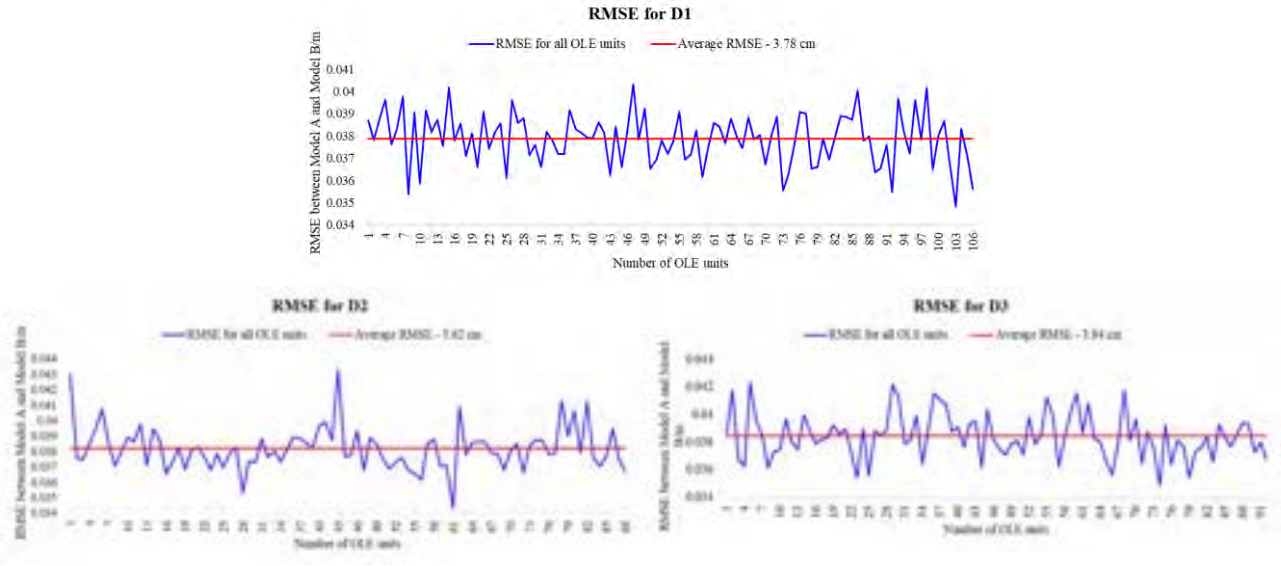

Figure 8. RMSE values for three datasets D1, D2 and D3

method that exploits the highly regulated and standardised nature of railways to generate gDTs of OLE elements for existing railways from PCD. Compared to existing methods, the proposed method is more consistent, less liable to human errors. The method was tested on an 18 km railway point cloud and achieves overall detection rates of 98.1% (F1 score) and 93.2% (F1 score) for point cluster detection of C sections and cables respectively. The accuracy of the automated gDTs of OLE elements was evaluated by minimising the mean Euclidean distance between the ground truth model and the automated one. The average RMSE of the model for all 18 km equals to 3.82 cm.

Abstract –

Logistics management plays an essential role in supporting the primary activities in manufacturing industries. Similarly, in the construction industry, logistics operations are a crucial part that directly influence the construction operations. Construction operations management requires various stakeholders to collaborate through effective communication and prompt information sharing. However, logistics management in construction is often challenged by insufficient information management, lack of formalized information standards and poor information interoperability among heterogeneous systems. Semantic Web technologies advance information management support and improve information interoperability. In this research, we present a domain-level ontology as a common information reference for standardizing and integrating construction logistics information, and finally to improve the efficiency and transparency of logistics information management. The proposed ontology provides information interoperability between logistics management and construction workflow management. The ontology was evaluated by automatic consistency checking and answering the competency questions (CQs) via SPARQL queries. Furthermore, we used actual schedule and material delivery data of a construction project to evaluate the proposed ontology to see if it could support the material kitting logistics practice. We provide a valid ontology that is able support the logistics information management for the construction. The research is limited to providing a single example application of the ontology. Future research should focus on extending the ontology for different specific solutions to yield standardized information management for construction operations.

Keywords –

Information; Construction logistics; Ontology; Construction operations

1 Introduction

Construction industry differs from the other industries because of the temporary project-specific organizations and strong interdependencies between the firms, materials and construction activities [1]. Fragmented construction supply chain makes it difficult to control the construction operations. Logistics practices support these operations and improve construction projects in terms of cost, schedule and planning [2]. Recently, logistics operations in the construction industry have been gaining importance. Logistics solutions are an important element for successful completion of the projects [3] and logistics specialists can improve on-site logistics to a large extent [4]. Due to the benefits of logistics in construction projects, companies are motivated to develop their own logistics processes [5].

During construction projects, significant amount of information is exchanged among the project partners. Construction logistics depend on detailed data and decisions about operations on-site and material needs [6]. Successful delivery of the materials is an important condition that affects the workflow and performance of the projects [7]. To achieve that, coordination is needed between the material supply chain and on-site operational decisions [6]. The logistics information should properly collaborate with the corresponding construction workflow to coordinate the logistics process to perform the operations. Because forecasting material deliveries is directly related to construction schedules, change in the material delivery impacts the execution of schedules [8]. Thus, accurate and timely information flow is required to manage the construction logistics activities efficiently [9].

Construction logistics can be considered complex due to the multiple stakeholders and fragmented tasks that are involved in the process [10]. Therefore, effective information exchange for communication and coordination among different stakeholders are vital for improving the management of the construction logistics process. This requires advanced information

formalization and interoperability among the stakeholders and various information systems.

However, there is no adequate information management standard that could formalize the information from the construction logistics process. A gap exists for linking the on-site construction operation information with the supporting logistics process. In the information management domain, ontology tries to provide a definite classification of entities [11]. In terms of information systems, Semantic Web technology supports representing, obtaining and utilizing knowledge [12]. This research is based on the hypothesis that the advancements in Semantic Web technology can help alleviate the information bottleneck in construction logistics. Determining the information requirements for logistics operations is significant to develop logistics practices. Mapping construction logistics with ontology would bring opportunities for interoperating logistics information with digitized situational awareness systems to improve construction workflow management.

In this research, we present an ontology as a common information reference for linking the material logistics information with the construction workflow. We describe a possible conceptual map design for the logistics and product data flow in construction. Moreover, we extend the ontology to a domain specific level presenting kitting logistics practice information. Kitting is one of the recently developed industrialized JIT-based logistics practices in which requirements for information management are obvious. In the following, we present background for construction logistics, kitting practice and ontology. Then, we describe our methodology and present our findings based on the proposed ontology. Lastly, we provide discussion and conclusion.

2 Background

This research combines two research streams: 1) Material logistics in construction; and 2) Semantic Web, ontology and their applications in the construction and logistics domains. In kitting logistics practice, the information requirements are evident and straightforward. Hence, combining these two research streams: developing an ontology for kitting practice could result in an application where all the information requirements are ready to be utilized in any construction project.

2.1 Material logistics in construction

Logistics practitioners face integration problems regarding the material and logistics information in their operations. In the construction industry, only about 40% of deliveries are fulfilled with the correct amount, time, location and information [13]. However, most of these activities are still managed by humans. Materials could be purchased too late causing delays or too early and getting damaged in poor storage conditions on-site [4]. Delivering materials to the site without a timely notice causes extra material handling and labour cost [14]. Proper logistics management requires complete and accurate information regarding the materials and delivery that is communicated between the project parties.

Construction logistics is an inherent part of construction projects [15]. It impacts important aspects of construction projects such as cost, completion time and plan accuracy [2]. A great deal of energy is spent on coordinating fragmented operations, procuring the required goods and other resources, coordinating materials and resources on the construction site [16]. Problems associated with such mistakes could be prevented via proper logistics management [7].

2.1.1 Kitting as an information-intensive logistic practice

Kitting is a logistics solution that was originally used in the manufacturing industry. It represents delivering the products or components organized, packed and as one package [17]. Figure 1 illustrates the kitting process; the materials that are delivered to the logistics center from the material suppliers are kitted and delivered to the work locations. It has been proposed that the practice could be used in the construction industry as well [18][19]. Recently, Tetik et al. [20] conducted research on the applicability and impacts of using kitting in the construction industry. Construction workers spent around 20% of their time moving materials and equipment to the installation location [21]. Thus, the workers on-site spend less time searching for or moving the materials when the materials are delivered to the assembly location as pre-sorted kits.

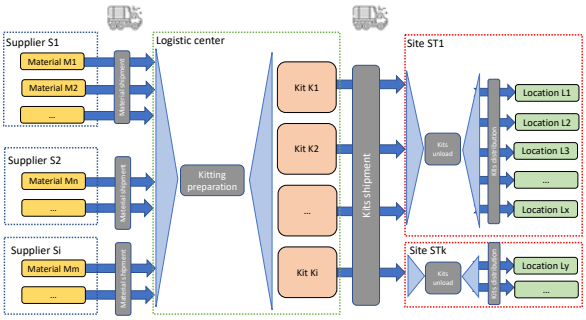

Figure 1. Kitting process

Kitting logistics practice is usually utilized with logistics centers and Just-in-time (JIT) delivery. Information required for kitting practice should be available to properly apply this solution. Currently, it requires manual efforts to collect and integrate this information during the planning phase of the projects.

Used together with logistics center and JIT delivery, improvements on waste and cost reductions as well as

increase in production rates are possible with kitting practice [21][22]. Kitting logistics practice required a smooth information flow between operations [23]. Said and El-Rayes [6] proposed an automated construction logistics optimization system to minimize the logistics costs and integrate the project and supplier data. It could be integrated with kitting practice to ensure material and spatial requirements. Logistics centers can be configured to track materials via using information systems [8]. These advancements create potential for automation. Potential of kitting logistics practice in the construction industry motivates mapping this solution on ontology to generate future opportunities in terms of standardizing the information flow and improving efficiency.

Based on available literature on kitting in the manufacturing industry, information requirements for kitting are number of kits [24], information about the parts [25], item numbers and quantities as well as assembly location [26]. Based on the information we obtained for the use case from a renovation project, we determined that the information relevant to the kitting practice includes material type, quantity, unit, supplier, kitting date, delivery date, kit (name/number), task and location that the kit will be used. This information needs to be explicitly available to apply the kitting solution.

2.2 Ontology and its applications in AEC industry

Ontology originates from the philosophy domain and is recently widely adopted in the domains of computer science and engineering. Gruber [27] defined ontology as "an explicit formal specification of a conceptualization". In other words, ontology is a formal conceptualization of domain knowledge that formally defines the concepts (classes), properties and the interrelationships between the concepts, which thus could share common understanding of the structure of information and domain knowledge [28][29].

In the Architectural, Engineering, and Construction (AEC) domain, numerous efforts of ontology development have been made to solve the problems of data integration [30], knowledge management [31][32], and information utilization [30][33]. Construction is known as an information-intensive industry. The benefit of the ontology-based approach is that construction information can be stored and reused under a systematic information management framework. Moreover, with the machine-readable representation, ontology is able to make the information and knowledge accessible to both humans and computers for further computer-aided construction management tools [34].

Meanwhile, in terms of the logistics and supply-chain domain, ontologies have also been considered a solution for managing the logistics knowledge and information. Daniele and Pires [35] suggested ontologies are able to improve the enterprise interoperability in the logistics domain. A logistics ontology was developed by Lian et al. [36]to semantically represent the logistics situation. Hendi et al. [37] introduced a logistics ontology as a core of logistics optimization framework to support the logistics management. Although these ontologies efforts provided conceptualization of the general logistics process, they are insufficient to specifically expand to the construction domain.

Developing an ontology for construction logistics could improve the information management by accurately specifying the information needs for materials and on-site as well as logistics center activities required to successfully perform the construction tasks. However, currently there are no ontologies that specifically represent the construction logistics process information, nor ontological works that create the links between construction and logistics ontologies. Thus, an ontology is developed for construction logistics in this study.

3 Methodology

Our chosen methodology is design science. Design science identifies a real-world problem and proposes and evaluates a solution to this problem [38]. Thus, we use design science to develop a solution to represent logistics practices in the construction industry with ontology to solve the practitioners' problems regarding logistics information integration.

Development of the proposed ontology requires its design to be described and desirably implemented. The scope of this paper does not include a real-life case implementation. However, we provide validation of the ontology and evaluate the ontology based on a real-life construction project's schedule and material information. Multiple data resources were used to develop and validate the ontology. We used document analysis and public materials to form an example use case. We used a planned project schedule from a company to realize the use case. We obtained the schedule and material list per kits of a renovation project. We used required material and kit information to answer the competency questions. The ontology was validated using competency questions and automatic consistency checking.

3.1 Ontology development approach

To develop such ontology, an ontology development approach is established initially. The ontology development approach in this research is a hybrid approach that draws mainly on METHONTOLOGY [39] and the approach by Grüninger and Fox [40]. The major steps of the ontology development approach are shown in the following Figure 2.

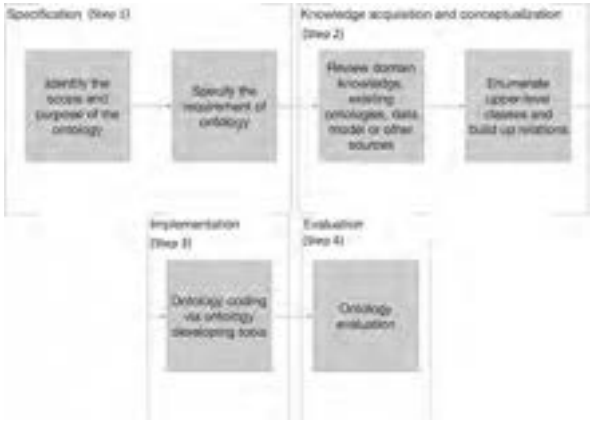

Figure 2. Ontology development process

3.1.1 Specification

The first step of the ontology development process is specification, which aims to first specify the scope and the purpose of the ontology by answering the following specification questions [39]:

What is the purpose? The purpose of the developed ontology is to formalize and structure the logistics information and simultaneously coordinate with the construction process information to improve the information exchange of the construction logistics operation.

What is the scope? The ontology is focusing on the construction logistics process and information flow of the material delivering. Meanwhile, the ontology is designed to be a higher-level ontology that only contains the higher-level concepts and relations of the construction logistics process.

Based on the scope and purpose, the requirement of the ontology can be identified with a list of competency questions. The competency questions (CQs) are a more detailed specification of the ontology requirements [40], that can be used to formalize the ontological model, concepts, hierarchy and relations. In this research, a workshop, consisting of participants from 17 Finnish AEC firms, was organized to define the CQs in compliance with the content of information that is required by all the stakeholders involved in the construction logistics (Table 1). The workshop showed that a material batch is an essential unit of analysis in logistics operations.

Table 1 A list of Competency Questions for the ontology

1.	What is the content of the material batch?
2.	When the material batch should be delivered?
3.	What is the status of the material batch? (packaged, shipped, received, used)
4.	Was the material batch delivered as planned?
5.	What is the corresponding activity of the material batch?
6.	What is the location of the corresponding activity of the material batch?
7.	Who is the responsible worker or firm of the corresponding activity of the material batch?
8.	What is the location of the material batch on site?

These questions were also used for further ontology evaluation to check if the ontology covered the desired content and if it can represent the domain knowledge.

3.1.2 Knowledge acquisition and conceptualization

After defining the ontology requirements specification, the second step of the ontology development process is to determine what domain knowledge for the ontology should be acquired and how it should be represented [39]. In this phase, relevant domain knowledge of the construction process and logistics process were reviewed. This is followed by the conceptualization process that all relevant terms of the concepts, class hierarchy, class properties including their range and domain in the ontology are defined to construct the ontological model.

3.1.3 Implementation

In terms of further implementation and application, the ontology should be implemented with a machine-readable format. This comprises the third step of the ontology development process (see Fig.2). In this research, the ontology was coded using Semantic Web Ontology Language (OWL) by using the Protégé environment. OWL is a computational ontology language that is designed for ontology development, which is a W3C recommended ontology language [41].

3.1.4 Ontology evaluation

Ontology evaluation aims to check whether developed ontology is satisfied with the specifications, fulfils its intended purpose and meets all the requirements, which consists of verification and validation [34]. In this research, the ontology evaluation consisted of automated consistency checking (verification), answering the competency questions based on a practical case example (validation). In the following sections, we present our results, namely the proposed ontology and its evaluation.

4 Findings: construction logistics ontology

In this section, the Digital Construction Logistics Ontology (DCL-Onto) that is developed based on the previously discussed approach is presented in detail as a

ontology can be applied to specific logistics solutions. We have provided a use case example to illustrate the application of the ontology in a project setting. The research was limited to not having a real project application of the ontology. Since there was not a logistics system in use to our knowledge that operates with a full kitting logistics information model, it was not possible to obtain enough data to test the ontology from a real project. Future work should focus on implementing the developed ontology in real-life applications. Moreover, for future research, an ontology-based solution needs to be developed taking advantage of computing technologies to support the logistics management practices.

Abstract –

In recent years, the use of intelligent construction equipment with sensors attached to construction heavy equipment used in civil engineering earth work has become commonplace. Sensors provide a variety of information on construction equipment, and this information is used to control the cutting edge of construction equipment called machine control and machine guidance. On the other hand, it is also possible to use the information obtained from the sensors in a wide range of applications to manage the construction progress at civil engineering sites. In this study, a network-based cloud system for soil volume progress management in the actual construction site was verified.

Keywords –

Intelligent Construction Equipment; Network system; As-built data; Construction Progress Management

1 Introduction

In civil engineering earth work sites, it is common to control the progress of construction in terms of soil quantity, volume. This is because construction volume is usually contracted by each material volume, and therefore the site manager daily wants to know the volume as soon as possible during construction. However, it is difficult to realize a means of accurately measuring the daily progress volume, for example, in the case of an excavation site, the construction volume is generally estimated from the average load capacity of the dump trucks used to haul the excavated soil and the number of hauls of dump trucks to be taken out of the construction site. In other words, there is no general method for accurately ascertaining the construction volume. Then, the purpose of this study is to obtain the daily progress volume by using the bucket cutting edge history information calculated based on the information from sensors attached to heavy equipment, and to make the progress of the construction work visible so that the site manager can easily understand the situation on the site.

2 System Configuration

The system used in this study was the X-53x Excavator machine guidance system of Topcon Corporation [1]. The system consists of the following, and the configuration of the system is shown in Figure 1.

(a)Tilt sensor 4pcs.
(b)Display
(c)Controller
(d)GNSS, Global Network Satellite System, antenna 2pcs.
(e)Communication routers to connect to the server
(f)Cloud Server of Data collection and management system, Sitelink3D [2]

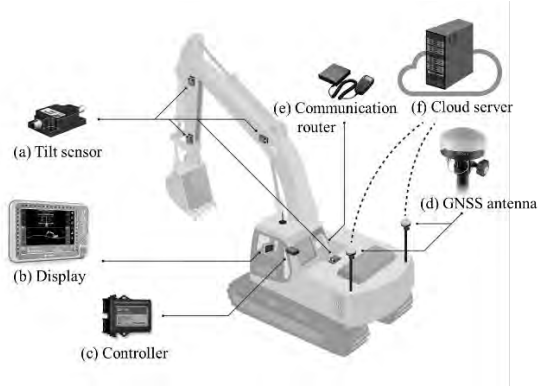

Figure 1. The configuration of the system

3 Construction Site

The construction site of this study was a civil engineering project to excavate and remove sediment

from the dam's lake bottom during the winter in order to increase the dam's water storage capacity, this was ordered by Nagano Prefecture and the contractor was Kinoshita Construction Co. Ltd. and the excavation work took 51 days. The planed excavation volume was 53,000 m^3 and the area was 24,000 m^2, and work was carried out by the three-layer bench-cut method. In terms of soil quality, it was mainly sandy soil that was easy to excavate, although some boulders appeared during the last phase of the work. A picture of the construction site is shown in Figure 2.

Figure 2. Construction site photo

4 System principle

The Excavator machine guidance system uses the angle information detected by angle sensors attached to the Boom, Arm, Bucket and Body of the Excavator and the coordinate information detected by the two Global Navigation Satellite System (GNSS) antennas, respectively, to measure in real time the coordinates of the Bucket cutting edge of the Excavator, generally the coordinates at the center, Pc(Xc,Yc,Zc) or the coordinates at right and left ends points Pr(Xr,Yr,Zr) and Pl(Xl,Yl,Zl) of the bucket. The coordinates measurement points are shown in Figure 3. The system displays the difference in height between the measured data and the design data in the z-coordinate (elevation) by comparing it with the three-dimensional design data entered into the system beforehand. The Excavator operator can see the difference between the cutting edge and the design surface, and the system is used for guidance in construction. The display image is shown in Figure 4.

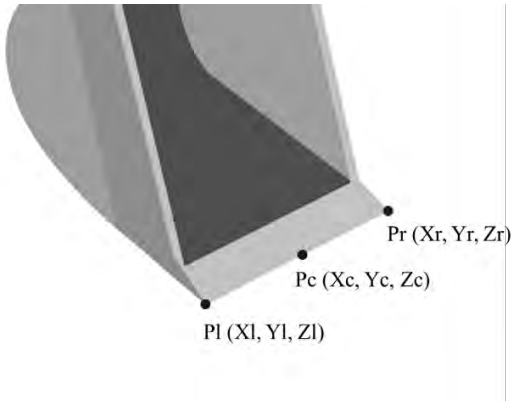

Figure 3. The coordinate measurement points of bucket cutting edge

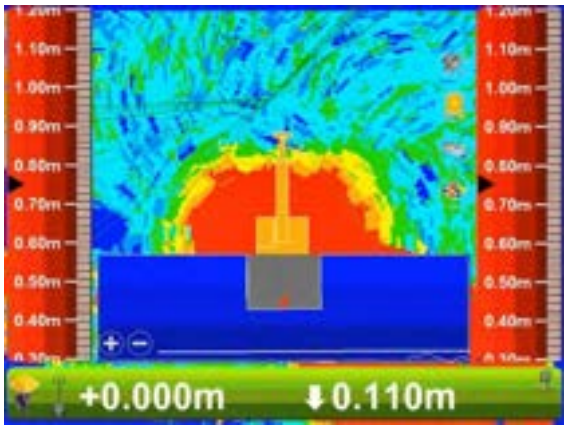

Figure 4. Display image

By using the cloud data collection and management system, Sitelink3D system, in this study, the coordinate data of the bucket cutting edge are transmitted through the mobile phone line in real time and stored on the server. The bucket cutting edge data stored on the server is automatically processed on the server and can be output as gridded mesh data. This data enables us to grasp the 3D shape of the construction site. It is also possible to calculate the daily construction volume, the excavation volume, by calculating the daily differences in the 3D geometry processed on the server. The Sitelink3D system can output grid mesh data and construction volumes as daily reports, allowing the site manager to visually grasp the day's construction results on a daily basis.

5 System Accuracy Verification

The purpose of this study was to verify the accuracy of the system in order to numerically verify the output construction volume. In terms of hardware accuracy, the errors of each sensor contribute to the system accuracy. In this study, the RTK, Real Time Kinematic, method was adopted as a method of GNSS, coordinate

measurement. RTK is one of the most accurate surveying methods for surveying moving objects in real time, with a 2-3 cm error in coordinating detection. In this study, a multi-GNSS type antenna was used to improve the stability of the detection of GNSS satellites, which can detect Japan's Quasi-Zenith Satellite System (QZSS), satellite. On the other hand, since the angle detection error of the angle sensor cannot be directly converted to the coordinate measurement error, the accuracy of the machine guidance system is generally discussed in terms of the total system error including the GNSS coordinate measurement error. It was confirmed that the system was calibrated prior to the start of construction, and that the coordinate measurement error was within ±5 cm as specified in the Accuracy Verification Test Procedure of the Ministry of Land, Infrastructure and Transport [3].

Next, I describe the error of gridding to represent the 3D shape of the construction site. The grid data consist of the Z-coordinates extracted when gridded with X and Y coordinates of a certain interval on the plane through which the line of the bucket cutting edge passes. Figure 5 shows an image of the grid data.

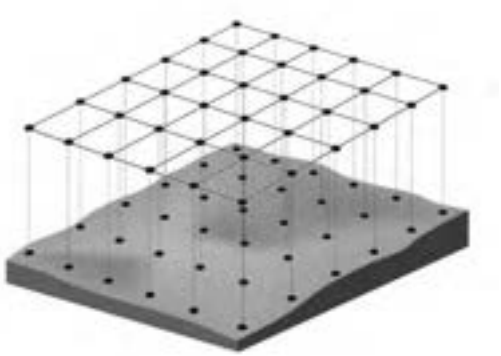

Figure 5. Image of Grid data

In this study, grids were created at 20 cm intervals in the X and Y directions. The grid data are different from the actual 3D shape because it is a polygon shape. The line of the bucket cutting edge is a straight line, so there is no error in the gridding process. On the other hand, it can be understood geometrically that the error in the direction of bucket rotation is small if the bucket moves in a flat plane, but the error is large if the bucket moves steeply. Here, I discuss the error when only the bucket is in rotational motion as a typical movement. The bucket used has a length of 1.5 m, so the rotational motion draws the shape of an arc of 1.5 m radius. On the other hand, the grid is represented by the z-coordinate, which is the arc divided by 20 cm. Figure 6 illustrates the difference.

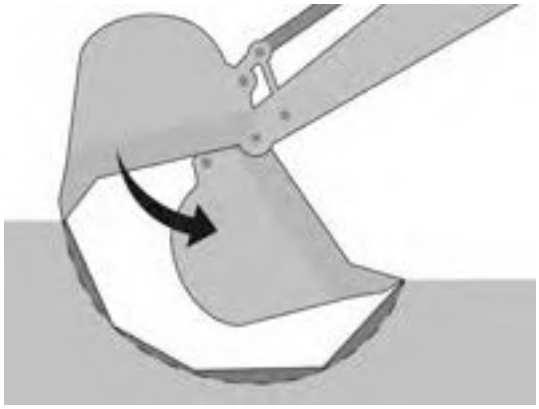

Figure 6. Image of gridding errors

The calculated volume error is the difference between the total area of the arc area and the area to be clipped by the grid data. For a turning radius of 1.5 m, this difference is calculated to be about 2%. The error of the volume by gridding process is assumed to be a typical value of 2%.

On the other hand, if we assume that the volume error is at most 5 cm larger than the error in the z-direction after the calibration adjustment, the volume error will contribute to that error in the depth direction. The volume of soil excavated at this site is 53,000m^3 and the area is 24,000m^2, and the average depth of excavation is 2.2m. The contribution of the system's error of 5 cm in the z-direction to the volume was calculated to be 0.05m / 2.2m = approx. 2%. Based on the above, we can estimate that the error in the overall volume calculation results due to gridding and system errors in this study is up to about 4%.

6 Obtained Data

The data obtained from the daily construction history of the Bucket cutting edge are grid data processed by 20 cm on the server. On the other hand, before the start of construction, the 3D point cloud data of the entire construction site is acquired by the UAV laser surveying, and the TIN, Triangulated Irregular Network, data, which represents the 3D shape of the construction area converted from the point cloud data, are acquired. The pre-construction TIN data are uploaded to the cloud server, and since this study is an excavation site, the current construction site shape can always be virtually formed on the server by updating the 3D shape data when the elevation of the bucket cutting edge of excavator passes lower than the pre-construction TIN shape.

7 Soil Weight Measurement System

In this study, in addition to the machine guidance

Excavator, a soil weighting system was introduced at the same time. The LOADEX100[4] of Topcon Corporation, which directly measures the weight of the soil held by the bucket by using hydraulic data obtained from the hydraulic sensor of the Excavator. This measurement data are sent to Akasakatec Inc's cloud-based soil management system, VasMap[5], which manages the weight of the soil per truck and the daily transport of the soil. The purpose of introducing LOADEX100 is to be able to accurately measure the amount of soil held by the bucket, which was not known before, and to be able to manage the exact weight of each dump truck loaded with soil. The acquired data are recorded digitally on a cloud server, allowing to know directly the daily hauling weight. In the past, the only way for dump trucks to avoid violating the Road Traffic Law by overloading was to load less than the truck's load capacity by considering the margin, but this system will allow for maximum efficiency in loading. As a result, the cost is reduced by enabling more efficient vehicle dispatch compared to the conventional method, contributing to increased productivity. In this study, the soil weight calculated from LOADEX100 was measured daily; however, since construction history data are measured in volume, the daily moisture content of the soil was measured and the soil weight was converted to volume as a reference for progress of volume measurement.

8 Data Reference

Three methods were used as references for the data to be obtained in this study. One is the periodic surveying with UAV laser scanner by a surveyor every two weeks and, in which the final shape is measured by a ground-based laser scanner. The survey results were used to evaluate the 3D grid data. Another one was to evaluate the volume calculated from the aforementioned weight measurements system, and the last one is volume calculations based on the conventional method by dump truck operation times.

9 Visualization

9.1 As-built Shape

The 3D as-built shape obtained from the grid data is shown in Figure 7. This figure shows the overall shape of the construction site, which allows the site manager to grasp the 3D shape of the site using information obtained from the cloud without actually going to the site. In addition, by comparing with the design data, it is possible to easily identify the un-constructed areas and the volume of un-constructed work.

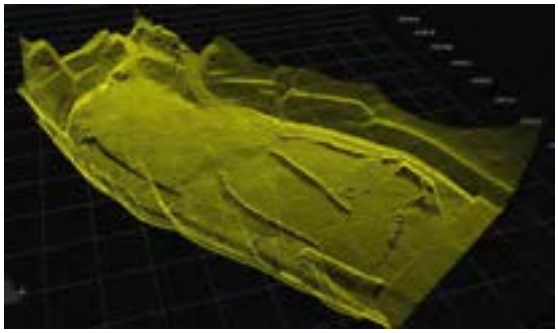

Figure 7. A sample of 3D as-built shape

9.2 Cut Volume

An example of a volume report output from the cloud data collection and management system Sitelink3D is shown in Figure 8.

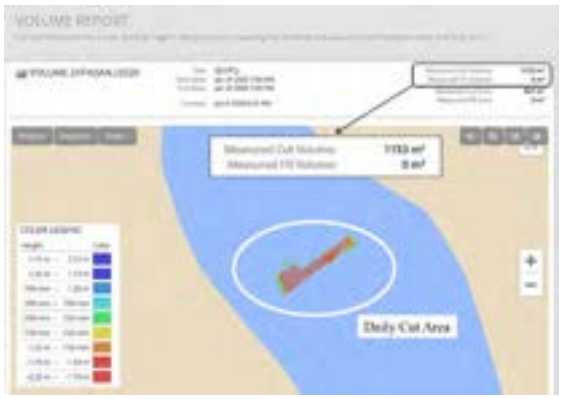

Figure 8. A sample of volume report output

In this report, the cutting depth of excavation in the area is shown in color as a daily report. In addition, the volume of cut volume for the day is displayed in quantity. By simply looking at this report, the site manager can get an idea of the cutting area and cut volume for the day.

The cumulative data obtained from this cut volume report is shown in Figure 9. The graph in the figure shows the cut volume based on bucket cutting edge history and laser 3D surveying, a soil volume measurement system, and the conventional method based on the number of dump truck hauls as a reference, all at the same time. This graph shows that the cumulative total based on the bucket cutting edge history data is not much different from the three references mentioned above. Finally, for the actual construction volume of 55,000 m^3 calculated from the laser survey, on the other hand, the calculated volume obtained from the bucket cutting edge history was 55,640 m^3, which is an actual difference of about 1.2%.

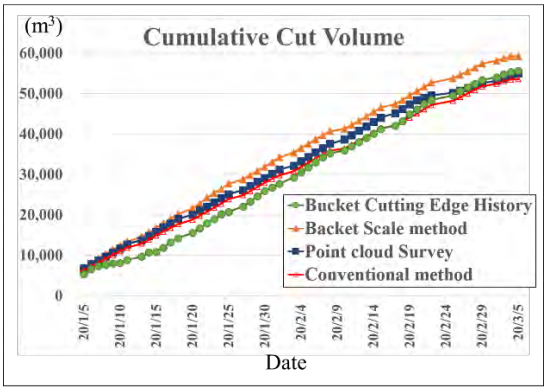

Figure 9. The cumulative cut volume data

10 Consideration

By conducting this study, we found the following. The accuracy of calculated volume of obtained from the historical data of the bucket cutting edge is approximately 1.2% of the total quantity of construction on site, this is consistent with the assumed system error mentioned above. However, if we focus on the daily construction volume, the volume cannot be accurately calculated when the history of the bucket cutting edge does not represent the construction shape due to the appearance of megaliths during the construction process, or when the excavated soil is temporarily placed in the field. Therefore, we feel that it is necessary to evaluate it in terms of numbers over a certain period of time. It has also been reported that accurate volume cannot be calculated even when the bucket edge is pierced into the ground at an acute angle without excavation due to accidental mishandling [6].

11 Conclusion

The historical data of the bucket cutting edge of the machine guidance excavator was used to visualize its construction progress. The volume quantities obtained from the historical data were accurate enough to track the daily construction progress. As a result, daily surveying work, for example, which was originally done as an additional work, can be greatly reduced by using the construction history data. From a productivity standpoint, not only does it reduce the workload of field agents at civil engineering sites, but it can also be used as a tool to more accurately assess the situation.

Incentivizing High-Quality Data Sets in Construction Using Blockchain: A Feasibility Study in the Swiss Industry

Jens J. Hunhevicz[a], Tobias Schraner[a] and Daniel M. Hall[a]

[a]Department of Civil, Environmental & Geomatic Engineering, ETH Zurich, Switzerland

Abstract –

Data sets are often incomplete and low-quality at the end of a construction project. This creates rework or hinders opportunities to use data during future activities of the facility lifecycle (e.g. facility management, renovation, demolition). This research prototypes and evaluates a novel process to use blockchain and smart contracts in construction projects to incentivize high quality data sets. The proposed solution is defined in collaboration with construction professionals. The process traces and saves project data while incentivizing participants to create high-quality data sets through reward tokens. To validate the process, an Ethereum-based blockchain prototype is developed. A simple case study is conducted in collaboration with local industry professionals to simulate how the prototype can function in a typical design bid build process used in Switzerland. The early findings and possible subsequent research steps are presented. Overall, it was found that such a blockchain based incentive systems has the potential to not only incentivize high-quality data sets, but also change the way of tendering and related construction processes.

Blockchain; Incentives; Data Management; Construction Projects

1 Introduction

As digitalization in the construction industry increases adoption of building information modeling (BIM) and other digital tools, there are new opportunities to better optimize and manage the operations, maintenance, and deconstruction over a facility lifecycle. The oft-mentioned goal is to create a real time digital twin of the asset.

However, usually digital data sets at the conclusion of construction projects are of low-quality. There can be many reasons for this, such as poor documentation in the first place, difficulties to find the data, or low reliability of the information [1]. When not done properly, the operations team must reconstruct a vast amount of the "as-built" or "as-is" BIM at great time and expense.

To avoid this, construction project teams should seek to handover complete, high-quality data sets at the end of the project. The data gathering should take place from as early on in the project as possible [2]. This challenge is not only technological but also process related [3]; it is important to also consider personal and organizational incentives to provide the data in the first place [4].

Blockchain is seen as a technology to improve transparency and collaboration in construction [5]. Blockchain can track transactions over time and store them in a trustworthy, distributed manner. It enables the building of trust between transacting parties and devices. Blockchain also offers the potential to decrease transaction time and reduce costs associated with intermediaries [6]. Most blockchains can execute *smart contracts,* which are code protocols running on top of a blockchain. On more sophisticated platforms like Ethereum [7], touring complete smart contracts can be used to automate workflows through predefined functions (often conditional if… then... statements), as well as to create so-called *tokens* to represent different kinds of transferable value. Since these tokens represent value, incentive systems can be designed to influence the human behavior when interacting with the created blockchain based process.

In the broader blockchain research space, there is much interest in this topic of crypto-economic systems design – i.e. creating a blockchain-based incentive system among multiple parties to align them towards a higher level goal [8]. For example, Zavalokina et al. [9] investigate a blockchain reward system for maintaining high-quality records for used cars in Switzerland. However, in reviews of proposed use cases for blockchain in the construction context, cryptoeconomic systems design is less often mentioned than other potential use-cases [10]. Only two studies have proposed use-cases where a token is used to incentivize multidisciplinary design teams [11,12]. Having said that, crypto-economic incentive systems could be a novel opportunity to tackle existing challenges of integrating technology and processes in the fragmented construction

industry [13].

This paper introduces a use case of crypto-economic system design to incentivize complete, high-quality data sets at the handover of construction projects. The novel solution proposes smart contracts and tokens to create a trustworthy track-record of data drops, to automate information flow activities, and to incentivize participants in the construction process to share high quality data sets.

2 Methodology

The systems design was conducted in collaboration with construction industry professionals. Research began with a preliminary feasibility study in collaboration with the blockchain workgroup of the buildingSMART chapter Switzerland. The group consisted of construction professionals with diverse backgrounds such as owner, architect, BIM manager, engineer, supplier, contractor, and facility manager. Over the course of one year, the group of industry professionals and researchers held monthly workshops to discuss various aspects of implementing blockchain in the proposed use case.

First, the group discussed the information flow and information categories needed to create a complete data set (chapter 3.1). At the same time, the group defined a use case demonstration (chapter 3.2) and construction process (chapter 3.3) to simplify and focus the investigations. The prototype consists of a basic house represented by a simple BIM model. The home should be procured and constructed using the design bid build (DBB) construction process that is typical in Switzerland.

After the process and data flow for the use case was defined, a first blockchain implementation was prototyped with Ethereum smart contracts (chapter 3.4). Finally, the potential incentive system for high quality data was described (chapter 3.5).

To validate the design, the workgroup participants were then asked in a subsequent workshop about their opinion of the solution (chapter 4). The early results are discussed regarding limitations, opportunities and future research areas for implementation of such a system (chapter 5).

3 Use Case

3.1 Information Flow

To design the subsequent blockchain prototype to incentivize complete data sets, there needs to be an understanding of the information that is typically shared and relevant for later use phases. In the mentioned workshops, potential information categories and relevant data fields were identified. Furthermore, expectations regarding high quality data sets in the scope of this use case were discussed.

3.1.1 Information Categories

Two information categories were identified throughout the workshop: technical and commercial information. Technical information was defined as data important for the subsequent use phase and later recycling of the elements. Commercial information is defined as data relevant and needed during the actual construction process and to control the process for data capturing.

Technical Information

For technical information, various efforts categorize important information for facility management. The data structure for the prototype was based in part on the data fields of the Construction Operation Building Information Exchange (COBie) [14]. COBie is an information exchange specification that defines a consistent structure about a projects facilities, spaces, floors, systems, installed equipment, and related documentation. It was developed especially for asset data without geometric information, which make it very convenient for the later blockchain prototype. Even though COBie represents a first step in the direction of addressing life cycle data challenges related to facility management, it still faces many challenges [2,3].

Commercial Information

For commercial information, the project workflow and the project participants provide the backbone of the process. During the workshops and prototype implementation, commercial data about the project was vital to design the blockchain system. Without this information, the smart contracts would not know from whom and when to request and reward data drops.

The commercial information required was identified during the workshops. Most of the commercial information comes from the tendering process. This also includes the associated prices and quantities of the items in question and the information about the bidding contractors such as insurances and declarations. In addition, information about the project's progression as well as deadlines or contractual information is important. This includes the documentation of decisions, the confirmations for tendering, and the final selection of tendered offers.

3.1.2 High Quality Data Sets

The workshops identified three attributes necessary for high quality data sets: completeness, correctness, and structure. *Completeness* is necessary to ensure that all information is stored. However, completeness should be balanced with complexity. A focus on the important data reduces cost and complexity in the process, since typical

buildings or infrastructure exists for many years. This is especially true for expensive systems such as blockchains. As little data as possible to create a complete date set should be saved. *Correctness* is important in order to draw the right conclusions from the information. Incorrect information can lead to subsequent mistakes and/or costly reconstruction of data. *Structure* is crucial to organize data for later use. Without a standard structure (naming, file type, database) the retrieval and processing will be challenging. The challenge is to fulfill these three attributes as best as possible through the blockchain based workflow and incentive system.

3.2 Use Case Demonstrator

To investigate the described use case in a realistic context, a simple house demonstrator is created using openBIM. The demonstrator has four elements: a door, wall, floor, and pump (Figure 1). These four elements represent the typical diversity of building components (e.g. make-in-place products, semi-finished products, and finished products). The demonstrator acted as a base to investigate the construction processes and related data to build these.

Figure 1. Demonstrator with four elements: floor, wall, door, and pump.

3.3 Construction Process

To start the investigation, a typical design bid build (DBB) process for Switzerland was analyzed for the use case demonstrator together with the buildingSMART Switzerland focus group, resulting in the process diagram pictured in Figure 2. The DBB process was chosen since it is still the most commonly used project delivery model in Switzerland. Furthermore, it simplified the communication with the construction experts, because they were all familiar with it.

Because the process scope should be as focused as possible, some simplifications were made. First, only four stakeholders were considered: the owner, planner, contractor, and supplier. In reality, many more stakeholders exist, including numerous sub-contractors. However, the most important interactions and tasks can be demonstrated with these four stakeholders. Second, some of the contractor tasks are compressed to keep the process diagram as short as possible.

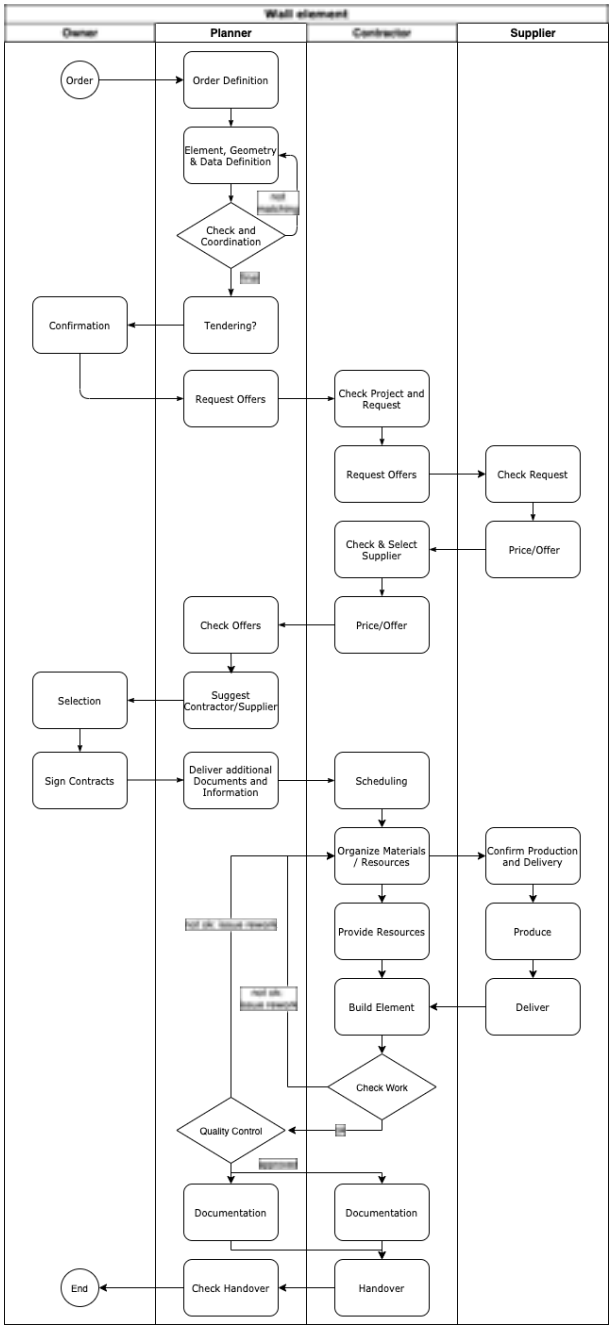

Figure 2. Process diagram of the construction process for the wall element of the demonstrator.

3.4 Prototype

A preliminary blockchain prototype was developed in order to test the feasibility of such a system. The focus was only on the first part of the construction process (see Figure 2): the project phase of element definition and tendering until the contract is signed (Figure 3). Furthermore, the supplier was not considered in the prototype; it is assumed the functions of the supplier

would be similar to the ones of the contractor. The prototype was developed for the Ethereum blockchain. Ethereum was the first blockchain that introduced touring-complete smart contracts [7]. These smart contracts can encode logic that will be executed when the according functions are called. Furthermore, they can hold and save data on the blockchain. The feature of smart contracts is essential for the proposed use case. Although there are many other blockchains that support smart contracts nowadays, Ethereum is still the biggest network with vast documentation available. It should be noted that there is no claim that Ethereum is the only blockchain framework for this use case. The proposed logic could be implemented on any other system that supports smart contracts.

3.4.1 Smart Contract Logic for Workflow

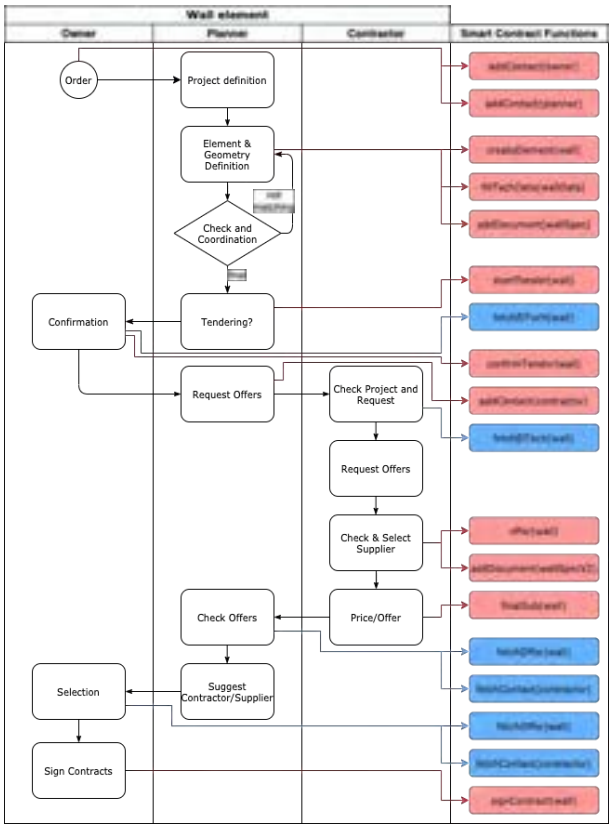

Figure 3. Workflow for the built prototype with smart contract functions. Red: write functions; Blue: view-functions to retrieve information.

The workflow pictured in Figure 3 was realized by coding the related functions for each necessary transaction into a smart contract. To write and test the smart contract in the Ethereum-specific language Solidity (https://solidity.readthedocs.io), the brower-based open-source tool Remix (https://remix.ethereum.org/) was used. Remix allows for fast writing and testing of the smart contract functions through an integrated JavaScript compiler that simulates the Ethereum virtual machine environment.

The smart contract includes different functions. Through so-called "state variables" the process order is defined. The variable is changed if a project step is completed. This is a very restrictive approach, because the next phase can only be started when the previous step has been completed. Each construction element contains these state variables, and the smart contract only allows to execute the associated functions. For example, if an element is in the state *ReleasedForTender*, only then can the owner confirm by calling the function *confirm()*, which would put the element into the subsequent state *Confirmed*. The function *offer()* would for example fail, since this is not the next workflow step. Furthermore, the smart contract logic ensures that functions can only be called by the correct parties. Each party has their own network address to identify itself. With the associated private key (similar to a password) the stakeholders can identify themselves and sign transactions, e.g. the execution of a specific function.

3.4.2 Data Structure

The data structure for the prototype has been defined based on the identified categories in chapter 3.1.1. The storage type *struct* was used in Solidity to store the information. A *struct* for both the technical information and commercial information was defined, which means it defines the data fields that need to be filled in during the work flow. If multiple entries are expected for one field, arrays are used. The *struct* is then applied to each element or product in the construction project. This was found to be the best suited solution because the BIM-based tender process is based upon each individual BIM element.

Different functions take care of filling the information related to the various data drops in the process. This is displayed in Figure 4. For example, the function *confirm()* only alters the state variable through the contractor signing that function. In contrast, the function *createElement()* called by the designer takes all the design parameters as input and stores them in the respective struct entries. The different data drops can be defined including who will need to do the data drop by calling the respective function and when this function can be called. The different view functions allow to retrieve and validate the information.

Finally, a *struct* for contact information was defined (Figure 4). This allows to save additional information about the stakeholder next to their Ethereum address. With only the public address-string (e.g. 0x25213E8E0964a98A017Ebbf36c633eFd006fe2ce), it is hard to see in reasonable time who belongs to which address.

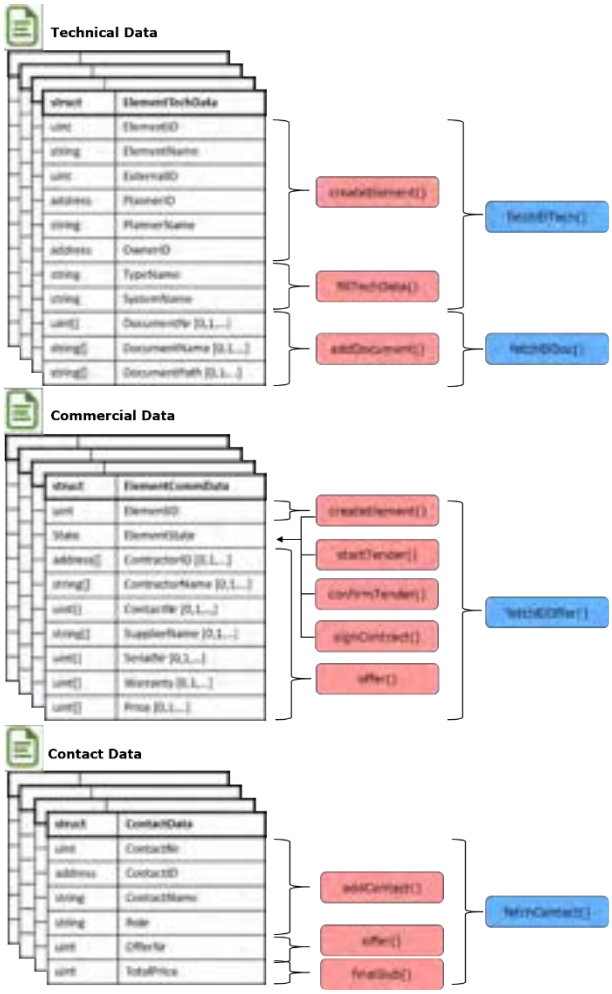

Figure 4. The data *struct*'s used in the prototype: technical, commercial, and contact. The functions modify the respective elements when called.

3.5 Possible Incentive Structure

The implemented prototype allows to build a blockchain-based incentive system along the introduced work flow. Tokens can be issued, transferred or burned together with the introduced blockchain function (see Figure 3). As briefly explained in the introduction, blockchain-based tokens represent value containers that could be used for currency, reputation, securities, or other value types [15,16]. Tokens are also coded through smart contracts. In the case of Ethereum, the most used token-types are called ERC20 (fungible) and ERC721 (non-fungible). Depending on the use case, both tokens types could be useful.

Figure 5 presents a schematic view on a possible structure. The idea is to incentivize data suppliers to only write high-quality data. This mainly applies to the correctness of data. To some extent, the smart contracts already take care on the structure and completeness aspect, since they force the actors to input the data as specified in the workflow rules and defined data fields. However, the quality of that data could be still low. As a solution, an additional role in the process of a data verifier can check the data transactions and confirm the quality. For now it is not further defined who will take on this role, but in general every capable stakeholder could do this. If the data quality is good, the data supplier receives some kind of reward token.

The challenge is then to design the right incentive system out of countless possible combinations. For this construction case, the authors imagine either financial rewards (tokens for micropayments or a stake in the project) or a reputation system (tokens represent reputation). Also a combination of both and/or multi token system is possible. Different solutions are part of the ongoing research. They should then be carefully tested to exclude possibilities of cheating or negative side effects. It is important that all actors in the system are incentivized in the intended way. Next to the considered construction participants, this also applies to the role of the data verifiers.

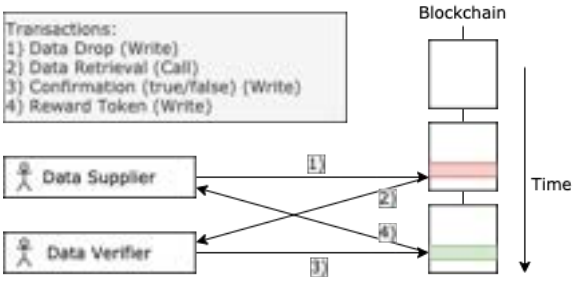

Figure 5. Schematic representation of the imagined incentive system to achieve high quality data sets.

4 Participant Assessment

The prototype implementation and ideas on how to incentivize high quality data sets through tokenization were presented to the buildingSMART workgroup. A first brainstorming session took place for each of the stakeholder's role in the system and potential benefits and drawbacks associated to it. The insights will be used in future research to iteratively improve the incentive system design. The following presents some preliminary insights and feedback from the participants.

All participants agreed that the blockchain based process can add value to today's working practice. The strict nature of smart contracts and the transparency of the process could already mitigate many of today's challenges regarding data structure and information completeness. Furthermore, the participants saw the blockchain-based incentive system as promising to

incentivize correct content (either through financial or reputational rewards), but also to potentially create a self-sustaining infrastructure. The construction professionals wondered who would pay for such a system, either in terms of transaction fees (in public blockchain network) or the overhead for the infrastructure and maintenance (private blockchain network) (see Hunhevicz and Hall [10] for more information on different blockchain network types). While in the first case the fees could be covered by each individual party (similar to post stamps for official sharing of documentation nowadays), the second case would need to be financed out of the system (e.g. through participation fees) or by the stakeholders. An independent funding source not related to one project stakeholder would support the adoption of such a system also across projects. The system should ideally be opt-in and attract the users through the associated benefits. The participants agreed that this would be the better option than forced participation through powerful parties, e.g. the owner. However, the exact design of the system – including both the incentive for high-quality data and the financing of the system – was seen as not straightforward and a major future challenge for adoption.

Overall, the participants perceive the system in two different ways. Some see the system as a project-specific implementation. Others considered it a market-wide system. This is surprising because the research initially targeted a data management system for a construction project. However, a market-wide integration would affect the tendering process and ultimately lead to a market protocol on which competitive offers for construction projects can be automatically managed in a transparent way. This could be done based on the reputation system where reputation can be derived from past data saved on the blockchain. Market-wide consequences of incentive systems might need to be considered in future research.

Furthermore, the need for privacy of sensitive information becomes apparent (especially from the viewpoint of suppliers and contractors). This creates potential issues with data visibility and privacy on public blockchain systems.

The owner was considered to be the stakeholder to benefit most from such a solution. Potential benefits include the higher data quality for the operation, more transparency for data and process analysis, fewer disputes, simplified contract signing (transaction signatures), more competition in tendering leading to better prices, price transparency, and subjective selection criteria for choice of contractor (in case of a reputation system).

Finally, it was challenging to identify if the perceived advantages by the workgroup stem really from the blockchain-based (incentive) system, or the more structured documentation process in general. There is need for future work to identify what can be achieved with conventional data structures and technologies, but better data management – and what can be achieved only with a fully-implemented cryptoeconomic system design for complete data sets.

5 Discussion

Since blockchain-based incentive systems for construction projects is a new concept, there is potential and challenges alike. The following sections discuss the limitations in this paper and point to future research work for improvement.

5.1.1 Use Case

The considered use case focuses on the DBB construction process in Switzerland with only a very limited amount of stakeholders. This should be extended and generalized for future implementation.

Also, a better differentiation between construction elements should be considered. Typical unfinished products and elements that need to be completed on site involve more stakeholders. In contrast, finished and prefabricated products could be ordered directly from the supplier. All these different possibilities would need to be captured. The process was conceptually developed for all four elements of the demonstrator, but it turned out that the project steps are largely identical for the different elements. They might differ though in the amount of needed suppliers to provide the products. For a use case of supply chain traceability, this would be important. But for the investigated use case of incentivizing data sets, the amount of suppliers is conceptually not further relevant to showcase the functionality. Having said that, this could change for scalability of the solution later on.

Finally, the implemented information flow, data categories, and high-quality data attributes are based on the workshop discussions. There should be more investigation on each aspect on the state of the art. Therefore, the chosen structure (based on COBie in the technical case) should be seen as a starting point to identify important information attributes, not as a final recommendation. Furthermore, the data categories might need to be extended. One example could be a definition of the required material information to track and implement a circular economy for building elements.

5.1.2 Blockchain Prototype

The main point of the prototype was to investigate if and how such a system could be implemented with the available tools. The implemented logic and functions will need to be refined.

In the future, investigations should target how to create the user interfaces (e.g. web based front end application) to conveniently interact with the system. Also, the smart contracts would need to be optimized to

better capture ownership properties, optimize gas consumption (i.e. cost for computation on-chain) to save on costs, allow for updatability of the contract, and comply with the latest coding best practice for security reasons.

All the data is currently saved on-chain, which is known to be very expensive and potentially creates issues with storage size down the road. A future solution could store part of the data off-chain with notarization on the blockchain. While this would allow to check whether data is changed, data would still need to be fetched off-chain. This complicates the use of smart contracts and is sometimes referred to as the "oracle-problem."

A public permissionless system (Ethereum) is used because the system is intended to exist thoughout the long life cycle of the facility. The Ethereum network incentives contributors to maintain it independently of who uses the network. This avoids efforts required to run a private network server infrastructure over such long time durations. However, there are many possible DLT design options available [10]. A more detailed investigation on the best suitable system should be part of future research. This should be also aligned with current construction and BIM software.

Finally, there are still challenges related to privacy protection of on-chain data (especially in public blockchains) and how to deal in general with the very strict nature of smart contracts in the context of processes that require some flexibility.

5.1.3 Incentive System

This paper introduces an initial incentive system concept. While the imagined incentive mechanism seems promising to motivate stakeholders to provide correct data drops, there is need for future research to study different and specific incentive systems for the introduced purpose based on financial, reputation, or other possible tokenized reward structures. As a starting point, a better understanding of each stakeholder's position and motivation in the system is important. It is also possible that there needs to be specific roles associated with the incentive system, e.g. the mentioned data verifiers. More investigation is needed on how to properly reward stakeholders for their work.

6 Conclusion

The paper proposes an innovative way to incentivize high-quality data sets in construction through blockchain based process management linked to reward systems. It makes use of blockchain to combine technological aspects of data management with personal and organizational aspects to share data in the first place.

The prototype demonstrates how such a solution can be built, as well as technical challenges that still remain. The most important include scalability, on-chain data storage, privacy of sensitive data in public systems, and the coding of smart contracts to remain somewhat adaptable to different construction processes.

The main area of future research is related to the design of possible incentive systems. Many combinations exists that should be assessed and validated. Furthermore, implications to the construction process and markets should be investigated. There could be consequences of beyond one construction project on general market forces and project delivery practices.

Also, the proposed system would benefit from a more detailed analysis on the effect of different parts of the proposed blockchain implementation on high-quality data sets. A blockchain based process without any tokenized incentive system might already benefit the structure and completeness aspects of data sets with data transparency and automation through smart contracts. Having said that, this alone might be also achievable through conventional IT solutions. The need for blockchain in this case should be carefully assessed.

The proposed incentive system has the potential to improve data correctness and completeness at the conclusion of a construction project. The use of such tokenized incentive systems would be a strong argument to use blockchain as a technological tool, since its real strength applies to (semi/automatic) value transactions in an environment with low trust.

Overall, blockchain-based incentive systems show promise to align construction stakeholders. This study intended to showcase this with a concrete example on how blockchain and smart contracts can enable a trustworthy track-record of data drops, automation of information flow related activities, as well as a token-based incentive for participants in the construction process to share high quality data sets.

Acknowledgment

The authors would like to thank the construction professionals of the blockchain group in the buildingSMART chapter Switzerland for their valuable insights and support during the workshops; special thanks for their efforts are given to Enrico Cristini, Erik de Ruiter, Tobias Jörn, Arthur Loosen, Daniel Schwarz, and Thorsten Strathaus.

Abstract –

As the world witnesses the fourth industrial revolution, construction remains a newcomer that lags in its adoption of technological innovations. The information-intensive nature of the construction industry, coupled with its multidisciplinary nature, has pushed construction to enter the era of Big Data and has provided fertile ground for research on Big Data. Numerous efforts have been undertaken to investigate the use of Big Data and its impact on construction. This paper builds on the existing body of knowledge and explores the implementation of Big Data throughout the different phases of a construction project. By synthesizing the extant research corpus, this empirical study provides insights into the current state-of-adoption of Big Data throughout the lifecycle of a construction project, its sources, capabilities, and benefits. The findings of this paper are combined into a Big Data Framework that summarizes the "what, how, where, and why" of Big Data implementation in the construction industry.

Keywords –

Big Data; Adoption Framework; Construction Industry; Project Lifecycle; Benefits; Use-Cases.

1 Introduction and Background

Industries worldwide are currently in the midst of the fourth wave of technological advancement, known as Industry 4.0. This wave of advancement is a collection of various technologies that promote innovation in industries through the convergence of humans, technology, and information [1]. The construction industry is not an exception to the pervasive digital revolution. The industry deals with sheer volumes of data arising from different disciplines throughout the different phases of a project.

Despite the information-intensive nature of the construction industry, it remains slower than other industries in harnessing the power of data [2]. Researchers have identified various barriers that prevent construction from fully exploiting information and communication technologies (ICT) and harvesting construction data. Example of barriers include the highly fragmented nature of the industry, the temporary nature of projects, the uniqueness and complexity of construction projects, the inadequate coordination and collaboration between stakeholders, the lack of ICT knowledge and skills, the lack of standardization, the challenge to change organizational culture, and the unclear return on investments [3].

The above-mentioned barriers pose a multi-dimensional challenge that can be tackled from different aspects. One aspect that this paper explores is ICT. Research in the industry showed that data captured through ICT can be used to address crucial issues associated with cost, planning, risk management, safety, progress monitoring, and quality control [4]. This collected data is the major source of Big Data, which, compared to small data sets or sampling, can help to draw a fuller, more trustworthy picture in all areas of construction [4].

Big Data in construction can be defined by five different attributes: volume, variety velocity, value, and veracity (5V's). The interdisciplinary nature of the construction industry produces large, heterogeneous, and dynamic construction data, which mirrors the volume, variety, and velocity attributes of Big Data [5]. Moreover, primary sources of Big Data in construction generate data in large volumes, numerous formats – including images and AutoCAD and Revit enabled files, and in near real time [6]. As for value and veracity, these two attributes are conveyed through the ability to extract information from construction's Big Data and detect and analyze patterns and trends [7].

Primary sources of Big Data in construction include 1) people who are continuously generating and sharing information, 2) IT-enabled construction equipment that gather, share and store data, and 3) internal Information Technology (IT) systems such as Building Information Modeling (BIM), planning and procurement software [8].

The vast accumulation of data from these sources, especially from BIM, has been studied by numerous

researchers. BIM serves as a starting platform to adopt Big Data approaches. [9] stated that Big Data is essential in "bridging BIM and building" (BBB), where technologies such as radio-frequency identification (RFID), cameras, Geographic Information System (GIS), global positioning system (GPS), and Augmented Reality (AR) capture real-time information from real-life physical project processes and synchronize it with BIM to track construction and generate as-built models. The authors developed a BBB conceptual framework that uses data beyond the construction phase of a project and generates architectures of real RFID-enabled BIM systems for prefabricated housing productions. In another study conducted by [10], BIM was extended to "dynamic BIM", an innovative approach which stores information from the early phases of the project through facility management, with a cloud-based system framework to effectively retrieve required information for various applications by Big Data analysis based on parallel processing of large data sets.

This integration of BIM and Big Data was classified by [11] as an example of a technological factor that drives Big Data adoption in the construction industry. Another example of a technological factor considered by the same study is the advantage of information derived from Big Data analysis such as decision making, planning, and simulations. The study also noted two other factors that drive the adoption of Big Data: organizational factors which reflect Big Data's ability to improve design and execution efficiencies and project management capabilities, and environmental factors which represent the availability of construction related technology that can collect, store, analyze and visualize Big Data [11] . Moreover, data that is being collected and stored by construction stakeholders can be analyzed to continuously assess and improve stakeholders' management maturity by generating new types of holistic and adaptive maturity models [12]. For example, social network analysis (SNA) and text mining techniques can be used to recognize patterns of communication within the organization and among project stakeholders, and evaluate the extent to which documents reflect project management processes [12].

In addition to the aforementioned drivers, Big Data presents new opportunities for construction firms to innovate and improve current construction processes [13]. Big data can empower project progress monitoring and optimize resources allocation by providing new ways to simplify the detection of performance deviations and give stakeholders more time for corrective actions on ongoing projects. This capability can be also extended to future projects by allowing stakeholders to build their knowledge to thoroughly understand the adopted practices [13].

To examine the status of Big Data research in construction, [6] performed an extensive study that analyzed Big Data research in construction and mapped out its orientation. The authors found that Big Data studies mostly focused on utilizing Big Data on construction projects to monitor progress and performance, enhance time and cost management, and inform better decisions. The authors also noted that other studies focused on site safety and worker safety behavior, energy management of buildings, decision-making framework design, and resource management and tracking during construction [6].

This paper builds on the existing body of knowledge and synthesizes previous research efforts into a framework that holistically summarizes the implementation of Big Data in the construction industry. To achieve the research objective, the study starts by first identifying applications of Big Data throughout the lifecycle of a construction project – from conceptual planning to demolition. Next, ten major benefits of adopting Big Data in the construction industry are extracted and discussed. Finally, a holistic framework that summarizes the "what, how, where, and why" of Big Data implementation in the construction industry is proposed.

2 Big Data Applications throughout the Construction Project Lifecycle

Numerous research efforts were reviewed and examined to extract potential applications of Big Data throughout the lifecycle of the construction project. The project phases used in this paper are those discussed by [14] who divided the project lifecycle into seven phases: concept planning, design, pre-construction, construction, commissioning, operation and maintenance, and demolition.

Throughout the review of the extant literature, the authors noted that some project phases were discussed interchangeably, namely conceptual planning and design, and construction and commissioning. Thus, this research grouped the seven phases into five stages, discussed below, to accommodate the Big Data literature.

2.1 Stage 1: Conceptual Planning & Design

A project lifecycle begins with conceptualizing the project and developing the design. During this stage, geospatial, a type of Big Data , can provide planners and designers with important information about the project location, infrastructure, public spaces and resources [8], [15]. [16] added that Big Data can also offer insights from previous projects about future residents, their behavior, and preferences, thus facilitating stakeholders' understanding of end-users' needs by and designing the project for optimization.

[17] discussed that Big Data can be integrated with BIM and online social networks to select sustainable energy solutions capable of optimizing the project performance. This can enhance project design and is particularly valuable for green buildings. Simulations can also be generated with Big Data to evaluate various design alternatives for space and efficiency, creating a new approach for producing innovative designs [16].

Another application of Big Data in the project early phases is found in the bidding process of traditional projects. Tender price evaluation is one of the central challenges that owners face during bidding. While owners collect project cost data from all bids, this information is generally not used after a bid is awarded. To take advantage of historic data, project cost data need to be stored in the cloud. Then, Big data algorithms can be designed and generated to mine the stored data and allow the evaluation of tender prices in real-time [18]. Stakeholders can also use Big Data to estimate their profit. [19] indicated that the company or industry benchmarks currently used to estimate profit are not accurate as they do not reflect project-specific variations. The authors argued that the architecture Big Data makes it possible to quickly examine large amounts of project data, identify underlying trends, and understand the dependence between profit margins and project attributes.

2.2 Stage 2: Pre-Construction Planning

The second stage is pre-construction planning, which includes planning the construction phase of the project. The effectiveness of this stage relies on the proper use of all available knowledge needed to develop an execution plan [20]. Big Data collected from similar historic projects can be analyzed and used to ensure the robustness of the project plan by reducing uncertainty and allowing more accurate forecasts, projections, and planning [20]. Pattern analysis, simulations, and trend analysis are three approaches that are frequently used to analyze data during pre-construction planning and aim to assess implications of current issues and decisions, detect early warnings and threats that can impact project performance, consider consequences of design assumptions, and simulate future scenarios [20].

Another application of Big Data in this stage focuses on predicting the behavior of stakeholders and analyzing the reliability of their commitments, their level of collaboration, and readiness to share knowledge [20].

Moreover, historic and new data collected during this stage can be used to simulate different construction activities and tasks, and thus, improving project performance. These simulations become very critical when automating activities or tasks, as the effect of automation on safety, productivity, and parallel-occurring tasks need to be carefully analyzed [13].

2.3 Stage 3: Construction & Commissioning

The third stage discussed in this paper includes the construction and commissioning phases of a project. Most Big Data applications in this stage are used in capturing real time or near-real time data to track project progress and create as-built 3D models [9]. [21] reviewed different applications that use computer visual techniques for monitoring and analyzing activities performed on construction sites. These visual techniques are found to have the ability to analyze static images, time lapse photos and visual streams. [22] proposed an application that uses 4D plan BIM and 3D as-built point clouds models to track construction progress. The point clouds were generated from site photologs using structure-from-motion techniques.

Real time data can also be gathered using as built-in smartphone sensors to collect equipment-related data. The status of an equipment, i.e. off, idle, or busy, and the type of work performed, i.e. dumping or scoping, can be analyzed to assist construction personnel to better utilize the equipment, inform better decisions, and ultimately, have better control of the project [23]. Moreover, [24] indicated that setting laser scanners and video cameras on blind spots across the construction site allows the collection of new data that can be beneficial to equipment operators, by providing them with 3D workspace data, automatic object recognition, and rapid 3D surface modeling in near real time.

In addition to sensors, applications of IT are also being embedded into construction machinery. An example of such applications include machine-to-machine (M2M) [25]. M2M can be used on construction machines to recommend overhauls for construction end users on site at the optimum timing. This data can also help manufacturers better understand and transform their business models, thus creating enhanced machinery.

[26] explored a Big Data application for real time construction quality monitoring application to provide timely collection and analysis of data from ongoing activities. The application is a real time construction quality monitoring method for storehouse surfaces of reinforced cement concrete (RCC) damps using GPS, global navigation satellite business techniques, sensor technology, and network transmission technology.

[27] proposed an enterprise integrated data platform (EIDP) to overcome challenges such as poor interoperability of data and inaccurate manual entries between the business management and the project management, showcasing the value of Big Data for construction companies.

Applications of Big Data have been also explored for earthwork processes. [28] combined photogrammetry and video analysis for measuring the exact machinery productivity and determine site-specific performance factors. Photogrammetry was used to determine the

volume of excavated soil, while video analysis was used to generate statistics such as loading and idle times.

Big data can also be used for human resources and labor. For example, [29] used Big Data to analyze worker behaviors in a metro construction in China. The study formed a behavioral risk knowledge base by combining vital unsafe behavior in multiple dimensions with the work breakdown structure of the construction. Then, the knowledge base, with the assistance of mobile applications and surveillance cameras, was used to detect unsafe behavior, analyze the factors affecting this behavior by Job Hazard Analysis (JHA), and match it with the predefined unsafe behaviors using Vector Space Model (VSM). All this information was also stored in a Big Data cloud platform and sorted by a Hadoop Distributed File System (HDFS).

2.4 Stage 4: Operation & Maintenance

The fourth stage includes the operation and maintenance phase of a project lifecycle. With properly installed technologies like RFIDs and sensors, facility managers can obtain the exact location and details of different building components to simplify monitoring, inspection and maintenance [9]. Beyond that, using BIM models and Internet of Things (IoT), Big Data can be generated for buildings to provide geometric and semantic information as well as state of building elements, all of which can be used to represent buildings within a virtual GIS environment for city monitoring and management applications [30].

Big Data that includes building information, in particular energy efficiency, has become one of the main concerns for a sustainable society. Despite the existence of current challenges – like analyzing accumulated data in a short time – Big Data analysis can be the solution for understanding energy consumption behavior and improving energy efficiency in the construction sector [31]. A successful example includes the analysis of energy consumption, environmental measures, and occupancy information using Big Data Analytics techniques to study building performance and visualize it on a building performance comparison application [32], [33]. This application was designed to handle large volumes of data with a user interface platform to change the options of the desired analysis. [34] reviewed sustainable construction management strategies that use quantitative Big Data approaches to monitor, diagnose, and retrofit the dynamic energy performance of buildings in use.

2.5 Stage 5: Demolition

The last stage of a project is demolition. Big Data gathered from construction waste management indicators, especially in the demolition of a project, can assist in managing the disposal of the deconstructed materials and reduce the waste generation of the contractor [4]. Examples of performance indicators include waste generation rates, costs associated with waste collection, storage, transportation and recycling, and revenues and savings from selling waste [35]. This data can also be beneficial for the public, where the government can use Big Data to manage construction wastes, and monitor air and noise pollution from construction activity [36].

3 Benefits of Big Data

Big data has a wide range of applications throughout the project lifecycle, as highlighted in the previous section. Various research efforts have also discussed the benefits that Big Data can offer to the construction industry. These potential benefits are discussed below and are summarized in Table 1:

- Enable data driven simulations and solutions for different on-site construction activities to optimize construction site layout and resource allocation [16], [17], [37]
- Enable the delivery of the right information such as project location, surrounding environment including traffic and parks, and infrastructure overview [15], [18]
- Enable the monitoring and assessment of various facility performance areas, specifically energy, and thus empowering facility managers to perform their work more efficiently [7], [30], [32]–[34], [38], [39]
- Enhance decision-making by accessing and analyzing previously collected data and identifying trends and patterns [3], [4], [7], [37]
- Enhance the flow of information between project stakeholders and across project phases. For example, this can be achieved with the applications that track real time or near-real time construction status and update as-built models for downstream players [7], [12], [37], [40]
- Facilitate collaboration and communication between stakeholders, which is of great importance, especially at the early stages of the project to align stakeholders' interests. Increase collaboration and communication ensure that all stakeholders have a clear understanding of the scope of work and expected outcomes [17], [20], [25], [37], [41]
- Improve project control including the location and status of labor, equipment, material and tools [21], [23]–[25], [28], [29], [42]
- Improve the accuracy of forecasting and promote better predictability, specifically during pre-construction planning where construction tasks can be simulated before execution to identify and remove barriers and constraints [7], [13], [17]–[20],

[36], [37], [43]
- Optimize project environmental performance, particularly waste management, during construction and demolition [4], [36], [44]
- Support electronic information management systems to centralize information throughout the project lifecycle [41], [45]

Table 1. Benefits of utilizing Big Data in Construction

Code	Benefits
B1	Enable data-driven simulations
B2	Enable the delivery of the right information
B3	Enable the monitoring and assessment of facility performance
B4	Enhance decision-making
B5	Enhance information flow
B6	Facilitate collaboration and communication between stakeholders
B7	Improve project control
B8	Improve the accuracy of forecasting and predictability
B9	Optimize environmental performance
B10	Support electronic information management systems

4 Big Data Framework

The culminating effort of this research is a holistic framework that provides an overview of the implementation of Big Data in the construction industry. Such technology frameworks can guide the adoption of technology in different construction firms and companies, develop implementation roadmaps, and revolutionize the construction industry to warrant project success [46]–[49]. The framework, illustrated in Figure 2, consists of four layers. At the core, the 5V's are outlined, representing the prerequisites of *what* is considered Big Data. The second layer discusses *how* Big Data is enabled. Data needs to be first properly collected from multiple sources including sensors, surveillance cameras, Radio-Frequency Identification (RFID) tags, laser scanners, Geographic Information Systems (GIS), operating documents, Global Positioning Systems (GPS), and BIM models, to name a few. Data can be collected throughout the project lifecycle when designing, planning, performing risk analysis, forecasting, among other activities. Next, Big Data engineering transpires where the captured data is processed and stored for current and future usage. Then, collected data is harnessed using different analytics forms such as data mining, statistics, and machine learning [5]. The third layer of the holist framework illustrates *where* Big Data is used and encompasses the seven phases of the project lifecycle introduced earlier in the paper. The size and color of the circles representing the phases is proportional to the frequent mention of the phase in the literature review. It can be shown from Figure 2 that Big Data applications in Construction, Commissioning, and Operation and Maintenance (i.e. stages 3 and 4) are frequently explored in the current body of knowledge. Finally, the fourth layer of the framework captures the reasons *why* Big Data should be implemented in construction and presents the 10 benefits identified in this study.

To illustrate how the framework can be utilized, a case study conducted by [9] about the use of Big Data to produce prefabricated housing is discussed. During the design stage, teams use BIM to completely design the project and extract the components that should be constructed and purchased. The BIM model can also show locations of auto-ID technologies to turn components into Smart Construction Objects that can communicate with each other and the end users. Another technology that was frequently used is RFID models and tags. RFID tags can carry information about the production of the prefabricated components and their status (such as: manufacturing, in-storage, delivery or received). Production of the prefabricated components can work in parallel with the "as-planned" schedule and the updated BIM model. Once the components reach the construction site, they are assembled and installed which is also reflected in the BIM model allowing the project team to track the progress of the work and develop the as-built model. This model will be transferred to both the commissioning and operation and maintenance stage, or facility management, which can help them easily identify one component form the other, monitor their performance, and simplify repair work. This data is also useful during the final stage, demolition, where the RFID tags used earlier in the project can show the location, design, and status of every component, allowing stakeholders to better plan for demolition and manage the generated waste. The use of Big Data throughout the different phases of the project leads to all the ten benefits discussed in Table 1.

Figure 1. Big Data Holistic Framework

5 Conclusions, Limitations and Further Studies

The adoption of Big Data is integral to the construction industry. This paper performed a thorough and comprehensive review of Big Data adoption in construction. This review was summarized in a framework that shows the "what, how, where, and why" of the Big Data implementation in the construction industry. As revealed in the framework, the existing research corpus shows that the proper adoption of Big Data is possible throughout the entire lifecycle of a construction project. By using the right sources to gather Big Data, the proper engineering practices to process and store this data, and the appropriate analytics to explore it, the construction industry can achieve major benefits.

The proper implementation can revolutionize the industry, promoting high-fidelity collaboration among construction players, enabling stakeholder-driven analysis, enhancing decision-making, increasing transparency and information exchange, and enhancing project performance. Moreover, the framework of this study reveals that most studies targeted the construction, commissioning, operation and maintenance phases of the construction project.

The findings of this framework are limited by the research body reviewed in this paper. Further interviews with subject matters experts can be pursued to explore new applications, challenges, and benefits of Big Data adoption that the existing literature has not yet covered. Further research efforts can also explore more Big Data use-cases and applications in the less-discussed project phases such as demolition. More research can also focus on connecting these Big Data applications across the project phases to enable the industry's biggest potential.

Abstract –

Excavators and trucks are important equipment for earthmoving work, which have major contributions to construction productivity. In order to control the work efficiency and productivity of earthmoving equipment, computer-vision (CV) methods have been proposed to monitor equipment operations from site surveillance videos. Existing methods can recognize equipment activities to estimate the working time and idling time; however, they are limited in analyzing the reasons behind the equipment idling and low productivity. Therefore, this research proposes a method to identify the main reasons that cause excavators and trucks idling by analyzing their interactive operations. In this method, the relationships between the excavator and the surrounding truck(s) in each group are analyzed to identify the potential reasons that cause the excavator's idling. The proposed method was validated with a video from construction site and the test results showed its effectiveness and efficiency.

Keywords –

Excavator; Interactive operation; Idling reasons

1 Introduction

Heavy equipment is one of three major resources in construction projects along with labor and material [1]. Efficient use of equipment is critical for construction cost control and time saving [2]. One way to increase the efficiency of equipment operation is reducing its idling time. When the equipment is idling, it has no contribution to production, and adds no value to the construction project. Therefore, minimizing idling time is important to improve the efficiency and productivity of construction equipment.

As cameras are recently installed to monitor construction sites, an increasing number of research studies have been focused on monitoring equipment work productivity by automatically analyzing surveillance videos with computer vision (CV)-based methods. Current research work has been focused on estimating equipment's productivity by identifying its states, such as working, moving and idling. However, existing methods did not fully consider the interactive relationships between different pieces of equipment, such as excavators and trucks, which is important for productivity analysis. This research aims to provide a CV-based method for identifying idling reasons of excavators based on the interaction analysis between excavators and trucks from construction surveillance videos. First, the activities of the excavators and trucks are identified using convolutional neural networks (CNN). Then, work groups of excavators and trucks are clustered. Finally, the relationships between each excavator and the surrounding truck(s) are analyzed to identify potential reasons that cause the idling. The proposed method has been tested in a case study and the results indicate that the average accuracy of the idling reasons identification is 93%.

2 Background

In recent years, CV technologies have been widely used for automatic construction equipment operation monitoring and efficiency measurement. In the early stage, researchers focused on developing methods to accurately detect and localize target equipment in video frames. Kim and Zou [3] used color space to detect and localize the excavator in video frames. Emarzadeh et al. [4] concatenated both HOG and the Hue-Saturation colors as descriptors, and used Support Vector Machine (SVM) classifiers to detect excavators, trucks and workers from site surveillance videos. In addition to the

previous work of equipment detection and localization, researchers developed methods for equipment operation monitoring. For instance, some researches attempted to monitor the excavators' operations by recognizing their activities. Gong et al. [5] and Golparvar-Fard et al. [6] used motion features extracted from consecutive video frames, and classified the features with SVM to recognize excavators' activities, such as hauling, dumping, swinging, etc. Instead of using feature-classification-based activity recognition, other researchers developed activity recognition based on context information extracted from images. Kim et al. [8] considered the sequential relationship of the excavator's activities in its work cycle, and used CNN and Long-Short Term Memory (LSTM) network to recognize digging, dumping and hauling activities. Instead of using activity recognition, Soltani et al. [8] detected different components (e.g. dipper, boom and body), and extracted the excavator's 2-dimensional (2D) skeleton from the poses of the detected components. For the productivity estimation, Chen et al. [9] proposed a framework which integrated detection, tracking, and a 3D CNN to recognize multiple excavators' activities (e.g. digging, swinging, loading, and idling). By analyzing the activity information, the number of cycles and the productivity of the excavator are calculated.

The literature review shows that existing research mainly focused on excavator's productivity estimation and operation monitoring. Idling is one of the main factors that causes excavator's low productivity; However, deducing the potential reasons of idling has not been deeply investigated using CV. In order to reduce idling time of excavators and increase their productivity, it is necessary to identify the potential reasons that causes excavators idling. This paper aims to fill the research gap in existing works, and focuses on identifying the potential reasons of idling.

3 Methodology

The methodology for idling reasons identification of excavators is shown in Figure 1, which contains three main steps. First, the excavators and trucks are detected and tracked to get their locations and activities in video frames. Second, excavators and trucks are clustered to analyze their interactive work states. Third, the idling reasons of the excavators are classified into four different cases based on the number, activities and locations of trucks, as well as the interactive work states of the excavators and trucks, which are calculated in the previous steps. The details of these three steps are introduced in the following sub-sections. The methodology of this paper is based on the assumption that the equipment does not have mechanical problems and all the operators have no health issues that may cause idling. These potential reasons of idling are beyond the scope of this paper.

3.1 Identification of excavators and trucks locations and activities

In the first step, detection and tracking methods are used to extract equipment's types and coordinates of bounding boxes in *K* video frames. YOLO-v3 [10] detector and multi-object deep Simple Online and Real-Time (SORT) tracker [11] are applied in this study for equipment detection and tracking, respectively. The YOLO-v3 and deep SORT are selected for their performance of high accuracy and speed in both CV and applications in the construction domain. Following the detection and tracking, the working and idling states of excavators and trucks are recognized using the method proposed by Chen et al. [9].

3.2 Excavator and truck clustering

The second step is to cluster excavators and trucks into different groups. In the real earthwork operations, excavators usually work with nearby trucks. Therefore, excavators and trucks are clustered based on their distances in video frames. First, the number of excavators *M* and trucks *N* are obtained from detection results. Second, the distance in pixels between each truck and each excavator in frame k (d_k) is calculated using Equation (1).

$$d_k = \sqrt{(y_k^e - y_k^t)^2 + (x_k^e - x_k^t)^2} \quad (1)$$

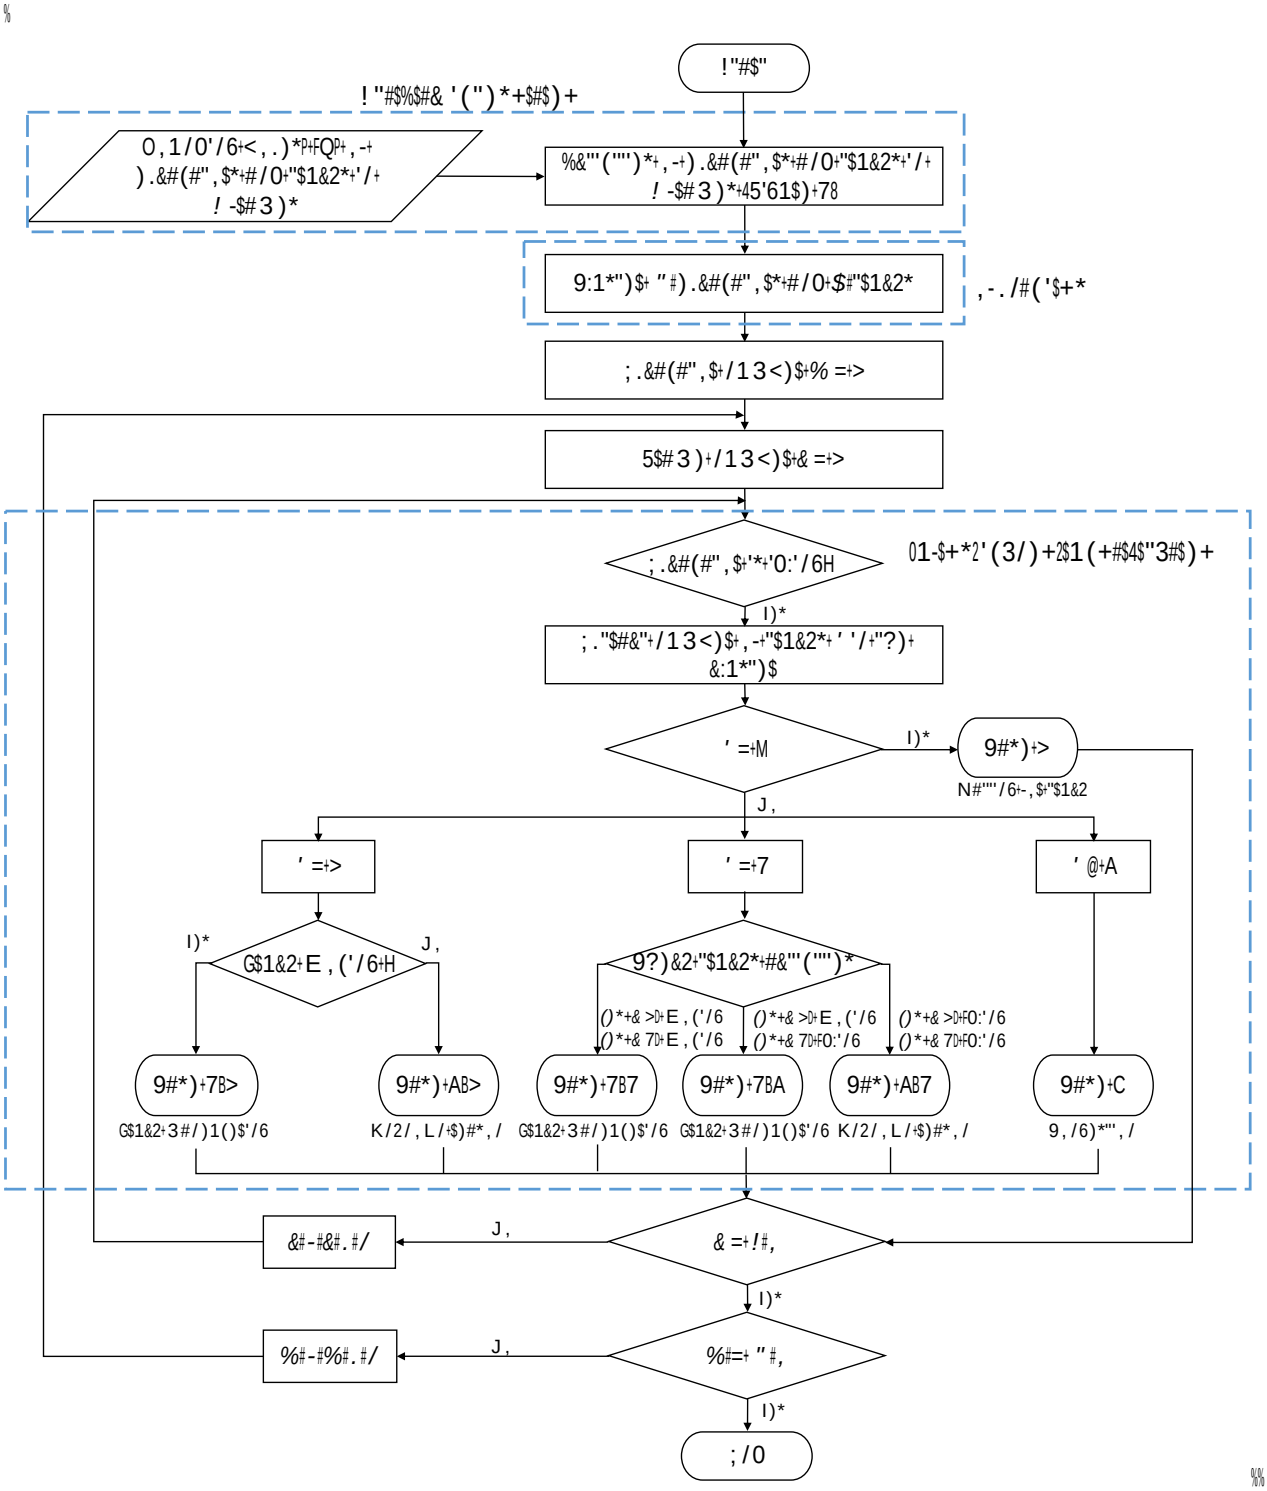
where (x_k^e, y_k^e), (x_k^t, y_k^t) are the centroid coordinates of excavator and truck in frame k, respectively. Accordingly, each truck is grouped with the nearest excavator. If the distance between the truck and the excavator is larger than the threshold, the truck will not be included in the group. The threshold is calculated using Equation (2).

$$Threshold\ (\mu) = 0.5 \times (w_k^e + w_k^t) \quad (2)$$

where w_k^e, w_k^t are the widths of bounding boxes of excavator and truck, respectively, in frame k.

3.3 Idling reasons identification

The third step is to identify the potential reasons why excavators are idling. These reasons are summarized into four cases, as shown in Table 1. For each idling excavator, the number of trucks n in the same group is calculated. If there is no truck in the group, the reason of the idling is classified into Case 1, which indicates that the excavator is waiting for a truck.



_+A3)(%F%_-,T8$*)#%,?%#$(%1),1,2(5%0(#$,5,-,A/

When there is only one truck in the group, the idling reason is determined by the activity of the truck. If the truck is moving, the reason is classified to into Case 2, which indicates that the excavator is waiting for the truck maneuvering to the loading position. Otherwise, there could be different reasons that cause excavator's idling as explained above. Therefore, in this condition, the reason of excavator's idling is classified into Case 3 (unknown reason). For Case 2 and Case 3, there are subcases depending on the number of trucks. When there are two trucks identified in the group, the activities of trucks have three conditions: both trucks are moving, one is moving and the other is idling, or both trucks are idling. These different conditions of trucks' activities could lead to two reasons of excavator's idling. If at least one of the two trucks is moving, the reason is classified into Case 2 (i.e. truck maneuvering). If both trucks are idling, the reason of excavator's idling is unknown, which is Case 3. When there are more than three trucks in the group, the idling of the excavator is classified into Case 4, which indicates too many trucks causing site congestion around the excavator.

Table 1. Potential reasons of the excavator idling

Case		Potential reasons
Excavator idling	Case 1	Excavator is waiting and there is no truck
	Case 2	Several trucks are maneuvering
	Case 3	Unknown reasons (e.g. operator, mechanical problem, safety issue)
	Case 4	Congested site with many trucks

4 Implementation and case study

In this section, the implementation of the proposed method is introduced, and three case studies are provided to demonstrate the performance of the proposed method. A computer with two NVIDIA GeForce GTX 1070 GPUs @ 3.4 GHz, 64 GB DDR, and Windows 10 system was used for the implementation.

4.1 Training and testing

First, to get the locations of the excavators and trucks in video frames, the YOLO-v3 detection model was trained to detect excavators and trucks in the video frames. A dataset containing 1,191 images of excavators and trucks (1,071 excavators, 871 trucks) was created to train the detector. In the training process, the learning rate is set to 0.1, and an Adam optimizer was used to adjust the learning rate during each epoch. The batch size was set to 6. It took about 10 hours with the validation loss not decreasing after 350 epochs. Then, the detection model was tested on the test dataset with 300 images (362 excavators, 421 trucks). The test results are shown in Table 2. The average accuracy of the detection is 82%, which shows that the model has a good ability to identify excavators and trucks in video frames.

Table 2. Detection results

Confusion matrix	Predict class			Model performance		
	Excavator	Truck	None	Precision (%)	Recall (%)	Accuracy (%)
Excavator	337	2	23	98	93	
Truck	6	303	112	99	72	
Average						82

4.2 Case study

In this section, a video of about 62 min of earthmoving work was used for testing. The video has the resolution of 1920 × 1080 pixels and the frame rate of 30 fps (110,914 image frames). In this video, one excavator has 2,645 s idling time and 1,052 s working time. The idling and working states of the excavator and trucks were identified based on the method explained in Section 3.1. The step of the sliding window was selected as 100 frames for both excavators and trucks idling states identification. The thresholds α and μ of the excavator were selected as 7 pixels and 2% of average bounding box areas. The threshold of trucks was selected as 10 pixels without considering the bounding box's area changing. The comparison of ground truths and estimated results are shown in Figure 2. The estimated idling and working times are 2,612 s and 2,085 s, respectively. The error rates are 1.2% and 3.1%.

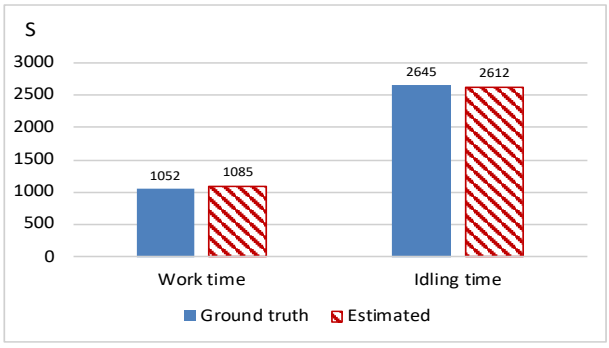


Figure 2. Estimated excavator idling and working time with ground truth

The idling time of the excavator was further analyzed to identify the reasons that caused excavator's idling. In this video, there are three kinds of reasons of excavator's idling: Case 1, Case 2 and Case 3. The accuracy of the estimated results of these three cases are 99%, 82%, and 98%, respectively as shown in Figure 3.

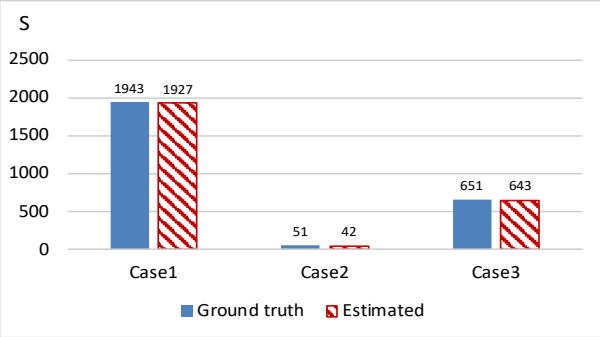

Figure 3. Results of idling reasons analysis with ground truth

The results show that the identification of Case 2 has the maximum error rate of 18%. The errors are mainly due to the failure of detection of partial appearances of trucks as can be seen in Figure 4. This case appeared from time T = 2,535 s to T = 2,540 s and T = 3,153 s to T = 3,156 s, which decreased the estimated moving time of trucks. If the errors of the detection results are excluded, the accuracy of these Cases 1-3 are 100%, 97%, and 99%, respectively.

The results of Case Study 1 show that during 62 min earthmoving work, the excavator's idling time is 60% of total operation time. The proportion of each case is shown in Figure 5. Among these three cases, Case 1 consumes 74% of the total idling time, which indicates a limited number of trucks were arranged to work with the excavator. By observing the video, it could be noticed that the average cycle time of trucks is about 20 min, and Loading time per truck is about 4 min. In the earthmoving work, more trucks should be arranged to cooperate with the excavator to reduce its idling time, since the utilization cost of the excavator is higher than truck. Therefore, to keep the excavator working at capacity, more trucks are required.

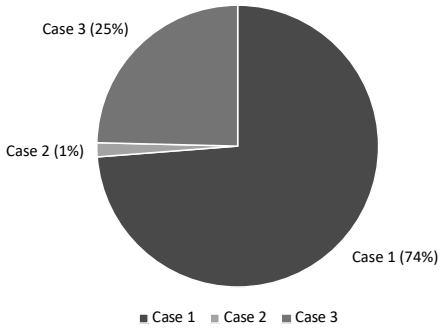

Figure 5. Percentage of the reasons for idling

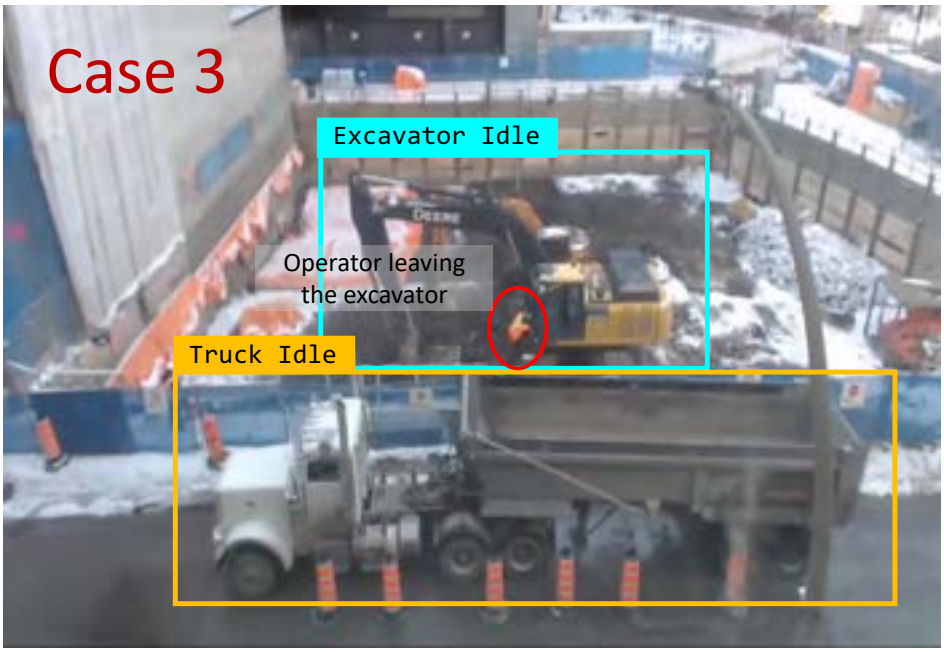
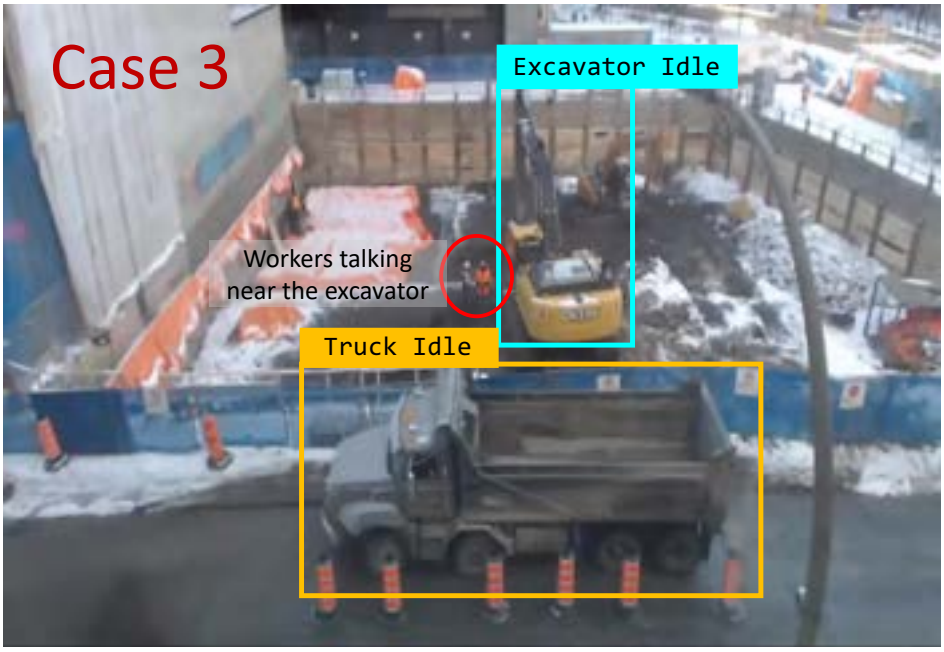
Case 3 consumes 25 % of the total idling time. From the video time T = 51 s to T = 520 s, it can be observed that the operator of the excavator left the equipment, as shown in Figure 6(a). From T = 3,159 s to T = 3,358 s, it can be observed that two persons were talking near the excavator, and the excavator started to work after they left, as shown in Figure 6(b).

Figure 4. Example of lost detection for the partial truck



(a) Operator leaving the excavator



(b) People talking near the excavator

Figure 6. Examples of Case 3

5 Conclusion and future work

This paper developed a novel CV-based method to automatically identify the idling reasons of excavator and truck based on their interactive work states. To the best knowledge of the authors, this is the first attempt to classify the reasons of equipment's idling into detailed categories using CV. The proposed method provides an efficient solution to explore the reasons of low productivity from site surveillance videos, which could contribute to the better understanding of the earthmoving productivity under complex construction site conditions.

Abstract –

The construction industry is forecast to grow from its already impressive size to unprecedented new heights. This significant expansion, along with the increased complexity and sophistication of construction projects, has placed more pressure on construction companies to maintain their vitality and grow in the modern market. As the fourth wave of technological advancements, known as Industry 4.0, continues to evolve, it becomes imperative for construction companies to adopt new technology to remain competitive – much like the Darwinian mantra, the companies must adapt or die. Although the construction industry is often labeled as conservative regarding potential advancements in technology, it has been experiencing a growing use of a wide range of 4.0 technologies. Using insights gained from the existing literature, this paper explores the current state of Construction 4.0 and discusses a four-layer implementation of Construction 4.0 in the industry. Seven Construction 4.0 technologies are first discussed, their integration throughout the project lifecycle is presented in a roadmap, their integration and connectivity with one another are outlined in an interaction roadmap, and the requirements necessary for achieving the 4.0 transformation are articulated. A case study is finally presented to showcase the proposed implementation plan.

Keywords –
Construction 4.0; Implementation; Roadmap; Integration; Interactions

1 Introduction

The construction industry sits at a crossroads. It is economically vital to the prosperity of nations, and a key player that affects our everyday lives. Yet, the construction industry lags behind other major industries in its adoption of technological advances [1]. Nassereddine et al. [2] noted that the complex nature of the construction industry and its heavy reliance of information require the adoption of new and emerging technologies. Challenges facing the construction industry span a multitude of reasons including the dauting decline in productivity, shortage in the workforce, low levels of research and development (R&D), and the inefficient and insufficient transfer of knowledge from project to project [3], add more pressure on construction to move from an industry that has resisted emerging technology to one that is embracing it. One industry that has been a source of innovation in construction is manufacturing [4]. From the many practices that construction has adopted from manufacturing, this paper focuses on the concepts of Industry 4.0.

Industry 4.0, a term coined by the German Federal Government to highlight the fourth industrial revolution [5], can be defined as "a new technological age for manufacturing that uses cyber-physical systems and Internet of Things, Data and Services to connect production technologies with smart production processes" [6]. Montgomery and Norman [7] noted that manufacturing has passed through three different revolutions before reaching Industry 4.0, namely, revolutions, mechanization, electrification, and digitalization. Schwab [8] explained that Industry 4.0 is the stage that enables the full integration between people and digitally controlled machines with the help of internet and information technology (IT). Lu [9] added that industry 4.0 supports the growth and evolution of various fields and industries. The automotive industry has greatly benefited from Industry 4.0, where manufactured cars are being 40% controlled by electronics [10]. The health sector has also taken full advantage of Industry 4.0 in creating new diagnostic methods and technologies to sequence genes [11].

The industry is said to transform the lifecycle process of products and production systems by increasing the connectivity and interaction among parts, machines, and humans [10]. This transformation is enabled and driven by nine fundamental technological advances, also referred to as pillars: autonomous robots,

Augmented Reality, Simulations, the cloud, Big Data and analytics, the Industrial Internet of Things, cybersecurity, additive manufacturing, and horizontal and vertical system integration [12]. It should be noted that the technology itself is not powering Industry 4.0: while most of the nine pillars are not entirely new to manufacturing, it is the full integration of these building blocks and their connectivity across the borders that define Industry 4.0 [3].

The construction industry has also experienced a radical transformation and made great strides in changing its status quo and embrace technological advancements [13],[14],[15]. Influenced by the gains that resulted from the fourth industrial revolution, researchers in construction began investigating the potential of integrating Industry 4.0 into construction. While construction is often compared to manufacturing, the former is approaching and embracing Industry 4.0 from a different direction [12]. Recently, the term "Construction 4.0" emerged in the 21st century construction research corpus [16]. The interest in Construction 4.0 is fueled by the development of various technologies, the drastic change in the needs of owners, the shift towards mass customization, and the need for green construction and sustainability [16].

Through a thorough literature review, this paper introduces a four-layer implementation plan and begins by discussing Construction 4.0 and seven of its most commonly cited technologies, namely: iBIM, AR, VR, robotics, 3D printing, AI, and drones. As a construction 4.0 approach is seen as a two-level integration effort: 1) integration of a Construction 4.0 technology throughout the construction project lifecycle and 2) integration and connectivity of Construction 4.0 technologies, each of those levels is examined in this paper. A roadmap for the integration of Construction 4.0 technologies across the project lifecycle is created and an interaction map of Construction 4.0 is developed. The requirements for achieving Construction 4.0 are also discussed. Finally, a case study is presented to highlight how Construction 4.0 can be realized by showcasing the four layers put forth in the paper.

2 Construction 4.0

According to the European Industry Construction Federation (FIEC), "Construction 4.0" is the counter part of industry 4.0 in the Architecture, Engineering & Construction (AEC) industry and it refers to the digitalization of the construction industry [17].

Rastogi [16] stated that the main goal of construction 4.0 is to create a digital construction site that monitors progress throughout the life cycle of a project by using different technologies. The adoption of Construction 4.0 will not only change the construction process, but it will change the organization and project structures, shifting the fragmented construction industry into an integrated industry [17].

2.1 Construction 4.0 Technologies

To understand the various layers of Construction 4.0, it is important to first understand the technologies that are enabling this transformation. While the existing research corpus discusses various Construction 4.0 technologies, this paper focuses on seven Construction 4.0 technologies that have been frequently cited. A brief introduction to each of these technologies is provided below:

Integrated Building Information Modeling (iBIM) is considered the higher level of traditional BIM and consists of three elements: (1) the integration architecture which defines major layers of iBIM and how they are interconnected, (2) the product model which defines the content and function of the object's behavior, and (3) the process model which identifies the interaction scheme and mechanism between model objects [18].

Augmented Reality (AR) is both an information aggregator and a data publishing platform that allows the user to (1) passively view displayed information, (2) actively engage and interact with published content, and (3) collaborate with others in real-time from remote locations [19]. AR is gaining increased momentum in the construction industry, and various use-cases are being explored and tested throughout the project lifecycle, such as promoting AR-enabled production planning [13] and enabling remote expert system [20].

Virtual Reality (VR) is a step further than AR on the spectrum of virtuality. VR creates a virtual and immersive experience for the user through headsets with 360-degree visions, allowing the user to experience a completely different environment. Li et al. [21] categorized the use of VR in construction into the hazard identification, which allows construction teams to sense, analyze, and extract potential dangers, and safety training and education, in which construction workers will train in a safe environment in comparison to on-site training, which might be expensive and hazardous.

Robotics uses machines that can perform or replicate human actions. While robotics has been widely used in manufacturing and aerospace, construction is following suit and is using robotics, mainly in the vertical construction sector [22]. This technology is heavily used in construction assembly work, especially for high rise buildings. SMART system developed by SHIMIZU in Japan, for instance, was used to construct more than 30 stories of an office building [23]. Additionally, different construction tasks such as painting, brick overlaying, and earthwork can be performed by robots [24].

3D printing, also known as additive manufacturing, is the process of creating a complex, physical 3D object from a CAD model. 3D printing has undergone 25 years of research and development, and as a result, the technology is currently used in different industries such as aerospace, automobile, and medical [25]. The construction industry is also exploring the use of 3D printing, mainly for small and medium-sized applications at the time being [26]. This technology is showing great potential for large scale implementations; however, a number of challenges such as layering effect which results in uneven surfaces with voids, tensile strength issues associated with the lack of steel reinforcement need to be overcome before the industry embrace this technology [27].

Artificial Intelligence (AI) is a term used to describe a machine that replicates the human cognitive functions [28]. One of the main components of AI is machine learning, where a machine learns from a set of data using statistical methods. According to a study by McKinsey & Company, AI is starting to gain momentum in construction [29]. The study highlighted three main current AI applications: (1) project scheduling optimization which is achieved by continuously testing a large number of plan alternatives and selecting the better option, (2) image recognition and classification which can be used to identify issues related to safety on site and to collect the information for future learning, (3) enhanced analytic platforms which collect and analyze building machine data and building sensor data to predict any issues related to maintenance.

Drones, also known as Unmanned Aerial Vehicles (UAVs), are unpiloted small sized aircrafts that are remotely controlled. In early 2006, drones were mainly used for military applications [30]. In recent years, their use in construction and other industries has been on the rise [31]. The construction industry is mainly employing drones for inspection and monitoring during surveying, construction, and facility management [32].

2.2 Construction 4.0 Roadmap

The first level of the Construction 4.0 integration efforts takes a lifecycle view for the integration of Construction 4.0 technologies. A project moved from its early planning phase, to design, construction, and then facility management. A technology is used to its full potential when it is integrated throughout the construction project lifecycle, where applicable [33].

For instance, several studies including [34], [35], [20] identified potential use-cases of AR throughout the project lifecycle. The blue, solid bars of AR in Figure 1 reflect the AR applications that have been tested and used on construction projects and the green, hatched bars represent the potential benefits of additional AR use-cases that are being explored.

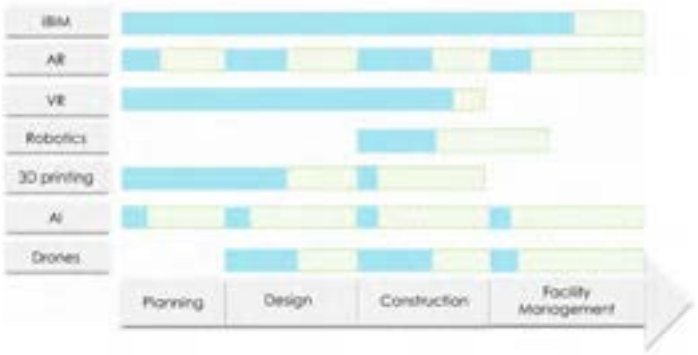

Figure 1. Construction 4.0 Envisioned Roadmap
(The solid blue bars represent the current use of a construction 4.0 technology
and the green hatched green bars represent the projected use of a construction 4.0 technology)

2.3 Construction 4.0 Interaction

The second level of the integration efforts demands an increased connectivity and interaction of Construction 4.0 technologies [36]. Aleksandrova et al. [37] noted that the full integration of digital technologies is a radical transformation in construction that creates a united digital ecosystem.

A scan of the literature on Construction 4.0 and its associated technologies was performed to identify current and future potential interactions. A map was then developed (Figure 2) to outline those interactions and illustrate potential synergistic efforts.

iBIM and AI can be thought of as core technologies

of Construction 4.0 and the impetus to connectivity [37]. Copper [38] added that BIM and cloud-based common data environment (CDE) are central to Construction 4.0 framework: BIM carriers the simulation feature that is a core component for Industry 4.0, and CDE acts as the data warehouse for all information related to construction project over its life cycle. BIM and CDE establish a single platform that helps integrate all of the construction project phases and link the physical and cyberspace [3]. Thus, allowing the implementation of Construction 4.0.

Some of the interactions outlined in Figure 2 are extracted from the existing construction research corpus, while others are extracted from adjacent industries, such as aerospace and medical, and are interactions yet to come to construction. For instance, Wake et al. [39] discussed the interaction between 3D printing and AR technology in a healthcare environment. The authors used these two technologies on a patient with a kidney tumor. A 3D printing transparent kidney model with the ability to color the tumor zone was first created. Then, an AR kidney model of the patient was created. These models were used before and during the operation to aid in the robotic partial nephrectomy operation.

(graphics downloaded from https://www.freepik.com/)

2.4 Construction 4.0 Requirements

Embracing Construction 4.0 entails several challenges that have been discussed by construction researchers. Industries are normally averse to change, and therefore it is initially resisted until it can be perceived as a guaranteed opportunity. Several authors [38], [40], [41] noted that the construction industry is no stranger to the resistance of change.

Researchers pointed out that the multidisciplinary nature and uniqueness of the construction industry results in an unclear understanding of the value proposition of Construction 4.0 technologies. In the past construction companies often relied on a project-thinking approach when managing construction projects. The shift to Construction 4.0 requires a change of the thinking-approach and the processes. The development of digital technologies and their adaption to the construction company's needs is highly dynamic, tailorable, and expensive. Additionally, when new technologies are introduced, employees and workers will need extra training. Therefore, construction companies will generate a surplus value only if the new technologies are integrated within the company's processes and can be used across projects. The switch to Construction 4.0 requires a process-oriented mindset, as opposed to the traditional project-oriented approach. However, this mindset shift pushes construction companies to digitize their existing processes, posing an additional challenge for two reasons: (1) existing process have mostly been designed before current digital tools were available, and (2) not every process can be directly digitized. Therefore, all existing processes have to be re-engineered to accommodate the shift in the mindset and support the 4.0 transformation of construction companies.

Figure 3 shows a general process to implement new digital technologies in a construction company, as required for the transition to Construction 4.0. Prior to re-thinking a process, the actual process must be first recorded and analyzed to explore how and where the technology(ies) could be used. A thorough analysis and documentation of the "status quo" of the existing process is crucial to successfully manage the technological changes. Assessing current processes helps in identifying the relevant decision-making structures and cost relevant process steps. The process-oriented approach also forms the basis for the identification of waste and inefficiencies in the company, and thus, becomes a prerequisite for the application of Lean management in the company.

Once the existing process has been investigated, the potential for innovation and integration of technologies, along with efficiency enhancement analysis, is assessed next. This includes an application analysis of the different technologies of interest, as well as the digital tools that are already in use. The structural needs as well as the existing barriers to innovation have to be identified. The structural needs include the aforementioned aspects of implementing the various Construction 4.0 technologies in the construction companies. Other considerations for companies to think of are the high investments associated with adopting technologies, the need to additional human resources, and R&D investments, all of which poses a major financial barrier.

For a successful transition to Construction 4.0, a construction company needs a vision of the digitization change process which fits the company's needs. This is especially important since Construction 4.0 goes beyond technology alone. It includes a change in the mindset of the all people involved (from field personnel to management) as well as of the processes in consideration. Hence, a clear vision, which is supported by these people, is important. Only when these requirements are met, companies can make the transition from the traditional project-thinking to process-thinking.

This shift also changes the organization and infrastructure of many companies i.e. their partners. Another consideration to address is the long-standing problem of longitudinal fragmentation that renders stakeholders nearly powerless to pilot their companies through this change [42]. Over the past decade, the construction industry has made significant changes to its structure as organizational changes have already been applied to companies which implement Lean management. The importance of some traditional departments decreases significantly, whereas some new departments emerge.

In addition to the challenges associated with moving construction towards a process-thinking industry, the lack of global standards and framework for implementation is another roadblock. Furthermore, Construction 4.0 heavily relies on various Information Technology (IT) systems, and, therefore, concerns related to data and cybersecurity must be addressed and stringent security standards must be put forth. Legal and contractual issues need to be also discussed to allocate risks among stakeholders.

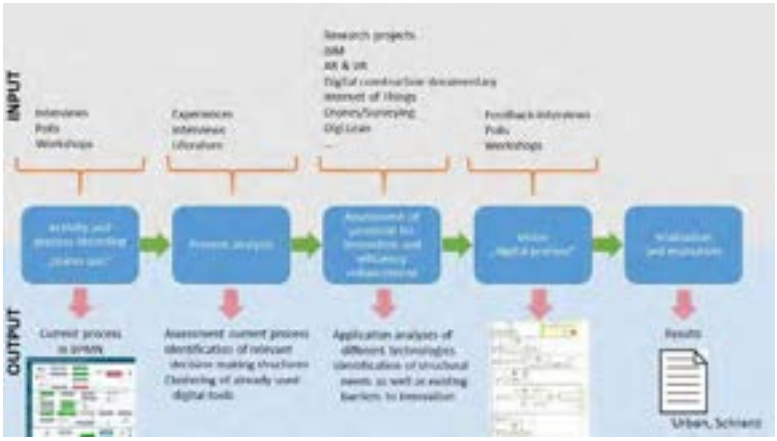

Figure 3. Process to implement Construction 4.0

3 A Case Study of the Two-Level Construction 4.0 Integration

To illustrate the two-level construction 4.0 integration, a case study where many of the previously discussed Construction 4.0 technologies act as a cross-linked system is presented.

Figure 4 shows a generalized data path for a future cross-linked system. All begins with a BIM model, which is created in a native modeling environment, like Revit or ArchiCAD. For a general use, the model is exported as an Industry Foundation Classes (IFC) file to a collaborative data environment on a BIM server. This export allows the model to be used in several of the previously discussed Construction 4.0 technologies. After exporting the model to a smartphone or tablet, the site supervisor and/or inspector (referred to hereinafter as user) can benefit from the visualization and interaction with the model on the smart device when e.g. inspecting a Heating, Ventilation, and Air Conditioning (HVAC) system. QR codes or RFID chips attached to a building component connect the smart device with the manufacturer's database of the building component.

This enables the user to access specific product data, which can be also transferred via BIM Collaboration Format (BCF) to the BIM server and, hence, back into the native BIM model. This two-way communication leads to a closed loop data transfer. Moreover, the manufacturer data, also referred to as semantic data, can be transferred to an .xml database that is then connected with the component's Globally Unique Identifier (GUID) in the BIM model. This information can be then retrieved by facility managers. This is especially valuable for maintenance- and safety-technical relevant data and leads to component-referenced manufacturer data.

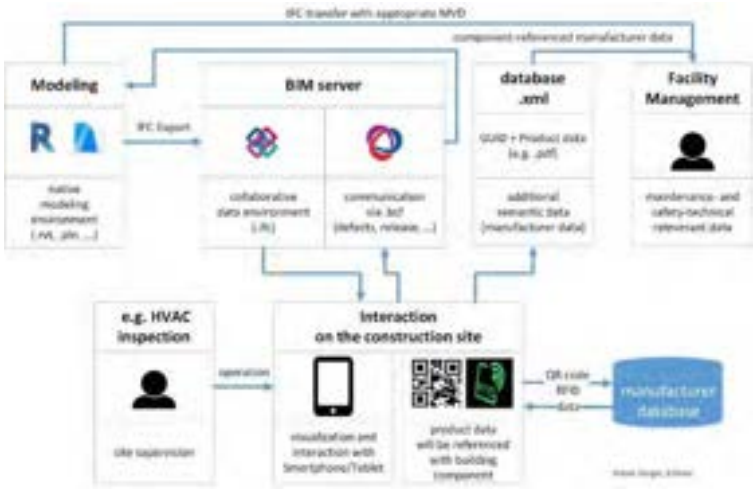

Figure 4. On-site inspection: closed-loop data transfer in a generalized form

For example, the BIM model normally contains the general specifications for a required fire protection flap. After the installation of the fire protection flap, the specific product data can be transferred into the BIM model. Then, the correct maintenance requirements for this product are available for the facility management. Another option is the usage of an IFC transfer with an appropriate MVD (Model View Definition) directly from the BIM model.

This closed-loop data transfer not only works during the construction phase, but also in the later operation and maintenance phase. Each time one or more building components are replaced, the new product data is transferred into the central BIM model.

Another technology that can be considered is Augmented Reality (AR). The authors worked on different use-cases for AR in Construction 4.0 [34], [43]. AR is one of the emerging technologies which has a great potential to transform the construction industry. The aforementioned closed-loop data transfer can be used with several AR use-case, e.g. for monitoring the progress of the construction site, visualizing augmented drawings or construction systems in the field, as well as conducting on-site inspection. In one of the research projects of the authors, AR-AQ-Bau [44], a specific AR use-case for on-site inspection has been developed. In this case, the BIM model was also exported to a BIM server and then an AR model was created using the game-engine Unity. The site supervisor can use this AR model to control the HVAC system on the construction site. The control can happen before the HVAC system is built, to check for instance, whether there is enough space for movement in front of inspection hatch. After the HVAC system is installed, the site inspection can monitor and check if everything is built correctly. This process or application not only works for HVAC but for the whole construction. In the AR device, the site inspection marks every defect or deficiency in the construction. Hence, the position of the defect in the building is stored in the AR model. Additionally, a description (text or audio) of the defect as well as photos can be added. All this information is then transferred back into the BIM model via BCF. On one hand, this helps to keep a record of all defects in a building and, on the other hand, improves the repair of existing defects. Additionally, the AR tool for site inspection is also very invaluable for the facility management during the operation phase.

The scan of QR-codes or RFID becomes easier with AR devices. After scanning the tag, the AR devices can be connected with the manufacturer's database and can retrieve the specific product data of the built-in component. This data is then transferred to the BIM model or another specific database (as described before).

4 Conclusions and Future Work

The fourth wave of technological advancement (Industry 4.0) and the digital transformation at its helm are pushing industries worldwide to embrace newer technologies to continue to remain competitive. Although the construction industry is not leading this change, it is not an exception to the digital revolution. The unique nature of the construction industry provides fertile ground for research on digitizing the industry and the term Construction 4.0. This research builds on the existing construction research corpus and discusses four layers of Construction 4.0 implementation. The first layer consists of the understanding the technologies associated with Construction 4.0. This research discussed seven frequently cited technologies, namely: iBIM, AR, VR, robotics, 3D printing, AI, and drones. The second and third layers defined the two-level of integration needed to implement Construction 4.0. The second layer presents a roadmap that outlines the integration of each of the seven technologies across the construction project lifecycle. The roadmap is a depiction of the current state-of-practice of the technologies and an outlook into future developments. The third layer offers insights into how the seven technologies can be connected and integrated together. An interaction matrix is developed to outline the relationships between the different technologies. It should be noted that the two-level integration cannot happen across the board, but rather only when applicable. The implementation of these three layers is only enabled when the fourth layer is realized. The fourth layer encompasses a set of requirements that construction companies must consider. At the core of these requirements is the necessary shift to process-thinking. Construction stakeholders must have the right mindset to pilot their companies through the disruptive Construction 4.0 storm. Finally, a case-study is presented to discuss the four-level implementation outlined in the paper. Future research efforts can extend on the seven technologies discussed in the paper and introduce additional elements of Construction 4.0. Additional research is also needed to verify the interactions between all the Construction 4.0 technologies.

Abstract –

As climate change increases the frequency and intensity of natural disasters, proactive disaster management is needed to reduce the damage caused by the natural disasters. Existing reports that record the scale, damage, and response of natural disasters can be used as references for proactive disaster management. However, it is labor-intensive and time-consuming to manually find the necessary information from a number of reports. Thus, this study proposes a natural language processing (NLP)-based question answering system (QA system) for proactive disaster management using the existing reports. This study is focused on paragraphs retrieval, which retrieves paragraphs that have a high similarity to a given question based on the word embedding. The National Hurricane Center's Tropical Cyclone Reports are used to evaluate the proposed method.

Keywords –

Deep Learning; Disaster Management; Natural Language Processing; Question Answering System

1 Introduction

Natural disasters have negative impacts on infrastructure such as structural failure. In recent years, as the frequency and intensity of natural disasters have increased due to the impact of climate change, the importance of disaster prevention has increased [1].

Analyzing historical data and extracting the necessary information can help disaster prevention. With the advancement of deep learning and natural language processing, many studies for information extraction use unstructured data such as text data. Wang and Taylor proposed a method for detecting urban emergencies using Twitter data and topic modelling techniques [2]. Sit et al. conducted a study to identify disaster-related tweets using deep learning, natural language processing, and spatial analysis [3]. Ragnini et al. proposed a data analysis method for disaster response and recovery using Twitter and sentiment analysis [4].

The Question Answering system (QA system) provides users with answers for questions regarding the data. The QA system is useful in finding the necessary information in a large amount of data. Chan and Tsai proposed a dialogue system that combines a QA module and a knowledge base for emergency operations [5]. Tsai et al. proposed a chatbot system called Ask Diana that provides users with water-related information [6].

Social media data, mainly used in previous studies, can satisfy the need of big data for deep learning models. However, they contain inaccurate or unnecessary data. Previous studies that proposed QA systems were mostly focused on extracting keywords. This keyword-based information is intuitive, but it is difficult to grasp the context of the information.

In this study, we propose a QA system for proactive disaster management. The purpose of the proposed system is to provide users with the necessary information to reduce the damage to the infrastructure caused by natural disasters, especially tropical cyclones. In this study, the Tropical Cyclone reports provided by the National Hurricane Center are used. Since tropical cyclones are one of the major weather phenomena that cause enormous damage to infrastructure, they are chosen as the subject of disaster management. We conduct paragraphs retrieval, one of the steps in the QA system, and represent its results.

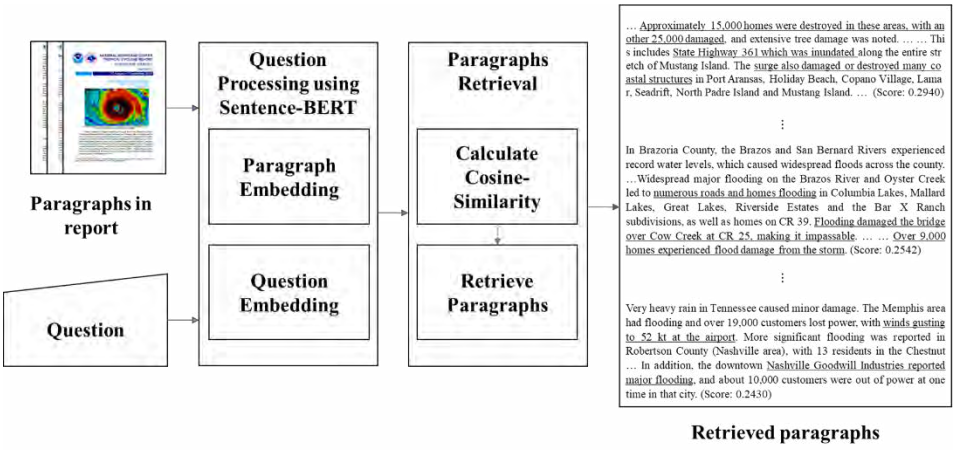

Figure 1. Overview of the proposed paragraphs retrieval in the QA system

2 Paragraphs retrieval using sentence-BERT

2.1 BERT and sentence-BERT

In the past, deep learning models mainly used in natural language processing were Recurrent Neural Network (RNN) models such as Long Short-Term Memory (LSTM) and Gated Recurrent Unit (GRU). The performance of RNN models is excellent, but they have a vanishing gradient problem. When the input sequence is long, the prediction accuracy is decreased by the vanishing gradient problem. To solve the vanishing gradient problem, Sutskever et al. proposed a seq2seq model using the attention mechanism [7]. In the Seq2seq model, the output word is predicted considering all the input words of an encoder. The purpose of the Attention mechanism is to improve the accuracy of prediction by focusing on the part of the input words associated with the predicted word. Vaswani et al. proposed a model called Transformer consisting of an encoder and a decoder using only the attention mechanism [8].

Bidirectional Encoder Representations from Transformers (BERT) [9] is a language representation model developed by Google based on Transformer. BERT is pre-trained with a large amount of Wikipedia and BookCorpus data using unsupervised learning. At the time of the publication, BERT achieved the state-of-the-art from 11 NLP tasks, including Question Answering tests [9].

Sentence-BERT is a model proposed by Reimers and Gurevych [10]. The existing BERT model is a word-based language representations model, and each word that passes the BERT has a dimension of 512. Tasks such as similarity comparison, clustering, and information retrieval take too much computational cost. To solve this problem, Sentence-BERT performs word-embedding in sentence or higher units.

2.2 Paragraphs retrieval

A QA system typically consists of three steps: 1) Question processing, 2) Document and Passage Retrieval, 3) Answer extraction [11]. A paragraph has one subtopic and is a unit that can be clearly classified within the whole text. Therefore, in this study, retrieval is performed on a paragraph basis. In particular, paragraphs retrieval is performed using sentence-BERT and the results are presented. These results show that sentence-BERT can be used in a QA system for proactive disaster management. Figure 1 shows the framework of this study.

2.3 Tropical cyclone reports

As mentioned above, this study uses public data to ensure data reliability, focusing on the tropical cyclones. To this end, Tropical cyclone reports provided by the National Hurricane Center (nhc.noaa.gov) are used. 12 reports, including the Hurricane Harvey report, and 404 paragraphs in them are used for this study.

3 Experiments and Results

To conduct the experiment, the 12 reports provided by the National Hurricane Center were reformatted into paragraphs and saved as Microsoft Excel file. Question embedding and paragraph embedding were performed using the Sentence-BERT. Using the cosine similarity, the similarity score between the question embedding and each paragraph embedding was calculated and the top five paragraphs with high scores were retrieved. Table 1 is the result of paragraphs retrieval on the Hurricane Harvey report. This study uses the same

Table 1. Results of paragraphs retrieval on the Hurricane Harvey report; underlined parts show the information regarding infrastructure damage.

Question	Top 5 most similar paragraphs in reports
What infrastructure has been damaged and What kind of damage has happened to the infrastructure?	Near the initial landfall location in Texas, wind damage was extreme in Aransas County, Nueces County, Refugio County and the eastern part of San Patricio County. Approximately 15,000 homes were destroyed in these areas, with another 25,000 damaged, and extensive tree damage was noted. … … This includes State Highway 361 which was inundated along the entire stretch of Mustang Island. The surge also damaged or destroyed many coastal structures in Port Aransas, Holiday Beach, Copano Village, Lamar, Seadrift, North Padre Island and Mustang Island. … … (Score: 0.2940)
	Major-to-record flooding occurred in Liberty County along the Trinity River with numerous roads inundated including FM 787. Many homes and subdivisions were either cut off or inundated, specifically north of the city of Liberty and in the Grenada Lakes Estates subdivision. … … High flows caused significant scouring of the state 105 (business) road; other roads were washed out as well, with bridge washouts or closures observed in many parts of the county. At least 1,000 homes were damaged in the county. (Score: 0.2636)
	In Brazoria County, the Brazos and San Bernard Rivers experienced record water levels, which caused widespread floods across the county. The hardest hit communities were in Baileys Prairie, Richard and West Columbia. Widespread major flooding on the Brazos River and Oyster Creek led to numerous roads and homes flooding in Columbia Lakes, Mallard Lakes, Great Lakes, Riverside Estates and the Bar X Ranch subdivisions, as well as homes on CR 39. Flooding damaged the bridge over Cow Creek at CR 25, making it impassable. … … Over 9,000 homes experienced flood damage from the storm. (Score: 0.2542)
	Major lowland flooding occurred in Matagorda County along the Tres Palacios River. Many roadways were under water, and homes in the El Dorado Country, Oak Grove, and Tres Palacios Oaks subdivisions flooded. Major flooding also occurred on the Colorado River at Bay City as levees were overtopped by 2 ft of water. High flows from the Colorado and Tres Palacios Rivers impacted river navigation for several weeks. Roughly 2,900 homes were damaged in the county. (Score: 0.2469)
	Very heavy rain in Tennessee caused minor damage. The Memphis area had flooding and over 19,000 customers lost power, with winds gusting to 52 kt at the airport. More significant flooding was reported in Robertson County (Nashville area), with 13 residents in the Chestnut Flats Apartment near the Nashville Fairgrounds evacuated due to the high water. In addition, the downtown Nashville Goodwill Industries reported major flooding, and about 10,000 customers were out of power at one time in that city. (Score: 0.2430)

uses the same question for all of the 12 reports. Examples of infrastructure damage information with in paragraphs are shown in Table 1.

Table 2 shows the results of paragraphs retrieval. all of the paragraphs retrieved from four reports (Harvey, Ingrid, Irma, and Issac) include information about infrastructure damage. In the other eight reports (Alex, Bill, Cindy, Dolly, Hermine, Imelda, Lee, and Michael), only a few paragraphs include infrastructure damage information. This is because the total number of paragraphs with infrastructure damage information in the eight reports was less than 5. In brief, the paragraphs retrieval has been performed well in all the reports.

Table 2. Results of paragraphs retrieval (the number of paragraphs showing infrastructure damage information / the preset number of paragraphs retrieval)

Tropical Cyclone	Result
Alex	1/5
Bill	2/5
Cindy	1/5
Dolly	1/5
Harvey	5/5
Hermine	1/5
Imelda	3/5
Ingrid	5/5
Irma	5/5
Isaac	5/5
Lee	2/5
Michael	2/5

Table 3 shows two paragraphs with different similarity scores. The one with higher score (0.2189) shows no information related to infrastructure damage, whereas the one with lower score shows infrastructure damage information. It seems to be because many words related to damage were used such as *"flood"* and *"death"*, even if there are no words related to infrastructure. This problem could be solved by fine-tuning for text classification using labeled data.

4 Conclusion

In this study, a paragraphs retrieval model, one of the steps in the QA system for proactive disaster management, was proposed and the experimental results were represented. The proposed model well retrieved the paragraphs including infrastructure damage information for all the 12 reports. The retrieved paragraphs can be used as an input in the next module (the answer extraction model) of the QA system. The proposed methods are expected to help disaster prevention and reduce the damage to the infrastructure.

Table 3. Retrieved paragraphs of the Hurricane Lee report; underlined parts show the information regarding infrastructure damage.

Paragraphs
Paragraph not including infrastructure damage information (Score: 0.2189)
Media reports indicate that flooding largely related to the remnants of Lee was responsible for at least 12 additional deaths in the eastern United States; seven people in Pennsylvania, four in Virginia, one in Maryland, and one in Georgia. Nearly all of these deaths occurred when individuals tried to cross flooded roadways in vehicles or were swept away in flood waters.
Paragraph including infrastructure damage information (Score: 0.1565)
Most of the damage from Lee was the result of storm surge or freshwater flooding. Storm surge flooding from Lake Pontchartrain <u>inundated more than 150 houses</u> in Jefferson and St. Tammany Parishes in Louisiana. Minor storm surge flooding was also reported outside the hurricane protection levees in St. Bernard and Orleans Parishes. Freshwater flooding was reported in low-lying areas of southeastern Louisiana and southern and central Mississippi. Several roads were inundated by floodwaters in Hancock, Jackson, and Harrison Counties Mississippi, while in Neshoba County in the central portion of the state, <u>35 roads were damaged with 5 of those completely washed out</u>.

Abstract -

We obtained various effects about 'Efficiency, Quality, Safety, Improving the work environment and Human resource development' through overall utilization of Information and Communication Technologies (hereinafter referred to as ICTs) in the excavation work and management at Yoneshiro-gawa River, a first-class river.

At the topographic surveying stage, we used the UAV and made three-dimensional topographical data. At the excavation stage (most excavations are under water), we used the machine controlled system and at the same time introduced a new system by which we could automatically grasp the amount of excavation (finished work). At the delivery stage, we could automatically get a predetermined form showing the work done by the excavation.

Overall utilization of ICTs; Underwater excavation; New system using excavation history data; New-3K [Kyuyo:salary, Kyuka:vacation, Kibo:hope]

1 Introduction

Recently in Japan, due to the effects of global climate change, we are facing severe and frequent disasters and need to take measures to prevent floods. In general, short-term measures are to cut and remove trees along the river and to excavate the bottom of the river in order to improve the flow of water in the river.

As one such measure against flood, we implemented the flood control project of cutting and removing the trees and excavating the bottom of the river in the Yoneshiro-gawa River at Noshiro city, Akita prefecture, Japan. In the process of this project, we used various ICTs. In particular, the use of 3D-machine controlled system in excavation work in muddy water was effective for efficiency and safety. On the other hand, we discovered the difficulty of understanding new rules on the usage and the management of these new technologies.

2 Construction overview

We cut the trees in an area of 300,000m2. And in part of the area where the trees were cut and removed, we set up a pilot area. This area was dug down to a certain depth, so it is difficult for trees to grow up in this area. The area was designed so that usually there is water, and once it rains and the water level rises, the mud at the bottom of the area is washed away. To construct this pilot area, we utilized various ICTs. (Figure 1, 2)

The construction project was done from 3th April 2019 to 31th January 2020. The cost was 250,000,000JPY. The supervisor was NOSHIRO work office of River and National Highway, Tohoku Regional Development Bureau, MLIT.JP. The contractor was OHMORI CONSTRUCTION Co., Ltd.

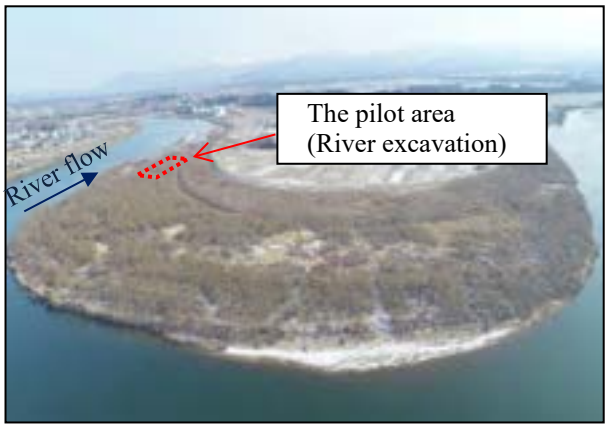

Figure 1. View of construction site (Before work)

2.1 Utilization status of ICTs in Construction

At the construction area we utilized several ICTs through the process of topographic survey, excavation and delivery.

Figure 2. The pilot area (River excavation) (After work)

2.1.1 3 dimensional survey

At the area of river excavation we utilized the UAV and took many photographs (700 photos) from the air(Figure 3,4). And many photographs (689 photos) were converted to 3 dimensional topographic data by the software(Table 1). And the 3 dimensional data were used for next excavation process.

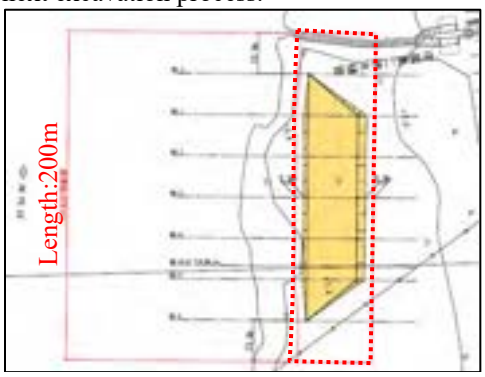

Figure 3. The area of 3D survey

Table 1. Equipment and software used

UAV	EAMS ROBOTICS UAV-E470SU1
Software of Photogrammetry	Agisoft Metashape
Software of 3D design	SITE-Scope Sitec3D (KENSETSU SYSTEM)

2.1.2 3 dimensional excavation

At the process of the river excavation (volume: 5,400m3) we utilized 3 dimensional machine controlled system. We didn't need elevation stakes, markers which are usually installed on site to show operator how much to excavate. Especially, because it was difficult to see the status of excavation in the muddy water, it was much more useful to use this 3 dimensional machine controlled system (Figure 5). In the clear water, operator and surveyor could see the status of the ground and check certain situation, but on the other hand in muddy water, they couldn't see nothing about the ground.

Table 2. Construction Information

Type	Earthwork River excavation
Place	R4.4k+80m- R4.6k+40m
Volume_ Excavation	5,400m3

Figure 5. ICT construction (3D-machine control)
(Appearance Guidance and the monitor which shows the excavation status in operation room)

2.1.3 Management of the excavation

By using the machine controlled system, we introduced a new system by which we could automatically grasp the amount of excavation required.

The system is that the position data of the bucket is converted to the data of the amount of excavation (finished work) and then sent to the clouded server and stored. And the data is automatically compared to the design date and shows the difference by colors, green color is completed and red is not. (Figure 6)

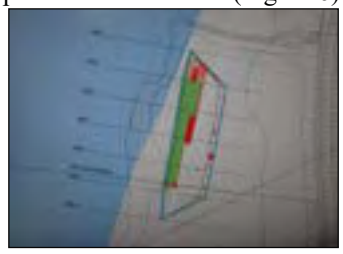

Figure 6. The monitor which shows instantly the excavation status at office connected to the site via internet

We could use this data for the management of excavation work. Previously, we needed to survey the level of the ground after finishing the excavation works to grasp the amount of the work. But by using this system, we need not to do such these survey and recording in the field required. (Figure 7)

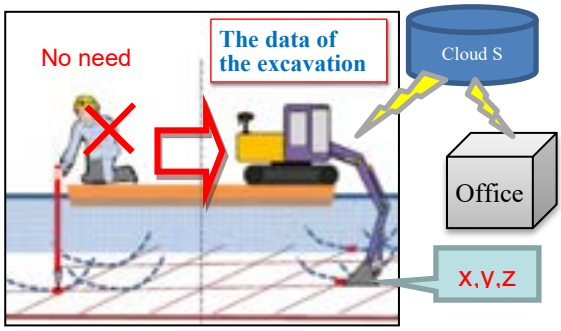

Figure 7. The image of the comparison of the previous method and new one

3 Analysis of effects and challenges

Through these works by using ICTs, we obtained effects about the efficiency, the quality, the safety, the improving of the work environment and the human resource development.

3.1 Quantitative analysis of the effect

In order to measure the effect on efficiency, we investigated the amount of work in each work that utilized ICTs. The amount of work was calculated as the total number of each work times multiplied by the number of each workers related. The amount of work by the normal method was calculated on the basis of the work experienced in the past, assuming the normal work.

Through all process the efficiency increased by 20%. The efficiency increased in each processes of the survey, the3dimensional design, the excavation and the inspection. But because of the growth of the data, the efficiency declined in the electronic delivery process. (Figure 8)

By the way, the average efficiency of 17 construction sites (excavation work) in Japan last year (2019s) increased 15%. (Figure 9) It shows that our work was more effective.

Figure 8. The efficiency of our work (Upper: Normal method, Lower: Utilize ICT)

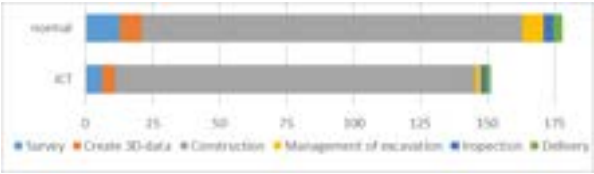

Figure 9. The average efficiency of 17 works (Upper: Normal method, Lower: Utilize ICT)

3.2 Quantitative analysis of the quality

The accuracy of excavation work passed all standard values. (Table 3)

- ✓ The average of finished height was -20mm, thought the standard value was +-40.
- ✓ And both the maximum and minimum value passed enough. Etc.

Table 3. Results of the accuracy

Mesurement Item			Standard value	In-house value
Flat Field elevation difference	Average	−20mm	±50	±40
	Maximum	57mm	±300	±240
	Minimun	−137mm	±300	±240
	Number of data	3880	over1point／m2 (3750points)	over1point／m2 (3750points)
	Area	3750㎡	—	—
	Number of failed data	0	within0.3% (11points)	within0.3% (11points)
Slope Field elevation difference	Average	−6mm	±70	±56
	Maximum	70mm	±300	±240
	Minimun	−144mm	±300	±240
	Number of data	1152	orer1point／m2 (928points)	over1point／m2 (928points)
	Area	928㎡	—	—
	Number of failed data	0	within0.3% (3points)	within0.3% (3points)

	Number of data within the standard value (ratio)		
	80～50%	50～20%	20%～
Variation at flat	0/3880 (0.0%)	102/3880(2.6%)	3778/3880(97.3%)
Varietion at slope	0/1152 (0.0%)	48/1152(4.1%)	1104/1152(95.8%)

3.3 Quantitative analysis of effect

We conducted a questionnaire survey on satisfaction with ICTs utilization at each 5 processes. Especially, "The management of the amount of excavation work" was the best score. And "The 3 dimensional excavation work" was the second best. The others were middle score (Figure 10). This means that the system (explained in 2.1.3), which can catch and record the data of the status of construction automatically, is much more useful than the usual method that surveyor need to survey many times constantly.

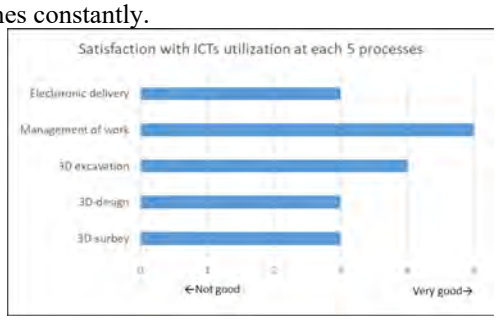

Figure 10. Satisfaction with ICTs utilization at each process

3.4 Other effects

In addition to the above, we obtained the following effects through utilization of several ICTs in this project.

1. The pictures taken by UAV made it easy to understand the whole view of the construction, so we could use it as a reference material for the meetings among the parties concerned.
2. We have improved safety as we have reduced the work done near construction machinery.
3. Young staffs were familiar with digital devices and could easily use them. (Perhaps enjoying!) This mean that we could assign young employees who don't have enough civil engineering skills this work. And this work could be done at home, so it is more efficient.

Figure11. Young staff easily used 3 dimensional data

3.5 Challenges to effectiveness

On the other hand, there were several challenges to effectiveness through the utilization of ICTs.

1. The new rule of the management of excavation work was newly created, so it was difficult to understand.
2. The excavated riverbed changed easily due to changes in water level, and the accuracy of the finished work required was normal. By relaxing the required accuracy, there is a possibility that productivity will be further improved.
3. This time, it was not a place with water flow, but when excavating in a river with water flow, a method of confirming the completed shape will be needed.

4 To conclude

Through the use of ICT in a series of processes, a certain level of efficiency and quality improvement has been achieved as a whole. Since it is a new technology and a new relationship, it is expected that the effects will be further improved by getting used to it. At that time, in order to promote the spread to smaller-scale construction, it is desirable to develop human resources for engineers who work together with both the public and private sectors.

The UAV survey this time was on flat land, but in the future it will help to expand the range of UAV utilization by developing the know-how and data for implementation on undulations and slopes.

Finally, increasing the opportunities for young people including women to play active roles by improving the work environment is very important in Japan, where the declining birthrate (declining young employee) and aging population are becoming issues. Especially in the construction industry, which was said to be 3K (KITSUI:hard, KITANAI:dirty, KIKEN:dangerous), the declining birthrate (declining young employee) and aging population are outstanding. Therefore, it is highly desired that the introduction of ICT will expand the opportunities for young people to play active roles and realize the new 3K (KYUYO:salary, KYUKA;vacation, KIBO:hope).

[a]Department of Precision Engineering, The University of Tokyo, Japan
E-mail: louhi@robot.t.u-tokyo.ac.jp

Abstract -

Concrete structures are heavily used in most modern societies and the population of structures in need of inspection is rapidly growing. On the other hand, the manpower for inspection is decreasing. This has brought into focus the need for automated inspection methods for concrete structures. The hammering test is a popular method for inspection that uses the sound resulting from a hammer impact on the surface of the structure for defect detection. Previous methods largely employed machine learning approaches for the automation of the hammering test. Weakly supervised methods used positive queries answers on sample pair similarity: a human user was questioned on the similarity of pairs of hammering samples and similar pairs were used to transform the feature space. However, it can be expected that dissimilar pairs would also be gathered in this process. Therefore, in the present paper is proposed a method for weakly supervised defect detection in concrete structures using hammering with both positive and negative answers to queries. After the initial feature space transformation based on positive query answers, another feature space transformation is introduced based on negative query answers. Experiments in laboratory conditions showed the effectiveness of the proposed method.

Defect detection; Infrastructure inspection; Weak supervision; Acoustic data; Clustering

1 Introduction

Concrete structures are featured heavily in most modern societies. This is especially true for social infrastructures such as tunnels, highways and bridges. Due to various factors ranging from simple aging to damage caused by environmental conditions, concrete structures require regular and careful inspection. This is a critical aspect for social infrastructures due to their large number of users, for which safety is of utmost concern [1]. Recent events such as the collapse of the Sasago tunnel in Japan [2] or the collapse of the Morandi bridge in Italy [3] have emphasized the issues caused by an ever-increasing population of aging structures facing an ever-decreasing population of workers tasked with inspection work.

Figure 1. A human inspector conducting the hammering test on the wall portion inside a tunnel. The hammer is used to hit the surface of the concrete structure and the returned sound used to assess the presence of defect beneath the surface.

One popular inspection method for concrete structures is the hammering test, illustrated in Figure 1. It consists in a human inspector using a simple hammer to hit the surface of the structure and assessing the presence of defects beneath the surface from the impact sound. Due to both its simplicity and non-destructive nature, it is widely popular. However, it requires a skilled human inspector to be able to distinguish impact sounds resulting from defect portions of the structures. Due to the manpower shortage and the population of structures in need of testing, the hammering test in its current, traditional form, is not effective. Therefore, the automation of the hammering test is highly sought after and has attracted much focus in recent years [4][5][6].

Previous works have mainly employed machine learning approaches to tackle this issue. Supervised learning approaches use training data to train classifiers to distinguish defect and non-defect sounds. In [7], a Neural Network was used with a Radial Basis Function in order to detect defects in concrete bridges by the sound of dragging chains. In [8], Time-Frequency Analysis was employed together with Ensemble Learning and achieved accurate classification of hammering samples into defect and non-defect classes. Furthermore, classification of defects samples into shallow and deep classes was also achieved. Supervised learning approaches often boasted remarkable per-

formance. However, they are limited by the availability of adequate training data. Indeed, if the training data does not correspond to the actual tested concrete structure, difficulties arises when attempting to produce a good model. Since concrete is an aggregate, each structure is unique and therefore, besides the fact that generating training data is a human labor intensive task, adequate training data may only be obtainable on site, i.e., on the very tested structure. This severely limits the practicability of such approaches.

Unsupervised learning methods, characterized by the fact that they to not require training data, offer an interesting alternative to this issue. In [9], clustering was used on Fourier spectrum of hammering samples with a correlation distance. In [10] and [11], clustering of audio hammering samples was considered along each hammering sample's hit location using a camera. Unsupervised learning approaches successfully bypassed the practical issue caused by training data. However, they generally have lacking performance compared to supervised learning methods in their optimal conditions. Furthermore, Unsupervised Learning approaches also incorporate strong priors, which requires careful consideration in the design phase.

Between supervised and unsupervised learning methods, weakly supervised approaches aims to combine the best of both worlds by only requiring *weak supervision*, i.e., a form of supervision which is less informative but also presents less burden on the human user than generating training data. In [12], an initial framework for the automation of the hammering test based on pairs of hammering samples a human user has indicated as similar was proposed. In [13], this initial framework was reinforced by the addition of hammering samples' hit location using a camera. In [14], an active query scheme was proposed to ensure more consistent weak supervision quality. Good results were obtained. However, only positive answers to queries were considered in those works: weak supervision is gathered from human users, through queries on sample pair similarity. Positive answers to such queries, i.e., the sample pair is similar, are known as *must-links*. Negative answers, i.e., the sample pair is dissimilar, are known as *cannot-links*. It is realistic to assume that the human user is limited in the number of queries it can answer to and while approaches such as [14] attempted to maximize the number of obtained must-links through active query, all the queries resulting in must-links cannot be ensured. This means that there will inevitably be cannot-links generated during the query process, which are not taken advantage of in previous work regarding automation of hammering test.

Therefore, in this paper, the objective is to achieve defect detection in concrete structures using acoustic data with both positive and negative answers to queries.

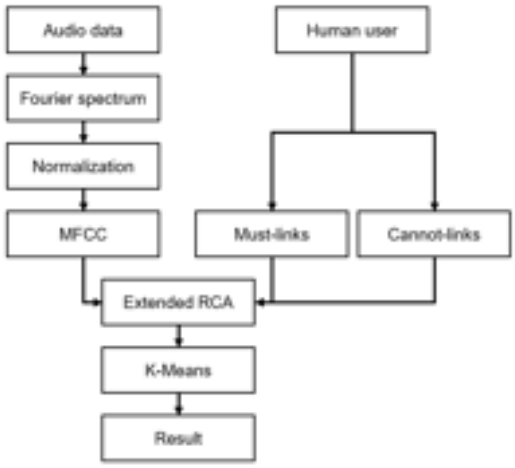

Figure 2. Overview of the proposed method.

2 Method

2.1 Overview

An overview of the proposed method is shown in Figure 2. The input, audio data, is first pre-processed: this involves a conversion to Fourier spectrum, normalization and conversion to Mel-Frequency Cepstrum Coefficients (MFCC). Then, weak supervision, provided by a human user under the form of must-links and cannot-links, is used to conduct a transformation of the feature space to match the human user's notion of similarity. Finally, separation between defect and non-defect samples is conducted by clustering using K-Means.

2.2 Initial Feature Space

Hammering samples are initially collected as audio segments. The first step of the processing is conversion to Fourier spectrum. Given a sound sample defined by $\mathbf{x} = (x_1, ..., x_d)$, its Fourier spectrum $\mathbf{a} = (a_1, ..., a_d)$ is calculated. Next, since there is no assumption about regularity of the input, i.e., the hammer strike is not assumed to be of constant force, a normalization to zero mean and unit variance is conducted as in (2), with $\bar{a}$ being the mean of the components of a_i as defined in (1).

$$\bar{a} = \frac{1}{d}\sum_{i=1}^{d} a_i, \tag{1}$$

$$a_i = \frac{a_i - \bar{a}}{\sqrt{\frac{\sum_{i=1}^{d}(a_i-\bar{a})^2}{d-2}}}. \tag{2}$$

In [10], the MFCC feature space was shown to be a good feature space for discrimination of defect hammering samples. MFCC are hand-crafted feature vectors originally

build for speech recognition and popular across several fields dealing with audio data [15, 16]. MFCC are suited for hammering samples because they emulate the human hearing and the human hearing is able to discriminate defect hammering samples from non-defect hammering samples.

To compute the MFCC, first the periodogram estimate of the power spectrum is computed. Then, what are known as Mel filterbanks, a set of N_{filter} triangular filters equally spaced in the Mel scale, are applied. The Mel scale is an empirical scale tuned to the sensitivity of the human cochlea, as in (3) with f the frequency in Hertz. The logarithm of the resulting N_{filter} energy values are further processed by Discrete Cosine Transform to finally obtain MFCC.

$$M(f) = 1125 * \ln(1 + \frac{f}{700}). \tag{3}$$

For the sake of clarity, in the remainder of this paper, the MFCC feature vector of a hammering sample will simply be noted as $\mathbf{x}$.

2.3 Weakly Supervised Feature Space Transformation: Extended Relevant Component Analysis

The feature space defined by MFCC is a good one for separating defect and non-defect hammering samples. However, improvements can be achieved by further transforming the feature space to match the human user's notion of similarity according to answers provided to queries. Those answers to queries can come in two forms: pairs of samples the human user considers similar are called must-links whereas pairs of samples the human user considers dissimilar are called cannot-links.

The previous work [14] only employed must-links through Relevant Component Analysis (RCA). RCA is a weakly supervised metric learning method initially proposed in [17]. While the authors in [17] puts the fact that RCA is only based on must-links as an advantage, as must-links are easier to generate compared to cannot-links, in practice it can be reasonably expected that the human user answering queries would be limited in the number of queries he can answer to, rather than in the number of must-links he can provide. This means that the querying process is very likely to produce cannot-links along must-links. Therefore, not using cannot-links to contribute to the feature space transformation is wasteful.

Extended RCA is an extension of the original RCA initially proposed in [18]. The feature space transformation matrix build upon must-links $\mathcal{M}$ differs slightly from what is used in RCA, as shown in (4). This allows to build a similar transformation matrix on the set of cannot-links C as well, as in (5).

$$\hat{\mathbf{C}}_{\mathcal{M}} = \frac{1}{2|\mathcal{M}|} \sum_{(\mathbf{x}_i, \mathbf{x}_j) \in \mathcal{M}} (\mathbf{x}_i - \mathbf{x}_j)(\mathbf{x}_i - \mathbf{x}_j)^T, \tag{4}$$

$$\hat{\mathbf{C}}_{C} = \frac{1}{2|C|} \sum_{(\mathbf{x}_i, \mathbf{x}_j) \in C} (\mathbf{x}_i - \mathbf{x}_j)(\mathbf{x}_i - \mathbf{x}_j)^T, \tag{5}$$

$$\mathbf{y}_i = \hat{\mathbf{C}}_C^{1/2} \hat{\mathbf{C}}_{\mathcal{M}}^{-1/2} \mathbf{x}_i, \quad 1 \leq i \leq N. \tag{6}$$

Therefore, given a dataset containing N samples, each sample $\mathbf{x}_i$ is first linearly transformed to $\mathbf{y}_i^{'} = \mathbf{C}_{\mathcal{M}}^{-1/2} \mathbf{x}_i$, using must-links, and then linearly transformed again to $\mathbf{y}_i = \mathbf{C}_C^{1/2} \mathbf{y}_i^{'}$, using cannot-links this time, as in (6). The transformation based on $\hat{\mathbf{C}}_{\mathcal{M}}$ aims to reduce the within-class scatter while the transformation based on $\hat{\mathbf{C}}_C$ aims to increase the between-class scatter.

2.4 Clustering

After the weakly supervised feature space transformation described in the previous section, separation of hammering samples between defect and non-defects is conducted using K-Means [19]. K-Means is simple iterative clustering algorithm that aims to achieve a partitioning of the dataset by minimizing the variance of each cluster S_k. Algorithm 1 shows a pseudo-algorithm of K-Means.

3 Experiments

Experiments were conducted in laboratory conditions using concrete test blocks containing simulated defects. The used setup is illustrated in Figure 3. The blocks were hit on several locations, once per location, using a KTC UDHT-2 hammer (head diameter 16 mm, length 380 mm, weight 160 g). This hammer is commonly used in actual inspection sites. Audio recording was done using a Behringer ECM8000 microphone fixed roughly at 0.5 m from the concrete test block and coupled with a Roland

Algorithm 1: Pseudo-algorithm of K-Means.

Data: Dataset D of N samples $\mathbf{y}_i$,
number of clusters K
Result: Partition of D into K clusters
Initialization:
Initialize cluster centroids $\mathbf{c}_1$,$\mathbf{c}_2$,...,$\mathbf{c}_K$ randomly;
while termination criterion not met **do**
Assign samples:
for each sample $\mathbf{y}_i$
$l_i \rightarrow \underset{k}{\text{argmin}} \|\mathbf{y}_i - \mathbf{c}_k\|^2$
Update centroids:
for each centroid $\mathbf{c}_k$
$\mathbf{c}_k \rightarrow \frac{1}{|S_k|} \sum_{\mathbf{y}_i \in S_k} \mathbf{y}_i$
end

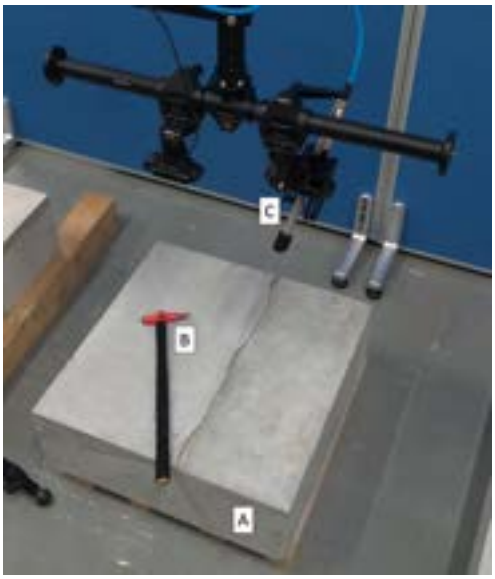

Figure 3. The experimental setup in laboratory conditions with (A) a concrete test block containing a simulated defect, (B) a hammer and (C) a microphone to record the hammering sound.

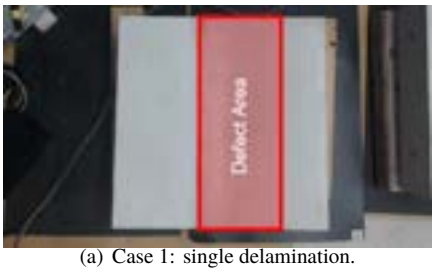


(a) Case 1: single delamination.

(b) Case 2: dual delaminations.

Figure 4. Concrete test blocks used in laboratory experiments containing man-made defects. Defect areas are therefore precisely known and indicated by light red overlays.

UA-25EX sound board at 44.1 kHz. MFCC were computed with $N_{filter} = 26$ and 10 coefficients. 30 queries were allowed for each run.

Two scenarios were considered, those are the same as featured in [14] and the setting $K = 2$ was used for both:

- Case 1: single delamination. This dataset contains 462 samples: 272 non-defects and 190 defects. The delamination is at an angle of 30 degrees.
- Case 2: dual delaminations. This dataset contains 270 samples: 155 non-defects and 115 defects. Two delaminations are present, both at an angle of 15 degrees.

A picture for both cases is provided in Figure 4.

4 Results and Discussion

In Table 1 is reported the average number of must-links and cannot-links obtained out of 30 queries over 50 runs. About half of the queries effectively resulted in cannot-links, which are essentially wasted queries for previous approaches. Since sample pairs were queried randomly, the ratio of must-links and cannot-links reflected approximately the datasets' ratio of defect/defect, non-defect/non-defect pairs and defect/non-defect pairs.

In Figure 5 are reported the average performance obtained over 50 runs in both considered cases for the approach of [12] and the proposed method. Error bars correspond to one standard deviation. The performance was measured using the Rand index [20]. The Rand index is a common measure of performance for clustering methods and is essentially a ratio of correctly clustered sample pairs over the total number of sample pairs in the dataset. It ranges between 0 and 1, with higher values of Rand index indicating the better clustering.

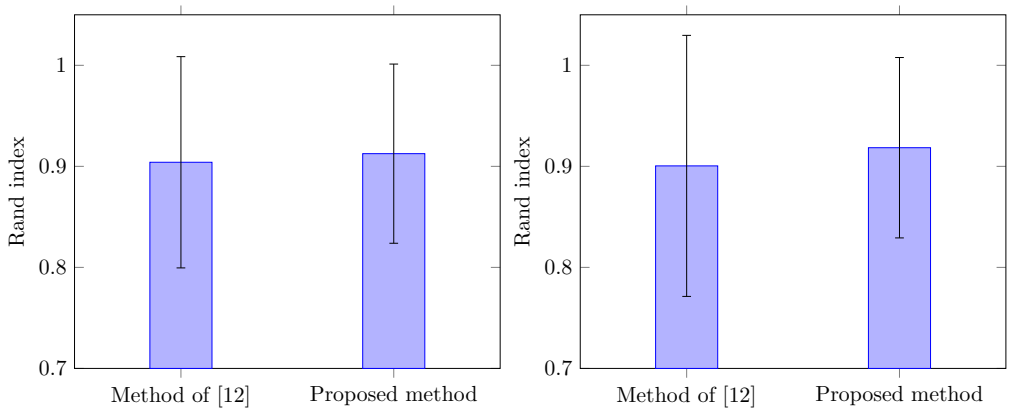
For both Case 1 and Case 2, it can be noticed that the proposed method achieved better clustering on average than the method of [12]. The spread of the output seems to be also narrower for the proposed method, indicated by lower values of standard deviation. This is especially noticeable for Case 2. This is certainly due to the increased number of constraints used in the feature space transformation by the proposed method, defining more precisely the target feature space.

The performance of the method of [12] on Case 1 is significantly lower than reported in the initial publication. This is due to the difference in number of effective must-links: while 20 must-links were allowed in [12] whereas in the present paper 30 queries were allowed, resulting in about only 15 must-links in average. This indicates that, depending on the dataset, a significantly larger number of queries is potentially required to obtain the desired number of must-links.

With the same number of must-links, the proposed method, that makes use of cannot-links as well, does perform better. However, the performance increase enabled by the additional feature space transformation computed based on cannot-links does not bring as much improvement

Table 1. Average number of constraints of each type over 50 runs for 30 allowed queries.

	Number of allowed queries	Average number of obtained must-links	Average number of obtained cannot-links
Case 1: single delamination	30	15.01	14.99
Case 2: dual delaminations	30	15.41	14.59



(a) Case 1: single delamination. (b) Case 2: dual delaminations.

Figure 5. Performance of the method of [12] and the proposed method. Average over 50 iterations reported, error bars correspond to one standard deviation. 30 queries were allowed and random seeding was used for each run.

per constraint compared to must-links. This potentially indicates that must-links are more informative and better suited for fine-tuning the feature space, at least within the RCA framework.

5 Conclusion

In the present paper was proposed a method for defect detection in concrete structures using acoustic data based on both positive and negative constraints. Using Extended RCA, an additional feature space transformation based on negative constraints was conducted following the first feature space transformation using positive constraints. Experiments in laboratory conditions using concrete test blocks showed that the proposed method achieved better results more consistently than the previous method that only used positive constraints.

As future work, we would like to further study the influence of negative constraints on the final feature space. As unavoidable by-products of the querying process, cannot-links should be employed to maximize the data provided by the human user. However, a straight inclusion of those negative constraints in the RCA framework might not be their only use. For example, negative constraints obtained early in the query process could be used in the selection process for the next sample pair to query the human user on.

Abstract –

In road maintenance, it is necessary to construct an environment that manages 3D data and maintenance information for its effectivity and efficiency. Engineers should be able to use 3D data not only for virtually reviewing the design of a facility, but also for analyzing building operations and performance. Using 3D data will thus improve the efficiency of operations and maintenance.

The primary objective of this research is to support road maintenance work using 3D data by combining point cloud data of terrestrial laser scanning (TLS) and unmanned aerial vehicles (UAV) with photogrammetry. TLS and photogrammetry technologies were used to survey pavement, landform, and bridge of road structures.

This research evaluated the accuracy of the usage of point cloud data by TLS and photogrammetry for road maintenance. This method can be used to check potholes and surface irregularities on pavement that can be easily and quickly confirmed by management. To evaluate the accuracy of 3D data of the bridge, we compare the 3D data with its design conditions. The 3D data describes the structure with high accuracy.

The 3D data could be used to develop a road maintenance management system that accumulates data and refers to the inspection results and repair information. The system can link inspection results and recondition information with the point cloud data for display, storage, and reference, facilitating the management of road cracks and areas for repair. The prototype system was developed using Skyline Terra Explorer Pro. It was visualized constructed 3D data on temporal sequence.

1 Introduction

Roads must be safe and maintained in good condition. Maintenance management is an essential operation that must be carried out effectively for maintaining, repairing, and rehabilitating roads. It is important to protect roads from large-scale damage and to carry out road maintenance in order to maintain services for the public. In addition, it is necessary to accumulate information produced during the entire life cycle of a road in order to analyze problems and solutions within a temporal sequence and to maintain roads strategically and effectively. In Japan, much road infrastructure was built over fifty years ago. Due to progressive deterioration in road infrastructure, ensuring proper maintenance of overall facilities to avoid potential problems is currently an important issue. In particular, in order to avoid or reduce substantial loss, deal with an emergency, prevent damage, perform emergency disaster control, and carry out disaster recovery, road administrators must maintain roads more efficiently. In current maintenance work, road administration facilities are represented on a 2D map, which is not suitable for pothole repair, inspection, or annual overhaul. Locating and analyzing a position can be difficult when using such a map.

There are many reported cases of damage to aging road structures. Existing structures are generally maintained rather than rebuilt, but blueprints and completion drawings may be unavailable for road structures that have been in service for a long time, and existing drawings may no longer reflect the current situation, hindering inspections and repairs [1]. To realize appropriate road maintenance, it is important to share information among all stakeholders, and easily shared 3D data with high visual fidelity are effective means toward this end. A road management system comprises functions for planning, design, construction, maintenance, and rehabilitation of roads. A fundamental requirement of such a system is the ability to support the modeling and management of design and construction information, and to enable the exchange of such

information among different project disciplines in an effective and efficient manner.

With the introduction of unmanned aerial vehicles (UAVs) and terrestrial laser scanners (TLS) in the "i-Construction" policy being promoted by the Japanese Ministry of Land, Infrastructure, Transport and Tourism, there will be increased use of 3D data in the future. Dense point cloud data were generated using three and over pictures which taken same points [2], [3]. Agarwal et al. and Frahm et al. were constructed 3D city by automated reconstruction [4], [5]. The 3D point cloud data are constructed on the basis of the Structure from Motion (SfM) range-imaging technique of photogrammetry using video camera data. The accuracy of 3D model by SfM were evaluated by several researches [6]. And, the generated point cloud data which measured the objects from several measurement points are integrated for representing the accurate objects. The integration method of point cloud data is iterative closest point method (ICP) [7], globally consistent registration method of terrestrial laser scan data using graph optimization [8], curve matching [9], [10], and automated registration using points curve [11].

However, there are outstanding issues related to TLS measurements. In particular, selection of appropriate measurement positions is difficult, data loss can occur, and increasing the number of measurements to obtain more detailed data increases measurement and data-processing times. Further, maintenance management systems for use of the generated 3D data are still under development. Data processing software differs according to the equipment used, and data storage can be complex.

In this study, we performed TLS, UAV, and camera measurements on road pavement, bridges, and slopes with the aim of realizing 3D data for road maintenance. We also devised a method for constructing 3D data for structures lacking existing drawing information. To do this, we attempted measurement methods and data generation for constructing highly accurate 3D data for a bridge from a small number of measurements. We also investigated functions for collectively managing the generated 3D data and visualizing results of inspecting the 3D data.

2 Use Cases of 3D Data

There are a number of survey methods for constructing 3D data using laser imaging detection and ranging (Lidar; laser profiler), laser-based photogrammetry, mobile mapping system, terrestrial laser scanning, and photogrammetry using a camera by UAV. Combining these survey methods according to site situations and structures enables surveys of civil infrastructure and construction of 3D point cloud data. It is necessary to understand the characteristics and specifications of the specific measurement instruments and choose suitable point cloud data for a use case for a road maintenance site.

In this research project, terrestrial laser scanning and UAV-based photogrammetry are used for usage scenes as shown in Figure 1. Usage scene 1 visualization of inspection results; Usage scene 2 visualization of damage on the structures; Usage scene 3 information management of inspection and damage; Usage scene 4 landslide; Usage scene 5 superposition of 3D data.

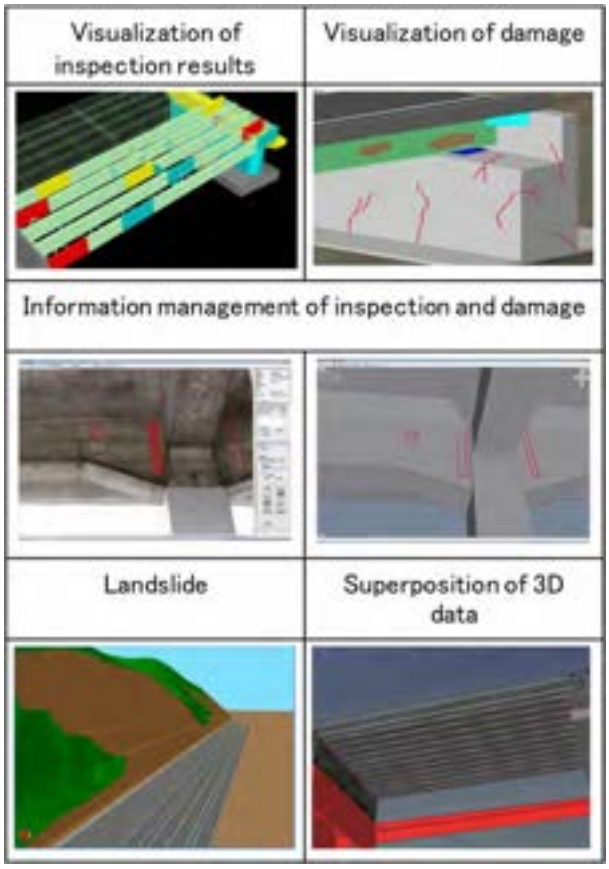

Figure 1. Usage scenes of 3D data

3 Measurement and Construction of On-site 3D Data

3.1 3D Data Measurements Using Multiple Devices

In addition to TLS and UAV images as used in our previous study [12], here we used SfM technologies to generate point-cloud data from camera images and combined the images and data to generate high-density 3D data. Equipment used were a laser scanner (Focus

3D X 330; FARO), a UAV (Inspire2 with mounted Zenmuse X5S camera; DJI), and a handheld camera (GoPro Hero6 Black; GoPro, Inc.).

3.2 Pavement Surface Measurement and 3D Data Construction

We performed TLS measurements in September 2019 on paved surfaces along the Shiraito Highland Way in Karuizawa, Nagano Prefecture. The Focus 3D X330 can perform high-density measurements of road surfaces over a range of about 10 m [12], so we measured 16 points at 20-m intervals based on an approximate 10-m radius, and constructed 3D data using the FARO SCENE data processing software. Figure 2 shows the 3D data of the pavement. To reduce the burden of image-joining tasks, we used triangular cones at 10-m intervals as targets during measurements. This reduced time required for joining tasks as compared with data construction in our previous study [12], but it was difficult to specify points in the 3D point-cloud data. In future studies we will investigate use of planar objects such as spheres and cylinders as feature points when combining images.

In combination with data collected in 2018, 3D data were constructed for a road length of about 580 m in Figure 3. The average error for point-to-point distances for joining locations in the measurement data was 4.7 mm, which was better than the accuracy of 8 mm required in this study. As reference points within the measurement range, we used slopes calculated from horizontal and vertical distances listed in the Shiraito Highland Way Toll Road Reference Point Survey and measured points near the reference points in the point cloud data. Comparing the obtained gradients showed differences of less than 0.5%, indicating that the gradients were essentially the same.

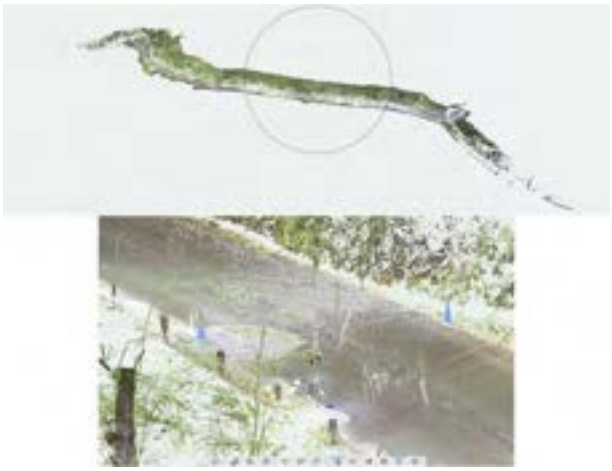

Figure 2. Joined road surface data

Figure 3. Joined FY2018 and FY2019 3D measurement data

3.3 Slope Measurement and 3D Data Construction

UAV measurements was performed in September 2019 on slopes of the Shiraito Highland Way in Karuizawa, Nagano Prefecture. Video images were extracted at 1-s intervals, and used the Metashape software package (Agisoft) to perform SfM processing on a computer with an Intel Core i9-9900X CPU, an NVIDIA GeForce RTX2070 GPU, and 64 GB RAM. The open-source point-cloud editing software package CloudCompare was used to overlay data constructed in FY2017, 2018 [12], and 2019 and performed differential analysis. Figure 4 shows the results, which indicate that the amount of accumulated sediment in the upper part decreased and that in the lower part increased in 2018 as compared to 2017, suggesting that sediment is flowing downward over time.

3.4 Bridge Measurement and 3D Data Construction

Measurements using TLS, UAV, and on-ground cameras were performed in July 2019 at the Warazuhata Bridge in Sennan, Osaka. We performed TLS measurements at six locations around the bridge, and combined data measured from pairs of diagonal points across the bridge with the 3D data constructed by SfM processing of images captured by the UAV and the camera in Figure 5. The upper figure of Figure 5 shows 3D data created by combining TLS and UAV photogrammetry. The lower figure shows 3D data created by combining data created from TLS and handheld camera images. As a result, we were able to provide data for the superstructure and the abutment sections, which were missing in the 3D data constructed from the two-sites TLS measurements, and we could construct 3D data showing the bridge length and width. For the bridge length and width, we compared measurement results in the 3D data constructed from the six TLS measurements with design specifications from the Kishiwada Civil Engineering Office and with on-site measurements. Table 1 shows the results, which suggest that the 3D bridge data constructed in this study has a

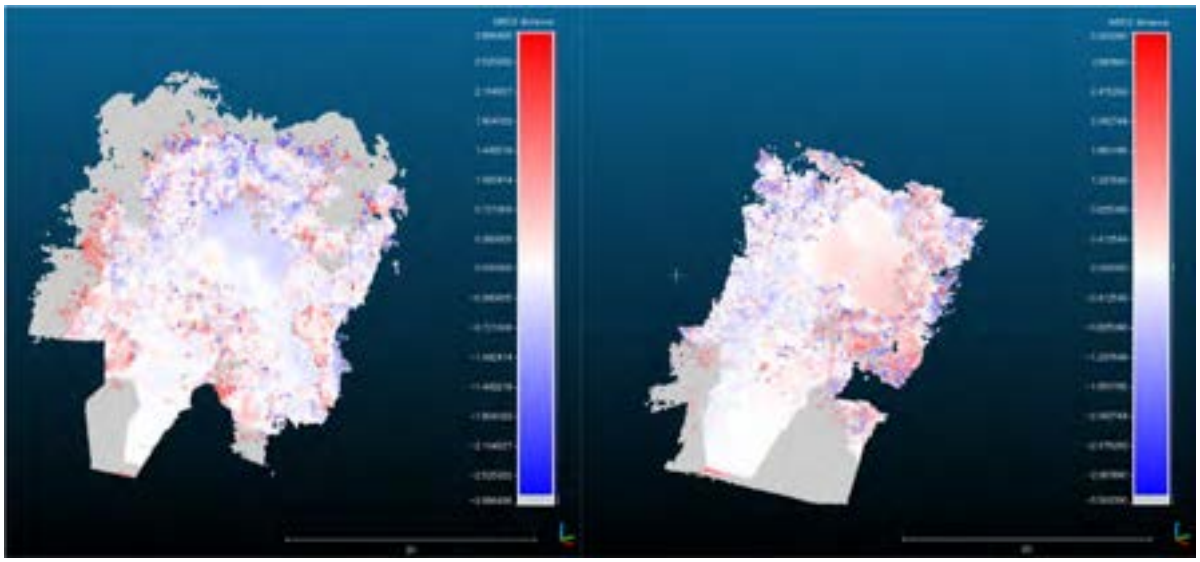

Figure 4. Differential data for (upper) FY2017 and 2018 and (lower) 2018 and 2019

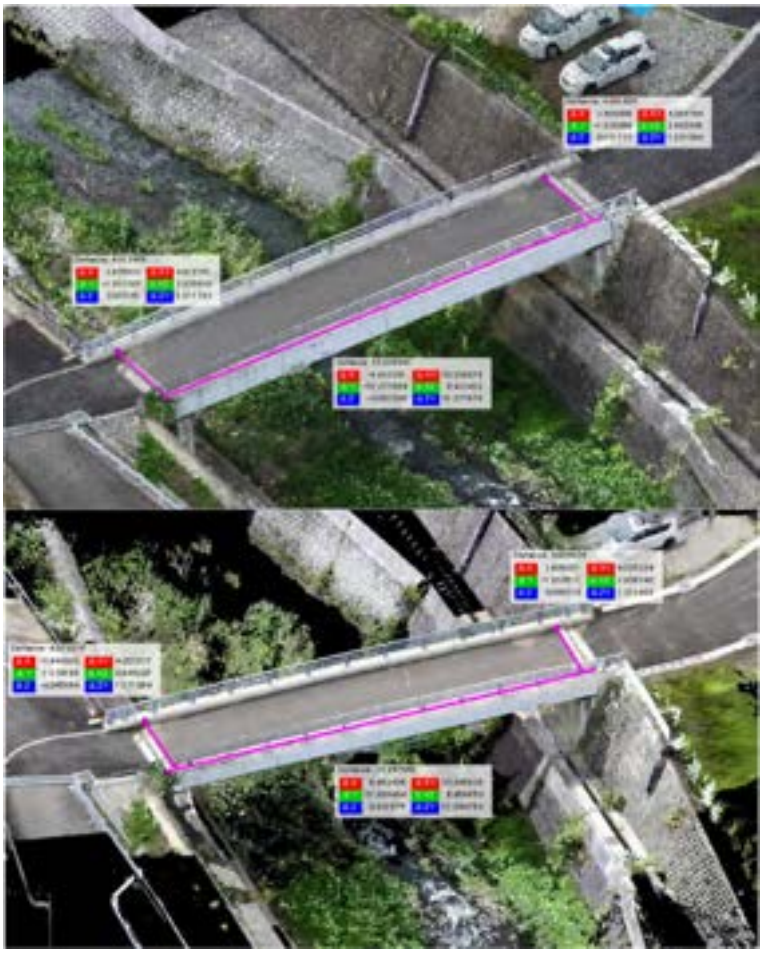

Figure 5. (Upper) 3D data combining TLS and UAV photogrammetry and (lower) 3D data combining data created from TLS and handheld camera images

level of development of around 200 as indicated in the level of development for three-dimensional model in civil engineering (Draft) [13].

The time required for TLS measurements at six locations was about 2 hours, while the time for two locations was about 40 min. In contrast, the UAV photography time was about 15 min including preparation and GoPro shooting time was about 10 min, suggesting their potential for shortening on-site measurement times.

To construct 3D data with location information, in November 2019 we took a series of photographs with a GoPro camera capable of acquiring location information at an unnamed bridge in Niigata City, Niigata Prefecture, and performed SfM processing to construct 3D data in Figure 6. Selecting an arbitrary point in the 3D data shows the latitude and longitude for that point. The data do not have the ground control points. The data were set using the latitude and longitude of GPS of GoPro camera. We arranged it using aerial photograph.

Table 1. Comparison of measured lengths and widths

	Length (m)	Width (m)
Design specifications	22.200	4.000
On-site measurement	22.253	4.025
TLS (6 locations)	22.258	4.013
TLS (2 locations) and UAV	22.229	4.052
TLS (2 locations) and camera	22.247	4.024

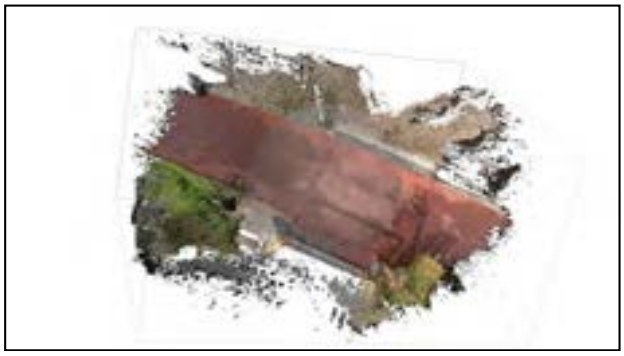

Figure 6. 3D data from SfM processing for a bridge

4 GIS Visualization of 3D Data

The 3D point cloud data for the road pavement surface and the bridge could be used to develop a road maintenance management system that accumulates data and refers to the inspection results and repair information in three dimensions.

An information system for road maintenance is proposed in this research project. This chapter discusses the information system, which uses point cloud data based on the definition of an information system. By definition, an information system collects, processes, transfers, and utilizes information in its own domain. Figure 7 depicts the definition of a road maintenance information system using point cloud data. A road maintenance system was considered based on the definitions within an information system. The road maintenance system can link inspection results and recondition information with the point cloud data for display, storage, and reference, facilitating the management of road cracks and areas for repair. In future work, point cloud data will be used to identify changes in the shape and condition of damage through spatial and temporal management.

Figure 7. Definition of road maintenance management system

4.1 Information Collection

Point cloud data for road infrastructure are collected using terrestrial laser scanning and UAV-based photogrammetry. In addition, maintenance and operation data, such as for inspection, rehabilitation, and repair, are collected on-site for the system.

4.2 Information Processing

Point cloud data generated by TLS contain noise data concerning trees and vegetation on a road. In information processing, such objects should be removed in order to represent road structures accurately. terrestrial laser scanning's survey range is confined to the visible range and the scan range of the scanner; therefore, it contains blind spots that are not represented

by the point cloud data cloud. Accordingly, surveyors need to move the scanner to multiple locations across a number of points in time. UAVs can acquire photographs or videos in-flight. Such visual records are used for SfM software and translated point cloud data. In addition, the point cloud data are colorized for visualization.

4.3 Information Transmission

TLS and UAV-based photogrammetry each have distinct characteristics with respect to survey time cost, scan range, and accuracy. Wide area and high precision point cloud data are generated by combining each set of data units. In addition, in this process, structural members and surface data, such as a triangulated irregular network, are extracted and generated in accordance with the purpose of usage. Furthermore, it is also possible to compare two different temporal data units for analysis.

4.4 Usage of Information

In this research project, instead of a surface model, point cloud data are used for road maintenance. A road maintenance information system is proposed, which has functions for detecting cracks and superimposing photographs based on point cloud data. In addition, a function is needed for reflecting inspection and repair events that have been represented on a two-dimensional map displayed on a smart device onto 3D point cloud data on-site. In the road maintenance system, the inspection result and repair information can be linked with 3D point cloud data and displayed, stored, and referenced. It is easy to detect road cracks and spots in need of repair. In addition, it is possible to determine changes in shape and damage using temporal management of point cloud data.

We arranged the constructed 3D data using absolute GIS coordinates, storing these data with corresponding inspection results. This should allow road managers to better grasp topographical information for the surrounding area and to store positional coordinates for stored locations, leading to more efficient maintenance. By road managers performing regular inspections and confirming and comparing 3D data before and after a disaster, this function can be applied to grasping the damage situation. We used Terra Explorer Pro (Skyline Software Systems) as GIS software for displaying 3D data. Absolute coordinates for road pavement and slopes were given using the “Align two clouds by picking (at least 4) equivalent points pairs” function in Cloud Compare and displayed on a 3D map. Because 3D data for the Warazubata Bridge did not have position coordinates and thus could not be displayed at an arbitrary position, we manually set latitudes, longitudes, and altitudes in reference to aerial photographs. Regarding the 3D data for the unnamed bridge in Niigata, comparing bridge positions on Google Earth showed no significant differences for latitude and longitude, but there were large displacements for altitudes, causing the 3D data in the map display to appear as if floating in air. We therefore corrected positions in reference to aerial photographs. Displaying the 3D data on a map confirmed cracks in the paved surface, and 3D data from two different periods could be displayed in Figure 8 and 9. These figures show the registration function of the system for accumulating the inspection and damage information on the point cloud data.

Figure 8. 3D Road surface data display in the system

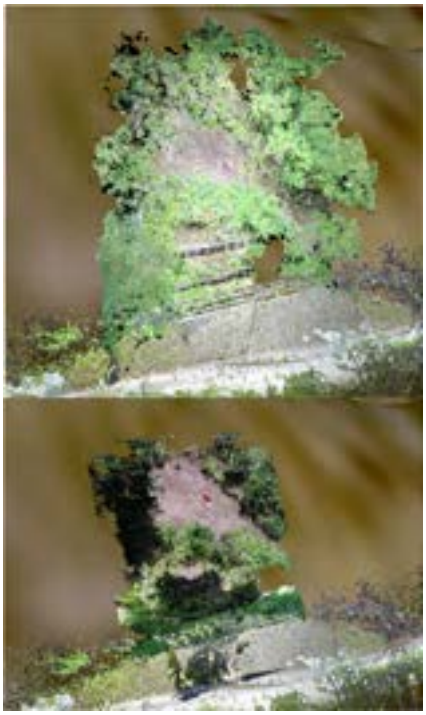

Figure 9. 3D land form data display in the system

5 Conclusion

In this study, we investigated a system for using TLS, UAV, and cameras to construct 3D data for road pavement, slopes, and bridges. The system provides absolute coordinates, displays them on a 3D map, and can store and reference inspection results at any location. Future tasks will include improving the efficiency of overlaying 3D data constructed in different years by setting positioning points during measurements, and creating 3D data with positional information for measurements of sediment runoff.

Abstract –

Approximately a half century has passed since the construction of expressways in Japan, and expressways have become decrepit over the decades. In order to ensure safety and security of expressways for the next generation, expressway companies have been carrying out large-scale renewal works of bridges and tunnels (hereinafter collectively the "renewal works" and individually a "renewal work").

Because renewal works are carried out while vehicles pass by the side of work zones, various types of safety equipment have been used to regulate traffic lanes such as rubber road cones, more rigid temporary barriers and so forth. However, speeds of passing vehicles are fast and, if a vehicle accidentally enters a work zone, rubber road cones cannot prevent from a vehicle entry which endangers workers' lives.

Therefore, East Nippon Expressway Company Limited (hereinafter "NEXCO EAST") group adopted traffic regulation technology by movable barriers, the Road Zipper System (hereinafter "the RZS"), for renewal works. Using the RZS is aimed at improving workers' safety by prevention of accidental vehicle entries and alleviating traffic congestion by more efficient traffic regulation.

This paper examines effects of the RZS introduction, enhancement of safety and prevention of traffic congestion associated with the use of the RZS in traffic regulations and lane reconfigurations according to the time of day, as well as future developments.

Keywords –

expressway; traffic regulation technology; traffic regulation for construction works; lane regulation; lane management; movable barriers; Road Zipper System; safety and security; traffic congestion alleviation; traffic congestion prevention

1 Introduction

The RZS is the lane management system by a Barrier Transfer Machine (hereinafter "BTM") transferring crash-tested barriers from one side to another (Figure 1).

The RZS is a system from a company in the USA, Lindsay Transportation Solutions LLC (hereinafter "LTS"). Nexco-East Innovation & Communications, one of NEXCO EAST group subsidiaries, is appointed to sell and lease BTMs and related products to expressway companies in Japan, based on a formal agreement with LTS.

Figure 1. BTM working situation abroad

An overview of the RZS is transfer of barriers from one side to another through an S-shaped conveyor mounted at the sides and bottom of a BTM (Figure 2 and 3).

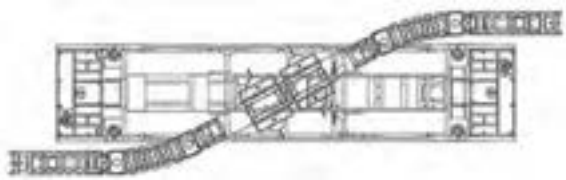

Figure 2. BTM Conceptual Diagram [1]

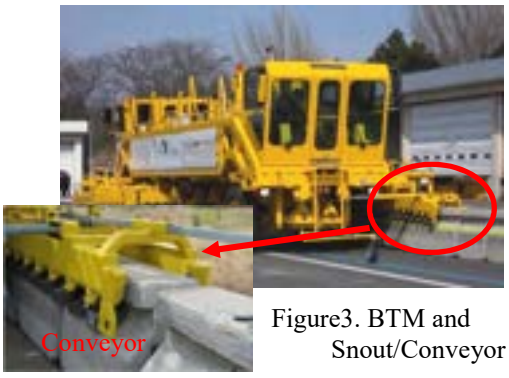

Figure3. BTM and Snout/Conveyor

There are three types of barriers used in the RZS. The main barrier is Concrete Reactive Tension System (hereinafter "CRTS") which is composed of reinforced concrete. (Figure 4).

Other than CRTS, there is a steel barrier called a Variable Length Barrier (hereinafter "VLB") which extends and contracts to adjust a shape and vertical grade of road and is set at regular intervals in alignment of CRTSs (Figure 5). The final component is a crash cushion installed at ends of the CRTS barrier alignment so as to absorb impact of a vehicle crash (hereinafter "Absorb") (Figure 6). There does exist different options within the RZS, but the systems deployed in Japan currently are referenced above and illustrated below.

Figure 4. CRTS

Figure 5. VLB

Figure 6. Absorb

2 Examination for RTS introduction

NEXCO EAST conducted a demonstration experiment on Joban Expressway from April through July in 2016 so as to confirm and examine effectiveness of the RZS for its future introduction in Japan (Figure 7).

Figure 7. Demonstration Experiment
(Left: rubber road cones Right: the RZS)

From the experiment, two results turned out superiority of the RZS in comparison to conventional equipment, rubber road cones.

The outcomes were found from image analyses; lanes were regulated by rubber road cones and the RZS respectively on the expressway, and three fixed cameras on over bridges and tracking cameras set up on a car for cone installation and a BTM captured vehicles' behavior while the vehicles were passing by the regulated lanes.

One result is the ratio of drivers' avoidance behavior to keep a distance from regulation equipment during installment and removal at night by the RZS was approximately 15% lower than by rubber road cones.

Another is the ratio of drivers stepping on the brakes while lanes were regulated at night by the RZS also turned out to be lower than the one of rubber road cones (Figure 9).

Those two results show the RZS ensures a higher level of safety and security towards vehicles and drivers.

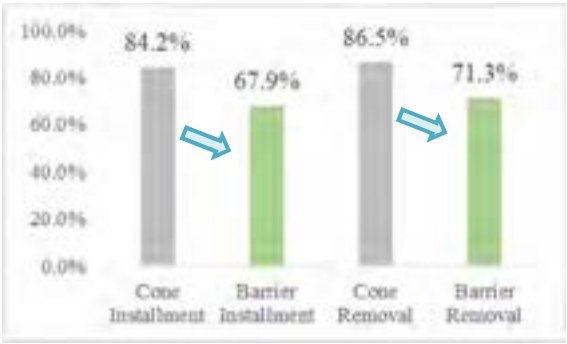

Figure8. Comparison of drivers' avoidance behaviour between uses of rubber road cones and the RZS barriers during instalment and removal [2]

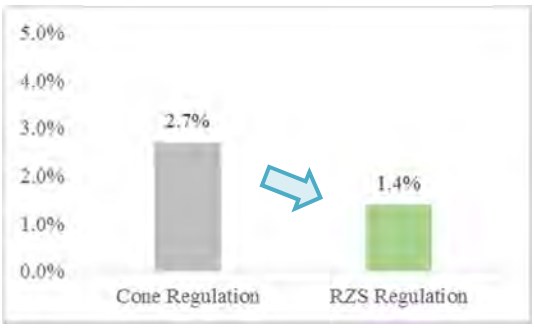

Figure 9. Comparison of drivers' actions of stepping on the breaks between uses of rubber road cones and the RZS barriers [2]

Consequently, NEXCO EAST fully introduced and utilized the RZS for traffic regulations for construction works in some projects such as construction of Tokyo-Gaikan Expressway and additional lane construction of Kan-etsu Expressway in Kanto Regional Head Office. In addition, the RZS has been used in several renewal works for regulating and opening lanes quickly and efficiently, and assuring safety and security.

The next chapter shows concrete examples of full introduction and utilization of the RZS with backgrounds, processes and evaluations.

3 Full introduction and utilization of the RZS

3.1 A renewal work of Shimamatsugawa Bridge of Hokkaido Expressway

Sapporo Operation Office, Hokkaido Regional Head Office of NEXCO EAST utilized the RZS for lane managements and regulations in order to alleviate traffic congestion in a renewal works, the project of floor slab replacement, at Shimamatsugawa Bridge.

About 47 years had passed since the Bridge opened and the Bridge severely deteriorated due to anti-freezing agents and some other influences.

3.1.1 Outline of the project site

The Shimamatsugawa Bridge is located between Eniwa Interchange (Interchange is used as an entrance and exit of an expressway. hereinafter "IC") and Kitahiroshima IC of Hokkaido Expressway (Figure 10).

The section between the two ICs is an important route and part of expressways in Hokkaido because it connects New Chitose Airport, the gateway of Hokkaido, and Sapporo, a major city.

A daily traffic volume of both up and down lanes between the two ICs is approximately 40,000.

Figure10. Location of Shimamatsugawa Bridge [3]

3.1.2 Traffic Regulation Examination

Since the section of the project site is considered to be important, it is difficult to close both up and down lanes for a long term. Therefore, the method regulating a down lane and dividing into two-way traffic was adopted while the floor slab replacement of up lanes were carried out.

Regarding to traffic characteristics in the section on Monday through Saturday, traffic volume rises in the morning on the up lane from Sapporo to New Chitose Airport, and the peak time is mostly at around 7 am.

This is associated with passengers using New Chitose Airport and commercial vehicles which are mainly from Sapporo. On the other hand, traffic volume increases in the afternoon on the down lane from New Chitose Airport to Sapporo, frequently at around 6 pm.

As clearly shown, there is a significant difference of hourly traffic volume between up and down lanes; the volume of one lane at peak time on both lanes surpass a traffic capacity (1,400 unit per hour) therefore it was predicted traffic congestions would happen every single day (Figure11).

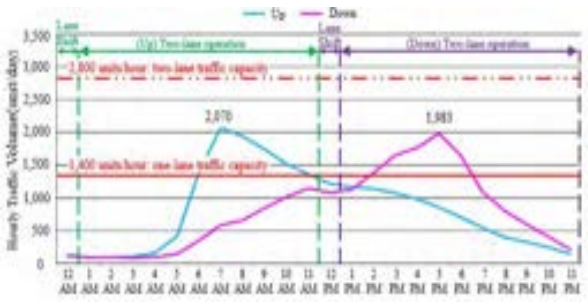

Figure11. Hourly traffic volumes of the up and down lanes between Eniwa IC and Kitahiroshima IC on weekdays [3]

On the purpose of traffic congestion prevention, three traffic lanes were ensured on the down lane by narrowing the width of road shoulder from 1.25m to 0.5m and traffic lanes from 3.50m to 3.25m.

A combination of two lanes and one lane for the up and down lanes were shifted by time of day from Monday through Saturday depending on the traffic characteristics (Figure 12).

Traffic volume of the up lane in Sunday afternoon does not go below the one-lane traffic capacity, hence two lanes were open operated as the up lanes so as to ensure access punctuality to New Chitose Airport.

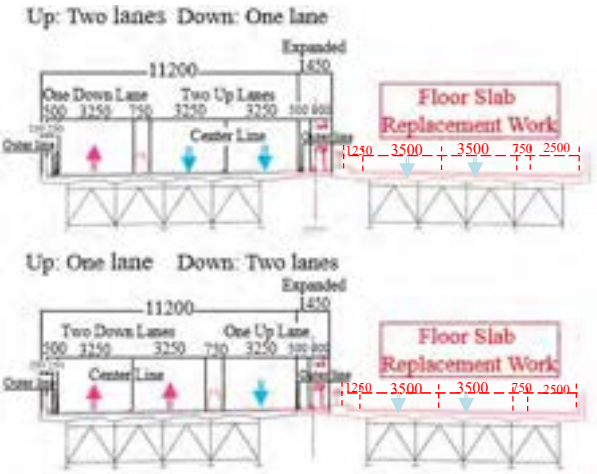

Figure12. Lane management cross-section view (unit: mm) [3]

With regard to daily lane shifting in two-way traffic, traffic administrator had an opinion towards a usage of conventional regulation equipment, rubber road cones, as temporary central median for two-way traffic regulation: there is a high risk of head-on vehicle collision in the heavy traffic section.

In addition, it is impossible to shift lanes by rubber road cones without expressway closure. In order to resolve and adjust the problem, the RZS was put on the table to ensure safety of vehicles and streamline lane regulation work since the RZS have proven records of lane managements and shifts in other countries.

The regulation plan of the renewal work was reviewed and changed to the one by the RZS: using temporary medians composed of barriers and transferring them by time of day for lane shifts. In the end, with the consent of traffic administrator, the RZS was adopted for the first time in Japan to regulate traffic by shifting lanes from one to two and vice versa on the expressway.

3.1.3 Traffic Regulation Operation by the RZS

Traffic regulations were implemented during the period from May 29th to July 12th, 2018, except for Sundays, by shifting the number of up and down lanes between 12 pm and 1 pm and 12 am and 1 am in a day by transferring temporary center median composed of barriers (Figure13 and 14).

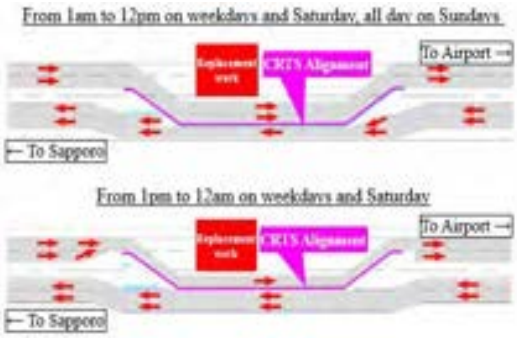

Figure13. Illustration of lane shiftting [3]

Figure14. Lane shifted by the RZS

3.1.4 Result of Traffic Regulation by the RZS

The results of traffic regulation by the RZS came out as follows.

- If conventional two-way traffic regulation was implemented, the estimated number of days and maximum length of traffic congestion during the project period would be 37 days and 18 km on the up lane and 27 days and 18 km on the down lane, while the actual occurrences of traffic congestion were 0 days and 0 km on the up lane and 6 days and 3.4 km on the down lane.
- On holidays, the estimation of number of days and the maximum length of traffic congestions were 5 days and 14 km on the up lane and 6 days and 8 km on the down lane. However, the actual number of days and maximum length were 0 day and 0km on the up lane and 6 days and 5.1km on the down lane.

The RZS contributed to safety of drivers by alleviation of traffic congestion compared to prediction both on weekdays and weekends, and reduction of major accidents by blocking breakthrough of temporary central medians.

3.2 A renewal work of Takase Bridge of Hokuriku Expressway

Nagaoka Operation Office, Niigata Regional Head Office of NEXCO EAST used the RZS for lane management and regulation in the project of floor slab replacement of Takase Bridge on the up line of Hokuriku Expressway in the direction to Nagaoka. About 40 years had passed since the Bridge opened and the Bridge had faced severe deterioration.

3.2.1 Outline of the project site

Takase Bridge is located right before diverging lanes of Nagaoka Junction between Nagaoka Junction and Nakanoshimamitsuke IC of Hokuriku Expressway (Figure15).

The Bridge includes a ramp (a speed change lane) of Hokuriku Expressway bound for Toyama therefore three-lane width was ensured at the site.

Figure15. Location of Takase Bridge [4]

3.2.2 Traffic Regulation Examination

The traffic volume in this section is relatively large and a cross section traffic volume of approximately 32,000 vehicles. In the case that floor slab replacement work is carried out on an up line, that up line is normally closed and two lanes on a down line are used as two-way traffic: one lane for the up and another for the down. However, it was highly predicted severe traffic congestions would happen on both of the one up and one down lane at this project site, which also requires large-scale traffic regulations.

Thus, in order to take an advantage of three-lane width of this Bridge, the floor slab replacement work was divided into three steps based on each of three traffic lanes (Figure16) and the width was reduced from 3.5m to 3.25m; two traffic lanes remained open while one lane was under the replacement work.

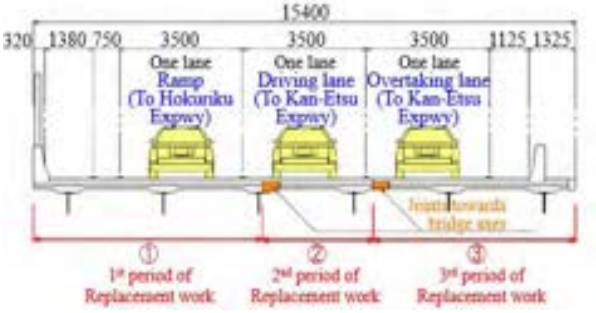

Figure16. Replacement work steps (unit: mm) [5]

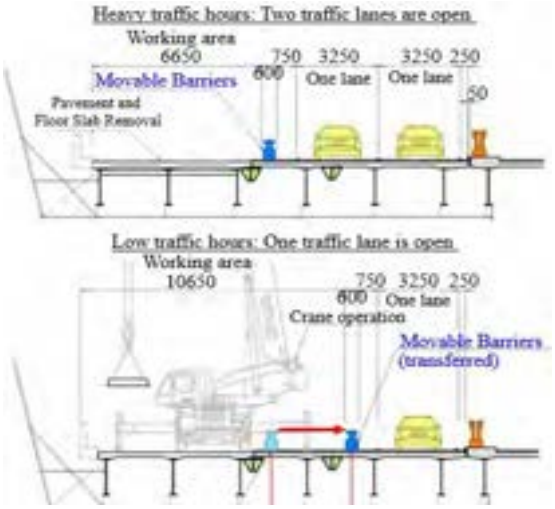

Figure17. Lane management based on hourly traffic volumes (unit: mm) [5]

By using this method, two lanes were always open while any lane was under the replacement work. Moreover, two lanes were closed for operation by a crane which requires larger working area, during time of low traffic volume, and lanes were shifted on a daily basis depending on the time of day (Figure17).

3.2.3 Traffic Regulation Operation by the RZS

For implementation of traffic regulations from the end of August to the mid of November, 2018, two driving lanes were secured from 7 am to 12 pm: the time period when hourly traffic volume is heavy on weekdays from Monday to Saturday. During the other time period from 12pm to 7 am, only one lane was open for traffic and the replacement work proceeded in the two closed lanes.

On holidays, two lanes were open from 7 am to 8 pm and one lane was designated as a traffic lane from 8 pm to 7 am the following day by RZS (Figure18 and 19).

Figure18. Traffic Management by the RZS

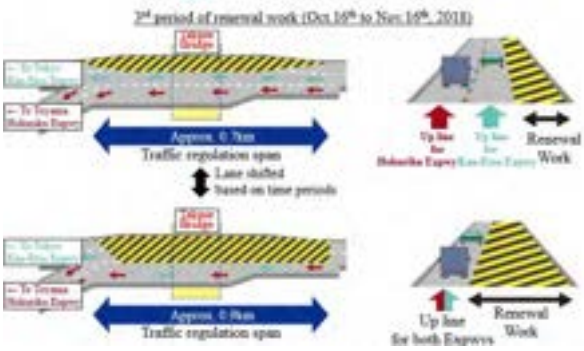

Figure19. Traffic regulation by the RZS in the 3rd period of renewal work [5]

This renewal work was completed within the scheduled period although it was difficult to manage a work process by the influence of rain on works accompanying the replacement work due to many rainy days.

During the project period, traffic congestions occurred twice and both were relatively small in scale: one is 3.0km at maximum for 30 minutes on Wednesday, September 26th and another is 1.7km at maximum for 2 hours on Saturday, October 6th.

From the perspective of congestion by traffic regulation for construction works, impacts on drivers was minimized and there were no breakthrough of temporary central medians and no major accident; hence, the RZS contributed to safety of drivers and workers..

3.3 The RZS implementation by another company, Central Nippon Expressway Company Limited

Although NEXCO EAST introduced the RZS for the first time in Japan, RZS is also used by Tokyo Regional Head Office of Central Nippon Expressway Company Limited (hereinafter "NEXCO CENTRAL") so as to regulate traffics in renewal work of Tomei Expressway.

They introduced the RZS in order to prevent serious accidents caused by breaking through temporary central medians, and to shorten a period of time for installment and removal of barriers used as the medians. Two examples of projects are listed below.

- Renewal work in 2017 (Numazu IC – Fuji IC, Tomei Expressway)
  Regulation: Two-way regulation by day and night
  Project: Floor slab replacement work of Akabuchigawa Bridge (down line)

- Renewal work in 2018 (Susono IC – Fuji IC, Tomei Expressway)
  Regulation: Two-way regulation by day and night
  Project: Floor slab replacement work of Kaminagakubo Bridge (up line) and Ashitaka Bridge (up line)

4 Future Developments

4.1.1 More uses and developments of the RZS

Currently, the RZS is being used in a number of renewal projects and construction works by NEXCO EAST and NEXCO CENTRAL.

In addition, Kansai Regional Head Office of West Nippon Expressway Company Limited is also planning traffic regulations for construction works and lane managements by the RZS for a renewal work of Chugoku Expressway. The uses of RZS on expressways has been promoted across Japan.

4.1.2 Modification of BTM for further safety and efficiency

Meanwhile RZS is widely used on expressways, there are also several challenges. One is a size of a BTM; RZS has been used a lot in other countries including America and expressways, highways and roads in those countries consists of more and wider traffic lanes compared to those in Japan.

Examples of BTM dimensions are in Table 1 and actual machines are shown in Figure19 and 20.

Table 1. RTS BTM dimensions

Element	BTM for traffic regulation for construction works [(Numbers) are without conveyors]
Width	4.32m (2.54m)
Length	14.8m (12.8m)
Weight	22t (20t)

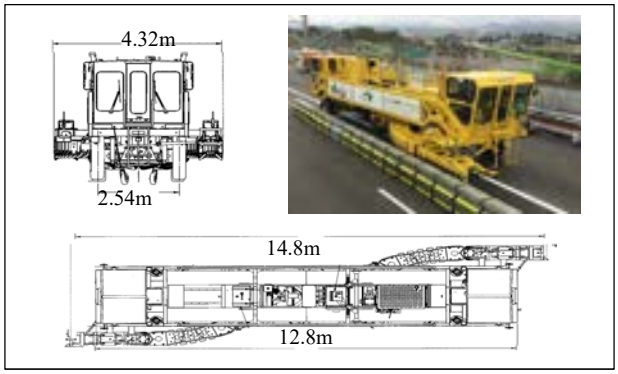

Figure 19. BTM for traffic regulation for construction works [1]

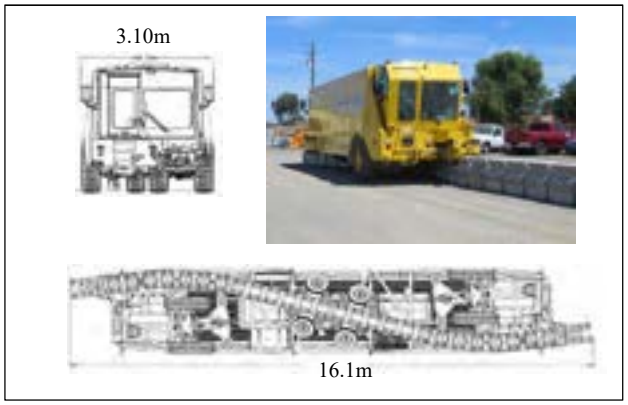

Figure 20. BTM for permanent lane management [1]

Other than a BTM for construction applications, there are other BTM models used for permanent lane management. Some have a width that fits within a traffic lane in Japan. However, the weight is heavier than 25t therefore investigation and confirmation about safety to pass through bridges and other road structures is necessary.

As a result, it does take time and effort to transport such a BTM.

In addition, the BTM exceeds general limits required by law for dimensions of vehicles in Japan therefore conveyors must be removed and transported by a special low-floor trailer, which also requires additional time, effort and expense.

Hence, in order to utilize RZS more safely and efficiently in Japan, after a request from NEXCO EAST, LTS agreed to and currently develop the new model "N-Class", a downsized BTM (named after NEXCO Group), for consideration of the machine size that the BTM fits and drives in the regulated area for construction (within the width of one driving lane) without removing conveyors and can be transported by a normal low-floor trailer rather than a special one.

5 Conclusions

The number of renewal works are expected to increase more and more in the future so as to ensure the safe use of expressways. However, there have been many accidents due to incursions of general vehicles into area regulated for construction works; hence, it is important to ensure safety of construction works in regulated area on heavy traffic lanes for a long span of time.

At the same time, it is necessary to carry out works in traffic regulation area more efficiently during limited time periods such as at night time with the low volume of traffic. It is believed that the RZS will contribute to improvement of safety and efficiency of traffic regulation for construction works

, and will be utilized by more companies and organizations as a measure to ensure safety and alleviate traffic congestion through development and improvement of the RZS.

Abstract –

Currently, road managers are required to maintain and renew road assets that are rapidly aging and damaged. On the other hand, due to the ever-increasing road assets, social problems such as cost reduction and shortage of engineers in maintenance and renewal are occurring. In particular, the "Road Bridge Periodic Inspection Procedure" was formulated in June 2014, and the periodic inspection is based on close-up visual inspection once every five effore, which requires enormous expenses and personnel. Therefore, efficient and economical inspection by applying non-destructive inspection technology is strongly required. For this reason, NEXCO West Japan Group has developed a digital camera inspection system (hereinafter referred to as Auto-CIMA) for the purpose of enhancing the structure inspection and improving efficiency.

Keywords –

Digital camera; Non-destructive inspection; Inspection; Crack;

1 Introduction

Auto-CIMA is a system that acquires high-definition images from digital cameras in order to grasp and inspect the state of concrete structures. Auto-CIMA can automatically paste the high-definition images that have taken and digitally check the surface condition of concrete. In addition, cracks and their widths (widths more than 0.1 mm can be visually confirmed in the image) and lengths can be automatically extracted, and the secular change of cracks can be grasped by accumulated data.

According to the verification from the development to the present, the inspection using Auto-CIMA has a condition that it is inefficient, but it does not require adjustment work or high place work by inspection, so it is economically advantageous. It has also been confirmed that the same inspection results as the close-up visual inspection can be obtained by combining with an inspection method that captures internal damage such as floating or peeling of concrete by infrared inspection.

Currently, we are verifying the applicability of Auto-CIMA as one of the inspection methods for periodical inspection, and it is expected that the efficiency of inspection using Auto-CIMA will be improved in the future. Here, I will report the outline.

2 Auto-CIMA

2.1 Overview of Auto-CIMA

Auto-CIMA is an inspection method that grasps the condition of the concrete surface of a bridge by acquiring high-definition images with a digital camera. The captured high-definition images are automatically pasted together and expanded in a plane, and the surface condition of the concrete can be confirmed on the digital image from the expanded image. Furthermore, cracks and their widths and lengths can be automatically extracted, and secular changes in cracks can be grasped by accumulated data. The Auto-CIMA shooting is aimed at a concrete plane and can shoot up to a distance of 40 m. Under this shooting distance condition, cracks with a width of more than 0.2 mm can be automatically extracted, and cracks with a width of more than 0.1 mm can be confirmed visually with a digital image. Table 1 shows the targets and specifications of Auto-CIMA.

Table 1. Targets and specifications of Auto-CIMA

target	specification
Hollow slab bridge	Shooting distance:2m～40m
Box-girder bridge	Shooting angle:Within 45°
Abutment	Shooting renge:Horizontal Within ±45°
Pier	Vertical Within ±30°

2.2 Features of Auto-CIMA

①Automatic shooting

Auto CIMA can photograph concrete planes by automatically operating a digital camera with an electric pan head shown in Fig. 1 on a PC. The shooting range for one shot is ±45° on the long side and ±30° on the short side, and the dimensions differ depending on the shooting distance. The shooting plan (shooting angle of view and direction) shown in Figure 2 is automatically set by setting the shooting range and shooting accuracy (0.5mm/pixel in NEXCO West Japan) on the PC. This eliminates erroneous measurement during shooting as much as possible.

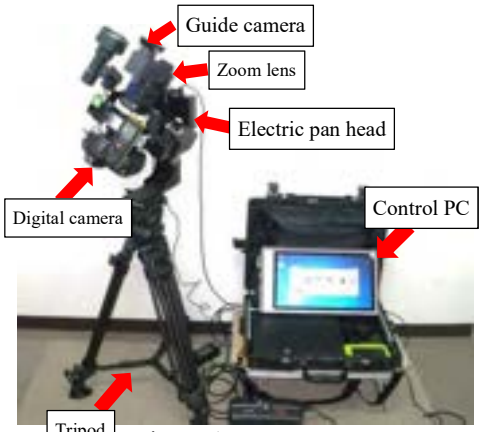

Figure 1. Auto CIMA

Figure 2. Shooting plan

②Image composition

Auto-CIMA can easily check the shooting status of automatically shot images (Fig. 3 (a)). Images that are out of focus due to obstacles such as electric wires during automatic shooting can be re-shot with manual shooting. It is difficult to recognize as a single image due to the color unevenness of the image composition. Therefore, the captured images are stitched together with high precision by image processing. (Fig. 3(b)). Since this high-definition image composition requires processing on a high-performance PC, it is performed indoors rather than immediately after shooting.

a) Simple pasting image b) High-precision stitched image

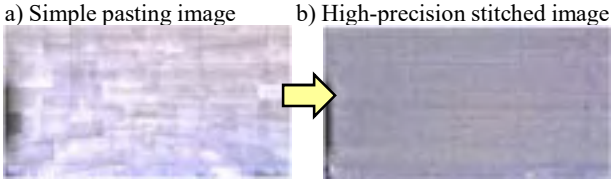

Figure 3. Automatic stitching image

③Automatic crack detection

The automatic crack detection on the concrete surface image uses an algorithm (line matching) to detect cracks as "continuous with lines". Compared with the binarization and contour detection generally used for image processing, dirt on the concrete surface is eliminated as much as possible, and it is specialized for crack detection as shown in Figure 4. Since the accuracy of the captured image is 0.5 mm/pix, the crack detection accuracy can recognize a 0.2 mm wide crack.

3 Application to visual inspection

The application of Auto-CIMA to proximity visual inspection was verified for the following four items.

①Inspection rate

Auto-CIMA is installed under the inspection target to perform the inspection, so there are some parts that cannot be photographed due to obstacles etc. We calculated the inspection rate for each bridge (see below) and verified the inspection range with Auto-CIMA.

Inspection rate (%):
Inspection area by Auto-CIMA (m^2) / Total inspection area (m^2)

②Inspection result

By comparing the visual inspection results with the Auto-CIMA inspection results, we verified whether it could be applied as an alternative method of visual inspection. In addition, Auto-CIMA can inspect only the damage appeared on surface, so the internal damage was inspected by the infrared thermography inspection.

③Cost and capacity

It was feared that Auto-CIMA inspection had lower work capacity than visual inspection. Therefore, in order to confirm the scope of application of Auto-CIMA, we compared and verified the cost and work capacity of visual inspection and inspection by Auto-CIMA.

④Application effect

We compared the work abilities of visual inspection with inspection combining Auto-CIMA and infrared rays (hereinafter, non-destructive inspection) to verify the effect of introducing non-destructive inspection.

3.1 Inspection rate verification

The scope of application was verified for the three bridges shown in Table-2. Table-3 shows the inspection rates for Auto-CIMA inspection for each bridge. The inspection rate of the superstructure was about 50% at the end span and about 100% at other spans due to the influence of obstacles (slopes, trees). The inspection rate for substructures is 0% for abutments and about 80% for piers, as in superstructures. As a result, it was confirmed that the inspection by Auto-CIMA can be applied to about 65% of the entire bridge.

Table 2. Target bridge(Inspection range verification)

Bridge	Type	Span	Shooting distance	Shooting area	Underpass
Bridge A	PC Box-girder	5span	30m	12,705㎡	River and road
Bridge B	PC Box-girder	5span	10～30m	12,296㎡	River and road
Bridge C	PC Box-girder	4span	10～30m	6,137㎡	Train

Table 3. Inspection rate (Inspection by Auto-CIMA)

	Inspection rate					
	Bridge A		Bridge B		Bridge C	
substructure	A1	0.0%	A1	0.0%	A1	0.0%
	P1	54.6%	P1	72.7%	P1	80.2%
	P2	96.3%	P2	62.7%	P2	74.1%
	P3	94.2%	P3	56.1%	P3	69.3%
	P4	62.7%	P4	69.1%	A2	0.0%
	A2	0.0%	A2	0.0%		
superstructure	A1-P1	45.4%	A1-P1	64.1%	A1-P1	81.9%
	P1-P2	100.0%	P1-P2	95.2%	P1-P2	100.0%
	P2-P3	100.0%	P2-P3	100.0%	P2-P3	100.0%
	P3-P4	100.0%	P3-P4	86.9%	P3-A2	95.7%
	P4-A2	47.7%	P4-A2	64.9%		
			average		65.5%	

3.2 Inspection results verification

From the bridges that were visually inspected, we selected RC hollow floor slab bridges and PC box girder bridges where blind spots are less likely to occur during shooting, and verified the inspection results for 12 bridges with 62 spans. The deformation detected by each inspection method was classified into the following patterns, and it was verified whether the nondestructive inspection could be applied as an alternative method with the same accuracy as the precision visual inspection. Table 4 shows the verification results.

Pattern A:
Damage found at the same position and in the same area as the visual inspection

Pattern B:
Damage that was confirmed by visual inspection but not by non-destructive equipment inspection

Pattern C:
Damage not confirmed by visual inspection but newly confirmed by non-destructive inspection

Table 4. Verification result of inspection result

Found damages		quantity	Match rate	Remark
Proximity inspection		229	-	
Non-destructive inspection	PatternA	224	97.8%	
	PatternB	5	2.2%	all delamination
	PatternC	353	-	

As a result of the verification, out of 229 deformations visually confirmed, 5 cases (Pattern B) were not confirmed by non-destructive inspection (concordance rate 97.8%). The damage that could not be confirmed by non-destructive inspection was delamination (no change in appearance) as shown in Fig. 4, and no damage could be confirmed by inspection by infrared thermography. We could not confirm it because it was lurking deeper than the range that could be confirmed by infrared thermography.

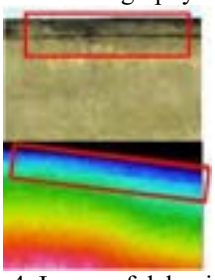

Figure 4. Image of delamination

In addition, nondestructive inspection (Pattern C) confirmed 353 new damages. Of these, 239 were confirmed by Auto-CIMA and 116 by infrared thermography. The new damage identified by Auto-CIMA was a crack. Since the inspection is performed with a high-definition visible image, it can be confirmed more accurately than the visual inspection, and it is considered that the inspection accuracy has improved. Especially, it seems to be very useful for the inspection of PC structures, etc. where cracks have a great influence on the soundness.

On the other hand, the damage newly confirmed by infrared thermography is characterized in that the damaged part can be seen due to the temperature difference. Therefore, a temperature difference occurs depending on the surface condition and the surrounding environment, and a sound part was erroneously detected as a damaged part. When it is judged that the sound part is damaged, it is judged to be worse than the original soundness in judging the soundness of the bridge, and it is judged that repair is necessary even if the bridge is not necessary to be repair. .. However, in most case spalling needs to be repaired, appears with surface damage such as cracks and rust. Since cracks and rust have been confirmed by Auto CIMA, there is no major change in soundness judgment.

Based on the above, as a result of non-destructive inspection, 97.8% of visual inspection damage was detected, and all damage that could not be confirmed was delamination, which was considered to be outside the detection range of infrared thermography. With non-destructive inspection, almost all visual inspection damage was detected, and soundness quality was obtained by using visible and infrared images together.

3.3 Cost and capacity verification

Cost and capacity verifications were performed on the bridges shown in Table 4 which were selected from RC hollow floor slabs and PC box girder bridges that are less prone to blind spots. In the verification, the inspection cost required for visual inspection and non-destructive inspection was compared with the number of inspected persons, and the applicable range of the inspection method was examined. The inspection cost was calculated by comparing the personnel cost with the cost required for the inspection (traffic regulation cost, machine cost, driver cost, security personnel cost, etc.). The number of inspectors was calculated by comparing the total number of inspectors engaged in on-site work and office work. In non-destructive inspection, as shown in Fig. 5, there are areas that cannot be inspected due to blind spots. Therefore, we decided to cover the range that cannot be confirmed by non-destructive inspection with visual inspection and add inspection cost. The verification results are shown below.

Table 4. Target bridge (Cost and capacity verification)

Bridge	Bridge Type	Span	Inspection size	Bridge	Bridge Type	Span	Inspection size
Bridge A	PC	2	108m	Bridge G	RC	7	108m
Bridge B		1	24m	Bridge H		9	24m
Bridge C		1	90m	Bridge I		2	90m
Bridge D		9	348m	Bridge J		6	348m
Bridge E		5	202m	Bridge K		5	202m
Bridge F		3	115m	Bridge L		3	115m

Figure 5. Blind spot range

① Comparison of inspection cost and number of inspectors

Table 6 shows the comparison result of the inspection cost and the number of inspectors between visual inspection and non-destructive inspection, and the consideration from the comparison of the inspection cost and the number of inspectors. The comparison results were calculated by arranging the percentage of nondestructive inspection when the visual inspection was taken as 100%. It also summarizes the under-girder height of each bridge and the characteristics at the time of inspection (necessity of traffic regulation, etc.).

【Consideration】

①Comparison of inspection costs

- For bridges with small spans and visual inspection in one day, nondestructive inspection always requires one more day to cover areas that cannot be inspected due to blind spots. Therefore, visual inspection is inexpensive. (Bridge A, Bridge B, Bridge C)
- For bridges with low under-girder height and no traffic restrictions, visual inspection costs are low. (Bridge D)
- For bridges that require traffic regulation, the cost of non-destructive inspection will be lower than visual inspection due to the impact of regulatory costs. (Bridge F, Bridge G, Bridge H, Bridge I)
- If the height under the girder is high, the inspection cost will be lower than the non-destructive inspection even if traffic regulation is not required for visual inspection. (Bridge J)
- The cost of non-destructive inspection of bridges at rampway is kept low because of complicated traffic regulations and time-consuming inspection. (Bridge K, Bridge L)

Table 6. Comparison result (Cost and capacity verification)

Bridge	Cost ratio (Non-destructive/visual)	personnel ratio (Non-destructive/visual)	Height under girder	Characteristic
Bridge A	178%	281%	16m	Visual inspection only for 1 day
Bridge B	122%	140%	10m	Visual inspection only for 1 day
Bridge C	126%	175%	15m	Visual inspection only for 1 day
Bridge D	108%	130%	6m since	The height under the girder was low and the visual inspection did not require traffic regulation.
Bridge E	93%	252%	Aithough 10m	The height under the girder was low and visual inspection required traffic regulation.
Bridge F	91%	158%	20m	Traffic regulation and bridge inspection vehicle required for visual inspection.
Bridge G	79%	148%	20m	Traffic regulation and bridge inspection vehicle required for visual inspection.
Bridge H	71%	525%	24m	Traffic regulation and bridge inspection vehicle required for visual inspection.
Bridge I	71%	92%	17m	Traffic regulation and bridge inspection vehicle required for visual inspection.
Bridge J	74%	138%	20m	The height under the girder was high and no traffic regulation was required for visual inspection.
Bridge K	37%	77%	25m	Visual inspection needs a lot of manpower due to a rampway bridge where the crossing condition is complicated.
Bridge L	21%	43%	26m	Visual inspection needs a lot of manpower due to a rampway bridge where the crossing condition is complicated.

②Comparison of number of inspectors

- At almost all bridges except rampway bridge visual inspection require less number of inspectors. (Bridge A-H, Bridge J)
- Due to the complexity of crossing condition roads, the number of non-destructive inspectors on rampway bridges is low. (Bridge K, Bridge L)
- Higher heights under the girder increase the efficiency of non-destructive inspection and may reduce the number of non-destructive inspectors due to traffic regulations. (Bridge I)

②Scope of non-destructive inspection

Table 7 shows the inspection methods that should be applied, which were confirmed by the verification conducted so far. The inspection method to be applied was decided by giving priority to the inspection cost. Furthermore, the under-girder height less than 10m was defined as “low”, more than 10m as “high”.

The bridges that were confirmed to be suitable for visual inspection were "bridges with short visual inspection days" and "bridges with low under-girder height that do not require visual traffic regulation". Non-destructive inspection is desirable for “rampway", "bridges that require traffic regulation under the bridges" and "high under-girder height bridges under the bridges".

Table 7. Applicable inspection

Inspection conditions			Comparison item		Applicable inspection
			personnel	cost	
Short visual inspection date			×	×	Visual inspection
Rampway bridge			○	○	Non-destructive
Height under-girder	low (Less than 10m)	No traffic regulation	×	×	Non-destructive
		Traffic regulation	×	○	Non-destructive
	high (10m or more)	No traffic regulation	×	○	Non-destructive
		Traffic regulation	×	○	Non-destructive

3.4 Application effect verification

The effect of introducing nondestructive inspection was verified by comparing that for visual inspection alone with the number of inspection days for introducing nondestructive inspection. The number of days of comparative inspection was confirmed by the number of days of bridge inspection within the jurisdiction of the Kansai branch of NEXCO West Japan. A non-destructive inspection was conducted on bridges that meet the conditions of Auto-CIMA shown in Table 1.

The verification results are shown in Table-8.

Table 8. Inspection days

Inspection method	Inspection days	Reduction rate
Visual inspection	12,463 days	−
Non-destructive inspection	10,136 days	18.7%

As a result of verification, if non-destructive inspection is introduced, numbers of days necessary for inspection will be shortened from 12,463days to 10136days, that is the efficiency will be improved by 20%.

4 Conclusion

As a result of the verification, the non-destructive inspection using Auto-CIMA confirmed the same inspection result as the visual inspection, and was confirmed to be applicable as an alternative method of visual inspection. In addition, we were able to confirm cracks in more detail than humans and improve inspection results.

Regarding the efficiency of the inspection, there were some areas where the inspection could not be performed due to blind spots, but with the introduction, the efficiency is expected to be improved by about 20%. However, depending on the conditions, the efficiency of the inspection may decrease, and it is necessary to be careful such as limiting the inspection target.

In the future, we will consider the development of guidelines and the use of automatic CIMA in the field to realize efficient and advanced bridge maintenance management.

MLIT's Initiatives for Promotion the Efficient Construction and Inspection by using new Technologies such as AI and Robots in Japan.

Kenichi Watanabe

Deputy Director for AI and Robotics for Construction and Maintenance, Policy Planning and Coordination Division for Public Works Project, Policy Bureau, The Ministry of Land, Infrastructure, Transport and Tourism, Government of Japan
E-mail: watanabe-k2q2@mlit.go.jp

Abstract –

The Ministry of Land, Infrastructure, Transport and Tourism (MLIT) is promoting the use of drones and other robots to improve the construction and management processes and improve the efficiency of infrastructure inspections, and is preparing an AI development environment that supports "human judgment." Specifically, MLIT is preparing "teaching data" which necessary for AI development and provides it to AI developers. In order to create an annotation rule for preparing teaching data, MLIT have started the working group of Industry-academia-government collaboration and are proceeding with discussions. At present, teaching data for cracks in bridges and tunnels has been prepared. MLIT is going to realize future advanced inspection, such as accumulating and using high-definition photographs with positional information taken by robots and inspection records in a 3D model. This will be possible to grasp the secular change of damage and deformation easily.

Keywords –

AI; Inspection; Teaching data; Drone; Bridge; Tunnel

1 Introduction

Currently, many of Japan's infrastructure is aging, while there is increasing risk of natural disasters such as typhoons and floods due to climate changes related to global warming. Japanese people are also in the face of challenges such as low birthrate and aging population. Under such situation, maintenance of infrastructure needs to be performing more effective and efficient, while the development and introduction of robot technology which support the work is required to proceed rapidly and intensively.

Therefore, MLIT and the Ministry of Economy, Trade and Industry (METI) in Japan have considered the needs of robots in a situation of social infrastructure survey, construction, maintenance and disaster management, including different needs from other industry fields in Japan and overseas such as IT, manufacturing, and so on. In order to consider measures for practical application such as clarifying the development and introduction fields of robots in, the "Next Generation Social Infrastructure Robot Development and Introduction Study Group" was established on July 16, 2013, "Next Generation robots for infrastructure development and introduction priority areas (5 key areas)" was formulated on December 25, 2013 (as shown in Figure.1).

Figure 1. Next Generation social infrastructure for robot development and introduction priority areas (5 key areas)

Therefore, MLIT had decided to establish "the on-site robot verification committee for the next generation social infrastructure" (hereinafter referred to as "the on-site verification committee") in 2014 February, to experiment on-site for the purpose of evaluating the robots. It was also the purpose to facilitate the development and introduction robots in the maintenance and disaster management field of social infrastructure.

The on-site verification committee had 5 subcommittees, 3 as the maintenance (the bridge, the tunnel, and dams and river), and 2 as the disaster

management (the disaster investigation and the emergency restoration). Experiments were conducted for each of the five priority areas.

The robots for maintenance of social infrastructure can take photographs which can detect damages of infrastructure such as cracks or corrosion. This can reduce the time which an engineer work on-site, and this can be also expected to reduce the time lost due to traffic closed for construction or inspection. But it is needed for an engineer to look at each photo for detecting the damage.

For further improving the efficiency of inspection work, it can be worth considering that creating three-dimensional model which shows the overall structure of the inspection object from inspection photos and organizing large amounts of photos on the 3D model. It can be also useful for grasping the changing over time of the infrastructure. Furthermore, it can be an efficient technique for such inspection to create and use artificial intelligence (AI) which can automatically detect damages on infrastructure from inspection photos.

In this paper, I show you “Initiatives and results of the on-site verification committee” in section 2,” Efforts to further improve the efficiency of inspection work” in section 3, and “Conclusion” in section 4.

2 Initiatives and results of the on-site verification committee

In fiscal year 2014 and 2015, MLIT had researched various robot technologies like drones or ROV related to five priority areas (FY2014: 67 techs, FY2015: 70 techs). MLIT had taken technological verification and evaluation for improving and promoting these technologies. For disaster management, two years verification and evaluation initiatives have made these robot techs to be used in site. On the other hand, the robot techs for the maintenance had many difficulties on achieving inspection efficiency and accuracy which were required, so it was decided to continue the verification and evaluation initiatives beyond year.

In FY2016 and FY2017, the situation and performance level to be achieved for practical use were set, while some of these robot techs were re-verified and re-evaluated the accuracy and the economic efficiency caused by shortening of work time (FY2016: 16 techs, FY2017: 16 techs). Figure 2 shows examples of the verified robot techs.

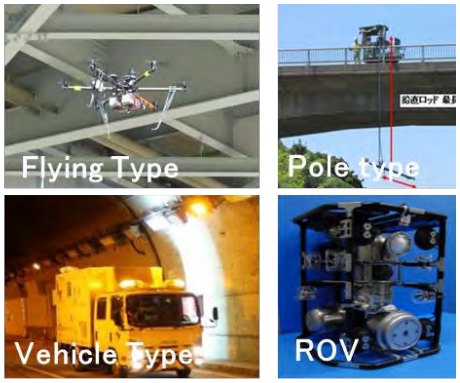

Figure 2. Examples of the verified robot techs

In FY2018, MLIT have written the manuals which described the method to use these robot techs in each situation such as bridge maintenance or disaster investigation. It has made the robot techs to be used in site.

The manual regarding road (bridge, tunnel) maintenance is described in detail below.

2.1 Road (Bridge, Tunnel) Maintenance Manual Using Robots

For the road infrastructures in Japan, The Ministerial Ordinance Revising Part of Road Law Enforcement Regulations has been issued and enforced in 2014 behind the rapid increase in aging road infrastructures. Therefore, regular inspections of road bridges and tunnels are conducted once every five years by close visual inspection, while evaluating its healthiness in stages.

The first round of inspections was completed in FY2018, and the road bridge periodic inspection guideline was revised in 2019, February through discussions on the revision of the periodic inspection guideline by the Road Subcommittee of the Council for Social Capital Development Road Subcommittee . The road tunnel regular inspection procedure was revised in March of the same year.

In addition, in the process up to the revision of the periodic inspection procedure, the direction was shown to utilize these technologies for periodic inspections. “Inspection support technology” such as infrastructure inspection robots will be determined by a professional engineer who has the knowledge and skills which are necessary for inspection of the parts, members, scope, and purpose of using these technologies.

Therefore, MLIT has established standard performance evaluation items that show the performance of inspection support technology, and then "the catalog" was made in 2019 February for the performance values submitted by the developer through

on-site verification.

Moreover, "the guideline" was compiled in same time. For professional engineers of the order and the contractor, the guideline shows the process of decision making to use these technologies on periodic inspection work.

3 Efforts to Further Improve The Efficiency of Inspection Work

The inspection support technology, shown in above section, can take photographs from which a professional engineer can detect damages of infrastructure such as cracks or corrosion. This can reduce the time which a professional engineer work on-site like marking with chalk or measuring with crack scale, and this can be also expected to reduce the time lost due to traffic closed for construction or inspection. However, it is needed for a professional engineer to look at each photo for detecting the damage.

For further improving the efficiency of inspection work, it can be worth considering that creating 3D model which shows the overall structure of the inspection object from inspection photos and organizing large amounts of photos on the 3D model. It can be also useful for grasping the changing over time of the infrastructure. Furthermore, it can be an efficient technique for such inspection to create and use AI which can automatically detect damages on infrastructure from inspection photos.

Two methods that MLIT is currently studying about AI are shown in below.

3.1 Damage Representation above 3D model

In the current inspection work in Japan, the contractor is not needed to deliver all of the photographs taken by inspection support technology, and it is often enough to deliver the photographs of the places where damage is recognized and damage information with the form defined.

The inspection support technology can take high quality and large images which can use to generate a 3D model. If it could record and accumulate accurate damage location above such 3D models, deformation of aging structure changing over time can accumulate inspection records of the structure in comparable form. The more information amount of inspection results is, the more useful diagnosis by a professional engineer can be expected.

The deliverable for making 3D model needs photos which show shape and location of damages, metadata of positional information of taken photos, and damage shape data added to the 3D model. If the standard which defined these data items and specification did not exist, it might make a situation that the damage 3D model only depended on the application which was used and managed the data. Incompatible and discontinuous data might store in that cases.

Therefore, MLIT have stipulated common data items and specifications related to the data required to create a 3D model. MLIT have also shown the method how to deliver the result of inspection through an application that creates a 3D model from photos taken by inspection support technology. So, " 3D deliverables manual for tunnel or bridges by inspection support technology (image measurement technique) " have created in 2019, March.

MLIT is going to verify the 3D model creation method using photographs are taken through the periodic inspection work. MLIT is also going to revise the manual while researching the inspection scene in which we can use 3D model efficiently. Through these initiatives, MLIT leads inspection work to improve.

I will explain the 3 types of deliverables that are defined in this manual: "inspection photo", "damage shape data", "Inspection photo metadata".

Each of the details are as follows.

3.1.1 Inspection Photo

This is raw data of photos taken by inspection support technology. For creating 3D model, photos should be taken not only of the damaged part but also whole of the structure including the sound part.

It is necessary for inspection photos to carry out appropriate quality control based on shooting condition which defined to secure the accuracy. In this manual, the conditions of inspection photos taken will be described referring to shooting conditions for teaching data which is essential to create AI. (As shown in Table 1.)

Table 1. Conditions for taking photos for the preparation of teaching data for bridges

When a crack of 0.1mm width is detected, the width shall be 0.3mm/pixel or less.
The field of view size should be determined according to the camera used.
Field of view size in longitudinal direction (mm) = Number of camera pixels in longitudinal direction x 0.3mm
Size of vertical field of view (mm) = Number of camera pixels in vertical direction x 0.3mm

	specification	points to remember
Camera model	Mirrorless camera or equivalent	Necessary to ensure stable image quality
		Sensor size: APS-C or larger
		Do not use contrast AF
		Necessary for depth of field
ISO sensitivity	ISO200 or less	Increasing the ISO sensitivity may smooth the image and make it impossible to detect cracks
Lap rate	Overlap and side-lap percentages are both over 30%	Necessary for compositing to the planar development
Shooting angle	Confronting directly (in principle)	Depends on the environmental conditions, but generally up to 10 degrees

3.1.2 Damage Shape Data

This is the information of damage position, shape, and area. When we create this data, we can choose two methods: 3D model or the layer structure drawing file

(2D). The damage shape data on 3D model is expressed by 3D polylines (cracking, etc.), a polygon (corrosion, free lime, etc.) which are described on 3D-CAD.

On the other hand, the damage shape data based on the layer structure drawing file (2D) is created by showing polylines and polygons indicating damage on 2D drawing that is superimposed with a layer structure that can be separated from the inspection photos. This corresponds to the data delivered as a damage diagram in the conventional inspection record.

3.1.3 Inspection Photo Metadata

This is the text data (CSV file) in which describes the information of coordinate system in which inspection target structure is located, and of the position coordinates and angle of inspection photo or camera.

The position coordinates and angle information are necessary to express at which position and angle the photo exists in 3D space. Representation methods of this information can be 3types: (1) center position coordinates and angle of the inspection photo, (2) center position coordinates of the camera and angle, and (3) four corner coordinates of the inspection photo.

This manual defines the representation methods of these metadata, and one example is shown in Table2.

Table 2. Conditions for taking photos for the preparation of teaching data for bridges

Item	Input condition	Description
Position Coordinate Entry Method	Required	Enter 0 if the positional coordinates are the center positional coordinates of the photo, 1 if it is the center positional coordinates of the camera, and 2 if it is the four corner coordinates of the photo.
Position Coordinate	Required (When the positional coordinate input method is "0")	XYZ coordinates (x, y, z) to show the center position of the inspection photo. Eulerian angle (α, ß, γ) or quaternion (q0, q1, q2, q3) that represents the slope of the inspection photo.
	Required (When the positional coordinate input method is "1")	XYZ coordinates for the center position of the camera (x, y, z) Eulerian angles (α, ß, γ) or quaternions (q0, q1, q2, q3) that represent the inclination of the camera.
	Required (When the positional coordinate input method is "2", 3 points or more)	XYZ coordinates (xUR, yUR, zUR, xUL, yUL, zUL, xDR, yDR, zDR, xDL, yDL, zDL) of the four corners of the inspection photo (top right, top left, bottom right, bottom left)

3.2 Automatic Interpretation of Damage Using AI

As previously described, from many photos obtained using the current inspection support technology, damage of structure has been read by hand. By utilizing AI, this damage reading procedure can be done automatically. It can be also a great help for the work of those who create inspection records. A future image of inspection procedure is shown in Figure 3.

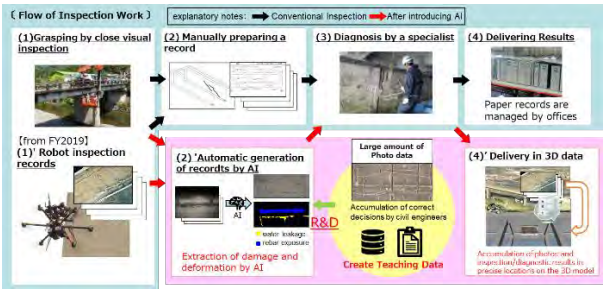

Figure 3. Future Images of Inspection Procedure

In conventional inspection procedure, a professional engineer needs to get closer to the structure to be inspected and check with his/her own eyes. So, inspection records (output) have been created from the visual information (input).

If this procedure is going to be achieved by AI, first, it will be needed to create the teaching data which is based on photos (input) and records(output) which have been acquired and made by a professional engineer.

These teaching data contains the tacit knowledge and know-how of the professional engineers of inspection. AI learning algorithm needs to learn based on teaching data like these.

The learned AI can infer results from inputs, so it can automatically interpret damages of the structure to be inspected from photos acquired by inspection support technology. To develop such AI, and to improve automatic interpretation by such AI to higher precision, it is necessary to prepare a large amount of teaching data. The teaching data is created by simply tagging (annotating) where in the photo acquired by inspection the damage is on the photo.

The inspection photo is owned by the manager of the structure like MLIT, and annotating requires the knowledge and skills of inspection professional engineers. So that, MLIT prepares teaching data as a cooperative area. MLIT is confident that this initiative can be a great help for firms to create AI needed in the fields of inspection.

An image of AI learning and utilization is as shown in Figure 4.

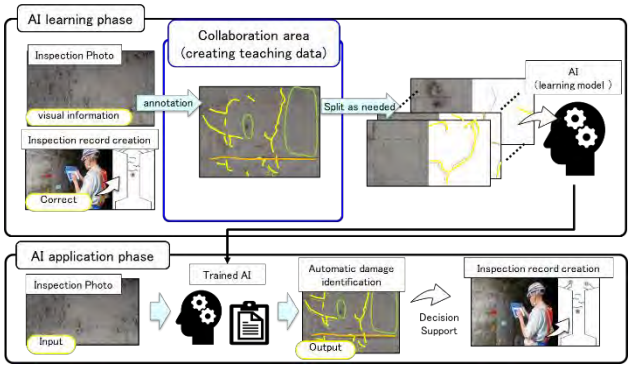

Figure 4. An image of AI learning and utilization

MLIT is considering the establishment of "AI Development Support Platform" for the purpose of creating teaching data, giving the data to AI developers, and evaluating the performance of the developed AI (Figure 5).

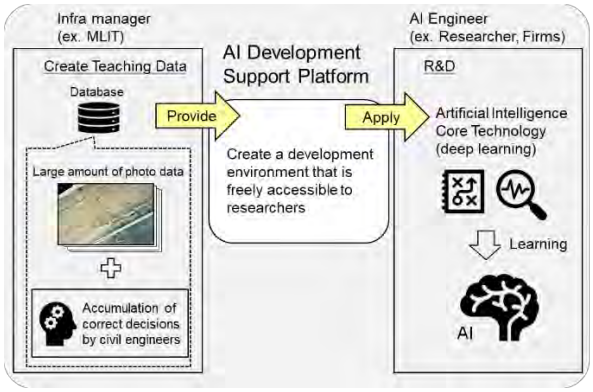

Figure 5. Outline of AI development Support Platform

MLIT have established the industry-academia-government collaboration working group for AI towards the establishment of the platform. In this WG, MLIT and WG members have considered a good quality and efficient way to create and deliver teaching data, and examined the ideal way of a data infrastructure that facilitates the acquisition, storage, analysis, and utilization of inspection data.

This WG has been held 3 times so far. The WG members have discussed specifications for the original photo used as teaching data, specifications of annotations, rules regarding provision of teaching data, sharing of schedule for future teaching data provision and prototype AI development, opinions exchange on prototype teaching data, and review of specifications of teaching data.

In addition, in order to improve the accuracy of AI, it is necessary to accumulate more inspection photos. MLIT is going to verify how to take a picture of the structure based on the technological progress of inspection support technology continuously, and "3D deliverables manual for tunnel or bridges by inspection support technology (image measurement technique) " should be revised as appropriate.

4 In Conclusion

In Japan, the skilled worker in construction site is decreasing, the infrastructure is aging, and it is important to maintain existing infrastructure effectively and use them longer.

MLIT initiatives will contribute a variety of inspection support technology development in the robot market, supporting the work of professional engineers in infrastructure inspection, accelerating the development and introduction of robots, and further improving the efficiency and sophistication of the overall infrastructure maintenance management.

MLIT will be contributing to the improvement of productivity of construction industry, while grasping the trend of technology seeds and worksite needs by the social implementation of new technology on construction site.

Abstract –

Plenty of variance lies in the development stage of a typhoon, including its location, direction, and surrounding meteorological conditions. Affected by such numerous contributing factors, it is not always easy for nowaday technology to make accurate typhoon forecasts. The experiences from the past typhoons may provide decision-makers with sufficient information to anticipate potential damage and thus develop appropriate strategies. The typhoon track plays a vital role in selecting appropriate historical cases based on the need to grasp the situation during the disaster preparedness phase. This paper summarizes our published journal article, which proposed an algorithm to compare the similarity between the current typhoon forecast track and all the typhoon tracks of the western North Pacific in the past. Based on the forecast track points of the current typhoon, the algorithm suggests a list of historical typhoons with the highest similarity in tracks. Hence, the tracks and the disastrous area of those historical typhoons can be used as crucial alerts and hints for disaster preparedness. Inside the algorithm, the mechanism follows the Recentness Dominance Principle, which is elaborated in our published journal article. The principle states that the more recent the forecast track point is, the higher the weight that it possesses and thus should be emphasized. For implementation, the study develops a user-friendly front-end interface that synchronizes the latest forecast typhoon tracks from six major meteorological institutions automatically, including CWB, HKO, JMA, JTWC, KMA, and NMC. The result comes with a convenient and concise search engine that assists decision-makers in finding similar historical typhoon records.

Keywords –

typhoon track similarity; search engine; user interface design; disaster preparedness; decision support

1 Introduction

Precise response strategies to typhoons rely on accurate forecasts. However, plenty of variance lies in the development stage of a typhoon, including its location, direction, and surrounding meteorological conditions. Affected by such numerous contributing factors, it is not always easy for nowaday technology to make accurate typhoon forecasts, causing the difficulties of developing precise strategies.

The experiences from the past typhoons may provide decision-makers with sufficient information to anticipate potential damage and thus develop appropriate strategies for precaution. The damage of a typhoon, caused by the winds and rainfall, is regarded as a consequence of the interaction between the typhoon and the land. Such interactions are affected by typhoon tracks, making the track a critical factor for disaster reduction of typhoon events. Based on the need to predict and grasp the situation, during the disaster preparedness phase, the typhoon track plays a vital role in selecting appropriate historical cases. Decision-makers may anticipate the impact of an upcoming typhoon by utilizing the historical typhoon records with similar tracks.

The categorization of historical typhoon tracks helps to analyze the patterns of damage caused by different typhoons. For example, the Central Weather Bureau (CWB) of Taiwan has determined nine categories of tracks of typhoons that invades Taiwan [1]. The CWB has also linked the behavior of wind and rainfall of typhoons with different tracks to different regions in Taiwan [1], supporting decision-makers to figure out the

potential damage of upcoming typhoons.

This paper summarizes our published journal article [2], which proposes a track similarity algorithm to compare the similarity between an upcoming typhoon forecast track and all the tropical cyclones (TCs) in the western North Pacific (WNP) in the past. A comparison model, which is the core of the algorithm, was first developed in our preliminary work [3], and in the present study, we further explore the details of the model and complete the comprehensive algorithm. We also developed a new information display panel featuring auto-importing forecast data. A literature review of typhoon databases is presented in Section 2, including a discussion of our preliminary work. The algorithm and its detailed discussion are discussed in Section 3. The design and implementation of the new panel are described in Section 4. More information can be found in the journal article [2].

2 Literature Review

Many studies about typhoons focus on forecast model performance. Classical prediction techniques are climatological or dynamic with different considerations. For example, Lee et al. [4] developed a climatology model for predicting rainfall at different areas for a specified typhoon center location. On the other hand, some recent studies discuss data-driven approaches to typhoon forecasts. For example, Rüttgers et al. [5] utilized a generative adversarial network (GAN) with satellite images for typhoon track predictions. Although precise forecasts support decision making, the deduction of damage from the distribution of rainfall and wind is not explicit and requires expertise. Also, forecasts cost computation time, hindering immediate reactions to emergencies. Hence, utilizing past typhoon records for developing quicker response strategies may be useful for decision-makers.

The experiences from the past typhoons may provide decision-makers sufficient information to anticipate potential damage and thus develop appropriate strategies for precaution. Wu and Kuo [6] states that significant mesoscale variations in weather are derivative from the interaction of typhoons and the complicated topography in Taiwan. Also, Huang et al. [7] has investigated the relationship between typhoon track, rainfall patterns, and flood peak time, concluding that that preferable rainfall types vary by typhoon tracks. For the preparedness and the emergency response phase of typhoon events in Taiwan, decision-makers seek the status of the disaster, the response strategies, and other relevant data of similar past typhoons for decision making support [2].

Several databases for TCs in the western North Pacific WNP have been developed, including the Taiwan Typhoon Database of CWB [8] and the Digital Typhoon Database of the National Institute of Informatics (NII) of Japan [9]. Such databases feature filtering by time, pressure, wind, rainfall, intensity, etc. However, searching by TC track is not commonly provided. The Taiwan Typhoon Database allows searching by the track categories proposed by the CWB, but the actual category that a forecast track belongs to still requires the users' determination. The task of track matching is less intuitive for users due to the lack of explicit integration with forecast and historical records.

T-search, a real-time historical typhoon search engine, was introduced by the authors to assist relevant personnel to intuitively search and review the historical typhoon information and efficiently develop corresponding response strategies [3]. A track similarity comparison model was also developed in the work. It also provided an intuitive cross-platform user interface for retrieving the historical typhoon records. T-search has been validated by a usability test and a three-year field test coordinated with the government of Taiwan. The real case study has shown that T-search enhances the accessibility to typhoon records. However, the preliminary work did not discuss the usage of each parameter in the comparison model, making the parameter setting without baseless. Also, the large number of typhoon records and track points resulted in long calculation times for the track similarity algorithm. Further, the system only allowed users to input the forecast data manually instead of automatically import, thus reducing the convenience of the system.

3 Methodology

This paper summarizes our published journal article [2], which proposes an algorithm to compare the similarity between an upcoming typhoon track forecast and all the past TC tracks in the WNP. The proposed algorithm is composed of the comparison model developed in the preliminary work [3] and a ranking strategy. In the present study, we decompose the comparison model into a static sector and a dynamic sector, propose a strategy to enhance the efficiency of the computation and set an order to ensure the discrimination of similarity. Also, the Recentness Dominance Principle (RDP) is introduced based on the presumption of the high uncertainty of the typhoon's direction during development [2]. The RDP states that those later user-specific track points are more relevant than the earlier ones, and thus their relative weighting should be increased. We extend elaborates on the preliminary work and provides the definition and interpretation of the time weighting. More information can be found in the journal article [2].

3.1 Comparison Model

The comparison model selects the most similar historical typhoon track for the user-specific track of the forecasted typhoon through track comparison and matching. For each past typhoon, the model calculates the similarity based on points of tracks, valid regions given by the user, time, etc., for the user-specific track points and quantifies scores for comparison. The similarity of the forecasted typhoon and each historical typhoon is calculated with Equations (1) and (2):

$$similarity(i) = \sum_{k=1}^{M}(1 + kw) \times \delta_k = \sum_{k=1}^{M}\delta_k + w\sum_{k=1}^{M} k \times \delta_k \quad (1)$$

$$\delta_k = \begin{cases} 1, d_{jk} < R_k \\ 0, otherwise \end{cases} \quad (2)$$

M is the number of the user-specific track points. k is the index of the user-specific track points starting from 1. i is the index of the historical typhoons. j is the index of the closest track point of the historical typhoon i to the user-specific track point k. w is the time weighting of all the user-specific points, which determines the importance of each point. The binary variable δ_k represents whether the historical typhoon track point j falls in the given valid region of the user-specific track point k. The valid regions corresponding to the user-specific track points are designed to restrict the distances between a forecast track point and historical track points, denoted as d_{jk} in Equation (2). At least one point of each historical typhoon track should lie within the valid region set by the user-specified radius, denoted as R_k in Equation (2), or the similarity scores of the typhoons are zero since they are determined to be too far.

For discussing the roles of k and w, Equation (1) is divided into the static sector and the dynamic sector. The static sector refers to the constant part constant part ($\sum_{k=1}^{M}\delta_k$), while the dynamic sector refers to the second component ($w\sum_{k=1}^{M} k \times \delta_k$). In the static sector, only the valid regions of the given track points are of concern, indicating that how many given track points of a forecast typhoon a historical typhoon passes. The dynamic sector includes time as a factor in the model by multiplying the time series (k) by the time weighting (w). The adjustment to the given time weighting emphasizes the importance of time of the track points.

Both the static sector and the dynamic sector impact the result of similarity comparison. An example is shown in Figure 1, with one typhoon passing through the last three input points with the score of $3 + 12w$, and the other passes through the first three input points and the last input point with the score of $4 + 11w$. In this case, the first typhoon has a higher static sector than the second, but if the time weighting w is greater than one, the second typhoon eventually obtains higher similarity. Hence, it is essential to discuss the usage of time weighting for a comprehensive explanation.

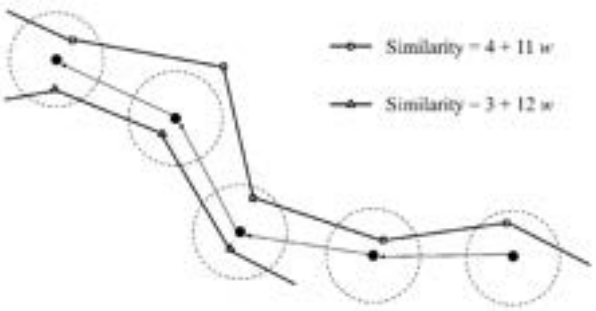

Figure 1. An example of two typhoon tracks for the similarity comparison demonstrating the impact of the dynamic sector [2].

3.2 Recentness Dominance Principle

The Recentness Dominance Principle states that the more recent the forecast track point is, the higher the weight that it possesses and thus should be emphasized [2]. Since a TC direction is highly uncertain during its developing stage, we tend to emphasize the importance of later track points by giving higher weightings to them. Following the RDP, the time weighting should be changed when more track points are given. The similarity score of a historical typhoon may be distorted in some circumstances if the time weighting is not adequately set following the RDP or does not correlate with the number of given track points.

For ensuring the RDP, we introduce the global recentness dominance time weighting (gRDW) and the individual recentness dominance time weighting (iRDW). They are obtained by the following approach (Equations (3) and (4)):

$$\widehat{w} = \max\{w_i : i = 1..|P|\} \quad (3)$$

$$w_i = \frac{s_{i,b} - s_{i,a}}{d_{i,a} - d_{i,b}} \forall \left(s_{i,a} + d_{i,a}w, s_{i,b} + d_{i,b}w\right) \quad (4)$$

$$P \equiv (s_a + d_a w, s_b + d_b w) \forall a, b \in \mathbb{N}(s_a > s_b \wedge d_a < d_b) \quad (5)$$

The value of gRDW (denoted as $\widehat{w}$ in Equation (3)) determines the number of the indeterministic score pairs (denoted as P in Equations (3) and (4)), which are defined in Equation (5). A properly specified value of gRDW eliminates the indeterministic score pair that contravenes RDP, and the similarity scores can then be calculated. In this study, the model equalizes the score of each score pair to obtain iRDW (denoted as w_i in

Equations (3) and (4)) for simplicity. To emphasize the recentness, the model takes the maximum of the set of iRDW as gRDW.

The dynamic sector of the model constructs a gRDW that ensures the dominance of recentness. To discuss the effect of setting different values of time weighting, we relax RDP by allowing users to set the preferred time weighting. Seven special weight groups are divided, giving different interpretations of the time weighting. One of the weight group, when w equals gRDW, is the critical value to ensure RDP. The remaining six groups are:

Over gRDW: $w \in (gRDW, \infty)$. In this case, the outcome of the similarity model remains identical to the outcome's time weighting set as gRDW, showing that exaggerating RDP generates the same result.

Positive related time weighting: $w \in (0, gRDW)$. In this case, the time weighting determines whether the impact of the dynamic sector can defeat the static sector, providing a trade-off between the two sectors. The closer values are to gRDW, the more influential the recentness.

Static sector: $w = 0$, only presenting the static sector's score. It eliminates the dynamic sector, presenting the neat summation of the historical typhoon track passing through the valid regions of the user-specific track points.

Negative related time weighting: $w \in (-1, 0)$. The recentness is proportionally decreased in this case, making older typhoons more important than recent typhoons.

Repulsion force weighting: $w = -1$. In this case, the comparison model reduces to $(\sum_{k=1}^{M}(1-k)$. Mathematically, the similarity score must not be greater than zero, referring to select historical typhoons who pass through none ($M = 0$) or only the first ($k = 1$) of the given points.

Reverse similarity: $w \in (-\infty, -1)$. In this case, the model simply eliminates all the historical typhoons that pass through the user-specific track points.

Setting time weightings with the six groups may not provide proper search results since they are obtained by relaxing the RDP. The actual usage of non-RDP time weighting is not yet clarified; however, the discussion of the behavior of search results with time weightings of different groups potentially provides insight for further usage.

3.3 Ranking Strategy

For the distinction of similarity between the historical typhoon tracks and the user-specific track, the ranking strategy is in five steps as follows:

1. Total similarity score;
2. Dynamic sector;
3. Static sector;
4. Month disparity;
5. Year gap.

First, the model sorts the past typhoons by the computed similarity scores with the user-specific track using Equation (1). The similarity score considers RDP by utilizing the time weighting assigned to each given track points with higher values for later points, indicating that the score is an index of general similarity. When the scores of some historical typhoons are equally matched, the dynamic sectors are compared first, and then the static sectors are compared, which reaffirms that RDP does matter. If the ranks still make no difference, the algorithm keeps comparing by the disparity of months, and the gap between the present year and the year of each historical typhoon. Finally, the comparison result should be clear.

4 Implementation

This study re-designs and develops a user-friendly interface that automatically synchronizes the latest forecast typhoon tracks from six major meteorological institutions of TCs in the WNP. The interface is implemented in the form of a web application, consisting of a front-end panel that displays the information and a back-end server that handles the data retrieving and the similarity comparison.

All required typhoon data are collected from the meteorological institutions. For the historical typhoons, the system utilizes the historical best track data of TCs in the WNP provided by the Japan Meteorological Agency (JMA), the regional specialized meteorological center of the WNP, and the South China Sea [10], as the references of similarity calculation. The TC data in the jurisdiction of the JMA since 1951 are retrieved from the JMA website. The system parses the raw data and extracts the approximately 1700 typhoons with the contained approximately 65,000 coordinates.

Meanwhile, typhoon track forecasts, the input of the system, are retrieved from several meteorological institutions that provide forecasts of present typhoons in the WNP. In this study, the real-time forecasts are obtained from the Integrated Multi-Agency Tropical Cyclone Forecast, which provides comprehensive information about current typhoon forecasts from several meteorological institutions, including the CWB, the Hong Kong Observatory (HKO), the JMA, the Joint Typhoon Warning Center (JTWC) of the US, the Korea Meteorological Administration (KMA), and the National Meteorological Center (NMC) of China [11].

Figure 2. The information display panel and the query result using Typhoon Maysak (2020).

The information display panel contains a map view built with OpenLayers libraries and a control panel for inputting track points. The system provides two input modes:

Center auto-import, which offers real-time feeds and forecasts of current typhoons provided by the meteorology institutions;

Manual input, which allows users to complete comparisons between any desired tracks and historical typhoon tracks by either keying in coordinates or clicking on the map view.

The integration of multi-institution forecasts allows the decision-maker to choose the exact institution as the forecast data provider considering the need. By auto-importing the forecast typhoon track, the time cost for manual input is reduced, and the accuracy of the track data is also improved.

Figure 2 illustrates the overview of the information display panel and the result using Maysak (2020) as an example. The control panel on the right lists all active TCs in the WNP and available forecasts from different meteorological institutions for users to select. In the case of Figure 2, the user selects the forecast data provided by CWB. After auto-import, the map view illustrates the forecast typhoon track points and all the valid regions. Next, the user activates the query. The system starts calculating, finds the most similar historical typhoons, and demonstrates the tracks of the selected historical typhoons on the map view. The control panel also lists the selected historical typhoons and directly links to the Taiwan Typhoon Database of CWB. With the support of the panel, it is convenient for decision-makers to review the historical typhoon records efficiently. The damages caused by typhoons can thus be forecast, and the response strategies such as evacuations and pump pre-allocations can be executed on time. More information can be found in the journal article [2].

5 Conclusions

This study has improved the preliminary work and developed a new information display panel featuring auto-importing forecast data, coming with a convenient and concise search engine that assists decision-makers in finding similar historical typhoon records. In this paper, summarized from our published journal article [2], we have discussed the details of the comparison model and completed the ranking strategy. In addition, we have stated the time weightings as a vital role of controlling the impact of time of each track point for the similarity algorithm. The use of RDP has been proposed regarding the effect of the number of track points. Furthermore, the effect of varying time weightings potentially provides insight for decision-makers to modify the time weighting for different purposes based on the need or their profession. We have also developed a new information display panel, featuring both the manual-input method and the center auto-import method to forecast track data, reducing the required time to import data and the possibility of making mistakes in

the exact locations of the track points. Several forecasters are additionally integrated into the system, providing various choices for the decision-makers. More information can be found in the article [2].

In future work, the algorithm's insufficiency of only considering track points as input should be solved. Since there are numerous factors that affect the damage of a typhoon, taking other factors such as the intensity of typhoons into consideration may enhance the search engine to get a better search result that meets up to the current scenario. Also, the algorithm can be adapted to utilize ensemble forecasting to comprehensively demonstrate forecasting uncertainty and support the decision-makers to evaluate the risk of different circumstances.

Abstract –

Cracks are one of the significant criteria utilized for diagnosing the disintegration of solid structures. Normally, a structural designer with specific information would assess such structures by checking for breaks outwardly, outlining the aftereffects of the examination, and afterward getting ready to investigate information based on their discoveries. A review technique like this is not without a doubt, as it requires manual chronicle of upwards of a few hundred thousand splits individually. However, it additionally cannot precisely identify the length and state of the breaks. To handle the issue, the industry has progressively looked toward utilizing AI detection to conduct a direct based assessment. Researchers are as of now building up a mobile-based intelligence equipped with AI analytics for recognizing splits and different imperfections, which will upgrade the proficiency of the investigation process and enhance the emergency response towards users. This study aims to provide an insight on the most efficient crack detection method by comparing several techniques. It was found out that the hybrid technique was the most efficient method to detect cracks. This technique combines the positive points from both the artificial neural network (ANN) and artificial bee colony (ABC) to come up with a more proper entirely new method.

1 Introduction

Structural systems in civil engineering are exposed to deterioration and damage during their service life. Damage is defined as a weakening of the structure which may cause undesirable displacements, stresses, or vibrations to the structure leading to sudden and catastrophic consequences. Damage that severely affects the safety and functionality of the structure and detection of it at an early stage can increase safety and extend its serviceability. Thus detection of damage is one of the most important factors in maintaining the integrity and safety of structures.

Visual inspections have always been the most common approaches used in detecting damage on a structure. However, these inspection techniques are often inadequate for assessing the health state of a structure especially when the damage is invisible to the human eyes. Thus, in many situations to ensure structural integrity, it is desirable to monitor the structural behavior when damage is not observable. Some numerical techniques such as the finite element method, artificial neural networks, genetic algorithm, and fuzzy logic have been applied increasingly for damage detection with varied success [1].

In recent decades there has been an increasing interest in using neural networks to predict and estimate the damage in structures. ANNs can be considered as an Artificial Intelligence (AI) technique and the structure of an ANN bears a very approximate similarity to the human brain. ANNs are employed when the relationship between the input and output is complicated or when the application of another available technique requires long computational time and the effort is very expensive [2].

ANNs are a powerful tool used to solve many real-life problems. They can learn from their experience to improve their performance and to adjust themselves to changes in the environment.

Damage detection as an inverse problem can be identified using ANNs from the measured responses under the excitation of the structure. The inverse problem is defined as the determination of the internal structure of a physical system from the system's measured behavior or identification of the unknown input that gives rise to a

measured output signal. The neural network can be trained to recognize the characteristics of an undamaged structure as well as those of the structure with elements of varying degrees of damage. The trained neural network will then have the ability to identify the location and the extent of damage of individual elements [3].

There are four levels of damage identification consisting of determination of the presence of damage in the structure, determination of damage location, and determination of the severity of damage [4]. The fourth level that is the prediction of the remaining service life of the structure is associated with fatigue life and fracture mechanics and will not be addressed in this review. In this paper, a review of the literature for damage identification and structural health monitoring based on measured dynamic properties by using ANNs during the last two decades is presented.

While there are a number of literature that discuss about crack detection methods, none of them provides a direct comparison between the methods to find out the one that has the best efficiency and accuracy rate. This is an important point that needs to be resolved as it may help designers to come up with the most efficient design from the very beginning to anticipate cracks on different surfaces. This is why this study aims to close this gap as a contribution to the field of research with the purpose to provide an insight for future researches, particularly within the crack detection discourse.

2 Literature Review

2.1 Cracks Development

Different types of engineering structures, including concrete surfaces, can have fatigue stress which can lead to creating cracks. This results in a reduction of local stiffness and can also result in material discontinuities. If such measures can be detected in an early manner, then proper actions can be taken to prevent any sort of damage and failure. Cracks on the concrete surface are one of the indications where users will be able to see the degradation of the overall structure. Manual inspection is often used for inspecting the crack properly [5].

In such a method, the sketch is prepared manually, and any sort of conditions related to irregularities are kept in record. However, there are shortcomings of using such a manual approach since this can be subjected to the knowledge and experience of the specialist who is investigating the case. To tackle the issue, the Artificial Intelligence-based system gets more popular now.

This is an objective-based practical solution. Using Artificial Intelligence, it is possible to identify the crack specifically. Such actions have prompted the creation of Cracks deep learning.

2.2 Cracks Detection through Artificial Intelligence

When the solid structures disintegrate, then there is a case of developing cracks. The structural designer is the person responsible for providing such information that will look for cracks.

The Artificial Intelligence or AI system is improving regularly. With its regular evolution process, the system is used on different cracks detection process. Some systems are used to find structural damage that can exist in major infrastructure, including- dams, skyscrapers, nuclear reactors, bridges, and other buildings defects.

This technique focuses on using video technology and examines it frame by frame to look for any sort of cracks. Artificial Intelligence (AI) is mainly used to track the cracks from one frame to another. A specific operator remains who reviews the specific frames of the video to find the cracks and understand what actions are needed.

AI detection technology helps to reduce any accidents or deaths. It focuses on the computer doing the hard work and gives the human operator specific information related to the cracks [6].

2.3 Cracks Detection Process

It has been known that if there is any tiny crack in the nuclear reactor or any other infrastructure, then it could lead to catastrophic consequences.

There could be cataclysmic consequences in high risk and sensitive areas, such as- nuclear reactors if there is unidentified or under-identified structural damage. The use of Artificial Intelligence helps to create an automatic crack detection system to find out cracks properly and not to misidentify the small scratches.

Therefore, the technicians are required to review the videos frame by frame basis. The process itself is time-consuming and there could be human errors as well [7].

It can be considered a tedious task to inspect any cracks manually. It is both complex and very time-consuming. In some cases, such actions can also pose a greater danger. Therefore, authorities are now moving towards AI detection that will help them to look for buildings' defects or cracks detection.

In such cases, there has also been the use of drones that look fly around the structures, capture the live feed to the AI algorithm so that it can find the right images and also classify them into cracks or non-cracks region [8].

In terms of deep learning, one of the challenging things is network training. There are several parameters involved in this and it also requires a huge level of data for training purposes. Some techniques are considered to be efficient whereas some others are not. There is a technique known as per-pixel window-sliding which can be used for crack detection. This process is considered extremely inefficient and could also contribute to a much

higher level of cost. However, there is an alternative to using the per-pixel window-sliding where users will be able to utilize the Convolutional Neural Network or CNN for pre-selection purposes that will help to divide the full-size image into few image blocks. Inspection enhancements procedures are also used to properly understand cracks detection. To process the cracks accurately, there have been propositions to use CNN for block-level crack detection [9].

2.4 Cracks Classifications

Cracks classification is considered to be an approach through which specific crack type can be found using machine learning algorithms. Crack detection normally identifies or looks towards the presence of a crack. On the other hand, cracks classification deals with the crack classification based on feature which has been extracted from the crack region [10]. It is essential to understand the type of cracking that has been identified. Therefore, the classification of such cracks is needed to be understood. After detecting the crack in the pre-processing phase, the next step involves the detection and classification of the type of cracks in the overall processing phase. The right kind of classification model is therefore important in such cases. These cracks can be classified into seven different categories as in the following- Alligator cracking, hair cracking, multi cracking, diagonal cracking, block cracking, longitudinal cracking, and transverse cracking [11].

2.5 Shapes of Crack

The form and size of the crack can sometimes indicate the underlying problem. Cracking can be horizontal, vertical, stepped, cogged, or a combination of all these. When assessing cracks, the width of the crack is often more important than the length of the crack.

Stepped cracks tend to follow the lines of horizontal and vertical joints in buildings, such as beds of mortar between bricks or blocks and may indicate structural movement.

Vertical cracks may indicate that structural components such as bricks or blocks have failed and so can be a sign of significant stresses within the building structure.

Table 1. Damage to Walls caused by the movement of Slabs and Footings, and other Causes [10]

Application	Data Analytics
< 0.1 mm	Hairline cracks
< 1 mm	Fine cracks that do not need repair
< 5 mm	Cracks noticeable but easily filled. Doors and windows stick slightly.
5 mm to 15 mm (or a number of cracks 3 mm or more in one group)	Cracks can be repaired and possibly a small amount of wall will need to be replaced. Doors and windows stick. Service pipes can fracture. Weather tightness often impaired.
15 mm to 25 mm but also depends on number of cracks	Extensive repair work involving breaking-out and replacing sections but also depends on walls, especially over doors and windows. Window and door frames distort. Walls lean or bulge noticeably, some loss of bearing

Cracks that are wider at the top or the bottom may indicate that there has been foundation movement, with the direction of the widening indicating the likely direction of the movement.

Horizontal cracks may indicate that an element such as a wall is failing, and this may present a safety concern.

3 Research Methodology

3.1 Study Using ML

In this work, the authors develop an ML algorithmic framework for failure detection and classification merging a pattern recognition (PR) scheme and ML algorithms applied to a damage and fatigue phase-field model. The authors consider an isothermal, linear elastic, and isotropic material under the hypothesis of small deformations and brittle fracture.

We simulate the phase-field model using Finite Element Method (FEM) and a semi-implicit time-integration scheme to generate time-series data of damage phase-field ϕ and degradation function

$$g(\emptyset)=(1-\emptyset)2$$

From virtual sensing nodes positioned at different locations across a test specimen. The authors introduce a PR scheme as part of the ML framework, in which time-series data from FEM node responses are considered as a pattern with a corresponding label. The authors define multiple labels for "no failure", "onset of failure" and "failure" of the test specimen based on tensile test load-displacement curve and damage threshold concept. Once

the patterns representing different states of the material are identified, the proposed ML framework employs k-nearest neighbor (k-NN) and ANN algorithms to detect the presence and location of failure using such patterns. In this study, the authors consider different failure types to further assess the performance of the framework. Also, by introducing noise to the time series data, the authors ascertain the robustness of the proposed framework with noise-polluted data, leading to the effective use in failure analysis under high sensitive/uncertain parameters and operators. The findings from this study will pave a way for the development of novel data-driven failure prediction frameworks, which can efficiently establish a link among the classification results (i.e., accuracy) and different phase-field model parameters, thus enabling the computational framework to identify those parameters affecting model's accuracy and updating them to achieve the best performance.

3.2 Cracks Modes

Various studies over the last decade have indicated that a beam with a breathing crack, i.e., one which opens and closes during oscillation, shows nonlinear dynamic behavior because of the variation in the structural stiffness which occurs during the response cycle. On the other hand, the effect of moving loads and masses on structures and machines is an important problem both in the field of transportation and in the design of machining processes. A moving load (or moving mass) produces larger deflections and higher stresses than does an equivalent load applied statically.

These deflections and stresses are functions of both time and speed of the moving loads. It is, therefore, essential to detect and control damages in structures subjected to a moving mass. Very few studies have been reported in the literature that deals with moving load or moving mass problems under the effect of cracks.

Diagnosing a cracked component by examining the vibration signals is the most commonly used method for detecting this fault. The fault detection is possible by comparing the signals of a machine running in normal and faulty conditions.

Depending on the crack's size and location, the stiffness of the structure is reduced and, therefore, so are its natural frequencies compared to the original crack-free structure. This shift in natural frequencies has been commonly used to investigate the crack's location and size.

Vibration analysis can also be carried out using Fourier transform techniques like Fourier series expansion (FSE), Fourier integral transform (FIT), and discrete Fourier transform (DFT). Identification and diagnosis of a crack in inaccessible machine members have gained importance in now a day using vibrational analysis and artificial intelligence technologies. Using a modern technology sensor is placed near the inaccessible internal machine component. The piezoelectric transducer of the sensor produces a vibrational signal which is transformed using Wavelet Transformation technology.

These signals are time and frequency-dependent. After extracting fault features, a proper artificial neural network is implemented for aiding of the fault classification. An intelligent fault diagnosis system is performed throughout combing the approach to fault diagnosis with an artificial neural network. An artificial neural network is proved as a reliable technique to diagnose the condition of a rotating member. In general, the cracks present in the beams are not always open or close condition. It always varies from time to time depending upon the situation. If the loads are static like load due to dead weight, the load of the beam, etc. and if the deflection is more than the vibration amplitude then the crack becomes an open crack, otherwise it will be breathing crack.

Beams are one of the most commonly used structural elements in several engineering applications and experience a wide variety of static and dynamic loads. Cracks may develop in beam-like structures due to such loads. Considering the crack as a significant form of such damage, its modeling is an important step in studying the behavior of damaged structures.

Knowing the effect of crack on stiffness, the beam or shaft can be modeled using either Euler-Bernoulli or Timoshenko beam theories. The beam boundary conditions are used along with the crack compatibility relations to derive the characteristic equation relating to the natural frequency, the crack depth, and location with the other beam properties.

4 Results & Evaluation

The form and size of the crack can sometimes indicate the underlying problem. Cracking can be horizontal, vertical, stepped, cogged, or a combination of all these. When assessing cracks, the width of the crack is often more important than the length of the crack.

The accuracy of the classifications was evaluated through an analysis of the confusion matrices, this being the most commonly used method to validate this type of model. This matrix contains information based on the percentages of observed and estimated data for each object is classified, in which different parameter that indicates the precision of the classification can be calculated [14]. The parameters that arise from the error matrix and the formula to calculate them are as follow:

Precision $$P = \frac{\sum_{i=1}^{m} x_{ii}}{N}$$

Accuracy $$P_A = \frac{x_{ii}}{x_{\sum i}}$$

Precision $$U_p = \frac{x_{ii}}{x_{i\sum}}$$

Coefficient Analysis

$$K = \frac{N \sum_{i=1}^{m} x_{ii} - \sum_{i=1}^{m} x_{i\sum}\ x_{\sum i}}{N^2 - \sum_{i=1}^{m} x_{i\sum}\ x_{\sum i}}$$

Where m = Total number of classes, N = Total number of pixels in the m reference classes, x_ii= elements of the main diagonal of the confusion matrix, x_∑i= sum of the pixels of reference class i and x_(i ∑)= sum of the pixels classified as class i.

4.1 Cracks Detection Using ANN Method

There are different classical methods which are used for cracks detection. One of the methods was known as an artificial neural network method. Bakhary (2007) considered applying Artificial Neural Network or ANN towards damage [12]. During the person's investigation, a certain type of ANN model has been created to apply towards Rosenblueth's point estimate method. This method has been verified through the simulation process of Monte Carlo. There has also been an estimation of the statistics of the stiffness. After that, the probability of damage existence was done and calculated based on the probability density function of the current undamaged and damaged states. Such a developed approach was applied to detect simulated damage in a steel frame model and another concrete [13].

There has been the use of ANN or Artificial Neural Networks by different researchers so that they identify the damage location properly and also by getting severity from different types of input as well as output variables. They help to provide an efficient tool in terms of pattern recognition. There have been several studies [10].

ANN and it has been concluded from most of the studies that the Artificial Neural Network or ANNs can provide the correct level of damage identification. This is especially true when the overall structural damage and the related changes in vibration properties are simulated numerically and they are considered error-free. Nonetheless, this needs to be noted that during practice, there could be uncertainties in the overall FE model parameters and there could be some modeling errors that are known to be inevitable [10].

The overall existence of having modeling error in the FE model because of the inaccuracy of physical parameters and structural properties may end up in vibration parameters. Furthermore, having measurement error in the data which is normally used as testing data in the ANN model can also be considered unavoidable. ANN prediction efficiency is mostly dependent on the accuracy of both these components. The existence of such types of uncertainties can also result in a false and inaccurate type of ANN predictions. Therefore, the authors can understand that there should be proper analysis related to the reliability of the Artificial Neural Networks or ANN models for any sort of structural damage detection.

4.2 Cracks Detection by Hybrid Technique

Research has brought in a new method so that the location as well as crack depth on any structure can be identified. One such method is known as a hybrid neuro-genetic technique. In this case, feed-forward multi-layer neural networks are trained through the process of backpropagation to learn about the input-output relation of the whole system [5]. After that, the researchers used a genetic algorithm to find out the different locations of the crack as well as its depth so that the difference from the measured frequencies can be minimized. Using neural networks for damage detection has been developed for many years. This is because they can cope with the different structural damage analysis without considering any intensive computation. Neural networks are considered to be a potential approach through which users will be able to understand and detect the structural damage. For such researches, it is required to have both the modal frequencies and the modal shapes as well for ensuring the neural network training so that the authors can understand more about the structural damage detection [10].

4.3 Discussion

Out of the described methods, the hybrid technique of crack detection provided the most accurate results in detecting cracks with at least 18% of accuracy above the other methods. This is seen as a great outcome from a crack detection method, which may ensure a significant enhancement in terms of identifying and fixing cracks on different surfaces.

In terms of deep learning, one of the challenging things is network training. There are several parameters involved in this and it also requires a huge level of data for training purposes. Some techniques are considered to be efficient whereas some others are not. There is a technique known as per-pixel window-sliding which can be used for crack detection [11]. This process is considered extremely inefficient and could also

contribute to a much higher level of cost. However, there is an alternative to using the per-pixel window-sliding where users will be able to utilize the Convolutional Neural Network or CNN for pre-selection purposes that will help to divide the full-size image into few image blocks. Inspection enhancements procedures are also used to properly understand cracks detection. To process the cracks accurately, there have been propositions to use CNN for block-level crack detection [5].

5 Conclusion

Cracks occur when solid structures disintegrate. These include concrete surfaces in which crack detection methods could help identifying any type of cracks, including transversal, longitudinal, and pothole. The challenge for this procedure would be network training, in which several parameters are involved in the determination of the location and severity level of the cracks. This study found out that the hybrid crack detection technique provides more accurate and reliable outcomes due to the fact that it combines both the ANN and ABC algorithms to help the designers locating and analyzing cracks. It is expected that this finding may contribute in answering several questions over the accuracy and reliability of various crack detection methods as well as help providing an appropriate response to the growing discourse over the field of research.

Abstract –

We have developed a mobile survey vehicle with a high-precision laser scanner measurements for deformation analysis, 20 video cameras for damage assessment on lining surface such as cracks and water leakage, and also a non-contact radar to detect lining thickness and cavity behind lining.

In this paper, we report the development of a non-contact radar survey system mounted on a mobile inspection vehicle to detect inner defects and cavities behind lining concrete, and examination of efficiency of utilizing an integrated diagnosis system to assess the soundness comprehensively as well as value of compiling database of various unsoundness conditions including inner defects by a 3D visualizing technology.

It supports the technical experts to evaluate the diagnosis and the cause of the damage in the tunnel. It contributes to efficient damage detection for tunnel inspection based on AI (Artificial Intelligence) and 3D visualization of various damage conditions, including inner defects.

Tunnel inspection; Mobile survey technology; Non-contact radar; Lining defects and cavity detection; 3D visualization; Artificial Intelligence

1 Introduction

Human visual inspection of road tunnels has been a common practice used in routine maintenance procedure to ensure its safety. It, however, has some problems; it requires traffic restrictions on at least one lane, and it is hard to make a fair judgement in dark and narrow spaces.

We have overcome some of the problems, by developing a mobile survey vehicle with a high-precision laser scanner measurements for deformation analysis, 20 video cameras for damage assessment on lining surface such as cracks and water leakage, as explaining the overview of the inspection vehicle in next section.

Our next challenges are to dispense hammering test of unnecessary normal parts. We introduced non-contact radar to detect lining thickness and cavity behind lining, and developed an inspection technology detecting the inner defects in concrete lining using rapidly scannable non-contact radar as a complement of hammering test. With non-contact radar system, which allows the vehicle to survey at 50km/h, concrete lining thickness and its back cavity has successfully detected.

In addition, in this paper, we examined efficiency of utilizing an integrated diagnosis system to assess the soundness comprehensively as well as value of compiling database of various unsoundness conditions including inner defects by a 3D visualizing technology. With the acquired data, analysis engineers overlay the result on the 3D model and integrate information such as position synchronized images, deformation contours, cavities and inner defects. It is expected to support the technical experts to evaluate the diagnosis and the cause of the deformation in the tunnel. By recording those damages in digital format, progressiveness can be correctly and accurately tracked off. After the first survey measurements, the cause and progress of damage is continuously monitored. It contributes to efficient damage detection for tunnel inspection based on AI (Artificial Intelligence) and 3D visualization of various damage conditions, including inner defects.

2 Overview of Mobile Inspection Vehicle

An overview of this mobile inspection vehicle is shown in Figures 1, 2. The following measurement data and functions are available for the tunnel inspection.

1. Laser Tunnel Surveys and Deformation mode analysis: The high-precision laser scanner with 1 million points/second is used to obtain high-density data, which enables us to objectively determine the

lining shapes and the deformation of the lining (deformation mode, joints, and level differences of cracks).

2. Tunnel Image surveys and Soundness assessment: Image of wall surface taken while travelling at 50-70km/h, the cracks of 0.3 mm or more can be identified. It is possible to draw an objective and accurate damage map, and to identify the progressive of unsoundness conditions and to estimate the causes of damage.
3. Radar Tunnel Surveys Cavity Evaluation: Non-contact radar system to detect lining thickness, back cavities, and inner defects (while travelling at 50km/h). The system aims to quickly detect hazard locations with thin lining and cavities [1]. This is the world's first radar antenna capable of high-speed detection with a separation of about 3 m. The details of the functions and development are indicate in next section.

The results obtained from these results can be used to support efficient close visual inspection and hammering test, and plan detailed inspections and repairs.

3 Development of Mobile Non-contact Radar

3.1 Radar for Inspection of Lining Thickness and Cavities behind Lining Concrete

3.1.1 Principles of radar survey

The principles of subsurface radar survey are those of indirect survey, which applies the physical characteristics of EM waves that reflect at boundaries between different substances.

Due to the damping nature of a substance, when an EM wave propagates through a medium, its energy is absorbed and the amplitude reduced as a result. Because of this, the general characteristics are that the reflected waves coming from deep locations lack adequate strength and thus are undetectable on radar records. This damping effect is closely interrelated with frequency; the greater the frequency the greater the damping effect, and vice versa. Therefore, to have a deeper survey depth, it is necessary to set a lower frequency.

On the other hand, a lower frequency which leads to a lower resolution, making it difficult to identify small configurations. There is thus a conflicting relationship; obtaining a high resolution requires high frequencies, while achieving a larger survey depth requires low frequencies (See Table 1). Because of this

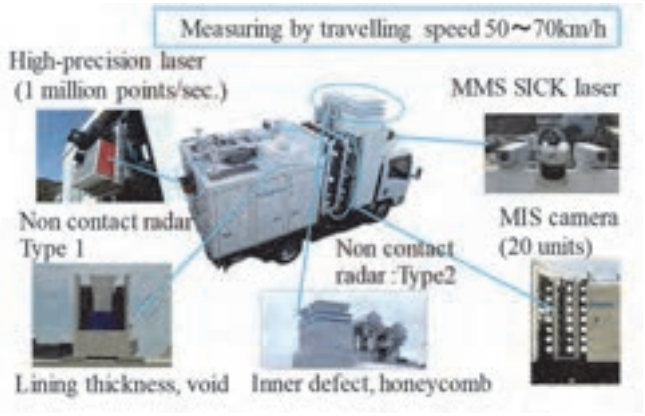

Figure 1. System of MIMM-R

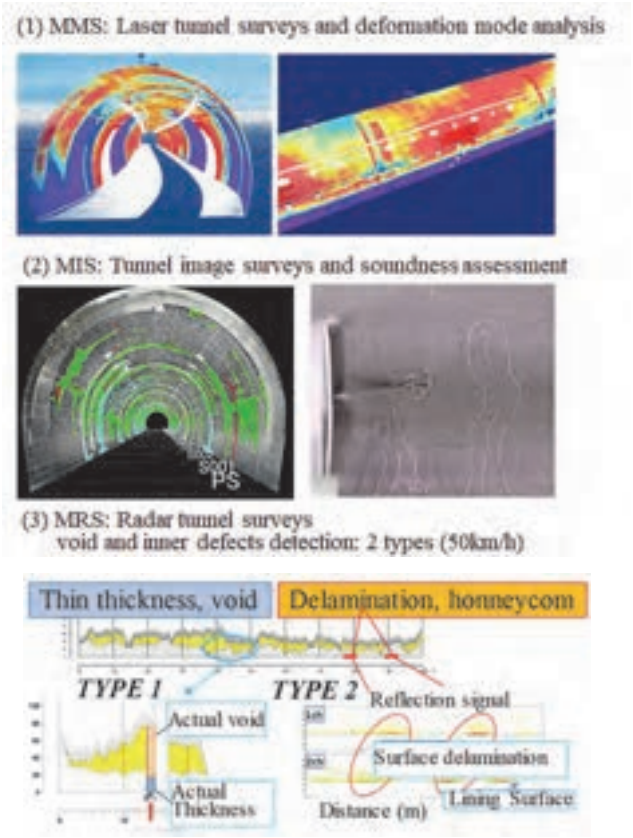

Figure 2. Function of MIMM-R

Table 1. Frequency and resolution

	High frequency	Med frequency	Low frequency
Frequency	1000GHz~	900～300MH	~300GHz
Detectable depth	~0.3m	~1.0m	~1.8m
With rebars	ctc 100mm	ctc 300mm	ctc 500mm
Depth image	Shallow		Deep
Resolution image	Fine		Rough

dependency of EM wave characteristics on frequency, an appropriate frequency should be selected according to the purpose and the target of a survey.

In improving the non-contact radar system to be applicable to tunnels, particular attention was given to the following two issues [2] .

3.1.2 Approx. 3m distance from the target in the non-contact radar system

The non-contact radar system makes it difficult to analyze the patterns of reflected waves further away from the target due to the damping and diffusion of EM waves. Based on the principles analysis that takes into account the polarity and coefficient of EM wave reflection as shown in Figure 3, the team managed to resolve the issue of reduction in detection performance in the non-contact radar system.

In the case of contact antennas, the diffusion characteristics of EM waves also caused difficulties in keeping an adequate distance. The contact-type bow tie antenna has no directionality and low sensitivity, and therefore should be touched with the target. On the other hand, the newly adopted horn antenna has a high directionality and high sensitivity, allowing to set a greater distance of 3m.

3.1.3 Realization of high-speed inspection

Improvement of the controller was necessary to obtain the same amount of data as the contact type while travelling at a speed of 50km/h or faster. To handle the extreme speed of EM waves, a sampler is used to divide a single trace, obtain the divided pieces and then reconstruct the same single trace shape. Data collection at a 50km or faster was made possible by enhancing the sampling speed, and speeding up the analog/digital converter.

3.1.4 Evaluation of Practical Use

To determine the practicability, past adequacy survey results obtained for a tunnel using the contact-type antennas and those by drilling were compared to the data obtained with the non-contact radar system, the differences of which were then analyzed and evaluated.

Regarding Sample shown in Figure 4, Data A and B were obtained with a conventional contact-type radar system and the newly developed non-contact radar system, respectively. The figure shows that they yielded more or less the same results.

The data obtained with the non-contact system were then compared to the actual lengths measured in a boring survey, which proved to have a high correlation as shown in Figure 4. Next, the analytical results for the radar survey were compared to the actual measurements taken by boring. These results show that the accuracy is generally 80-90%, which is sufficient for practical use.

3.2 Radar for Inner Defects Detection

3.2.1 Development Background and Target

In the field of SIP (Cross-ministerial Strategic Innovation Promotion Program in Japan) infrastructure maintenance, renewal and management technology, we have developed the technology under the theme of "Development of Internal Defect Inspection Technology and Integrated Diagnosis System for Tunnel Lining Using High-Speed Non-contact Radar" (completed in fiscal year 2016), and have achieved good results in the development of radar for internal defects as a support system for percussion inspection [2] [3].

Of various irregularities found in tunnel lining concrete, exfoliation of block pieces is regarded important in tunnel management because it gives direct impacts on users, and the timing of its occurrence is difficult to predict. In particular, certain inner defects including discontinuous joint loosening, honeycombs and poor material quality that do not involve cracking, water leakage or level differences on the surface are extremely difficult to detect unless a proper hammering test is carried out. Survey vehicles could not detect these inner defects if they were of the non-contact type and travelling at a high speed. Such inner defects often occur around and along joints, as shown in Figure 5. Given these, for the radar system designed for inner defects detection, the target size of areas to be surveyed was set at 5cm and 1m in the longitudinal and transversal directions, respectively.

The antennas of five domestic and five overseas companies were investigated prior to the development of the radar antenna. The results of the survey showed that a maximum separation of about 1 m is the limit for the existing antennas to detect defects in concrete. In road tunnels, a separation of about 3 m is required to allow for a driving survey without traffic control, due to constraints caused by clearance limit and obstacles such as signs and jet fans. As a result, this led to the development of an original antenna.

3.2.2 Verification Results

Figure 6 shows the schematic diagrams of the two types of radar systems, figure 7 shows the installation and measurement status of the internal defect radar antenna. The antenna specifications are shown in Table 2, and the verification results of the developed antenna are shown in Figure 8.

The results of the verification are as follows; internal cavities of known size and location were accurately detected in the full-scale test model of New Bridge at Nagoya University. The depth of the search for cavities, surface delamination and honeycomb in the lining concrete is about 20 cm, and the developed

method can support efficient inspection by screening the problem areas before the hammering test.

4 Damage Detection with AI

4.1 Damage Detection Using Deep Learning Based Semantic Segmentation

In the post-processes of measurement, it requires a lot of time and efforts to manually detect damages and record them on a damage map. In order to reduce manual efforts, we have applied deep learning and semantic segmentation models [4] [5]. In particular, it is expected that the semantic segmentation models can be improved to practical detection of degradation [6].

4.1.1 Training dataset

Using 200 spans of tunnel inspection images, annotate three types of damages; water leakage, free lime and cracks. In our previous studies, discrepancies between the damage on the inspection photographs and the annotation data, It could be affected its low accuracy of detection. In this study, we annotated the degradation in pixel level.

4.1.2 Model Architecture

The damage detection network is built on the SegNet, which is deep convolutional encoder-decoder architecture designed for multi-class pixel-wise segmentation and developed by members at the University of Cambridge, UK.

4.2 Experimental evaluation

To evaluate the performance of the model, out-of-sample images are used for inputs, and detects water leakage, free lime, cracks. Figure 9 shows the results and its ground truth.

4.2.1 Evaluation for water leakage and free lime detection

As a result of water leakage and free lime detection, it assumed that simple degradation are mostly extracted. However, the degradation where the damages are compounded or covered by a repair net tend to fail to be detected.

4.2.2 Evaluation for crack detection

Although cracks that are clearly visible in the images are generally detected, narrow cracks and those that were difficult to distinguish from chalks or shadows were over detected.

On the assumption that the model trained with various types of cracks in the images can extract cracks in all sizes and conditions, however the trained network has failed to converge and resulted in over detection.

By examining the cause of failure, the initial model

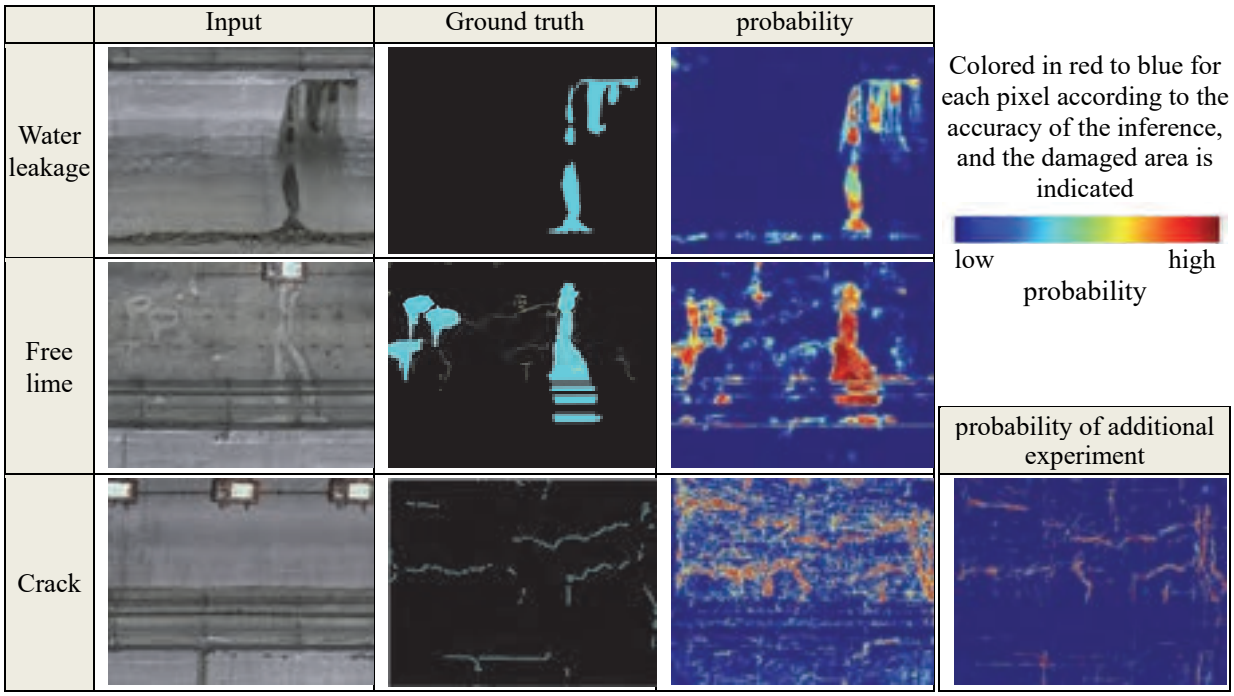

Figure 9. Results of damage detection using AI

has trained with a mixture of images in various qualities. The images in low quality could be a cause of non-convergence in the training process. In additional experiment, new training data has been set only with high-quality images, and it has achieved successful training process. The bottom right image in figure 9 shows the result from the retrained model, which has been achieved the desired performance.

5 Visualization in 3D

The mobile inspection vehicle is capable of not only image measurement also geometry measurement by built-in laser scanners. It enables to construct 3D model based on the point clouds of the laser, and to generate composite images and obtain the deformation position in synchronized accurate position. Figure 10 shows the 3D model including deformation information.

The image layer and deformation map layers are superimposed on 3D model based on coordinates and positions of the laser point cloud.

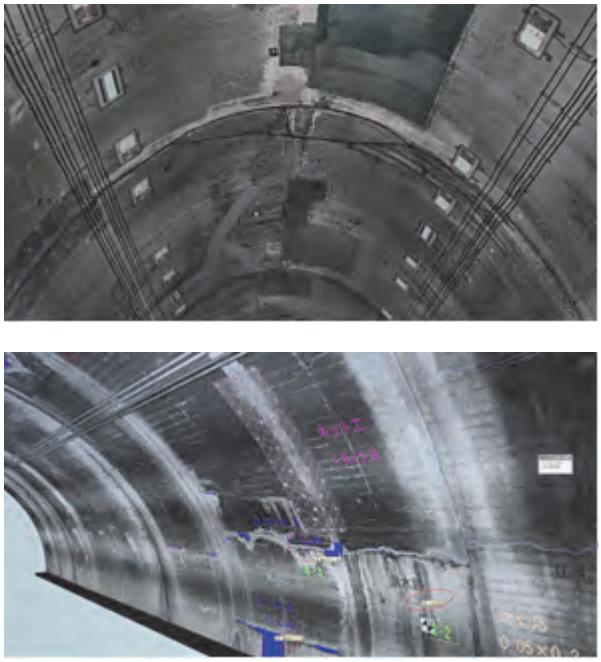

Figure 10. 3D models（bottom: damage map）

6 Development of Integrated Diagnosis System

To support diagnosis evaluation, it is necessary to comprehensively analyze not only images but also data from laser and radar units;

(1) Detecting degradation, such as cracks, water leakage and free lime, from acquired images

(2) Identifying deformation mode and damaged position by utilizing laser point clouds, estimating the cause of the deformation mode, and identifying progressive degradations

(3) Detecting lining thickness and cavity behind concrete lining with analyzing acquired data from radar units

To diagnose correctly and certainly, a system which is capable of intuitively displaying details of those information is needed. The integrated diagnosis system to assess the soundness comprehensively and compiling a database of various unsoundness conditions, including inner defects by a 3D visualizing technology. The overview of the integrated diagnostic system is shown in figure 11. The integrated diagnostic system has the functions listed below.

(1) Point clouds analysis: Automatic detection of construction joints, extraction of cross-sectional shapes and span axes for each span, deformation mode analysis

(2) Damage map generator: Lining surface images are combined with the positional information of point clouds to create a damage map of cracks and leaks.

(3) Radar measurement analysis: The results of measurement and analysis of internal defects, lining thickness and cavity can be synchronized with the point cloud information and displayed in 3D, contour, longitudinal and transverse views.

(4) 3D visualization: A function to support the estimation of the cause of deformation and diagnosis by displaying the results of image, laser, and radar analysis in 3D and superimposing them on each other.

(5) Database: Stores images and records of multiple tunnels and inspection, deformation and countermeasure history.

To develop the function that detect progressive degradations, measuring the difference in relative position of the detected degradation in two different years. Also, the system has export function that allows integrate the both in 2D and 3D visualized result into other database systems, which make it possible to use the analyzed data for linking to BIM models. The system analyzes and visualizes the obtained data in 3D, and also visualizes and exports in 2D when necessary. These results are used to optimize the priority of the implementation of countermeasures, budget allocation, and to provide support services for facility management.

7 Conclusions

While visual inspection requires human labors to manually judge by sight, the integrated diagnosis system, which effectively utilize technologies, supports visual inspection to improve the efficiency of diagnosis, to extract deformation objectively and accurately, and to draw damage maps efficiently.

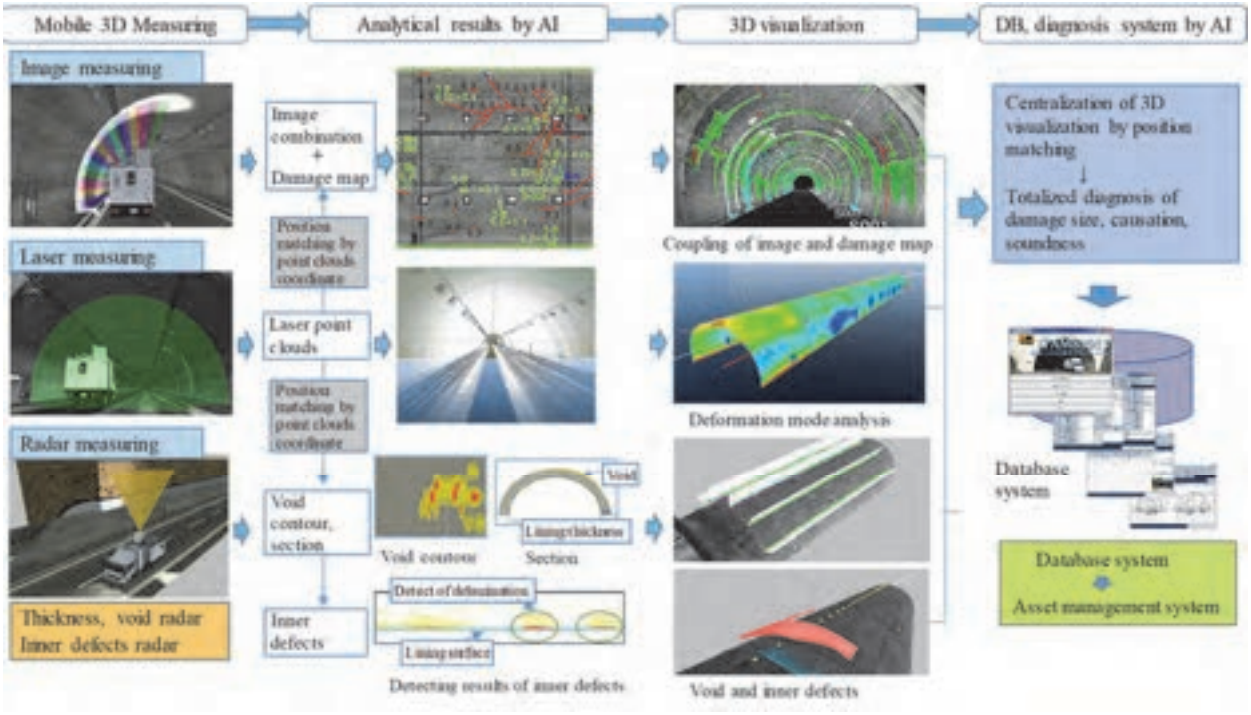

Figure 11. Totalized diagnosis and asset database system using 3D visualization and AI

It is not suitable to completely replace humanity to technologies, since it is responsible to human to make judgements to ensure the safety. However, it is sufficiently possible to use the results from the mobile measurement and its analytical data to conduct effective human visual inspection. The Usage of mobile inspection vehicle before conducting a human visual inspection, will reduce the cost and time involved in the overall workflow. Pre-inspection by the vehicle extract areas that requires attention at visual inspection and hammering tests. The visualization in 3D supports to understand integrated information of cameras, lasers and radars, and to appropriately judge the diagnosis and soundness.

The application of AI to inspection and diagnosis is in the development, although some results have been achieved. It will be our next challenges to improve accuracy of damage detection, reliability of evaluation and quality. Also, as a supportive technology for overall maintenance management, we will work towards the establishment of the system and the achievement of safe and secure society through smart tunnel management.

Applications of Building Information Modeling (BIM) in Disaster Resilience: Present Status and Future Trends

S. Khanmohammadi[a], M. Arashpour[a] and Y. Bai[a]

[a]Department of Civil Engineering, Monash University, Australia
E-mail: sadegh.khanmohammadi@monash.edu; mehrdad.arashpour@monash.edu; yu.bai@monash.edu

Abstract –

Natural disasters such as bushfires, wildfires, hurricanes, earthquakes, and floods cause significant socioeconomic losses with associated damages to communities. From 2005 to 2014, the worldwide damage caused by disasters has been more than US$1.4 trillion, with 0.7 million deaths and 1.7 billion people affected. In order to reduce the negative impacts of disasters and strengthening communities, the disaster resilience topic has been receiving increased attention to maximize the ability of communities to adapt and recover fast. Disaster resilience can benefit from Building information modeling (BIM) as an effective tool to facilitate informed decision-making. This article provides a comprehensive review of the existing literature on BIM applications in disaster resilience. Past research studies are categorized by the year of publications, type of disasters (fire, earthquake, flood), phase of the disaster (mitigation, preparedness, response, recovery), and target groups (buildings, infrastructures). The paper aims to provide a holistic review of research trends and patterns, emerging technologies, benefits, challenges and limitations, and research gaps.

Keywords –

BIM; Building information modeling; Bushfire; Disaster; Earthquake; Evacuation; Fire; Flood; Resilience; Review

1 Introduction

Based on the report of the United Nations Office for Disaster Risk Reduction (UNDRR), the number of disasters associated with natural hazards has increased over the past two decades. Consequently, communities should be prepared to recover from the impacts of disasters. A disaster-resilient community should withstand a natural hazard with a tolerable level of losses and adopts mitigation actions consistent with the desired level of protection [1]. The number of scientific research studies on disaster resilience has increased dramatically in recent years as shown in Figure 1.

Integration of disaster resilience and Building information modeling (BIM) provides an effective tool to help decision-makers visualize what is to happen in a simulated environment [2]. Similar to research on disaster resilience, the number of studies on BIM has increased over the past 20 years as presented in Figure 1. Although many BIM applications have been explored in the literature, applications for disaster resilience is scarce.

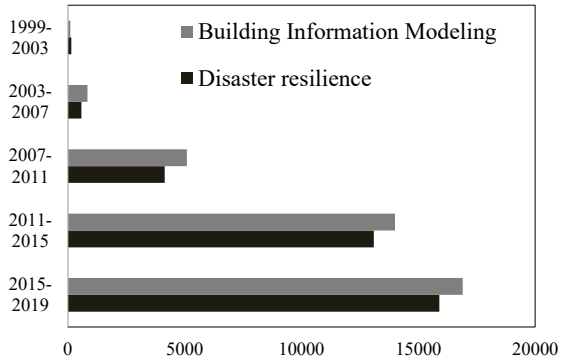

Figure 1. Number of publications on "Disaster resilience" and "Building Information modeling" in Google Scholar during the past 20

This research carries out a systematic review of the relevant literature with the following objectives: (1) classification of papers on BIM applications for disaster resilience; and (2) scoring the papers based on relevance; and (3) categorizing the selected papers based on the type and phase of disasters; and (4) identifying the research gaps in the literature, and outlining the potential future research directions.

Following the introduction, section 2 describes the research methods adopted in this paper. Section 3 provides an overview of the current literature on BIM applications for disaster resilience. The detailed BIM applications are categorized and described in Section 4. Section 5 outlines the identified research gaps and opportunities for future research. Finally, the conclusion is presented in Section 6.

2 Research methodology

The review method was informed by the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines [3]. In the first step, about 30 BIM review papers were assessed, and the papers on the disaster resilience area were shortlisted. In the second step, two search attempts were conducted to find relevant studies. The keywords of the first attempt comprised building information modeling, BIM, and resilience, which resulted in finding 63 papers. In the second attempt, keywords such as building information modeling, BIM, disaster, flood, hurricane, tornadoes, volcanic, wildfire, earthquake, tsunami, and storm were utilized, and 251 research studies were found. The studies found in the two attempts were merged and the duplicated papers removed. In the next step, the evaluation of article titles was conducted to find the most suitable papers. Consequently, the outcome contains 123 papers.

In order to select the most appropriate papers, a selection system was needed. The selection system of these papers considered four important paper quality indexes such as authors' expertise, paper citations, and journal quality. Indexes are described as below:

- **Authors' expertise:** The authors' expertise is a critical index for the quality of the paper. The h-index of authors can be a good measure in order to show their expertise.
- **Publication date:** new publications can demonstrate the trends of current research; thus, they are more interesting for researchers. The current paper reviews papers that have been published during 2007-2020.
- **Paper citations:** Number paper citations are a measure of validity. Papers published before 2018 without at least 10 citations were excluded from this review.
- **Paper type:** Only books and journal publications are considered in this review paper.

All 123 papers are evaluated based on the above indexes. Consequently, 42 papers are detected as the most relevant papers that should be reviewed in this paper. Using the abovementioned approach, a comprehensive analysis of the literature was conducted. The comprehensive literature review provides useful information about identified gaps and opportunities for future research. The process is demonstrated in Figure 2.

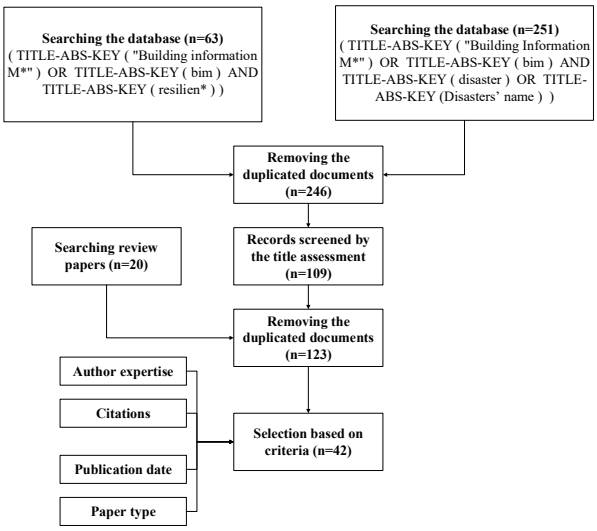

Figure 2. The process of the systematic review

3 Analysis of publications

The database of the nominated papers contains articles published from 2007 to 2020. However, about 39 percent of the selected papers are published after 2019. This means that the attention to the BIM applications for disaster resilience has been increased. Most of the selected papers has not been reviewed by the past review papers. Only 4 papers [4]–[6] among 44 papers have been reviewed by Tang et al. [7]. The selected papers have been published in 25 different journals. The journals with more than one included paper and their research impact are shown in Table 1. Based on the database of selected articles, an analysis was performed on the content of the article titles and abstracts to identify the most occurring topics. VOSviewer was utilized in this paper. Constructing and viewing bibliometric maps can be done by VOSviewer. The size of the label and the circle of an item is determined by the weight of the item. In addition, the distance between the two circles reveals the relatedness and similarity between them. The lighter colors show more recent papers as the graph guide. The output of VOSviewer is shown in Figure 3.

Table 1 Top journals in BIM applications for disaster resilience

No.	Journal name	No. of papers	CiteScore 2018

2	Advanced Engineering Informatics	5	5.72
3	Journal of Computing in Civil Engineering	4	2.55
4	Water (Switzerland)	2	2.66

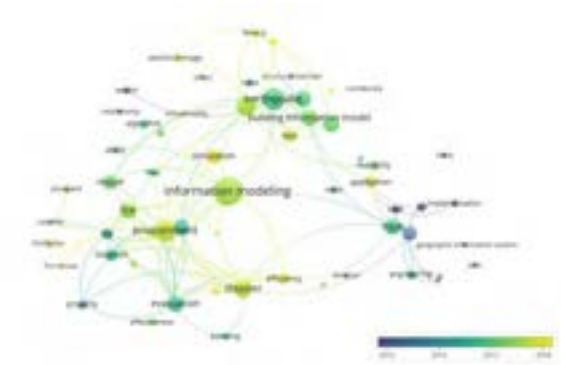

Figure 3. Main research areas in BIM applications for disaster resilience and its trends

4 Discussion

The database of the papers contains the most outstanding papers on BIM applications for disaster resilience. The BIM applications can be categorized based on the phase of the disaster. Four disaster phases (preparedness, mitigation, response, and recovery) are considered in this paper. Disaster preparedness is persuading organizations to realize the hazard that has to be faced. Loss reduction by identifying the risk assessment is disaster mitigation. Disaster response is associated with the post-disaster situation and it contains actions such as damage assessment and evacuation. Post-disaster activities that restore or improve the pre-disaster conditions can be defined as disaster recovery [8]. In addition to disaster phases, the selected papers analyzed the BIM applications based on disaster types. The database comprises the application of BIM for fire, earthquake, and flood.

4.1 Fire

Based on the publication date, it can be mentioned that the BIM application for fire response is the first BIM application for disaster resilience. Structural fires are common urban disasters. Traditionally, the 2-D maps guided people to find the exit routes in emergencies such as the fire in buildings. The outdated approach has a few critical limitations. For instance, it is possible that people cannot interpret 2-D maps correctly. The BIM applications for fire are generally related to preparedness, mitigation, and response phases.

4.1.1 Pre-disaster rescue route planning

BIM can be an appropriate tool for visualizing and providing insight. Pre-disaster rescue route planning concentrated on finding the shortest route. GIS historically utilized for finding the evacuation routes. However, in order to information transformation, Isikdag et al. [9] presented a combination of BIM and GIS to find the rescue routes. Li et al. [6] designed an algorithm for finding the location of trapped occupants at building fire emergency scenes based on BIM and GIS integration. A graphical interface for user interaction is provided by the model. Chi et al. [10] proposed that evacuation regulation can be done based on static rescue routes evaluation and BIM models. Designers can check their design by the proposed methodology, and revise it if it is mandatory. The distance of the exit routes is assumed as the longest possible distance.

4.1.2 Dynamic rescue route planning

Not only should the rescue route be short, but also it must be safe and obstacle-free. These rescue routes may be changed during the disasters based on the fire condition. Consequently, rescue routes should be determined dynamically. In most cases, firefighters lose a great amount of valuable time to get familiar with the site. BIM-based 3D model can help them to find invaluable information about the building easily. Shiau et al. [11] create a web-based fire control system based on BIM. The characteristics of the building material are accessible in the 3D map. A lot of fire detectors and monitors are available in the building, and their information is integrated by the 3D map. Firefighters could find the best relief program based on the material type around the fire location. Wang et al. [12] utilized BIM as a comprehensive building information model to provide real-time guidance for fire evacuation. The shortest evacuation routes generated by the A* search algorithm. The results of the path finding algorithm should be safe with no obstacles. Users can show the result of the path finding on their mobile devices using virtual reality. In addition, the developed methodology can propose a suitable path for disabled evacuees. Yoon et al. [5] presented a smartphone-based, in-building emergency response assistance system that can provide useful information about the location and physical status of victims. The location of the victims can be determined by Wi-Fi signals of the smartphone. The status of the victims is assessed by asking themselves or sensors in their phones.

Happening a disaster in a surrounding building may block a few entrances and exits and change the navigation routes. To remedy this problem, Tashakkori et al. [13] proposed a model that considers the information about the interiors and exteriors of the building in the fire management system. Chen et al. [14] integrated Internet of Things (IoT) technology and BIM in order to monitor the real-time situation during a fire disaster. The system controls the LED guide pointers to help evacuees find the best routes. Chen et al. [15] integrated network analysis with building information modeling (BIM) to help responders can find the rescue routes by using the developed graph. The route selection

procedure is a function of distance, risk of the disaster, and people congestion in this study. Chou et al. [16] developed a framework of dynamic evacuation procedures for departments. The best fire rescue paths are calculated based on the shortest path algorithm. Bluetooth sensor outputs show the information of temperature and smoke of routes. The best routes are updated based on this information.

4.1.3 Evacuation route considering human behavior

The crowding effect should be considered in rescue route planning as well. For this goal, human behavior is required. Cheng et al. [17] considered the individual characteristics (e.g., confusion and nervousness in an emergency event) in the mobile guidance device of the proposed BIM-based model. Marzouk et al. [18] present a framework to help managers to plan for labor evacuation in construction sites. BIM and agent-based simulation are utilized in the mentioned framework. The Evacuation Simulation Model contains an agent-based simulation approach to simulate the labor evacuation considering labor behavior. Mirahadi et al. [19] developed a tool that is named EvacuSafe. EvacuSafe can be useful to increase the evacuation safety performance by considering fire risk and population crowd risk. It comprises an agent-based model to predict the behavior of the residents. Ma et al. [20] a fire emergency management system based on the BIM platform. The developed system can consider the behavior of evacuees during fire disasters. People can find optimal paths such as obstacle-free and minimum distance by using technologies. Then, they will select their way. The fire management system effectively manages fire disasters based on fire conditions and people's behavior.

4.2 Earthquake

Earthquake is the second disaster type which can be managed by BIM. Earthquakes are major threats to many societies across the world [21]. Early research studies tried to prove the applicability of BIM for enhancing the seismic resilience of buildings. A research study by Welch et al. [22] is devoted to investigating the possible BIM application in seismic resilience area. Welch et al. [22] argue that BIM application for earthquakes can be classified into 3 groups. First, BIM comprises detailed information about building for seismic risk assessments. Second, BIM can be combined with structural health monitoring to protect critical buildings such as hospitals. Third, BIM can pave the roads of information communication in the emergency shutdown in order to efficiently make decisions to identify, prioritize, and manage risks. In this paper, the research studies on BIM application for earthquakes are classified anticipating the as-damage BIM model, design guidance, search and rescue application, and fire due to the earthquake. Anticipating the as-damage BIM model, and design guidance belongs to the preparedness and mitigation phases. However, search and rescue applications, and fire due to the earthquake belong to the response phase.

4.2.1 Anticipating as-damaged BIM model and loss estimation

To calculate the building strength accurately and demonstrate the anticipated damages after earthquakes, Anil et al. [23] developed an as-damaged BIM model. This model contains strength analysis and visual assessment including structural analysis models, building geometry and specification, material properties, reinforcement information, and damage records. The earthquake damages are predicted based on FEMA 306 guideline. The approach to forecasting the as-damage BIM model of a building based on its as-built BIM model is described by Ma et al. [24]. In addition, Zeibak-Shini et al. [25] anticipated the as-damaged model by developing an algorithm to assess the location and damage of each component of reinforced concrete frames with masonry infill walls. Ma et al. [26] forecasted the damage sequence information of a building based on BIM. Zhang et al. [27] highlighted the fact that due to hidden structural elements, building deflection evaluation after earthquakes is difficult and cost-intensive. On the other hand, this task plays an important role in occupant safety and should be determined. Sensors are able to solve this problem and provide updated information about building deflection. The output of the sensors can be easily visualized for users by using BIM.

Xu et al. [28] developed a BIM-based seismic loss evaluation based on FEMA guidelines. Consequently, decision-makers are able to observe the distribution of damage and loss in a virtual walkthrough. Considering the fact that FEMA guidelines require detailed information to predict building damages. In addition, the building components in the BIM model may have various levels of development (LODs). Xu et al. [29] found that some components may not have enough detailed information for analysis based on FEMA guidelines. They developed a framework to estimate the seismic loss of a model with various-LOD BIM data considering uncertainties. Vitiello et al. [30] implemented a BIM model in order to determine the most cost-effective retrofit intervention that can be determined based on the seismic loss estimation of each intervention.

BIM can be used in the design procedure as well. Non-structural building elements play an important role in performance-based earthquake engineering. Perrone

et al. [31] developed a tool for the seismic design of non-structural building elements based on BIM. It is shown that the BIM model information eases the seismic design procedure of sprinkler piping systems. Furthermore, the finite element analysis needs accurate geometric characteristics of building elements. This accurate information can get available by BIM. Ren et al. [32] introduced a framework that can conduct a finite element simulation for a building based on BIM.

4.2.2 Search and rescue application and post-disaster fire

Traditionally, rescuers should enter the damaged building to collect information. This task is dangerous and time-consuming. Bloch et al. [33] provided a BIM approach in order to help search and rescue teams after earthquakes. The interior of the damaged building is estimated using the as-built and as-damaged BIM model. The developed framework can accelerate the procedure and save the search and rescue teams. Xu et al. [34] taught inhabitants how to survive in earthquakes by visualizing non-structural damages. 3D information BIM model of the building is the basis of the structural analysis and Virtual Reality analysis.

Fire disasters are common after seismic disasters. In most modern buildings, fire sprinkler systems are installed in order to protect the building against fire. However, sprinkler systems may sustain damages due to earthquakes. The effect of the spread of the fire owing to sprinkler systems damages is studied by Xu et al. [35]. In addition, Lu et al. [36] developed a simulation framework of indoor post-earthquake fire based on BIM. In this study, the post-earthquake fire, building damages, fallen debris are estimated. Considering the damages and fire conditions, the rescue route can be determined in a virtual reality scenario. The results can be used as a training tool for building occupants.

4.3 Flood

The third frequent disaster type in BIM research studies is flood disasters. Due to climate change, the number of flood hazards has been increased recently. In addition, high settlement density highlighted the risk of economic losses due to floods. The BIM application for flood hazards are more recent and are mentioned in below. Most of BIM applications for flood hazards are related to preparedness, mitigation disaster phases.

4.3.1 Damage assessment

The flood damage assessment should be done for each building separately. This requirement needs detailed information about buildings. BIM model is able to satisfy this condition based on Amirebrahimi et al. [37]. Based on this study, the effect of the flood on the building can be calculated and visualized. Amirebrahimi et al. [38] completed the past study by integrating BIM and geographic information systems (GIS). Considering the fact that the most application of GIS is related to an outdoor and large-scale geographical feature, and the most application of BIM is associated with indoor objects, BIM and GIS integration is a proper combination for flood damage assessment. BIM is responsible for building information, and GIS is responsible for flood information. Lyu et al. [39] recommended that BIM and GIS integration can be a suitable tool for city managers in order to assess the flooding hazards.

BIM has been used to investigate the impact of a dam on the downstream by Rong et al. [40]. The dam discharge and flood routing are simulated by BIM. The downstream flood risk is evaluated by simulating the dam operation under different water levels. The treats due to the reservoir flood discharge for the building is analyzed. The results of a case study show that reservoir flood discharge is a treat for a city on the downstream. Moreover, the potential flooding hazards for coastal cities can be anticipated by BIM. Traditional approaches utilize 2D modeling for flood hazards. However, their results are not appropriate for vertical fluctuations. Rong et al. [41] integrated BIM and GIS to simulate the wave propagation more realistically based on high-resolution topography data. The proposed methodology can provide detailed information about flooding hazards such as flood extent, axial velocity, and vortex structures, etc.

4.3.2 Real-time monitoring

BIM is capable to use in real-time monitoring the flood hazards. Edmondson et al. [42] developed a BIM model that comprises smart sensors. The BIM model can predict floods by real-time monitoring and reporting of sewer asset performance. This approach can be used in order to evaluate the risk of inundation of metro systems due to flooding hazards. Lyu et al. [43] presented a framework that comprises GIS and remote sensing. In this research paper is recommended that the integration of GIS, Global Positioning System (GPS), and BIM can is a tool for visual management of 3D geographic spatial location information. Consequently, managers can monitor the risks of inundations in the metro tunnel dynamically.

In addition to real-time monitoring of the water level, BIM can be used in real-time monitoring of the water diversion projects to find the defections. Insufficient inspection and late problem detection may lead to disastrous results. Liu et al. [44] proposed a framework to optimize the inspection process. Unmanned aerial vehicle (UAV) and BIM integration are used in the proposed framework. The BIM model is dynamic and it comprises timely-updated safety information. The

model is shown in the Web environment.

4.4 General : Post-disaster construction

Biagini et al. [45] proposed utilizing BIM for the restoration of historical buildings. The main concern for the restoration of historical buildings is an on-site intervention. In order to efficient on-site intervention, a complete information plan should be provided for executing the restoration plan. Tradition restoration methods provided 2D maps that generally comprise insufficient information. BIM allows users to build a 3D model of the historical buildings and link a variety of information to it. The post-disaster construction permits can be facilitated by BIM. Nawari et al. [46] proposed a framework that can accelerate the construction process after a disaster. BIM and Blockchain integration can be utilized in any transaction related to post-disaster construction. Consequently, extra processing fees, paperwork, and the time required to issue building permits can be eliminated. Messaoudi et al. [47] developed a BIM-based virtual permitting framework that is able to improve the efficiency of obtaining the construction permit in Post-Disaster recovery efforts. Determining the type of the construction permit, applying the newly developed permitting framework, and deciding about the result of the permit is the main procedure of the framework. Moreover, Pizzi et al. [48] utilized BIM to ease the reconstruction process after an earthquake. The main tasks of the BIM model are (1) compliance with regulatory (2) contextual modeling of various disciplines (3) clash detection among different disciplines (4) coordinating building documents. All BIM application for disaster is demonstrated in Figure 4.

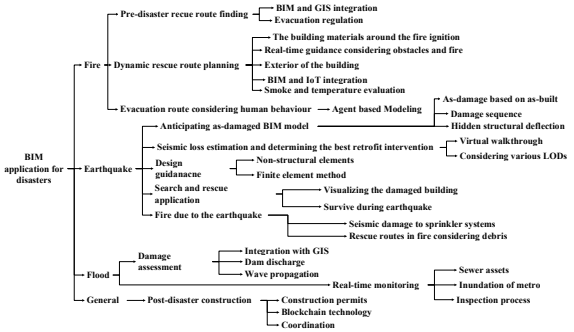

Figure 4. BIM application for disasters

5 Research gaps and future directions

Increasing the number of natural disasters makes disaster resilience an interesting research area these years. New technologies such as BIM has a great capability to enhance the resilience of the communities. After reviewing the relevant literature, existing research gaps have been detected. First, past studies have concentrated on fire, earthquakes, and floods. However, the resilience of the communities against other disaster types such as wildfires, hurricanes, and storms can be enhanced by BIM. For instance, the real-time monitoring of wildfire and bushfire stratus can be a helpful tool to reduce negative impacts. West et al. [49] argued that effective training procedures can increase the resilience of the community against wildfire and bushfire. As stated before, BIM is an ideal tool for training procedures. Second, the BIM application recovery and reconstruction process can be expanded. For example, the demolition process of damaged buildings is a critical task that can be hard without new technologies. BIM application for the demolition process is neglected in past studies. Third, most of the past studies on BIM application for disaster resilience are qualitative. More quantitative research approaches can be useful for decision-makers.

6 Conclusion

BIM applications in order to enhance disaster resilience are reviewed and classified in this paper. In order to conduct an unbiased analysis of the literature, this paper employed Preferred Reporting Items for Systematic Reviews and Meta-Analysis (PRISMA). BIM application for resilience enhancement due to fire, earthquake, and flood are studied by past researchers. Past studies generally emphasized on information transformation and visualization as two critical characteristics of BIM. Fire in buildings and finding the appropriate rescue routes, earthquake and flood damage assessment and visualizing the damages have been studied in the past. BIM can guide people to find short and safe rescue routes and prevent crowding. Earthquake damages and losses can be anticipated and visualized by BIM. Flood damage assessment can be done by integrating BIM and GIS. Findings show BIM applications have advanced in recent years but there is room for improvement when it comes to quantitative approaches. Furthermore, it is suggested that future studies could utilize the BIM application for other disasters such as bushfires. For instance, real-time monitoring, one of BIM applications, can be utilized to visualize and assess the risk of bushfire disasters. Real-time monitoring can be facilitated by using BIM and IoT integration. The findings are expected to provide useful insights to researchers in this context.

Integrating BIM- and Cost-included Information Container with Blockchain for Construction Automated Payment using Billing Model and Smart Contracts

Xuling Ye, Katharina Sigalov and Markus König

Department of Civil and Environmental Engineering, Ruhr-University Bochum, Germany
E-mail: xuling.ye@rub.de, katharina.sigalov@rub.de, koenig@inf.bi.rub.de

Abstract –

Payment issues are necessary in the construction industry, often manifested by high levels of arrears and long-term payment delays. An automated payment could be a solution to speed-up the payment process after successful completions. In this paper, a framework is proposed for the automated payment via Building Information Modeling (BIM), Linked Data, Smart Contract and Blockchain technologies. Geometrical and payment-related data are stored as BIM-based linked data. Linked Data technology connects a BIM model with its related Bill of Quantities (BoQ) and Quantity Take-Off (QTO). Based on the transparency, traceability and collaboration of the Blockchain technology, an automated payment can be secured. To integrate such an information container with Blockchain for the automated payment, an additional information model called Billing Model (BM) is proposed. Thereby, each Billing Unit (BU) stores one or more construction work tasks with a related payment and a related due date. Together with the corresponding Smart Contract rules, the BM can automate payment via a Blockchain. Several aspects of improvement and further development are discussed in the end.

Billing Model; Building Information Modeling (BIM); Information Container; Blockchain; Smart Contracts

1 Introduction

Low margins and relatively low productivity have been the issues of the construction industry for decades [1]. The main reason for this lies in the low degree of digitization within the construction sector despite the increasing scale and complexity of construction projects. Relying mainly on drawings or paper-based documentation does no longer satisfy the increasing needs of construction projects. In addition, unsatisfactory software interoperability in the Architecture, Engineering and Construction (AEC) industry makes coordination between clients and contractors unnecessarily difficult. As a result, no single source can provide an integrated, real-time view of project design, costs or schedules. To make things worse, Caldas et al. [2] state that a large amount of construction documents, which necessarily contain graphical and non-graphical information that must be communicated between project team members, are needed to describe the characteristics, specifications and execution plans of building products, such as drawings, specifications, schedules and cost estimates.

These problems of contract management in construction can be reduced by applying newly available digital technologies and working methods. Building Information Modeling (BIM) has become a widely accepted solution for making the whole lifecycle of a construction project digital. By integrating “cost” into a BIM model, budget and cash flow planning and cost controlling can be enabled. After the implementation of smart contract applications by Ethereum [3], non-currency data can be stored in the Blockchain. Based on the transparency, traceability and collaboration of the Blockchain technology, it could be a good solution to enable digitalization of the contract management and the automation of the payment process.

However, because of the traceability of Blockchains, the data stored in a Blockchain will be repeatedly copied and stored in different blocks, even when modifications are only slight. As a result, the data storage of Blockchains is extremely expensive [4]. Moreover, because of the consensus mechanism and verification of Blockchains, the transaction speed is relatively slow compared to central network systems. It is time-consuming and arduous to store all the data of a construction project entirely in the Blockchain and therefore not worth the effort.

According to the points mentioned above and the available technologies, this paper presents a concept for the generation and application of an information

container (BIM Contract Container or BCC for short), which is to be used as a basis for automatic payment transactions in the construction industry. For this purpose, a billing model is introduced, which is the basis for the creation of a smart contract.

2 Related Work

2.1 Digital Models in Construction

By integrating "cost" into the BIM model, a cost budget and the corresponding financial representations can be instantly generated. The purpose of using BIM for cost is to provide accurate and reliable cost estimation based on the digital 3D model, and eliminate errors caused by manual measurements or estimations [5]. To exchange digital building models for building constructions, the Industry Foundation Classes (IFC) were developed and standardized internationally by buildingSMART [6]. With the help of the IFC, geometric and semantic building information can be exchanged independently of the manufacturer. The Bill of Quantities (BoQ) are created for the tendering and awarding of construction works [7]. An international standard for the description of BoQ information does not yet exist. Nevertheless, there is a standardized format for data exchange, which was created in Germany by the Joint Committee Electronics in Construction (GAEB) with the GAEB XML standard [8]. The GAEB XML format has been proposed to serve the agreement of a German uniform exchange standard for service specification and thus to support all requirements for electronic processes concerning public notice, contracting and accounting in the execution of construction works [8]. The building model can be used to determine quantities that are assigned to the individual BoQ elements. The calculation of the individual quantities based on the components of the BIM model is called Quantity Take-Off (QTO).

In recent years, some formats have been developed in order to use and exchange information from various data sources (often files). For this purpose, the individual data sources are described and linked using metadata. The links are saved explicitly. Data sources, metadata and links are generally referred to as information containers. In the simplest case, an information container comprises only one data source without links. If the data sources are in the form of files, the data exchange of an information container is realized as an archive file (e.g. as a zip file). The BIM-LV container according to DIN SPEC 91350, for example, enables standardized data exchange between digital building models and digital service specifications [9]. DIN EN ISO 21597-1 defines a similar approach to building and exchanging linked information using linked data concepts [10]. An information container according to DIN EN ISO 21597-1 is described using the Resource Description Framework (RDF) [11]. ISO 21597-1 was developed for the standardized data exchange of linked data sources using a generic information container format as shown in Figure 1. A container includes a header file "index.rdf" in the top-level folder. A container shall have at least three folders. The "Ontology resources" folder may be used to store ontologies providing the object classes and properties that shall be used to specify the contents of and links between the documents within the container. The "Payload documents" folder and "Payload triples" folder may contain nested folders to allow groups of associated digital resources to be held together and referenced as a group (e.g. a building information model with its associated reference files or a set of linked spreadsheet documents). A container according to ISO 21597-1 can also be used to exchange data and forms the information basis for the approach presented here. Building models, BoQs and QTOs are linked with the help of a container and used in the creation of a billing model.

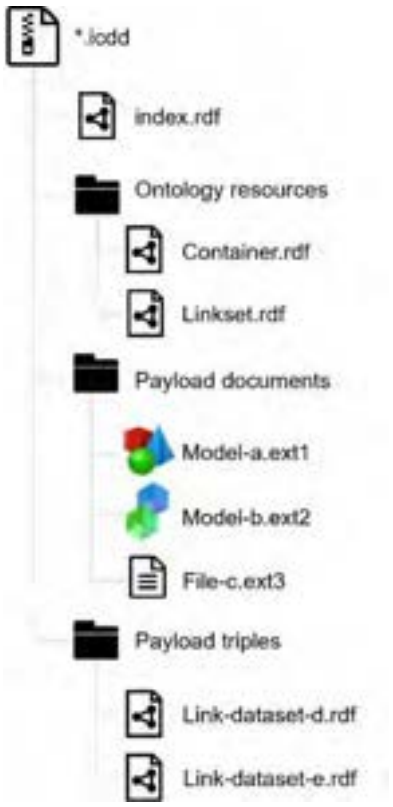

Figure 1. The structure of an information container according to DIN EN ISO 21597-1

2.2 Blockchain and Smart Contract

Blockchain is a distributed ledger technology, where "distributed" is managed by a decentralized peer-to-peer (P2P) network [12] and "ledger" is realized as an

electronic database comprising a chain of blocks [13]. In this network, the transactions are verified, validated and combined into blocks. The blocks are then chained together. Thus, the procedure is based on a chained block structure that grows linearly. The data in the Blockchain is immutable and cannot be manipulated or deleted. Blockchain has the following key characteristics: decentralisation, persistency, anonymity and auditability [14].

The Blockchain concept was developed from the Bitcoin technology first proposed by the pseudonymous Satoshi Nakamoto in 2008 [15]. However, the Bitcoin (i.e. the origin of Blockchain) was a non-programmable system suitable only for cash transactions. The situation starts to change after smart contracts come into the stage of Blockchain. The smart contract, first proposed by Szabo in 1996 [16], is a digital agreement which self-executes itself. Since Buterin et al. [17] have embedded smart contracts in their Ethereum Blockchain system in 2014, Blockchain has become a platform with programmable applications. This way, more possibilities and more applications in more fields than just finance have come to the Blockchain stage. However, due to the limited Blockchain storage and relatively slow transaction speed, it is does not make sense to store all the project-related data in the Blockchain as mentioned above. Many researchers suggest the notion of off-chain data storage, which is a conventional or a distributed database to store the data outside of the Blockchain. For example, Xu et al. [18] propose an architecture using Blockchain for connecting application layer within off-chain data and off-chain control.

In the construction industry, a great deal of research has been done on using Blockchains due to their enormous potential. For example, Li et al. [19] reviewed 73 papers from 2014 to 2018 on the applications of Blockchains in the construction industry. The reviewed applications lie in smart energy, smart cities and the sharing economy, smart government, smart homes, intelligent transport, building information modelling (BIM) and construction management, as well as business models and organizational structures. In 2020, Kasten [20] pointed out that research related to Blockchain applications in engineering or manufacturing has been growing fast after 2016, especially in data validity (e.g. BIM). In particular, Shojaei [21] states that smart contracts can provide a new type of work breakdown structure, which can automate the process of compliance and payment. Moreover, Li et al. [22] emphasize that smart contracts are one of the key complementary concepts to BIM, which can represent the construction project requirements in a computable way and automate contract clauses. However, Eschenbruch et al. [23] point out that using smart contracts in construction contract and payment automation still faces many legal issues.

3 Methodology

This paper proposes a framework for automated contract, invoice and billing management, as shown in Figure 2. The framework focuses on automating the payment between clients and contractors. The payment-related transactions are no longer defined in a paper-based construction contract, but rather mapped in a smart contract. Each payment-related transaction can be considered as a billing unit, and billing units must be defined in a digital way so that an automated payment can take place. For this purpose, billing units contain information about the construction work items and building elements and are based on the information from the BIM model, the BoQ and the QTO. All billing units together compose a billing plan, which together with the BIM model, the BoQ and the QTO is referred to as a billing model.

A billing model is generated accordingly, and serves as a data basis for smart contracts. The billing model, in collaboration with the smart contract, enables the automation of the delivery and acceptance process. If the client checked and confirmed a construction task reported by the contractor, the payment will be automatically transferred from the client bank to the contractor bank. A Common Data Environment (CDE), as an off-chain storage, handles all the payment-related files. For this purpose, a BIM Contract Container (BCC) is used, which contains all payment-relevant data (i.e. the BIM model, the BoQ with QTO and the billing model). For a secure and resource-efficient storage of the information in a Blockchain, only the URLs and hash values of the files stored in the CDE are used. The following three subsections detail how to filter payment-related transactions from a construction contract to a smart contract, how to generate a billing model, and how to automate the payment.

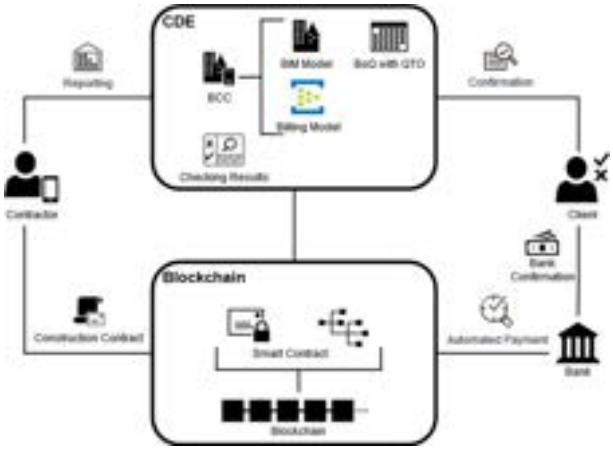

Figure 2. The overview of the proposed framework

3.1 Construction Contract to Smart Contract

Due to the complexity and the legality of a construction contract, a smart contract will not be able to replace a construction contract completely. The starting point is to filter out the payment-related transactions from the conventional construction contract. On the one hand, this is about the services and billing units to be provided and, on the other hand, the remuneration assigned to them. The payment-related data can be obtained via the BoQ and QTO. Based on a BIM model and a BoQ with QTO, a corresponding billing model is created, which is then automatically processed via smart contracts. Hash values of the smart contract, the BIM model and the BoQ with QTO are included in the paper contract to identify the billing basis of the contract.

Once confirmed, any contractually relevant data cannot be changed unnoticed. All subsequent modifications or extensions must be agreed between the contracting parties, and be stored as an update of all the former versions. The relationships from a construction contract to a smart contract can be viewed in Figure 3. With the help of completion notifications of the contractor and confirmations of the client, payment instructions are automatically sent to the involved banks and payments are performed out immediately. Such processing modalities or processes are expressed in the smart contract with if-then relationships.

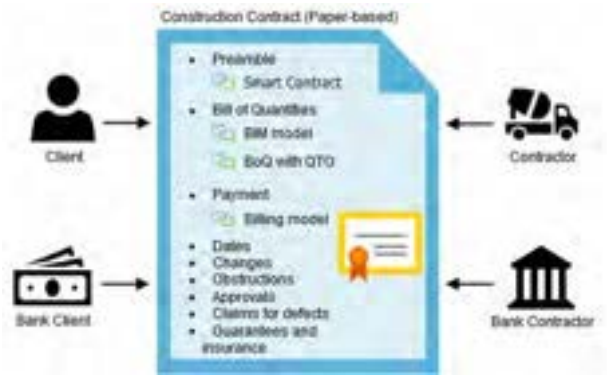

Figure 3. Integration of a smart contract into a construction contract

3.2 Billing Model

In order to automate payment transactions, a billing model has been developed based on the BIM model. Depending on the type of contract used and the underlying service description, the billing model can have different contents. In this context, a billing model is equivalent to a digital payment plan. The basis for the preparation of the payment plan is a service specification (i.e. a BoQ with QTO), which is linked to the BIM model. A service specification contains hierarchically structured elements, whereby the smallest element is a quantity split. The payment plan consists of billing units that can be clearly identified by a generated unique ID. Each billing unit contains one or more construction work items from the underlying service description with a total amount to be paid and a completion date. If the billing unit is completed and accepted on schedule, the contractor will get the agreed payment of the billing unit.

The used XML Schema Definition (XSD) of a billing model is visualized in Figure 4. A billing model consists of general billing model information (*BMInfo*) and several billing unit(s). Each billing unit contains one or more items, and the items may contain sub-items. Each item could be a single element or a group of service specification elements. In addition to the items, each billing unit stores short and long descriptions, the total quantities, the unit and the total price. The *CompletionDate* of a billing unit indicates the latest completion date of all the construction work tasks in this billing unit.

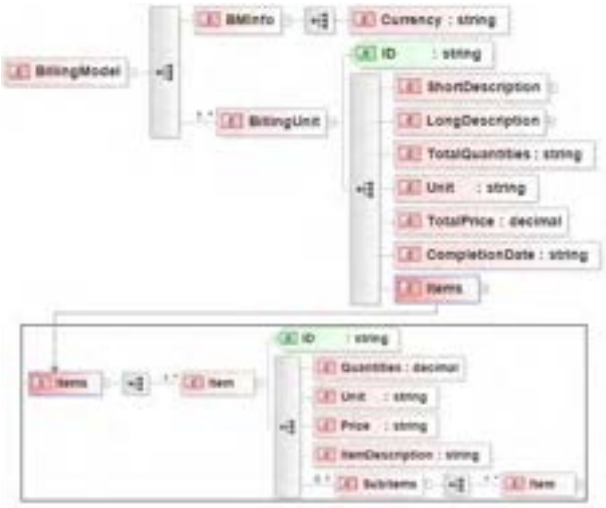

Figure 4. Visualization of the XML Schema Definition (XSD) of a billing model

To generate a Billing Model, a software tool as shown in Figure 5 has been implemented. A BIM model can be imported in the form of a BIM-LV container (Figure 5a), which contains IFC files (i.e. BIM models), GAEB files for service specification (i.e. BoQs with QTOs) and the LinkSet files to build up the links between IFC files and GAEB files. In this way, by selecting an element of the BIM model (Figure 5b), the corresponding linked BoQ item (Figure 5c) will also be selected. Multiple BoQ items in the GAEB Parser can be selected and formed as the items of a billing unit in the billing model (Figure 5d). The overall quantities, unit and total price of a billing unit are automatically generated based on the information of selected items. To successfully generate a billing unit, the

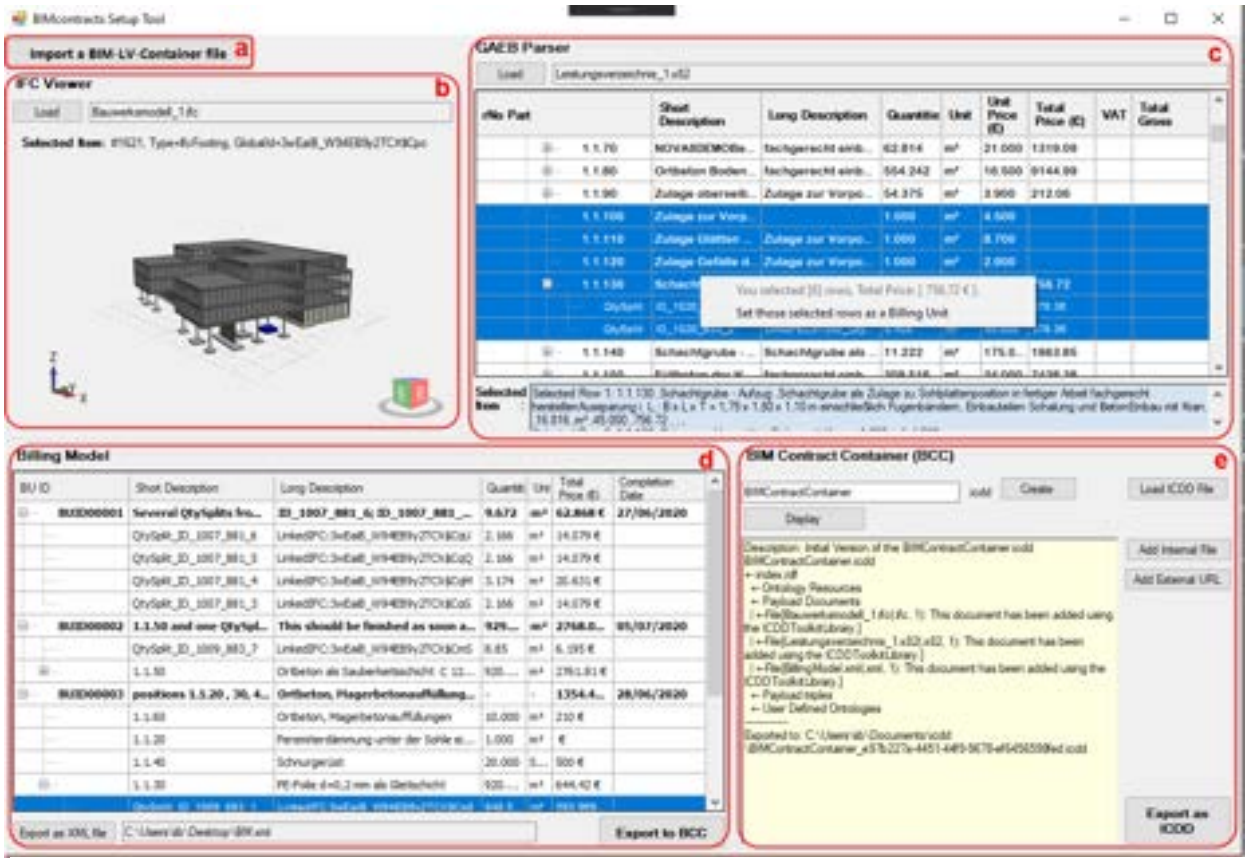

Figure 5. Implemented prototype for generating a billing model and a BIM Contact Container (BCC): (a) "Import a BIM-LV-Container file" button, (b) the IFC Viewer component, (c) the GAEB Parser component, (d) the Billing Model component and (e) the BIM Contract Container (BCC) component.

client needs to fill in the short description and the completion date of the billing unit. The long description of a billing unit is formed by the IDs of the selected items by default, which can be modified by the client. If an item is selected, all its sub-items will be selected and become the sub-items of the selected item in the billing unit (Figure 5d). When an item is linked with an IFC element, its long description in the billing model will display the *GlobalID* of the linked IFC element. For data exchange, an XML-based data format of billing models has been developed. Such an XML-format billing model can be directly exported to a BIM Contract Container (BCC) using the framework presented in Hagedorn [25]), or stored as an XML file. A generated billing unit in XML format is shown in Figure 6.

Figure 6. A billing unit generated via the software tool shown in Figure 5.

3.3 BIM Contract Container (BCC)

An information container (called the BIM Contract Container, or BCC for short), which contains the list of services (i.e. the BoQ with QTO), the digital building model (i.e. the BIM model) and the agreed billing model, can be generated via the software tool (Figure 5e). The loaded IFC file and GAEB file are automatically added to the container. The agreed billing model can be exported to this container afterward (as introduced in section 3.2). In this way, a BCC is generated accordingly.

The BCC's folder structure is shown in Figure 7. The content of such a BCC is stored in a ZIP64 encoded folder with the extension .icdd. The RDF index file includes the overall description. It contains all necessary documents and link sets of the container. The building model ("BuildingModel.ifc") is considered as an internal document and therefore its referenced file is stored inside the "Payload documents" subfolder. Its assigned format is IFC2x3. The BoQ and QTO ("BoQ_gaebxml.x86") and the billing model ("BillingModel.xml") are also stored in the "Payload documents" subfolder. Apart from these documents, the container description also refers to linksets, which includes the linking for the BoQ and billing model. The contents are therefore defined in two separated files named "BoQLinks.rdf" and "BillingUnitLinks.rdf", and stored inside the "Payload triples" subfolder.

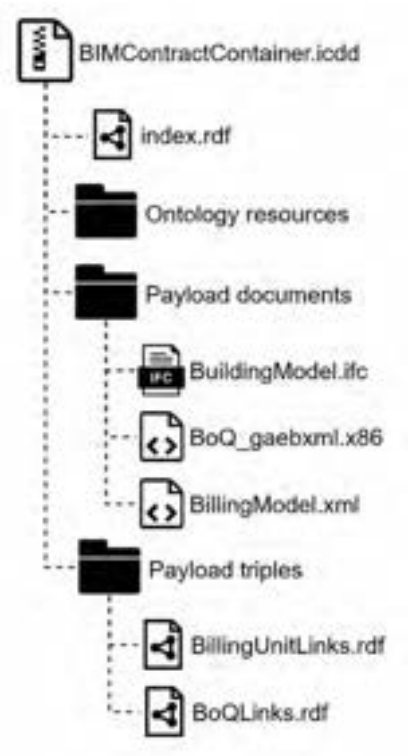

Figure 7. The folder structure of the BCC

3.4 Billing Process

Subsequently, based on the individual construction works and calculated quantities, a schedule and time planning can be made, taking into account the design and the building site. For this purpose, individual activities are defined, connected and saved as a network plan. The durations can be determined, for example, considering the selected construction methods and calculated quantities. The components of the BIM model are then linked to the individual activities using the calculated quantities.

A billing process with corresponding rules is created for each billing unit and stored in the smart contract. Such a billing process can be instantiated for each billing unit in the smart contract and linked to the digital billing unit of the billing model stored in the BCC. A simple and defect-free process for a billing unit is shown in Figure 8. The actions (start of construction works, report of the completion, checking and acceptance, execution of the payment and confirmation of the payment) are viewed as a sequential process.

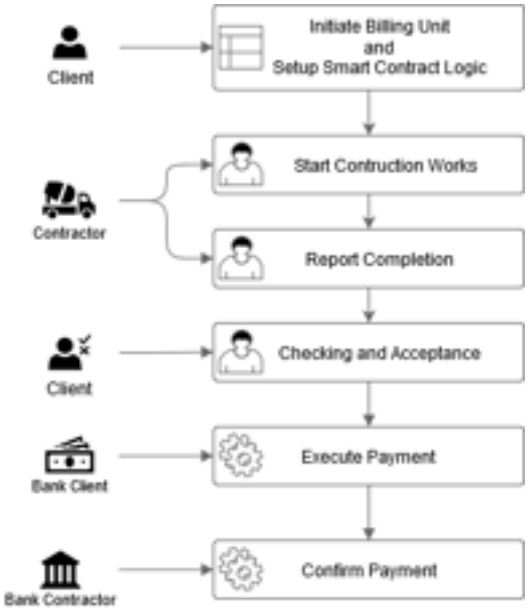

Figure 8. A defect-free process of a billing unit via BCC and smart contract logic

After the client finishes the "Checking and Acceptance" process, the possible smart contract logic as shown in Figure 9 can be executed. The values of *CompletionDate*, *isPartialPaymentAllowed*, *RejectionThreshold* and *Penalty* are predefined in the smart contract based on the construction contract and the billing unit, while the values of *FinishedDate* and *AcceptanceRate* are obtained via the actual acceptance process. When the contractor reports completion, its *FinishedDate* will be recorded. This *FinishedDate* can be

compared with the *CompletionDate* set in the billing unit. The acceptance results of the client can be represented as *AcceptanceRate*. Only if the contractor completed the works as scheduled (i.e. the *FinishedDate* not later than the *CompletionDate*) and the client fully accepted the works (i.e. the *AcceptanceRate* is 100%) will the contractor get fully paid. If the contractor did not finish the work as scheduled, he/she will either get the payment with a penalty deducted or be refused to be paid altogether. If it is allowed to have partial payments and the value of *AcceptanceRate* is more than the *RejectionThreshold*, the contractor can get a partial payment. In other cases, the client refuses to pay.

```
if(FinishedDate <= CompletionDate)
{
   if(AcceptanceRate == 1.0)
   {
      Payment Execution;
      PaymentStatus = "Fully Paid";
   }
   else if(isPartialPaymentAllowed == true
     && RejectionThreshold < AcceptanceRate < 1.0)
   {
      Payment = Payment*AcceptanceRate;
      Payment Execution;
      PaymentStatus = "Partial Paid";
   }
   else{PaymentStatus = "Payment Refused";}
}
else if(AcceptanceRate == 1.0)
{
   Payment = Payment - Penalty;
   Payment Execution;
   PaymentStatus = "Paid With Penalty";
}
else{PaymentStatus = "Payment Refused";}
```

Figure 9. A smart contract logic for the "Execute Payment" step

4 Conclusion and Outlook

Digitization is widely considered as the solution for the optimization and automation of processes in the construction industry. However, the current practice of a construction project still relies on paper contracts and conventional communications, which are time-consuming and non-transparent. This paper presents a framework for simplification and automation of payments during the construction process by combining the BIM contract container (BCC) with smart contracts. All the project-required data (i.e. the BIM model, the BoQ with QTO, and the billing model) are stored and linked in the BCC. The BCC is stored in an off-chain storage (i.e. CDE), while the sensitive and important information (e.g. the hash values of the documents stored in the CDE, results of acceptance procedure and payments) is safely stored and recorded in the Blockchain. Integration of the billing model and smart contract automates the payments between the client and the contractor during acceptance procedures.

This study has several limitations. First, the subcontractors are not taken into account in this study. Moreover, to define the smart contract rules, there are a lot of logic and legal issues to be settled, which are not handled in this study. Finally, the payment procedure during a construction process is more complex and has more factors to be considered in the future.

Acknowledgment

This work is part of the BIMcontracts research project which is funded within the scope of the "Smarte Datenwirtschaft" technology program run by the German Federal Ministry for Economic Affairs and Energy. The Ruhr-Universität Bochum, Universität Duisburg-Essen, FREUNDLIEB Bauunternehmung GmbH & Co. KG, Kapellmann und Partner Rechtsanwälte mbB and adesso SE (Consortium leader) are involved in the consortium. The authors would like to express their gratitude to the support and funding for the project activities. A further acknowledgement is addressed to the FREUNDLIEB Bauunternehmung GmbH & Co for the provided BIM models and construction data.

Abstract -

The evaluation of indoor risks is a paramount issue in building design and construction. Conventional methods that rely on handcrafted rules or drills are insufficient for this task as they either fail to accurately depict the sophisticated spatial attributes and people's cognition abilities or are not suitable during the design phase of the building. This paper puts forward a novel computational framework with a reinforcement learning-based paradigm to automatically assess the evacuation risk posed by the indoor space through intelligent agents. Our model focuses on the agent's exploration behaviours as it gains knowledge to locate the optimal path from an initial location to an exit. The cost of this knowledge acquisition process is then used to capture the risk posed by the initial location of the building. The work aims to shed new light on utilizing agent-based techniques in evaluating building safety.

1 Introduction

The evaluation of indoor risks posed by emergency situations such as fire and earthquake has been a critical issue in building design and construction management. Imagine a situation where a designer is planning the interior space of a building. It is important to identify potential emergency situations and assess the level of risks of the designed indoor layout before commencing development. One of the key safety criteria is how effective the interior layout enables building occupants to evacuate during an emergency. A well-designed interior layout should in principle enable people in the building to quickly find optimal evacuation pathways and escape, thereby greatly reducing human casualty. Yet, to characterise the indoor environment and hazards, a huge amount of variables need to be taken into consideration that includes not only the spatial features of each interior location, placement of structural and non-structural elements, but also people's behavioural and cognitive traits. This demands an objective, cost-effective, and general method to assess indoor risks which differentiate risks of different indoor locations, truthfully reflect the spatial features, and are not biased by human input.

So far, however, most commonly used methods to evaluate indoor space risks rely on fixed sets of well-defined criteria, e.g., the equations in SFPE handbook of fire protection engineering [1]. It is easy to see that limitation with this common practice: In a building with complex indoor layout structures, applying a set of prescriptive rules to evaluate risks is deemed to be too coarse to account for the differences among the spatial features of the locations, and the erratic and complex behaviours of building occupants [2]. Another common way to evaluate evacuation effectiveness is by conducting evacuation drills. However, this approach introduced various issues related to ethical, practical, and financial constraints [3]. For example, drills will hardly recreate the sense of urgency in a real-world emergency and the effectiveness of evacuation drills greatly relies on whether people actively engage in the training. Moreover, conducting evacuation drills has one obvious shortcoming: we can only perform evacuation drills after the entire interior layout has been developed. Thus, it is not a suitable way to reveal potential risks during the design phase [4].

A desirable scheme for assessing indoor evacuation effectiveness during the building design phase must satisfy the following:

1. Firstly, as the evaluation should take place during the design phase where no physical involvement of human participants is possible, the scheme should exploit computerised modeling and simulation techniques to achieve its goals.

2. Secondly, the evacuation process's effectiveness relies on the evacuees' physical and mental ability. Therefore the assessment must be carried out based on the behavioural patterns of evacuees.

3. At the design phase, however, no input will be avail-

able on the specific features of the building occupants. It is therefore desirable for the risk assessment to be independent from the features of any specific evacuee. Similarly, the specific emergency situation that triggers the evacuation may greatly impact the evacuation process. Therefore, the assessment should also be independent from any specific emergency situation. In summary, the output of the assessment would be a form of *risk score* that measures the level of safety guaranteed by the indoor environment given the interior building layout in a generic setting.

4. Then, as an indoor environment has complex layout structure and locations may have vastly different spatial features, it is important to have a location-based risk assessment where risk scores are associated with individual location points. This has the result of a type of "heat map" that visually illustrates areas of potential hazards in the building where building occupants may face a greater level of risks.

5. Lastly, the scheme should be sufficiently general so that it can be applied to different layout plans and reveal their differences.

This paper proposes a novel framework for computing risk scores of indoor locations given a layout plan. The risk score reflects in a generic sense how much the interior layout supports effective evacuation of a building occupant from a specific location spot. The computation is agent-based in the sense that reinforcement learning (RL), commonly seen in the development of artificial intelligence agents, as an integral part of risk assessment. RL has demonstrated wide applicability in improving the performance of AI systems in many fields [5, 6]. Yet, to the authors' knowledge, our work is the first to incorporate RL in building risk assessments. The aptness of the RL paradigm in our setting lies in the fact that we model an evacuee as a reward-driven decision-maker, i.e., an agent who can assess the physical space while finding an optimal evacuation pathway.

In a nutshell, our framework defines the risk score using the efficiency of an agent – which is initialised with no knowledge regarding the building layout – in finding the optimal evacuation path through exploring the indoor environment. This framework has the following advantages:

Firstly, by applying machine learning algorithms on evacuees who have no prior knowledge regarding the indoor layout, the behaviours of the evacuees are generated in run-time through their interactions with the indoor environment. This avoids handcrafted behaviours of evacuees, thereby giving an unbiased evaluation of the effectiveness of evacuation.

Then, as we let the same agent start its exploration from all location points in the indoor environment, the obtained scores can be compared with each other in an objective way. Through this, one can easily generate a unified heat map of the indoor layout.

Thirdly, the proposed risk score takes into account the cognitive aspect of the agent by focusing on the dimension of *knowledge acquisition*. In other words, the risk score of a location point is defined as the cost for an evacuee who starts from the location points to identify the optimal evacuation path through repeated simulated exploratory evacuation. A location that facilitates higher safety is seen as one that incurs the lower cost of knowledge acquisition, while a more risky location is one where an evacuee needs to spend a lot more effort finding the optimal evacuation path. In comparison with other classical methods for evacuating location-based evacuation effectiveness such as computing the distance between a location and the nearest exit, our formulation is more realistic as it takes into account the behavioural aspect of evacuees and thus is a more reliable and robust safety index.

It is important to note that, while our formulation of the risk score is based on a simulation of evacuation behaviours of an evacuee, the aim of this model is not to mimic the actual evacuation during an emergency scenario [7]. To do that, many factors such as dynamics of the physical space during an emergency (e.g., fire), people's reaction to crowd movements (e.g., herding, stampede, etc.), as well as behavioural traits such as panic and altruism need to be addressed. Our work does not address these factors, as they are specific to particular emergency situations.

2 Related work

2.1 Building Safety Evaluation

The most standard practice to evaluate building safety is to adhere to a set of rigid rules which lays out best practices in building design. One of the main weaknesses of such approaches is that it is not able to accurately and deeply depict the erratic and complex behaviour and movement pattern of evacuees in a building under urgent conditions. Therefore, modeling and simulating emergency evacuation is essential to provide valuable insights about building safety and evacuation management [8].

In 1998, Ming [9] proposes a fire safety assurance approach including the fire safety assessment method for high-rise buildings in Hong Kong. In 1999, Ming [10] proposes a fuzzy fire safety assessment approach based on fire risk ranking techniques. The research at this stage carries out an emergency safety assessment on the completed buildings, the purpose is to evaluate the emergency safety risks of the buildings and formulate appropriate rectification plans to ensure the safety of the buildings.

Since the 2000s, researchers have shifted their attention towards the evaluation of building safety in real emer-

gency situations. In 2001, Ellingwood [11] studied the emergency safety of buildings under earthquake disasters. In 2008, Anagnostopoulos et al. [12] studied the post-earthquake emergency safety assessment of the building and provided support for the post-disaster rescue work plan. Carrying out research in a real emergency play an important role in reducing casualties and property losses under various disaster conditions.

In recent years, it has become a new research direction to carry out safety evaluation on design and construction stage. In 2010, Gangolells et al. [13] discussed the safety considerations of building construction at the design stage using a risk analysis method, aiming to reduce construction risks in advance. In 2011, Oien K et al. [14] conducted a research on the theoretical basis of building safety evaluation, which provided an important reference for subsequent research. In addition, based on the behaviour of people in the building under emergency evacuation conditions, carrying out building emergency safety evaluations to serve the safe evacuation of people under emergency evacuation conditions has become the focus of relevant research. In 2018, Bahr [15] conducted extensive discussions on the safety engineering and risk assessment of system based on practical methods in his work.

2.2 Evacuation modeling

We now review theories and models for evacuation simulation.

Flow-based models. Flow-based models use the density of nodes in flows to simulate the features of the people flow. Henderson [16] firstly argued that the behaviour patterns of pedestrian crowds are similar to gases or fluids. Bradley [17] applied Navier–Stokes equations to describe the motion of high-density pedestrian crowds. Helbing et al. [18] summarised that for medium and high-density pedestrian crowds, its motion patterns are very similar to fluids. For instance, people's footprints in snow look similar to streamlines of fluids. Flow-based models could apply the complete network model to develop the optimal evacuation plan in terms of the minimum evacuation time. However, the main restriction of flow-based models is it makes wrong assumptions of people's homogeneity. These assumptions make this type of model difficult to simulate people's different physical abilities, behaviour patterns, and characters. That is, the sociological factors of group decision-making processes that play a crucial rule in all emergency evacuation scenarios could not be simulated and defined in flow-based models.

Cellular automata. Cellular automata evacuation models involve discretization space and model people's evacuation process by single individual cells. One of the earliest cellular automata evacuation models was proposed by Perez et al. [19]. Daoliang et al. [20] applied a two-dimensional cellular automata model to simulate the evacuation dynamics of occupants. Yu and Song [21] proposed a model to simulate pedestrian counter flow in an corridor considering the surrounding environment. Kirchner et al. [22] proposed a stochastic cellular automata model to simulate the friction effects and clogging phenomenons in the crowd during the evacuation process.

Due to the simple shape of grids and predefined behaviour rules of evacuees, cellular automata models hardly to simulate unique characteristics and behaviour patterns for different types of evacuees, like women or kids. Therefore, most of the complex sociological factors among evacuees cannot be simulated in cellular automata models.

Agent-based models. An agent-based model is a system that comprises many intelligent agents which can be used to build heterogeneous characteristics and behaviour patterns. Instead of a global goal, each of the agents has a local goal to achieve [23]. Camillen et al. [24] evaluated different evacuation strategies in closed spatial environments, they demonstrated that due to the dynamic environment, traditional simulation models are difficult to simulate the evacuation process accurately. Only agent-based models are able to capture the dynamic characteristics of certain closed spatial environments properly. More recently, Sumam et al. [25] focused on the impacts of various evacuation behaviours and determined their efficiency in terms of the final evacuation rate. Yang et al. [26] present a prototype that uses agent-based modeling to simulate deep foundation pit evacuation in the presence of a collapse disaster. Şahin et al. [27] proposed an approach which combines a multi-agent model with fuzzy logic to simulate common human and group behaviour during safety evacuation. Kasereka et al. [28] proposed an intelligent Agent-Based Model enabling the modeling and simulation of the evacuation of people from a building on fire. Gonzalez et al. [29] propose a simulation model to find out optimum evacuation routes during a tsunami using Ant Colony Optimization (ACO) algorithms.

3 A New Agent-based Framework for Assessing Risk Score

We describe our computational framework to assess the risk score given input layouts. A prototype of our framework is implemented using the NetLogo platform. NetLogo is a programmable agent-based modeling environment designed and authored by Wilensky [30]. The physical space in a NetLogo environment is realised by a set of *patches* that represent location points. An agent is a special entity in the framework which can be in a patch at any given time instance. The NetLogo platform has built in function that enable us to define the states, perception and decision making functionalities of the agent, before letting the agent to start its simulated runs, i.e., evacuation

in the building.

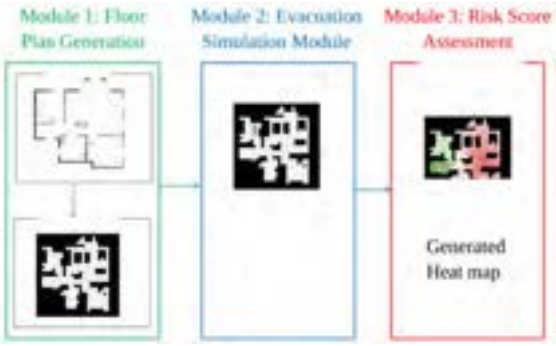

Figure 1. Framework of our approach, with three main modules.

Broadly speaking, our framework consists of three main modules (as shown in Figure1): the floor plan generation module, evacuation simulation module, and risk score assessment module.

First, the indoor space is represented by a digital model that is to be processed by the NetLogo platform. This digital model captures the interior layout and regions that are reachable by the evacuee. The many spatial attributes of the interior layout are represented in the floor plans, such as pathways, exits, corridors, furniture, etc. This digital representation is going to serve as the input to the next module which performs RL algorithm to assess the evacuation risk and generate risk scores.

The second module is the core part of the framework and it simulates the exploratory behaviour of an evacuee in the building. The main idea is we focus on the exploration behaviours of the agent as it gains knowledge in order to locate the optimal path from an initial location to an exit. This corresponds to a process of knowledge acquisition. As discussed above, the cost of the knowledge acquisition process is then used to capture the risk posed by the initial location of the building.

The third module is used to generate risk scores. In particular, we apply the evacuation simulation assuming the evacuee starts from every location points of the physical space. In this way, this module will generate a risk score for every location point. Using these risk scores, one may derive an overall risk score for the entire floor plan, that is, a quantitative measurement of the input floor plans' safety level in terms of emergency evacuation. Moreover, we will generate a heat map based on each patches' risk score.

3.1 Module 1: Floor Plan Generation

The first module performs preliminary processing of floor-plans: we label the inaccessible areas (like walls or large cabinets) and the exits, and then import the modified floor plan. The system will generate a virtual plan base on the coloured floor-plan. Figure 2 shows the coloured original real-world floor-plan of a hospital and the generated virtual plan in Netlogo separately. The black patches represent the inaccessible area, and the white patches represent the accessible area, that is agents could arbitrarily move in white areas. Finally, the blue patches represent the exits.

Figure 2. The coloured original real-world floor-plan of a hospital (left) and the digital representation in Netlogo (right).

3.2 Module 2: Evacuation Simulation Module

The main task performed by this module is to assess the evacuation risk posed by the indoor space automatically. Here we use one of the well-known machine-learning paradigm, reinforcement learning (RL), to model a person's cognitive behaviours. An RL agent is a reward-driven decision-maker who's able to adjust behaviours and improve performance based on the external environment through repeated trial-and-error. In this way, RL aims to mimic the cognitive process of operant conditioning in humans and animals. Imagine someone starting from an arbitrary location in a building that aims to escape the building by finding the nearest exit. Suppose that this person has no knowledge regarding the physical space. The person may explore the space by conducting *trials*, i.e., walking in the indoor area until reaching an exit point, or coming to a location that has already been visited in the same trial. Within each trial, certain knowledge is developed by the person that indicates how easy it is to find the nearest exit from this location.

To realise the exploration and learning process above, we formalise the evacuation situation using finite *Markov decision processes* (MDP): An MDP is a tuple $\langle \mathcal{S}, \mathcal{A}, \delta, r \rangle$ where $\mathcal{S}$ is the finite set contain all the states, $\mathcal{A}$ is the finite set contain all the actions, $\delta : \mathcal{S} \times \mathcal{S} \times \mathcal{A} \to [0, 1]$ is the dynamic function, $r : \mathcal{S} \times \mathcal{A} \to \mathbb{R}$ is the reward function. The goal of MDPs is to determine a policy $\pi : \mathcal{S} \mapsto A$, a function which maps states to actions, with the maximum

expected reward:

$$\arg\max_{\pi} \mathrm{E}\left[\sum_{t=0}^{T-1} r\left(s_t, a_t\right)\right] \tag{1}$$

where $s_{t+1} = \delta\left(s_t, a_t\right), a_t = \pi\left(s_t\right)$ and T is a final time step.

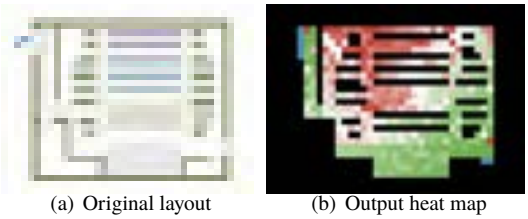
In our setting, the MDP represents the indoor environment of the agent. The set $\mathcal{S}$ of states represents the set of all patches in the digital representation of indoor space. Note that there are only three types of patches in our digital floor-plan layout: black (inaccessible area), white (accessible area), and blue (exits). Agents are only able to walk on the white patches. The action set $\mathcal{A}$ consists of four elements: up, down, left, and right. We assume that these actions will deterministically causes the agent to move from one white patch to another patch in the respective direction. If the target patch is a black wall, the agent will stay put in this time step. An policy directs the agent's movements. To realise the knowledge acquisition process, we assume that the MDP is unknown to the agent, and through a model-free RL algorithm, the agent iteratively improves its knowledge regarding the environment by keeping track of a *valuation function*.

This scenario can be handled by a well-established RL algorithm, *Q-learning*. Q-learning has been the most widely-used approach with demonstrated efficiency and reliability guarantee [31]. The key idea of Q-learning is incrementally approximating the valuation (Q) function of each state-action pair based on the rewards received. To be more specific, in each round, the *Q-value* will be updated from Q_t to Q_{t+1} base on old value (i.e., Q_t) and the maximum Q-values of the next state (i.e., s_{t+1}) using a temporal difference mechanism:

$$\begin{aligned} Q_{k+1}\left(s_t, a_t\right) = & Q_k\left(s_t, a_t\right) \\ & + \alpha\left(r_t + \gamma \max_a Q_k\left(s_{t+1}, a\right) - Q_k\left(s_t, a_t\right)\right) \end{aligned} \tag{2}$$

We now introduce the work flow of the safety assessment module below: A *path* is a contiguous sequence of patches $p_1, p_2, \ldots, p_\ell$ where every patch p_i where $1 \leq i < \ell$ is white and p_{i+1} is reachable from p_i by one of the moves. From a patch p, the *shortest path* to exit is the path that starts from p and ends at an exit that contains the least number of patches.

Our agent performs *trials* to explore the indoor area from every white patch p. In each *trial*, the agent starts by initialising the $Q(s, a)$-values to 0 for every patch s and action $a \in \mathcal{A}$. As the agent traverses through the patches, it will update its Q-value as defined above. When the agent arrives at the exit patch, the module checks whether the agent has found a shortest path to the closest exists in terms of its Q-values for each patch-action pair. If no shortest path is identified based on the Q-value, we will start a new trial from the starting patch; on the other hand, if the shortest path has been identified, the module will record the total number of patches this agent has walked through during the all the trials which started from the same initial patch p, this number is denoted by C_p.



(a) Original layout (b) Output heat map

Figure 3. Original layout and heat map of an theater. Retrieved May 22, 2019, from `https://www.cadpro.com/draw-floor-plans/`

3.3 Module 3: Risk Score Assessment

For any white patch $p \in \mathcal{S}$, let d_p be the length of the shortest path that starts from p. To account for the impact made by different sizes of the floor plan (i.e., the number of patches $|\mathcal{S}|$), we divide C_p by d and set:

$$\sigma_p = C_p / p \tag{3}$$

We define this value σ_p as the *risk score* of the patch p.

We will generate a heat map base on each patches' risk score. We calculate the overall average of σ_p and denote the result σ as the *risk score* of the entire indoor space. We try to use this risk score σ to make the indoor location-based risk quantitative and allow people to judge the configuration of the floor plan as a whole.

4 Experimental Validation

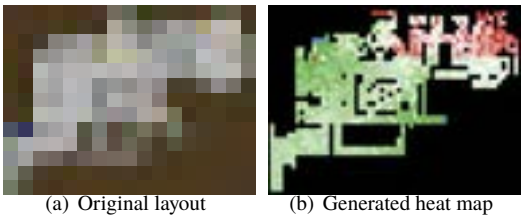
Parameters setup. We apply frequently-used parameters in Q-learning here. In the following experiments, we set ϵ as 20%, α equal to 0.2, γ equal to 0.9, respectively. Here $\epsilon = 20\%$ means random actions are taking 20% in all actions for the agent's behaviour. We set the path reward -1 to correspond to the time cost during the exploration, and we set the exit-reward to 10 as the reward of finding the exit. Since the Q-learning process is non-deterministic, the choice of the agent's move is not the same in each episode, so we run our model 20 independent episodes for each experiment.

4.1 Case Study 1: A Theater

Figure 3 is a floor plan of a theater[1]. Here, we execute our program on this floor plan and output the heat map. The area near the exit door have a relatively low output risk score (green area), which means such areas are easy to evacuate; meanwhile, the areas far from the exit get high output risk score. This result is matching our expectation and common sense. Moreover, the top left corner is covered with dark red. The reason is there are too many obstacles (i.e., chairs.) around. So it is difficult to quickly evacuate from this area in an emergency situation. If a shooter stormed into this theater and starting hurt people, this dark red area might become a dead-end corner. The heat map shows that our prototype program can judge and measure the safety of different sub-areas. From this heat map, we could get some useful design suggestions: we might need to open an exit door at this red area for safety concerns.

One main advantage of our framework is, we could calculate sub-area risk score base on the risk score of each patch. For example, the risk score of the green left-bottom corner is 471; the risk score of the red left-top corner is 1466; the average risk score value of the whole theater is 848.6. This makes our program has more flexibility and capability. We could only focus on the important part of the building which we are interested in.

4.2 Case Study 2: Auckland Hospital



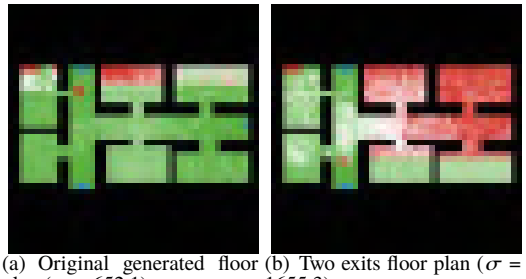
(a) Original layout (b) Generated heat map

Figure 4. Original layout and generated heat map of Auckland hospital [32]

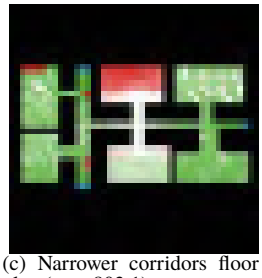
Figure 4 shows the original layout and generated heat map of one floor of Auckland hospital, respectively [32]. There are six exits in the original map, as shown in Figure 4(a). Now we remove four of them and generate corresponding heat map, as shown in Figure 4(b), and see what difference it will make. From the graph, we can see the map was separated into two different parts: the left part got two exits and fewer obstacles. Therefore, it has a much lower risk score; the right part has a very complex layout, many obstacles around, some narrow corridors, and dead ends. So we can guess there should be some exits in the red part, just like the original layout. This case study shows that our program does have some ability to understand the structure information embedding in the floor plans.

[1]retrieved May 22, 2019, from `https://www.cadpro.com/draw-floor-plans/`

4.3 Case Study 3: Rational Configuration Design



(a) Original generated floor plan (σ = 652.1) (b) Two exits floor plan (σ = 1655.3)



(c) Narrower corridors floor plan (σ = 803.1)

Figure 5. Rational configuration design

This case study aims to demonstrate that our framework has the potential to provide decision support to designers by allowing flexible adjustment to the indoor layout and observing the resulting risk score. For this, we manually generate an artificial indoor environment that consists of several rooms linked by two corridors. We imagine the situation where a designer is facing a number of design decisions that include setting the number of exists and adjusting the width of the corridors. By applying our model, the designer is able to predict the likely impact to risk scores of the interior space of tuning these parameters.

The number of exits. We first check the difference of the risk score by varying the number of exits. We apply the control variate method here, which means the only thing we change is the number of exits. Figure 5(a) shows the orignal floor plan with six rooms and three exits. The risk score σ is 652.1.

Now we reduce the number of exit to two and rerun our program. We give the output heat map in Figure 5(b). Now the floor plan has a much higher risk score: σ = 1655.3. From the heat maps we generated, we could have some insight view of the whole layout of the current building,

like if a certain area has a relevantly high risk score, we might consider adding an exit in this area. The more exit we have, the lower risk score we will achieve. We could set up a proper threshold risk score value to balance the risk score σ and the number of exits.

The width of corridors. We then check how the width of corridors affects the risk score of a floor plan. We reduce the width of the original vertical corridors from four grids to two grids and the original horizontal corridors from four grids to a single grid, as shown in Figure 5(c). By comparing the original floor plan, we find that the narrower corridors floor plan has a higher risk score: σ = 803.1 compared to the original risk score: σ = 652.1. This means narrower corridors make people difficult to evacuate, especially for the two rooms in the middle. This experiment is causing alarm that we must not use the main corridors for storage or rebuild the corridor without permission. We should keep all escape route free and unobstructed evacuation from the premises.

5 Conclusion

The evaluation of indoor risks is a paramount issue in building design and construction. This paper puts forward a novel computational framework to automatically assess the evacuation risk posed by the indoor space through intelligent agents. In particular, we model a person's cognitive process when exploring the indoor space in search for an exit, and then capture the risk using the cost of such process. Such an automated process to evaluate the safety conditions of indoor spaces could help evaluate the risk without deploying safety inspectors or conducting an evacuation drill. Our framework is a cost-effective solution than rule-based risk evaluation or evacuation drills since we perform the evaluation procedure in a simulation environment instead of requiring expensive expertise or conducting an evacuation drill in real buildings. Our framework has also high flexibility because the evaluation procedure could be conduct at any stage of construction, even in the sketch stage, if deemed necessary. Our case studies show that the proposed framework can understand the structure information embedded in the floor plan and offer some reference suggestions for structural design and risk evaluation.

We believe that the proposed method provides a new perspective to evaluating building safety through the lens of computational agents. There are many ways to extend the current work. Future studies could consider a dynamic environment where multiple agents interact through exploring the environment. We also could extend our prototype to the multi-agent system to provide insights into the mechanisms and interactions for panic and crowding under urgent situations. From an application perspective, the idea proposed in the paper can be developed as a plug-in in a building information management (BIM) system that automate the evaluation of evacuation risks.

Abstract –

With the recent rapid advancement of vision technologies, recognized research widely applies to resolve the construction industry's remaining problem as known quality, cost, time, and safety. However, there are few studies on how to place visual devices for effectively collecting images/videos on construction activities. This study proposes a framework for camera planning using 4D BIM and visual programming language (VPL) that considers construction's nature. A case study was also implemented, whose results reveal the proposed method's enormous potential in camera positioning, simulation, and schedule installation.

Keywords –

4D BIM; Camera planning; Visual data; Visual Programming Language

1 Introduction

Currently, construction managers still face the provision of quality, safety, time, and cost reduction projects. For these purposes, researchers have studied many different approaches aimed at achieving a higher level of automation throughout the project cycle. Computer vision technology (CST) has been one of the past decade's main directions, which has proven to be cost-effective, accurate, and easy to implement. The utilization of CST reveals in four main categories including (1) construction progress monitoring [1–3] , (2) quality control [4–6], (3) logistic (material, equipment,.etc.) [3,7,8], (4) safety management [9–12].

How to get visual data has become one of the critical and challenging questions for CST's success in the construction industry. Accordingly, it should be considered from the planning stage. First, it is the choice of data collection equipment that fits the job's needs. Recent innovations include making portable cameras such as smartphones, 360-degree camera devices, and UAVs accessible. These camera systems have led to an unparalleled rise in the number of images and videos routinely taken at construction sites [13]. Besides, fixed cameras still account for a large part of their usage through cost and real-time monitoring. The planner needs to choose which camera systems adapts to the condition of the project. For instance, the identification and tracking of construction-related workers' progress require a fixed camera for real-time monitoring. Therein, a high-resolution camera as a 360-degree camera is necessary to detect the wall's crack in the inspection process. Second, schedule planning is needed regarding the placement of installing the camera. Choosing locations with progress in mind will avoid unnecessary reinstallation for cameras and other monitoring equipment.

In the field of construction, Albahri [14] attempted to find an optimal positioning of cameras in indoor buildings using Building Information Modeling (BIM). Camera placement optimization also studies by Kim in the construction project. However, these studies have omission the changeable of constraints due to scheduling during construction progress. It leads that even project planner has camera placement plan, but they do not know when they can install during construction progress.

Building information modeling (BIM) has become an essential step to the digital management of construction projects, helping facility and construction managers with decision making [15]. 3D BIM can automatically provide the geometrical and nongeometrical attributes of these elements to be considered in the optimization camera placement process. Moreover, when integrating with scheduling into 3D model, as known, 4D BIM can provide visual the change of constraints.

This paper aims to propose a framework for camera installation planning that applying 4D BIM and Visual Programming Language (VPL). The proposed framework consists of four steps as "predefine camera parameter," "Camera Placement Optimization," "Installation Plan," "Visualization." The remaining of this work includes the following. Section 2 reviews the related study; section 3 defines the objective of research; then, the proposed framework is explained in section 4. A case study is implemented for evaluation following section 5. Finally, the author summarizes the method and discussion.

2 Literature Review

2.1 Camera Placement Problem in Construction management

Visual data acquisition is an essential first step in applying computer vision in the construction site. Depending on the quality of the data collection, the results of image processing-based may be the difference. Therefore, useful guidance for camera installation is crucial to the success of the subsequent adopt computer vision algorithm in the construction industry [1].

In practice, camera positioning is generally performed manually, relying on experts' expertise or observations [15]. Manual processes make camera placement time-consuming and cost-effective. Several researchers have made efforts to solve the Art Gallery Problem (AGP) [16]. In the field of construction, various researches put effort into solving this issue with a different objective. Kim [17] proposed the hybrid simulation-optimization of camera placement on construction job sites. Contributes in (1) interviewing expert to the identification of critical concern when installing fixed cameras, (2) developing a systematic framework for camera placement, and (3) visualization and quantification of the camera system network. While Yang [18] applied dynamic programming and developed general algorithms to the camera coverage and cost problems.

While the previous works showed promising results in seeking optimal camera configurations, there are still elements remaining concern. Camera type selection relies on the purpose of the visual data needed. Furthermore, the camera installation plans need to determine related to the progress of the project.

2.2 BIM and Visual Languages

Eastman [19] described BIM as a digital representation of the building process that simplifies interacting and exchanging information within a digital structure. The BIM model application was applied to a wide range of construction aspects, including improved safety, efficiency in the management of quality, and the optimization of project times and costs. In the indoor buildings, Albahri [15], for example, attempted to find an optimal camera positioning via BIM. Visual Programming Languages support utilization BIM easily. It adopted in different studies recently, such as KBIM code [20] or Khan [21], uses BIM to optimize fire extinguishing installations.

After conducting a review of current studies, this paper aims to develop a camera installation planning framework using 4D BIM and VPL that takes into account the characteristics of the construction industry.

3 Propose Framework

The goal of this study is to (1) select the type of camera which is fixed or portable system according to task intended in the schedule, (2) deliver the amount and position of the camera for the specific working space (following scheduling), (3) integrate the camera installation plan into BIM 4D, and (4) simulate the view of the camera in BIM.

Following the objective, the author proposes the framework for camera planning in construction, as illustrated in Figure **2**. It comprises four steps that are "predefine camera parameter," "Camera Placement Optimization," "Installation Plan," "Visualization."

3.1 Step 1- Predefine Camera Parameter

4D BIM extracts the working space for each activity and schedules information. The planner should pick the camera style proper to the activity information, based on the visual data's intent. In this article, the author selects two common camera forms as a (1) fixed camera, which hangs on the wall for surveillance to detect and monitor much of the manual construction operation. And (2) portable camera, for easy inspection of quality. In our research, we choose the 360-degree camera representing for portable system.

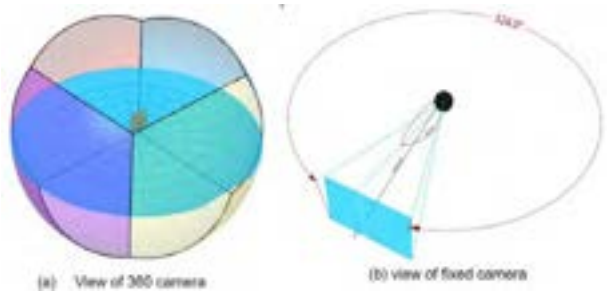

Figure 1. The view of the camera

After choosing the type of camera, the need to consider is to determine the camera's coverage, from which can calculate the number of cameras needed for an activity working area. Figure 1 shows the working area of 360-degree cameras and fixed cameras.

3.2 Step 2- Camera Placement Optimization Module (CPOM)

In step 2, the CPOM converts mathematical information to computer-readable data using visual programming tools. First, this module includes determining the number of cameras and these placements. The following formulas are utilized for calculation.

(1) The number of the camera (N) using for specific

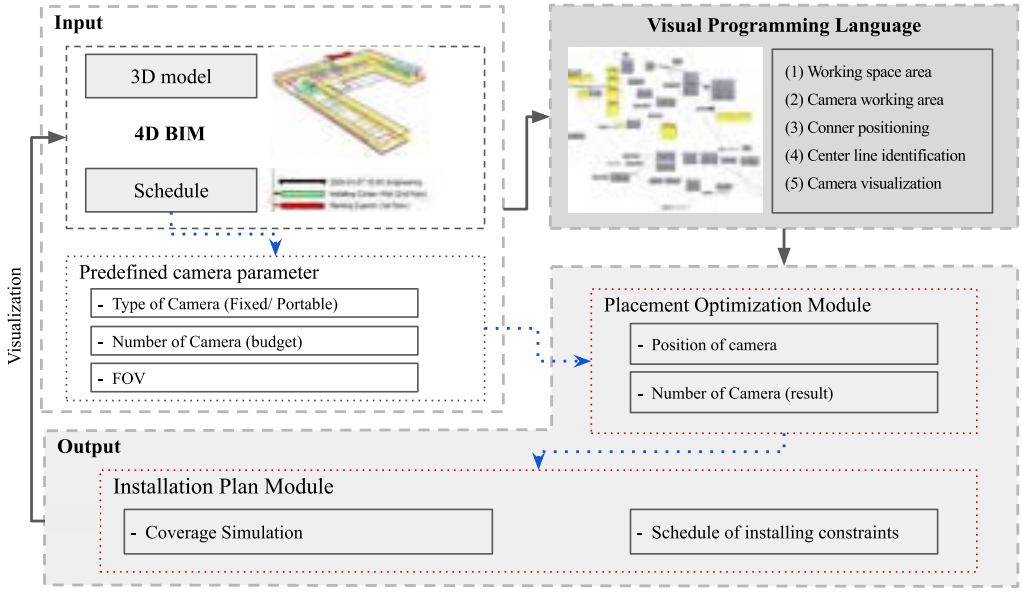

Figure 2. The framework for camera installation planning in construction

activity working area (i).

$$N_i = \frac{\text{volume of activity working area}}{\text{Camera working area}}$$

The camera position is represented by the values of X, Y, and Z coordinates. The (X, Y) variable is coordinated in the 2D working area, while Z is the camera's height.

(2) $0 \leq Z \leq H$ (H- the height of the wall)

The author analyzes two kinds of cameras (fixed and portable cameras) to assess the camera location. Following O'Rourke's theory [16], the fixed cameras were placed in the corner of the activity working area. For the portable camera, the software uses VORONOI grid logic to create the optimized centerline working field. Then the place is set to lay at the centerline.

3.3 Step 3- Installation Plan

After completing step 2, the planner made a final inspection by simulating camera network activity. It helps planners visually predict the monitoring area. This simulation also allows planners to adjust camera position and visibility. Due to construction nature, the construction process has not completed a number of potential camera installation locations identified in step 2. For example, the potential wall that has camera placement is construction. Therefore, the need to schedule cameras installation according to activity progress. Camera planning can also be beneficial in considering moving completed work areas to operating areas. It contributes to cost savings for contractors and still perform best.

3.4 Step 4- Visualization

Finally, the camera position and installation plan can be visualized in 4D BIM. The information can be communicated with related work crews (safety manager, supervisor) in a construction job site in various channels, including mobile devices.

4 Case study

To validate the proposed framework's applicability, the authors performed a case study planning for sample building's interior work. In the case study, the progress of constructing three rooms is evaluated, shown in Figure 3. The initial stage of the camera plan is conducting in Figure 4. The planners (1) insert the 3D model and room space volume box. Then, they (2) choose the camera type for usage purposes. For each type of camera, the permeameter inputs are the difference. The 360-degree camera can be adjusted by the height from the ground, range of view. With the fixed camera, the planner can choose the Conner position, height from the ground, rotation angle, and the working window. After visual programming analyzing, the results are illustrated in Figure 6.

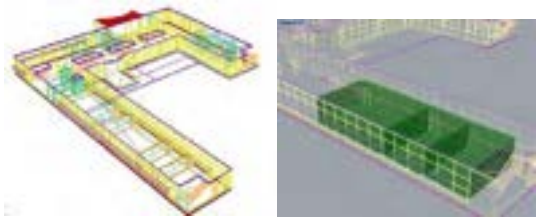

Figure 3. The case study project

Figure 4. Input information

Figure 6(a) shows the results of 360-degree camera placement. Therein, the blue range is the visible view, and the red area is block view in Figure 5, and 6(b) describes the camera view simulation. The schedule of camera planning also presents in Figure 4 as the day installation.

Figure 5. Fixed camera simulation

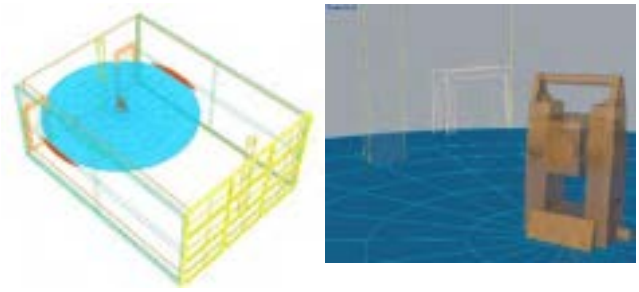

Figure 6. 360-degree camera coverage result

5 Discussion and conclusion

Establishing camera installation planning to collect visual data based on dynamic construction site requires significant manual and labor-intensive tasks. Most construction provides original installation plans without considering the progress. The study proposed a framework for camera installation planning using 4D BIM and VPL. To validate the proposed framework's applicability, the case study was conducted considering the project's construction planning. The results showed camera selection after task purpose. The system also visualizes the camera plan in 4D BIM, simulating camera view. Proper camera placement is expected to collect adequate video/image data quality and successfully support vision-based monitoring tasks.

Several research challenges need improvement. For example, the study considers the level of detail following the weekly or monthly schedule. Moreover, the case study uses two task monitoring and quality inspection. Future studies need to examine activity-based visual data. Moreover, the delay is a critical issue when implementing the construction phase. It may affect camera installation plans.

Abstract –
Based on case studies within the construction industry, the application of location-based construction scheduling and utilizing software-based rule checking has delivered promising research results. We first explain a path on how the lessons from existing work practices can be used in digitalizing construction processes. This includes the objective of describing how the digital transformation of construction drawings and work break down structures lead to safe and lean work environments that crews – according to occupational laws and regulations – should face.

To achieve this objective, we present our ongoing work towards a unifying formal (logic-based) domain model that consists of: (1) a semantically rich ontology of construction schedules, work breakdown structures, and safety concepts; (2) rules for undertaking construction activities that avoid unsafe and wasteful situations.

This paper displays the case study of a newly built fire station for validation of the developed prototype. This experience illustrates that safe and lean allocation of work crews can be planned before construction starts. The outlook presents it's potential in future applications in the construction industry, e.g. resource allocation, as well as in research, e.g. automated work progress tracking by comparing actual vs. planned data.

1 Introduction

All project stakeholders that facilitate design, planning, construction and operation play a vital role in achieving project objectives for cost, schedule and quality. However, few recognize that design and planning can play a critical role for the safety, health and well-being of construction workers, maintenance staff or users during an entire project life-cycle. Although significant research has been undertaken in occupational construction safety, health and well-being, human-assisted software tools for detection and prevention of hazards embedded in construction schedules hardly exist in practice.

Example: Figure 1 illustrates a building information model (BIM) of a (real) building under construction. The roof panels were planned to be installed in sequence. One particularly ubiquitous hazard is that of a *fall* hazard: falls on construction sites account for approximately one third of all fatalities and numerous more severe accidents leading tragically to loss of life, serious and minor injuries [1].

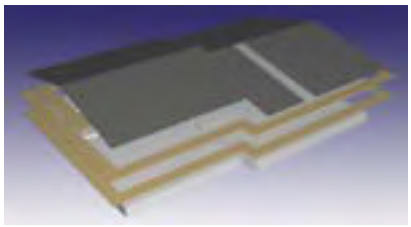

Figure 1. 4D BIM of roof panels under construction.

The edge of a working platform on which workers are occupied with a task that has a drop of more than approximately 2m is widely deemed to be categorized as a hazardous leading edge in many of the world's construction safety codes. In such situations, a fall protection system may prevent a worker from colliding with the ground, structure, or any other obstacle during a free fall and limit the impact force on the body of the worker during fall arrest.

Unfortunately, few projects utilizing BIM model fall protection (e.g., guardrails, safety nets, and covers for holes or openings on roofs) and personal protective equipment (PPE) (e.g., harnesses, lanyards, and temporary anchor points) are not part of the standard object libraries in commercial BIM software. Furthermore, a user-friendly software component to plan the use of PPE that is easy to use, fast, and perhaps can consider work progress, in brief here called a safety analysis system that assesses safety code compliance over the project schedule, does not exist.

Moreover, leading edges can be further distinguished based on the geometry of the work platform (i.e., in this

example the steepness of the roof's slope, and the location of the edge relative to the slope), and tasks or next activities in a construction schedule.

As shown in Figure 2, in time step t_1 the first roof panel is installed, creating four leading edges (one edge on each side of the panel). In the very next time step t_2 the next roof panel is installed, causing the rightmost leading edges from t_1 to disappear (a transient edge). In contrast, the upper leading edge in t_1 will remain until the very last roof panel is installed on the far side of the roof (a persistent edge), and the leftmost edge and lower edge are permanent, and will still exist even when the building is completed (permanent edges).

Edges are further distinguished based on their position on the slope: the upper edge being at the top of the slope is dealt with differently than the lower edge at the bottom of the slope where preventative measures employ safety nets for catching workers, material and/or tools that may accidentally slide down and fall off the roof.

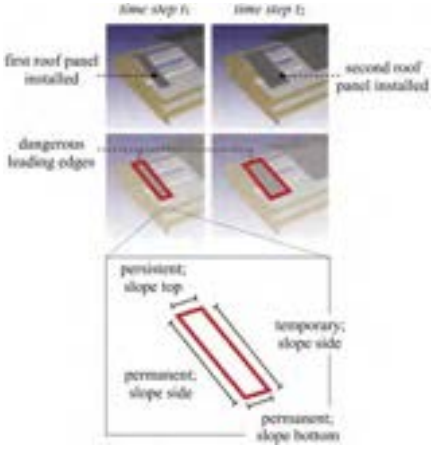

Figure 2. Part way through a construction plan. Roof panels are being installed sequentially in time steps t_1 and t_2. The dangerous leading edges that exist in each partially constructed state are distinguished based on the geometry of the roof slope, and the temporality of the leading edge based on the next construction task in the plan.

In general, measures to prevent fall hazards on roofs include installing fall protection and workers using PPE, or combinations of both. Depending on the type of work, the leading edge is always protected using a fall protection system. Workers without sufficient instruction or training and the right supervision often disregard wearing a personal fall arrest system [2].

Importantly, 4D building information models (4D BIM) are often *incomplete* in that the designer has omitted certain key pieces of information, e.g. the particular order in which roof panels will be installed. It makes it difficult to assess whether a safety code is complied with or not at a particular time step. This motivates the role of **default reasoning** in safety analysis, so that we might assert by default certain details that are missing from an incomplete BIM, and **hypothetical reasoning** that uses what-if scenarios to abduct missing information that would result in a particular situation, e.g. *"Suppose that the roof has to be completed in 5 workdays, can we fill in the blanks in the construction schedule in a way that meet with the availability of the crew and safety and health resources?"* Thus, we require:

- a semantically rich domain model of different features in a 4D BIM (such as leading edges and the refining semantic categories);
- a knowledge base of formal rules that can take a 4D BIM, analyze it, and augment it with these new concepts, injected as new, special kinds of *objects* in the model; and
- a reasoning engine that can take hypothetical statements about construction plans and missing details in the BIM and identify and mitigate resulting safety hazards using adequate methods that are consistent with safety codes and typical construction practices.

2 Related work

Work on roofs is highly dangerous and proper precautions are needed to control the risk. The main causes of death and injury are falling from roof edges or openings, through fragile roofs and through skylights. Many accidents could be avoided if the most suitable equipment was used and those doing the work were given adequate information, instruction, training and supervision. Roof work requires careful planning, particularly where work progresses along the roof. Sloping roofs require scaffolding to prevent people or materials falling from the edge. Another issue is that the small size and economic pressure of roofing companies often does not allow the execution of such best practices.

While Prevention through Design (PtD) concepts have been practiced for many years [3], most of the existing risk mitigation approaches are done manually, and are thus prone to error or not performed at the right time [4]. Several other key reasons contribute to such unacceptable practices: (a) the disconnect in a fragmented construction industry does not allow owners, architects, engineers, contractors and subcontractors to exchange their respective competent knowledge within the disciplines via an open, shareable platform, thus causing poor designs and unsafe execution and (b) the process of preventing hazards starts too late, often in the construction planning phase only, and involves safety and health experts who have to manage multiple projects at the same time.

More recently, research on Job Hazard Analysis (JHA) [5] and safety rule checking [6-8] that can automatically detect and resolve known hazards embedded in individual work activates have been introduced.

However, there is still a wide gap in standardization of safety concepts and software tools and a lack of strong requests from project owners and contractors to demand such solutions. An extensible, intuitive to apply, integrated suite of safety analysis software tools for construction is currently still missing. In part, the reasons are the complex, dynamic nature of construction projects and the multifaceted roles of its stakeholders. Aligning design intent with construction schedules and allocating resources (labor, material, equipment) is a demanding task. *Lean* in the field of construction safety refers to designing safe workplace, for example, using virtual construction models that attempt to bring construction process and safety product information to the job face [10]. Although research has shown that the creation of automated construction schedules is possible based on a priori knowledge about processes of activities and historical crew data, process related safety information has been left out so far for the majority of potential applications [11].

3 Methods

3.1 SafeConDM: an Ontology of Construction Safety

An example illustrates the German construction safety regulation for fall prevention (Figure 3) [12]. Similar to other countries, the code states that a guardrail must be installed at a leading edge if a worker could fall more than 2m, or a covering must be applied if the drop in a hole on the work platform is greater than 9 m^2.

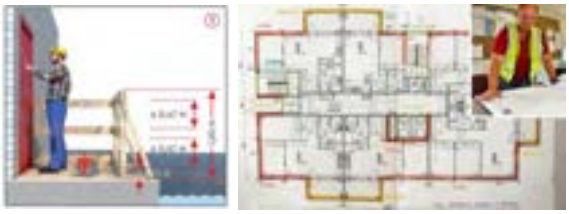

Figure 3. Examples: Safety regulation for fall prevention [12] (left) and manual hazard identification and mitigation (right).

To detect and prevent, for example, a fall-from-height hazard and apply a protective guardrail system, in an ideal case, a designer would design-out the hazard (so it does not appear during construction or later in maintenance). In reality, a safety engineer manually identifies the hazardous locations on a paper-based drawing (e.g., colors in Figure 3 indicate types and locations where protective equipment needs to be installed) or substitutes unsafe construction methods with a safer method (e.g., instead of workers using ladders that can tilt, workers should apply a scissor lift platform).

We aim to develop software tools that can automatically assess such codes on a given BIM of a construction site. BIMs are an object-oriented formal representation of buildings, including classes such as door, wall, or slab. Furthermore, in the field of *construction planning*, 4D BIM is used to model how a BIM is planned to be erected in a series of discrete time steps, i.e. a 4D BIM is equivalent to a sequence of partially constructed BIMs that represent the building under construction.

Our approach has been developed based on previous research in ontological and logic-based approaches to Construction Safety including [5,6]. To illustrate this, we integrate our approach into a broader existing ontological framework for construction safety. Figure 4 illustrates the *construction safety ontology* by Zhang et al. [5] extended with new (abstract) classes: spatial artefact and hazard space [13]. The authors hereby distinguish the following three modelling layers:

1) *Construction Product Model:* building products and relations, such as doors, walls, stories, slabs;
2) *Construction Process Model:* the construction plan including resources (equipment, materials, labor);
3) *Construction Safety Model:* construction safety knowledge (potential hazards, regulations, mitigating steps).

We define pertinent spatial artefacts [14] that capture semantic information about regions of empty space based on construction site activities, and human perception and behavior (movement, visibility, falling spaces, activity, etc.). Similarly, we model hazards as spatial artefacts whose existence and (geometric) definition is often a simple expression involving topological relations and geometric operations between regions (intersection, union, offset etc.), i.e. the *algorithm* for hazard detection is often as simple as clash detection. Spatial artefacts are modeled on the same ontological level as any other object in the product model, i.e. they inherit from the abstract class Product.

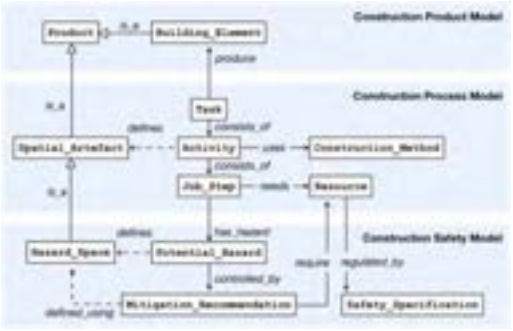

Figure 4. Construction Safety Ontology from [5] extended with spatial artefacts to create SafeConDM [13].

3.2 The shape of meaningful *empty spaces* in construction safety

Consider the region of empty space around an object such as a fuse box or valve; this region is meaningful

because a person must be located in that region to perform a particular act (e.g., operate on the fuse box). The geometry of this *functional space* region depends on properties of the person (consider electrician, mechanic, etc.), the task, and the object. Agents (e.g., workers and vehicles) have a movement space which are the regions in which they can move (travel) within. Excavators and other heavy equipment have an *operational space* required for rotating and depositing dug up material. People and sensors have *range spaces* (which can be further refined into: *visibility space, hearing space, reach space*), and so on. These are examples of spatial artefacts, a modeling approach that was initially developed for human centered architectural analysis [14-18].

The idea is that human behavior and experience is formally modelled as regions of empty space in which those behaviors and perceptual experiences take place. By doing this, behavior and experience (such as where a person needs to stand to see a particular object, i.e. *visibility space*) can be *represented* as "objects" in a BIM, on the same ontological level as other building objects such as doors, walls, slabs, and so on. Moreover, they can be *reasoned about* in a similar way to other BIM objects that instead have a material extension, e.g. clash detection can now be used to reason about whether a worker is in danger of a heavy vehicle strike by finding the intersection between the worker's *movement space*, the o*perational space* of the vehicle, and the *blind spots* of the vehicle operator seated in the cab. Concretely, in a BIM such as IFC, spatial artefacts form an abstract class that is a subclass of *IfcSpace*.

Example. Consider the previously discussed natural language code about a specific fall hazard: *"A platform that has a leading edge to a drop of more than 2m must be secured by a guardrail."*

We define a new spatial artefact called *Fall Space*, parametrically defined as: the region in which a person will fall by at least height `DANGEROUS_DISTANCE`, i.e. in the German code example the parameter is set to 2m. The dangerous platform edges can now be precisely, formally defined as: "where a *Movement space* horizontally meets (touches) a *Fall Space*".

There are a number of desirable properties of using spatial artefacts from a knowledge engineering perspective: the formalization is (a) very faithful to the original natural language code (semantics only, without any additional clauses for speeding up rule checking which would clutter the formalization and obscure the intended meaning), (b) easy to understand and verify by other planners (transparent); (c) directly applies to different contexts without changing the declarative statement that formalizes the code (portable), i.e. the geometry of Fall Space is customized according to the project and context, whereas the concept dangerous edge as defined above does not need to change. Importantly, this provides a uniform approach for modelling a large range of human-centered concepts (movement, visibility, performing tasks etc.) that can seamlessly be integrated within a BIM, and are effective "building blocks" for formalizing a broad range of hazards in a clear and transparent way.

In Tables 1 and 2 we list the spatial artefacts that we use to define fall hazards. We develop two new classes of spatial artefacts: *Falling spaces* and *Hazard spaces*. We ground the geometry of the spatial artefacts in our models based on the specific context of construction. We encode rules about hazards as the spatial definition of specific (subclasses of) hazard spaces.

Table 1. Construction site spatial artefacts

Spatial Artefact	Description
Movement space	Regions in which an agent (e.g., construction worker, manager, and visitor) can travel.
Movement corridor	Specific pathways along which a group of agents (e.g. crowds) is moving.
Functional space	Region in which an agent must be located to perform a given function or use a given object.
Work area	Area where an agent is occupied with a given task (e.g. electrician working on a fuse box).
Range space	Regions carrying information about how an object can be detected by an agent.
Visibility space	Region in which there is an unobstructed line of sight to a given object.
Blind spot	Region to which a vehicle operator has obstructed line of sight.
Fall space	Region in which an object or agent will fall by a dangerous distance.
Broad fall space	Region through which an agent can (easily) fall.
Narrow fall space	Region that is too narrowly shaped for an agent to (easily) fall through, but through which equipment and material could fall, or in which an agent's ankle could get stuck or sprain.
Operational space	Region that an object or vehicle may occupy to perform a given function.

3.3 Reasoning about hazards in construction

4D BIM introduces time to model a (possibly incomplete) construction plan. We encode this in Answer Set Programming (ASP) using two new predicates. Each element can optionally be assigned to a symbolic time step *construct/2*. The set of time steps form a partial order through an intransitive relation *next/2*: given time steps t_i, t_j then the interpretation of *next*(t_i, t_j) is that t_j occurs directly after t_j such that there does not exist time step t_k where *next*(t_i, t_k) and *next*(t_k, t_j). The temporal relation *before/2* between time steps is the transitive closure of *next/2*. Finally, 4D BIMs express temporal dependencies between elements: *dependency/2* between two BIM elements *A*, *B* means that element *A* must be constructed before *B*.

The following code snippet describes a series of slabs s_1, s_2, s_3 optionally assigned a time step, and their temporal dependencies. ASP derives the partial order *before/2* and the total order *next/2* of time steps.

Table 2. Construction safety hazards defined as spatial artefacts.

Subclass of hazard spaces	Hazard category	Description	Spatio-temporal definition
Fall hazard space	Slips, trips and falls	A person in these regions is at risk of falling from a dangerous height.	Intersection of movement spaces and broad fall spaces.
Sprain ankle hazard space	Slips, trips and falls	A person in these regions is at risk of twisting their ankle by walking into a small hole.	Intersection of movement spaces and narrow fall spaces.
Falling object hazard space	Struck by	A person in these regions may get hit by a falling object (e.g. tools, materials).	Subset of movement spaces that is directly below a narrow fall space (e.g. their vertical projection overlap).
Falling material corridor	Struck by	A person in these regions is at risk of being hit by an object falling from an active work area directly above.	Subset of movement spaces that is directly below the intersection of narrow fall space and work area.
Travelling vehicle strike hazard space	Struck by	A person in these regions is at risk of being hit by a moving vehicle.	Intersection of vehicle movement space (or corridor) and worker movement space (or corridor).
Operating vehicle strike hazard space	Struck by	A person located in these regions is at risk of being struck by a heavy vehicle in operation.	Intersection of vehicle operational space and worker movement space. The presence of blind spots further increases the risk.
Electrocution hazard space	Electrocution	A person located in these regions is at risk of electrocution.	Functional space of fuse box.

```

3.4 Evaluating consistency

Given a declarative formal encoding of construction safety codes, we can evaluate the consistency of such statements on a given BIM using off-the-shelf solvers that have spatial reasoning support; we opt for using a logic programming paradigm where the knowledge base consists of Horn clause rules of the form: $h \leftarrow b_1,\ldots, b_n$, where proposition h is true (the rule head) if propositions $b_1,\ldots, b_n$ are all true (the rule body). Horn clauses strike a balance between being sufficiently expressive to capture logical IF-THEN relationships between symbolic terms, while still being computable (unlike full first-order logic). We specifically use ASP, a logic- programming paradigm developed within the artificial intelligence community, that supports both deduction and other forms of non-monotonic reasoning (including default reasoning and hypothetical reasoning) and is computationally efficient. Similar to Prolog, ASP has a knowledge base of facts and rules of the form: "*Head :- Body.*" meaning that if the Body is true, then the Head must also be true. Rules with no Head are ASP integrity constraints, written as "*:- Body.*" meaning that the Body must not be true (i.e. as a logical expression: Body implies False). Head and Body expressions consist of literals, representing propositions that can be either True or False, and ASP reasoning engines are specifically designed to rapidly find combinations of deduced facts that are consistent with all given domain rules (referred to as models or answer sets).

We have extended the base language of ASP beyond propositions so that a set of consistent facts must also be spatially consistent, e.g. a 2D point can never be both inside, and outside, of a given polygon [19]. We use our extension of ASP that also supports spatial reasoning, called ASPMT(QS) [19], by encoding a building information model and derived artefacts as ASP facts, encoding the inference of hazards and responses as ASP rules and constraints, and implementing safety checking via ASP's answer set search. We have implemented ASPMT(QS) based on clingo [20], a complete ASP system composed of a grounder (gringo) and a solver (clasp).

Example. The following ASPMT(QS) rule states that, for all movement spaces that meet flush (touch horizontally) with a fall space in the same time step, then deduce a fall hazard space object. In this example, fall hazard spaces are modeled as the intersection of movement spaces and fall spaces, offset by a threshold of 200mm.

```
fall_hazard_space(H, Time) :-
   timestep(Time),
   movement_space(M, Time),
   fall_space(F, Time),
   topology(externally_connected, M, F),
   H_ = intersection(M,F),
   H = buffer(H_, 200).
```

We then derive the semantic refinements of fall hazard spaces based on their temporal duration in the construction plan. Firstly, a part of a fall hazard space (H) at timestep T is defined to be *permanent* (Hp) if it is still

there in the final timestep (Te), i.e. it is the intersection between fall hazard space H at time T, and a fall hazard space He in the final timestep Te:

```
permanent_fall_hazard_space(Hp, T) :-
   timestep(T),
   timestep(Te), not next(Te, _),
   fall_hazard_space(H, T),
   fall_hazard_space(He, Te),
   Hp = intersection(H, He).
```

Conversely, a part of a fall hazard space (H) at time step T is temporary (Ht) if it does *not* exist in the final time step (Te), which is computed by subtracting the final fall hazard spaces (He) from H:

```
temporary_fall_hazard_space(Ht, T) :-
   timestep(T),
   timestep(Te), not next(Te, _),
   fall_hazard_space(H, T),
   fall_hazard_space(He, Te),
   Ht = difference(H, He).
```

A temporary fall space is *transient* at T if it disappears in the very next time step Ti:

```
transient_fall_hazard_space(Ht, T) :-
   timestep(T), next(T, Ti),
   temporary_fall_hazard_space(H, T),
   temporary_fall_hazard_space(Hi, Ti),
   Ht = difference(H, Hi).
```

A temporary fall space is *persistent* at T if it still exists in the very next timestep Ti:

```
persistent_fall_hazard_space(Hp, T) :-
   timestep(T), next(T, Ti),
   temporary_fall_hazard_space(H, T),
   temporary_fall_hazard_space(H_, Ti),
   Hp = intersection(H, Hi).
```

Similarly, movement spaces are created as the volume 2m directly on top of slabs, subtracted by walls, columns and other movement obstacles. Fall spaces are the volume of space between the top surface of each object, and the next surface directly above (or the "sky") with the lower 2m subtracted. For this first prototype we simplified the calculation of movement spaces as the top surface of slabs subtracted by movement obstacles (columns and walls with voids where windows and doors will be placed), and we simplified fall spaces by taking a 2D bounding box of the site on each building floor and subtracting the slabs on that floor.

Note: The final time step Te is identified as the time step that does **not** have any *next* time step, i.e. "not next(Te,_)". In ASP underscore refers to an "anonymous" variable that does not need to be named. In the above rules, we assimilate object IDs to their geometric representation in ASP's internal geometry database. Moreover, topology relations and Boolean operations on polygons (intersection, difference, buffer) are evaluated using external Python libraries (Polygon, PyClipper) and non-linear real arithmetic solver *z3*.

4 Case study and results

A fire station is a structure or other area for storing firefighting apparatus such as fire engines and related vehicles, personal protective equipment, fire hoses and other specialized equipment, extended the nature of fire emergencies. Fire stations around the world also provide an important role in training volunteering or professional fire fighters or search and rescue personnel on site and educating the public regarding fire and safety (Figure 5). Most fire or Emergency Medical System (EMS) stations are municipally owned and usually require public bidding. In rural areas, many firefighters contribute labor time, increasing the potential risk on such projects.

Construction budgets and schedules respectively vary by the project. Due to the large number of such buildings, preference is given to systems design and functionality (which can be repeated once available).

The fire station model in this case study consists of a building with several levels. We focus on the roof aggregate consisting of 24 panels and 1 chimney opening. The chimney is added after the roof panels are installed. Supposing the roof is installed in the anti-clockwise order from the lower right corner, we assign each panel with a time step ranging from 1 to 24 (Figure 5). ASP then identifies fall hazard spaces (permanent, transient and persistent) at each time step. Moreover, permanent and persistent fall hazards are mitigated depending on the location of fall hazard spaces with respect to the slope, e.g. leading edges on the bottom of the slope require safety nets to capture falling objects, leading edges on the top or the side of the slope require guardrails, small openings on the slope require a cover (Figure 5). Table 3 shows fall hazard spaces and mitigation measures at 3 representative time steps.

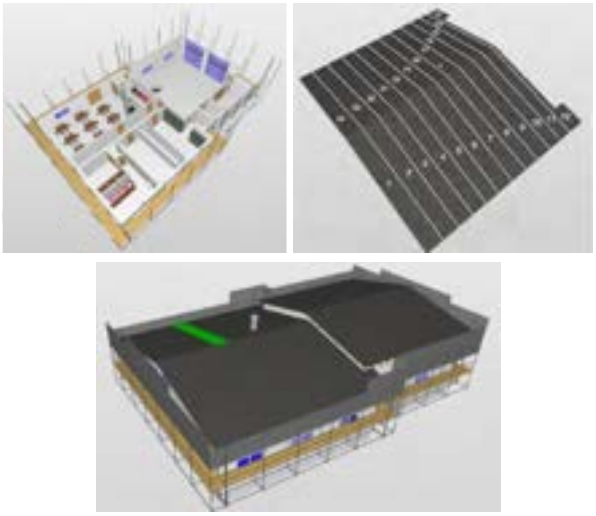

Figure 5. Main functions of a fire station on first floor (top left), order of roof panel installation (top right),3D view of the fire station model incl. protective safety nets on scaffolding with a single highlighted roof panel.

Table 3. Identified fall hazard spaces and proposed mitigation measures at t = 5, 19, and 24. Permanent (red), transient (green), and persistent (purple) fall hazards; Non-transient fall hazards are mitigated using a combination of safety nets (orange), guardrails (blue), and coverings (pink).

	t = 5	t = 19	t = 24
Fall hazard spaces			
Mitigation measure			

Figure 6 shows the quantity of safety protection materials needed at each time step. While these quantities were automatically generated, it shows a nearly linear demand for safety nets. Midway the project (t = 13) the peak of demand for guardrail is reached (panels on the other side of the roof allow removal of earlier installations). The demand for coverings becomes a non-null constant at t = 17 when the roof panel with one sole opening (for the later installation of the chimney) is installed and requires protection.

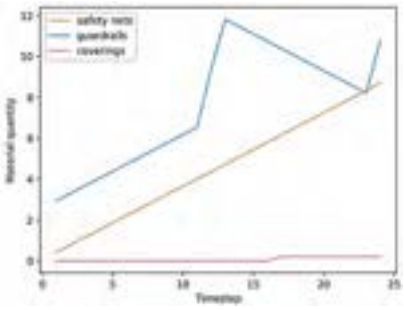

Figure 6. Requirement of safety protection equipment as roof panels are installed successively.

Providing a project manager or a safety engineer with such visual and quantitative information can impact decision making. Noteworthy examples are: (a) understand the location of fall risks associated to specific tasks in a construction schedule and (b) ordering the right quantities of protective equipment when needed. In a further step, if done continuously throughout a project, responsible personnel can seek forecasts of potential demands of (fall) protection resources and align with proper construction methods. On this particular project, due to the roof covering the entire and relatively small building area, resource leveling would not offer much potential savings [21]. However, depending on the amount of time needed to install one roof panel, an alternative fall arrest system (e.g., lanyard and energy absorber instead of guardrails, safety nets, and a hole cover) could be employed to protect the workforce who is installing the roof panels [22].

In this paper, we natively integrate an internal geometry database within ASPMT(QS) to manage large amounts of complex geometric data. To do this, we generate the polyhedral mesh representation of BIM objects via our modified version of IfcConvert (IfcConvert+). ASPMT(QS) then retrieves object geometries and deduces spatial artefacts using previously defined rules. Table 4 presents model statistics and ASPMT(QS) runtime. Compared to previous research [6,9] the runtime has significantly improved to a level where practitioners could apply it.

Table 4. Model statistics and runtime.

Number of BIM objects		1273
Average number of vertices		35
Number of spatial artefacts	Movement spaces	24
	Fall spaces	30
	Fall hazard spaces	66 (of which: 24 permanent, 22 transient, 20 persistent)
Time to generate 3D meshes from IFC via IfcConvert+		340 seconds (1218 meshes; total of 870k triangles)
Time to generate all spatial artefacts		0.181 seconds

5 Conclusion

We have presented a work in progress domain model of safety concepts on a construction site, and an approach for reasoning about safety compliance and mitigation strategies that integrates with 4D BIM construction schedules using Answer Set Programming (ASP) extended to natively support spatial reasoning. A key feature of our approach is the role *spatial artefacts* for representing and reasoning about semantically rich regions of worker perception, behavior and activities. We demonstrate this modeling approach with *fall hazards*, spatial regions where a worker is at risk of falling from a dangerous height. We refine fall hazard spaces according to their position in relation to building elements (e.g. with respect to a sloped roof) and temporal persistence (according to the 4D BIM construction schedule). These refinements are critical for reasoning about alternative mitigation plans that make tradeoffs against cost and construction progress (*lean* construction), particularly when 4D BIMs are incomplete, such as the installation of guard rails or safety nets. Our empirical evaluation on a real 4D BIM shows that our approach runs fast enough to be practical to use on large 4D BIMs.

In our future work we are expanding the scope of hazards to include a wide range visuo-locomotive features that are critical to safety in construction. In order to demonstrate further competitiveness over existing approaches, future testing may focus on highly complex 4D BIMs. Monitoring as-planned vs. as-built situations may yield further insights in how technology [23,24] or

combinations thereof can assist future decision making in construction safety and health planning and mitigation.

Actions to Realize Efficient Project Risk Management using the BIM Method

M. Eilers, C. Pütz, M. Helmus, A. Meins-Becker

Chair of Construction Management, University of Wuppertal, Germany
E-mail: eilers@uni-wuppertal.de, puetz@uni-wuppertal.de

Abstract –

At the beginning of a construction project, cost, time and quality are defined, which must be adhered to throughout the entire construction process. Compared to other industries, risk management in the construction industry is often treated negligently. Risk management is rather an additional documentation task than an effective project management and controlling instrument. However, systematically applied risk management and successfully implemented counter-measures offer the opportunity to significantly increase the result of the construction project. Information gained from an efficient risk management system can automatically be used as empirical values for subsequent projects, thus increasing the achievement of quality, cost and time targets in the long term. The application of the BIM method opens up new possibilities in terms of the automatic linking of risk management information to other processes, which have not been exploited to date.

The research project "BIM-based risk management" examines the application of risk management in construction projects on the basis of literature research, numerous interviews with experts and an online survey. The content of the analysis is the strategy of companies in implementing the classic phases of the project risk management process consisting of risk identification, risk assessment, risk control and risk monitoring. The result shows, that there is no consistent systematic approach to the use of risk management systems in the construction industry. Individual approaches, such as the use of Excel templates to identify risks, are being implemented, but there is no linking of information across projects or departments, which means that the great potential of project risk management is not sufficiently exploited.

On this basis, the research project develops an ideal-typical process for the application of risk management in construction projects. The resulting BIM use case risk management shows how this information can be automatically generated and made available via the BIM process.

1 Procedure and principles

Within the framework of the research project "Measures for the implementation of an efficient project risk management by using the BIM method" of the chair of Construction Management of the University of Wuppertal, solutions are being developed how the information linkage associated with the application of the BIM method can be used to improve risk management. The classical risk management process (see Fig. 1) based on DIN ISO 31000 is a sub-area of project management which is implemented over all life cycle phases of a project, involving all project participants and involving different business units. Together, the project participants identify potential opportunities and risks for the project at an early stage and take proactive countermeasures by means of the process steps of identification, assessment, control and monitoring. The risk management cycle is a continuous process. This means that the cycle is constantly repeated in the course of project processing [1]. Only project risk management is considered in the project. The aim of project risk management is to increase the transparency of risks in a construction project and to derive and evaluate measures to reduce unknown parameters and determine realistic target figures. This leads to a higher achievability of the project goals in terms of costs, deadlines and quality. Project risk

management is distinct from corporate risk management, whose overriding goal is to maintain the company.

In the research project, which has been running since January 2019, the current application of risk management in construction projects was first examined. In view of the ever-increasing demands for a partnership approach to projects between client and contractor, the project deliberately considers both sides and in particular their interfaces in terms of risk management.

Through numerous expert interviews and an online survey, the strategy of companies in implementing the project risk management process was analysed. When looking at the existing risk management processes in terms of the flow of information, level of detail and responsibilities, differences in the approaches to risk management and the priority given to the issue became apparent.

2 Risk management

The term risk refers to the deviation from project goals caused by influences on productivity. The project objective is to complete a project on time, within budget and in line with quality standards [2]. The term risk includes both positive and negative deviations from targets. The positive deviation from goals is called opportunity, the negative deviation is called danger [3]. Since mainly the negative deviations can cause construction delays and cost increases, the term risk is used in this paper to refer to the negative deviation in particular. For the correct application of a risk management system it is necessary to create an awareness of risk management in the company, the organization or the department. A risk management system must be integrated within the company or the organization or project at various organizational levels. On the one hand, it must be integrated at the normative level, where the goals of the company or project are defined. An implementation on a strategic level, determines the risk strategy to achieve the defined goals. The risk management system, the focus of this paper, is implemented at the operational level [4].

The risk strategy defines the objectives to be achieved by risk management. The risk strategy must contain the following specifications [5]:

- The type of risks to be taken
- The level of risk tolerance
- The limit of the risk-bearing capacity
- The time limit in which the risks are dealt with
- Specifications on the risk management process

DIN ISO 31000 specifies a process structure for risk management, see Figure 1 [6].

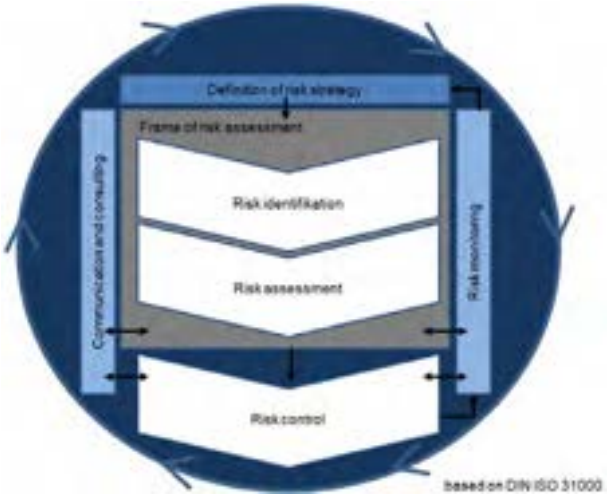

Figure 1. risk management process

The core of this process structure is transparency and openness. The process can only be successfully implemented if risks are not covered up, but are addressed openly. However, risk assessment and treatment cannot be carried out without defining an area of application, the context and setting risk criteria, see Figure 1. Throughout the cycle, continuous communication, documentation and review is required [7]. The risk management cycle is a continuous process. This means that the cycle is repeated in the course of project processing. The reason for this is that risks can change or new ones arise as the project progresses [8].

In the course of the risk management process, communication and consultation means that expertise from a wide range of fields is taken into account in the risk management process and that, as a result, different perspectives are considered in the identification, assessment, control and monitoring process. This also serves to obtain the necessary information required for risk management. Communication and consultation should take place between all those involved in the project or company [9].

Continuous monitoring and review of the existing risk management system is necessary to ensure the quality and effectiveness of risk management. In order to communicate the results of risk management, it is necessary to document risk management on an ongoing basis. This can provide information that is necessary, for example, for decision-making [10].

In order to apply a risk management process, the scope, context and criteria must be defined. This means that a risk strategy is defined as described above [11]. The definition of the scope includes a specification of the risk management processes and tools used and the necessary

means and responsibilities. A definition of the cycle of involvement and an analysis of interfaces with other projects and stakeholders are also part of the definition of the scope [12].

In addition, the environment in which the defined objectives are to be achieved must be analysed. The environment has a significant influence on the design of risk management. The external and internal relationships are defined. External interrelationships include, for example, political, legal and social aspects, whereas internal interrelationships include responsibilities and roles in the company or project [13].

Risk criteria are necessary for risk assessment. Therefore, they must also be considered. Risks can be assessed from a variety of perspectives within the company or organization, such as individual sub-projects of a major project or different levels within an organization. Since the approach and procedures differ depending on the viewpoint, criteria must be defined for risk assessment. For example, the type, extent and measurement of effects and the decision-making criteria for risks are defined [14].

3 Steps of the risk management process

The environment of all risk management processes is the risk strategy. This is used to formulate objectives and framework conditions. The next steps are the sub-processes identification, assessment, control and monitoring. Continuous controlling, careful documentation and regular communication and advice complete the risk management control loop [15].

3.1 Identification

The aim of risk identification is to identify all existing risks that could jeopardise the achievement of objectives. In risk identification, a distinction is made between cause, event and effect. A cause results in an event that has an impact on the project objectives. This distinction is important because countermeasures for dealing with risks can only be developed if the cause of the effect is known [16].

With regard to the method of risk identification, a distinction is made between the type of recording, the time of recording and the integration of the identification into the structure of the company or project [17].

It is important to complete the risk identification before starting the analysis [18].

3.2 Assessment

In the course of the risk assessment, the probability of occurrence and the extent of damage of a risk are estimated. This can be qualitative (e.g. low, medium, high) as well as quantitative (e.g. 50%, €50,000 loss). Based on the risk assessment, it can then be decided whether or not the identified and assessed risks are handled in the following ways[19]:

- No further action is taken
- Options for risk treatment exist
- Whether further analysis is needed for understanding
- The existing control system must be maintained
- project objectives may need to be adjusted if necessary.

For this purpose, the risks that are to be treated with the highest priority must first be determined.

The assessment of risks can be divided into gross and net assessment. In the net risk assessment, only the residual risk is assessed with a countermeasure. The gross risk is therefore the purely assessed risk. The gross risk thus represents the entire extent of the risk, whereas the net risk only shows the residual risk after countermeasures. It is assumed, however, that the countermeasures to reduce the scope of the risk occur to the extent assessed [20].

3.3 Control

In the risk management process step, countermeasures are developed to deal with the risks. The effectiveness of the selected countermeasures is then assessed. If the remaining residual risk remains too high, a further or, if necessary, new countermeasure is defined. This results in an iterative process [21].

How a risk is treated depends on the risk behaviour of the company or project and the risk strategy that has been defined [22]. A basic distinction is made between cause-related and effect-related measures [23]. Cause-related measures reduce the probability of a risk occurring, whereas effect-related measures reduce the extent of damage [24].

A distinction is also made between active and passive measures. Active measures contribute to reducing the probability of occurrence and/or the amount of damage, thereby changing the risk structure. Passive measures, on the other hand, aim to minimize the extent of damage. An attempt is made to compensate for the occurrence of a risk [25]. The combination of several coping measures is also possible and common in order to keep the residual risk low [26].

A distinction is made between five different risk management strategies [27]:

- Avoidance
- Reduction
- Transmission
- Insurance
- Acceptance

With regard to the order of priority of the application of coping measures, there is no fixed order. This must be determined individually. All measures depend on the cost-benefit ratio, but also on the time schedule, the qualitative dependencies and the applicability.

3.4 Monitoring

As already explained, communication and consultation, recording and reporting, as well as monitoring and reviewing are also part of the risk management cycle according to DIN 31000, and these components of the cycle should take place at all stages of the process [28].

The risk management process of a company or project must always be reviewed. This part of the risk management process is therefore also called risk controlling [29]. On the one hand, risk controlling serves to determine whether the desired effectiveness of the management measure has been achieved. On the other hand, it serves the right insight if a risk has to be re-evaluated or a countermeasure is not effective. It must also be checked whether a risk no longer exists, for example, due to a change in planning, and whether the change in planning gives rise to new individual risks [30].

4 Study on the application of risk management in the construction industry

In order to gain an insight into the application of risk management in construction practice from the perspective of the client and the construction company, expert interviews and an online survey were launched by the University of Wuppertal. The structure of the web-based survey corresponds to that of the expert interview.

The online survey was completed at the end of September 2019. 249 participants took part in the survey. Among the participants are 50 construction companies, 47 private builders, 34 planning/architectural offices, 31 participants from the field of consulting, 25 public builders, 6 experts, 3 from the craft sector and 54 from other fields. The findings of the survey are summarized below.

4.1 Positive approaches visible in practice

Around 60% of the companies surveyed implement risk management in accordance with a uniform company-wide risk strategy. Risks are identified for the first time at the acquisition stage or at the start of a project and are continued through the subsequent project phases. Risks are usually recorded in Excel applications or the company's own software applications. Communication channels for risk management are generally short and, thanks to open discussion cultures, there are few fears of communicating risks.

The interviewed experts recognize advantages for the project business through risk management: Risks that are recognized early have a positive influence on the further course of the project. Costs are saved, customers are retained and experience and improvement potential for follow-up projects is generated. There is improved control of costs and cost transparency throughout the entire construction phase, and through the integration of the risk management system, all those involved are able to improve the reliability of deadlines and costs.

4.2 Identified problem areas

Instead of uniform guidelines for dealing with risks and a systematic approach, a good third of companies rely purely on the experience of their employees.

Risks are considered in greater depth in the bidding phase, but are neglected in the execution phase. When assessing risks, the effects of deadlines are usually not taken into account in the offer. Risk assessment is largely intuitive and is shaped by the experience of the individual employee. The risk assessment usually ends with the acceptance and is not continued until the end of the warranty. Companies often have clear divisions between the departments of acquisition and project execution or planning and implementation on the client side. After project completion, the knowledge gained is only transferred to a few colleagues in discussions at communication level. None of the companies carries out a systematic evaluation of the risks after project completion and a systematic transfer of this information to subsequent projects.

4.3 Conclusion of the study

Overall, it became clear that risk management is by no means accorded importance in every company. For about half of the companies surveyed, risk management hardly plays a role in their projects. The cost and schedule of a project is usually determined by higher authorities and the project participants lack the necessary room for maneuver. There is potential for a stabilisation of risk management processes: Regular identification of risks, adjustment of assessments and linking to other processes have so far hardly been used to make risk management more effective. There is often no consistent systematic approach to the use of risk management systems. It is more a combination of individual approaches, which are not sufficiently linked and therefore information is lost or not fully used. In view of the imbalance of many current major projects, the potential of an industry-wide application of risk management processes is evident here.

5 Outlook using BIM

The mentioned research project has the aim to show the development possibilities of risk management into the method BIM. Therefore, the participants of the study were asked for which use cases and to what extent they currently use the BIM method to generate integration potentials for risk management. The survey showed that BIM is already being used in companies. The most frequently used use case is the use case of 3D modelling and collision check. The 3D modelling is set up in the planning phase and attributes are defined to support the prefabrication process. In addition, the models are used to generate carcass and fit-out dimensions, which serve as a basis for the bill of quantities and costing. Schedules and costs are usually not yet linked in the respondents' BIM models. In some companies, there are also company specifications to digitalize the complete planning and construction processes. Tablets are also often used for construction site operations. These enable access to the documents, checklists and work aids in the cloud. In addition, barcodes are sometimes stuck into every room on the construction site and the site manager has the option of calling up the attributes and information important for the room via tablet. The complete defect management is generated daily via the tablet of the site manager and the information stored in the cloud. The areas of construction site logistics, modularization, systematization of construction products and components are currently the focus of integration into the execution. In addition, some of the construction companies also want to use their project model for later operation and extract an as-built model from the data and attributes. The aim is to use BIM to create a complete digitalization of the processes from the construction site or project. As a use case, construction companies have their own focus such as quantity take-off, calculation and quality assurance on the construction site. Developers usually use BIM to focus on 3D coordination. Documentation is an important use case for all parties involved. A market analysis of risk management software carried out in parallel to the surveys also revealed, that there is currently no BIM-capable offering, for example with an ifc interface.

5.1 Process modelled risk management

As the study shows, risk management is currently regarded and implemented as a separate process in most companies. There is currently no link to other project processes such as scheduling or cost planning. To be able to use the advantages of the BIM method for risk management, the process must first be linked to the other project processes.

The first step in linking with the BIM method in the research project is therefore to model the risk management processes and link them to the other project processes. For this purpose, the risk management process described in chapter 2 and 3 was created/modelled with the help of the Business Process Modelling Notation 2.0 (BPMN 2.0). Figure 2 shows an extract of the process and gives an overview of the type of modeling.

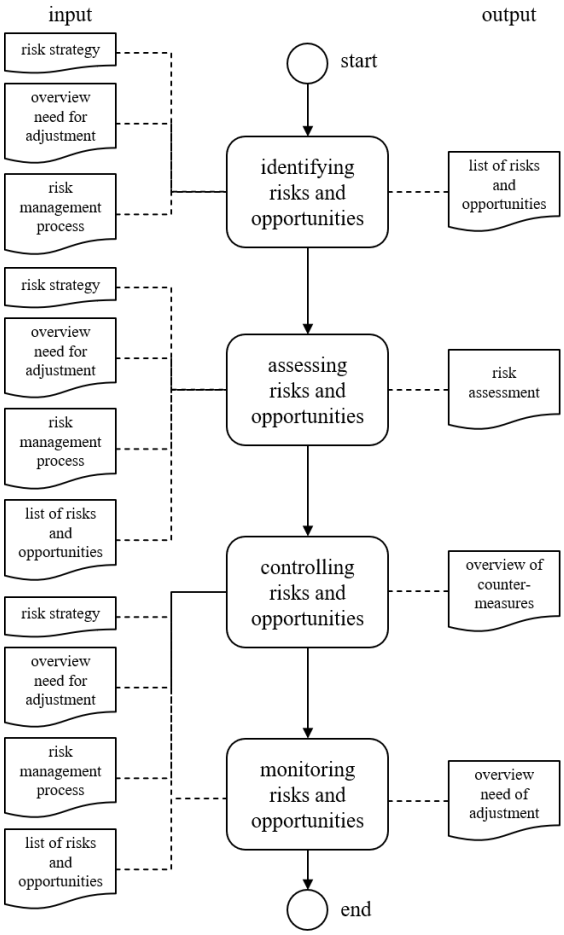

Figure 2. risk management process in BPMN 2.0

Each step of the risk management process shown in Figure 2 is broken down in more detail in further levels of the process model. The process "Identifying risks and opportunities" is divided, for example, into the process steps "Describing risks/opportunities", "Defining a short description", "Determining the cause and effect of the risks" and "Assigning a risk/opportunity category". In this way, all process steps are linked to one another and clearly presented.

In a second step, the modelled risk management processes are then linked to the other processes of the shown project, for example, cost control. In this way, it becomes clear at which point in the project, risks must be identified, assessed and controlled on the one hand, and which processes provide information in order to better

assess risks on the other. Figure 3 shows an example of this information linkage.

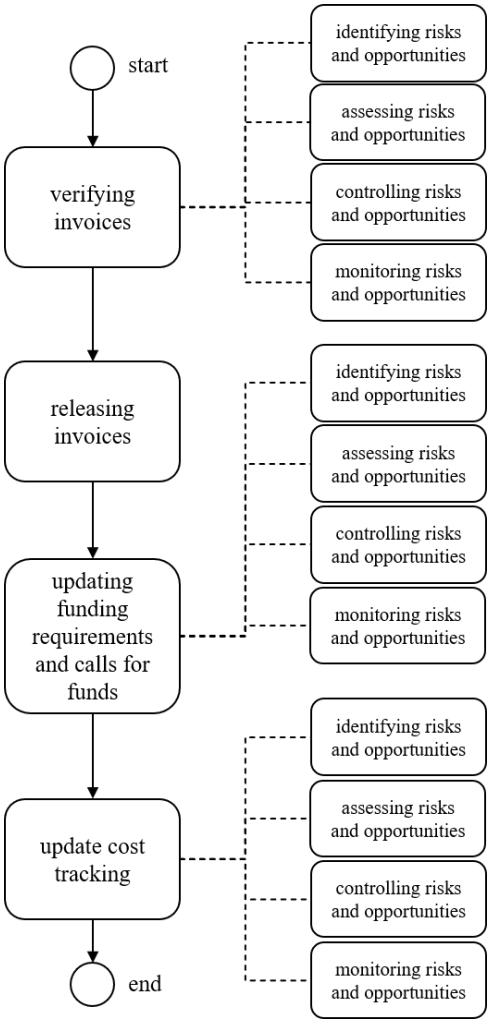

Figure 3. risk management processes linked to the process of cost management

The risk management process is represented on the process level, in which the methods and digital tools of a construction project are applied. The documents required for the risk management process in this section are formulated at a deeper, more detailed level.

The created risk management process now serves as a support process for the process steps in a construction project over the complete life cycle phase. In the further course of the research project, critical paths/processes in a construction project are analysed and the support process is integrated into them. This resulted in an overview of the critical processes for the different phases and from the point of view of the client and the construction company. Helpful tools and documents are formulated for each of these processes. The overview serves to link and identify potentials for the application of BIM.

6 Outlook research project BIM-based risk management

Processes have to be concretized, digitalized in the companies and responsibilities defined. Forms in the company and in the individual project phases must be digitalised and linked to software options. Checklists and required documents should be maintained regularly through experience and market adjustments and should be centrally stored for each employee.

In the further course of the research project, which will run until the beginning of 2021, optimization possibilities will be worked out based on the results of the survey so far and further potentials will be identified by using digital tools. A short self-check was developed for companies interested in a check of their own risk management processes. By ticking off the points, both approaches already successfully applied are made clear and ideas for further potential are offered.

In the coming months, a possible integration of the Building Information Modeling (BIM) method will be examined. To this end, the first step will be to link the risk management processes with the other processes of a construction project. The resulting process model will then show which information from the project activities should be used for risk management and, vice versa, which information is generated by risk management for the further course of the project. The BIM method is intended to enable a structured collection of risk management data. With increasing planning accuracy, the linking of information can be continued down to the component level. The linking of identified risks with components of the digital building model in the realization phase, promotes the integration and thus the acceptance of risk management and visualizes its advantages for the project result. The principle of the BIM method "first plan - then build" allows an early consideration of risks already from the planning phase to increase the reliability of deadlines, costs and quality.

Abstract –

In order to dramatically improve the productivity and safety of tunnel construction, we are developing a new construction production system "Shimizu Smart Tunnel". Based on the concept of "Digital Twin", it utilizes data sensing technology and information communication technology to acquire all kinds of data from people, machines and environment at construction sites. Using the data, we have implemented "Safety 2.0" that realizes collaborative safety technologies between humans and machines and "Safeguard support system" that reduces human error. We introduced a "Human-Machine contact risk reduction system" at actual sites.

Keywords –

Safety2.0; collaborative safety; risk reduction system; Safeguarding Supportive System

1 Introduction

Japan is facing the problem of a declining birthrate and an aging population and a decline in the working-age population. In the construction field, the number of engineers and skilled workers has decreased, and the construction production system has to be changed. In 2017, construction-related casualties accounted for about 30% of all industries, of which more than 70% of fatal accidents were related to falls, construction machinery and dropped loads.[1] The rate of work-related fatalities per 100,000 workers in each country shows that in some countries the rate is lower than in Japan. (Figure 1) [2] Especially in the UK, the rate of decline is very large. We have to learn from the West how to improve occupational safety. [3],[4]

The Ministry of Land, Infrastructure, Transport and Tourism has announced "i-Construction," which utilizes new technologies such as digital data acquisition, ICT, IoT, AI, and robotics. By 2025, it aims to improve productivity by 20% and solve problems in the construction sector. The Ministry of Health, Labor and Welfare aims to realize a society where people can work in good health and peace of mind in a safe environment free from occupational accidents. In 2022, it has set a target to reduce the number of work-related fatalities in the construction industry by more than 15%. [5] The Ministry of Economy, Trade and Industry has announced "New Robot Strategy" in 2015, aiming to strengthen and spread the use of robots, to popularize them, and to acquire international standards.

A robot is defined as a machine that has three elements: sensor, intelligence/control system, and drive system. Construction machinery, like automobiles, is expected to accelerate remote unmanned operation, automatic operation, and robotization.

In this paper, we report the results obtained through the practical introduction and trial of the human-machine contact risk reduction system to the construction site.

Figure 1. Comparison Occupational Fatality Rate (per 100,000 people). Processing based on [2].

2 Improved safety and productivity

In the construction field, it is required that humans and machines work together to ensure work safety.

2.1 The Concept of Safety 2.0

The human-machine collaborative work consists of a human area, a machine area, and a collaboration area. Here, Safety 2.0 is explained. (Figure 2) [6],[7],[8]

Safety0.0 is a state in which there is no concept of machine safety in the machine domain and it is a hazard to humans, and the collaborative domain is also the hazard domain. A state in which we try to ensure overall safety with only human safety technology. Safety1.0 is a state where the concept of machine safety has been introduced into the machine domain, and together with human safety technology, each ensures safety. The principle of isolation and suspension is established by fool proof and fail safe. Safety 2.0 is a state in which a collaborative safety mechanism that shares information using ICT is incorporated in each area of man and machine, enabling safe work in the area of collaboration.

In the construction field, it is difficult to realize the principle of "Isolation and Suspension" in the construction field, and the avoidance of residual risk is in the state of Safety 0.0, which largely depends on human safety technology.

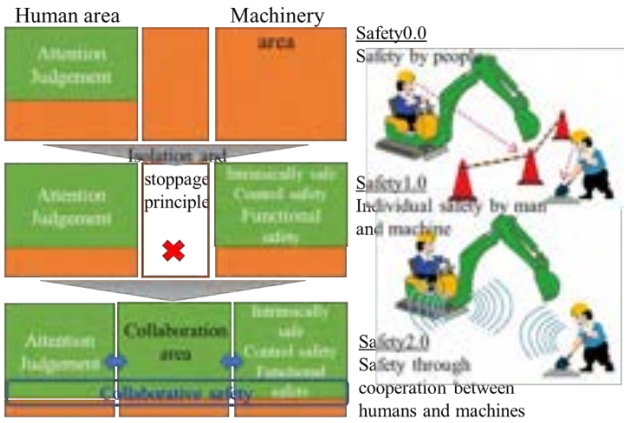

Figure 2. The Concept of Safety 2.0

2.2 Safeguarding Supportive System

In the international standard ISO12100, risk reduction measures for ensuring safety are based on an essentially safe design, safeguarding measures, and a three-step method based on provision of information on use. However, measures to avoid residual risk depend on human safety technology, and human error leads to serious occupational accidents.

There is a misunderstanding that human error can be avoided by attention, education/training/motivation, and multiple checks. The error occurrence rate of a person increases when the consciousness mode is fatigued, strained, or unsteady. Moreover, even if a person understands the work standard and can execute it, there is a case where the improvement of the productivity is prioritized, and the work standard is not intentionally observed. People must be aware that they have the property of causing an error.[9]

Dr.SHIMIZU et al. have reported comprehensive safety management that incorporates a "Safeguarding Supportive system" that prevents human error by combining appropriate ICT equipment.[10],[11]

In contracting duties, construction workers are required to constantly anticipate changes in the surrounding environment and residual risk and implement appropriate protection measures in addition to the original skill implementation.

The relationship between the hazard and the occurrence of harm and the "Safeguarding Supportive system" is shown in Figure 3.

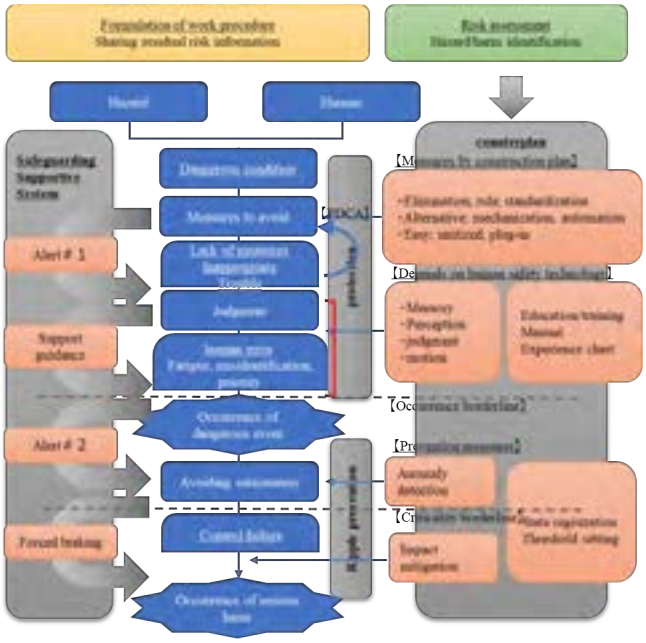

Figure 3. The relationship of harm and the "Safeguarding Supportive system"

2.3 Shimizu Smart Tunnel

Shimizu Corporation is advancing digital reform of its construction production system. In the field of civil engineering, in 2016, we started the development of "Shimizu Smart Tunnel". This system is based on the concept of "Digital Twin". (Figure 4)

In the physical space, various sensors, control devices and communication devices are installed on people and machines, and material supply, position and orientation of people and machines, movement status, condition, work environment, safety and quality, engineers and skilled labor Workers and production process information are aggregated on a digital platform

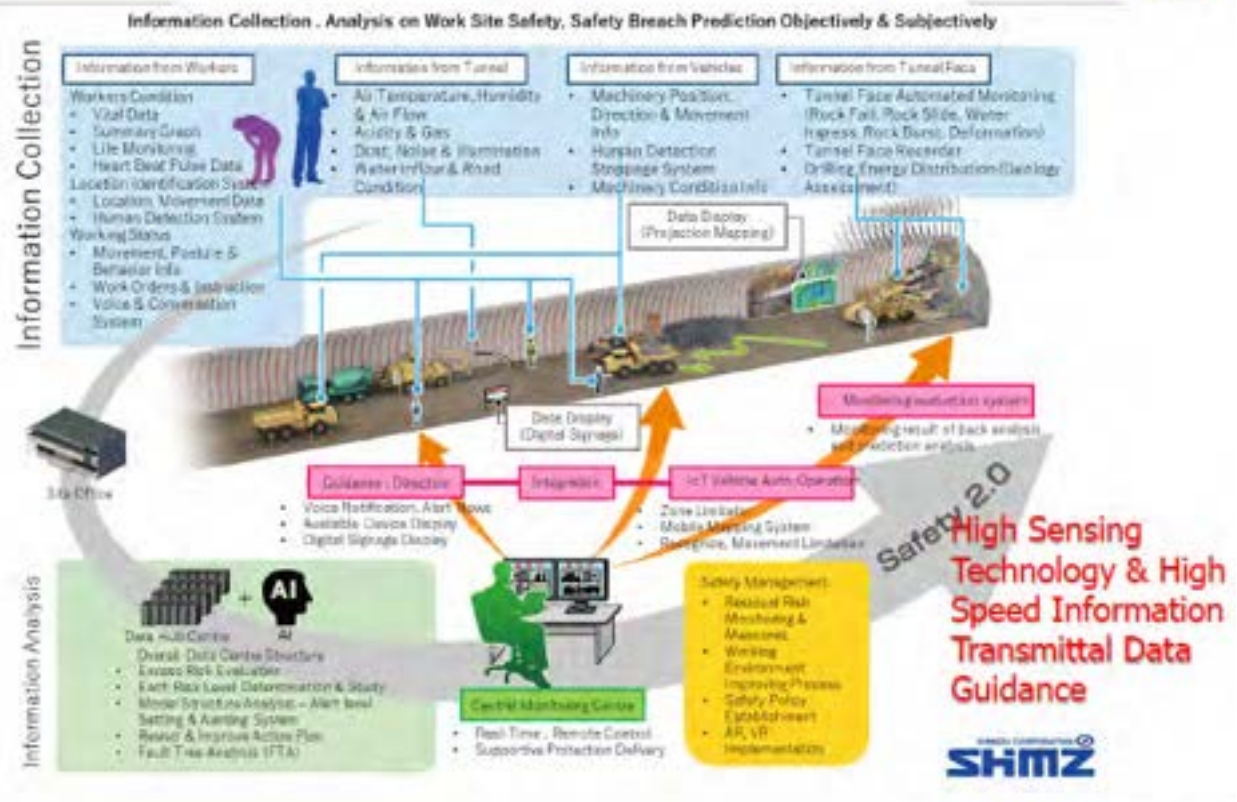

Figure 4. The Concept of Shimizu Smart Tunnel

in cyberspace. It is equipped with a support system that provides feedback to the site in real time through AI analysis and simulation analysis of information that changes moment by moment.

In tunnel construction, the collapse of the face and the contact between people and machines lead to serious disasters. The Shimizu Smart Tunnel will incorporate a safety support system to eliminate these serious disasters.

3 A Practical Approach

The development team of the safety support system selected the actual construction site and tried to introduce Safety2.0 from Safety1.0 by the practical approach.

3.1 Preparation

The safety support system development team held a workshop with experts. In addition, we investigated the safety awareness of the people concerned at all tunnel sites of Shimizu Corporation and reviewed and created safety teaching materials. we learned the following lessons.

- It is important to understand the concept of machine safety and prerequisites.
- It is necessary to rebuild an appropriate safety philosophy through appropriate risk assessment.
- Framework is important to implement and function Safety 2.0.

3.2 Goal Setting

The goals were set as follows.

- Development of a risk assessment method that is compatible with machine safety.
- Site managers and workers understand the concept of safety system.
- Site managers and workers should learn how to operate the safety system and adjustment procedures.
- Obtain "Safety 2.0" certification for the implemented safety system.

3.3 Scope of Development

In general, the construction of mountain tunnels is a cycle work that repeats blasting and mechanical excavation work, mucking work, steel support work, concrete spraying work, and rock bolt installation work. Within 100m from the face (tunnel excavation surface),

the machines will be replaced, and the work will continue day and night. The composition of the machines used in the construction is decided at the time of formulating the construction plan, but the risk was extracted by applying a new risk assessment method to the site already in operation.

The development target was set to "mucking work" from the viewpoint of developing "collaborative safety between humans and machines", and we developed the " Human-Machine contact risk reduction system".

3.4 Zoning of Work Areas

The work area for "mucking work" has been divided into a working zone, a moving zone, and a parking zone. The mucking work of excavated soil is performed in a working zone within a range of 100 m from the face.

The tire shovel, which has started from the parking zone about 230 m from the face, travels in the moving zone of about 100 m and enters the working zone. The tire shovel puts the excavated soil scraped by the hydraulic excavator into the hopper near the rear of the working zone. The tire shovel collaborates with the hydraulic excavator to repeat loading into the hopper and finish the mucking work. After that, the tire shovel exits the working zone and retreats to the parking zone to complete the work.

The work area moves forward as the tunnel excavation progresses.

3.5 Risk Extraction

The risks extracted in the mucking work are the following four items that occur irregularly.

- Unauthorized workers enter the working zone and come into contact with operating machines.
- In the work zone, the driver who gets off the machine contacts another machine in operation.
- A machine starting from the parking lot comes into contact with people around
- The retreating machine comes into contact with the person who was in the parking lot.

3.6 Piloting a “Human-Machine contact risk reduction system”

3.6.1 System Component

A directional receiver was placed at the boundary between the working zone and the moving zone, and a normal receiver was placed every 10 m in the moving zone and the parking zone, and the whole was divided into 14 blocks. And a receiver was installed on the ceiling of the machine driver's seat. It receives the BLE (Bluetooth Low Energy) transmitted by the driver and monitors the presence of leaving the machine. Two transmitters are installed for each person and machine. The transmitter transmits a BLE signal that identifies the individual. The receiver installed in the tunnel mine configures a mesh network with multiple units, and the received BLE signal is stored in the cloud server from the Gateway via the on-site network. In the cloud, the positional relationship between the person and the machine is specified from the collected information, and the difference from the set permission state is determined. When an abnormality is detected, an alert signal is transmitted to the warning lighting device. The warning lighting device is arranged at the boundary between the working zone and the moving zone. When the PLC (Programmable Logic Controller) receives an alert signal, it immediately emits a loud alarm and simultaneously projects a blinking red and white LED beam light on the face. (Figure 5,6)

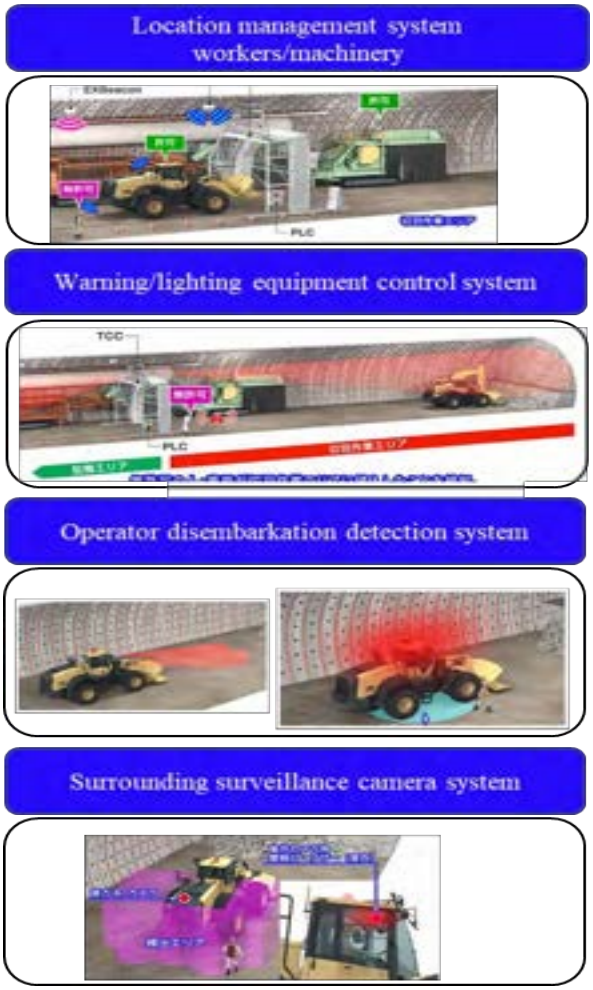

Figure 5. Human-Machine contact risk reduction system

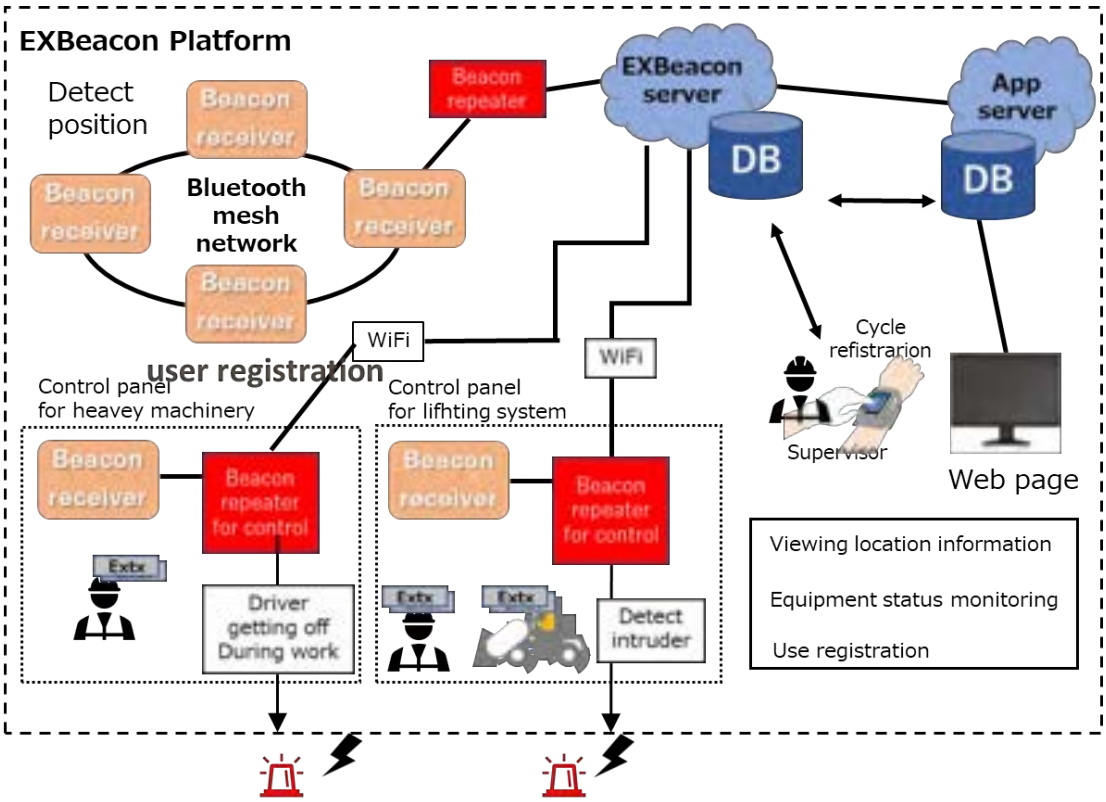

Figure 6. System block diagram

3.6.2 Site of Application

This system was introduced to the construction of the Kumamoto Route 57 TAKIMUROZAKA Tunnel West (first stage) construction (high standard road, construction extension = 2,679m, excavation section = 107m2).

3.6.3 Rules of Operation

- The site manager should register the mucking work permission ID and combination conditions before the work.
- Daily inspection of the system should be carried out by all supervisors and workers before starting work.
- The person in charge of monitoring carries the control tablet.
- The person in charge of monitoring switches the safety system to the "mucking mode" during mucking work.
- When the warning lighting system is activated, the machine operator makes an emergency stop.
- The person in charge of monitoring cannot cancel the alarm until the cause of the alarm is eliminated.
- The site manager collects the number of reports, IDs, and logs to inform workers and improve work.

3.6.4 Procedure for Adjusting the Safety System

Since a large machine is installed inside the tunnel mine under construction and the machine operates in a narrow work zone, the radio wave system tends to be unstable. Even in this introduction, several malfunctions occurred. There was a big difference between the ID position reproduced in the cyber space on the cloud and the position in the actual physical space, causing the ID position to move confusion in the tunnel in the cyber space. Further, at the boundary between the work zone and the moving zone, there was a false detection that a worker in the moving zone was in the working zone.

BLE transmission/reception in a tunnel mine is apt to cause multipath due to the reflection of the machines located in the mine and the moving machines. Even if the reception strength is weak, if the number of BLE transmission receptions fluctuates, it may be erroneously determined that there is a transmitter in the vicinity. The safety system adjustment procedure was established for these problems.

Step1. Divide the adjustment scene into whether the machine is operating or not.

Step2. In a static environment where there is no machine operation, repeat the receiver placement verification at intervals of 50 cm, analyze the radio wave intensity characteristics, and determine the optimal installation position.

Step3. In a dynamic environment with machine operation, analyze the radio wave strength characteristics and determine the optimum combination of reception strength thresholds.

3.6.5 Implementation Process Framework

Generally, when introducing a new system to the field, it is important to understand the theory, foster appropriate operation methods and improvement consciousness, and share consciousness with the development team. If the site manager and workers have a voluntary intention, they will succeed. is there. The education of safety concept and the new system by the development team was repeated using animated videos. A dedicated instructor was assigned to the site to practice the operation confirmation and inspection methods of the new system equipment at "On Job Training (OJT) ". OJT was repeatedly carried out for the mechanical and electrical engineering staff because the procedure for eliminating false positives requires specialized technical knowledge to analytical the radio characteristics and reset thresholds.

3.6.6 Effects of Introduction

Here, the introduction effects are summarized.

- Unauthorized entry into the work zone and disembarking from the driver's machine could be quickly shared as a risk.
- The warning from the warning lighting device surely guided the stoppage of the machine operation, and the risk of being overlooked became zero
- The loud alarm and the intense red and white flashing projection caused psychological strain on the machine driver, and the initial action of the machine stop for the risk occurrence was accelerated.
- Workers began efforts to prevent short-circuiting work violations. This is because warning issuance leads to a reduction in work efficiency. Intentional disembarkation from the machine in the work zone was reduced.
- The frequency of cleaning and checking not only the equipment that constitutes the safety system but also the machine itself has been improved. In addition, they became more sensitive to machine failures and reduced the frequency of repairs.
- The safety system operation at the installation site has received level 1 certification from IGSAP (Safety Global Promotion Organization) as a technical measure that complies with Safety 2.0. [12]

4 Conclusion

This paper has seen a trial example of a safety system for collaborative safety for human-machine collaboration. The risk assessment in the construction field was reviewed based on the flow of machine safety.

The concept of coordinated safety (Safety 2.0) and Safeguarding Supportive system was highly evaluated by workers and field managers who work on the front lines of the field. “We understand the need, and I feel that productivity will be improved by the support system.” (Figure 7)

Figure 7. Warning by blinking LED light

It is expected that robot technology will continue to evolve in the future, and a more advanced production system will be constructed in which humans, machines, and the environment will be firmly connected by IoT and IoP (Internet of Process). Standards, standards, rules and frameworks are important for maximizing the Safety 2.0 effect with a Safeguarding Supportive system.

Abstract

A long-standing problem in the field of automated reasoning is designing systems that can describe a set of actions (or a plan) that can be expected to allow the system to reach the desired goal. Artificial Intelligence (AI) techniques provide the means to generate plans and to reason with as well as provide explanations from stored knowledge. However, these methods, which employ little domain knowledge and are originally used in AI for planning, proved inadequate for complex real-life problems such as project planning. As a result, more recent research adopts the knowledge engineering methodology as an efficient approach for developing planning systems. This paper highlights the limitations of existing project planning tools. It also illustrates the power of AI techniques in the construction planning domain through a summary and critique of previous and current research in AI planning. It then concludes with a suggested approach for development. From the study, it was found out that a proper application of the AI technology requires full support in form of a Data Bank, which, unfortunately, becomes one of the most significant hurdles in its adoption. To deal with this limitation, it is recommended to adopt the ANN.

Risks Planning; Construction Planning; Risks forecasting; Neural Network; Support Vector Machines

1 Introduction

Utilization of artificial intelligence in planning involves the use of a planner generator which follows the sequence of actions for presenting the solution of a problem. Artificial intelligence can provide a powerful tactic for managing the risks and ambiguities in construction planning. Utilization of artificial intelligence can be efficient when employed in different phases of construction which involves estimation of production, management of risks, and plan schedules. With the recent development in the construction industry, different artificial intelligence systems have been used and widely applied for forecasting risks [1]. The economics of the developed countries can be improved and fulfil the crucial role of the construction sector. Time, cost, and quality performance the construction project my years though successful construction projects. The duration of the construction project can be a problem as accurate predictability is hard to be achieved. It is not the cause the construction process usually faces many factors that sometimes involve unpredictable variables that can be the result of various factors [2]. These variations or changes usually hinders the completion of projects in the estimated time and become the reason to lead the way towards the latest in the process of construction [3].

The prediction of risk regarding the construction project is based on both internal and external sources which upon identification can help the project managers to have a clear and accurate forecast for the effective management approach towards the construction project. Construction projects are complex and dynamic [4]. Providing an efficient tool for the analysis of the factors which are involved in the risk can provide an accuracy of determining the factors in the construction projects. Recently several models of artificial intelligence have been applied in different fields of engineering and science. Various studies included and researched on the involvement of various artificial intelligence models for the completion and conduction of the research regarding construction project management [5]. Different artificial intelligence methods are being used in the forecasting of the final project duration and risks.

2 Literature Review

2.1 Decision trees

Morgan and Sonquist (1963) dealt with the automatic interaction detection and proposed a fresh method for the regression and analysis of data which is being recognized as decision tree learning [6]. Breiman et al., (1984) also suggested the idea of the algorithm that majorly consisted of 2 phases; In the 1st phase, this solution space is separated with a binary or multi-way split. in the second phase, to every node of partition, a constant model is applied. these well-known procedures are subjected to two pitfalls which are named as overfitting and selection bias. and this method is collectively known as classification and regression trees [7]. This method is not perfect as the overfitting problem emerged as a result of the lack of significance of statistical data. Although some of the information is maximized to divide the decision tree, there is no other significant method of determining whether the split is justified or not. Another major limitation of this processing includes the selection bias which is derived from the fact that most points are preferred.

To upgrade the shortcomings or trees, another method known as bagging predictors was introduced. It involves the arrangement of different trees on the bootstrap on the test set giving us the final estimation by the prediction of average values from each tree. To remove the barriers in begging predictions another method known as random forests were introduced which involves the selection of random numbers of the predictors from each split [8].

Despite the fact that there have been a number of literature that attempt to discuss about AI application, there is none discussing about how ANN may help project managers establish and maintain proper Data Bank. Thus, this is where this study is attempting to fill as it looks to close this gap in the field of research.

2.2 AI Limitation

The limitation of this increase includes their instability even when there is a small difference in the learning data. Selection of the variables and cut points for the selected variables hang on the observations made in the learning sample. If there is a change in the first splitting variable due to a minor change in the learning data, then there is a probability that the structure of the entire tree might have been altered. Therefore it can be concluded that the single predictions have a high variability rate [9].

2.3 Construction simulation

Most of the construction projects involve repetitive activities such as the movement of the projects. If the decisions taken goes in the wrong direction they can cost a lot of expense along with time and energy. while if the project planning involved the right decisions at the right planning state a substantial time, money, effort, and energy can be spared. Due to the stochastic nature of the process of construction, the data collected from the preceding experiences and projects can help in the elimination of errors and risks. Because planning engineers can make an improved evaluation of expected productivity rates [10]. In the traditional method, the planning engineers manually add and adjust the productivity record for the establishment of expected values and figures. Due to the rising complexity and size of the project decision making and planning were becoming inaccurate because of human errors. To ease this complexity of estimation introduction of simulation, pickney has helped in various operational and managerial projects. it is a powerful tool that is being used as artificial intelligence in the systems for the prediction and accuracy of estimations regarding the construction processes.

Although construction simulation is a potent tool that is being applied by various companies for resource planning, designing, and analysis of the construction method. It is still dependent upon the human corrections as it only estimates depending upon the data which is being saved and processed in this system. As it cannot make any assumptions irrespective of the data. Therefore, it does not provide complete independence [11].

2.4 Productivity Assessment

These days productivity management is considered a key concern regarding the management of projects in the industry of construction. As the project varies, the level of productivity regarding construction also varies according to the atmospheric and organizational situations. the impact of factors affecting the productivity of the project is considered important in the productivity estimations. These factors can affect both positively and negatively on productivity. Human factors, weather conditions, change orders, and materials management can be the possible factors for determining the productivity rate of any construction project. At the initial step in the creation of a model for the productivity estimation identification of these factors can lead to better planning utilizing artificial intelligence because AI can predict possible risks through effective calculations [12].

Moselhi et al. [13], Introduced a supportive system that was able to make the decision named WEATHER for the prediction of climatic conditions regarding the efficiency of operations during the construction. This model was developed to make the estimations in the construction productivity to have a better prediction regarding activity durations and patterns of weather to

improve the planning and scheduling of the model to reduce the risk which can affect productivity. Moslehi et al. [14] then utilized the simulation system in 57 different projects to check the impact of changes during construction projects.

It was then discovered that there is a straightforward correlation between labor components of change orders and production damage in all kinds of projects. These predictions from then are being used in the estimation of losses regarding the changes.

2.5 Artificial Neural Network – ANN

ANN is a mathematical model that is being used to search for the finding the patters among t eh huge datasets when during the construction planning there are complicated relationships found between inputs and outputs. Through ANN attempts are made to stimulate and make it able to function and operate as a human neural network system. One of the major achievements is the capability to learn from the mistakes and this system due to this ability is approaching the heights of perfection. As ANN Act like a black box and cannot be used for the explanation of the reasoning process Therefore it can be restricted to the areas where there is no need for the explanation. It is well suited to the problems where the value of input-output relations is not being researched [15].

In recent years ANN has been widely used in the forecasting and prediction of the models which are being used in the construction industry. Researches are being made in different areas of construction management which includes cash flow predictions, risk analysis, optimization of resource, and construction productivity assessment.

2.6 Fuzzy Logic

As compared to ANN fuzzy logic was developed and introduced to resolve the necessity for systematic reasoning that can improve conform to human logic. Fuzzy logic is aimed at connecting the input space to an output space. Fuzzy models have their basic rule which contains the list of all the rules. Through the parallel evaluation, the inference procedure is performed. In different areas and fields of construction management, the concept of fuzzy reasoning is being applied. Car and Tah [16], used the fuzzy model to relate and address the risk assessment and analysis. They explained that risk information of a specified project is based on the items and procedures which are to be utilized during the process. These items are catalogued and are customized for each project. Therefore, the results would be according to the requirement of that project. The implementation of fuzzy logic makes the use of descriptive linguistic variables for the description of risks and their associated consequences.

Zhang et al. [17], demonstrated the relevance of fuzzy logic in discrete event simulation. The fuzzy simulation uses the fuzzy sets to explain the quantity of the resources which are required for the activation of an activity. These activities are regarded as constants incorporating the fuzzy logic rule to control the stimulation of behaviors. They further explained that the length of the construction project changes with the change in amounts of supplies implicated in the procedure of action. Fuzzy simulations give an alternative to the uncertainties of the models by contemplating the dynamic characters of the operations being done during construction in real-time situations. The results of experiments depict that flexibility in demand regarding the resources can have a positive effect on productivity which is being practiced at construction sites.

Paek et al. [18], implemented a multi-criteria methodology of decision-making with the use of a fuzzy-logic system for the selection of a design or build proposal. To reduce the cost of construction and reduction of time and money, several design projects are introduced and proposed in opposition to the traditional methods for the building. However, for this purpose there is a need to maximize the degree of technical factors and minimizing the cost of construction, the evaluation method is filled with uncertainties. To remove or minimize these uncertainties, this study was aimed at utilizing the criteria of decision-making method with efficient usage of a fuzzy logic system. This system is introduced to assist in making the decision which is a better-suited design proposal to satisfy the needs and requirements regarding the physical and environmental conditions along with the reduction of cost.

Fuzzy logic and ANN both complement each other. ANN can learn from the data, but its limitation involves the unavailability of explanation regarding the value of the input-output mapping process. Fuzzy reasoning offers a systematic reasoning procedure which is more compatible and closer to human logic and intuition. But its limitations include the need to make itself to adopt techniques of self-regulation to differentiate it from other areas. The constraints of these two procedures led to the introduction and development of another AI system known as a neuro-fuzzy system. Hybrid intelligent systems include the term neuro fuzzy as the fusion of both techniques i.e. ANN and fuzzy logic [19]. This fusion led to overcome the restrictions of both techniques as the shortcoming of one technique is covered by another. Although the utilization of neuro-fuzzy technique is being practiced it still is not common.

2.7 Genetic Algorithm

Genetic algorithm (GA) is it mattered which is developed by the optimization of artificial intelligence

base techniques, which imitates the natural mechanism of evolution. The genetic algorithm has boosted the structure optimization and parameter fine-tuning procedure of neuro-fuzzy systems. An evolutionary approach is used to find the solution to problems for finding the best options for a potentially better future. In GA random individuals are selected for the production of a population which then evolves itself through the evolutionary procedure in a natural way by mutating and altering the properties of a population. The performance of every representative of the population depends on some standards of fitness. These fitness criteria then determine the basis on which the next generation is selected and which characters are to be migrated in the next generation [20].

Due to advancements in technology AI has made its way in every field of life including construction planning and risk management along with better decision making to minimize the costs and effects of the variables. AI has enabled the planning engineers to go for more complex construction plans minimizing the efforts, costs, and errors regarding construction projects. These days the use of hybrid systems which includes the use of artificial intelligence can enhance the accuracy and productivity of the construction operations and projects. Further modifications in the upgrade of these systems are making its marks in these systems predicting the variables with much more accuracy and precision. The limitations of artificial intelligence or systems including AI is sticking of these systems to the data provided. Even the hybrid systems like neuro-fuzzy systems are unable to follow the rules through which the human intuition can be proposed. In other words, it can be interpreted as it functions like neural networks as a black box without having a clear interference of human thinking procedures. The method for the selection of variables is not conducted even in the advanced systems of AI for the selection of input variables which are necessary for the specification of neutral or deteriorating factors [21]. The major restriction of AI is its inability to make decisions as it is still dependent upon the humans for the data entry. It only analyzes and interprets the data that is being fed to the system. But still, these limitations cannot deny the usefulness of its use in various engineering fields and especially in construction planning which is helping this industry by minimizing the risks of aftershocks from the variables.

3 Research Methodology

Because of the risk management, the executives have become a fundamental strategy in the advancement of any development venture; by and by, its usage includes the utilization of the essential ideas, for example, "Hazard" and "Vulnerability". These ideas are regularly befuddled and used like equivalent, in any event, when they are unique as seen in Figure 1.

Risks: are recognizable and quantifiable potential occasions or factors; from which, negative (perils) or positive (possibilities) results may happen 250.

Vulnerability: alludes to obscure and unforeseeable occasions or factors; which no measurement or practically no distinguishing proof is conceivable.

Subsequently, it's essential to separate between these two ideas; a large portion of the dangers are conceivable to recognize and control, they can be arranged in Perils and Possibilities, while vulnerabilities are consistently startling and additionally not quantifiable. Figure 1 presents the conduct of vulnerability and hazards through the diverse venture stages. At the early stages, the vulnerability has a significant impact on the venture condition than dangers; therefore, as the task progress along the improvement stages, the nearness of risks become higher than the vulnerability, or the most part since vulnerabilities are distinguished and measured as explicit undertaking dangers. A short time later they are overseen to accomplish the undertaking possibilities and to keep away from its risks.

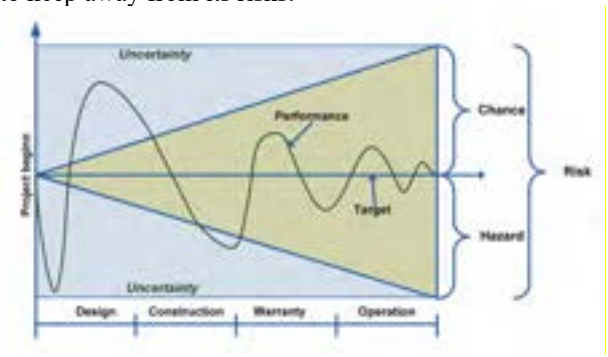

Figure 1. Risks & Uncertainty

3.1 Risks Evaluation Methods

Risks examination strategies manage the assessment of dangers; Risks measurement implies that probabilities can be related to anticipated qualities or results; nonetheless, its adequacy relies upon the past strides in the RMP because those means are the establishment of the entire procedure. The arranging procedure for executing Risk the board is a critical stage, it gives the chance to the venture and hazard supervisors to clarify and depict in subtleties what chance administration is about, why it is imperative to have a risk group, what is normal from them and what are the expectations. Consequently, threat reporting and verbal exchange play a crucial function beneath the threat analysis process; it is also an outstanding chance to discover with the crew any doubts or questions about the threat management method and also a risk for convincing the project stakeholders, the executives and the relaxation of the

crew about the advantages of imposing a serious quantitative risk analysis.

Risk analysis is the most important milestone for performing an advantageous quantitative assessment. All these processes outline the requirements to be attended on the search of inputs and the definition of stochastic fashions and their functions; consequently, the utilization of quantitative strategies like Monte Carlo Simulation shall turn out to be a requirement for danger analysis. Checklists are in most cases used for threat identification; they are necessary and beneficial for the identification but not sufficient for the analysis.

3.2 Artificial Neural Networks

Although this approach is relatively new in the business world, the unique idea used to be developed in the '60s together with the algorithms and some theoretical approaches. Nevertheless, the lack of ability with the computers´ processors stored this technique in the shadow for many years. ANNs comprise their structure, exclusive sections of layers, the middle ones generally are known as the hidden layers. The conceptual process of ANNs is conformed of an enter vector, a switch function, and an output vector (see Figure 5).

The switching characteristic with its limits is very frequently referred to as a "black box", this is due to the fact at this phase an inside system for adjusting and calculating new weight for the network is performed and this system is now not found by means of the designer.

The foremost gain of ANNs is that the entire process (training and testing) mimics the human's intelligence reasoning. In different words, it learns via the experience: Once an excellent database is developed, the chances to acquire dependable predictions with ANNs are very feasible.

One instance of the practicability of the ANNs is the Neuronal Risk Assessment System (NRAS) developed by using Maria-Sanchez. 254 This approach indicates a very practical manner for implementing ANNs for assessing the risks in infrastructure projects. The essential goal of the gadget is to decide the contingency quantity based on unique mission risks. The consequences exhibit the capabilities of ANNs to mimic the data, offering a wonderful new strategy for performing chance analysis. In addition, in modern times it is feasible to discover business reachable ANN tools.

3.3 Support Vector Machines

The SVM is a technique from the synthetic Genius that has proven excessive attainable for its applicability in the threat analysis. Vapnik defines this technique as a statistical mastering theory; [22] it works below the identification, screening, and separation of the information in hyperplanes primarily based in a support vector. In this form, the information is categorized in various dimensions (hyperplanes); as a 2d step simulations are done via growing statistics internal of the numerous hyperplanes. The SVM lets in to research from a described database and from this gaining knowledge of the procedure to forecast feasible results, in this form it is possible to perform simulations with a greater legal responsibility derivate from the studying process.

From these three techniques SVM represents a very promising technique because it allows us to examine from the statistics and simulating besides assumptions (like MCS); the simulation is primarily based on the recognized hyperplanes, which make bigger certainty. However, the technique is based on the synthetic talent theory and requires a considered quantity of facts to operate its learning process.

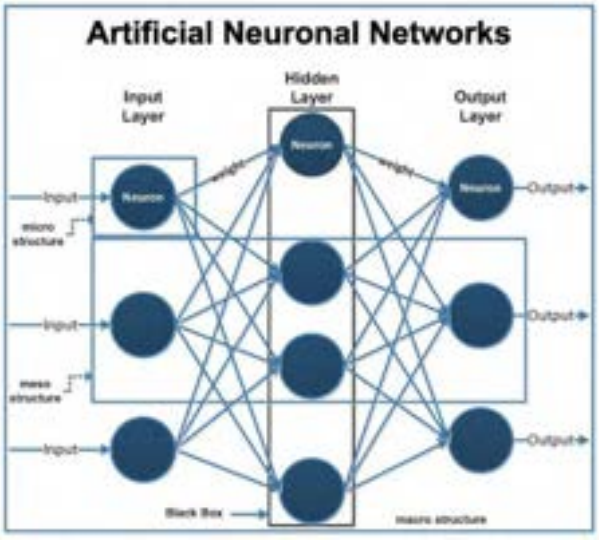

Figure 2. Artificial neuronal Networks Functionality

4 Experiment

The Support Vector Machine ought to emerge as a methodology of the synthetic intelligence that will be used in the chance analysis; it lets in a first step to perform a studying system to display screen and separate the before amassed data in hyperplanes. As 2d step, it implements a simulation system in order to convey probabilities to the anticipated danger or value. But the utilization of danger analysis in the praxis relies upon the availability of the required tools to operate this kind of evaluation for the threat evaluation practitioners. Until these days there is no commercial application of the SVM, therefore for its employment is crucial to create computer programs.

Thus the mixture of ANNs and MCS shall emulate its functionality, from existing commercial programs. The downside of MCS is the use of assumptions in its

procedure. This can lead to dispersion will increase with the inputs and in the corresponding delivered results, or in in the worst case, into blunders and misconceptions; for example, when the threat analyst does now not have ample experience, can create ambiguous surroundings to the whole process and this can affect the excellent and outcomes of the complete implementation.

MCS allows simulating dangers but the inputs nevertheless need to be described as a section of the qualitative analysis. Better inputs can be observed through ANNs: They enable predicting values from defined records banks; therefore it represents an essential useful resource for the definition of inputs for the MCS. Consequently, the mixture of both strategies shall minimize the opportunity of mistakes, by means of defining the initial values with the ANNs and the use of MCS for the simulation process.

ANNs are one of the new strategies from the synthetic Genius discipline that have emerged and observed its applicability in risk analysis. It has two key steps for enforcing in danger management. However, a vast database is wished in order to educate and check the network. Different network designs can be done and for some algorithms, the training and trying out process can be extra effortlessly done if the design is environmentally friendly and practical.

4.1 ANNs Prediction

The software of the ANNs needs a facts bank of the advantageous ability relying on the relevant criteria. For lack of measured web site facts, it was created based totally on the components and values through the ability of the addition technique in building machines. The statistics bank includes a wide variety of 12 criteria; via the formulation, we can decide the "exact" end result (important for the check of the ANNs) of the superb capacity. For each of the 12 standards a range was determined and thru the utilization of a random generator quantity one thousand one-of-a-kind result combos have been created, having the end result and criteria a direct relation.

The textual content criteria have been created with the utilization of numerical facts and they were replaced with text for its checking out in ANNs. At the give up each and every system was once deleted, final just the numbers and text without any relation rule, for the assessment of the ANNs.

ANNs estimate the manufacturing-based totally in the Data Bank, the regular manner with the aid of ANNs is as seen in Figure 3. The Data Bank needs to be elaborated and loaded into the ANN program, the impartial and dependent criteria must be specified.

The second step is to get to know the method (training) for the ANNs has to be described properly with error tolerance. Afterward, when gaining knowledge of the procedure is concluded, the trained ANN ought to be examined for its liability. When the checking out system is efficiently achieved, the prediction takes place.

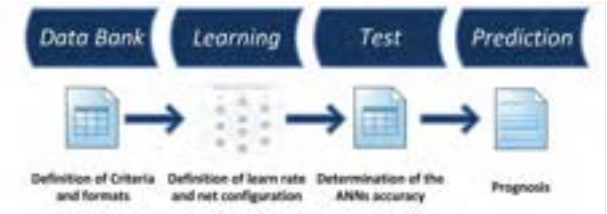

Figure 3. Artificial neuronal Networks Functionality

For the present instance, two results/outputs were searched. It is necessary to remark that these two consequences had been acknowledged through the formula, for that reason it was once extensive to affirm how dependable had been the outcomes produced through the ANNs.

5 Conclusion

The utilization of the ANNs collectively with the MCS permits increasing the simplicity in the data with the aid of identifying the inputs for the simulation process. The studying manner contained in the ANNs permits to decrease the variant (maximum and minimum values used with the distribution functions and for this reason in the histograms) delivered by means of the MCS. This system mimics the human procedure. Each and every deliberation carried out through experts, resumes the comparison of similar standards and experiences from completed comparable situations reproduces this contrast system with excessive liability. Pondering by the different facet does now not permit to function such dependable quantitatively valuation; the subsequent utilization of MCS lets into combination editions in a smaller range collectively as correlations with different criteria. Finally, the MCS grants better hazard evaluation and reliable quantification of risks.

Another advantage is that the learning process approves to encompass concerns of uncertainty. In the presented instance each result was once created for the checking out of the ANNs.

When actual facts are collected, they represent real results. For this reason, the ANNs will analyze to simulate the issues of uncertainties and would provide results that could be nearest to reality.

An important hurdle for the ANNs is the required Data Bank. One of the most attribute houses of the development enterprise is the specialty of each and every infrastructure project; therefore, the variations in the standards are not constant or similar in many cases. This may complicate the improvement of an accountable Data Bank. On the other hand, the consideration of text and

uncertainty influences in the amassed criteria may additionally even confer simpler tasks and flexibility once a Data Bank is created. The mixtures of these two threat evaluation techniques possess an outstanding possibility for imposing threat administration with the use of defined databases. The project managers typically remember in specialist support for deciding price estimates, project planning, sources needed, etc. ANNs are the perfect system to furnish this understanding as soon as an ideal database is available. For example, if a set of fees estimate statistics is available, then an ANN can be constructed based on that records and complete price predictions can be gained whilst simulating the networks.

Development of A Mobile Robot pulling An Omni-directional Cart for A Construction Site

Yusuke Takahashi[a] , Yoshiro Hada[a] and Satoru Nakamura[a]

[a]Tokyu Construction Co.,Ltd.
E-mail: takahashi.yuusuke [@] tokyu-cnst.co.jp

Abstract -

We have been researching a mobile robot that pull a cart with equipment to improve productivity at construction sites. In this field of research, a cart having front wheels as swivel wheels and rear wheels as rigid wheels have been used. However, at the construction site, in many cases, wheels of a cart have only swivel wheels in order to easily transport them in a narrow space. We aimed to be able to transport a minimum width of 1200 mm by pulling this cart by a robot. However, when this cart is pulled using a simple 1-axis connection, there is no guarantee that a cart will follow the same trajectory as a robot. For example, a cart will move significantly out of the trajectory of a robot as it turns a curve. At this time, it is expected that a cart will collide with the building under construction or the materials placed on the site. This paper describes the results of a theoretical and experimental confirmation of the features of a cart and examination of its solution.

Keywords -

AGV; Mobile robot; Omni-directional cart

Figure 1. A mobile robot.

1 Introduction

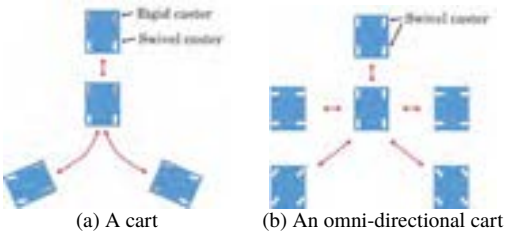
In Japan, the workers involved in the construction industry are aging. It is expected that many workers will retire in 10 years and there will be a shortage of workers. Therefore, in this research, we decided to aim at improving the productivity of the construction site by automating the transfer work by pulling a cart with a mobile robot. We assumed that we would transport the aisles of Japanese buildings, and targeted aisles of 1200 mm or more. Therefore, the robot needs to use a small size.

There are several methods for transporting materials by a robot. For example, there is a method in which a robot pulls a cart with materials[1][2][3]. In this case, the robot can be made smaller and lighter than the material. Therefore, there is a possibility of traveling on the target passageway. On the other hand, it is necessary to control the traveling of a robot in consideration of the movement of a cart. There is a method to put materials on a robot[4]. In this case, controlling the running of a robot is simple. However, in order to realize stable running, the weight of the robot needs to be larger than the weight of the material, and a robot tends to be large. Therefore, it may not be possible to travel on the target passage. For the above reasons, the method of pulling a cart was selected in this research.

In order to control the traveling of a robot, it is necessary to theoretically verify the motion characteristics of a cart. There are theoretical researches about a cart with front wheels as swivel wheels and rear wheels as rigid wheels[5][6][7][8][9]. On the other hand, an omni-directional cart which is a slewing wheel for all the wheels is used in a construction site. The reason is that the materials are manually transported even in a narrow way. There are few theoretical researches on this cart. In this research, this omni-directional cart is connected to a robot to improve the convenience. However, when this cart is pulled using a simple 1-axis connection, a cart deviates from the trajectory of a robot. Therefore, it is expected that a cart will collide with surrounding buildings and materials. In order to reduce such a risk, this research theoretically examined the movement of a cart during a curve. In addition, in order to confirm that this theoretically result is useful, we conducted a traction experiment and compared the results.

2 A mobile robot

This chapter describes a robot. A robot used in this research are shown in the Figure 1 and the specifications are shown in the Table 1. This robot is jointly developed by Tokyu Construction Co.,Ltd. and THK Co.,Ltd. A bumper and an LRF（Laser Range Finder） are installed in front of the robot to automatically stop working when



(a) A cart (b) An omni-directional cart

Figure 2. The motion characteristics of a cart.

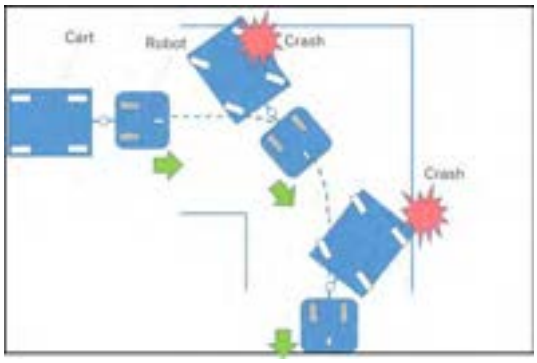


Figure 3. Behavior of an omni-directional cart on curve.

an operator or an obstacle approaches. A cart connects to the back of this robot.

3 An omni-directional cart

A cart with only swivel wheels has the characteristics of being able to move in all direction. Therefore it is hereinafter referred to as an omni-directional cart. On the other hand, a cart with front wheels as swivel wheels and rear wheels as rigid wheels is hereinafter referred to as cart. First, the motion of characteristics of an omni-directional cart are described in this chapter. Second, the results of theoretically examining the motion of a cart when traveling on a curve are described.

3.1 Characteristics of an omni-directional cart

The motion characteristics of a cart are shown in the Figure 2-(a), and the motion characteristics of an omni-directional cart are shown in the Figure 2-(b). From a Figure 2-(a), a cart can move in a front-back direction, but cannot move in a lateral direction unless wheels skid. When moving diagonally, there is a characteristic that a curve is drawn. However, as shown in a Figure 2-(b), an omni-directional cart can move in the lateral direction in addition to the front-back direction. These features of an omni-directional cart benefit when traveling in a narrow space on a construction site. When this cart is pulled using a simple 1-axis connection, a cart moves in all directions. It means that a cart will move significantly out of the trajectory of a robot as it turns a curve. For example, when connecting a cart as shown in a Figure 2-(a), a cart can move in the same trajectory as a robot. This is because the inertial force acting on a cart during the curve balances the frictional force generated on a rigid wheel and the road surface. On the other hand, when using a cart shown in the Figure 2-(b), the direction of the wheel changes, so the frictional force with the road surface becomes very small. Therefore, it is expected that a cart will swing outward due to inertial force as shown in Figure 3. At this time, it is expected that a cart will collide with the building under construction or the materials placed on the site.

Table 1. Specification of a robot.

Size	W600mm × D800mm × H400mm
Weight	120 kg
Speed(MAX)	0.5 m/s
Running time	8 hours

3.2 Motion model of a cart

The motion of an omni-directional cart on the curve was theoretically examined. In this research, it is assumed that a robot travels at a constant velocity $\dot{\phi}$ on a curve with radius r at coordinate x-y. A omni-directional cart is towed using a simple 1-axis connection. The model of this system is shown in Figure 4.

The force balance for a robot is expressed by the following equation.

$$M_1\ddot{x} = F_x - T_x \tag{1}$$

$$M_1\ddot{y} = F_y - T_y \tag{2}$$

The force balance for a cart is expressed by the following equation.

$$M_2\frac{d^2}{dt^2}(x + l_2\sin\theta) = T_x \tag{3}$$

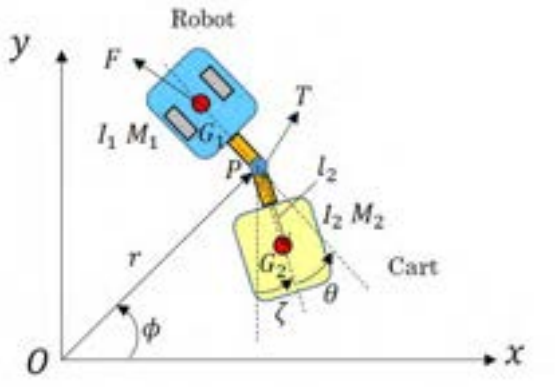
$$M_2\frac{d^2}{dt^2}(y + l_2\cos\theta) = T_y \tag{4}$$

$$I_2\ddot{\theta} = T_y l_2\sin\theta - T_x l_2\cos\theta \tag{5}$$

Transform Equation (1) and (2).

$$T_x = -M_1\ddot{x} + F_x \tag{6}$$

$$T_y = -M_1\ddot{y} + F_y \tag{7}$$



M_1 : The mass of a robot. [kg]
I_1 : The moment of inertia of a robot. [kg・m^2]
F : The tractive force of a robot. [N]
M_2 : The mass of a cart. [kg]
I_2 : The moment of inertia of a cart. [kg・m^2]
T : The force exerted on a cart by a robot. [N]
l_2 : The PG_2 distance. [m]
θ : Relative angle between robot and cart. [rad]
ζ : The direction of a cart. [rad]
r : The turning radius of a robot. [m]
ϕ: The angle of P. [rad]

Figure 4. A Model of the system.

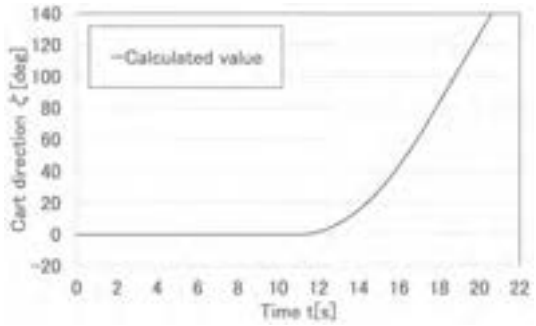


Figure 5. Direction of an omni-directional cart on the curve (Calculated value).

Table 2. Specification of the calculation.

M_2	150 kg
I_2	142 kg·m^2
l_2	0.90 m
r	2.00 m
$\dot{\phi}$	0.25 rad/s

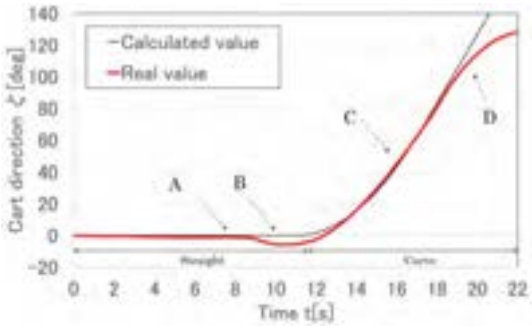

Figure 6. Direction of an omni-directional cart on the curve (Calculated value vs Real value).

From Equation (3) and (4), the following Equation can be obtained.

$$M_2(\ddot{x} - l_2 \sin\theta\dot{\theta}^2 + l_2 \cos\theta\ddot{\theta}) = T_x \tag{8}$$

$$M_2(\ddot{y} - l_2 \cos\theta\dot{\theta}^2 + l_2 \sin\theta\ddot{\theta}) = T_y \tag{9}$$

Substitute Equation (8) and (9) into Equation (5).

$$M_2 l_2 \cos\theta\ddot{x} - M_2 l_2 \sin\theta\ddot{y} + (I_2 + M_2 {l_2}^2)\ddot{\theta} = 0 \tag{10}$$

Transform Equation (10) with respect to $\ddot{\theta}$.

$$\ddot{\theta} = -\frac{M_2 l_2}{I_2 + M_2 {l_2}^2}(\ddot{x}\cos\theta - \ddot{y}\sin\theta) \tag{11}$$

To analyze the motion of a cart, we should solve Equation(11) for θ. However, it is difficult to get analytical solution because this equation is non-linear. Therefore, we analyze it numerically by the Euler method. The pitch width is

$$\Delta t = t_{n+1} - t_n \tag{12}$$

and we can get numerical solution as follows.

$$\dot{\theta}_2(t_{n+1}) = \dot{\theta}_2(t_n) + \ddot{\theta}_2(t_n)(t_{n+1} - t_n) \tag{13}$$

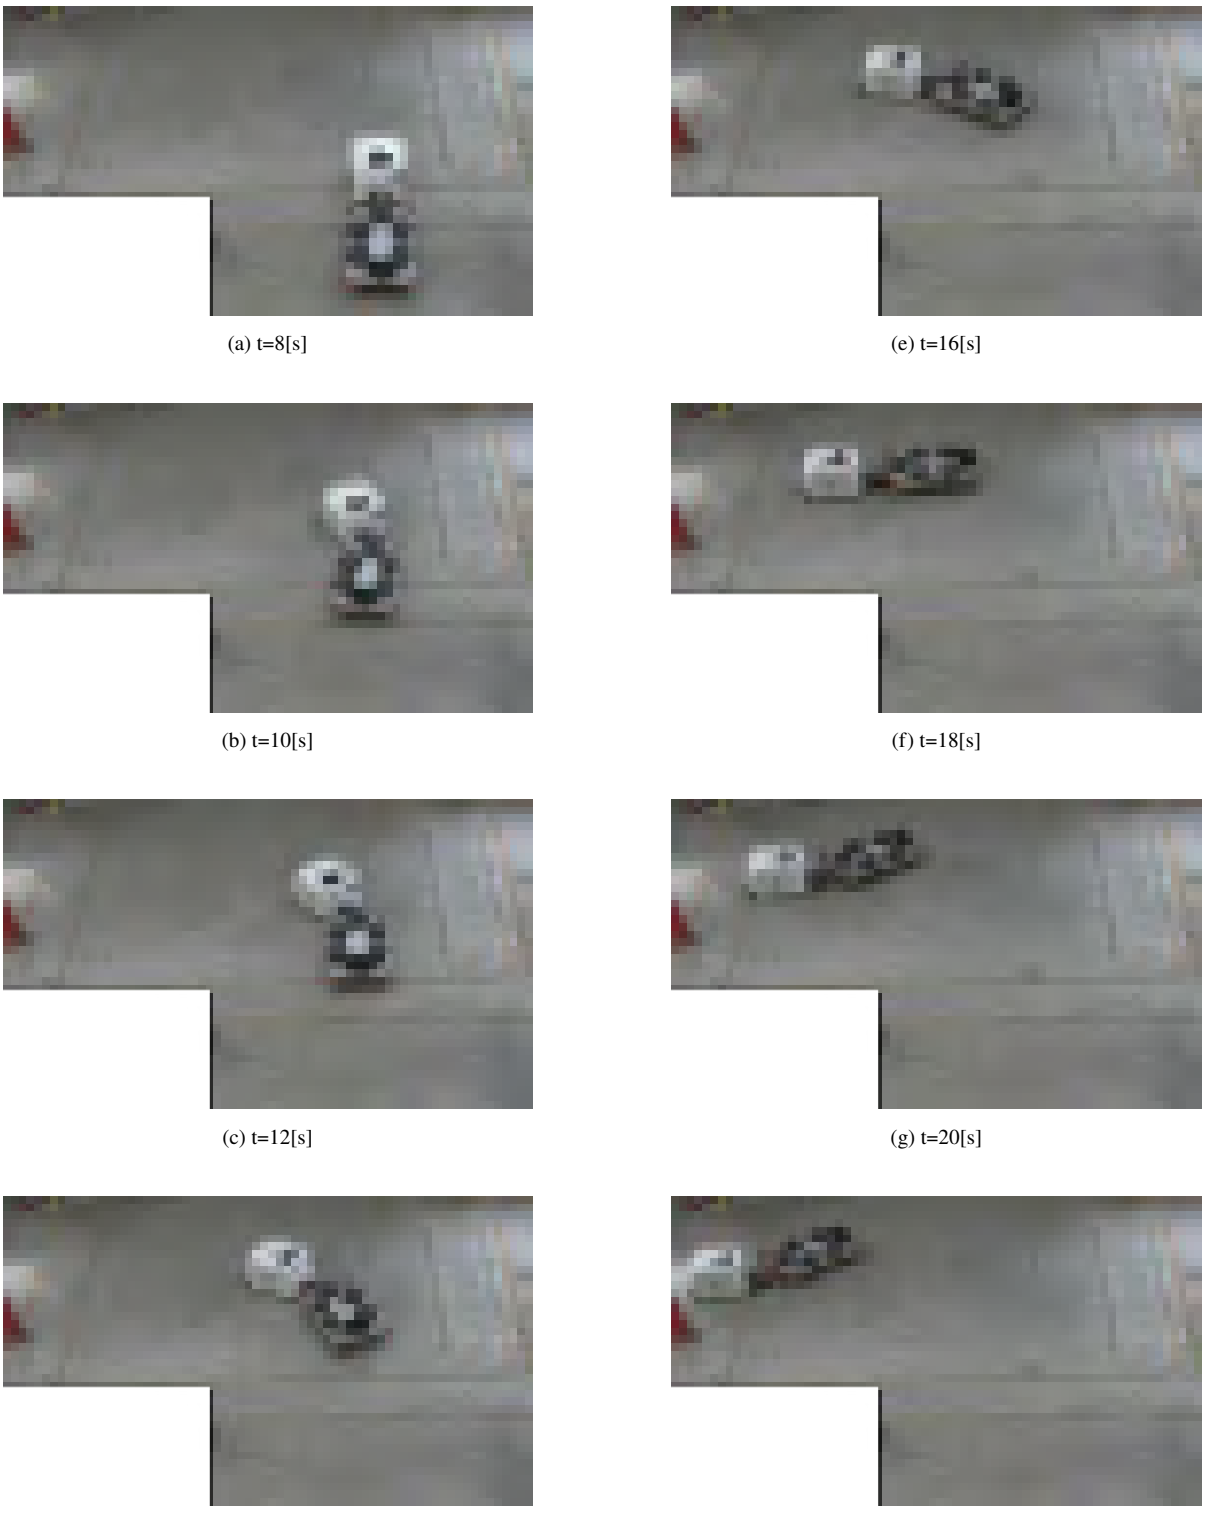
$$\theta_2(t_{n+1}) = \theta_2(t_n) + \dot{\theta}_2(t_n)(t_{n+1} - t_n) \tag{14}$$

When initial conditions are following Equations.

$$\dot{\theta}_2(t_0) = \dot{\theta}_2(0) = 0 \tag{15}$$

$$\theta_2(t_0) = \theta_2(0) = 0 \tag{16}$$

The motion of the robot is expressed by following equations.



(a) t=8[s]

(e) t=16[s]

(b) t=10[s]

(f) t=18[s]

(c) t=12[s]

(g) t=20[s]

(d) t=14[s]

(h) t=22[s]

Figure 7. Behavior of a cart during experiment.

$$x = r\cos\phi \tag{17}$$

$$y = r\sin\phi \tag{18}$$

The second derivative of Equation (17) and (18) is as follows.

$$\ddot{x} = -r\dot{\phi}^2\cos\phi \tag{19}$$

$$\ddot{y} = -r\dot{\phi}^2\sin\phi \tag{20}$$

Robot turns at a constant speed.

$$\ddot{\phi} = 0 \tag{21}$$

A cart direction ζ is expressed by the following Equation.

$$\zeta = \phi - \theta \tag{22}$$

We performed a simulation as shown in Figure 3, and assuming first a straight(0s∼12s), next a curved at 90deg (12s∼18s), and finally a straight(18s∼22s). The parameters used the conditions in the table 2. The result of the simulation is shown in the figure 5. It was theoretically found that the direction of a cart gradually increased as the curve started, and a cart sways over 90 deg at t=17s.

4 Comparison of a pulling experiment and a simulation result

An omni-directional cart was connected to the robot and the behavior of a cart on the curve was observed. In this chapter, the conditions of the experiment and the experimental results are explained.

4.1 Experimental conditions

In this experiment, a robot and an omni-directional cart were connected by a simple 1-axis connector. The experimental conditions were the same run as the simulation under the table 2. An IMU(Inertial Measurement Unit) was attached to the back of a cart. This sensor is equipped with geomagnetic sensor and can measure the direction ζ of the cart.

4.2 Experimental results and consideration

The experimental results are shown in Figure 6. Furthermore, the state of the experiment is shown in Figure 7. For comparison, Figure 5 is overlaid on Figure 6. In Figure 6, we divided into 4 sections and compared a experimental result with a simulation result. That is, Section A (0s∼9s): Straight, Section B (9s∼12s): Transition from straight to curve, Section C(12s∼18s): Curve, Section D(18s∼22s): Transition from curve to straight.

At first, the experimental value and the calculated value were almost the same in the section A(Figure 7-(a)). Next, there was a difference between the experimental and calculated values in the section B(Figure 7-(b)). Since the connecting point between a cart and a robot (Figure 4 - point P) is away from the robot's reference point (Figure 4 - point G_1), it is considered that the turning of a robot moved the connecting point to the outside and the direction of a cart changed. The experimental value and the calculated value were almost the same in the section C(Figure 7-(c)∼(f)). Finally, there was a difference between the experimental and calculated values in the section D(Figure 7-(g)∼(h)). As a result of confirming the actual operation of a robot and a cart, it was found that the cause was that a robot and a cart mechanically contacted with each other and the movement of a cart was suppressed. Such a phenomenon may damage a robot or cause a cart to collide with surrounding materials and buildings.

We considered that there are three ways to solve this problem. The first is a method of attaching a rigid wheel to an omni-directional cart. However, this method may lose convenience at a construction site. Moreover, an accident may occur due to forgetting to attach the parts. The second method is to add a spring/damper to the connecting device. By this method, there is a possibility that the behavior of a cart swinging outward can be suppressed. The third is a method of devising the traveling control of a robot. For example, it is conceivable that the inertial force can be reduced by decelerating as much as possible during a curve, and the swing of a cart can be suppressed.

5 Conclusion

In this research, we aimed to improve the productivity of a construction site by automating by pulling a cart with a robot. When pulling a cart by a robot, it was important to develop it in consideration of the motion of a cart. For this reason, first, we theoretically examined the motion characteristics of an omni-directional cart when traveling on a curve. As a result, it was found that the direction of a cart gradually increased as it began to curve and swayed outward. Next, we conducted the pulling experiment and observed the behavior of a cart. As a result, it was found that the same tendency as the theory was shown in the curve section. On the other hand, after the end of the curve, there was a discrepancy between the calculated value and the experimental value due to the touch of a cart. In order to solve the problem of an omni-directional cart that a robot greatly deviates from the trajectory of a robot in the curve, a method of attaching a swivel wheel to an omni-directional cart, a method of adding a spring/damper to the connecting device, and a method of driving control

of a robot was considered. In the future, we will set the target trajectory of a cart based on this calculated value and examine these methods.

6 Acknowledgements

In conducting this research, we received a lot of advice from THK Co.,Ltd.（Hitoshi Kitano, Tetsuya Sakagami, Akihiro Iimura, Tsubasa Usui, Takashi Naito, Syota Arakawa, Kosei Mochizuki, Hirokazu Tatsuzuki）regarding the development of the robot and the control system as well as the experiments. We would like to express our gratitude to them.

Abstract -

Modern heavy machinery, including mobile cranes, are increasingly equipped with information systems in the form of head-down displays that present supportive information. Due to the physical presence of head-down displays, they are usually placed far away from operators' line of sight, thus the information is unintentionally overlooked. This paper investigated the use of transparent displays in mobile cranes, which enables supportive information to be presented near operators' line of sight without fully obstructing their view. We developed both virtual and physical versions of the transparent display, which show information related to the lifting capacity and its influencing factors. The virtual version was developed using the Unity game engine with the data from the official load charts for a specific mobile crane model were incorporated into the mobile crane simulation. The physical version was made using off-the-shelves items, such as glasses, LEDs, super glues, insulated copper wires, and an Arduino. We then connected the virtual transparent display with its physical counterpart using an asset called Uduino, which enabled the Unity game engine to send data to the Arduino. The result in this study showed that the virtual transparent display and its real counterpart were functioning as what we intended. The developed prototype would be used in future user evaluations, thus we could determine to what extent this approach would affect the operators' performance and experience.

1 Introduction

Cranes are one kind of heavy machinery specifically used for lifting and moving objects from one place to another. Cranes come in different types, such as mobile cranes and tower cranes. Operating a crane is a complex task that continuously demands significant cognitive workload from the operator [1, 2]. When lifting a load, the operator has to remain cautious, as the crane's parts or the lifted load may collide with nearby people or structures. The operator also needs to ensure that the operation is always done within permissible conditions, such as permitted load weight or wind speed, thus the crane's balance can be maintained [3]. Crane-related accidents can harm lives and properties of both workers and non-workers [3, 4].

Modern cranes are increasingly installed with information systems in the form of head-down displays that provide supportive information to the operator [3]. The head-down display is usually placed far from operational areas, since the presence of the display can obstruct the operator's view. However, this placement makes the supportive information is unintentionally overlooked by the operator. The benefit of having such supportive information is diminished if the operator does not use it.

In this study, we explored another way of presenting supportive information in mobile cranes through the use of transparent displays, which emit their own light but look transparent when the light is off. This way, the supportive information can be presented near line of sight, without obstructing the operator's view. Mobile cranes were chosen as the use case, since they were responsible for around 70% of all crane-related accidents [4]. Looking at the causation factors, human errors contributed about one-third of total accidents, where the main reason was due to operators used the crane beyond the permissible operational limits. Here, we focused on visualizing information related to the lifting capacity and the factors that influence it as the information presented on the transparent display. These kinds of information were chosen as they play vital role for performing safe lifting operations [5]. Similar information can also be found on the Load Moment Indicator (LMI) system, which is commonly installed in various types of cranes [3].

2 Related Work

Many studies have been done to investigate new ways for visualizing information to the operator of heavy machinery, including mobile cranes. Although the proposed approaches vary from one study to another, the common ones are projecting the information on the windshield or directly on the object of interest (see Sitompul and Wallmyr [6] for the review). However, most of the studies were conducted in simulations, and thus it is difficult to determine to what

extent the proposed approaches would work in real machines.

There were several studies that tried to build the physical visualization system, which could be deployed in real machines. In the context of mobile cranes, Fang et al. [2] investigated the use of bigger head-down displays, where the operator could see multiple views around the machine, as well as the supportive information. In the context of tractors, Fernandez et al. [7] explored the use of head-mounted displays, where the information, such as navigation and which areas that have been treated, can be shown as it appeared directly on the object of interest. Still in in the context of tractors, Palonen et al. [8] also used a head-mounted display, but they probed on how to visualize the environment that was occluded by the machine's part, thus the operator could observe blind spots around the machine. There were three studies that explored the cabin's windshield as a place to visualize the information. Both Rakauskas et al. [9] and Englund et al. [10] respectively used a projection head-up display to present the information on the windshield of snowplowers and forest harvesters. In the context of off-shore cranes, Kvalberg [11] considered using a transparent display that could be installed on the windshield.

Based on the studies mentioned above, it is still difficult to decide which approach as the most suitable one due to two main reasons. Firstly, the studies were often limited to technical evaluations only, except for Rakauskas et al. [9], Englund et al. [10], and Fang et al. [2] who carried out some user evaluations in their studies and each evaluation was for a different kind of heavy machinery. Therefore, more studies are still needed to determine to which extent the proposed approaches could benefit the operator. Secondly, each option has its own advantages and disadvantages. Although Fang et al. [2] found that the operators performed better when using the bigger head-down display compared to when the operators had no support, the operators still commented that the bigger head-down display was still considered too small and the presence of the display could also obstruct their view. Head-mounted displays are another option that allows the operator to see the information exactly within the line of sight, but this approach could be ergonomically uncomfortable for the operator, especially for long-hour usages [12]. In addition, considering that the operator is required to wear a protective helmet, wearing multiple head gears may not be a viable option for the operator. Both projection head-up display and transparent displays are the other two options, as the operator could see the information without wearing additional equipment. The main drawback of projection head-up displays is the projected information may deteriorate in bright environments [13]. On the contrary, transparent displays are strong against external light, but they are still limited in terms of colors, as only green and yellow are currently available [14]. In addition, the information being shown is static to what has been determined when the display was manufactured.

Figure 1. The transparent display prototype for off-shore cranes that was made by Kvalberg [11]. The light-emitting diodes (LEDs) were manually controlled by setting two values on the computer program: one for the indicator and one for the limit. The LEDs that formed the 5-digit numbers were lit to visualize the value of the indicator. The LEDs that formed a triangle warning were lit if the indicator value was higher than the limit value.

Taking into account the fact that all proposed approaches are still in the exploratory stage, as well as both advantages and disadvantages of each proposed approach, we were interested to further explore how transparent displays could be utilized in mobile cranes, similar to what Kvalberg [11] has done (see Figure 1). In our prior study [5], we have determined what kinds of information that should be presented on the windshield, how the information should be visualized based on the capability of transparent displays, and gathered feedback from six mobile crane operators regarding this proposed approach. Although the operators perceived the effort of bringing information closer their line of sight positively, our prior study was still limited to the operators' understanding on the proposed information visualization and where to place the information on

the windshield. There is a need for high-fidelity prototypes, which could later be used to evaluate the proposed visualization approach in certain scenarios. Therefore, it would be possible to determine to what extent this visualization approach would improve or hinder the operators' performance and experience.

3 The Prototype

In this study, we developed both virtual and physical transparent displays that act as a replica of each other. Both virtual and physical displays visualized the information related to the lifting capacity, such as the boom length, the load radius, and the lifting percentage. Based on our prior study [5], we found that these kinds of information are essential for performing safe lifting operations and the operators would also like to have them to be presented on the windshield. The remaining of this section describes how both virtual and physical transparent displays were developed.

3.1 The Simulation

To speed up the development, we used an available mobile crane simulation that was purchased from Unity Asset Store [15]. Therefore, we did not have to develop everything from scratch. The simulation has two fully functioning mobile cranes that can be played immediately, but the one that we used in this study was the one named 'HTR1045' in the downloaded project (see Figure 2). Although not the exact replica, the virtual mobile crane in the simulation has a close resemblance with the Liebherr's LTC 1050-3.1 compact mobile crane [16]. A notable difference is the boom of the LTC 1050-3.1 crane has five telescopic booms, while the boom of the virtual mobile crane only has four telescopic booms. The virtual environment was made of a flat ground without additional weather conditions. We kept this initial setup, since a mobile crane should be operated on the flat ground and permissible weather conditions due to safety reasons [17, 18].

Since we aimed to develop a prototype that could be used in certain scenarios, it is important that the presented information on the transparent display is not arbitrary and the information is shown based on the run-time situation. To do so, we had to continuously measure the machine status, such as the boom length, the load radius, the lifting capacity, and the lifting percentage. As the virtual mobile crane has a close resemblance to the Liebherr's LTC 1050-3.1 crane, we used its two official load charts [16, pp. 23 and 29] as the source of information on how the lifting capacity of the virtual mobile crane should change based on the boom length and the load radius. Two load charts were used, since the LTC 1050-3.1 crane can be used using the 4.8-tonne counterweight or the 6.5-tonne counterweight.

Figure 2. The virtual mobile crane and the virtual environment used in this study.

The rest of this subsection describes the modifications that we have made on the initial simulation.

3.1.1 Establishing a Metric Measurement in the Simulation

Based on the original code in the initial simulation, the Unity coordinates were often multiplied by 3.6 to define the length of one meter inside the simulation. However, the reason behind this decision was unknown and we had to establish a constant metric system in the simulation, since the load charts in [16, pp. 23 and 29] were documented in meters. From the load charts, the maximum boom length for the LTC 1050-3.1 crane is 36 m. Instead of using the unknown conversion rate, we defined a new conversion rate by dividing the maximum boom length of the virtual mobile crane measured in Unity coordinates with the LTC 1050-3 crane's maximum boom length, which gave us a conversion rate of 0.88264784. By multiplying Unity coordinates with the new conversion rate, we were able to establish another constant metric that defines the length of one meter in the simulation. This calculation was always used for measuring the boom length and the load radius.

3.1.2 Storing the Values from the Load Charts into the Simulation

We stored the values from two load charts in [16, pp. 23 and 29] directly into the simulation, which enabled the virtual transparent display to automatically find the specific information that should be presented. To automatically find the values based on load charts during the run-time, a lifting capacity class was made, which acted as the look-up table for the lifting capacity. As the values were taken from the load charts, the class comprised of

three fields: boom length, load radius, and their corresponding lifting capacity. Boom length and load radius were represented as arrays, while the corresponding lifting capacity was represented as a matrix. To determine the corresponding lifting capacity, the indexes of the arrays were used as the table representation of a load chart, where both boom length index and load radius index decide the lifting capacity value. `CurrentLengthIndex` and `CurrentRadiusIndex` were set to be the active index values based on the current state of the virtual mobile crane. Both indexes were managed by `GetBoomLengthIndex()` and `GetRadiusIndex()` methods that took the values of the current boom length and the current load radius of the virtual mobile crane. For example, when the boom was extended to 36 m, then the index value was set to 10 (note that the index value started from 0). If we used the load chart for the 6.5-tonne counterweight [16, pp. 23], when `CurrentLengthIndex` was 10 and `CurrentRadiusIndex` was 7, then the lifting capacity was 8 tonnes. The `GetLoadCapacityInTonnes()` method then looked up the values in the lifting capacity matrix based on the values of `GetBoomLengthIndex()` and `GetRadiusIndex()`. See Figure 3 for an illustration that shows how the lifting capacity class works.

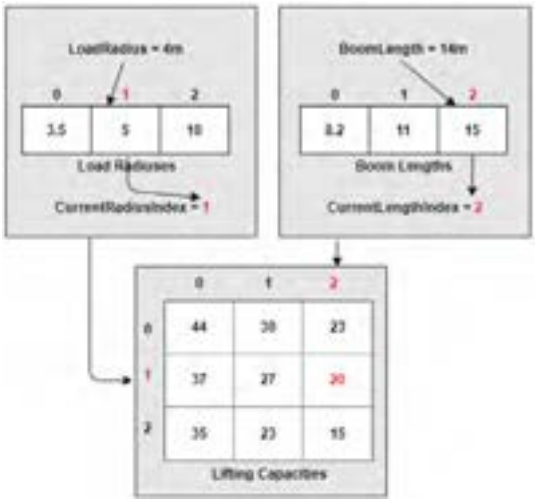

Figure 3. An illustration that shows how the lifting capacity class works inside the simulation. The numbers in red color indicate the activated indexes. The class automatically finds the lifting capacity value based on the indexes of both boom length and load radius.

As the load charts contained the values for some of the states of boom length and load radius, the lifting capacity class could show the lifting capacity for the states documented in the load charts only. Due to this limitation, we automatically set the lifting capacity to the next available state when the boom length or the load radius were between two documented states in the load charts, as shown in Figure 3. This decision was made, since setting the lifting capacity to the next available set would make the lifting capacity to be slightly lower than the actual one, and thus more preferable from safety point of view.

3.1.3 Adding the Virtual Transparent Display into the Simulation

We added a graphical user interface (GUI) into the simulation, which served as the virtual transparent display (see the right image in Figure 4). The virtual transparent display was designed based on the revised version of one of visualization concepts that we designed and evaluated in our previous study [5]. Three kinds of information are shown on the virtual transparent display: (1) the current boom length, (2) the current load radius, and (3) the lifting percentage (see the left image in Figure 4). The lifting percentage was calculated by dividing the weight of the lifted load with the lifting capacity for the current state of boom length and load radius, and then multiplied by 100.

Based on the measurement of boom length and load radius described in Section 3.1.1, the values of boom length and load radius could be in decimals, but the virtual transparent display only shows the values of boom length and load radius in integers, as shown in the left image in Figure 4. If the decimals are between 0.1 and 0.5, the values are automatically rounded down. If the decimals are between 0.6 and 0.9, the values are automatically rounded up.

As illustrated in the left image in Figure 4, the lifting percentage is visualized using ten blocks, where each block indicates that 10% of the lifting capacity has been used. Since each block indicates 10% of the lifting percentage, one block is turned on if the lifting percentage is anywhere between 0.1% and 10.0%. For example, when the lifting percentage is 20.1%, then the first three blocks from the bottom are turned on. The operator needs to ensure that the top block is not turned on, since that means the virtual mobile crane is approaching its limit and the risk of tipping over is high.

3.2 The Physical Transparent Display

Our approach for making the physical transparent display was similar to what Kvalberg [11] has done for the transparent display prototype in off-shore cranes (see Figure 1). We used WS2812b light emitting diodes (LEDs), which allowed us to control the LEDs individually. A WS2812b LED has four pins, where one pin is for the supply voltage, one pin for the ground, one pin for the input signal, and another pin for the output signal [19]. We initially wanted to use the 2 mm x 2mm LEDs, since that means we could use glasses with smaller dimension. However, we later found that those LEDs were too small

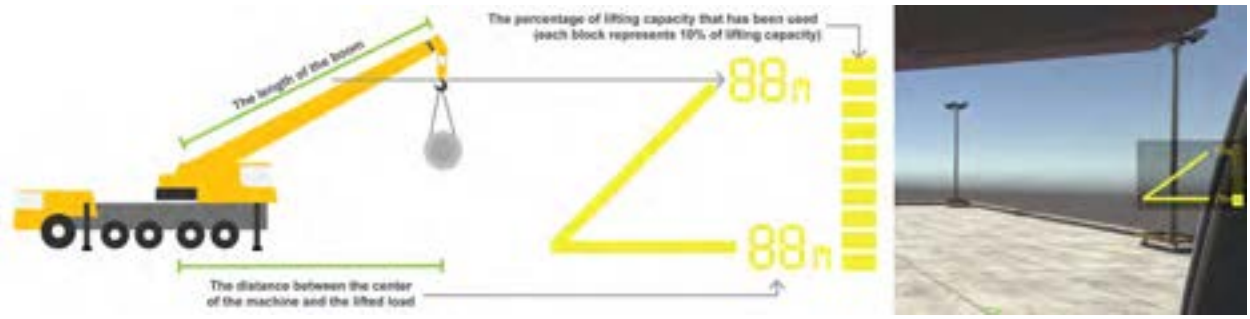

Figure 4. The left image shows the meaning for each kind of information shown on the virtual transparent display. The right image shows how the virtual transparent display looks like inside the simulation.

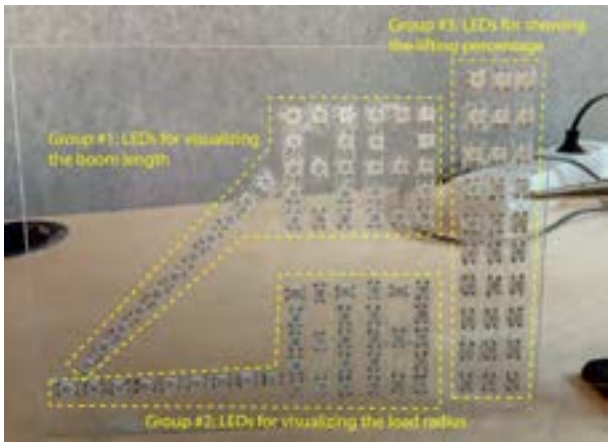

Figure 5. The LEDs were attached on a glass and arranged in a way that resembled the design of the virtual transparent display. The LEDs were divided into three groups and each group was assigned to visualize specific kinds of information.

to be soldered manually. We then decided to use the same type of LEDs, but the dimension was 5 mm x 5mm. The LEDs were then attached using a superglue to a glass with dimension of 20 cm x 12 cm and thickness of 1 mm. The connection between one LED to another was done using insulated copper wires with diameter of 0.1 mm. We used 102 LEDs and arranged them in a way that the LEDs would resemble the design of the virtual transparent display (see Figure 5).

We used an Arduino Mega2560 microcontroller and a FastLed library [20] for controlling the LEDs. To make the control simpler, we divided the LEDs into three groups, where each group was respectively assigned to visualize the information about the boom length, the load radius, and the lifting percentage (see Figure 5). Each group of LEDs was connected to one specific pin on the Arduino. For the number of LEDs that we used for the physical transparent display, the power supply from the USB cable was enough to power all the LEDs, thus we did not use an external power supply in this study. Although the LEDs used for the physical transparent display could display any color by changing the values of red, green, and blue (RGB) on each LED, we decided to use the yellow color since real transparent displays are available in yellow or green only [14].

3.3 Connecting the Simulation with the Physical Transparent Display

We used an asset called Uduino, which was purchased from Unity Asset Store [21], to connect the physical transparent display with the virtual one. Uduino enabled the Unity game engine to send data to Arduino via a USB cable. In this study, the Unity game engine was continuously sending the data about the boom length, the load radius, and the lifting percentage to Arduino. Based on the input data, Arduino automatically decided which LEDs that should be turned on or turned off. For example, if the virtual transparent display shows that the boom length is 10 m, the physical transparent display should turn on several LEDs in the group that visualize the boom length, so that the number 10 can be formed. The same thing also applies for visualizing the load radius. Specifically for the lifting percentage, the first two bottom rows of the LEDs are turned on if the lifting percentage is 20%.

4 Result

In this section, we present two examples that demonstrate the integration between the virtual transparent display and its physical counterpart. The examples shown in this section were taken when the virtual mobile crane was using the 4.8-tonne counterweight and lifting a 1-tonne load. Note that it was possible to manually adjust the brightness of the LEDs. We found that the LEDs were

Figure 6. The examples that show the integration between the virtual transparent display and its physical counterpart. The examples were made when the virtual mobile crane was using the 4.8-tonne counterweight and lifting a 1-tonne load. The left image shows the boom length was 19 m, the load radius was 14 m, and the lifting capacity was 20% used. The right image shows that the boom length was 36 m, the load radius was 30 m, and the lifting capacity was 90% used.

quite bright for indoor environments, thus we decided to use only 10% of the brightness in this study.

The left image in Figure 6 shows that the boom length and the load radius of the virtual mobile crane were respectively 19 m and 14 m. The lifting capacity for that state of boom length and load radius was 6.3 tonnes. Since the virtual mobile crane was lifting a 1-tonne load, the lifting capacity was 15.87% used. Based on the setting of the virtual transparent display, which is described in Section 3.1.3, the first two rows of LEDs from the bottom were turned on.

Similar to the previous example, the right image in Figure 6 shows that the boom length and the load radius of the virtual mobile crane were respectively 36 m and 30 m. The lifting capacity for that state of boom length and load radius was 1.2 tonnes. Since the virtual mobile crane was lifting a load with the same weight, the lifting capacity was 83.3% used, and thus the first nine rows of LEDs from the bottom were turned on.

5 Conclusion and Future Work

In this paper, we have developed a prototype that consisted of a virtual transparent display and its physical counterpart. The kinds of information were shown and how they were visualized were determined based on the result of our earlier study [5]. The virtual transparent display was hosted in a mobile crane simulation developed in the Unity game engine, which was a modified version of an available mobile crane simulation. The physical transparent display was made using off-the-shelves items, such as glasses, LEDs, super glues, insulated copper wires, and an Arduino to control which LEDs that should be turned on or turned off. The virtual transparent display was connected with its physical counterpart using an asset called Uduino, which enabled the Unity game engine to communicate with Arduino. The information shown on the prototype was not arbitrary, as the relevant data were imported from the official load charts, and the information was shown based on the run-time state of the virtual mobile crane, which are in contrast to the prototype developed by Kvalberg [11]. The developed prototype in this study was shown to be functioning as what we intended.

The study in this paper was limited to the development of the virtual transparent display and its counterpart. Due to the ongoing pandemic situation, we were unable to involve mobile crane operators to obtain their feedback on the developed prototype. In the future, the developed prototype would be evaluated in two possible settings. The first setting is where we could evaluate the physical transparent display in real mobile cranes using the Wizard-of-Oz method [22], where another person would control the virtual mobile crane, while trying to mimic what the operator is doing when performing lifting operations using the real mobile crane. According to the operator's view, the information presented on the physical transparent display would appear to resemble the status of the real mobile crane. Therefore, it would still be possible to carry out the evaluation without actually using or modifying any existing system in the mobile crane. However, we nonetheless need to adapt the lifting capacity in the simulation according to the load chart of the real mobile crane that would

be used, thus the presented information remains relevant for the operator. The second setting is to conduct a user evaluation in the mixed reality environment, where the transparent display is physical, but the environment is virtual and projected to the wall, similar to the mixed reality setup used by Wallmyr et al. [23]. In this case, we need to further modify the virtual environment in the simulation, thus the lifting scenario inside the simulation could resemble the real-world scenario.

Finally, the information shown using the virtual transparent display and its physical counterpart in this study was based on the LTC 1050-3.1 crane and its official load charts. It is possible to use a different mobile crane model as the use case, given that the 3D model that resembles such mobile crane and its official load charts are available. The proposed approach could also be modified and applied to excavators, since excavators also have the concept of lifting capacity and load charts provided by manufacturers [24].

Development of Simple Attachment for Remote Control (DokaTouch)

Kazuki Sumi[a]

[a]Fujiken co., Ltd.

E-mail: sumi@fujiken-co.jp

Abstract –

The development of the DokaRobo series for remotely controlling construction equipment began in 2007, and life-size humanoid robots (The DokaRobo No. 1 and 2) were developed. The DokaRobo series is installed in the driver's seat and can be easily installed by a single adult. After repeated tests and interviews with users, it was realized that the robot needs to be frequently switched between remote control and manned operation, and it is desirable to have a remote control unit that can be manned even when it is installed. The compact retrofit device "DokaTouch" was developed based on the concept that it would improve the work in the bad environment if an ordinary construction machine could be remote-controlled more easily. In this paper, the present configuration and functions of the DokaTouch are explained, and its application to the future construction site is reported.

Keywords –
Unmanned Construction Machinery; Internet; LTE

1 Introduction

In recent years, large-scale natural disasters have been occurring frequently, and there is a need for urgent and rapid recovery work to save lives and prevent secondary disasters. In addition, remotely operated construction equipment that can be used in a wide range of areas with multiple units is also needed. The greatest advantage of remotely operated construction machinery is that it can safely carry out unmanned construction work in adverse environments, such as disaster areas. However, it is also desirable to have an operator on board the machine for emergency or detailed work that is difficult to do by remote control. Therefore, it is necessary to secure the passenger space even if the remote control device is installed. In order to solve this problem, we have developed a remote-controlled construction machine by installing a compact actuator unit for each control device.

The system must be able to transport, install, and operate the equipment easily and smoothly to respond to emergencies such as disasters. In addition, it is necessary to reduce the discomfort of remote control by faithfully reproducing the operation with low latency. The biggest advantage of DokaTouch is that it is compact, lightweight, and highly functional, and can be used with general-purpose construction equipment that can be procured on site. In addition, the system allows the operator to use not only the operator's eye view from the cockpit, but also the overhead view of the machine. The operator can work remotely from a distance via the Internet, and can also use a control device that feeds back the sound, vibration and posture of the construction equipment.

DokaTouch is aiming to create an economical and easy-to-use remote control system by eliminating custom-made parts as much as possible. In the case of Internet connection, it is possible to monitor the operation status and assist the pilot, which will improve safety and reduce the shortage of operators. The inexpensive and highly functional control device "DokaTouch" will be widely used for construction work during normal operations. It can be used on a daily basis to speed up the recovery process in the event of a disaster.

This paper introduces an attachment-type remote-control actuator, "DokaTouch," which can be attached to the operating levers and pedals of general-purpose construction machinery to enable remote control.

2 Purpose of Development

Currently, remote control of construction equipment is meant to enable rapid recovery work in places where human life is at risk in the event of a disaster. To achieve this goal, the system must be able to respond to emergencies, but it is not realistic to have a dedicated

machine on standby for training in the event of a disaster, which is costly and unpredictable. In the future, we may see remote-controlled aircraft deployed to every corner of the country. Until then, it is necessary to install and use remote control devices whenever necessary.

Familiarity with the operation of a remote-controlled machine is a very useful experience in case of disaster. A remote-controlled system for on-site construction would be a good preparation for disaster response without special training. Therefore, a safe, easy-to-use, and inexpensive system is needed. Each disaster site has different conditions, and the working procedures and types of equipment used are different. For example, various types of machines such as excavation, loading, transportation, and land preparation will be required. The following is a list of requirements for the remote control system of construction machinery.

(1) Lightweight and easy to install, easy to transport the main body, and about half a day's installation time for two people.

(2) Easy to handle, general-purpose machines can be used as they are.

(3) Easy to set up and positional calibration can be done in a short time.

(4) The 3D image is easy to work with and to understand the site conditions.

(5) Compatible with various types of construction equipment, mainly shovels, but also crawler dumps, bulldozers, bulldozers and uneven terrain carriers.

(6) No radio qualification and application is required to use it.

(7) It is compatible with WIFI and internet connection.

3 Configuration of Dokatouch

3.1 Hardware Configuration

DokaTouch enables remote control of construction machinery by attaching an actuator to the control lever, pedal, switch, etc. and controlling them simultaneously. Fig 1 shows the photo of the backhoe. The retrofit actuators are compactly attached to the levers for both hands and feet. Fig. 2 shows a picture of the manned operation. Fig.3 shows the DT1 for a single axis. Fig.4 shows the DT2 for for two axis.

Since DokaTouch is a unit module, it does not require assembly work and can be used immediately by attaching it to each operating device. The drive unit is mainly a rotary type servo motor, but a stepping motor or linear actuator can also be used depending on the conditions of use. In addition to the drive unit, the system consists of a control unit, a communication unit, and a power supply unit, which is installed and fixed at the rear of the driver's seat. The power supply unit is powered by 24V DC from the battery of the construction equipment. A sub-battery can also be installed as an auxiliary power source. The frame of the drive unit is made of aluminum or CFRP (carbon fiber reinforced plastic) for a lightweight, strong structure. The use of CFRP prevents deformation due to impact and absorbs shocks during operation, transportation, installation and removal. Table 1 shows the specifications of DokaTouch.

Various types of DokaTouch are available, and they can be used for various types of construction machinery. Table 2 shows the various types of DokaTouch. The multi-functional joystick can also be used.

Figure 3. DT1

Figure 4. DT2

Table 1. Specification

Item	Content
Size	B300mm × L300mm × H250mm
Weight	1Axis : 1kg-3kg , 2Axis : 2kg-5kg
Power	DC24V , 300W(max)
Actuator	Servomotor , Stepping motor
Flame	Aluminum , Duralumin , CFRP

Table 2. Type of DokaTouch

TYPE	Operation part	Operation
DT1	Lever	1 Axis
DT2	Lever	2 Axis
DT3	Lever	3 Axis
DTP	Pedal	1 Axis
DTH	Handle	1 Axis
DTK	Rotary switch	3 Points
DTD	Dial	Any position
DTS	Push-button switch	1 Axis
DTR	Relay switch	1 Axis

3.1.1 SW Servo Type

Several servo motors are mounted on the upper part of the joystick, and each switch is pressed by a lever connected to each servo horn. Fig.5 shows the small servo motor attached to the switch.

Pros:

- Good response time.
- The servo motor allows a stepless setting.
- Installation is easy when using a servo unit.
- Each switch is equipped with an individual servo motor and can be operated simultaneously.

Cons:

- Difficult to operate with the switch installed. (Lighter servos with back drives can be used.)

3.1.2 Thumb Robot Type

The joystick is operated with a 3-axis robot attached to the top of the switch. Fig.6 shows a joystick with a thumb-robot attached.

Pros:

- Multiple switches can be operated by indicating their positions.
- The servo motor allows a stepless setting.
- Manned operation is possible with the device attached. (The device is placed in a position where it will not interfere with button operation.)

Cons:

- Simultaneous operation of multiple buttons is not possible.
- Responsiveness is not as good as that of the direct-attached servo motor type.

3.1.3 Wire Actuation Type

A wire-driven switch operating device is attached to the top of the switch on the joystick. Fig.7 shows the wire-driven joystick.

Pros:

- The light weight of the device makes it resistant to vibration.
- The servo motor can be used for a stepless setting.
- The servo motor unit can be made waterproof.
- Easy installation and removal of the device.
- Can be operated while mounted.

Cons:

- Responsiveness is worse than the direct servo motor type due to the elongation of the wire.
- Wiring space is required.

Figure 5. SW Servo Type

Figure 6. Thumb Robot Type

Figure 7. Wire Actuation Type

3.2 System Configuration

The system configuration of DokaTouch is shown in Fig.8. The edge PC processes the camera image and communicates with the network. The microcomputer acquires sensor data from IMU, etc., and controls the actuator based on the operator's operation information. The microcomputer is connected to the edge PC via serial communication. The network configuration of DokaTouch is shown in Fig.9. DokaTouch is connected to the server on the Internet, and it can be accessed by

any device that can use a browser, regardless of whether it is a PC or a smartphone. WebRTC is used for the video system, and MQTT is used for the operation commands, and the HTTP server is used for the GUI.

ired.

3.3 Software Configuration

The main control unit consists of an edge PC and a microcontroller, and various functions can be added to the system. This system has the following functions.

- Control the robot using a joystick, and remote control via the Internet.
- Remote control through the Internet.
- Grasping the posture of construction machinery using a gyro sensor attached to the robot.
- Camera tracking using a gyro sensor attached to the operator's head.
- 3D display of binocular camera images using a head-mounted display.

tion.

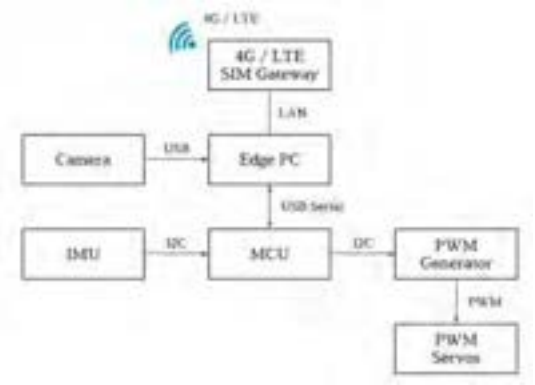

Figure 8. System Configuration

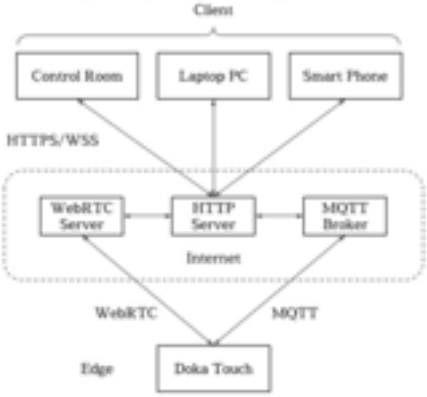

Figure 9. Software Configuration

4 Features of DokaTouch

DokaTouch can be installed in the driver's seat of general-purpose construction equipment when and where it is needed. This system allows work to be performed by remote control from a safe location. The features of this system are safety, small size and lightweight, and high performance.

4.1 Hardware Configuration

A small servo motor of 60 watts or less is used to ensure safe operation. The main drive unit uses one or two DC servomotors with a maximum torque of 100kg-cm, connected and linked to each other. One servo motor is used for each axis, and multiple axes can be used by combining units. The standby current at startup is 2A or less, and about 12A at maximum during operation. The turn-on/off of the safety lever of the machine is controlled by a separate circuit. In an emergency, the safety lever can be operated independently..

4.2 Software Safety

A software multi-safety system is used. To ensure safe operation, several measures are taken. First, each servo motor can be set to have a range of motion. To prevent the levers and pedals from rotating at unexpected angles and damaging the motors, the rotatable angle range is set for each servo motor in advance. This value is stored in the flash memory in each servo motor. Next, the maximum torque setting is set at a lower value for joints that do not require the torque of the servo motor to prevent the possibility of damaging surrounding objects when they move in an unexpected manner. Finally, as a countermeasure for communication errors, a function to stop at a safe position if communication is lost is provided.

4.3 Easy Install

Each device is small and light enough to be carried in the driver's seat by one person. The weight of the single-shaft type is about 2 kg, and the weight of the two-shaft type is about 4 kg. This is because it would be difficult for more than one person to work on the narrow driver's seat when it is installed over a door on one side. Since the equipment is dispersed, it can be transported in a small storage case in a car. Each device is fixed by using the armrest support part of the driver's seat and lever mounting bolts. Because they are attached to the existing levers as attachments, there is no need to remove any parts and no need to modify them. It takes one person about half a day to complete the installation and about two hours to dismantle it..

4.4 High Functionality

Our goal is to be able to use general-purpose machines at the site, regardless of the manufacturer or model. At present, the system can be installed on most of the backhoes, and we are planning to install it on the bulldozers and rugged terrain vehicles in the near future.

4.4.1 Any manufacturer or model

The conventional method of installing a device on the driver's seat makes it difficult to adapt to various types of construction machinery because the position of the levers (distance, height, and direction) is different for each machine. DokaTouch solves this problem by installing an actuator module directly to each lever. In addition, DokaTouch is very small, less than 300mm wide and 300mm long, so that it can be operated by a manned operator even when the equipment is installed.

4.4.2 User Friendly Interface

The remote-control unit is equipped with two operating levers (boom, arm, bucket, and slewing lever), two traveling levers (to move the crawler when moving), and button switches (to activate various operating motions). The maneuvering lever is controlled so that the target position of the work lever on the actual machine is calculated in response to the angle of fall and the operation is the same as at the time of boarding. Depending on the status of communication, there may be a delay, so the operator must pay attention to the delay. The gyroscope is installed in DokaTouch, and it is possible to prevent the machine from tipping over while working by grasping the inclination of the machine.

As an option, a bilateral operation system can be implemented, such as a rigid steering lever if the machine is in a dangerous condition. In addition, by attaching angle sensors to the operator's shoulders and arms, a master-slave operation system can be implemented to synchronize the arm movements with the bucket.

The operation situation from the control room is shown in Fig.10.

4.4.3 Easy calibration

Since the positions of levers and pedals must be taught to the operator after installation of the DokaTouch, positional calibration can be easily performed by the teaching function. After the machine is started up, the positions of the work lever, the traveling lever, and the foot pedal for the actual machine are taught by hand in the calibration mode. If the neutral position is fixed, move the movable range of each lever back and forth, left and right, and instruct it. After that, check if the operation is within the range of motion.

4.4.4 3D Head Mounted Display

Two FullHD (1920×1080) cameras are mounted on the head, which are converted to 3D images by a special device and transmitted. By using composite images, the amount of data can be reduced and the delay can be reduced. If the image is displayed on a head-mounted display, it is possible to feel a three-dimensional effect, which makes it easy to judge perspective and unevenness. By displaying the simulated image on the display, when an abnormality is detected, the part of the display changes to yellow or red depending on the alarm level, making it possible to check the abnormality while operating the system. Fig.11 shows a combined image from the binocular cameras. This image is displayed on the head-mounted display for each eye.

The camera head, which corresponds to the human head, has three axes of pitch, roll, and turn, and the gyroscope on the pilot's head enables the viewpoint tracking. The gyroscopic sensor on the head enables the pilot to track his or her viewpoints. A picture of the stereo camera is shown in Fig. 12.

4.4.5 Can be Operated via the Internet

The heavy equipment is equipped with a SIM that enables the use of mobile phone networks (4G/LTE). Therefore, if the machine is installed in an area where a mobile phone network is available, users can operate the machine from anywhere in Japan where they can access the Internet. Since the remote control and video transmission radios use the wireless LAN standard, no qualifications or licenses are required for radio operation.

4.4.6 Record and Play Mode

On a construction site, similar tasks may be repeated many times. To reduce the burden on the remote operator, a motion program can be created by recording the position data of the operating lever during the operation. For repeated operations, it is possible to activate the appropriate work motion to assist in the maneuvering.

Figure 10. Operation Room

Figure 11. Stereo Camera Images

Figure 12. Head Mounted Display

5 Issues and Future Development

At present, the efficiency of remote control by DokaTouch is about half of the efficiency of on-board operation. For the improvement of the efficiency, it is necessary to reduce the delay in operation and visual information between the operator and the actual device. Therefore, it is necessary to provide a reliable communication line. In order to supplement the visual information, the information of distance and ups and downs to be able to judge the working position and the surrounding situation is necessary. For this purpose, it is effective to display information on the screen from the operator's eye view of the camera or by installing a distance sensor or rangefinder on the machine itself. It is also possible to combine this information with XR (Mixed Reality) to provide an efficient work environment. By attaching sensors to the bends, it is possible to improve the operating environment while providing feedback on the condition of the construction machinery.

In the future, we must develop a system that is compatible with CIM (Construction Information Modeling) and allows multiple construction machines to work together.

6 Conclusion

We have developed DokaTouch, which can be remote-controlled safely and efficiently from anywhere in Japan, for use in dangerous construction work. DokaTouch is a compact and lightweight device that can be attached to each control unit of a general-purpose construction machine, and is equipped with an advanced software system. In the future, the system will be developed to control multiple construction machines and be expected to be used for various construction tasks.

Abstract –

Currently, humans work in high-risk environments such as earthwork sites with construction machine. Such works are expected to be replaced by robots, but autonomous technologies of current robots are not sophisticated enough to deploy to such tasks. Thus, it is reasonable to use robots that can assist humans in cumbersome tasks and dangerous situation. These robots must have high repeatability, speed, power, and safety. As a preliminary study on human assistive robots, this paper designs and develops a powerful and backdrivable robot gripper. To provide powerful output suitable for construction works, we adopt an oil-hydraulic-driven actuator. To provide backdrivability for geometric and mechanical adaptability, we adopt magnetorheological fluids (MRFs), which can change its apparent viscosity, quickly, continuously, and reversibly, based on the strength of the applied magnetic field, as the working fluids in the actuation system. MRF largely affects the dynamic range of viscosity and response time, so we develop special type of MRF suitable for construction works. We then develop a small size vane type rotary actuator that consists of a passage in the vane and an electromagnetic circuit to efficiently apply the magnetic field to MRF passing through the passage. The backdrivability can change based on the current applied to the coil and output torque can change based on the flow rate from the pump to the electro-hydrostatic actuator. Finally, we develop a robot gripper (similar to the size of human hands) with two fingers (three interconnected joints) actuated by one MRF actuator. From preliminary evaluation experiments, we confirmed that the developed robot gripper could change backdrivability and output torque depending on the coil current and pump flow rate.

Keywords –

Robot gripper; Magnetorheological fluid (MRF); Electro-hydrostatic actuator (EHA)

1 Introduction

Robot grippers and manipulators have been extensively researched in the past decades and they have become one of the most popular research topics in robotics. This is due to the fact that there is a wide demand of robot grippers in the field of industrial robots, medical field, and for humanoid robots. Generally, robot grippers are involved in the task of grasping of objects. However, it is not just limited to that. If the robot gripper is attached to a manipulator, it can be used for object manipulation and pick and place operation as well.

Robot grippers have different classification types. They can be classified based on the number of fingers, which includes robot gripper with two fingers [1], three fingers [2] with some even commercially available. Also, there are flexible [3] or multiple fingers [4], [5], and the most famous ones in the recent days is the grain filled flexible ball gripper (universal gripper) [6]. Another type of classification is based on actuation system. The grippers can be classified as tendon driven, pneumatic [7], vacuum [8], [9], electric, and hydraulic. Each has its own advantages and disadvantages as described in Table 1.

From Table 1, we can understand that the hydraulic actuation system provides high force output. This is useful for construction machinery and heavy-duty operation. However, in case of a sudden collision, we need to ensure safety which can be achieved through backdrivability. In most robotic systems, backdrivability is introduced with the use of series-elastic actuators [10]. The major problem in using this is the difficulty in design of elastic elements to damp the oscillations. By considering the problems, we use a different type of hydraulic system called electro-hydrostatic actuator (EHA) [11]. The principle involves using same number of pumps with actuator. This system provides ease of maintenance due to its modality and backdrivability due to absence of valves. This principle has been used in knee joint of robot [12],

Table 1. Different types of actuation system

Actuation type	Merits	Demerits
Tendon driven	Low weight	Complex to control, loosening of tendon with high force (low durability)
Pneumatic	Small size, low weight	Complex to control, high cost
Vacuum	Versatility	Cannot be used for complicated objects
Electric	Low cost, easy to control	Low force output
Hydraulic	High force output	High maintenance cost

wearable robot [13], and tendon driven hand [14]. We combine the advantages of EHA system with a different type of functional fluid called magnetorheological fluid (MRF).

Construction and heavy-duty operations which are currently being performed by human operators often involve cumbersome tasks and dangerous environments that are potential risks for the operators. The barrier to the automation of such tasks has been the development of versatile, powerful, and efficient grasping tools, i.e., robotic grippers. Grippers are also very useful for the teleoperation applications [15] where the human is moved away from an unsafe environment. Therefore, in these types of applications, it is reasonable to develop robot grippers. These robots must have high repeatability, speed, power, and most importantly, they need to be safe. As a preliminary study on human assistive robots, in this paper, we discuss the design and development of a powerful and backdrivable robot gripper which can be used to assist on-site human workers. As discussed previously, the backdrivability is essential to provide for safety. When a system is backdrivable, it can be pushed back to its initial position which will help in situation when there is an occurrence of collision.

To provide powerful output suitable for construction works, we adopt an oil-hydraulic-driven actuator. To provide backdrivability for geometric and mechanical adaptability, we adopt magnetorheological fluids (MRFs) as the working fluids in the actuation system. MRFs are a functional fluid that can changes its apparent viscosity, quickly, continuously, and reversibly, based on the strength of the applied magnetic field. MRFs largely affect the dynamic range of viscosity and response time, so we also discuss the use of special type of MRF which is suitable for application in construction robots because most of the current commercially available MRF is not suitable for robotic applications, and then we develop several MRFs suitable for robot grippers. Subsequently, we develop a small size vane type rotary actuator that consists of a passage in the vane and an electromagnetic circuit to efficiently apply the magnetic field to MRF passing through the passage. The backdrivability can change based on the current applied to the coil and output torque can change based on the flow rate from the pump to the electro-hydrostatic actuator (EHA) system. The EHA system gives us the merits of the electrical system of ease of control and hydraulic/hydrostatic system gives us the high force output. Finally, we develop a robot griper (similar to the size of human hands) with two fingers and the finger has three inter-connected joints actuated by one MRF actuator. The main advantages of our gripper are:

- High power output
- Safety due to backdrivability
- Ease of control and robustness

From preliminary evaluation experiments, we confirmed that the developed robot gripper could change backdrivability and output torque depending on the coil current and pump flow rate of the functional fluid.

The rest of this paper is organized as follows. Section 2 describes the functional fluid and design of actuation system and gripper. Section 3 reports the experiments that were conducted and describes the results that were obtained. Section 4 draws conclusions and discusses possible future work.

2 Design of Robot Gripper

In this section, we explain about the design of robot gripper with high output force and backdrivability. We make three distinction while describing the design process (i) functional fluid, (ii) actuation system, and (iii) gripper design.

2.1 Functional Fluids

The commercially available products are MRF-122EG, MRF-132DG, and MRF140-CG, respectively, and all these MRF are manufactured by LORD Corporation [16]. We previously developed compliant linear device using MRF [17]. They are differentiated by the number of magnetic substances present inside the oil suspension. When the commercially available MRFs are kept ideal for long time, in the system or outside the system, the magnetic substances inside it settle down. The settling takes place due to the gravitational force and leads to stability and dispersibility issues in MRF. Due to these issues, the MRFs cannot guarantee the reliability when precise control is needed. To overcome these shortcomings, we have developed a special anti-sedimentation type MRF. This MRF is more stable, more powerful, and hence more suitable for next generation human-coexistence robots. We discuss its development and related experiments in [18]. We use this anti-sedimentation type

MRF as the functional fluid for the actuation system.

2.2 Actuation System

We use an EHA system which consists of various components. Firstly, we have made a hydraulic vane type rotary actuator. The actuator uses MRF as functional fluid. The actuator provides a rotation of up to 90°. The upper drawing of Figure 1 shows the internal structure of the actuator. There are two ports, one inlet and one outlet. Both ports are connected to a single bidirectional hydraulic pump via a connector. The pump is responsible for pushing the MRF in and out of the actuator. Inside the actuator we have a vane which rotates when it is pushed by the fluid. We have a small space above the vane shaft. This gets filled with MRF and create a low friction fluid seal. This seal is created by fluid being always presented in the small gap at high pressure. When we fill the fluid inside the actuation system, we ensure that high pressure is maintained in it. Solid seal and no seal approaches have been tried before and they have resulted in problems such as low power, poor backdrivability, oil leakage etc. Hence, in our approach with this new type of seal, we overcome the above problems and achieve high response rate as well.

We have a small extension on the side of the actuator which is made of soft Magnetic Steel (KM-31) whereas, the rest of the actuator is manufactured using Aluminium (A2017). On this extension, we wound a coil to create an electromagnet which can switch ON/OFF using a control strategy. We use MRF as functional fluid which can change its rheology with the application of electromagnetic field as discussed in Section 2.1. Depending on the strength of the magnetic field, the fluid will change its properties. When the magnetic field is high, the flow rate is slow. When the magnetic field is low, the flow rate is high. The strength of magnetic field and flow rate are inversely proportional. The direction of the flow of MRF inside the actuator is solely controlled by direction of rotation of the bidirectional pump. However, the flow rate of MRF is controlled by both, the bidirectional pump and also the strength of the magnetic field. The system has high backdrivability because the end effector of the actuator can be pushed back to its original position in case of a contact with any obstacle.

The size of the actuator is 41 mm x 75 mm x 45 mm. The pump is connected to the rotary actuator using a connector. This connector is specially designed to have two ports to fill the MRF in the actuation system at high pressure. The bidirectional pump that we use is TFH-080 a small axial piston pump by Takako Inc. We selected it because it is small in size and produces a displacement of 0.80 cm^3 which is sufficient for our application. We use a small brushless DC motor which rotates the pump shaft in clockwise or anti-clockwise direction as per our need. We use Faulhaber BP4 with a planetary gearhead of type

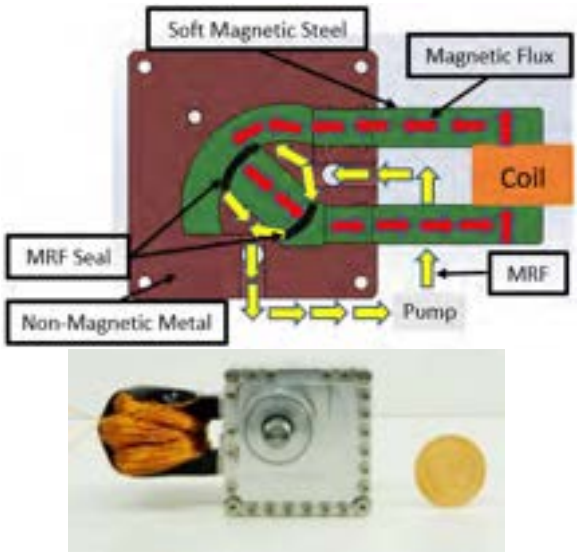

Figure 1. Vane type rotary actuator

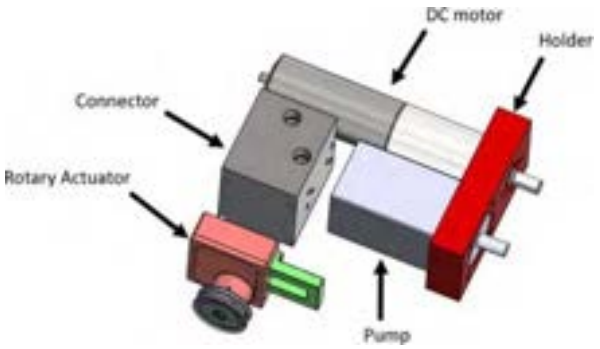

Figure 2. Exploded view of actuation system

32/3R. The pump and the brushless DC motor are attached to a holder and connected using timing pulley and belt. The exploded view of the actuation system is given in Figure 2.

2.3 Gripper Design

For the gripper, we developed two identical fingers. We designed this gripper with the following goals in mind:

- Efficient transmission of torque from actuator shaft to fingertip.
- Maximum contact between object and finger for an adequate grasp.
- Ability to grasp variety of objects.

The idea is to ensure that the object gets grasped by contact between the distal phalanx and the proximal phalanx with the extra support provided by the palm cavity created by the arrangement of the fingers in front of each other. The finger is designed using a six-bar linkage mechanism. The primary actuation is provided by a shaft

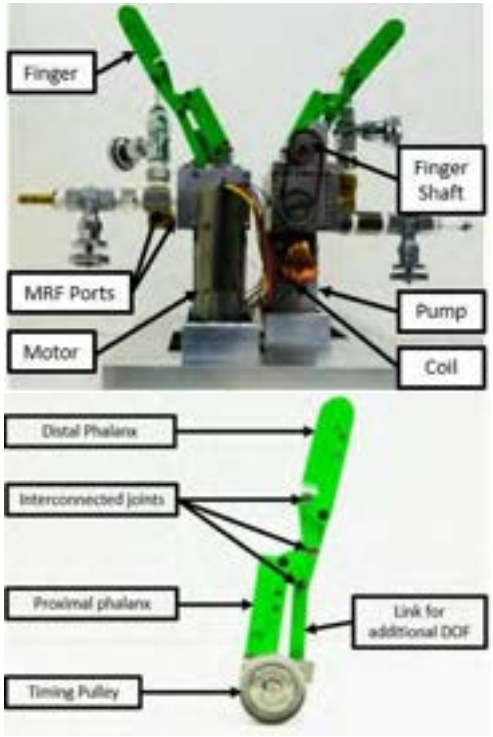

Figure 3. Gripper and finger design

which is connected to the actuator shaft via a timing pulley and belt. There is a holder which serves the dual purpose of supporting the shaft for free rotation and also as mechanical stoppage for finger. The stoppage ensures that the finger does not open beyond the angle of 120° when we want to use it for grasping objects. There is another link at the back of the finger which is responsible for transfer of actuation to the distal phalanges (fingertip). We use a clamp link to connect it with the main actuation shaft. For each of the fingers we achieve a two-degree-of-freedom (DOF) operation with one actuator. A robot gripper with fingers resembling the human finger is designed. Each finger has two phalanges giving two DOF because the motion of the proximal phalanx is directly coupled to the motion of the distal phalanx via a link. This is how we achieve underactuation. Figure 3 shows the gripper and the finger design.

For the rotation/ movement of link, we use hinge pin with ring which rotates over a bushing made of polyacetal resin. The hinge pin and bushing arrangement ensures that play maintained between the links is minimum. The links are made using Zortrax M200 Plus three-dimension (3D) printer.

3 Experiments and Results

We conducted two type of tests; torque test and grasping test. The first test is to evaluate the torque output at the actuator shaft. The second one is the grasping test in which we show the grasping operation of the gripper and evaluate the size limit in which the gripper can operate.

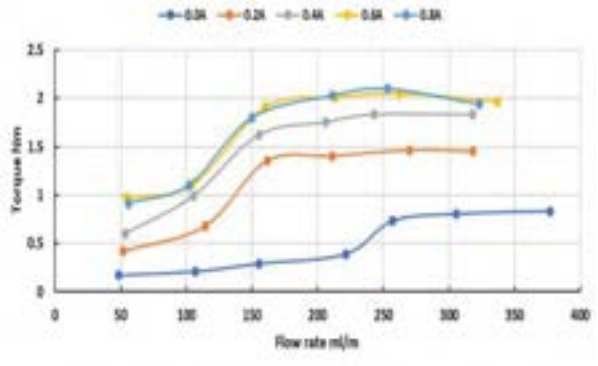

Figure 4. Torque v/s Flow rate

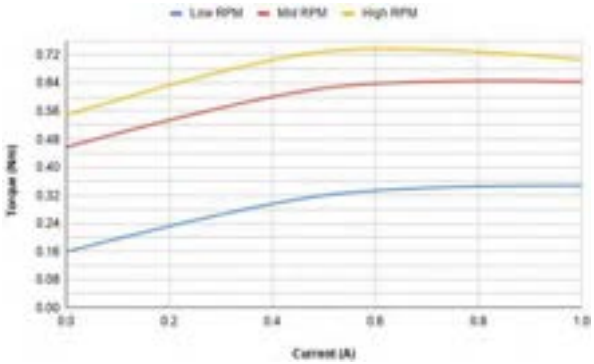

Figure 5. Torque v/s current

3.1 Torque Test

For this test, we measure the static torque at the actuator shaft by changing the speed of motor rotation. With pressure sensors, we measure the flow rate of the MRF inside the system. We plot the graph of torque (Nm) v/s Flow rate (ml/m). We use current control to switch On/Off the magnetic field. When the current is high the electromagnetic field is higher and vice-versa. We record values for the graph for current at 5 stages; 0 A, 0.2 A, 0.4 A, 0.6 A, and 0.8 A. We observe that the flow rate increases with increase in the speed of motor. The result is a non-linear relationship between torque and flow rate as shown in Figure 4. Also, we observe that the torque increases as we increase the current in the coil. This happens due to solidification of MRF inside the system. More force is required to achieve same flow rate when the MRF in the system has been solidified due to electromagnetic field. In Figure 4, we also observe a slight decrease in torque output at higher current and a state of stagnation after the achievement of a certain flow rate. We perform another torque test at a constant speed as we increase the current to electromagnet, as shown in Figure

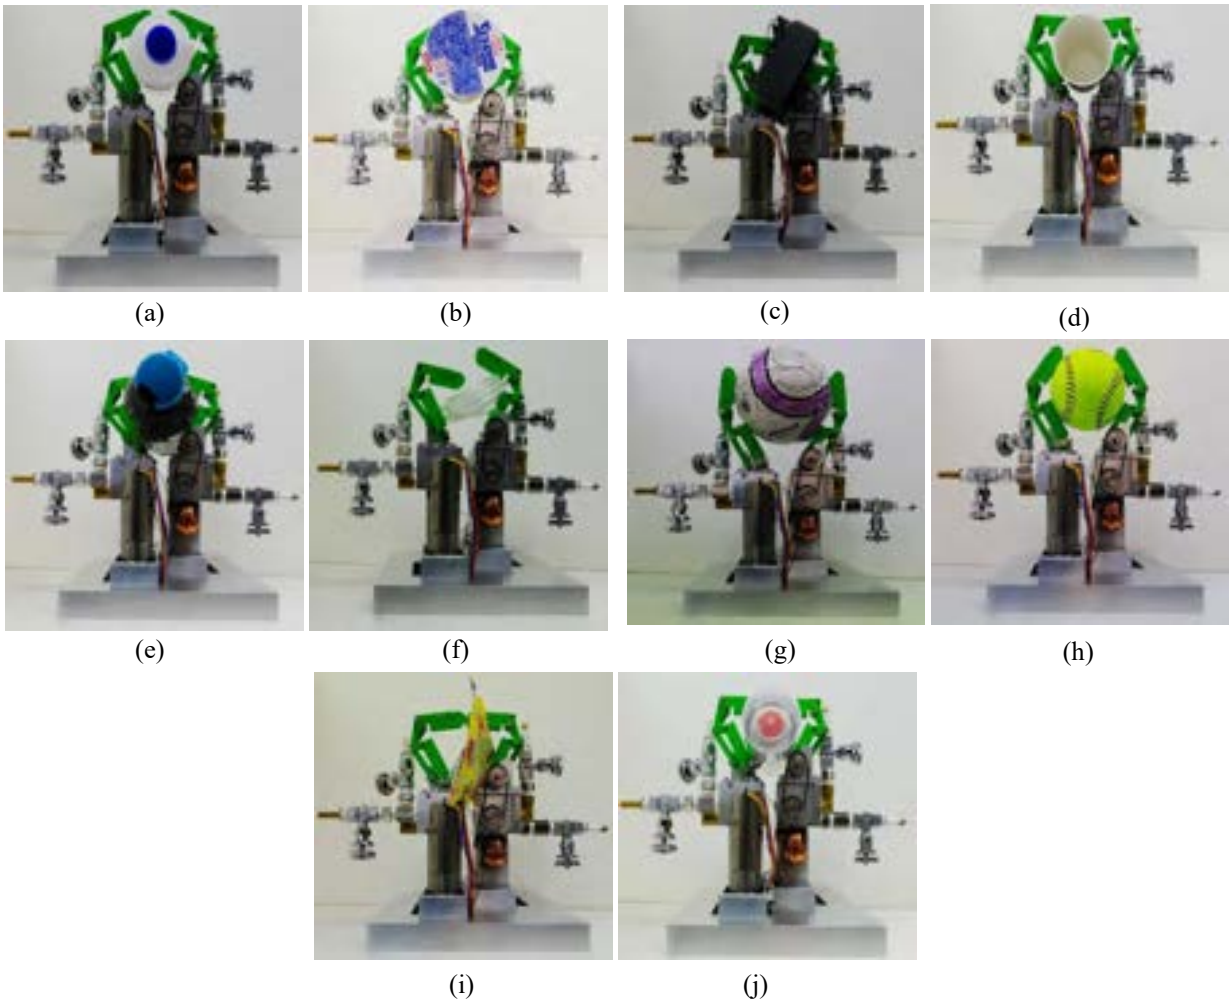

Figure 6. (a) small bottle, (b) cup noodles, (c) multi-meter, (d) cup (e), water bottle, (f) folded tube, (g) small football, (h) baseball, (i) detergent, and (j) spray can

5 to verify our observations. From the tests, we can conclude that the actuator can achieve a maximum torque output of 2.1 Nm.

3.2 Grasping Test

We perform the grasping test using different type of objects. Some of the objects that we used are (a) small bottle, (b) cup noodles, (c) multi-meter, (d) cup, (e) water bottle, (f) folded tube, (g) small football, (h) baseball (i), detergent , and (j) spray can, as shown in Figure 6. Our desired goal of grasping objects which are heavy is achieved. In some cases, like small objects which are heavy, the gripper is unable to grasp them. We believe that the reason this happens is because the size of the finger is large which renders grasping ineffective. Also, sometimes there is a difficulty in the grasping of objects which have a smooth exterior. The texture of the 3D printed distal phalanges causes this issue. With the use of an anti-skid tape on the phalanges, we solved this problem. We also tried removing object without opening the grasp. We did this to demonstrate reaction of the gripper for the condition in which object hits an obstacle/ collision during the process of grasping or pick and place. The gripper held on to the object based on the threshold value that we decided for constant grasping.

4 Conclusion and Future Works

This paper presented a robot gripper using electro-hydrostatic actuator (EHA) system. With the EHA system we combine the advantages of high power of hydraulic system with ease of control of electric system. As functional fluid, instead of using oil and conventional hydraulic fluid we use magnetorheological fluid (MRF) whose viscosity can be controlled by varying the magnetic field. We used a special type of MRF which is

suitable for robotics applications. Through this, we achieve speed and stiffness variation in finger motion. We explained the internal structure of the actuation system, the design of the finger and its working. We achieve backdrivability because of the design of our hydraulic actuation system. Hence, the system is safe. We performed Torque test and grasping test to verify our design and its functioning.

In future, we plan to work on a few key points. Firstly, to reduce the size of finger to increase the dexterity of object grasping and manipulations. This will help in making the gripper more robust. Also, we plan to use tactile sensors on phalanges. The sensor data can be analyzed and trained to be used for the purpose of object recognition in future applications.

Abstract –

Although the amount of building construction in Japan is not expected to decrease in the next few years, there has been a decrease in the number of fire resistive covering workers over the years. In this study, to overcome the shortage of construction workers, we developed a spraying robot for fire resistive covering. Optical sensors such as LiDARs and cameras may not work efficiently in dusty environments under spraying; therefore, we proposed a spraying method that would feasibly work without using them.

The robot is composed of traveling, lifting, and traversing devices, and a robot arm; it can move autonomously if a map of the working area is created in advance. We carried out several experiments to obtain the optimum spraying work data for each beam size in advance. Having the optimal spraying work data for each beam size, and grasping the position error and posture of the robot, the robot can spray accurately when sensing data for spraying is not available. By registering the work data in the work list according to the stop position and beam size, the robot can automatically spray multiple beams continuously.

We applied the developed robot to a building construction. After spraying, the shape of the sprayed covering was measured using a LiDAR, which verified the thickness. The specific gravity was observed to be higher than the regulation, and the quality was equivalent to that of workers. The spraying speed was approximately 80% of that of workers. In the future, the robot will have the potential of attaining the same construction speed as workers by making various improvements to it, as well as making it spray automatically.

Keywords –

Building Construction Robot; Fire Resistive Covering; Construction Automation; LiDAR

1 Introduction

In recent years, there has been a remarkable shortage of construction workers in Japan[1]. In particular, the number of workers for fire resistive covering spraying work in Japan has been significantly reduced because of poor working environments. In past study, the authors conducted a basic experiment of fire resistive covering spraying automatically using a robot arm and confirmed that the quality of fire resistive covering sprayed by the robot arm was equivalent to that sprayed by skilled workers[2]. As a next step, we developed a fire resistive covering spraying robot (hereinafter, spraying robot), and tested spraying. Subsequently, the spraying robot was applied in a construction site. This thesis describes the its development and results of its application.

2 Robot Development

2.1 Past Development Cases

In Japan, over 30 years ago, several companies had been developing spraying robots. Skilled workers taught those robots spraying motion and they could not move to the spraying position easily. However, the development was interrupted because the construction performance of robots were lower than workers[3]. There were various reasons for this, including the low level of technology at the time and the high cost of development and so on. In recent years, the robot arm has become cheaper, easier to use and an environment for easy development has been established. On the other hand, SLAM in the field of autonomous mobile robot has become available to anyone. There are two major methods of SLAM. One is a method using vision and the other is a method using shape matching with point cloud data. Both methods have been used in the construction field in recent years[4][5]. Therefore, we

decided to start the development of the spraying robot in-house.

2.2 Robot Specifications

In order to replace a spraying worker with a robot, we assumed the work system shown in Figure 1. We set a high technical level goal where the robot could move, align and spray automatically by itself rather than be operated remotely by a dedicated operator.

The developed robot is shown in Figure 2, and its specifications are shown in Table 1. Table 1 shows the applicable construction sites. The targets of the robot's spraying are the girders and beams on the standard floors of middle or high-rise buildings. The robot is relocated to the upper floors by a crane or a construction elevator. The size and weight of the robot are such that it can be loaded on the platform of the construction elevator (2500kgf class). Because the robot sprays for girders and beams at a raised place, a lifting device is indispensable. Because widening the spraying area improves work efficiency, we install a traversing device that can move in the beam direction. In the case of large spans (more than 20 m), the maximum girder height is 1.5 m and the floor height is about 4.5 m; therefore, the workable floor height is set to 5.5m with some margin. We install to a travelling devise four mecanum wheels that can be finely adjusted in all directions when positioning the spraying robot. This is because the robot may move slightly in all directions.

2.3 Robot Control

The parameters involved in the spraying control of the robot include spraying distance, moving speed, pitch, and angle. The set value varies depending on the part of beams (lower flange bottom, its top, its edge, web, upper flange bottom, its edge), and changes according to the required fire resistive time specification of the fire resistive covering (specified coating thickness). We created a program that automatically assigns these control parameters to each beam size (beam height, beam width, plate thickness), and automatically creates robot work files. If we have structural design data in advance, it is possible to create spraying work files for all girders and beams of any construction without teaching by skilled workers.

We conducted an experiment in advance to evaluate the optimum parameters that could be used to effectively spray each part of the girders and beams in terms of quality. The spraying robot moves to the set girder and beam locations and aligns to them within a threshold. The working data of the spraying robot is corrected according to its stopping position error. The robot was operated on these principles.

If we create the map data of working area based on the distance data of the surrounding shape acquired by the two 2D-LiDARs installed at the diagonal corners of the robot and the initial position of the robot is specified, the position and direction of the robot are determined by SLAM. It can be calculated in the map using a

Size	3.3 x 1.15 x 1.5 m
Weight	2350 kg
Workable floor height	5.5 m or less
Workable beam height	1.5 m or less
Maximum Spray Width	3.8 m or less

commercially available dedicated sensor.

2.4 Safety

Two 2D-LiDARs are installed to set the protection area and the alarm area; the robot stops when something breaks in the protection area, it slows down when in the alarm area. Additionally, a bumper sensor is attached around it to stop the robot when it contacts something. The situation when entering the set area and the operating status of the robot are clearly indicated by two warning lights, melody, alarm sound, etc, to make it easier for the surroundings to be understood.

2.5 Environmental Consideration

When spraying the fire resistive covering, a large amount of unwound rock wool discharged from the nozzle is scattered and suspended. For robots, there is a high risk that the scattered material will enter the joints and precision parts of the equipment and cause malfunctions. Therefore, to create an environment friendly to robot spraying, we developed the dust scattering prevention nozzle shown in Figure 3. By enclosing the discharged rock wool in a water mist, this nozzle can significantly reduce the amount of dust scattering and contribute to the stable operation of the robot. The results obtained from measuring the amount of dust scattering in the construction test confirmed that the amount was reduced to approximately one-third of the conventional spraying nozzle used by workers.

2.6 Spraying Experiment

After developing the robot, spraying experiments were carried out a few times at an in-house facility to confirm the thickness, and specific gravity of coverage sprayed by the robot. In the spraying experiments, the formation of high-quality coatings on each part of the H-section steel that is assumed to be a beam at a construction site, confirmed the robot control conditions proper. We also conducted an automatic construction test of the robot. Automatic construction is a series of spraying flow, in which the robot moves autonomously from the starting point to the spraying position, and after automatic alignment, sprays the fire resistive covering. In this test, we confirmed the optimum threshold value for the positioning error of the traveling device.

3 Application to a Construction Site

3.1 Purpose of Application

To collect the actual construction data, the robot sprayed the fire resistive covering on the girders and beams of a building construction site. Here, the actual construction data refers to the confirmation of sprayed quality, work efficiency, and verification of effectiveness of automatic construction.

Figure 4 shows steel girders and beams before spraying by the robot. Figure 5 shows the floor plan of the girders and beams to be sprayed, and Figure 6 shows the robot layout during spraying a girder. The spraying target was a total of thirty girders and beams with a floor height of 3.64 m and 1-hour fire resistive specifications. For both the girders and beams, the spraying area was divided into three to five parts on one side in the beam direction and sprayed at a total of six to ten positions on both of their sides. In each beam, a robot was placed on a line offset parallel to the center line, a traveling device ran in the girder or beam direction, and coating was sequentially sprayed onto the beam surface. The automatic construction procedure is shown below. The construction status is shown in Figure 7 and Figure 8.

1) Create a map of the construction area
2) Create a route for the autonomous movement of the

6) Spraying on the other side of girders and beams
After that, repeat 3) to 6)
7) Pressing sprayed fire resistive covering using trowel (by a worker)

3.2 Performance Assessment

We measured the fire resistive covering thickness and specific gravity of the sprayed covering after it was pressed by a worker using a trowel. The result of spraying girders and beams after pressing is shown in Figure 9. Two types of methods were used to obtain the measurements: randomly using a measuring pin, and overall using a laser scanner. Figures 10 and 11 show the measuring pin and laser scanner, respectively. The specific gravity of the sprayed covering was calculated

from the weight of the sample taken from the dry sprayed covering.

Figure 9. Girders and Beams After Sprayed

Figure 10. Measuring Pin

Figure 11. Laser Scanner

3.3 Application Results

3.3.1 Effect of Automatic Construction

To confirm the effect of automatic construction, we performed both automatic and manual construction. Automatic construction is a series of automatic running, automatic alignment, and automatic spraying. In manual construction, remote control is used to run, and align, whereas automatic control is used to spray. The construction efficiency between automatic and manual construction was compared.

3.3.2 Construction Quality

Figures 12 and 13 show the histogram and normal distribution of the measurement results of the covering thickness using a measuring pin. The average covering thickness was 45-50 mm, and both were well above the 1-hour fire resistive limit of 25 mm. The specified thickness of the girder and beam measurement points were exceeded at 97% or more.

Figures 14 and 15 show the measurement results of the covering thickness using laser scanners (typically between lines 4 and 5, and between lines 6 and 7 at the site). We obtained the measurements before spraying

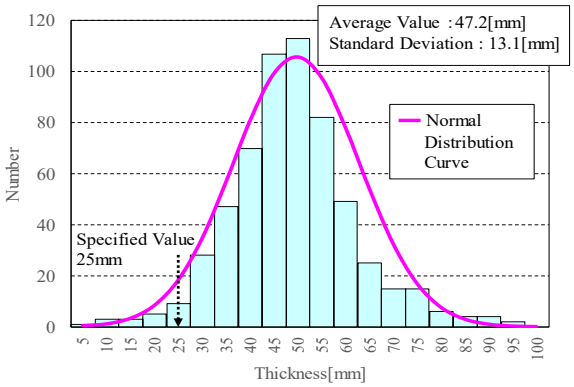

Figure 12. Results of Covering Thickness Measurement Using Measurement Pin (Girder)

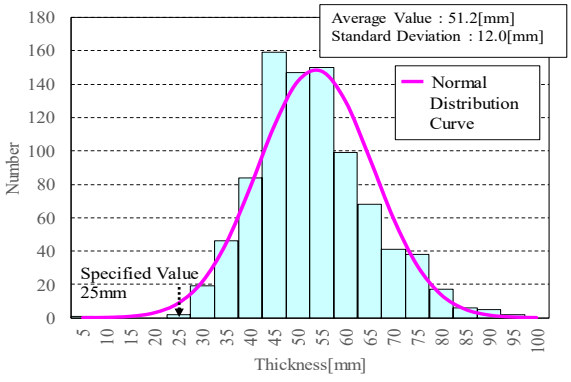

Figure 13. Results of Covering Thickness Measurement Using Measurement Pin (Beam)

the steel girders and beams, using a laser scanner. After spraying, we measured the surface of the covering again. After post processing the point cloud data, we calculated the difference between the point cloud data before and after spraying using software called CloudCompare. The heat map of the covering thickness calculated by this softwear is a view oriented from southwest to northeast. In these figures, the areas less than 25 mm of the an hour fire resistant specification are displayed in blue and the darkest green, and all other colors represent 25 mm thickness or more. A thickness less than 25 mm was found around the sleeves and around the stiffener of the north-south girder and beam joint, most of the other parts had a specified thickness of 25 mm or more. These data are consistent with the covering thickness measurements obtained using the measuring pin. After spraying using the robot, areas with insufficient thickness were repaired by workers.

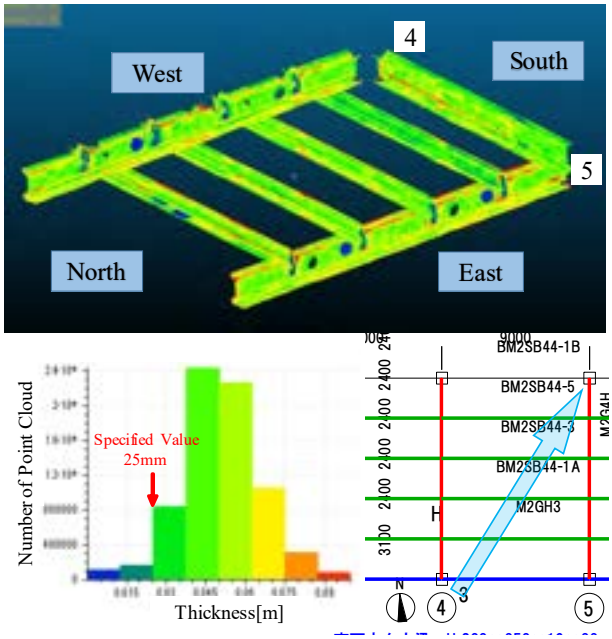

Figure 14. Results of Covering Thickness Measurement Using Laser Scanner (Between line 4 and 5)

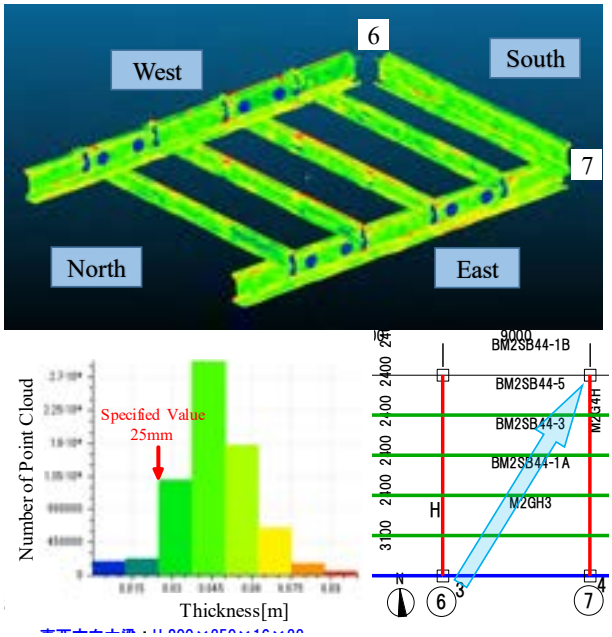

Figure 15. Results of Covering Thickness Measurement Using Laser Scanner (Between line 6 and 7)

The specific gravity measurement results were approximately 0.35-0.40, which did not fall below the construction management standard value of 0.28, during the entire construction period. There was no difference observed between the robot's manual construction and manual construction in both the coating thickness and specific gravity.

3.3.3 Working Time and Work Efficiency

Figure 16 shows the sprayed area per day of the automatic and manual construction. In this figure, the sprayed area per day of conventional spraying by a worker was set to 1. The sprayed area of the automatic construction was approximately 80% and the manual construction was approximately 50% of a skilled worker.

Figures 17 and 18 show the results of the automatic and manual construction, respectively. These figures shows the time ratio of spraying (=mondatory work), preparation/movement/alignment/nozzle cleaning (=subordinate work) and meeting/breaks (=other) when the time from beginning the work to the end of work is 100%. In manual construction, it took a lot of time to move and position the robot manually, and the spraying time per day (the net time when the material was discharged) was maintained at about 20%. In automatic construction, the spraying time per day was approximately 45%, which was an increase by roughly 25% compared to the manual construction. On the other hand, as shown in Figure 16, the sprayed area per day in automatic construction is around 80% of the necessary to reduce the time devoted to cleaning.

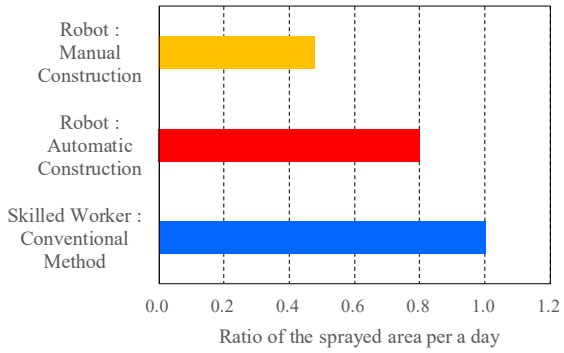

Figure 16. Comparison of Sprayed Area per Day

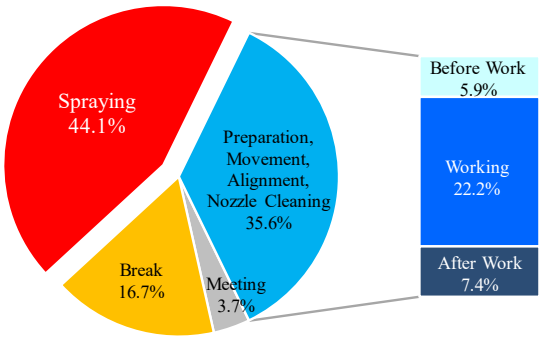

Figure 17. Working Time Analysis per Day (Automatic Construction)

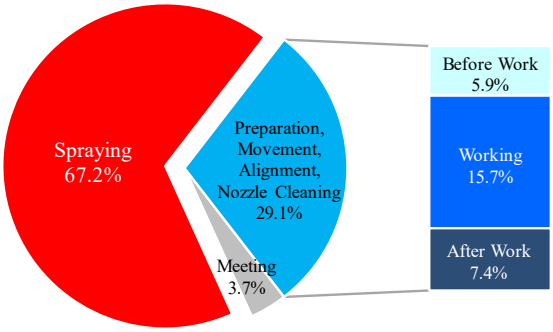

Figure 18. Working Time Analysis per Day (Automatic Construction with Improvement Plan)

4 Discussion

First, regarding the movement and alignment of the spraying robot, both were performed automatically and manually, and compared. Consequently, compared to the manual operation, the sprayed area per day in the automatic operation was improved by 70%. This indicates that work efficiency cannot be improved because movement and alignment take time by manual operation. So, it is essential for the spraying robot to travel automatically and to align automatically.

Next, regarding the measurement of the coating thickness, the measuring pin and the laser scanner were used in two ways. The normal distribution and average value of the covering thickness showed approximately the same value. From these results, the effectiveness of the measurement of the covering thickness by the laser scanner was verified. Because measurement using the measuring pin is manual work, a lot of man-power is required for post-processing. On the other hand, measurement using the laser scanner requires a long time for post-processing; moreover, it takes long time to obtain the results although most of the work is done automatically. From these strengths and weaknesses, work efficiency can be improved significantly by using the measuring pin to measure a part of area, getting immediate results, and obtaining the measurements later the rest of whole area by using laser scanners.

Finally, we describe the future productivity improvement. The nozzles were easily clogged with material, making the cleaning time long; thus, work efficiency did not improve. In the future, we plan to develop a new nozzle that does not require nozzle cleaning. It is also expected that this will improve work efficiency and exceed the sprayed area per day of skilled workers.

5 Conclusion

In this study, to save on labor in fire resistive covering work, a fire resistive covering spraying robot that sprays the fire resistive cover was developed through experiments and was applied at a construction site. The following findings were obtained.

1) The fire resistive covering sprayed by the robot at the construction site achieved quality results that satisfied the specified values for thickness and specific gravity.
2) The sprayed area per day of robot automatic construction is 1.7 times higher than that of manual construction. The effectiveness of automatic construction was confirmed.
3) Because it was necessary to secure the cleaning time of the spray nozzle, the sprayed area per day of automatic construction was approximately 80% of that of a skilled worker.
4) In the future, by developing a spray nozzle that does not easily get clogged by rock wool materials, and performing automatic construction, it will be possible to improve the sprayed area per day to a level equivalent to that of a skilled worker.

Abstract –

The installation of curtain wall modules (CWMs) is a risky activity carried out in the heights and often under unfavorable weather conditions. CWMs are heavy prefabricated walls that are lifted normally with bindings and cranes. High stability is needed while positioning in order not to damage the fragile CWMs. Moreover, this activity requires high precision while positioning brackets, the modules, and for that reason, intensive survey and marking are necessary. In order to avoid such inconveniences, there were experiences to install façade modules in automatic mode using robotic devices. In the research project HEPHAESTUS, a novel system has been developed in order to install CWMs automatically. The system consists of two sub-systems: a cable driven parallel robot (CDPR) and a set of robotic tools named as Modular End Effector (MEE). The platform of the CDPR hosts the MEE. This MEE performs the necessary tasks of installing the curtain wall modules. There are two main tasks that the CDPR and MEE need to achieve: first is the fixation of the brackets onto the concrete slab, and second is the picking and placing of the CWMs onto the brackets. The first integration of the aforementioned system was carried out in a controlled environment that resembled a building structure. The results of this first test show that there are minor deviations when positioning the CDPR platform. In future steps, the deviations will be compensated by the tools of the MEE and the installation of the CWM will be carried out with the required accuracy automatically.

1 Introduction

The European construction sector constitutes an immense market. It is one of the main industrial employers in the European Union, contributing about 9% of its GDP, with an annual turnover of more than €1,500 million and a direct workforce of 18 million people [1]. Despite the fact that the construction sector is a fairly traditional sector, trends such as smart construction, involving advanced materials, innovative processes and concepts and green approaches, are becoming more noticeable.

The curtain wall modules (CWMs) are the building envelope technological system which represents the boundary condition between indoor and outdoor environment with the goal to guarantee and preserve the designed building performances. For this purpose, the as-built façade needs to guarantee the correct installation of the CWMs to achieve the performance assessed by project specs detailed in the design phase and validated with tests conducted under EN 13830. This critical but fundamental moment of installation phase requires a full accomplishment of operative instructions to guarantee the performance achievement with a strict accuracy of its component installation. Indeed, because the CWM setting is a millimetric activity due to the absolute position of façade, the installation process and regulations guarantee that the as-built façade corresponds to the design. For this reason, even if some mechanical regulations are possible through specific façade's components (bolts, screws, anchors), installers today have a central role. In addition to the installation operations to guarantee the correct setting of the CWM in line with project specs, other relevant issues related to site activities need to be managed such as risk control,

preservation of the safety of personnel involved, and correct maintenance of the equipment used. The safety of personnel involved in all site activities (not only the one responsible for façade) is the most crucial aspect. The safety procedures are independent of specific building components, but related to general principles to be pursued for each activity during site operations based on national and local norms. In this frame, façade related risks (e.g., lifting materials, equipment placement, exclusion zones, falling restrain for personnel and material, weather condition during lifting operations) are some of the risks to be considered during CWM installation to preserve the safety operation of the site activities. In this scenario, to pursue the quality of installation while reducing its risk to preserve the site personnel's safety, automation through robot is an opportunity worth being investigated.

In order to cope with these issues, different robots for installing, painting, cleaning, delaminating, maintaining and inspecting any kind of facade were developed in the past. More specifically, several robotic devices have been classified for façade module installation [2]. Besides these single task robots, on-site factories like ABCS [3] and SMART [4, 5] developed techniques for installing fully prefabricated façade modules during the erection of new buildings. Apart from façade modules, there were experiences in on-site assembly of walls like in the Rocco project, in this case, for assembling building blocks [6]. Lee et al. [7] developed a robot on top of a platform that helps the human operator to handle a CWM. The most recent instance of the installation of a façade module with a robot dates to a manually operated robotic crane [8]. Test results show that in worst case the achieved repeatability of handler end-effector positioning is 7.0 mm. This result might not be sufficient for the installation of CWMs. Regarding the cable robots for installing façade elements, a tendon suspended platform robot was envisioned [9], but the definition degree of that solution did not show further detail, especially regarding the necessary cranes to support the loads and forces of the cables. Moreover, that solution did not show any type of on-board tools.

Cable-driven parallel robots (CDPR) are a subclass of parallel robots [10]. Instead of rigid links, they use cables to manipulate a mobile platform. The principle is to drive a mobile element in up to 6 degrees of freedom (DOF) by attaching cables to the mobile element and by synchronously controlling their length from a base frame with winches. At least 6 cables are required for controlling all 6 DOFs of the load, while often no more than 8 cables are used for better performance. The most well-known example of such robots is aerial cameras for stadiums [11] working with 3 DOF and 4 cables, and the first concept for manipulating all DOFs of a load dates back to the 1990s [12]. Today, they have already proven their benefits, in particular for large scale industrial applications [13, 14, 15]; indeed, the principle of a CDPR can be adapted to move heavy payloads over large dimensions. For the same reasons, CDPRs have being theorized in the past for several construction applications, from manipulating elements, contour crafting, to building inspection [9, 16].

In the HEPHAESTUS project, a redundantly constrained cable robot was built. The redundancy of using eight cables to control the six degrees of freedom of the platform increases the available workspace volume. Only few related works involving cable robots in the field of construction can be found. In [17], a concept for a cable robot for large-scale assembly of solar power plants is introduced. In [18], a cable robot concept for a contour crafting system is described. In [19, 20], cable-robots for automated brick laying can be found.

The work performed within the HEPHAESTUS project [21] features for the first time that a CDPR is designed, built and deployed specifically for the construction sector, with the primary purpose of installing CWMs, which encompasses two main tasks: bracket installation and module installation. The advantages of cable robots in HEPHAESTUS are their large workspace, high payloads, reconfigurability and modular components, which make it easily transportable.

2 Concept description

The aforementioned tasks (bracket installation and module placement) require high relative and absolute accuracy. To accomplish such accuracy, it is necessary to foresee the precision of the CDPR, which was estimated to have a tolerance of 40 mm [22] in previous phases. Therefore, in previous stages of the project, it was foreseen that there would be two means for installing the CWM: the CDPR for the rough positioning and the Modular End Effector (MEE) along with its tools for the fine positioning.

2.1 CDPR

From a geometrical point of view, a CDPR is an association of cables of variable lengths linking a drawing point attached to base frame, and a fixing point attached to the mobile element or platform. How these drawing and fixing points are positioned in space, respectively in the general frame and the mobile platform frame, and how they are connected together formulate a configuration.

2.1.1 CDPR calculation

The geometrical design of the CDPR presented in Figure 1 can be summarized as the definition of the following parameters: (i) number of cables, (ii) geometry of the structure, (iii) geometry of the platform, and (iv) cable configuration. Based on previous studies indicating

that CDPRs driven by eight cables have appropriate performances [23], this number of cables was chosen. The parameters (ii) and (iii) are defined by the positions of the drawing points and attachment points respectively (see Figure 1). The cable configuration (iv) defines the pairs of drawing and attachment points that are connected by cables. Therefore, significant efforts in the design of this CDPR were dedicated to the definition of an appropriate set of parameters (ii), (iii) and (iv).

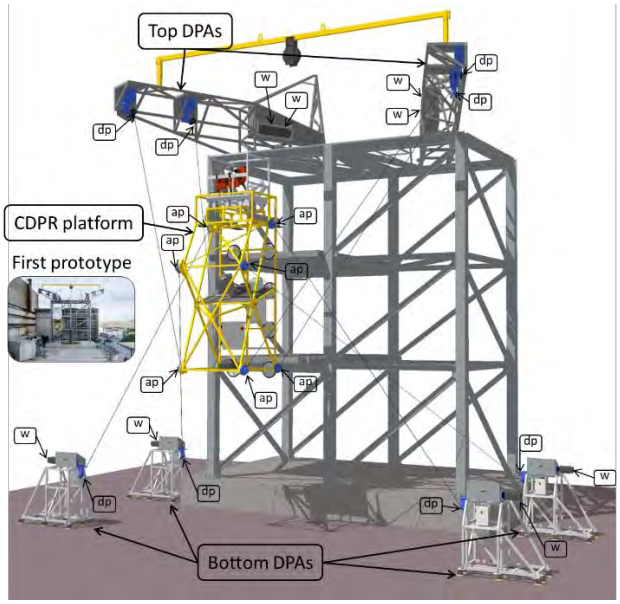

Figure 1. Hephaestus CDPR prototype

The abstract goal of finding an appropriate set of parameters was formulated as an optimization problem. The cost function of the proposed optimization problem is the maximal cable tension, directly linked to the Safe Working Load (SWL), obtained during operation across the building facade. The choice of this cost function is motivated by the direct relationship between the SWL and the cost of the machine. Minimizing the SWL leads to minimizing the maximal loads that are applied on the mechanical parts of the CDPR and, therefore, the cost is minimized. In addition, the constraints of the optimization problem include the positioning accuracy which should meet the precision necessary for the installation of the CWMs. Further details on the geometrical optimization of the Hephaestus CDPR prototype can be found in [24].

2.1.2 CDPR hardware

The Hephaestus CDPR is composed of 7 subassemblies. The first set of subassemblies provides the means of controlling the lengths of the cables. These subassemblies are fixed to the building, which works as the base frame for the robot. They are called drawing point assemblies (DPA in Figure 1) and come in two types. The first type is fixed at ground level, materializing the lower drawing points (dp in Figure 1) of the proposed configuration (one per assembly). The second type is attached to the building top slab. Each top DPA materializes two among the top drawing points. There are, therefore, two top DPAs and 4 bottom DPAs (see Figure 1).

Each drawing point need a winch, a swivel pulley at the location of the drawing point, and a force sensor for monitoring the cable tension. The components are the same for all drawing points. The travelling sheave winches (VICINAY winches WB21.L30S.1: SWL 15.7 kN, drum torque 2128 Nm, velocity 30 m/min, cable travel 16m, see w in Figure 1 and Figure 2) are powered by a servomotor with brake and absolute multi-turn encoder integrated, associated to a gearbox and wire rope spooling mechanism synchronized with the grooved drum.

The swivel pulley installed at the theoretical location of the drawing point rotates around a vertical axis; it guides the cable towards the matching fixing point. The force sensor is embedded in the shaft of the sheave directing the cable from the winch to the swivel pulley. The steel wire rope is a Ø11mm non-rotating cable with a minimum breaking load of 115.5 kN.

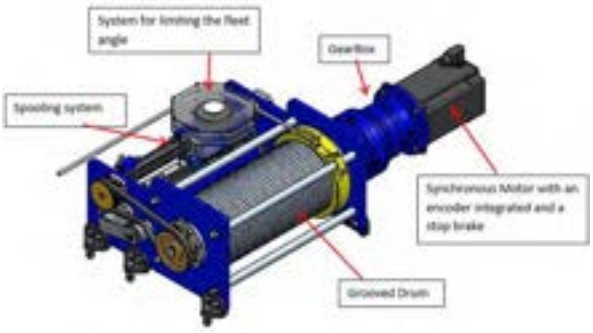

Figure 2. CAD view of the VICINAY Winch WB21.L.30S.1

The mechanical structure of the DPAs is designed in order to transfer the load from the swivel pulleys and the winches to the anchoring elements. They were designed to show a displacement of less than 50 mm at the drawing point location when loaded with the winches' SWL. Steel anchorage plates are embedded during the construction of the concrete building in the third (top) slab. The supporting structures are later welded to these anchorage plates in the correct position so that the DPA are in the correct coordinates with the required tolerances, with the drawing point positions being monitored continuously by a surveyor with a total station

Another CDPR subassembly is the platform (see Figure 1 and Figure 5). It features the 8 fixing points

placed accordingly to the dimensions set in the configuration, as well as the various tools and power systems for the MEE. The total weight of the fully loaded platform reaches 1460 kg, in which 350 kg accounts for the carried CWM.

The norms applied during the design are ISO 4301, ISO 16625 and FEM 1.001. All elements have been designed with a safety factor of at least 5.6 in order to match the M5 mechanism group requirements.

The final CDPR subassembly is a weatherproof electrical cabinet housing the central control unit. It features the servomotor drives, the associated power units, the central PLC where the central control is implemented, and the associated inputs and outputs acquisition system. The cables towards the platform (data and power) are directed to it by means of a cable chain mechanism fixed to a beam installed between the two top DPAs.

2.2 MEE and its components

The MEE is the set of tools that performs each of the activities necessary for installing the CWM onto the structure of the building. The MEE is fixed to the CDPR platform (see Figure 5). In the case of the HEPHAESTUS project, two main activities need to be performed. First, there is the fixation of the bracket onto the concrete slab. This task is achieved by a robotic arm. Second, there is a placement of the CWM modules onto the brackets. This task is achieved by a vacuum system attached to the CDPR platform that picks a CWM from an inclined magazine and releases the CWM when it is placed onto the brackets.

2.2.1 Robotic arm and its tools

Selected tools need to be manipulated by the robot in order to mount brackets to hold the CWM to the building. The most versatile method is in-situ mounting and this was the chosen approach in this project. The list of actions needed to be handled by the robot is concluded: drilling of holes for anchor bolts, picking and placement of bracket over holes, picking and placement of anchor bolts in holes, setting of bolts into holes, and tightening of anchor bolts nuts to set torque. A Universal Robots UR10e was selected as the tool manipulator. This was done based on previous experience with this robot and its possibilities and limitations, specifically regarding drilling in concrete. The robot arm also allows for excellent adaptability to changes based on underway project learnings. The arm was mounted on a custom structure made of profiled aluminum bars. A tool-changer system was integrated to give the robotic arm the possibility to manipulate a variety of tools.

Four tools were put together to achieve the needed customized functionality: 1) the drilling tool, 2) the bracket picker and holder, 3) the setting tool with a hammer function, and 4) a tool to torque the nut of the anchor.

The cycle is completed by the robotic arm returning to the bracket holder, and releasing the vacuum and magnets from the slab and bracket correspondingly, before the bracket holder is returned to the tool dock.^

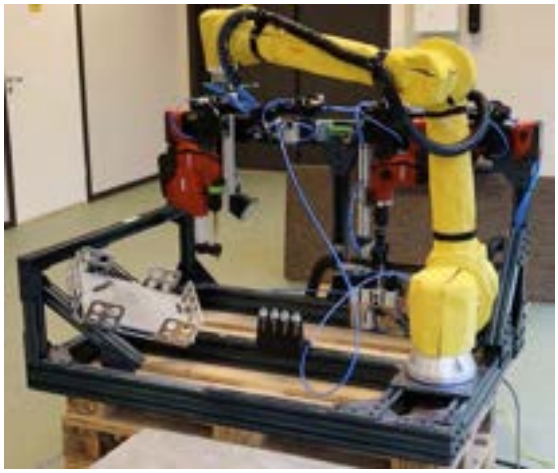

Figure 3. Robotic arm and its tools before mounting on the CDPR platform.

2.2.2 Stabilizer of the robot's frame

One of the issues regarding the accuracy of the robotic arm relied on the stability of the frame that hosts the robotic arm and its tools while performing tasks.

For achieving such needs, a linear system with vacuum cups was defined, tested and prototyped. This linear system was conceived for hosting forces of up to 1500N.

Figure 4. Stabilizer of the robot's frame prototype during the opening of the stabilizers.

The linear system consisted on two subsystems: the linear actuators and the machined steel profiles (see Figure 4) that run along the rails with the help of carriers.

2.2.3 Vacuum Lifting System for picking and placing the CWM

The Vacuum Lifting System (VLS) is capable for

picking and placing the CWM of 350kg during operations that require inclined plans.

The VLS is designed to grip, in vertical position, a CWM of the aforementioned mass, with a smooth glass surface, and a surface A_{zx} of 5.1m² . The CWM is a parallelepiped with three different faces $A\,(A_{yz}, A_{zx}, A_{xy})$ perpendicular to x, y, z axes with values $A = (0.68 \quad 5.1 \quad 0.3)^T m^2$ and showing a maximum aerodynamic coefficient c_a at 1.32. It would be possible to work in both dry and wet states, without ice, with the friction coefficient being estimated 0.2 (μ in *(3)*). The VLS is dimensioned to lift a load greater than or equal to twice its design load with the minimum relative vacuum pressure q_r. Finally, the altitude should be at least 900m from sea level, the temperature between -5 to 40 ºC, and accordingly the wind pressure q_w during service is estimated lower than 125N/m² and the vacuum differential pressure q_r at least equal to 600 mbar. The system creates a grip force f_g between the surfaces of the CWM and those of the $n = 8$ suction cups, showing a diameter d of Ø360 mm. The total load solicitation vector $\boldsymbol{s}$ is the sum of: the CWM mass m multiplied by gravity vector g, and by acceleration $j = (1\ 1\ 1)$ m/s² due to the movement, and the forces due to the wind action f_w, each factorized with the applicable partial safety coefficients ($\gamma_p = 1.1$), which are expressed as follows:

$$f_g = n\frac{\pi \cdot d^2 \cdot q_r}{4} = 48.86\ kN \qquad (1)$$

$$f_w = c_a \cdot q_w A = (112 \quad 841 \quad 50)^T N \qquad (2)$$

$$s = \left(\frac{m(g+j)}{\mu \cdot (1\ 1\ 1)^T} + \frac{\gamma_p \cdot f_w}{(\mu \quad 1 \quad \mu)^T}\right) = \begin{pmatrix} 2.52 \\ 2.52 \\ 20.8 \end{pmatrix} kN \qquad (3)$$

The current VLS design is validated by f_g being greater than twice any component of $\boldsymbol{s}$.

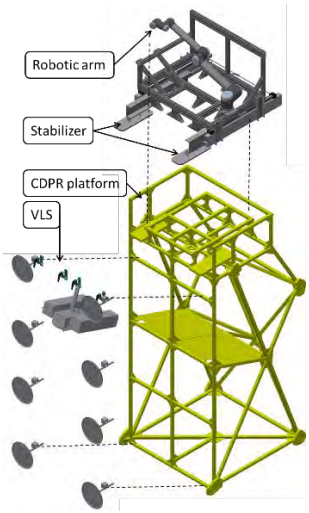

Figure 5. location of the MEE on the platform.

The VLS, and its warnings and safety measures are connected to the Beckhoff control and therefore it can be activated automatically as explained in the next section.

2.3 Control system

In Figure 6, the scheme of the hardware and wiring of the HEPHAESTUS robot is shown. The system consists of 4 PCs in total. Starting from the left side in the scheme, a standard PC is used to execute a software tool to automate the façade panel installation. This tool commands the steps in the correct order to mount the facade modules. Furthermore, it provides a GUI for the operator to control the whole HEPHAESTUS robot. It is connected to a total station via TCP/IP, which can measure the absolute pose of the cable robot platform and to the IPC on which the cable robot controller is running. The cable robot controller is based on the TwinCAT 3 software from BECKHOFF [25]. It consists of a soft-PLC and a motion controller. The latter can either be a Beckhoff CNC, or an advanced motion controller. The IPC is connected via WLAN (CANopen) to the Radio Control, via Ethernet (EtherCAT) to the safety sensors, I/Os, force sensors and drives.

Furthermore, the IPC has an Ethernet (EtherCAT) interface to the IPC of the MEE, which is integrated within the EtherCAT network as an EtherCAT slave. On the MEE IPC a PLC is implemented to control the MEE system consisting of the ROS-PC to control the UR-Robot, the stabilizer, and the vacuum system.

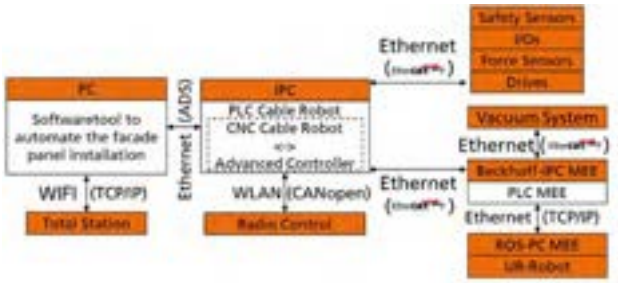

Figure 6. Scheme of the hardware and wiring of the HEPHAESTUS cable robot.

The main application controls the interactions between the user and the main controller. The application UI shows cable robot data, such as cable tensions, and each state the robot is performing in real time. It also allows the user to intercept each state, pausing the operation, or to stop the task. It is connected to the cable robot controller, allowing the user to move the cable robot and see the state the cable robot and the MEE are in at any moment, allowing the user to operate and control it, and the total station controller, allowing the user to obtain position and rotation measures at will.

A precise kinematic model is necessary in order to guarantee a satisfying positioning accuracy of the CDPR. Since the pose of the platform is computed based on the winch motor positions, cable sagging and elongation may be considered [26]. Among other aspects related to the position tracking control for CDPRs, these are still ongoing research subjects addressed in this project.

2.4 State Machine

The main controller is designed to operate as a state machine that controls all the individual controllers. Likewise, it is designed to work separately from the UI, merging the real time environment with the UI thread, and it controls all the error controllers to broadcast individual error signals. There are two main operations that the robot must do in order to complete the CWM installation successfully: first drill and set the brackets in the correct positions, and then set the CWMs in the corresponding brackets. To do both of them there are several states that the controller must follow, each one of them linked to a specific controller (cable robot control, MEE control or total station control). Each state, as shown in the simplified state machine diagram (see Figure 7), has an optional breakpoint where the user can stop the operation if a malfunction is detected. Besides these two main operations, the state machine contains also the semi-automatic initialization states of the total station.

3 Prototyping and tests

The first demonstration tests were performed in TECNALIA facilities in Derio, Basque Country (Spain). Once all the components of the demonstrator were installed, the operation of all the components (motors, movement of the robot, positioning in relation with the steel structure, sensor, etc.) was verified. This was the first time the different elements of the robot (winches with cable pulling on the platform/base) and the higher-level control of the robot that makes the coordination of the winches were put together.

3.1 Building structure used for the demonstration

For this purpose, a steel structure has been erected matching the foreseen dimensions of the demonstration building: 10.2m high, 8.80m wide, and 2.7m deep. Two concrete slabs have been installed at the first and second floor to perform all tests required for installing one CWM.

The steel structure has features to accommodate the top DPAs on the top floor; the bottom DPAs are directly anchored to the ground (Figure 1).

The higher platform empty weight more than expected and the SWL lower than originally planned (respectively 1110 kg instead of 910 and 15.7kN instead of 20) led to the nominal transit positions of the top row of panels not being accessible. The transit distance for the top floor panels therefore needed to be reduced from 600 to 450 mm.

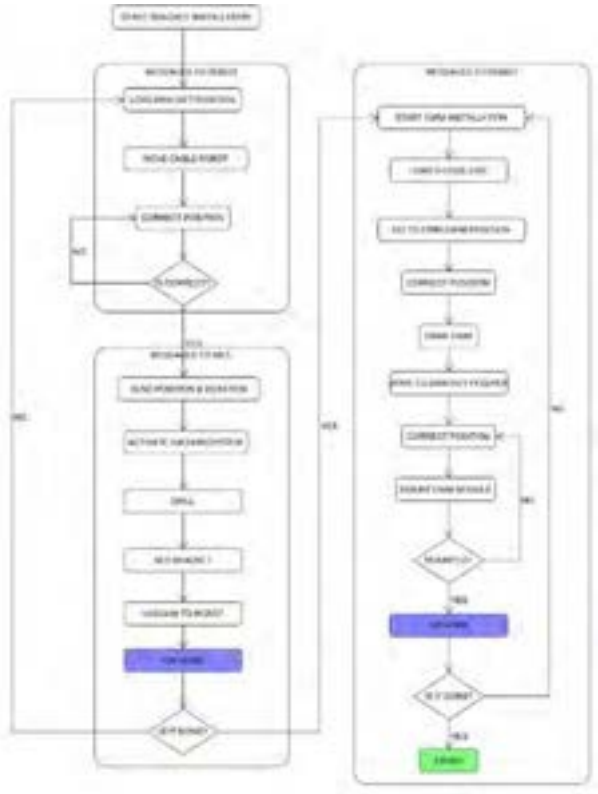

Figure 7. Simplified state machine diagram

3.2 Installation of the CDPR

After the erection of the building, the DPAs, mobile platform and control cabinet were brought to the building site. The top DPAs (2500kg each) were installed on the building top floor by the means of a mobile crane. The bottom DPAs (1100kg each) can be moved around using a forklift. Once the DPAs have been installed, calibration must be carried out.

Calibration of the drawing point positions is performed thanks to the integration of total station targets onto the swivel pulley assemblies. Each swivel pulley assembly features 4 targets; their positions are used to build a local frame to reconstruct the current position of the associated drawing point. In order to calibrate the full system, apart from the A and B points, there are 3 Leica 360º targets [27] attached to the cable robot platform in order to track it on the move, 3 Leica 20x20 mm reflectors attached to the cable robot platform in order to calibrate the origin point of the MEE with respect to the cable robot platform frame, and at least 3 Leica 20x20

mm reflectors to triangulate the building from the total station. It is highly advisable to calibrate all the prism and reflectors at the same time to achieve best possible accuracy.

The calibration procedure has been performed at the same time as the installation of the DPAs, with the drawing point positions being monitored continuously by a surveyor with a total station. The objective was to have the DPAs installed as close as possible to their theoretical positions: the distance to the theoretical positions was measured at maximum 19mm.

3.3 Results

The first results of the demonstration show a better performance than expected in previous phases of the research project (see Figure 8 and check video in [21]). The maximum position error of the CDPR is about 20mm and the max orientation error about 0.8deg. Moreover, the preliminary results show a promising repeatability (with an accuracy of 1-2 mm) of the CDPR while moving the platform within the workspace. However, more tests are necessary to define better this parameter. The deviations in respect to the desired position were supposed to be adjusted by the MEE while fixing the brackets. However, due to time constrains during the installation of the CDPR and the MEE, some calibration issues appeared and the transformed of the MEE with regard to the 0,0,0 point of the building was not achieved properly. For that reason, some deviations occurred during the placement of the bracket. This is a topic that will be improved in the next phase.

Figure 8. MEE and CDPR in operation as in [21]

4 Conclusions and future work

The first test of a CDPR for installing CWMs was achieved with better than expected results. However, there are still some points that need to be improved:

- Improve the calibration of the MEE in regards with the building in order to achieve a better accuracy.
- The detection of the CWM while it stands on the magazine and measuring its location.
- Detection of the brackets that are already fixed on the building slab in order to adjust, if necessary, the CDPR path while placing the CWM.

In order to seek for future commercialization, a market research was carried out which found a growing awareness from building owners and residents about comfort and health as well as political and economic drivers (e.g: nZEB and other EU directives, incentive schemes and favorable tax regimes, especially for green construction). Technological innovations will complete these drivers, making investors, policymakers and professionals (i.e. architects, designers as well as façade manufacturers) accelerate the adoption of construction robots. Therefore, the goal is that in the coming years the innovations mentioned in this paper will reach the market with the following exploitable results: i) CDPR for vertical works: suitable for handling, moving and placing CWMs; ii) MEE: including several tools to automate the insertion of a connector onto the building´s structure; iii) curtain wall adapted to robotic installation: for fixing elements of the CWM to slab; CWM to bracket; and connection between CWMs; and iv) Hephaestus system: as an integrated solution for handling and installing CWMs. To facilitate commercialization of new device categories, standards can do the following:

1. Standardize the components and interfaces from which it is made in order to allow for faster development and efficient supply chains ("interoperability").
2. Standardize the processes and infrastructures surrounding the new technology or product/service.
3. Ensure quality and efficiency of the technology and/or its development processes in order to minimize the risks for the involved stakeholders.

During a final demonstration stage of the project, the robot will complete the installation of a set of CWMs covering part of the façade of a demo building particularly built and enabled for these activities. This demo building has been erected in the machinery park owned by ACCIONA and is located in Noblejas, Toledo (Spain), so that the performance of the cable robot can be demonstrated in a real construction environment. The emo building was erected with three floors and a total height of 10.2 m, and the façade is 8.5m wide. To access the various floors of the demo building during demonstration activities, a staircase has been installed on the back side of the building where no facade panels will be installed. The Hephaestus system will be validated, among other performance indicators, in terms of time required to complete the operations for the CWM placing, the accuracy, the efficiency and the usability for workers of the construction sector. Also, special care will be taken in order to fulfil the safety requirements and recommendations for these robotic operations.

Abstract -

Collaborative robot (co-robots) are being increasingly deployed on construction sites to assist human workers with physically demanding work tasks. However, due to inherent safety and trust-related concerns, human-robot collaborative work is subject to strict safety standards that require robot motion and forces to be sensitive to proximate human workers. Robot simulations in online digital twins can be used to extend designed construction models, such as BIM, to the construction phase for real-time monitoring of robot motion planning and control. Robots plan work tasks and execute them in the digital twin simulations allowing humans to review and approve robot trajectories. Once approved, commands can be sent to the physical robots to perform the tasks. This paper discusses the development of a system to bridge robot simulations and physical robots in construction and digital fabrication. The Robot Operating System (ROS) is leveraged as the primary framework for bi-directional communication and Gazebo is used for robot simulations. The virtual robots in Gazebo receive work tasks from a BIM model to plan their trajectories, and then send the commands to the physical robots for execution. The system is implemented with a digital fabrication case study with a full-scale mobile KUKA KR120 six-degrees-of-freedom robotic arm mounted on a track system for an additional degree-of-freedom, and evaluated by comparing the pose between the physical robot and the virtual robot. The results show a high accuracy of the pose synchronization between two robots, which provide the opportunity for further deploying to real construction sites.

Keywords -

Digital Twin; Co-robots; Robot Operating System; Human-robot Collaboration

1 Introduction

Due to the 3D characteristics of construction work (dull, dirty, and dangerous) [1], construction sites can be hazardous and harmful working environments for human workers. The construction industry ranks the highest in occupational injuries and fatalities across all U.S. industries [2]. Robots deployment on construction sites can help relieve these issues [3]. For instance, the construction robot can group with human workers on job-site to assist with physically demanding tasks, while human workers focus on the work process plan and decision-making [4]. However, such human-robot collaborative work suffers from safety and trust-related concerns [5, 6], and is subject to strict safety standards [7]. For example, the robot must be restricted for speed and force while collaborating with nearby human workers. A real-time human and robot tracking system can ensure safety by providing the information of the robot state to human workers [8].

The Digital Twin (DT) offers opportunities to virtually mimic the conditions of the physical (real) environment in allowing for a cyber-physical system (CPS) [9] where information of the current and forecasted future states of the robot can be displayed [5]. Figure 1 shows the physical robotic arm and its Digital Twin. Madni et al. [10] defined four levels of Digital Twin (Pre-Digital Twin, Digital Twin, Adaptive Digital Twin, and Intelligent Digital Twin) based on the level of intelligence. The Adaptive Digital Twin combines user interface and machine learning with normal DT, whereas the Intelligent Digital Twin further utilizes reinforcement learning to process the state in a partially observed and uncertain environment.

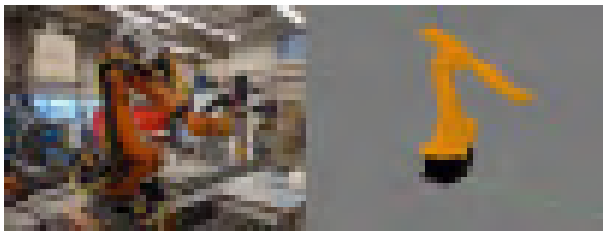

Figure 1. The physical robotic arm (left) and its Digital Twin (right).

One of the major aspects of the DT is the synchro-

nized model [11]. The DT first constructs the virtual model based on the physical environment, then records and tracks the changes in the physical environment and reflects them in the virtual model. The virtual model can be extracted from the designed construction model such as BIM or scanned 3D point cloud of the as-built environment [12, 13]. On the other hand, a communication mechanism is required to synchronize the data between the physical environment and the virtual model [9]. The communication is bi-directional so that the virtual model can reflect the changes of the physical environment, and the user can determine the next steps in the virtual model and send the command to the physical environment.

To address the issue of human-robot collaboration in construction work, we develop an online Digital Twin system to bridge the virtual robot and physical robot in construction and digital fabrication. We utilize Robot Operating System (ROS) [14] to construct the framework of the system and create a robotic arm model representing the physical robotic arm in Gazebo simulation environment [15]. In terms of bi-directional communication, we use MQTT [16] to connect the virtual robotic arm with the physical robotic arm. The mechanism of checking the synchronization between the physical robotic arm and the virtual twin is also developed. The proposed framework can be adapted to any robotic arm models reflecting physical robots. We implement the system in a fabrication laboratory with a full-scale mobile KUKA KR120 six-degrees-of-freedom robotic arm, and evaluate by comparing the pose of the physical robotic arm with the virtual robotic arm.

2 Related Work

Digital modeling methods, such as 3D visualization or BIM, are used in the construction industry for design, management, and operation throughout the building life cycle [17, 18]. These modeling methods document the project information and provide a platform for stakeholders to record changes, collaborate and resolve conflicts [19, 20]. In order to achieve a high-quality collaboration, the model must be fully synchronized with the physical environment. It is time and cost prohibitive to manually update the model [21]. Thus, existing research focuses on automatically generating and updating the 3D model [22]. Collecting the 3D point cloud is one of the methods for generating the 3D model of the indoor environment [23]. This type of method requires a registration method for obtaining 3D points from camera or laser scanner [24, 25, 26], and then applies segmentation method to separate objects and reconstructs the semantic model [27, 28]. Object recognition algorithms are also applied to identify different objects in the point cloud [29, 30].

A similar approach can be used to integrate a construction robot with digital modeling methods for visualization and task planning [31]. For example, Yang et al. [32] utilized BIM and robot path planner to find and visualize the construction process of the modular construction. However, these types of systems are typically not synchronized between the virtual model and physical robot and require further adaption [33, 1]. The robot Digital Twin (DT) system developed in this work fulfills the demand for real-time data exchange, which is wildly utilized in the manufacturing industry, digital fabrication, and human-robot collaboration assembly [34, 35]. For example, Naboni and Kunic [36] used DT for complex wood structure manufacturing and assembly. Furthermore, by combining with other techniques such as Augmented Reality, the synchronization and communication mechanism of robot DT system can be improved [37].

3 Robot Digital Twin System

The proposed online robot Digital Twin system is shown in 2 and consists of three modules: the physical robot module, the virtual robot module, and the communication module. First, the virtual robot module includes the Digital Twin for visualizing the robot and the motion planner for planning the trajectory and solving the inverse kinematics (IK). Second, the physical robot module includes the real robotic arm and the embedded sensors for measuring joint angles. Finally, the communication module includes the MQTT communication protocol for data exchange and synchronization. The system is developed in Robot Operating System (ROS) since it is the meta-operating system that provides a message exchange mechanism between platforms across a network. For instance, the motion planner in the virtual robot module plans a trajectory and then sends the control commands to the DT robot for execution and visualization. Figure 3 shows the data exchange between each platform. The detailed description of each module is provided in the following subsections.

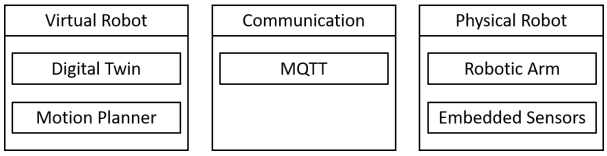

Figure 2. The framework of the online robot Digital Twin system.

3.1 Virtual Robot Module

We use ROS Gazebo and rviz to develop the DT in the virtual robot module on a Linux PC [15, 38]. The Gazebo is a real-world physics simulator that creates a world and

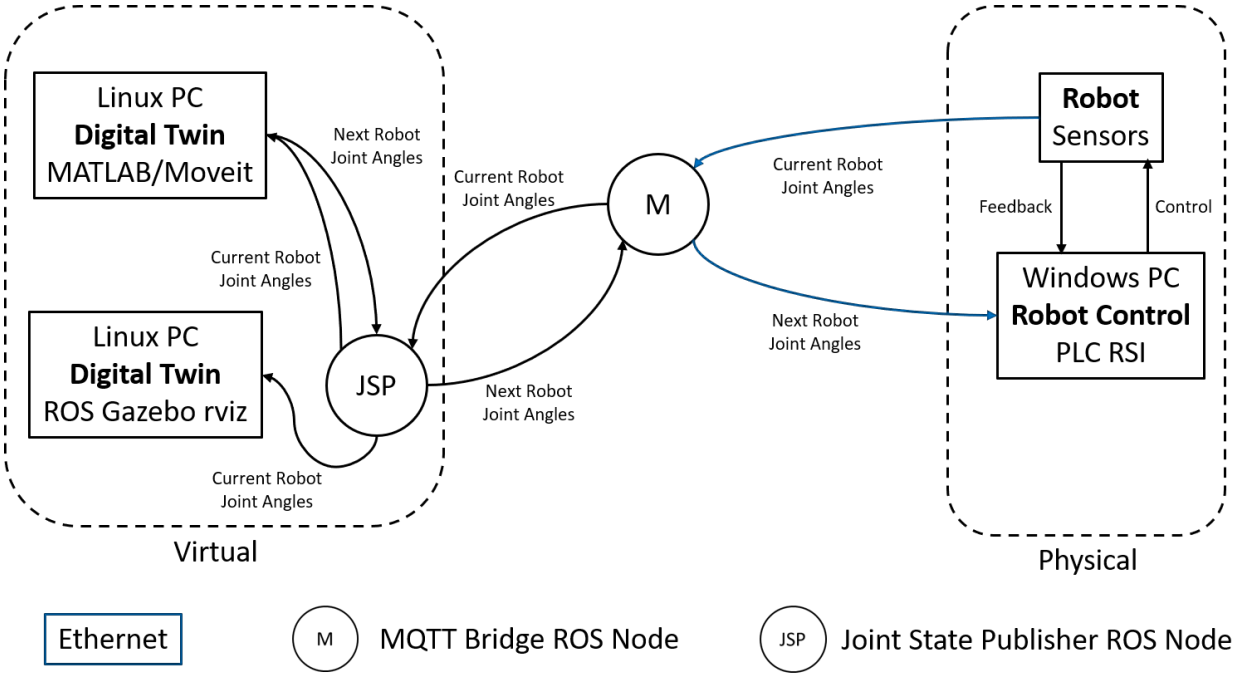

Figure 3. The flowchart of the data exchange and each platform.

simulates the robot, whereas the rviz is visualization software that can read and display the data from Gazebo or real-world sensors. The robotic arm model is imported to the Gazebo and rviz, as shown in Figure 4. The joint angles of the robotic arm are exchanged between the two programs to ensure synchronization.

In order to plan the specific construction task or motion, a motion planner is required in the module. Either MATLAB or MoveIt! can be used as the motion planner to achieve the task [39]. The Robotic System Toolbox in MATLAB can plan the trajectory and solve the inverse kinematics of the robot. However, it suffers from the latency issue and is not fast enough for real-time planning purpose. On the other hand, the MoveIt! is a motion planning package for ROS, which plans the motion inside rviz and sends to Gazebo. Figure 4 top shows the interface of the MoveIt! motion planning in rviz. The start state, goal state, and time parameters can be customized and determined by the user as input to the motion planner. The result of the motion planning will then be demonstrated in rviz and sent back to Gazebo for execution. Both MATLAB and MoveIt! can be run on the same Linux PC as the DT, or run on a different PC and connected through network.

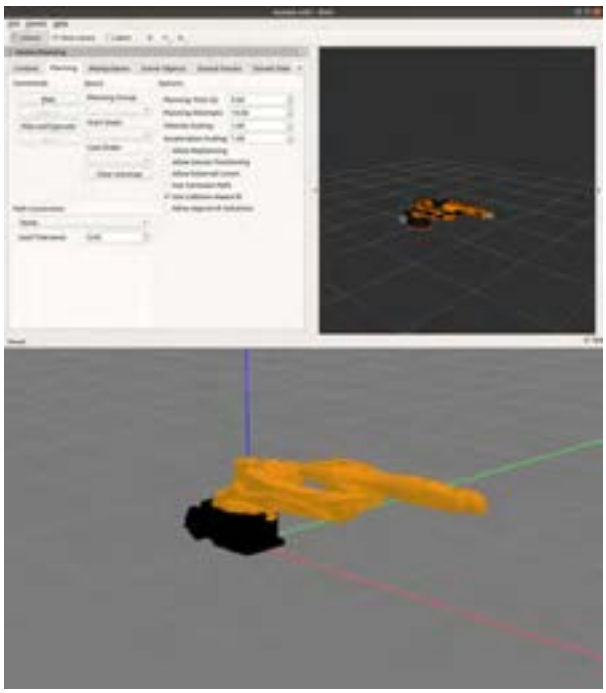

Figure 4. The robotic arm in Gazebo (bottom) and rviz with MoveIt! package (top).

For the data exchange, only the current robot joint angles and the next robot joint angles are displayed within the virtual robot module. Both Gazebo and rviz read the current robot joint angles to visualize the robot state. The MATLAB or MoveIt! package read the robot joint angles, determine the next robot joint angles, and send back to Gazebo and rviz for execution. The joint state publisher (JSP) is the ROS node for publishing the current robot

state to different ROS nodes, including the current robot joint angles from the physical robot module.

3.2 Physical Robot Module

We utilize the KUKA KR120 robotic arm on the track system as the physical robot for the DT system, as shown in Figure 5. In the current version of the online DT system, the track system is not included in the virtual robot module. The programmable logic controller (PLC) and robot sensor interface (RSI) are running on a Windows PC to control the robotic arm and retrieve the sensor data. The embedded encoders on the robotic arm are used to measure the joint angles and read by the RSI. After activating the robotic arm, the system first records the current robot joint angles as the origin of the robot for robot controlling purpose. Once the physical robot receives the next joint angles from the virtual robot, it will calculate the differences of the joint angles and then uses the recorded origin to control the robotic arm in the relative mode. The robot control command and the sensor measurement are two data exchanges inside the physical robot module, as shown in Figure 3 right side.

Figure 5. The KUKA KR120 robotic arm for the physical robot module.

3.3 Communication Module

Finally, the communication module links the virtual robot module and the physical robot module. We use MQTT communication protocol for data exchange between ROS system in the virtual robot module and the PLC in the physical robot module. The MQTT communication protocol is capable of real-time communication and thus is suitable for smooth robotic control. We develop an MQTT Bridge ROS node (M) to connect the MQTT to the ROS system, as shown in the middle of Figure 3. The MQTT Bridge node is run on the same Linux PC as the DT system to exchange the joint angles with JSP node and connect with PLC in the physical robot module through Ethernet. The data exchange frequency in the MQTT Bridge is set to be 250 Hz to ensure the transmission speed and avoid jitter effects on the robotic arm.

The joint angles of the robotic arm are the main data stream exchanged in the MQTT bridge ROS node. Figure 6 illustrates the data structure and exchange process in the MQTT bridge ROS node. The data stream concatenates the robot joint angles from A1 to A6 with a plus-minus sign and comma. Each joint angle is rounded to three decimal places and pads zeros to the left. Thus, the length of the data is consistent and easily retrieved by PLC. After receiving the joint angles data from the virtual robot module through the ROS topic, the system first converts the data to python string for easy storage and access. Next, the data is converted to the MQTT string type and sent to the physical robot module. This process can also avoid the garbled text issue when directly converting from the ROS topic to the MQTT string type. The data stream from the physical robot module is also processed with the same procedure and data structure and sent to the virtual robot module.

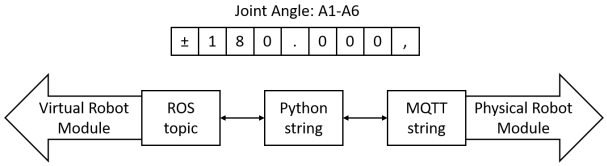

Figure 6. The data structure and exchange in the MQTT Bridge ROS node.

When exchanging the data between the virtual robot module and the physical robot module, the system must ensure the control commands are executed completely and the pose of the physical and virtual robot is synchronized. We develop a robot pose checking algorithm to confirm the synchronization between the two robotic arms. Algorithm 1 shows the pseudo-code of the pose checking algorithm (PCA). The algorithm takes the current virtual robot pose $\theta_{virtual}$, current physical robot pose $\theta_{physical}$, and the next robot pose θ_{next} as input. First, the PCA calculates the difference of $\theta_{virtual}$ and $\theta_{physical}$. If the difference exceeds the pre-defined threshold, the next joint angle θ_{next} will be assigned with the current joint angles $\theta_{virtual}$ to ensure the physical robot can reach the desired joint angles. The trajectory also needs to be re-planned to reflect the new current joint angles. On the other hand, if the difference does not exceed the threshold, the robot will simply execute the next joint angles.

Algorithm 1 Pose Checking Algorithm

procedure NEXT POSE($\theta_{virtual}, \theta_{physical}, \theta_{next}$)
  $diff(\theta) \leftarrow |\theta_{virtual} - \theta_{physical}|$
  if $diff(\theta) > threshold$ **then**
    $\theta_{next} \leftarrow \theta_{virtual}$
    Re-plan the trajectory based on θ_{next}
  else
    $\theta_{next} \leftarrow \theta_{next}$
  end if
  return θ_{next}
end procedure

4 Experiment and Results

4.1 Experiment

The online robot Digital Twin system is implemented and deployed in the Digital Fabrication Laboratory at the Taubman College of Architecture and Urban Planning at the University of Michigan. Two KUKA KR120 robotic arms are the target physical robots, as shown in Figure 1 and Figure 5. To evaluate the proposed system, we conduct an experiment to verify the pose between the physical robot and its DT are synchronized during trajectory execution. Figure 7 shows the procedure of the online robot Digital Twin system experiment. One reaching task trajectory is prepared and executed in MATLAB and Gazebo DT, then the joint angles are sent to the physical robot. Figure 8 shows the planned reaching task trajectory (pink line) in MATLAB. We use the embedded encoders on the KUKA robotic arm to measure and record the joint angles of the physical robot.

4.2 Results

The joint angles of the physical robot and the virtual robot are recorded and compared with each other. Figure 9 shows the results of the virtual and physical robot joint angles. Each line represents the angle of each joint (A1, A2, A3, A4, A5, and A6) in radians. The trajectory from the virtual robot consists of 1,500 waypoints and the measurement from the physical robot includes 18,802 data points. The result showed that the line of each joint angle had the same trend in two robots, which demonstrated the consistency of the synchronization between the two robots.

To further evaluate the accuracy of the synchronization, we calculate the average error and the maximum error of each joint angle between the two robots. Table 1 lists the result of the average and the maximum joint angle error. The average errors of each joint angle are less than 2.4e-05 in radians and the maximum errors of each joint angle are less than 2.1e-05 in radians. These results indicate that the synchronization of the virtual and the physical robot demonstrated high accuracy. The proposed pose checking

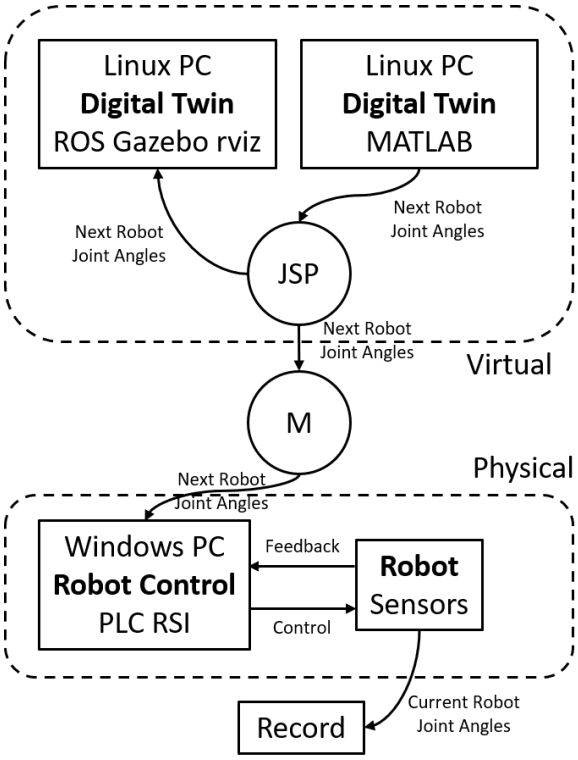

Figure 7. The procedure of the online robot Digital Twin system experiment.

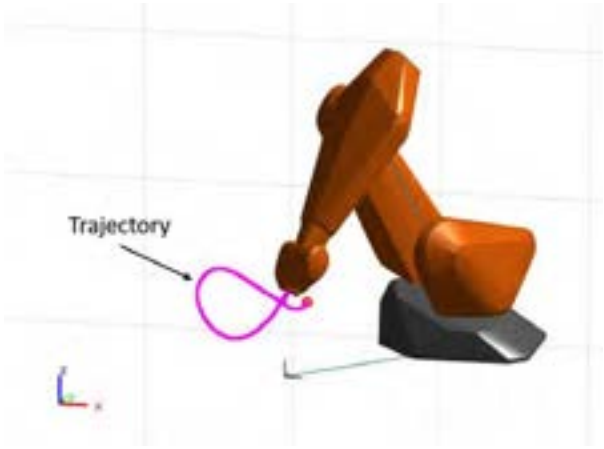

Figure 8. The planned reaching task trajectory (pink line) in MATLAB.

algorithm (PCA) also helped minimize the latency during the transmission.

5 Conclusion

This paper presented the initial development of the online robot Digital Twin system for human-robot collabo-

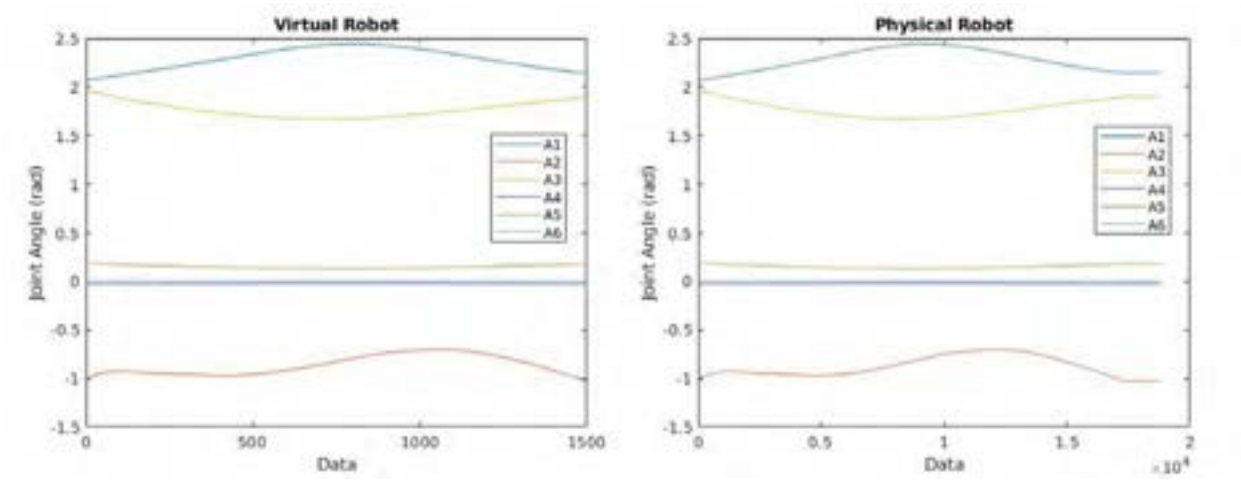

Figure 9. The results of the virtual and physical robot joint angles.

Table 1. The average and the maximum joint angle error between the virtual and the physical robot.

Joint	Average Error (rad)	Maximum Error (rad)
A1	1.5269e-06	1.7232e-06
A2	1.9848e-06	2.2391e-06
A3	2.2334e-05	2.0717e-05
A4	2.2993e-07	2.8146e-07
A5	6.2252e-06	7.0128e-06
A6	4.3442e-06	3.9486e-06

ration in the construction and digital fabrication. The system includes the virtual robot module, the physical robot module, and the communication module. We leveraged ROS Gazebo and rviz to develop the virtual robot module, i.e., Digital Twin of the physical robot, and connect to the physical robot module through MQTT Bridge in the communication module. The joint angles of the robotic arm are exchanged and synchronized between two robots. We also utilized MATLAB or MoveIt! package to plan and control the robotic arm in the virtual robot module, then send the command to the physical robot module for execution. In addition, we developed a pose checking algorithm (PCA) to ensure the pose of the two robots were synchronized.

The system was implemented and deployed on a KUKA KR120 robotic arm in the digital fabrication laboratory. Although we developed the system for the specific KUKA robotic arm, it can be easily adapted to other robot models. We evaluated the system by comparing the joint angles between the virtual and physical robot in a planned trajectory, and calculated the average and maximum errors. The results showed that the proposed online robot Digital Twin system could plan the robot trajectory inside the virtual environment and execute it in the physical environment with high accuracy. In ongoing work, we are designing the user interface for displaying the information of the physical robot in Digital Twin. We are also developing the robot planning mechanism such that the robot can first demonstrate the planned trajectory inside Digital Twin before executing by the physical robot. The human can thus expect the movement of the robot in advance and approve the task. Finally, we are designing and conducting more case studies for evaluating the proposed online robot Digital Twin system.

Abstract –

This article reports work-in-progress of a parallel kinematic robot development for construction with main focus on the concept phase. We assume the weight distribution of the proposed structure enables integration of robotic components into construction equipment while enabling tailoring of important characteristics such as accuracy, stiffness and workspace toward application needs. We describe challenges as well as kinematics, simulation and an experimental setup for evaluating performance of the proposed concept in a construction experiment using a concrete build system.

Keywords –

Parallel kinematic manipulator; Construction robotics; Concrete build system

1 Introduction/preliminary work

The community building sector in Sweden has an annual turnover of around SEK 500bn with 500,000 employees in 20,000 companies. However, productivity development is very low and has been for a long time. Low profitability and the absence of strong drivers of change are preserving the sector. For instance, in mass production of reinforcement, plasterboard, insulation, steel profiles and concrete, one person hour produces material for more than 50 m² of exterior wall with high profitability. At the same time experience show that for finished (built) exterior walls, one person hour has often only produced less than 1 m², this independent of construction material, whether, prefabricated or site-built. Swedish and international efforts to improve productivity in construction have often landed in prefabrication of composite components and building information modeling (BIM). However, the success of trying to increase productivity and profitability through this approach has been limited, mainly due to compound product complexity, inability to handle variations in deliveries, high fixed services and best widespread fragmentation in a project-based construction process [1].

In the manufacturing industry, customer focus, digitization and use of robots enabled mass customization and increased productivity. However, in the construction sector, the degree of automation is very small and in principle none of the players work with flexible customer-based production. Investments have been made but large-scale solutions have failed. The utilization of robots in the construction sector is limited by adaptation to the construction site, rapid and agile change of work steps and that the sector needs a balanced and small-scale collaboration between man and machine at the construction site. Today, the construction sector has about 3 times the number of accidents and load-related illnesses compared to other operations in Sweden, and the situation makes it difficult to improve the working environment and safety as well as to reduce both climate and environmental impact. Recent literature surveys support these findings and list hampering factors such as lack of interoperability, tolerance management, experts, power and communications as well as design for human installation procedures, high initial investment and risk for subcontractors, immature technology, unproven effectiveness, and low R&D budgets, among others [2, 3, 4]. At the same time, there are indications that automation is needed in AEC for continued growth [5].

To target these issues at a national level a Swedish center for construction robotics [1] is being formed in collaboration with the Swedish concrete industry. The center aims to develop, adapt and demonstrate automation solutions for construction before being put to use at construction sites, and act as a knowledge

[1] Swedish national center for construction robotics, http://www.lth.se/digitalth/byggrobotik/

transfer channel from academia to Swedish industry within construction robotics. Efforts now being carried out in associated national research projects aims to demonstrate a feasible automated construction system for small concrete house production in Sweden. The hypothesis is that the use of small-scale robotics gives feasible construction automation. Two robot automation approaches are being tested: utilization of off-the-shelf industrial robot arms from the manufacturing industry for automation of in-situ processes, and utilization of parallel kinematic manipulators (PKMs) for use in-situ and for prefabrication processes.

The type of PKMs put forward in this article fit, in our opinion, well for automation of construction tasks. The weight distribution of the robot with mass concentrated to stationary parts suits well for integration into construction equipment. Corresponding light-weight arm systems can be tailored toward processes in important robot characteristics such as accuracy, stiffness, and workspace.

This article describes our experimental setup and motivation behind selection of the two robot types as candidates for construction work, as well as reporting work-in-progress regarding development of PKMs for construction. The rest of the article is outlined as follows: a test process is described (masonry using the Finja Exakt build system[2]). This is followed by a short description of the off-the-shelf robot system (important as we plan for comparison of performance between the systems). Then a general overview of parallel kinematic manipulators is given to illustrate the machine concept, followed by work-in-progress reporting on initial steps we needed for adaptation to construction experiments. Currently open problems regarding integration, safety and interaction are then discussed briefly. Last, future work and current conclusions end the article.

2 Masonry process

The targets for experiments in current projects are processes needed for small concrete house construction, such as shown in Figure 1.

This particular house type is constructed using a build system based on a refined type of concrete blocks. The process of placing the blocks to form the outer walls is not that time consuming (about two days manual labor by two persons), but it is heavy and non-ergonomic work involving a total lifting of several tons of material during short time. Fully or partially replacing manual labor in this specific process would remove a strenuous work task. From a robot automation point-of-view the process contains most challenges that need to be addressed for robot application on-site, such as safety, calibration, performance, workspace, etc. Furthermore, commercial automation solutions exist (HadrianX [6], SAM100 [7]) as well as research prototypes (in-situ fabricator [8,9]) for benchmarking and comparisons.

Figure 1. House type targeted for masonry robot automation

2.1 Manual masonry process

The Finja Exakt system consists of a family of insulated blocks that are available on pallets of around 40 blocks per pallet. The system consists of a number of blocks to handle different situations such as corners, windows and doors. The weight of individual blocks vary between 15 and 20 kg. Blocks are stacked in layers of 200 mm including a 3 mm thin layer of Exakt mortar, with possibility of a half layer of 100 mm. The length of an individual block is around 600 mm. The Exakt system exists in three different widths, 290, 350 and 400 mm. We limit ourselves to consider only the 350 mm width for experiments.

The manual process is specified in Finja Exakt manuals[3]. The steps involved are visualized in Figure 2; starting from a slab and a blueprint, the first layer of blocks is layed down with care taken to accurate placement of openings and care taken to achieve an even layer height. Mortar is applied using a special tool for application (white box). Every few layers (not each layer) reinforcement is applied. Custom block sizes needed for corners and openings (windows and doors), are solved by on-site sawing of blocks, see Figure 3.

3 Research contribution

Within this paper we show our recent work-in-progress towards building a construction robotics lab including a PKM and an industrial arm robot to explore robotic aspects of construction processes. Our main contribution belongs to the development of the PKM and to the final development of the process customized industrial arm robot for construction tasks. Next to the robot development our contributions comprise in investigating application aspects of construction processes. These aspects include e.g., logistics, material flow, safety, collaboration, and risks. The first process we explore the mentioned aspects for is masonry.

4 Industrial construction robot

Industrial robot arms were originally developed for long series manufacturing, typically batch production in automobile industry, with the robot specializing in dirty and dangerous processes, such as welding and painting, as well as highly repetitious tasks such as pick- and place operations. The main important characteristics being high repeatability and low cycle time. An industrial robot is typically placed in a well-organized cell within a production line. In construction the most similar environment is in prefabrication where similar thinking may apply, though with different materials. Prefab wood house production already has automation solutions involving robotics. For prefab concrete the main application so far seems to be 3D printing, but then featuring large Gantry structures built to scale. For on-site production there are several factors to consider:

The environment is less structured than in a traditional robot cell, furthermore it may be unique for each new construction site. Figure 4 shows a typical small house slab cramped with construction material and cabling.

In the construction context considered, adoption to the blueprint typically happens at centimeter tolerance. Blocks are also allowed a few millimeters of placement tolerance since a grouting process evens out small errors. Accumulation of errors are not tolerated. On-site robot systems need efficient on-site calibration methods and/or accurate positioning sensing.

Mobility is probably required unless prefabrication on-site is sufficient (it very well may be) since the house is much larger than the workspace of the typical robot arm. In such case, the form factor of the robot and mobile platform should fit standard openings in the construction and adhere to pressure limitations posed by slab or use workarounds such as distributed steel plates. A small form factor also needs to ensure stability to allow utilization of robot performance.

Figure 4. Typical small house slab cramped with construction material and cabling

The protection class of the robot system needs to handle the on-site conditions, which includes abrasive materials and weather conditions. Most current industrial robot brands are available in IP67 editions which however is not enough leading to the need for protective clothing.

Opposed to manipulating a material flow through a cell, the robot system needs to adopt to the less structured material logistics on the construction site, or to enforce more structure to suit the automation process.

Safety, interaction and collaboration are important subjects. They are therefore given a separate section later in this paper.

The concept to be tried out is integration of an off-the-shelf industrial robot arm with an off-the-shelf piece of construction equipment as mobile platform, similar to what is seen recently in literature (the in-situ fabricator). Unlike the fabricator we will put focus on integration of the robot system into an automation system including considerations for the build system used. The system will be used for comparison with the PKM robot described next.

5 Parallel kinematic machines (PKMs)

Parallel kinematic machines (PKMs), classified as robots whose arms have concurrent prismatic or rotary joints in so-called closed kinematic loops, differ from the standard serial manipulators in several important aspects and complementary broadens the applicability and use of robots [10]. With a significantly higher stiffness in relation to the inertia/moving mass, PKMs typically either show up in (I) industrial pick-and-place systems where the very high accelerations due low moving mass – for so called delta and cable robots the actuators could be mounted in the stationary frame and thus get low moving mass – one gets significantly shortened cycle times in comparison to what is achievable with serial manipulators at the corresponding energy budget. or (II) are used in industrial applications where the high stiffness and/or positioning accuracy are required; different machining operations such as grinding, deburring and cutting, where structures like Stewart-Gough platforms or different gantry manipulators provide beneficial configurations. Parallel kinematic structures are also quite common in active or passive fixtures. Cable driven robots have emerged during the last decade and one can find examples from suspended camera system in sport stadiums to large wire robots in industrial settings [11]. An often-advocated shortcoming of PKMs is the smaller workspace with respect to the footprint of the robot, compared to the typical serial manipulators, and the risk of collisions between PKM-links/cables and obstacles within the workspace. However, whereas this may be true in many industrial applications, the masonry of walls is a task where the workspace is very suitably tailored to a new PKM structure. Furthermore, the strength, stiffness, and positional accuracy of the PKM within this workspace makes it a competitive alternative. The Gantry-Tau PKM was developed for achieving a large, open workspace for structures in e.g., the aerospace and windmill industry where the reconfigurability concept encompassed and integrated calibration as important part of the concept [12]. Further development of the latter PKM-concept is an important step towards efficient use in AEC applications.

5.1 PKM for masonry

Here we present work-in-progress to adapt a PKM structure to automate the selected masonry process (see Chapter 2.1). Our work so far considers kinematic aspects (e.g. workspace, stiffness) and mechanical aspects (e.g. joints, drive concepts) as well as guidelines and standards relevant for collaborative robots [12, 13, 14]. The lab sized PKM is part of the experimental setup we build (Figure 5).

The work scenario contains: the PKM placed parallel to the wall we want to build at some distance from the wall. The end effector will be utilized for pick and place of blocks. Our first experiment will include pick and place of blocks with no humans in the robot cell with no collaboration taking place. Since we need Exakt mortar as a first layer a human will applicate one layer of Exakt mortar while the robot stops completely. Thereafter the robot will pick a block from a palette and place it at the needed position for building a wall. After placing one layer of blocks the robot stops again and the human applicates the next layer of Exakt mortar. As a next step the robot starts to perform pick and placement of next block layer and so on. Parallel to these experiments we will perform experiments with the industrial construction robot with regard to automated

Exakt mortar application which will be later adapted into the PKM experiments.

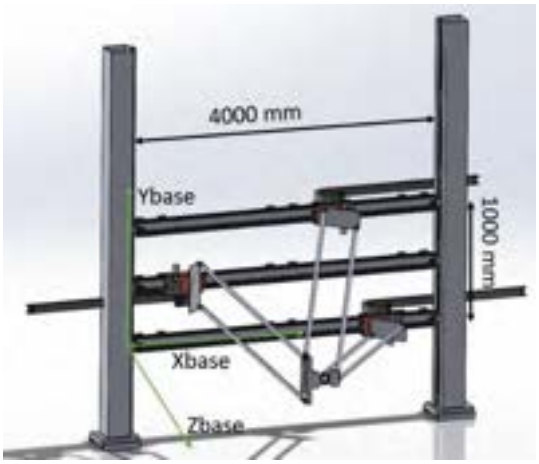

Figure 5. CAD of lab sized PKM with coordination system and wrist dummy

PKM development has so far been divided into four main parts. At a first step we investigate the basic PKM mechanism and structure to realize the translatory movement (basic PKM - translatory movement). In a second step we investigate the wrist, the end effector and the drive concept for the end effector to realize the rotatory movement with modular parts, adaptable for different applications (advanced PKM - rotatory movement). In a third step we have to investigate movable support structure to bring our PKM in a full sized version to the construction side or other relevant application places (support structure). The fourth step includes implementation of safety and interaction for human robot collaboration. This division into four parts (translatory movement, rotatory movement, support structure, safety and interaction) is very important since our aim is to bring the PKM into different application areas with different human robot interaction levels. Further explanations contain the PKM development regarding the translatory movement and the implementation of safety and collaboration.

5.2 Basic PKM – translatory movement

The basic PKM for construction tasks (Figure 6) consists of three kinematic chains. Each chain includes an actuator, which is realized by motor driven carts moving on tracks. A total of six links is used. These links have fixed length and are connected to the carts and the wrist in a 2-2-2 configuration. Joints used for the connections are at this stage spherical joints with a tilting angle of +/-45 deg. Two of the carts are placed on one side and the third cart is placed on the other side in comparison to the wrist. By this configuration we are already able to realize the three translatory degrees of freedom (DOF). The wrist itself consists of a support platform, where the fixed length links are connected to and of a tool platform with which we realize the rotational DOFs.

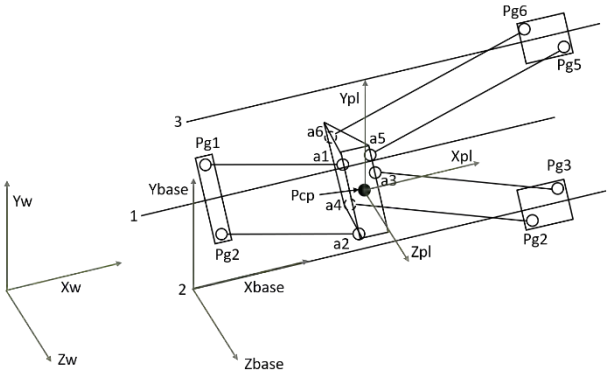

Figure 6. Schematic construction PKM for translatory movement with notation for variables and parameters

Since the wrist transmits the translatory movement and realizes the rotational DOF it has a key function in our PKM. Furthermore, the chosen connection points from links and wrist have a high impact on stiffness. The best regarding stiffness is to choose the distances between the links as big as possible.

For figuring out the best combination of distances between tracks, length of links and distances between links in dependency of workspace we realized the kinematic modeling. The kinematic model contains a defined cubic workspace in which we proof the reachability of the platform center point (Pcp). Further we described the inverse kinematics from Pcp over connections links/wrist (a1, a2, …, a6) to connection links/carts (Pg1, Pg2, …, Pg6) to carts. After this we calculated the intersection points of the links with the tracks to check if there are intersection points in the defined areas along x-axis. In case of intersection points we had to figure out which of the intersection points are valid. Moreover, we had to proof the angles between the links and the wrist and the links and the carts. We did this because we used spherical joints with +/- 45 deg tilting angle. After this procedure we found out which points in space are reachable with our configuration. Figure 7 shows reachable workspace in green for a PKM with 4000 mm tracks, 500 mm distances between tracks in y-direction, length links 2 and 3 = 1722 mm, length links 1 = 1648 mm. With this configuration it will be possible to build a wall with length = 1,8 m

and height = 1,5 m which will be appropriate for our experimental setup. For later use of the PKM on the construction site calculations will be adapted to design an upscaled version.

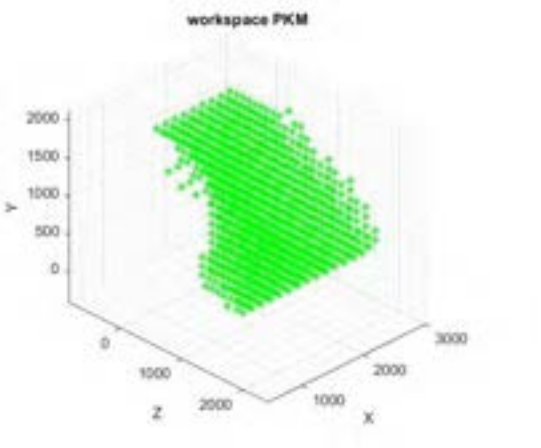

Figure 7. Result workspace calculation – Reachable points in space of platform center point for translatory movement

Due to the fact, that we want to perform first experiments to evaluate stiffness, torsion and workspace with the calculated parameters, we decided to build a downscaled version with parts to realize translatory movement (Figure 8).

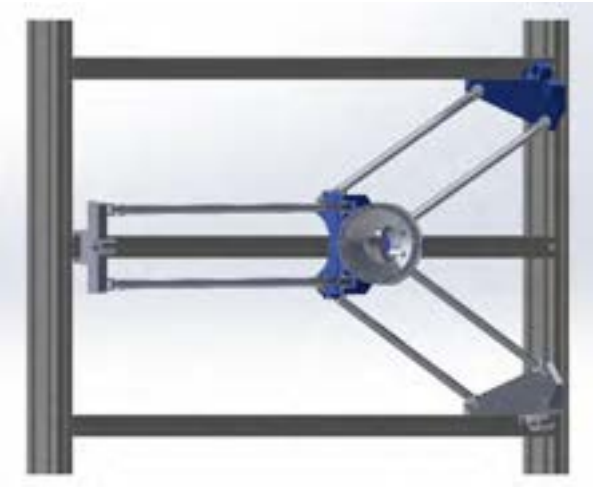

Figure 8. CAD PKM – designed for downscaled version

To fasten up the mentioned process, we designed the downscaled version of the PKM for first experiments with 3D-printed and out-off the shelf made parts and a functional support structure (Figure 9).

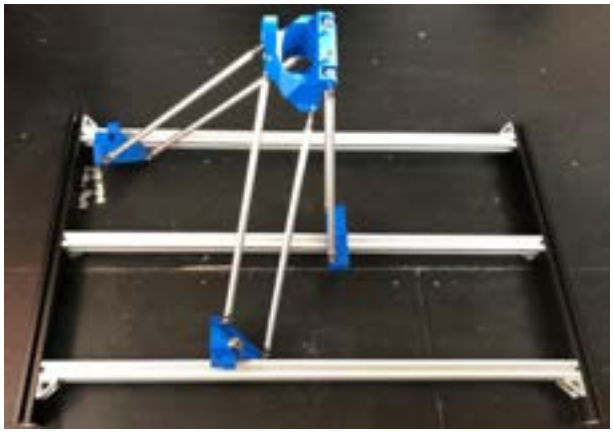

Figure 9. Realized downscaled PKM with 3 DOF

6 Experimental setup

Our experimental setup in the construction lab will contain the PKM placed parallel to the wall to build as well as a palette of blocks with the aim to perform pick and place experiments of blocks (Figure 10). Not shown in the picture, but planned, is the industrial arm application on the opposite side of the wall to perform experiments regarding pick and place, gluing and sensor integration. Since safety and interaction will be needed already in the lab, we will start to integrate some safety features in the shown application, which is described in the next chapter.

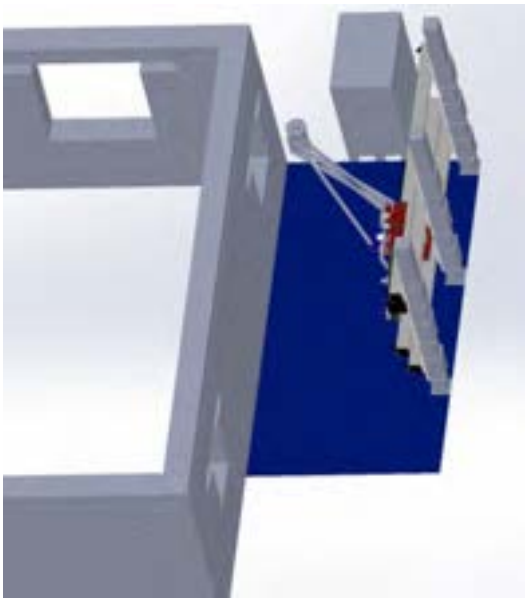

Figure 10. Experimental setup for PKM

6.1 Safety & interaction

The machine directive needs machines to fulfill stated requirements before they are considered safe for use. Traditional industrial robot cells disallow human presence during autonomous operation and ensure this situation by surrounding the cell with safety systems. Another approach is represented by collaborative robots where a limit in allowable utilized energy allow humans to work in close collaboration with the machine despite autonomous operation. The unstructured and perhaps changing environment on the construction site pose challenges for safe autonomous robot automation.

How can and must safety look like on construction site? Different approaches:

- Physical protection
- Disallowing human presence
- Supervised operation
- Detection of human presence

By limiting access to the robot structure itself by, for instance, providing an enclosure for the robot it is easier to limit access during operation. Approaches to small mobile robot factories often suggest enclosure of the robot in a container. Enclosing the entire work area (all or part of the construction site) for autonomous work provides safety by disallowing human presence altogether. Supervision of the operation at all times with personnel equipped with dead man's switch and emergency stops. Automatic detection techniques of human presence, such as laser planes. But this requires an uncluttered environment (no occlusions) for robust operation. There is no obvious option. This remains an open problem.

Another consideration is human interaction with the robot system. In a masonry automation system, examples could be refilling of mortar, requiring a human to get close to the robot system, or division of labor between a human and machine in the masonry process. These issues also remain open problems.

7 Future Work

Developing the drive concept for the wrist and the end effector as well as building the PKM in the lab. Part of the masonry process will be tested with the robot structure (the path for pick and place blocks). Moreover, we will carry out a feasibility study regarding the pick and place application of the blocks. Parallel to this realization we will create a simulation of the whole process. We will use this simulation to figure out cycle times in dependency of all process elements (robot, palette bricks, wall). Other work for next year contains implementing the gluing/cement application process as well as the needed hardware (pump, pipes, tool) for this process. We want to realize a tool changing system with which we can change between a gripper and a saw or a combination tool consisting of a gripper and a saw. We further need a block fixing station for sawing and a measuring system to define the needed length of the blocks before sawing. Another future process will be plastering.

8 Conclusion

With this paper we have shown work-in-progress of a parallel kinematic robot development for construction with main focus on the concept phase. There are many open questions and challenges remaining, some of them listed in this article. Robot challenges include large workspace, efficient calibration procedures, safety concepts, and human-machine interaction ability with regard to construction workers.

9 Acknowledgements

The authors gratefully acknowledge the support received from Boverket/"Innovativt Bostadsbyggande" (#6438/2018) and VINNOVA/"Innovativ Agile Construction for globally improved sustainability" (ACon 4.0 #2019-04750) as well as the support received from Robert Larsson (Cementa AB), Petra Jenning (Fojab), Cognibotics AB and Miklos Molnar (LTH). These projects provided the opportunity to investigate the use of parallel kinematic manipulators in construction applications and to develop a parallel kinematic manipulator for specific construction tasks.

Abstract –

The Design-to-Robotic-Production and -Assembly (D2RP&A) process developed at Delft University of Technology (DUT) has been scaled up to building size by prototyping of-site a 3.30 m high fragment of a larger spaceframe structure The fragment consists of wooden linear elements connected to a polymer node printed at 3D Robot Printing and panels robotically milled at Amsterdam University of Applied Science (AUAS). It has been evaluated for suitability for assembly on-site without temporary support while relying on human-robot collaboration. The constructed architectural hybrid structure is proof of concept for an on- and off-site D2RP&A approach that is envisioned to be implemented using a range of robots able to possibly address all phases of construction in the future.

Keywords –

Architecture; computational design; optimization; robotic production; robotic assembly

1 Design-to-Robotic-Production and -Assembly

Design-to-Robotic-Production and -Assembly (D2RP&A) links design to materialization by integrating all (from functional and formal to structural, environmental, etc.) requirements in the design of building components. It establishes the framework for robotic production at building scale. The main consideration is that in architecture and building construction the factory of the future will employ building materials and components that can be robotically processed and assembled. D2RP&A processes incorporate material properties in design, control all aspects of the processes numerically, and utilize parametric design principles that can be linked to the robotic production.

The developed 1:1 prototype (Figure 1) is a 3.30 m high fragment of a larger structure and consists of variously sized wood elements (linear members and panels) that are milled according to functional, structural, and acoustic requirements and a 3D printed polymer node. The employed D2RP&A approach builds up on knowledge and know-how developed at Robotic Building (RB) Delft University of Technology (DUT) since 2014 [1]. It combines off-site additive and subtractive D2RP with on-site human-robot D2RA (Figure 2) and the challenge has been the integration of various D2RP&A techniques.

Figure 1. Prototype of the hybrid structure built in laboratory conditions

The architectural approach relies on principles such as continuous variation and material hybridity. While continuous variation implies that the structure is defined as adaptive mesh with high-low resolution tessellation

(with patterns varying in size and shape (Figure 3) and volumes transitioning into surfaces and vice versa), material hybridity emerges from combining wood and polymer-based elements.

2 Material hybridity

Buildings consists of various material systems. In a first iteration a series of studies exploring connections between multiple materials have been implemented. Materials considered were wood, recycled wood, reinforced Polypropylene and various steels.

2.1 3D printed nodes

Complex nodes connecting many linear wood beams are usually designed for maximal loads and are not optimized in terms of shape or structural strength for global and local requirements. The proposed additive D2RP approach aims to optimize nodes and a first polymer node (Figure 1) has been generated by connecting several linear elements in such a manner that a sequence for assembly without temporary support using robots is achievable. A second metal node (Figure 2) has been developed aiming to exploit and advance, respectively, knowledge developed in clay [1] and polymer [5] 3D printing. This knowledge combines structural optimization with adaptive material design and optimized robotic paths for printing without support material.

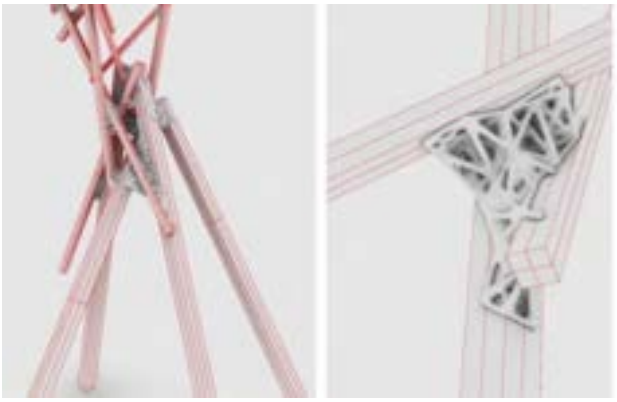

Figure 2. Optimised structural node for metal printing

2.2 Wooden spaceframe and panels

As a carbon-neutral renewable resource the wooden spaceframe consisting of linear elements with various sizes has been designed to explore D2RP&A at relatively large scale using a 3D printed node. The spaceframe is designed to accommodate paneling that together address structural and acoustic requirements and are produced by employing a packing procedure and milling (Figure 3). The panels were designed to be mounted on the structure and for the purpose of this proof-of-concept exercise they were rationalized to rectangular shape.

3 D2RP for Material Hybridity

Material hybridity requires taking into consideration various material performances. Thus, D2RP needs to integrate several requirements for materials, tools, and procedures in design.

3.1 3D Printing

The linear wooden elements of the spaceframe are connected by 3D printed nodes, which can reach a high level of complexity due to the employed additive D2RP process. The nodes are from glass-fiber reinforced Polypropylene and various steels. The produced 1:1 reinforced Polypropylene prototype is a proof of concept illustrating the flexibility of the joint to allow for connections of large-scale wooden elements of varying sizes placed in diverse angles. The node connects three large timber pieces of 140x140 mm. While 3D printing of polymer components using structural optimization and adaptive material design to fine tune stiffness has been extensively explored, 3D printing with various steels and the combination with another material such as linear wood elements needs further investigation.

In the next iteration, the goal is to structurally optimize the spaceframe in order to achieve a highly efficient distribution of nodes and linear elements. The thickness of the linear elements is then chosen according to the structural analysis in order to minimize material, and reduce the total weight of the structure. The reduction of the weight leads to a further reduction in stresses in the linear elements, and therefore smaller elements can be used and nodes are customized to fit local and global stiffness requirements. This D2RP process is run in Karamba, Grasshopper where several safety factors can be considered, such as overall and material safety factors that will compensate for the structural irregularities of the wooden elements.

3.2 3–4D Milling

The basic panels were produced at Amsterdam University of Applied Science (AUAS) by employing a

packing procedure that allowed to pack linear elements of various sizes within the bounding box, which for the purpose of the exercise were rationalized to rectangles (Figure 4). Since the panels had to integrate acoustic and structural considerations, they were structurally optimized using Karmaba in order to minimize material usage. Furthermore, they were acoustically optimized. In order to increase interior comfort, it is important to decrease direct reflection and thus, create a scattering geometry in order to transform noise into ambient background sound. Large flat surfaces generate strong specular reflection, which is unwanted. In addition to absorption, the goal is to achieve diffused or scattered sound waves by manipulating overall geometry and surface treatment.

The surface treatment of the panels (Figure 3) addresses sound waves in two ways: One addresses the mid-high frequency range, where the global shape of the prototype diffuses or scatters the sound in the chosen frequency range. The other addresses the higher frequencies, which are effectuated by the detailed surface treatments. The sharp edges cause diffraction, therefore increasing the absorption coefficient for the higher frequency sounds. By tuning the surface treatment, the scattering and the absorption coefficients can be controlled and surfaces can be shaped to match the acoustic requirements of the space.

The 6-axis robotic arm can reach further and approach the material at more angles than a 3, 4, or 5 axis milling machines thus facilitating performative geometries. A larger cylindrical bit was used to remove the material efficiently, while for the small-scale surface textures resulted a smaller bit was used (Figure 4).

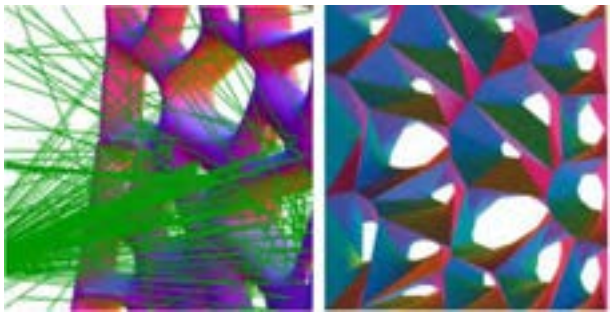

Figure 3. Acoustic simulation on specific surface tectonic

The acoustic simulations have been implemented in Acoustic Shoot, Grasshopper. This plugin imitates the acoustic ray tracing process. The next step is to create accurate surface textures according to the requirements and to predict their behaviors using more accurate mathematical models. The current ray tracing simulations do not take into consideration the behavior of the different wavelengths, when compared to the dimensions of the surface textures. Furthermore, conducting physical measurements is paramount for determining the absorption and scattering coefficients locally, based on local surface details.

Figure 4. Panels with integrated acoustic and structural performance robotically produced at AUAS

4 D2RP&A on - and off - site

D2RP implied prefabrication of building components using robotic additive and subtractive production systems for 3D printing nodes and 3-4D milling surface tectonics of panels.

D2RA on-site implied at this stage that the assembly focused only on the spaceframe with the 3D printed node not the panelling ‘Figure 1’. D2RA required some level of human-robot interaction. While robotic stacking of linear elements in controlled environment (Figure 5) has been explored in a previous project [2], the assembly of freestanding structures needed and still needs investigation with respect to identifying the sequence of operations as well as challenges for human-robot interaction while reducing use of temporary support. Similar to strategies and concepts for large-scale projects developed at ETHZ [3] a multiscale production system was proposed that employs building component optimization based on geometry analysis, structural and acoustic optimization.

The process is based on a human-robot on-site production approach wherein the material, in this case timber, is brought to the site together with the robotic production setup. The production strategy involves robots that cut the elements and place them in space based on their specific angle and connection point, and the humans fix i.e. screw the elements in place. The spaceframe, panels and joints are thus prefabricated and are assembled on site with help of robots. The size of the structure is in this case restricted to the size of the robot reach and the height of the truck on which the robots are fixed [4].

The challenge is to choreograph the interaction between humans and robots employing machine learning

(ML) and computer vision techniques, such as OpenCV and DNN in order to find nodes' location, detect the related linear elements, pick and transfer them with a gripper to the intended location, while considering obstacle avoidance (human safety). The idea is that a human will navigate the arm with the hand, and in order to move it from the intended location, which is near the node to its final location, which is next to the node.

The proposed D2RP&A approach is still work in progress, and the proof of concept presented in this paper has been implemented using various mapping, modeling, simulating, and prototyping techniques that identified challenges that need to be tackled.

Figure 5. Huma-robot stacking of linear elements tested in lab conditions

5 Conclusion

The space frame fragment is proof of concept for a hybrid on- and off-site D2RP&A approach that is envisioned to be implemented using a range of robots and in collaboration with humans. Challenges of the envisioned on- and off-site construction process are various from HRC to environment related challenges involving rough terrain, wind, rain, dust, and temperature fluctuations. Previous projects such as the Factory-on-the-Fly by Odico [6] or In-situ Fabricator by ETH Zurich [4] have tackled some of the challenges, however, the question of how on- and off-site approaches need to be combined and human-robot collaboration needs to be choreographed, require further exploration. While all these projects transported the robotic arms in containers that could either open up or could be completely removed, the integration of design, production, and assembly as HRC processes and the handling of outdoor unstructured environments requires further specification.

The project presented in this paper identifies a series of processes from design to production and assembly that require integration. It challenges the fragmented, inefficient, and expensive processes of today's building construction practice and proposes novel multi-performative D2RP&A strategies. While some aspects of these strategies have been developed only conceptually, others have been already modelled, simulated or prototyped. The next step is the development of the HRC approach, which relies on practical methods facilitating collaborative sawing [8], collaborative polishing [9], etc. and involving Artificial Intelligence (AI) that enables physical collaboration between robots and humans. Furthermore, other materials such as circular wood and steel are considered. The ultimate goal is to advance data-driven design approaches for the robotic production and assembly of mass customizable multi-material building components and deploy HRC techniques for testing the blueprint of future robotic building.

Acknowledgments

This paper has profited from the contribution of students and researchers from the Robotic Building Lab at TU Delft and Digital Production Research Group at AUAS. The presented project could not have been implemented without the support of industrial partner 3D Robot Printing.

Abstract – Building tasks that carry out on the building façade, such as painting, cleaning, and maintenance are often to be described as dangerous, dirty, and demanding. Recently, researchers and institutes are developing autonomous and semi-autonomous On-site Construction Robots (OCR) for those aforementioned applications. The most of façade working OCR is either suspended or supported by the secondary structure. The biggest challenges for these types of methods are obtained stability while carrying out the task against external elements such as wind and inertia caused by the step motors. There are very limited resources that discuss positioning and stabilizing methods. In this paper, a novel localization system for OCR will be introduced, which is based on the on-site construction robot commissioned by The Construction Industry Council Hong Kong (CIC) and developed by the Chair of Building Realization and Robotics (br2) at Technical University of Munich (TUM). The research presents the preliminary concept of a stabilization method that can be adopted on most of the suspended OCR type. The proposed system will localize the initial position, alter the OCR into the correct working pose, and secure the system to place. At the time of this writing, it is only limited to the conceptualization and proof of concept of the system. The control scheme is validated in simulation. The proposed approach is expected to be expanded into other applications in the future.

Keywords –
Construction robotic; localization; Stabilization

1 Introduction

To adopt automation and robotic technology with the aim to augment human performance is not a new concept in the construction industry. In fact, since the late 1970s and the early 1980s, many research institutions, universities, and construction machinery companies have conducted research and development (R&D) initiatives. In the early 1980s, Japan's construction industry started to face a shortage of skilled workers due to the fact that working condition of conventional construction sites was considered dirty, dangerous and difficult by the young generation. The construction industry had begun to fall behind the manufacturing industry [1]. Until today, there are over 150 Single-Task Construction Robots (STCRs). Most of the systems were developed to be used on the construction site. Each type of robot was designed to focus on a particular on-site work task. In general, automation and robotic technologies are often referred to as a solution to solve many profound industry-related issues, such as declining productivity, skilled labour shortage, safety, and quality. The increased popularity of robots is expected with improved economic incentive and wider applicability [2]. Some construction processes can be automated while others not, even the one that can be automated in the other sector, such as manufacturing sector might not be realized in the construction context. For instance, the construction sector is fundamentally different from that in the manufacturing sector in many aspects. The difference can be reflected in the following characteristics including working environment, distribution of materials, the allocation of the robot and human function, skill sets, and information transformation [3]. Therefore, to develop a practical application for the construction industry the system designers must be proficient in traditional construction methods, building structure, engineering management and other disciplines, and understand the auxiliary knowledge about microelectronics, mechanical design, manufacturing, and automation, so interdisciplinary teaching and cooperation in the field of construction robotics is essential.

There are increasing demands of working in great heights, due to the popularity of high-rise buildings. Yet, high-rise construction often prone to issues that affiliated with working in great heights. In this paper, the author will use the multifunctional façade finishing robot that was developed through the consulting project commissioned by the Construction Industry Council Hong Kong (CIC) as a case study. When the proposed

OCR system is suspended in great heights and to be exposed in the external environment. It is vital for the system to maintain stability while operation, and to position itself securely and accurately. This paper will focus on the development of a practical solution that can potentially address the challenges associated with localization, stabilization, and positioning tasks in respect of the suspended type of OCR system. The method can be adjusted and adopted when executing a similar development.

2 Background

Many construction tasks require labour to perform repetitive motions while to be suspended in great heights. For instance, cleaning task for high-rise buildings fitted with glazing curtain wall system, painting for high-rise building façade, and various maintenance tasks that need to be carried out from building façade. As mentioned earlier, working in heights imposes considerable safety hazards. It may sound contradictory but in the construction industry, on-site operational health and safety are one of the most critical areas that the industry trying to improve and very often overlooked. Construction accidents are influenced by multiple circumstances, such as workplace organization, equipment, training, risk awareness, and individual attitude. Hence, in many cases, it is hard to predict or to prevent accidents from happening. According to research regards to contributing factors in construction accidents, falling from heights is one of the biggest contributors to construction-related accidents [4]. In addition, working in heights also increases the opportunities of suffering other types of injuries, such as slips, trips due to unpredictable working condition. Many tasks involve working in heights are usually physically demanding even for the fit and younger workers [5]. Evidently, many developed economies in the world experience the aging workforce due to demographic changes. For instance, in Hong Kong, approximately 25.83% of the workers are above 50 years of age. Compared to a younger worker, workers 50 years and over will expose themselves to a higher risk of injury [6].

Consequently, researchers have been developing OCRs that provide full or partial replacement of the tasks that used to perform entirely by human. Automation does not offer all the solutions to the identified challenges, yet can provide an alternative method that enhances human performance and improve on-site operational [7]. In principle, façade OCRs can be divided into three main functions include rendering, cleaning, and inspection. The examples of some of the applications can be seen in Table 1 .

Table 1. Examples of the applications in on-site construction robot

Manufacturer	Robot	Country	Application	localization method	Façade type
Taisel	Exterior wall painting	Japan	Rendering	Guide rail	Vertical, flat
Kajima	Façade inspection robot	Japan	Tile façade inspection	Parapet, wall clamps and supported by cables	Vertical, flat
Fraunhofer, SIRIUS	Glazing curtain wall cleaning robot	Germany	Façade cleaning	Wheels and cables	Protruding
Louvre, Robosoft	Glazing curtain wall cleaning robot	France	Façade cleaning	Vacuum cups	Vertical, flat

The aforementioned systems also demonstrate various localization methods that have been adopted for a diverse range of application. Each system were tailor made for a specific configuration of building design that means the system is not applicable to be used for other buildings. Along with high operational costs, and complexity, many systems are not be able to commercialize successfully.

CIC commissioned the Chair of Building Realization and Robotics (br2) at Technical University of Munich (TUM) to research and develop construction robots and automation strategies that are tailor-made for the Public Housing Construction (PHC) sector in Hong Kong. As part of the project, the project team have to identify the requirements of the stakeholders, functional, non-functional requirements, and the circumstances of the construction site. There are other factors could also influence on the final decisions, such as technological, social, political, and economical. The project has been divided into six stages. The first phase consists of initial research, literature review, preselection, and proposing use case scenarios. The second stage includes an online survey, questionnaires, and on-site visit. The third stage is co-creation workshops. The fourth stage is concept development and detailed design of the proposed system. The fifth stage includes the construction of the mock-up and discussion of dissemination and exploitation strategies. The final stage is to develop a roadmap that provides a guideline on how to execute the remaining project a short-, mid-, and long-term basis. In the end, the Multifunctional Façade and Exterior Finishing Robot were chosen to be developed as a stimulator to the PHC industry. During the development stage, the project team have identified numbers of issues, in which the system positioning, stabilization imposes serious implication on the overall performance of the proposed OCR.

3 Research challenge and objective

Diverse localization methods were adopted in the façade application OCRs that have been developed in the past. However, they were designed to operate on the specific type of building façade. For instance, the Taisel exterior wall painting robot is positioned with guide rails. The guide rails are not an additional fixture for the building, yet the architect was made aware that the exterior wall painting robot will be equipped, hence the guide rail was included as part of the design feature of the façade to accommodate the robot. Evidently, the façade OCRs is tend to be developed and operated on specific type of façade and to manage unique configuration and material.

According the research, the project team realised that the existing façade OCRs are not applicable to the PHC façade type. This is due to the complexed geometry shape of the façade design. The external façade is constructed with prefabricated concrete panel. As shown in Figure the prefabricated concrete façade (PCF) element consists of two major protruding sections, both are designed to support air-conditioning equipment. The edge at the bottom of the panel overshadowing the floor level below, especially during the hottest hour of the day. Another function of the overhanging edge is to divert rainfalls during the subtropical monsoon seasons in Hong Kong. The advantage is that the PCF is identical for every elevation of the building.

Figure 1. Typical public housing construction type

Because of the complexed shape, a high level of accuracy is required for the painting task, in particular to keep an even paint coverage throughout every sections of the PCF. When dealing with a flat surfaces, this requirement is achievable even with the conventional supporting solution, such as suspended working platform that is often referred as gondola. The gondola is suspended by cables, which supported by wall clamps that installed to the parapet wall. When hanging in mid-air, it is very difficult to keep the gondola in absolute stable motion, due to wind, inertia, and movements caused by the operator. In the case of CIC project, as part of the design requirement, the proposed OCR was developed based on the conventional gondola platform that is widely used in Hong Kong construction industry for various façade tasks. The system need to be stable and retain levelled with the reference wall surface prior to carry out painting task and to ensure the required functional performance can be achieved.

The main challenge faced by the proposed OCR is how to design a system that is capable of self-diagnose the position, and to keep the working platform stable during operation. The primary design objectives of the system are, first, the system is to be expected to come to a stop once the system reaches the correct position. Second, after stopping, the system needs to remain stationary and to keep perfectly horizontal to the building façade. Third, the system should able to detect moments caused by either the external force or the momentum of itself. Once displacement has been detected, the system is required to correct the position automatically.

The proposed localization method presents the following improvements to the existing method. The design will not require any temporary or permanent additional fixtures and fittings other than the one has been used in a conventional manner. With a minor adjustment to the design, the system can be adapted to a large variety of building façade. The improved stability will accommodate a variety of automated applications, which demands an immobilized working condition. In terms of semi-automated application, human labour will also benefit from a stationary working platform to avoid the risk of occupational injuries. The next section will describe the development method in detail [8].

4 Method

The proposed Multifunctional Façade and Exterior Finishing Robot is based on the design of conventional gondola, the additional frame below the gondola hosts the robot end-effector, the space between the frame structure constitutes the robot working trajectory. Supported by the common roof supporting system, the robot can descend from the top to the bottom of a high-rise building while executing a task. Two electric motors near the hoisting devices on top of the robot are used to actuate the up and down movement. Through the addition of various sensors, the ultimate goal is to achieve a fully automated façade processing robot system. The robot system is highly modularized, meaning that the shape and size of the robot can be easily changed in accordance with the design of the target buildings, see Figure 1.

The localization system compresses of counterbalance design. It is compatible with all types of prefabricated façade panels used in Hong Kong PHC sector. The system consists of three subsystems, which include a detection system, stabilization system, and final

positioning system [8].

1. **Detection system**: equipped with two linear actuators that provide moment along X and Z-axis. A limit switch module is installed at the end of the X-axis.

2. **Stabilization system**: consists of three rotation servo actuators interconnected with counterbalance bars. At the tip of the final link a clamping device along with pressure sensors are installed. In addition, an inner industrial vacuum suction device is equipped in between the clamps.

3. **Final positioning system**: comprised off two retractable vacuum suction cups, they are able to secure the system to the final position. They are also able to withstand wind loads under normal circumstances.

All three subsystems can be adjusted when applied to another building and only minimum setup time is needed.

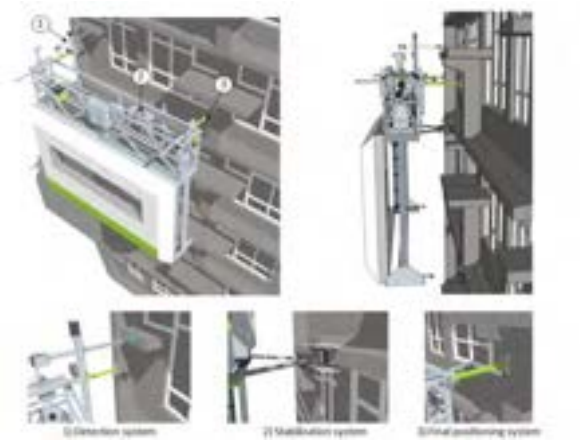

Figure 1. The design of the localization system

4.1 The design of the localization system

4.1.1 The mechatronic design and the kinematics of the system

The kinematic model of the localization system is shown in Figure 2. Based on the Denavit-Hartenberg (D-H) convention, the coordinate transformation between two consecutive link frames $\{i-1\}$ to $\{i\}$ can be defined as:

$$^{n-1}T_n = \mathrm{Rot}_{x_{n-1}}(\alpha_{n-1}) \cdot \mathrm{Trans}_{x_{n-1}}(a_{n-1}) \cdot \mathrm{Rot}_{z_n}(\theta_n) \cdot \mathrm{Trans}_{z_n}(d_n), \quad (1)$$

where $\mathrm{Rot}_{x_{n-1}}(\alpha_{n-1})$ defines a rotation of angle α_{n-1} around the x_{n-1} axis, and $\mathrm{Trans}_{x_{n-1}}(a_{n-1})$ defines a translation of a_{n-1} along the x_{n-1} axis. The transformation matrix $^{n-1}T_n$ is a composition of rotations and translations to move from a frame $\{i-1\}$ until it coincides with the frame $\{i\}$.

Accordingly, the D-H parameters for this model is shown in Table 2, where d means the offset along previous z to the common normal, θ means the angle about previous z, from old x to new x, a means the length of the common normal (Assuming a revolute joint, this is the radius about previous z), and α means the angle about common normal, from old z axis to new z axis [8] and [9].

Table 2. The D-H parameters of the localization system model

α_{n-1}	a_{n-1}	θ_n	d_n
$-pi/2$	0	0	d_1
$pi/2$	0	$-pi/2$	d_2
$-pi/2$	0	0	d_3
$pi/2$	0	$\theta_4 + pi/2$	0
$pi/2$	0	θ_5	0

With the D-H parameters, the transformation matrix from the robot base frame to the end-effector can be calculated using joint variables. The end-effector pose can be obtained by multiplying the transformation matrix as follows:

$$^0T_e = {}^0T_1\,{}^1T_2\,{}^2T_3\,{}^3T_4\,{}^4T_5\,{}^5T_e, \quad (2)$$

where $^{n-1}T_n$ is the transformation matrix as shown in (1).

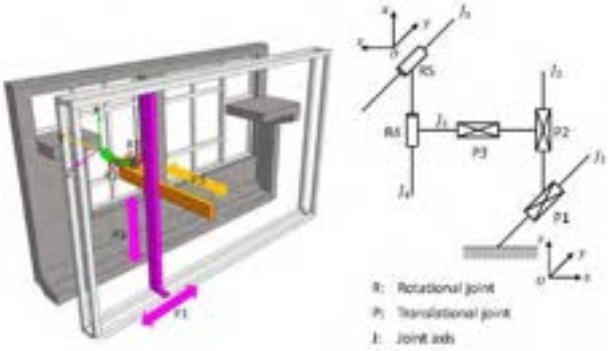

Figure 2. Kinematic structure of the localization system.

4.1.2 The work principle of the design

The localization process can be divided into six steps.

Step 1: Robot descends along the cable operated by the conventional step motor. The system will stop descending when the limit switch make contact with the protruding feature of the PCF.

Step 2: Due to inertia and external forces, at this moment the system may swing swiftly. The system is

designed so the stabilization system is aligned with the overhanging edge of the PCF. The stabilization system will be reaching out and press onto the surface of the edge. Once the pressure sensor detects even force has been distributed across the sensor the clamping device will retract and form a firm grasp to the edge, while the inner suction cup secures the system in place [8].

Step 3: once the system is stabilized, the stabilization system detects if the position is horizontally aligned with the PCF façade, if it is not, then the system will correct the position by using impedance control method.

Step 4: The robot extends the retractable vacuum grippers toward the wall at the proper length, then to grasps the wall to fix its position.

Step 5: the robot will detect any deviation between the real position and the ideal one. If there is any deviation the system will offsets, and the step three and four will be repeated.

Step 6: after the painting application has been complicated. The vacuum suction cups and clamps will be unfastened. The system is ready to decent to the lower floor level.

4.2 The control of the localization system

To achieve the above processes, several controllers for the localization system should be designed. Based on whether the robot will interact (have contact) with the target building, the controllers are divided into two categories: position controller and force controller. The former guides the robot to a precise position, while the latter attempts to maintain a compliant contact between the robot and the environment. We take the stabilization system as the example to illustrate how to achieve the stabilization with the abovementioned controllers.

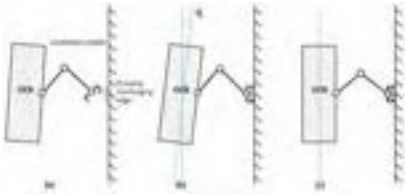

Figure 3. The three phases of the localization system (LS) for stabilization. (a) The LS moves towards its front direction to get in touch with the building wall; (b) The LS attaches its end with the wall and fixes its pose; (c) The LS eliminates the pose error.

As shown in Figure 2, the goal of the stabilization system is to find the wall, attach the gripper with the wall and finally adjust the pose of the robot. To achieve that, the following control laws are adopted [8].

4.2.1 The proportional-derivative (PD) control law

The dynamics of the robot system can be described in the form of the equation

$$M(\theta)\ddot{\theta} + C(\theta,\dot{\theta})\dot{\theta} + N(\theta,\dot{\theta}) = \tau, \quad (3)$$

where $\theta \in \mathbb{R}^n$ is the set of configuration variables for the robot and $\tau \in \mathbb{R}^n$ the torques applied at the joints, and M, C, and N are the inertia, Coriolis and gravity-related matrix, respectively. In practice, the robot is controlled by τ.

Before the localization system starts to act, and after it holds the wall firmly, the system should always keep a high precision for the movement or keep itself exactly where it is. This could be achieved with the PD controller:

$$\tau = -K_v\dot{e} - K_p e, \quad (4)$$

where $e = \theta - \theta_d$, and θ_d defines the desired configuration of the robot. K_v and K_p are positive definite matrices indicating the coefficients of the PD controller. For second-order systems, the relationship between K_v, K_p and the damping D of the system can be described as

$$D = \frac{K_d}{2\sqrt{K_p}}, \quad (5)$$

which helps to provide an initial value to adjust the expected response of the system [8].

4.2.2 The impedance control law

During the states where the robot and the wall are in contact, the robot should prevent rigid collisions between itself and the wall. In that case, the PD controller, which only targets at moving to the goal position in joint space, will not fulfil the requirement. We need to redesign a controller to provide a compliant force in the task space. When contact occurs, the robot should handle the contact in a soft, compliant way.

In such case, the dynamics of the robot system in the task space can be rewritten as

$$M_x(\theta)\ddot{x} + C_x(\theta,\dot{\theta})\dot{x} + N_x(\theta,\dot{\theta}) = J^{-\top}\tau + F_a, \quad (6)$$

where x is the pose of the end-effector in task space, J is the Jacobian and F_a is the external force applied to the end-effector. The postscript of M_x, C_x, and N_x indicates that the matrix is an equivalent of the matrix expressed in task space with

$$M_x(\theta) = J^{-\top}M(\theta)J^{-1} \quad (7)$$
$$C_x(\theta,\dot{\theta}) = J^{-\top}C(\theta,\dot{\theta})J^{-1} - M_x(\theta)\dot{J}J_a^{-1} \quad (8)$$
$$N_x(\theta,\dot{\theta}) = J^{-\top}N(\theta,\dot{\theta}). \quad (9)$$

Still, the robot is controlled by τ:

$$\tau = J^{\top}(\theta)\big[M_x(\theta)\ddot{x} + C_x\big(\theta,\dot{\theta}\big)\dot{x} + N_x\big(\theta,\dot{\theta}\big) - F_a\big]. \quad (10)$$

Then the desired acceleration trajectory $\ddot{x} = a$ can be designed in the task space. Regarding the contact force, a dynamic impedance model can be expressed as

$$M_d(\ddot{x} - \ddot{x_d}) + D_d(\dot{x} - \dot{x_d}) + K_d(x - x_d) = F_a, \quad (11)$$

where $x_d(t)$ and $x(t)$ are the desired/real motion, respectively. M_d, D_d, and K_d are the desired inertia, damping and stiffness, respectively. In this case, if a soft and compliant contact is desired, it can be achieved by choosing

$$a = \ddot{x}_d + M_d^{-1}[D_d(\dot{x}_d - \dot{x}) + K_d(x_d - x) + F_a]. \quad (12)$$

Substituting Eq. (10) into Eq. (12), there will be

$$\begin{aligned}\tau = M(\theta)J^{-1}(\theta)\{&\ddot{x}_d - \dot{J}(\theta)\dot{\theta} \\ &+ M_d^{-1}[D_d(\dot{x}_d - \dot{x}) \\ &+ K_d(x_d - x)] + C(\theta,\dot{\theta})\dot{\theta} \\ &+ N(\theta,\dot{\theta}) \\ &+ J^{\top}(\theta)[M_x(\theta)M_m^{-1} - I]F_a\}.\end{aligned} \quad (13)$$

Further, if M_d is chosen as

$$M_d = M_x(\theta) = J^{-\top}(\theta)M(\theta)J^{-1}(\theta), \quad (14)$$

then the control law becomes

$$\begin{aligned}\tau = M(\theta)J^{-1}(\theta)\{&\ddot{x}_d - \dot{J}(\theta)\dot{\theta}\} + C\big(\theta,\dot{\theta}\big)\dot{\theta} \\ &+ N\big(\theta,\dot{\theta}\big) \\ &+ J^{\top}(\theta)[D_m(\dot{x}_d - \dot{x}) \\ &+ K_m(x_d - x)],\end{aligned} \quad (15)$$

which do not require the contact force F_a feedback anymore. With Eq. (15), the compliant motion which limits the contact forces at the end-effector could be achieved [8].

4.3 Simulation of the proposed system

4.3.1 Setup of the simulation

The proposed localization system is verified in robot simulation environment ROS (Robot Operating System) + Gazebo. Gazebo is an open-source 3D robotics simulator, which is widely applied in robotics research area. In this simulation, it is hoped that the validity and effectiveness of the design could be verified.

4.3.2 Process of the simulation

To proceed, a simplified robot model is firstly established in Gazebo. Following the link-joint relationship of the robot, the model is expressed in sdf format [10]. The size of the model and the corresponding inertia property are set as the measured value in the CAD designing software. Finally, a Gazebo plugin is programmed to send the joint commands from the controller to the simulator. A framework structure is depicted in Figure 3.

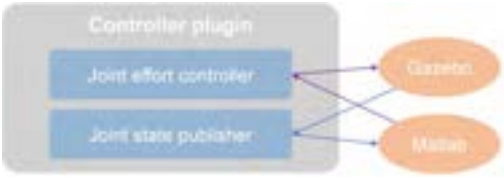

Figure 4. The framework structure of the simulation. The simulation is implemented in Gazebo. The controller is designed in Matlab. Using ROS communication mechanism, Matlab receives the current joint states from Gazebo, determines the joint efforts and sends them to Gazebo to achieve the final movement.

4.3.3 Data analysis

For the first stage, after fine-tuning the parameters for the PD controller, it could drive the localization system (LS) to the standby state fast and steady. For the second stage, the impedance controller could guide the robot to the right direction and achieve the contact with a very soft impact, see Figure 5.

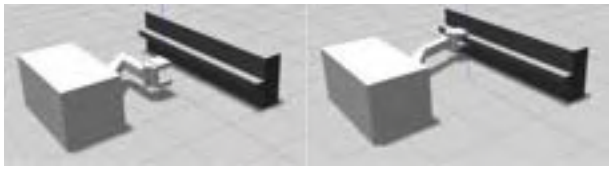

Figure 5. The localization process in the simulation. Left: the standby state. Right: the grasping process.

5 Future work

At the time of this writing, the proposed stabilization system is still under the Proof of concept (PoC) stage. There still many tasks and will take time and extensive tests to develop them into a practical application. The following tasks need to take into consideration when further developing the proposed system.

- For the detection system: to select the appropriate sensor technology for the specific construction operation environment. For example, a laser sensor may be sensitive to dust particles or reflective surfaces such as glazing and metal, but on the other hand, a gyroscope sensor may require high precision of the reference façade.
- For the stabilization system: it is necessary to develop an active and passive compliant control method to eliminate the external influence (i.e. the

wind, an unexpected collision).

- For the final positioning system: it is necessary to develop a robust position controller to guide the end-effector docking position.

It is crucial to test the localization system before the final pilot runs to reduce the risk of system failure, damage, or safety hazards. To test the effectiveness of the localization system, it is necessary to build a fully functional simulation or prototype that can be used for laboratory testing as well as pilot testing [8].

6 Conclusion

The paper proposed an innovative localization system for the Multifunctional Façade and Exterior Finishing Robot that developed in the CIC project. The proposed system consists of three subsystems, which include a detection system, stabilization system, and final positioning system. The objectives of the localization system including to assist the robot to localize the initial position, current the robot's position into the accurate operation pose, finally to grasp the façade and secure the robot to place. In order to achieve a fully functional application, several controllers for the localization system should be designed. As a PoC, two controllers were developed and described in the paper: position controller and force controller. The localization system was developed based on PD control law, the impedance control law was used to avoid rigid collisions between the robot and the façade. The controllers are designed in Matlab. Using ROS communication mechanism method, and simulated by using Gazebo simulator. As mentioned earlier, at the time of this writing, the proposed localization system limited to the conceptualisation. A fully functional robot application and extensive pilot testing are necessary to develop the PoC further.

Abstract -

This research presents a novel method for a data flow that synchronizes building information with the robot map and updates building components to their "as-built" states, in order to facilitate an on-site mobile construction process. Our experiments showcase mobile mapping and localization of a robotic platform featuring segmentation, plane association and quantitative evaluation of deviations. For the users of the on-site mobile robotic system, we present a suitable interface that allows for task level commanding and the selection of target and reference building components (i.e. walls, floor, ceiling). Additionally, this interface seamlessly integrates the online workflow between building construction and the robot map, updating the target building components to their "as-built" states in real time and providing a visual representation of additional task-specific attributes for building components in the robot map, in addition to geometries. This is presented as a first step toward integrating users of the system into the proposed robotic workflow to develop decision-making strategies for fitting building tasks to local references on-site.

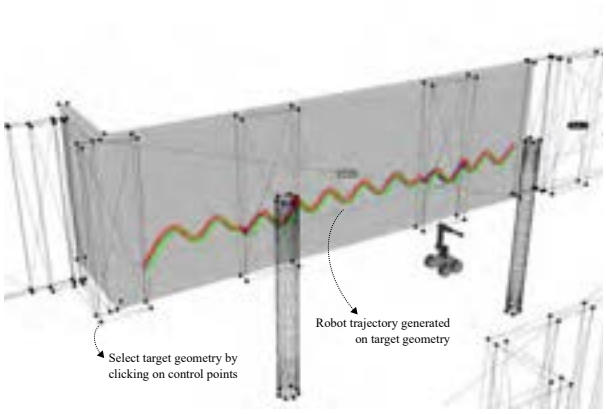

Figure 1. Robot trajectory representing the building task, generated on selected target geometry.

1 Introduction

Robotic technologies are widely applied in the off-site prefabrication of building components, where the strength of high-tech assembly lines can yield their full potentials: robots and work-pieces are in fixed locations with constant conditions, and building components can be mass-produced without the need to dynamically adapt the process. However, the majority of building tasks are executed directly on construction sites. In contrast to off-site prefabrication, on-site building construction often deals with dynamically changing conditions of large scale building components in spatially complex and cluttered environments. Furthermore, on-site work inherently generates deviations from the "as-planned", which is the state of the design as it should be. This requires craftsmen to register the differences and adapt the building tasks according to the "as-built" condition, which is the state of the construction as it is [1].

To facilitate an on-site construction cycle in an unbroken digital chain, a mobile construction robot must be able to understand the context within which it is working: it must localize itself via a robot map, both globally and locally, in reference to the already built components and the task being executed. In addition, it must be able to detect and understand any divergences between "as-planned", and "as-built" conditions. To achieve this in an on-site robotic construction process, a key challenge is linking the building information to the mobile robot's internal representation of the world (referred to as a robot map) and perception of its surroundings, using on-board sensing. This information is often represented as point clouds where the underlying geometric relationships are unknown. Such linkages between the building information and the mobile robot allow to cope with any divergences and the associated inaccuracies of the building materials and components, and to apply decision-making strategies while executing building tasks. To facilitate this link, there must be a flow of data between the complex building information and the construction robot.

In this paper we present:

- An online digital workflow between the building model and robot perception

- A suitable interface that allows the users of the on-site mobile robotic system to fit building tasks to local references on-site
- Real-time adaptation of the building components (i.e. walls) with respect to measured "as-built" state

2 State of the Art

Recent developments indicate an increased use of mobile robots on jobsites to monitor, track progress[1], or register differences[2]. Still, the problem of how to manage the flow of data between mobile robots that build and the complex building information is an emerging topic. Early automation attempts in the 1990s sought to replace manual processes with robotic building technologies in the construction sector, and resulted in early-stage mobile construction robots such as [2, 3, 4, 5], all of which lacked the hardware ability to interface to the complex building information. An early attempt to have a mobile construction robot with a limited interface using integrated sensing abilities, for localizing itself with respect to the building components for executing building tasks on-site is exemplified in [6], but still not enabling real-time adaptation of building components.

A large amount of research is dedicated to automated modelling of "as-built" states of building components [7, 8], and localizing camera and laser sensors in a Building Information Model (BIM) as well as tracking construction progress [9, 10, 11, 12, 13, 8]. While these works show an integration of BIM with static and mobile sensing, the assumption is that the "as-built" status reflects the "as-planned" status and the problem of progress tracking is then defined as detecting the presence or absence of discrete building components. In this paper, we address the challenge of having an online data flow for an on-site mobile construction process by detecting and communicating metric deviations, such as walls being placed several cm differently than "as-planned". Detection of such metric deviations enable the adaptation of building models beyond mere presence or absence of building components.

Current research in the field, such as [14, 15], has put forward novel approaches for software interfaces that facilitate the adaption of "as-planned" building information in an on-site mobile construction process. In the case of [14], for the task of automated brick-laying, the planned geometries of two pillars are fitted to the robot map, and their as-built location is extracted to generate the robot tasks for fabricating a brick wall between them in a mobile robotic construction process. In the case of [15], a similar approach is implemented locally. By tracking visual features of the geometry that is being built, each discrete steel member is registered with stereo vision and locally corrected, all facilitated by the interface between the robot perception and the building information during the execution of the building task. These works demonstrated the feasibility and necessity of deviation measurements to adapt and execute construction tasks online, but they were limited to specific pre-programmed geometries and tasks.

It has not been demonstrated so far to establish an online data flow for an integrated robotic construction process and a flexible work area selection directly on job sites, localizing the construction robot both globally and locally in reference to the already built components (local references such as walls, floor, ceiling). With this research, we propose the online deployment of the building model into the robotic construction process, aiming to introduce a real-time method to plan a robotic workflow by fitting building tasks to local, selected references on-site, via a suitable interface.

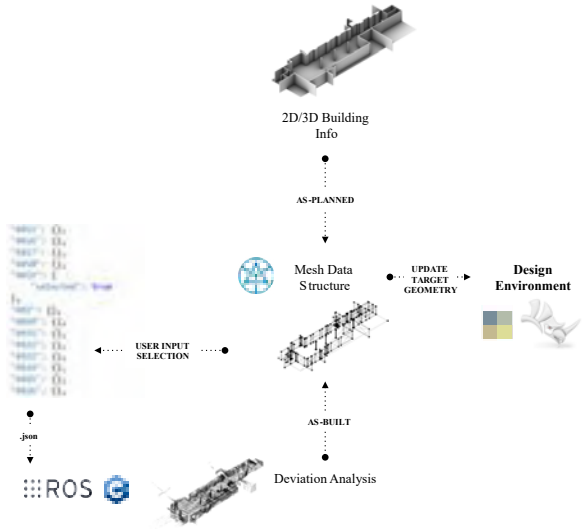

Figure 2. Overall workflow.

3 Method

Towards a generalized workflow, our method considers an abstraction where a building task is executed (i.e. as a robot trajectory) on a selected target geometry. To execute such a task, the robot requires poses of the trajectory in a local coordinate frame, which we anchor at given reference geometries. In this section, we describe a method that can execute such a task although the location and orientation of the target mesh faces (belonging to a target geometry), with respect to the reference mesh faces (belonging to reference geometries), may diverge from the "as-planned" state.

The procedure for the proposed method consists of the

[1] https://www.doxel.ai/
[2] https://www.scaledrobotics.com/

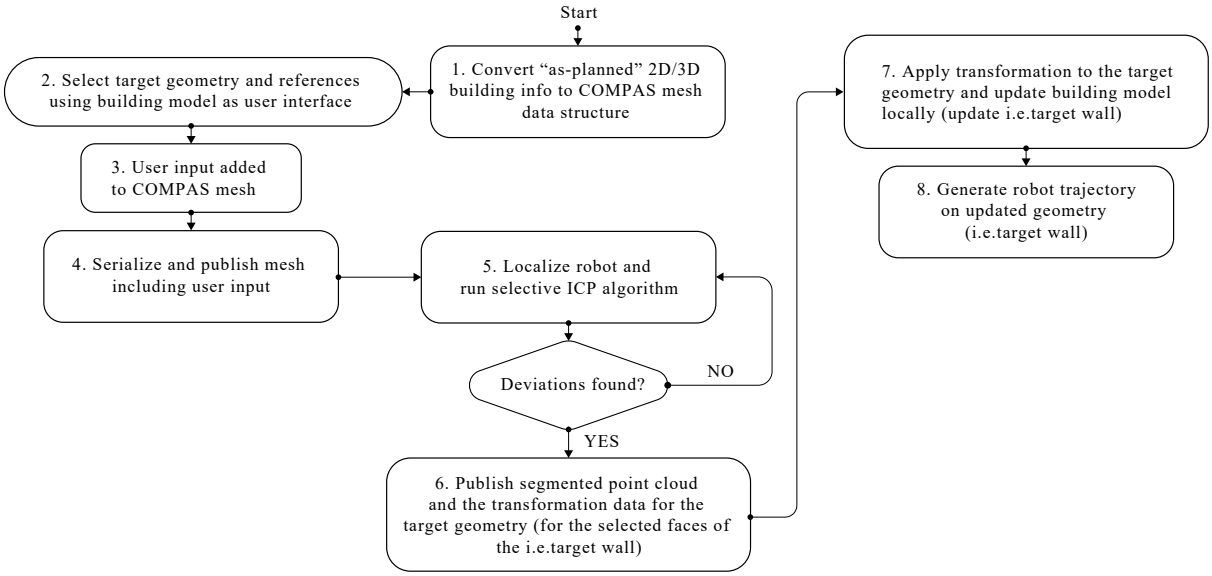

Figure 3. The procedure for the proposed method.

following steps (Figure 3): Firstly, the mesh data structure representing the building components is generated from the “as-planned” 2D/3D building information, as described in subsection 3.1. Secondly, the user selects the target geometry and the references by clicking on the control points for bounding the areas of interest, and the program executes necessary steps to find the target and reference mesh faces that contain all given points as vertices. This is then included in the mesh data structure via labeling the target mesh faces as "selected" and the reference mesh faces as "reference", as described in subsection 3.2. Following this, the mesh data structure containing the user input is serialized and published as a message in the ROS environment running the robot controller. Next, the robot is localized and the ICP algorithm is executed on-site, as described in subsection 3.3, using local references (coined selective ICP) [16]. The calculated transformation is published back and imported into the building model. As described in subsection 3.4, the transformation is applied to the target geometry and the building model is updated locally in the design environment. Finally, the robot trajectory representing the building task is generated on the "as-built" target wall. These steps are also shown in an accompanying video[3].

3.1 Building Model Data Structure

A schematic overview of the data representation communicated to the robot is shown in Figure 4. This

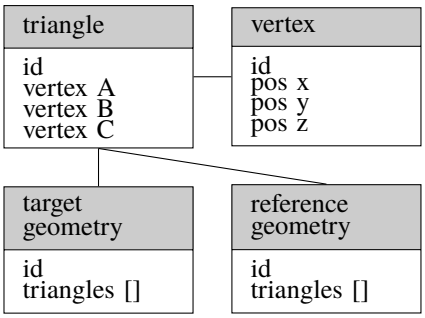

Figure 4. Data representation communicated between the building model and the robot.

data representation is initially generated from the "as-planned" 2D/3D building information, using the open-source, Python-based computational framework COMPAS[4] and visualised in 3D modeling software Rhino (Figure 2). It contains the mesh data structure of the COMPAS framework that allows for storing and adapting geometry and topology, aiming to represent the continuously changing building information and the robot trajectory (representing the building task) in relation to *target geometries*, i.e selected faces of the target wall. Like this, robot trajectory planning and generation from the design environment is aligned with the "as-built" state and the robot map (Figure 1). The communication between the robot controller - running in a ROS[5] environment - and the Python-based

[3] https://youtu.be/pu4hb_nZNUw

[4] https://github.com/compas-dev/compas

[5] https://www.ros.org/

design environment is established using the ROS Bridge library roslibpy[6]. Additionally, the kinematic model of the mobile robot is visualized in the design environment using the COMPAS FAB package of the COMPAS framework. This allows users to visualize the current robot state and task status in relation to the building model in the later stages of the process as well (such as i.e. feedback- based plaster spraying - that comes after Step 8 of the procedure shown in Figure 3) - which is not included within the scope of this paper.

3.2 Building Model as User Interface

The building model described in 3.1 - with the necessary abstraction level - is used directly on-site for task level commanding and for the selection of the target geometries and the necessary references, which are the relevant faces of the neighboring meshes, constraining the work area for the building task in the x, y and z axes. Firstly, the user selects the target geometry by clicking on the control points (located on the corners of the geometries) for bounding the area of interest (Figure 1), and the program executes necessary steps to find the target mesh faces that contain all given points as vertices. The same steps are repeated for the selection of the references. Next, the selected vertices are labeled in the mesh data structure, which is then serialised and communicated to the robot.

3.3 Robot Localization

The robot localizes against the building model using measurements from the 3D LiDAR described in subsection 4.1. In this way, the user provides an initial coarse alignment during robot start-up. The robot subsequently aligns the LiDAR scan with a sampled point cloud from the mesh as described in [17], using the Iterative Closest Point (ICP) algorithm [18]. To increase accuracy and overcome ambiguities, the alignment is constrained to a few *reference mesh faces* [16]. Here, these reference mesh faces are selected through the interface described in subsection 3.2 and communicated to the robot as described in subsection 3.1. Consequently, all LiDAR scans are aligned to the selected reference frame when measurements on the *target mesh faces* are extracted.

3.4 Adapting the Building Model to As-Built

When the robot is localized, deviations between "as-planned" and "as-built" can be measured on the target geometry. Candidate planes from the LiDAR scan are extracted in order to find the plane associated to the target geometry. Given measured distances d_{it} between points i on the candidate plane c and the target plane t, we associate planes by:

$$\arg\min_{c} \ \lambda_1 \min_{i} d_{it} + \lambda_2 \frac{1}{N} \sum_{i} d_{it} + (1 - \lambda_1 - \lambda_2)\,\mathrm{rot}(c, t)$$

where λ_1, λ_2 are tuning weights. The geometric transformation between "as-planned" and "as-built" can then be found as the translation between the plane centroids and rotation $\mathrm{rot}(c, t)$ between the face normals of the target geometry. As the current sensor setup does not allow the measuring of points over the whole height of the building components (i.e. walls), the z coordinate of the centroid cannot be estimated and therefore the z translation is not considered in the experiments. Upon detection of the geometric transformation, it is applied to the target geometry and the building model is updated locally.

Figure 5. Mobile robotic platform used in our experiments, here with an additional arm mounted.

4 Experiments

Experiments are presented in three subsections. The first subsection describes the robotic platform; the second subsection showcases the online selection of references and the work area and the third section focuses on the deviation detection and update of the target geometries locally in the building model. All experiments are conducted at a parking garage, which is set up as a mock construction scene at ETH Zurich.

4.1 Robotic Platform

The experiments are conducted on our open-source robotic platform[7] that consists of a wheeled base with LiDAR and IMU sensors, as shown in Figure 5. The platform's capabilities of high-accuracy manipulation [17] and

[6] https://github.com/gramaziokohler/roslibpy

[7] https://github.com/ethz-asl/eth_supermegabot

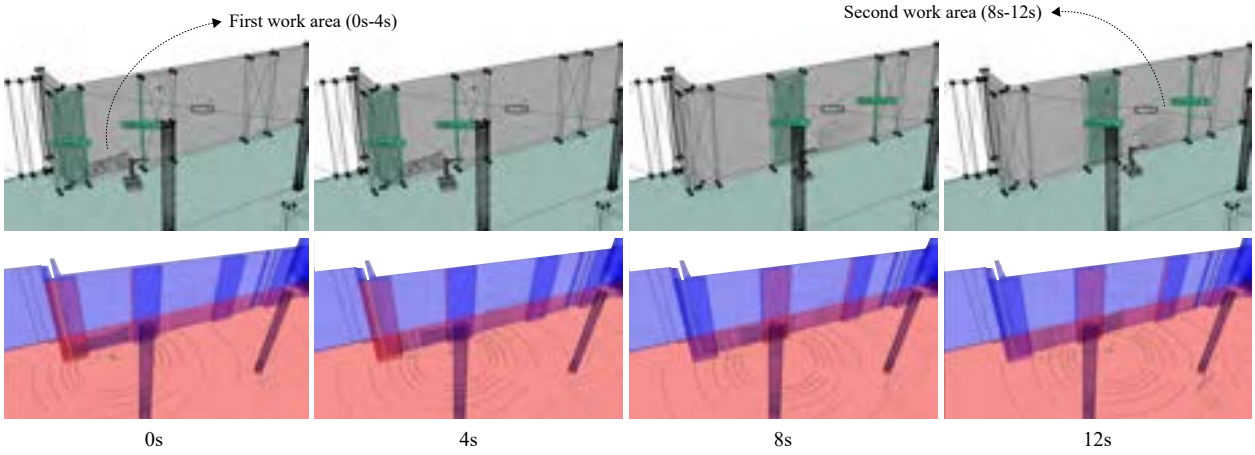

Figure 6. Top row: Online selection of references and work area. Bottom row: Robot map and perception.

localization in cluttered environments [16] were validated in earlier works. Since no manipulation for the execution of the building task is tested within the scope of this paper, the robotic arm was not mounted on the mobile platform in our experiments.

The LiDAR sensor used has an accuracy of 2 cm, 16 beams, and an opening angle of 30°, leading to height measurements on target walls of approximately 1 m. The scope of this work is therefore not a precise deviation analysis or sensing benchmark, which is out of the capabilities of the used sensors, but the demonstration of an integrated online workflow. The demonstrated workflow is not specific to the sensors used here, and can in fact be applied to any robotic platform that has the capability to localize in a robot map and to measure spatial information on selected geometries.

4.2 Online Selection of References and Work Area

In the first set of experiments, steps 1-4 of the procedure shown in Figure 3 are tested in order to showcase the initial steps of the online data flow proposed for synchronizing building information and the robot map. Initially, for the first work area shown in Figure 6, relevant references X, Y, and Z are selected, where X refers to the reference constraining the work area in the x-axis, and Y and Z, refer to the ones constraining the work area in the y and z axes. Without the need to reload a new building model to the robot off-site, the references are shifted on-site (as described in subsection 3.2) to the ones shown in Figure 6, at 8s. This successfully demonstrates a flexible, online method for work area selection to execute a building task (i.e. plaster spraying), for which fitting to relevant and local references on-site is crucial.

4.3 Deviation Detection and Update

In the second set of experiments, steps 1-8 of the procedure shown in Figure 3 are tested in order to showcase the update of building components to their as-built states for tolerance handling to facilitate an on-site construction process. For a selected set of target geometries shown in Figure 7, Walls 1-3, the same set of references X, Y, and Z (shown in Figure 7) are selected as described in subsection 3.2, constraining the work areas in x, y, and z axes to execute the selective ICP algorithm on-site. Robot trajectories are then generated on updated target geometries.

Table 1. Geometric transformations calculated for the target geometries, resulting from deviation detection: Translation of the mesh face centroid and rotation of the mesh face normal

Target	X Translation	Y Translation	Rotation
Wall 1	−30 ± 11 mm	−23 ± 34 mm	1.1 ± 1.4°
Wall 2	−13 ± 1 mm	−109 ± 1 mm	2.0 ± 1.4°
Wall 3	−5 ± 50 mm	36 ± 42 mm	0.9 ± 0.1°

5 Results

In all conducted experiments, the robot correctly associated its measurements to the selected target geometry and was able to provide associated sensor readings in the form of a point cloud, in addition to a parametric analysis of the deviation. This is important, as it allowed for updating the target geometry and for adapting the robot trajectory, representing the building task. The geometric transformations calculated for each target geometry are presented in Table 1.

Within the scope of this paper, the experiments focused

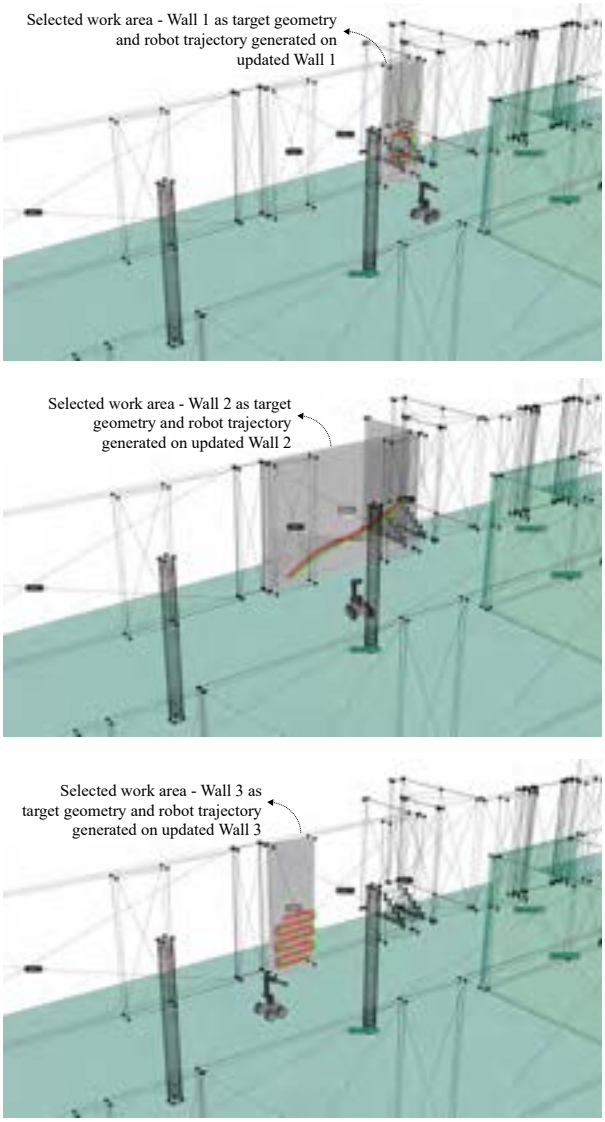

Figure 7. Deviation detection on selected target geometries, Walls 1-3, and generation of robot trajectories on updated target geometries.

on demonstrating the online workflow of the robotic construction system. In order to assess achievable degrees of precision, tests will be performed with higher-quality sensors on the robotic platform, and results will be compared to a ground truth site survey derived from measurements with a tripod system.

6 Conclusion and Outlook

In this paper, we present the first implementation steps of a novel method for an online data flow to synchronize building information with the robot map for facilitating an on-site construction process in an unbroken digital chain. This is established via linking the generation of robot trajectories, representing the building tasks, to the "as-built" states of selected building components directly on-site. Within the experiments presented in this paper, this is achieved by updating the target geometries in the building model, via the selective ICP algorithm executed directly on-site. Online deployment of the building model as an interface for including human actors into the robotic construction process is also tested, introducing a flexible method to plan a robotic workflow by fitting building tasks to local references on-site. However, these experiments do not extend to the actual execution of the tasks, which involve i.e. feedback-based plaster spraying, grinding, chiseling, etc. For these steps, in-process robot trajectory adaptation will be established with continuous process control, using visual feedback for acquisition of the current state of target geometries i.e. spraying, chiseling, and grinding surfaces. The overarching goal of this research is the development of a digital toolbox, so that the compatibility of the proposed workflow can be tested on different mobile robotic platforms deployed for on-site construction.

Within the scope of the experiments presented in this paper, the proposed method facilitated the digitization of crucial task information, i.e. selection of relevant references for building tasks for importation back into the building model and robot map. In further development, we will explore methods of dispatching task-specific instructions via different types of interfaces and experiment with on-site robotic workflows based on human collaboration and aim to further leverage the strengths of both humans and robots, enhancing the capabilities of digital construction processes.

Abstract –

In recent years, new technologies have improved the monitoring of construction progress by using the as-planned BIM of a building and comparing it with the current state of construction (i.e., the as-is model) to identifying differences and generating a progress report. However, in most cases, the different components required for the progress reports are still done by human operators. Those inspections typically consist of time-consuming and repetitive processes, making them a great candidate for automation, which can improve the quality of the methods used to monitor and assess the progress of buildings during the different construction phases.

This study proposes the development of an autonomous robot equipped with different sensors to collect data that can be used to conduct an automatic assessment of the state of construction, improving the current tedious and error-prone data collection and documentation processes. The proposed methodology is divided into three components: 1) Development of a robotic system able to navigate through construction sites in an autonomous way, 2) Data collection, and 3) Comparison of as-is with as-is conditions to identify discrepancies and generate a progress report. This paper focuses on the first two elements of the process.

The proposed robot is equipped with a 3D Terrestrial Laser Scanner (TLS). In addition, a robotic arm with a gripper is included so the robot can interact with different elements to achieve an autonomous robust robotic system. To test the autonomous navigation of the robot (including obtaining the optimal path through the building), the actions of the robotic manipulator, and the generation of the progress report, a simulation test was developed under the framework ROS (Robotic Operating System).

1 Introduction

During the last years, new technologies have made the assessment and inspection of buildings much more efficiently and with better quality. However, in many cases, these inspections and assessments are still done by human operators who can induce errors in the process. Thus, a typical manual inspection entails time-consuming and repetitive processes that are usually carried out by two operators. This all leads to that, after some time, the operator is more susceptible to making mistakes and, therefore, might report a wrong assessment. The importance of the construction in the last years has brought to the table a need to automate and improve the quality of the methods used to assess buildings along with the different phases of construction projects.

By using an autonomous robot equipped with different sensors, an automatic assessment and inspection system can be used to perform this task, improving its quality and making it a much faster process.

The proposed methodology is divided into three components: a) development of a robotic system that can navigate through construction sites in an autonomous way (navigation and localization algorithms), b) data collection and c) analysis to quantify installed items, comparing as-is with as-planned conditions (BIM and project schedule). The work presented in this paper focuses on the two first components and provides details of the autonomous robotic system.

1.1 Previous work

The rising popularity of BIM models has allowed construction professionals to plan in a much more organized way all the construction processes before actual construction begins. However, up to this date, there is still a gap in how to keep track of the actual progress of construction tasks in an efficient way.

Photography and visual inspection are nowadays the most common way to compare the as-built model with

the BIM reference (i.e., as-planned model). That means that someone has to collect all the images through the construction site and later inspect them in order to generate a report. In general, this process is very tedious, time-consuming, and human dependent, meaning it can lead to inaccuracies and subjective assessment regarding the actual state of construction.

With the development of terrestrial laser scanning (TLS) technologies, some of these reports are now being generated by using 3D point clouds [1]–[3] instead of visual inspection or 2D photographs [4], [5]. This process has significantly improved the way the as-built model is compared with the as-planned BIM model, with the point cloud containing a much higher density of data and, therefore, allowing the operator to inspect the building in more detail. However, a higher amount of data implies longer time requirements for the inspection and report generation. In addition, this 3D data collection is still supervised and handled by a human operator, which again is a very time-consuming process.

Research has already been done regarding the data processing stages [6], [7], improving the autonomous data analysis characteristic of the process. Automatic segmentation algorithms are able to analyze the raw data coming from the 3D point clouds and identify the different structural elements of the building [7]–[13]. Some of them focus on general aspects of the building, such as the recognition of large indoor spaces [7]. Others concentrate on particular structural elements such as the detection and identification of cylindrical components [13], which can later be used in order to assess the proper location and type of the installed components. The use of additional information such as thermographic data [14] can also be used in order to identify the structural elements. This way, an automatic report can be generated by comparing the generated as-built model with the as-planned BIM [3], [15]–[17].

However, few approaches deal with the automation of the data collection process. By automating the data acquisition, the whole process can become completely autonomous, and the system would be able to automatically collect the data, generate the model, and create a report to assess the progress of the building. Adan et al. [18] propose an autonomous system in order to gather data from the building and to generate an as-is model; however, it does not take into account the as-planned BIM model. Ibrahim et al. [19] present an autonomous robotic platform able to collect 3D geometric and RGB data from the building. The data acquisition process has to consider that the quality of the data must be good enough in order to process the information and generate the model [20]. Therefore, a good strategy has to be designed, considering the fact that the BIM model of the building is available, which can be used to obtain the floor plans in order to plan a valid path.

The method proposed in this paper fulfills the aforementioned requisite, hence becoming a fully autonomous system that automatically collects data using the existing (as-planned) BIM model, navigates through multi-story buildings, collects and processes data to generate a progress (as-is) model of the building, and later compares the as-is model with the as-planned model in order to generate a progress report of the building by identifying discrepancies found in terms of quantities, dimensions, locations, etc.

The scope of the work presented in this paper focuses on the autonomous collection of the data. It does not consider the generation of the as-is model and the progress report. The rest of this paper is organized as follows. Section 2 presents the proposed robotic system and an overview of the main points from the data collection process. Section 3 gives a preview of the work conducted by the authors related to the model generation and automatic comparison between the as-planned and as-is models with the ultimate goal to generate progress reports in an automatic way. Section 4 shows the experimental tests for the navigation and data collection in a simulated environment. Finally, Section 5 summarizes all the work.

2 Robotic system and data collection

This section addresses key elements of the robotic system and the overall process of the collection of data that would be used for the generation of the as-is models.

2.1 Robotic system

This section presents the different aspects related to the required characteristics of the mobile platform. Due to the complexity of the approach, a well-designed and equipped robotic platform is necessary. The platform is mainly composed of three elements, the mobile robot, the sensors, and the actuators. An example is shown in Figure 1.

2.1.1 Mobile robot

First, the locomotion aspect. Robots used in construction are usually limited to either tracks, legs, or outdoor all-terrain wheels [21], [22]. These locomotive systems are efficient when it comes to moving through rough terrain; on the other hand, they are not very precise, and they can be difficult to control in small indoor scenarios. However, means and methods of construction, as well as construction materials, have evolved during the last few years, making construction sites more approachable to robotic systems. For example, drywall is widely used for indoor construction, which, when compared to using bricks or any other conventional construction method, does not generate that much debris or dust.

(a) (b)

Figure 1. (a) Robotic platform based on Robotnik Kairos with UR10-e, (b) 3D scanner (Leica BLK 360)

Therefore, all-terrain locomotion systems are no longer necessary to achieve optimum navigation through a construction environment. Omni-wheels or any other kind of holonomic system would allow the robot to achieve much higher levels of control and precision, without sacrificing freedom of movement through the construction site.

2.1.2 Sensors

One of the key aspects is the localization system of the platform. GPS or any other satellite-based localization systems are widely used for outdoor scenarios, achieving a reliable and precise real-time position of the robot. Since our project is aimed to work indoors, this is not a valid option. Visual-based localization systems would need to have markers installed through the construction site. Since the approach is designed for the robot to be working in different stages of the construction process, this environment might be in constant change, which would not make the installation of visual markers a reliable method. Since the BIM model of the building will be available, information from the floor plans will be used in conjunction with LiDARs in order to obtain a precise and real-time position of the robot.

The type of data that the robot needs to collect includes, but is not limited to, structural geometry data of the building, thermal information, colored visual information, and surface reflectance information. Therefore, several sensors, such as 3D scanners, thermal cameras, and RGB-D cameras, are needed. The 3D scanner could be similar to the Leica BLK 360 (Figure 1b), which provides 3D geometric data, RGB color data, and thermal infrared data. This scanner also has a wide FOV of 360° (horizontal) / 300° (vertical) and a range of up to 60 m, which for most interior applications is more than enough. The ranging accuracy is 4 mm @ 10 m / 7 mm @ 20 m. Owing to its reduced size and weight (165 mm in height and 100 mm in diameter, and 1 Kg), this is a good scanner candidate for a mobile robotic platform.

2.1.3 Actuators

Finally, in order to facilitate a fully autonomous behavior on the scene, the robot will need to interact with the environment (e.g., obstacle removing, door opening, elevator access). To do this, a robotic arm with a suitable gripper is placed at the base of the robot. Given the platform will move through an inhabited construction site, populated with other construction workers, it is a must that this system complies with the collaborative robot background. This means the robot must be safe enough to be able to work side by side with human beings. The chosen robot arm, UR10-e, belongs to the spectrum of collaborative robots.

2.2 Navigation and data collection

The overview of the entire process is shown in Figure 2. This subsection presents the different elements related to 'Part 1: Flor plan extraction' and 'Part 2: Autonomous navigations & Data acquisition'.

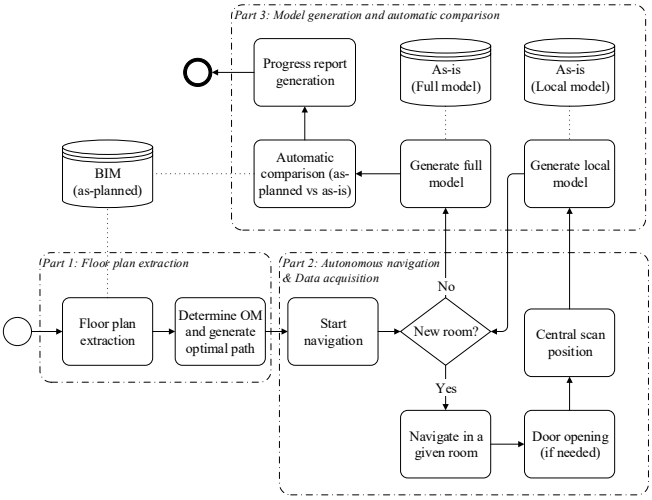

Figure 2. Overview of the navigation and data collection process

2.2.1 Floor plan extraction

All valuable information extracted during the 3D data processing stages is used for the positioning and secure navigation of the mobile robot. This consists of the following stages.

2.2.2 Optimal path generation

The only input the system is getting from the very beginning is the Industry Foundation Classes (IFC) file of the building. This file contains all the information related to the BIM model. A proper methodology to

understand the structure of the file needs to be developed to automatically extract the information needed for each one of the stages (Figure 3).

Since a single file can describe multiple buildings, the first distinction that can be found inside an IFC file is the building tag. Under the building tag, there are multiple levels or stories of the building. Within the same level or story, all the defined spaces can be extracted, that is, all the different rooms and corridors inside the same floor. Lastly, the rooms and connections between the different spaces can be identified (Figure 3).

One of the main things to be considered in order to extract the information from the IFC file is the type of information present in it. The definition of the spaces, for example, can be provided in different ways in the tag IFCSHAPEREPRESENTATION [23]. There are multiple types of representation, but they can be separated into three main blocks: 2D curve representations, solid model representations, and surface model representations. The ideal scenario is the one where all the available representations can be found within the same file, in order to access each, one of them depending on the kind of information that needs to be extracted.

At this point, all the information required to proceed with the first step in the process has been extracted. Now, in order to provide the robot with a safe and approximate representation of the scene, an obstacle map (OM) of the current floor needs to be generated. This will guarantee safe navigation. The OM is obtained from the accumulated point cloud and the current floor plan (i.e., map).

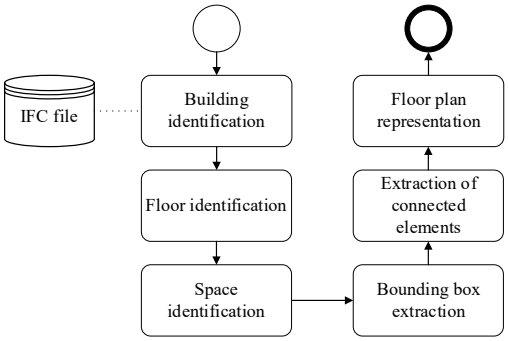

Figure 3. Structure within the IFC file in order to extract the floor plan representation.

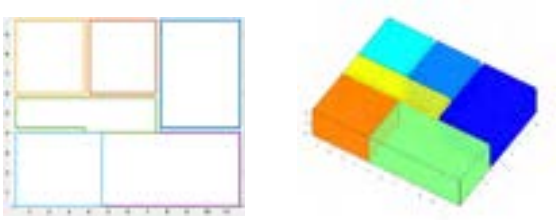
In order to alleviate the post-processing stages, the 2D curve representation would be of a suitable type to extract the 2D floor plan (i.e., map) from the IFC file. If the IFC file does not contain a curve type representation, the 3D solid model or face representation (BREP) could then be used to generate the 2D map. Figure 4 shows a 2D curve representation and a BREP representation extracted from two different IFC files.

With the 2D representation of the floor plan extracted, a morphological set of operations are applied in order to generate a binary occupancy map, that is, the OM of the robot.

The robot will always begin the autonomous data acquisition process in the center of a room, indicated by the user as an input. In order to visit the other rooms on the same floor, a global navigation algorithm generates a room visiting schedule. According to this schedule, the robot moves towards the closest non/visited following room, updating on each iteration the list of visited rooms (Figure 5). More details on the generation of this schedule can be found in [18].



(a) (b)

Figure 4. (a) 2D and (b) BREP representations extracted from the IFC.

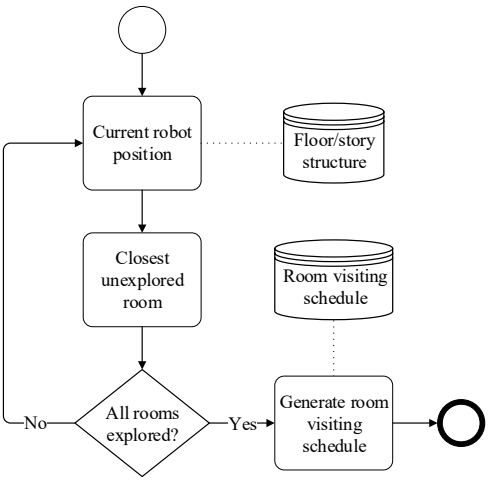


Figure 5. Generation of room visiting schedule.

The generated path needs to make sure that the robot visits all the individual rooms of the building, maximizing the coverage of all the structural elements present in the construction site.

This OM gets updated with each single scan performed by the robot before moving to the next goal, in order to add all the obstacles not present in the floor plan extracted from the IFC file.

2.2.3 Autonomous navigation

In addition to obtaining the map, the robot needs to know its position inside the map. This is accomplished

by matching the data points provided by the LiDARs with a horizontal slice obtained from the point cloud at the height of these LiDARs, combining it with the boundaries of the 2D floor plan extracted from the IFC file. This is done using an Adaptive Monte Carlo Localization (AMCL) algorithm [24].

The path planning algorithm then yields an off-line theoretical path that the robot must follow by moving towards the different locations based on the existing BIM model. This path will have different stages. First, the robot needs to exit the current room, and therefore a path towards the exit door will be generated. Once the robot is in front of the door, it has to determine whether the door is either open or closed. This can be achieved by reading the front LiDAR data in order to detect a void. If the door is closed, a door opening approach will be executed. If the door is open, a second path will then be generated towards the entry room of the next room in the visiting schedule. Again, a procedure that detects the state of the door will be executed, with the door opening approach performed if needed. The third and last path in the sequence aims to lead the robot towards the center of the room in order to perform the next scan.

The NAVFN path planning algorithm will be used for the robot to navigate between goals. It is the most common global planner used in ROS (Robotic Operating System). This path planner is based on the Dijkstra's algorithm [25] approach.

If the robot encounters a closed door on its way to the final goal, it will begin a door opening approach. Since the coordinates of the door are already known from the IFC file, the robot will position itself in front of the door, in order to perform a detailed scan of the center section to detect the doorknob. Once the doorknob has been detected and the main parameters that define the door have been identified, the robot can safely open the door and continue its path towards the center of the room. A more detailed explanation of the door opening process can be found in [26].

The localization and the autonomous navigation would be implemented first in a simulated environment and then transferred to the real robot. This paper only focuses on the simulation part.

2.3 Data acquisition

As previously stated, every time the robot enters a new room, it performs a new scan from the center of the room. Of course, this will vary depending on the shape of the room. For example, corridors are treated as rooms by the algorithm, but due to the geometry of corridors, if the length of the room is larger than the maximum range of the 3D scanner, more than one scan will be needed to obtain the full geometry. That is why some factors need to be taken into account in order to compute the number of scans needed to digitize the room in its entirety. These factors depend mainly on the size of the room, the range of the scanner, and the shape of the room itself (concave or convex rooms).

The 3D scanner provides not only geometric data but also RGB, reflectance, and thermal information. This means that the generated point clouds have different layers of information, which will be used in subsequent 3D data processing stages.

In addition, all the data is progressively registered using the localization data coming from the robot. This position is obtained by fusing the data coming from the wheels odometry (read by the wheels' encoders), the Inertial Measurement Unit (IMU), and the output from the AMCL using the LiDARs. Also, all the data is time-stamped for further inspection. This data is registered for each room (in case multiple scans were needed for a single room), resulting in multiple raw local models representing different rooms of the current floor.

The resulting raw data is an accumulated point cloud of the whole building or a global model composed of all the singular 3D point clouds obtained in the different rooms. This accumulated point cloud includes all the sub-layers containing information about the surface reflectance, the 3D geometry, the RGB data, and thermal information captured by the cameras embedded in the Leica BLK 360.

3 Model generation and automatic comparison

After completing all the tasks indicated in Section 2, the raw data acquired is not structured in any way. Semantic meaning to all the collected data through the different stages of the process needs to be added. This is where the as-is model generation comes in place. Due to space constraints, only key components of these elements form the overall process are presented below.

3.1 As-is model generation

The segmentation process is aided by the fact that a semantic model of what the building is supposed to look like (i.e., as-planned BIM model) is available. Therefore, the raw data only needs to be fitted to the already existing model.

In order to do that, the first thing is to identify the envelope of each space. That is, a BREP representation of the current state of the building. For that, the BREP representation obtained from the BIM model in earlier stages will be used. With the obtained geometric faces, the raw 3D data obtained from the building is fitted to the planes defined by the BIM model, locating which ones have or do not have data. This will determine whether the plane has been constructed or not.

Based on the existent data, it can be determined which of these faces is present in the current model and those that are not.

3.2 Autonomous progress report

With the as-is model generated from the raw data obtained, the evaluation of the progress of construction can be done. With the semantic information for the main elements of the building, such as walls, ceilings, columns, floors, as well as secondary elements like doors, windows, and wall-mounted objects, a progress report can be generated. This progress report would contain, amongst other things, the percentage of completion of all these elements with respect to the planned schedule.

4 Experimental test

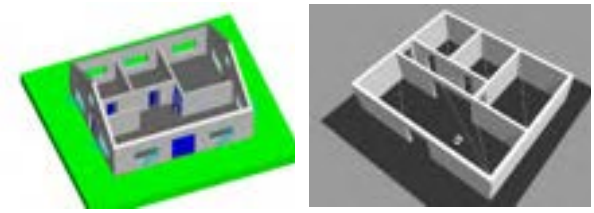
This section summarizes the experimental tests for the navigation and data collection under the framework ROS using the robot simulation software Gazebo and Blensor in a simulated construction environment.

4.1 Simulation test

In the current state of the research, the first part of the approach has been tested in simulation, successfully extracting the information from the IFC file and achieving autonomous navigation throughout the simulated environment.

Given the widespread use of BIM, there are plenty of available resources with different IFC files presenting different characteristics. For the current test, a simple two-story building was used. Given we are only testing the automatic IFC feature extraction and the autonomous navigation, the test focused on just the first story of the building, since the movement between floors is not the goal of this paper.

Multiple software is used in order to perform these simulations. First and foremost, Revit is used in order to inspect the IFC file and modify the state of the simulated building if needed (Figure 6a). For the robot simulation stages, the Gazebo simulation tool, natively working in ROS, was used (Figure 6b). This platform can test the different approaches regarding the robot, such as the localization and autonomous navigation or the door opening techniques. In order to obtain simulated 3D data, the Blensor add-on for the Blender software [27] is used. Finally, MATLAB is used to extract the features, control the robot, and process the obtained data.



(a) (b)

Figure 6. (a) Visualization in Revit of the IFC file of the tested building. (b) The same model inserted in Gazebo.

Once the building has been simulated with the information from the IFC file, the outline geometry of each one of the spaces within the floor is extracted from the IFC file. The location and size of each one of the openings (i.e., doors) are included in this map containing the previous information, and after applying an infill morphological operation to the void spaces between the different outline of the spaces, an OM map for the robot is generated (Figure 7).

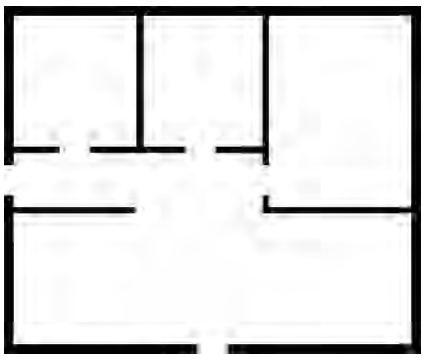


Figure 7. Obstacle map obtained from the information retrieved in the IFC file.

By using the obstacle maps and the inter-room navigation algorithm, the robot can autonomously visit the entire floor. Figure 8 shows the robot autonomously planning a path to navigate through the different rooms. In this figure, the cloud of small red arrows surrounding the robot represents the uncertainty in the position of the robot. That is why in its initial position (Figure 8a), the uncertainty is bigger than in the following positions, where the robot has already navigated through the scene and fully identified its localization. The local costmap calculated by the local planner is represented by the blue cells surrounding the obstacles. Figure 9 shows the accumulated raw data collected by the robot after performing a 3D scan in each of the visited rooms.

5 Conclusions and outlook

This paper presents the early stages of what aims to be an autonomous approach to perform inspections during the construction process in order to generate a progress report automatically.

Given a generic IFC file, a methodology to automatically extract all the different elements of a building has been presented.

A test, under simulation conditions, has been conducted on an IFC file of a two-floor building. Our system computes 2D obstacle maps, takes simulate 3D data of the rooms, and provides safe autonomous navigation of the robotic platform.

Ongoing work focuses, on the one hand, on developing new 3D data processing algorithms, in order to provide a semantic as-is 3D model of a multi-floor building. On the other hand, we aim to establish a procedure that easily compares as-planned to as-is 3D models and automatically generate a building progress report. This work also includes testing the findings from the simulation using the proposed robotic system in a real-world environment.

Abstract

Recently 3D management solution utilizing BIM/CIM is expected for construction and inspection management. Especially for inspection utility, big data such as huge number of inspection pictures and sounds should be managed with location data of taking data and should be taken with high quality and resolution on 3D world. This paper describes the total solution for 3D management system using Robots and AI technology.

Keywords –

BIM/CIM; Robot; Deep Learning; 3D

1 Introduction

In recent years, the deterioration of social backbone in terms of industrial infrastructure and social infrastructure has become a social problem. It has become necessary to solve many problems such as increase in the number of inspection and repair locations, aging of workers engaged in maintenance and management and decline in the number of employees, and pressure for reducing the maintenance and management cost. Especially for social infrastructure, in 2014, it became a requirement to carry out close-up visual inspection once in every 5 years for maintenance and management of all bridges, which are said to be 720,000 in total in Japan. In the case of close-up visual inspection conducted by workers based on the old inspection procedure, it is expected that continuing sound maintenance and management in future will be difficult.

As a solution in this situation, various new technologies such as the use of robots and drones and automatic extraction of damage by deep learning are being examined. In addition, research and development of three-dimensional unification technology for the integrated management of enormous amount of information obtained by robots and drones is also underway.

On the other hand, the initiative of i-Construction is underway in the field of construction and civil engineering, and by using BIM/CIM (Building Information Modeling / Construction Information Modeling), three-dimensional models are linked and developed in a series of processes such as planning, research, design, construction, and management, and a mechanism for sharing information at each stage has been developed [1].

In the present paper, in light of the above background, as a method for sustainable infrastructure maintenance and management, we developed a mechanism that uses digital twin technology, automatically extracts damage from various data acquired by inspection robots with deep learning, and associates them with a time axis on a 3D drawing. In addition, by assuming a case of a structure where drawings are lost or a case where there are attached equipment not reflected in the drawings, we also worked on methods such as CAD conversion from three-dimensions points group data obtained by 3D scanner and photogrammetry.

2 Digital twin technology

The digital twin technology [2] proposed by Professor Michael Grieves of the University of Michigan in 2002 is a technology that reproduces the real world in real time in a digital space in a linked manner. It is a technology that makes it possible to contribute to preventive maintenance by using acquired data, such as understanding the current situation digitally and making changes and predictions by conducting various simulations.

For the digital twin in infrastructure maintenance, first of all, it is important to obtain the latest shape and configuration of the structure, and it is necessary to accurately model attached equipment and repair marks that are not yet reflected in the construction drawings. On the other hand, a system that induces third party damage and that increases social losses such as traffic

congestion when taking measures such as suspension of sharing in data acquisition is not desirable. At the same time, it is also necessary that is a method for making a complex structure into a detailed three-dimensional structure.

Especially in the case of a large-scale structure, when trying to restore a complex structure in the digital space with an accuracy that contributes to infrastructure maintenance and management, if 3D restoration is done from continuous images with 90% overlap by a drone etc. using photogrammetry technology, the data size of the restored data becomes huge because thousands of images of a few MB size each are joined. The joining process itself takes a lot of time, and at the same time, there are some problems to be solved before putting it into practical use, for example, it requires a high-performance PC for viewing the restored data.

Therefore, in infrastructure maintenance and management, it is necessary to acquire data for understanding the latest shape and configuration of the structure and data of inspection quality required for maintenance and management, and it is necessary to acquire and restore data with the accuracy required for each of them.

In the present paper, the data for understanding the shape and configuration is acquired at a resolution that will allow understanding the shape and configuration, and the data size is further compressed by CAD. Moreover, the inspection data for checking cracks in concrete is acquired at a resolution that can detect the cracks of 0.1 mm size. After that, these data is merged for solving the above problems.

Figure 1 shows a panoramic view of the steel plate girder bridge, and Figure 2 shows a 3D points group obtained by mounting a 3D scanner on the robot Turrets (Figure 3) [3] that can access the girder of the steel plate girder bridge from the back of the bridge.

Figure 1. Three-dimensional point groups model of the whole bridge view

3 Damage extraction by using AI

Recently, AI has been used in various scenarios such as crack extraction of concrete and corrosion extraction of steel structure by using deep learning. Even in infrastructure maintenance and management, the Ministry of Land, Infrastructure, Transport and Tourism is playing a central role for making preparations such as rolling out the "AI development support platform" [4].

As for extracting cracks in the concrete, from the high-quality camera images taken, cracks are extracted by using semantic segmentation, and the cracks are then displayed in different colors according to the crack width and crack length. It is expected that because of this the inspection staff will not miss the inspection of cracks (Figure 4) and it will shorten the preparation of crack diagrams when preparing inspection records (Figure 5).

Turrets is equipped with a high-definition camera that can detect cracks of 0.1 mm size, and it is also equipped with a lighting device to obtain appropriate photographic images even in dark environments. Therefore, it is possible to obtain pictures with good image quality.

Figure 4. Bridge deck crack extraction image

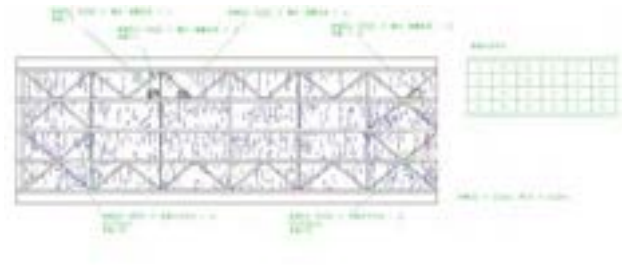

Figure 5. Inspection record

On the other hand, in the case of damage such as corrosion, after the target site is identified, deep learning and image processing technologies are used to automatically calculate the corrosion position, corrosion area, etc.

By associating these deterioration data with 3D drawing data with a time axis, the inspection staff can accurately understand the current state of the structure from a remote location, and it becomes possible to correctly diagnose the state of the structure.

In addition, since it has a time axis, the reusability of data is high, and it is easy to observe changes over time, which can contribute to the planning of future repairs.

4 Three-dimensional model and BIM / CIM conversion

Various types of data for structures including photographic images obtained by robots are often large amounts of data when compared to that of conventional inspections conducted by inspection staff. Therefore, if the various data obtained are randomly stored, the reusability will be poor, and it will take a lot of time to organize the data, which will reduce the advantages of using a robot.

One of the advantages of using robots is that the position information obtained from the sensors used to control the robots can be used as self-position information, and it can be associated with the acquired data to automatically organize the data. In addition, by managing the acquired data with position information in three dimensions, it is possible to intuitively overlook the damage situation in the entire structure compared to the two-dimensional management as shown in Figure 5.

On the other hand, in i-Construction, which is being promoted in the field of construction and civil engineering, integrated three-dimensional data management by using BIM / CIM is progressing. Therefore, integrating maintenance and management information into BIM / CIM not only offers the advantage that the data obtained in maintenance and management operations can be intuitively managed in three dimensions, but it also allows integrated management of design and construction data and maintenance and management data. In that respect, it is very effective that it can be used to estimate the cause of damage.

Give that, a mechanism was developed for unifying the robot's self-position and the BIM / CIM coordinate system, managing various data obtained by the robot in the BIM/CIM coordinate system, and then correlating them with the attribute data IFC (Industry Foundation Classes) used in BIM/CIM. In addition, it is often difficult to correlate with BIM/CIM data when the robot acquires self-position, for example, in the case of structures with old construction without BIM/CIM drawings, structures with attached equipment not reflected in the drawings, and structures that were repaired.

Recently, there is a measuring device called 3D scanner that can acquire the surrounding conditions with high precision in a three-dimensional points group. A method to make a new BIM/CIM by using this was also developed.

Figure 6 shows the Turrets (Figure 3) equipped with a three-dimensional scanner that is scanning while moving over the structure. It was possible to obtain the three-dimensional points group data shown in Figure 1 and Figure 2 by combining the multiple points group data at each measurement position obtained here.

In addition, Figure 7 and Figure 8 show the results of surface estimation from the obtained three-dimensional points group data and CIM conversion.

Figure 6. Turrets equipped with a three-dimensional scanner

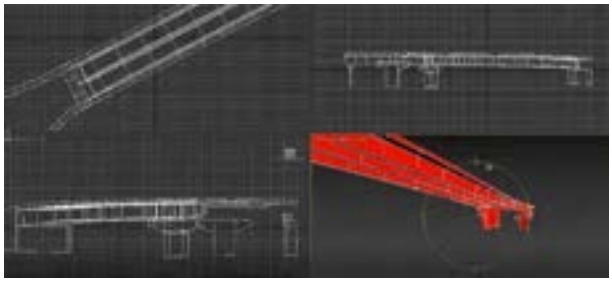

Figure 7. CIM conversion from three-dimensional points group data

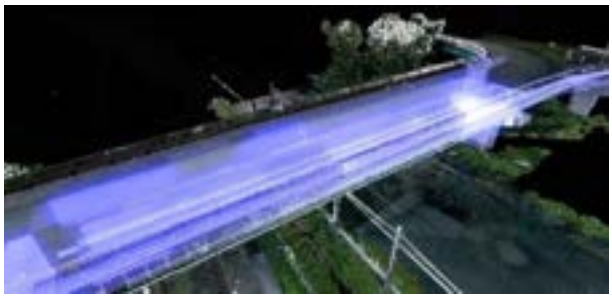

Figure 8. Superimposing three-dimensional points group data and CIM

5 Data superposition for digital twin

Up to the previous section, by correlating various data acquired by the robot with position information, it became possible to automatically extract and automatically measure the damage by using image processing technology and AI such as deep learning. In addition, by mounting a 3D scanner on the robot, three-dimensional points group data of the structure was acquired and converted into CIM. Since all of these data are managed in the BIM / CIM coordinate system, and the acquired data were superimposed on the three-dimensional points group so that they could be correlated with the IFC, which is the attribute data, and the damage condition could be intuitively understood.

Superimposition of the acquired images calculates the shooting position of the robot (camera center) from the postures of each joint of the robot, converts it to the BIM/CIM coordinate system, and measures the distance up to the shooting surface with the sensor mounted on the robot. Furthermore, the image size at that distance is estimated from the camera parameters, and its neighboring points are searched and correlated from the three-dimensional points group.

By the above processing, it became possible to arrange the images on the three-dimensional points group as shown in Figure 9.

Figure 9. Image superposition on three-dimensional points group data

At this time, since the damage in the image is extracted by deep learning etc. and displayed on the image, the worker can intuitively understand the damage location on the three-dimensional points group on which the image is superimposed (Figure 10).

Figure 10. Digital twin data

In addition, since these images associated with IFC can also be associated with other data described in IFC during design and construction, it is expected to contribute to preventive maintenance such as investigating the cause of damage occurrence and estimating future growth of damage from the relationship with design values, materials, and

completion inspection data.

6 Conclusion

In the paper, as one of the methods that effectively contribute new technologies such as robots and deep learning to infrastructure maintenance and management work, a digital twin technology based three-dimensional integrated management method was proposed. It is expected that future technological innovations will facilitate appropriate maintenance and management of the infrastructure, where aging has become a social problem.

However, while each technology is expected to be labor-saving, some problem have been pointed out such as the enormous data size and some operational issues like subsequent browsing of the data. Therefore, in this paper, we acquired the data with the required accuracy according to the purpose, converted it into three-dimensional data, and developed a sustainable infrastructure maintenance and management method by making it compliant with BIM/CIM.

In particular, as the number of skilled inspection personnel is expected to decrease in the future, it is necessary to propose to asset owners the diagnostic information that contributes to preventive maintenance from these new technologies. By setting up a mechanism that can correlate the acquired data and the position information and manage this information with a time axis, it is expected that efforts will be made for automation of diagnosis in the future.

In the future, we would like to deepen the digital twin technology that would allow inspection personnel to properly diagnose the infrastructure by accumulating data at various times for structures constructed in various environments.

Abstract -

Widespread use of autonomous robots in on-site construction has been limited because it is impractical to preprogram robots to perform quasi-repetitive tasks due to the relatively loose work tolerances and deviations of as-built work from the project design. Robotization of field construction work must thus be conceived as a collaborative human-robot endeavor capable of planning and improvising during the performance of construction tasks. Although humans can control robot motion through teleoperation, it is often impractical due to the range of a robot's motion and associated safety issues arising from heavy or large construction materials. An intuitive and safe bi-directional interface is thus needed to enable construction robots to seamlessly interact with and partner with human co-workers. This paper proposes a framework that allows human-robot interaction and collaboration within a real-time, process-level, immersive virtual reality (VR) digital twin that is created by combining the as-designed BIM model and the evolving as-built workspace geometry obtained from on-site sensors. Humans can use the digital twin to remotely demonstrate a task plan to the robot. The robot understands the communicated objectives and plans its motion to complete the task, which is communicated back through the system for human evaluation and approval before the robot executes the task. A case study involving imperfect rough carpentry (i.e., stud framing) and a 6DOF KUKA drywall-installing robot arm is conducted to demonstrate and evaluate the digital twin system.

1 Introduction

The construction industry is one of the largest sectors of the economy, accounting for up to 13% of GDP worldwide [1]. However, as one of the most labor-intensive industries, the construction industry is suffering from shortage and aging of the labor force [2, 3]. On one hand, the construction site is unstructured and dynamic. On the other hand, the construction work imposes considerable physical demands on workers. These facts lead to high fatality and injury rates in construction workers [4, 5]. In addition, the productivity of the construction industry has barely increased over the past few decades [6]. More recently, the outbreak of the Covid-19 pandemic has caused serious economic impact and schedule delays on construction projects since it is hard to maintain social-distancing while working in close proximity on construction sites [7]. This has highlighted the need for construction techniques that can allow workers to perform tasks remotely, allowing for reduction in the number of on-site workers or their physical separation while on site.

Robots can manipulate heavy objects and could potentially relieve construction workers from excessive physical demand, alleviate labor shortage, increase productivity, and promote remote construction. Although robots have already boosted the productivity of several industries, some attributes of the construction industry inhibit the wide application of construction robots [8]. First, the unique and static nature of the construction product requires robots being able to move to the workspace, accurately localize themselves, and conduct a series of different actions on the product [9, 10]. Second, the unstructured construction site limits the workspace of the robot and adds to the difficulty of robot motion planning and localization [11, 12]. Third, the moving workers, components, and construction equipment require robots to be able to comprehensively perceive the environment and make quick responses [13].

In addition, construction work has relatively loose tolerances [14, 15]. The evolving as-built structure and some construction materials may deviate from designed geometry, which requires adjustment of high-level task plans accordingly [16]. Although the recent development of artificial intelligence algorithms allows robots to be programmed with adaptability, it is not cost-effective or practical to equip and program construction robots with such high perception ability and adaptivity to cope with all potential issues on construction sites [17]. Human-robot collaboration (HRC) combines human beings' cognitive ability with robots' competency in power, speed, and accuracy, and has thus become a promising solution for robotizing construction work.

Several HRC methods have been adopted in the construction industry. An intuitive method for collaborative human-robot construction is to lead the robot by directly applying forces to the robot or the object carried by the robot through physical contacts, such as MULE135 (Material Unit Lift Enhancer) [18] and curtain wall installation robot [13]. It relieves construction workers from high physical stress while retains their operation agility. However, it still requires human workers to be present alongside the robot. Considering the needs of performing construction work remotely, several teleoperation techniques have been proposed for construction robotics, such as joysticks [19], haptic devices [20], wearable sensors [21], and vision detection systems [22]. Although teleoperation can protect workers from potential dangers on-site, operating robots with multiple degrees of freedom (DOFs) requires expertise. The robot is moving at the same time as human operation and the human needs to figure out and lead the robot through the full manipulation path. There are also safety issues caused by the limited perception of working environments [13]. Recently, the emergence of commercial head-mounted devices promoted the application of immersive virtual reality (VR), augmented reality (AR), and mixed reality (MR) in HRC. For example, VR has been used to study worker reactions while sharing workspaces with robots and AR has been used to give worker instructions to cooperate with robots [23, 24]. Therefore, a safe and intuitive HRC interface for construction robots that takes advantage of immersive technologies and allows remote operation is proposed.

The objective of this paper is to propose a real-time, process-level, immersive VR digital twin for intuitive and remote human-robot collaborative construction work. The human worker performs high-level decision making and supervision in an immersive VR digital twin of the construction site. The robot is responsible for detailed motion planning and task execution on-site. The detailed motion plan and robot status information are visualized in VR for human approval before actual execution. A case study involving imperfect rough carpentry (i.e., stud framing) and a 6DOF KUKA drywall-installing robot arm is conducted to demonstrate and evaluate the digital twin system. The construction site and robot arm are emulated in the Gazebo simulator that allows rapid prototyping of robotic tasks and direct subsequent transfer of the methods to the corresponding real robotic platforms [25].

2 Collaborative Human-Robot Construction System

Figure 1 gives an overview of the proposed collaborative human-robot construction framework. The human worker interacts with the robot through an immersive VR interface developed in Unity3D. The Oculus Rift S VR headset and the Oculus Touch controllers are used to create the VR experience. The immersive VR interface is connected to the robot operation environment (i.e. the construction site environment in which the robot performs the task) via the Robot Operating System (ROS) as the computational core. The computational core is responsible for computation and data processing. It also acts as the communication tool between the human and the robot. In this section, the immersive VR interface and the computational core are discussed in detail. The operation environment is discussed later in the case study.

2.1 Immersive VR interface

2.1.1 Immersive VR environment

The immersive VR environment is the digital twin of the construction environment. There are two common methods of developing the VR model of a construction site. One of them is to use the 3D CAD model, such as Building Information Modeling (BIM) [26]. It is fast and convenient to be loaded as a VR scene but it cannot reflect actual construction site environment since the built structure could deviate from design and there would be obstacles stacking on-site during construction. Another method is to construct point clouds from laser scanners or RGBD cameras [27]. However, it takes significant computational resources to construct the point cloud of a construction site and use it in VR. Therefore, this research uses a combination of the as-design BIM model and as-built point clouds of workspace obtained from the sensors to create the VR digital twin of the construction site (Figure 2).

The general construction site environment is generated from the BIM model. For the non-critical components, the BIM models are directly loaded and used in VR. It creates a realistic construction environment VR experience. The non-critical components indicate components that are outside the robot workspace or components that are inside the robot workspace but their deviations from design do not influence user decision making and robot execution processes. The BIM models of the critical components are set as semi-transparent so that the user can visualize how the structure is designed and supposed to be built.

Meanwhile, the robot workspace is captured by RGBD cameras placed on the construction site. The RGBD images are sent to the computational core for processing and then transferred to Unity3D for visualization in VR in near real-time. The point cloud overlays the semi-transparent as-design BIM model so the differences between the as-design and as-built geometry can be inspected. Point clouds can also capture the dynamic conditions in robot workspace, such as workers and obstacles, and show it in the VR. The human worker can view the as-built workspace conditions for decision making, such as deciding how and where to install the next component.

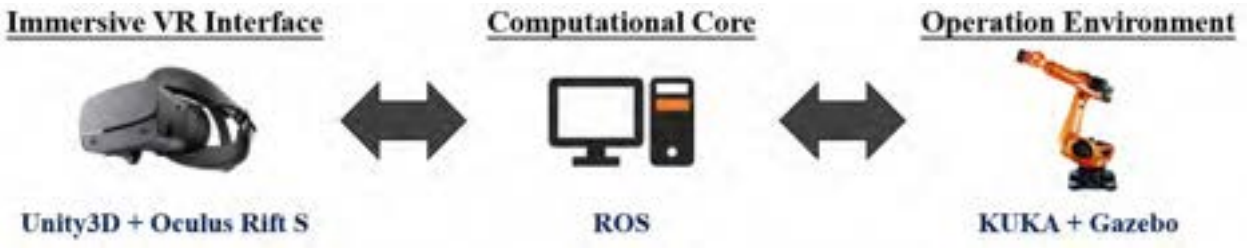

Figure 1. Collaborative human-robot construction system overview

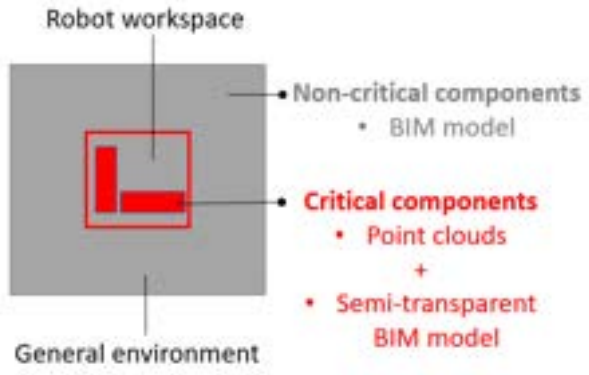

Figure 2. Immersive VR environment construction

2.1.2 Robot digital twin model

There are two full-scale robot models in the VR scene, which overlap with each other in the original state. One of them shows the planning state of the robot. It is used to visualize the robot motion plan (Figure 3(a)). The other one shows the actual state of the robot for execution status visualization (Figure 3(b)). The two robot models are referred to as the "planning" robot and the "execution" robot respectively in the rest of this paper. The KUKA robot arm model is built in Unified Robotics Description Format (URDF) in the ROS computational core, which has the same size and configuration as the actual robot [28]. The model is then transferred from ROS to be loaded as a game object in VR using the ROS# library [29]. The VR robot models preserve the kinematic and dynamic properties of the robot and can be controlled by subscribing messages from the computational core.

2.1.3 Interactive VR elements and functions

One of the advantages of immersive VR is that the user can have realistic experience while overcoming some restrictions of the real world. For example, users can receive extra information that they cannot directly achieve from the real world, such as the comparison between the as-design and as-built geometry, and overcome some real-world constraints, like gravity.

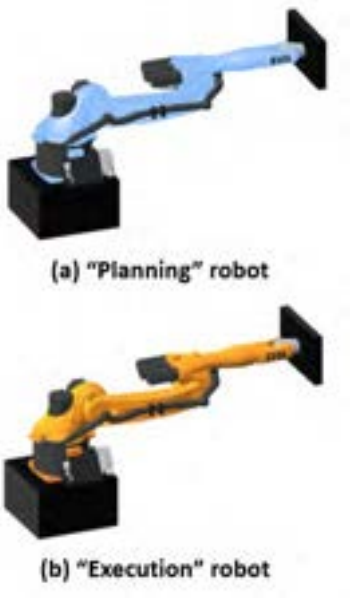

Figure 3. VR robot models (a) "planning" robot (b) "execution" robot

Our digital twin system includes several interactive VR elements. An interactive billboard with two functions has been developed. First, it shows the user system messages that cannot be directly obtain even from the actual construction environment, such as warning messages from ROS. Second, the billboard can also be used as an input device inside VR where the user can give commands to the system by interacting with the buttons on the screen. Users' sight could easily be occluded in complex construction environments. Therefore, instead of fixing the billboard to one location, our system allows users to manipulate it with the VR controller and adjust its pose and view at their convenience. The billboard can be suspended in the air as how it has been placed. As the environment changes, users can always put the billboard at a new desirable position. Some interactive construction materials have been created for pick-and-place related tasks, which can also be grabbed and suspended in the air, for the user to perform high-level task planning. It should be noted

that although the paper mainly discussed pick-and-place related cases, the system can be generalized to many construction tasks by adding customized interactive elements and functions.

2.2 Computational Core

ROS has been used as the system computational core. ROS is an open-source system that combines a variety of tools and software libraries for robot operation [30]. It can communicate with Unity3D, Gazebo, and the actual robot. In our system, ROS is also responsible for sensor data processing, motion planning, and robot control besides communication.

2.2.1 Communication

The system communication framework is shown in Figure 4. ROS# is used for communication between ROS and Unity3D [29], and *gazebo_ros_pkgs* is used to interface Gazebo with ROS [31]. As the program starts, Gazebo starts to constantly publish sensor data and robot states to ROS. In the meantime, ROS processes the sensor data and publish the processed data and robot states to Unity3D, which is then visualized as the point cloud and the state of the "execution" robot in VR. Based on the point cloud, the user develops the task plan and sends it to ROS after confirmation. ROS then generates a collision-free motion plan accordingly.

The motion plan is sent back to Unity3D and is visualized by the user on the "planning" robot. If the user is not satisfied with the motion plan, they can either adjust their task plan or request another motion plan from ROS which in turn generates a new motion plan in response. Upon user approval, a message is sent to ROS which converts the motion plan into execution commands to control the actual robot. As the actual robot executes the work, updated robot state messages are received by ROS and Unity3D. The "execution" robot in VR moves accordingly.

2.2.2 Sensor data processing

Several Microsoft Kinect cameras are placed on the virtual construction site in Gazebo to capture robot workspace. The RGBD images captured are converted into point clouds. Point clouds from different cameras are transformed into the world frame based on respective camera positions and rotations and then concatenated into one single point cloud. The point cloud is then downsampled with the voxel grid filter. Finally, it goes through the self-filtering process. Self-filter removes visible parts of the robot from the point cloud based on the current robot state.

2.2.3 Motion planning

After receiving the user-specified task plan, the corresponding end-effector pose is calculated. The robot then plans a trajectory to that pose so that both the robot itself and the object carried by the robot do not collide with the environment. The motion planning is conducted by MoveIt, a robotics manipulation platform in ROS [32]. The point cloud after processing discussed earlier is further processed by OctoMap into a 3D occupancy grid map of the environment [33]. The Open Motion Planning Library is used as the motion planner and the Flexible Collision Library is used for collision detection [34, 35]. The inverse kinematics is calculated by the Kinematics and Dynamics Library numerical jacobian-based solver [36]. The joint velocity and acceleration limits are taken into consideration to time-parameterize the generated path. After that, the time-parameterized path is sent to Unity3D as separate states for visualization on the "planning" robot.

2.2.4 Robot Control

When the user approves the trajectory plan in VR, ROS will be notified with an approval message. The *ros_control* package is then used to convert the approved trajectory plan into robot control commands [37]. It obtains joint state data from the encoders of robot actuators and generates output with PID controllers to robot actuators.

2.3 Case Study

A drywall installation case study with a 6DOF KUKA robot arm that is capable of real construction work has been conducted to evaluate the immersive digital twin system. The user guides the robot arm to pick up a drywall panel placed on the ground near the robot and place it on a wall frame that is built with deviations from design. Figure 5 shows the robot operating environment in Gazebo, which represents the actual construction site, and its VR digital twin in Unity3D. Three Microsoft Kinect cameras are used to capture the robot workspace environment in Gazebo.

Figure 6 shows the point cloud before and after processing. Points on the ground panel are also removed with the RANSAC plane segmentation algorithm. In VR, a drywall panel is set to be the interactive construction component, which is in the same shape as the actual drywall. The user will first observe the wall frame geometry from the point cloud and decide how to install the drywall panel onto the frame. The user can then demonstrate the task plan by grabbing the interactive panel and placing it at the desired installation position. The buttons on the interactive billboard provide options for fast and accurate adjustment of the orientation of the interactive panel.

The robot will first pick up the drywall panel on the floor and then wait for the user to specify the task plan. The

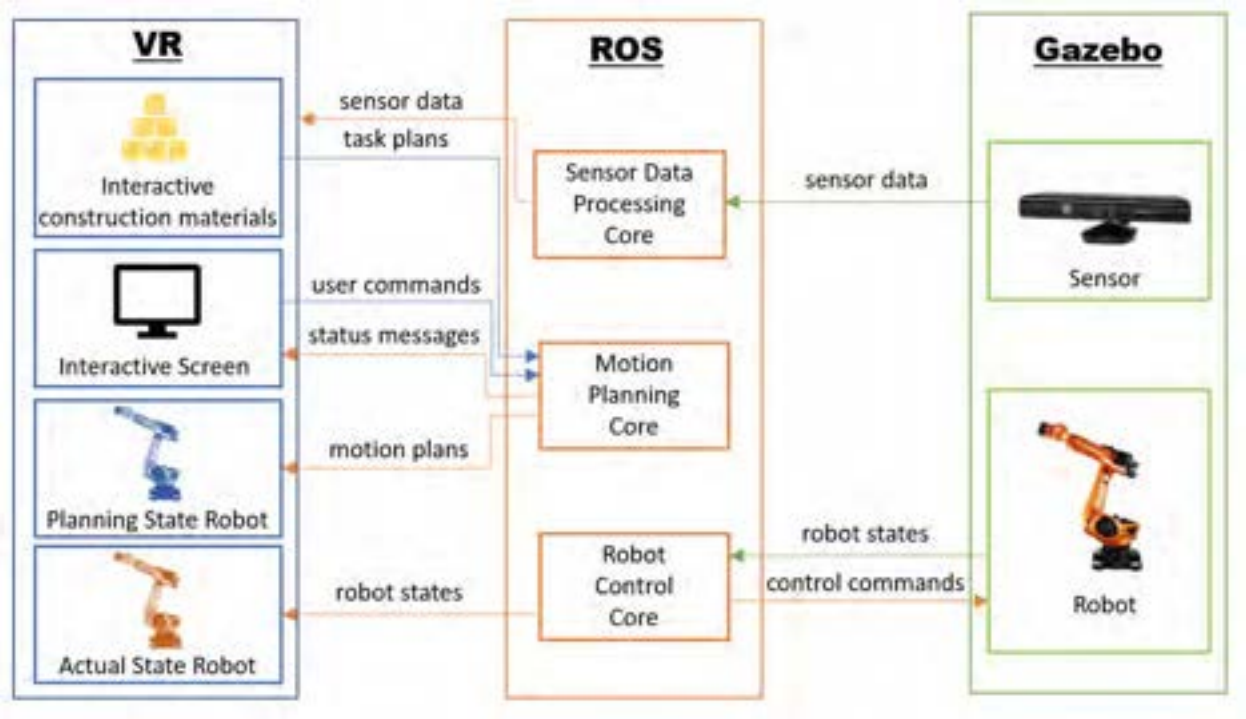

Figure 4. System communication framework

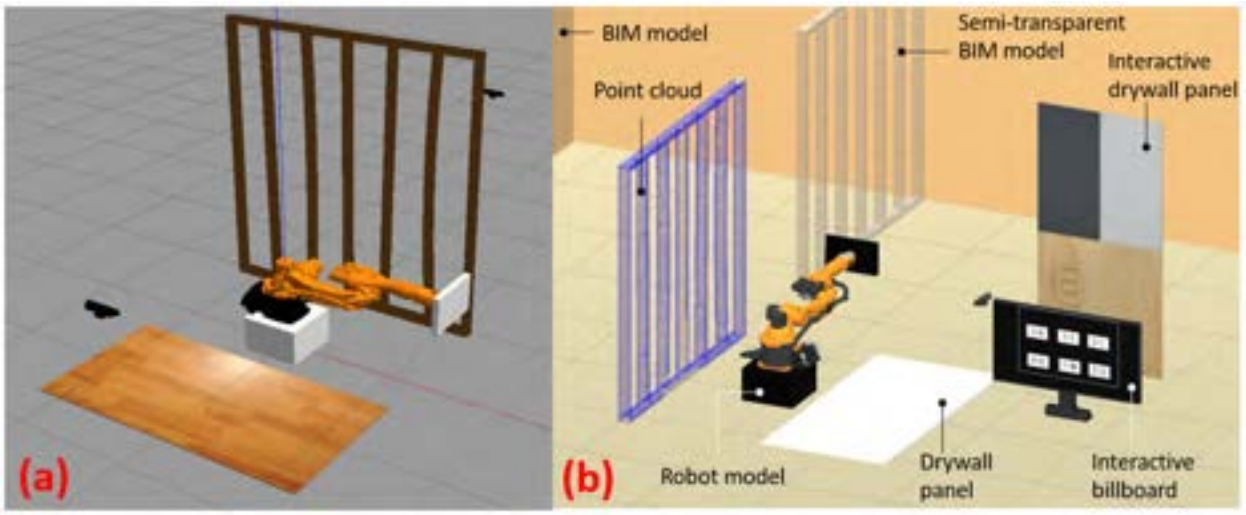

Figure 5. (a) Robot operation environment (b) VR environment

user can know whether the robot has successfully picked up the panel from the billboard and the panel will change color after being picked up. After the user confirms the task plan, ROS starts to develop the detailed motion plan to place the panel to the user-specified position while sending planning status messages (e.g. in progress, success, reasons of failure) to the user via the billboard. After motion planning, the "planning" robot demonstrates the plan to the user while the actual robot stays still (Figure 7).

Upon approval, ROS controls the actual robot to execute the approved motion plan and update the user with execution status messages. At the same time, the "execution" robot is synchronized with the actual robot by subscribing to the actual robot state messages so that the user can perceive actual robot status from VR (Figure 8).

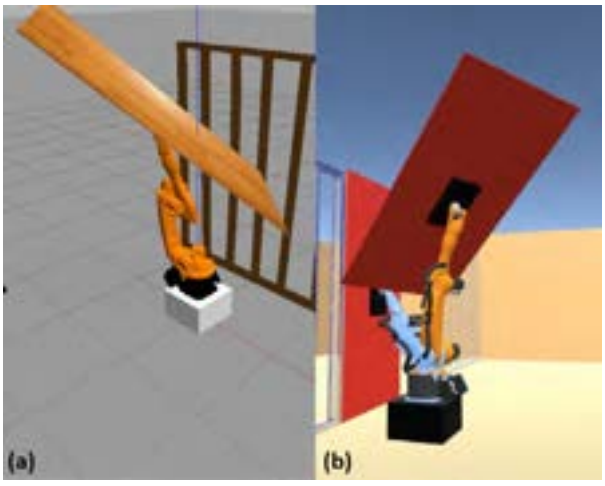

Figure 8. Synchronized movement of (a) actual robot and (b) execution robot

3 Conclusion

In this study, a real-time, process-level, immersive digital twin system for collaborative human-robot construction work is proposed. The system has several advantages. First, human workers can visualize construction site conditions and collaborate with the robot remotely, which protects them from potential dangers on the construction site. Second, the communication network allows the human worker and the robot to exchange task plans and status information in near real-time. Third, it allows the human worker to improvise high-level construction plans based on as-built construction site geometry. Last, the robot develops its motion plan and carries out physical construction work on-site, which significantly reduces human workload. In ongoing work, our research team is experimenting with real robots and implementing the immersive digital twin system with mobile robot arms.

Abstract -

This paper presents the developments achieved via the Social Cooperation Program "Intelligent Construction System," from three primary perspectives: environmental measurements, improvements in remote operability, and improvements in efficiency and automation of remote operation. For improvements in remote operation, environmental measurements of the disaster sites are critical. Therefore, a method to integrate the data from drones and ground-based vehicles in order to generate 3D maps was proposed. Another method for estimating the changes in soil volumes through a 3D map based on drone data was also proposed. Finally, to estimate the trafficability in disaster sites, a cone index-based method employing spectral images was proposed. Improving remote operability is essential to facilitate improved working conditions for operators. Considering this, a method providing human operators with a bird's-eye view of remotely operated machinery from any perspective was proposed. Additionally, to avoid the tumbling of remotely operated machinery, a running stability presentation method was proposed; this method presented the human operator with a tumble risk index. For improving efficiency and automation, an automatic camera control method, based on requirements of construction machine operators, was proposed. Using this method, the need for a dedicated human camera operator could be bypassed. Furthermore, for the automatic measurement of construction time and content, a method based on deep learning and using cameras for recognizing the actions of construction machinery was proposed. Preliminary experiments on some of the proposed methods in real environments yielded promising results.

1 Introduction

Japan experiences several earthquakes and volcanic eruptions as it is located on a crustal deformation zone. Moreover, the country also experiences heavy rainfall due to its dense forests (accounting for approximately 70% of the country's area). Such environmental conditions result in several natural disasters such as lava and debris flows due to volcanic eruptions, landslides caused by earthquakes, and flooding of rivers due to heavy rainfall. In the event of such natural disasters, it is necessary to promptly conduct appropriate investigations and restoration activities in order to prevent any further damage. However, disaster sites, i.e., the areas affected by these natural disasters, present a certain amount of risk due to secondary disasters. Disaster recovery efforts should be implemented soon after a disaster. Thus, considering the potential risk of secondary collapses or disasters, remotely controlled robots and remote-operated construction machinery are employed, which allows the human operators to work from a safe distance. However, such methods are associated with low work efficiencies, and they also prolong the time required for disaster recovery efforts. Therefore, a more efficient and intelligent construction system is necessary. For this purpose, a Social Cooperation Program "Intelligent Construction System" was organized by The University of Tokyo and Fujita Co., Ltd, in October 2017. The goal of this program was to research, develop, and establish an intelligent construction system for the inspection of infrastructures as well as for repair and disaster recovery efforts. This program focuses on utilizing in-

telligent construction technology achieved via advanced equipment, such as unmanned ground vehicles (UGVs) (including remote controlled robots and unmanned construction machines), drones, and information and communications technology.

This paper presents the advancements achieved via the Social Cooperation Program "Intelligent Construction System," from three main perspectives: environmental measurements, improvements in remote operability, and improvements in efficiency and automation of remote operation. For the environmental measurements, we introduce methods for generating 3D maps, estimating changes in soil volume, and determining trafficability. To improve remote operability, we introduce methods for providing a bird's-eye view of remote-operated machinery and for avoiding the tumble of UGVs. Finally, for the improvements in efficiency and automation, we introduce methods for presenting images via automatic control of external cameras and recognizing the actions of construction machinery.

2 Environmental measurement

2.1 Generation of 3D map with scale and slope information

At a disaster site, the topography and surrounding environment vary with respect to time. Therefore, unmanned construction machines should be operated based on the disaster scenes measured over a wide area as well as real-time data regarding changes in topography and surrounding environments. Therefore, studies have been conducted on environment map generation using UAVs [1]. To better understand the different conditions of a disaster site, we are developing a 3D map generation method that integrates data measured via drones and unmanned construction equipment [2]. By integrating the data acquired from drones and the inertial measurement unit (IMU) sensors mounted on UGVs, this proposed approach generates a 3D map comprising scale and slope information, as shown in Figure 1.

In addition, to monitor the ground information of disaster sites, we are developing a method to estimate the variations in soil volumes [3]. The ground at disaster sites is altered due to the gradual unloading of landslides and sediments. With regard to this, the proposed method compares a local map after terrain change with a global map prior to terrain change, in order to obtain the changes in soil volume as a 3D.

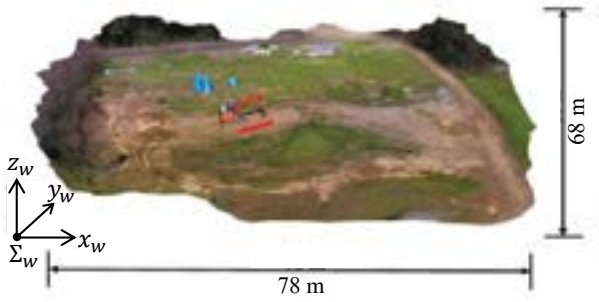

Figure 1. 3D map with scale and slope information

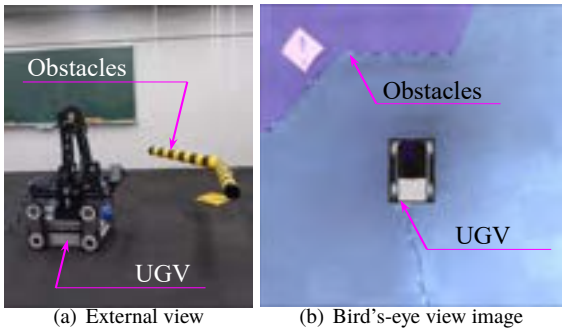
2.2 Trafficability judgment of UGV by ground measurement

Disaster sites can comprise soft soils, which cannot be traversed using UGVs, because such vehicles can get stuck and tumble in soft soils. Therefore, several researchers have studied the judgement the trafficability of UGVs [4]. However, no studies have focused on the non-contact judgement of trafficability with soft ground having a cone index of less than 200 kN/m^2, such as a landslide disaster site, as a target. Therefore, to ensure safe operation of UGVs at disaster sites, we are developing a method for judging the trafficability of UGVs without contact, based on the cone index [5]. The cone index is determined by the soil type and its water content. For this method, ground surfaces are evaluated via a multispectral camera, and the soil type and water content of the ground are estimated. The cone index is calculated based on these estimation results and used to determine the trafficability of UGVs.

3 Improving remote operability

3.1 Bird's-eye view image presentation

Remote-operated UGVs are effective for disaster recovery and inspection work in environments that are difficult for people to enter. When working with a remote-operated UGV, it is necessary to present an image to the operator. If the operator is presented with multiple camera images, the effectiveness of recovery or inspection efforts can be degraded. A single video depicting the surrounding environment is more effective. Therefore, several studies have been conducted on image presentation for improving the remote operability of UGVs [6]. To ensure improved operability, to view the remote-operated UGV as a single image, under this project, we are developing a bird's-eye view image that can be viewed from any angle. The proposed method generates a bird's-eye view image by using a laser range sensor and multiple fish-eye cameras mounted on a UGV [7]. The proposed method involves measuring the surrounding environment using a laser range sensor and generates a 3D mesh model of the wall. The wall is assumed to be perpendicular to the ground. A bird's-eye view image in an indoor environment is generated by projecting the image acquired from each fisheye camera on the generated 3D mesh model. By presenting a single bird's-eye view image, it is possible to recognize the rel-



(a) External view (b) Bird's-eye view image

Figure 2. Obstacles presentation on bird's-eye view image

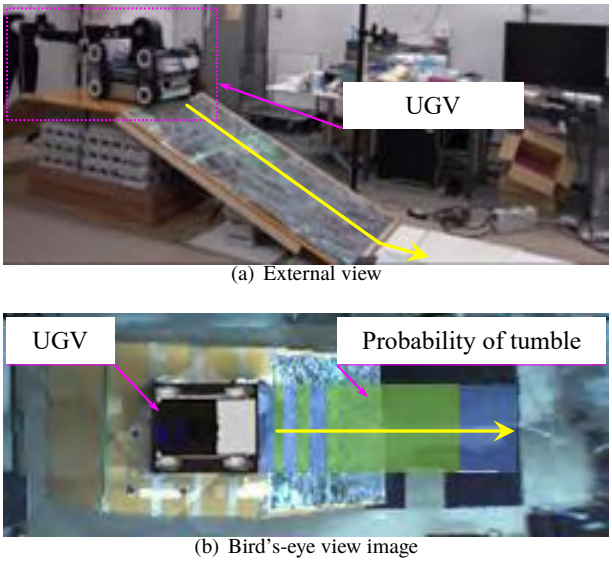
ative positions of the UGV and the wall and to improve remote operability in an indoor environment.

Furthermore, the path of the UGV can be obstructed by obstacles. Information regarding the relative positions of the UGV and obstacles can be effective for obstacle avoidance. Therefore, we are also developing a bird's-eye view image depicting the obstacles, as shown in Figure 2 [8]. This method generates a bird's-eye view image with a fish-eye camera mounted on the UGV. In addition, the surrounding environment is measured using the distance sensor mounted on the UGV. Finally, the obstacle is presented in the bird's-eye view image by integrating the different types of information. By presenting a single bird's-eye view image, it is possible to recognize the relative position of the UGV and the obstacle and to improve remote operability.

These methods involve measuring the distance to the object with a sensor. However, we are also researching a method to estimate the depth from only image information [9]. In this study, high- and low-spatial-frequency features were extracted from two images with different viewpoints, and two types of features with different frequency features were extracted. We generated a single feature by mixing these two different features. Finally, the depth was estimated via depth regression based on a single feature.

3.2 Tumble avoidance

When driving on the uneven grounds of a disaster site, it is necessary to avoid tumbles. However, it is difficult for operators to avoid tumbles using only information from the UGV's onboard sensor feedback. Therefore, several researchers have studied the tumble avoidance of UGVs [10]. We are currently developing a UGV running stability visualization method [11]. This method calculates the "stability" of a UGV using 3D ground surface information acquired via environmental measurements, through a



(a) External view

(b) Bird's-eye view image

Figure 3. Presentation of the probability of tumble

dynamics simulation. Thereafter, the probability of a tumble along the route selected by the operator is presented, as shown in Figure 3. In addition, we are constructing a method for the autonomous avoidance of tumbling; in this method, a manipulator mounted on the UGV is autonomously controlled to mitigate any detected tumbles. This method prevents the UGV from tumbling by moving its center of gravity via the autonomously controlled manipulator. Accordingly, the posture of the UGV is altered and its stability is improved.

4 Improvement of efficiency and automation

4.1 Image presentation by automatic control of external camera

During the embankment work of unmanned construction, the operator operates unmanned construction machinery based on external camera images. In such cases, the unmanned construction machine and the external camera are operated by the machine operator and the camera operator, respectively. Such an arrangement can lead to operation-related issues, because the camera operator may not present the view required by the machine operator. Several studies have been conducted on image presentation for remote construction [12].We are currently developing a method for the automatic control of external cameras [13]. In this method, to present the images desired by the machine operator, the video presented to the machine operator, the operator's gaze, and the machine operator's voice were recorded and analyzed, in an actual unmanned construction site. Based on the results, the required speci-

Figure 4. Automatic control External camera image

fications of the external camera image were extracted. The proposed method automatically controls the pan, tilt, and zoom of external cameras based on the extracted requirements for embankment work. Thus, appropriate external camera images are automatically presented to the machine operator, based on the construction requirements, as shown in Figure 4. Equivalent results were obtained for work time and visibility through a comparison between the image obtained using the proposed method and the image operated by the camera operator.

4.2 Hydraulic excavator action recognition

For effective management of construction machineries, it is essential to quantitatively determine the operation times and actions of these machineries. There are several studies on the action recognition of hydraulic excavators based on images [14]. In previous research, the action of the hydraulic excavator was recognized via deep learning, based on learning from actual hydraulic excavator videos. However, collecting a large amount of video data of actual hydraulic excavators is a significant challenge. To improve generalization, it is necessary to collect a large amount of data on hydraulic excavators of different sizes, colors, and shapes. Therefore, we are developing a method for recognizing the actual hydraulic excavator action via deep learning using simulation data of the hydraulic excavator action as a training dataset [15]. This method involves creating the data for recognizing the action of a hydraulic excavator in the dynamics simulation. We focused on three actions—digging, piling, and turning. These actions are learned based on simulation data. Then, a video filter is used for each data point to address the gap between the simulation data and the actual data. As a result, the action is recognized with an accuracy of 53.7%. This result shows the effectiveness of the proposed video filter, which is more than 20% higher than the action recognition result obtained using CNN+LSTM under the same data condition.

5 Conclusion

This paper presents the advancements resulting from the Social Cooperation Program "Intelligent Construction System" for environmental measurements, improvements in remote operability, and improvements in efficiency and automation of remote operation. For the environmental measurements, we introduced methods for generating 3D maps, estimating variations in soil volumes, and determining trafficability. For the improvement of remote operability, we introduced methods for presenting a bird's-eye view of remote-operated machinery and for the tumble avoidance of UGVs. For improving efficiency and automation, we introduced methods for presenting appropriate site images via automatic control of external cameras and for recognizing the actions of construction machinery.

As future efforts, we plan to validate the proposed methods at actual construction sites. In addition, we aim to further improve the construction efficiency, reduce manual labor, and improve intelligent construction.

Abstract -

Concrete is a major contributor to the environmental impact of the construction industry, due to its cement content but also its reinforcement. Reinforcement has a significant contribution because of construction rationalisation, resorting to regular mats or cages of steel bars, despite layout-optimisation algorithms and additive-manufacturing technologies. This paper presents an automated framework, connecting design and fabrication requirements for the optimisation of spatial layouts as of reinforcement of concrete structures, by the means of robotic filament winding.

Keywords -

Automated construction; Concrete structures; Reinforced concrete; Strut-and-tie models; Layout optimisation; Wound reinforcement; Digital fabrication; Additive manufacturing; Robotics; Robotic filament winding; 3D winding; Coreless winding; Trajectory planning

1 Introduction

This paper presents research on the automated reinforcement of concrete structures, investigated in the framework of the research project *Automating Concrete Construction* (ACORN) [1, 2].

1.1 Context

The construction industry is responsible for nearly 50% of the UK's carbon emissions [3]. More specifically, concrete construction is the main culprit, with more than 5% of the carbon emissions worldwide. The environmental impact of reinforced concrete stems from the amount of cement as well as the amount of reinforcement [4]. Layout optimisation applied to strut-and-tie models can find optimised tensile reinforcement for various concrete elements [5, 6]. However, these optimised layouts are not affordable, or even feasible, without significant post-rationalisation to build such reinforcement from stiff bar elements. Extreme rationalisation resorts to the use of standardised reinforcement bars, mats and cages, which require a higher amount of material and energy to produce. However, the use of advanced fabrication strategies and additive manufacturing, combined with robotics, provides an opportunity to automate the fabrication of complex optimised layouts of reinforced concrete structures using flexible filament materials.

1.2 Literature review

Short fibres can improve durability, provide a minimum tensile reinforcement against cracking and isotropic strengthening [7]. However, short fibres do not reinforce specific directions to carry high local tensile stresses based on an optimised layout. Reinforcement mats can carry higher tensile stresses, but the use of non-optimal, homogeneous and orthogonal meshes demands more material, and their placement is hard to automate, requiring patching and overlapping to map large-span plates or shells with double curvature [8, 9]. High, local, oriented tensile capacity can be provided by long fibres, or filaments [10]. Moreover, filaments are suitable for automated additive manufacturing [11], as commonly proven in the automotive industry to produce composite parts thanks to robotic filament winding [12]. For instance, the technology FibreTEC3D [13, 14], developed by Daimler and CIKONI, winds spatial layouts to produce mechanically-optimised components. In the construction industry, Spadea *et al.* [10] wound shear reinforcement for concrete beams using a rotating mandrel as core and Prado *et al.* [15] wound filaments to form composite shells using robotic arms holding boundary frames, instead of using a core. Filament winding of tensile reinforcement offers the flexibility to produce complex but optimised shapes and is suitable for automation using robotic arms. Moreover, achieving coreless winding removes the constraint of laying the filament on the surface of a core object, whose fabrication can be saved.

1.3 Outline

This paper presents an automated framework for the optimisation of tensile reinforcement for concrete structures that are suitable for robotic filament winding. Section

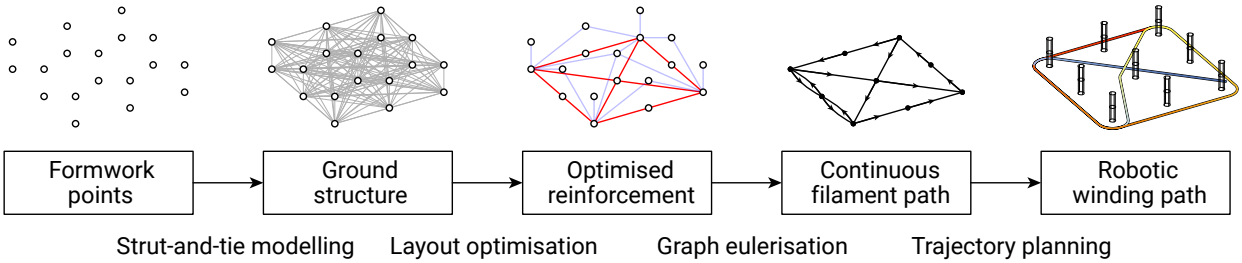

Figure 1. Workflow for the robotic filament winding of tensile reinforcement for concrete structures, including fabrication-informed generation, optimisation and rationalisation.

2 presents the automated framework, taking into account the constraints of the formwork system during the process of structural optimisation and the additive-manufacturing strategy for fabrication rationalisation. Section 3 applies this framework to a standard, benchmark plate with numerical results comparing the material quantities before and after rationalisation.

2 Automated framework

The workflow, illustrated in Figure 1 and detailed in this section, includes structural optimisation and rationalisation informed by fabrication requirements according to the following steps:

1. Define the winding points in the formwork system;
2. Generate a ground structure based on these points, which includes all the admissible winding passes;
3. Optimise the layout of this ground structure to obtain a strut-and-tie model with a minimal amount of tensile reinforcement;
4. Rationalise the tensile layout for robotic filament winding by creating a continuous path using graph Eulerisation;
5. Generate the trajectory for robotic winding around the formwork elements.

2.1 Formwork system

For coreless winding of a spatial layout made of a flexible filament, winding points are necessary for anchoring and deviating the filament and for tensioning it before concreting.

Such winding points can be included in the formwork of any structural system, such as beams, plates or shells, as illustrated in red in Figure 2. These elements must be designed according to the formwork strategy, be it rigid timber frame or flexible membrane, for instance. Stiff pins that can transmit the shear forces of the tensioned filament to the formwork can be reused, by covering them with a sliding lost cap and by removing them before demoulding, and the resulting void subsequently grouted.

The higher the density of these elements, the more diverse the range of potential reinforcement layouts, although these elements have a cost in terms of production time and material consumption. The position of these winding points serve as input for structural optimisation, informed by the available design space.

2.2 Structural optimisation

The structural design of the reinforcement for concrete structures is based on layout optimisation using a strut-and-tie model.

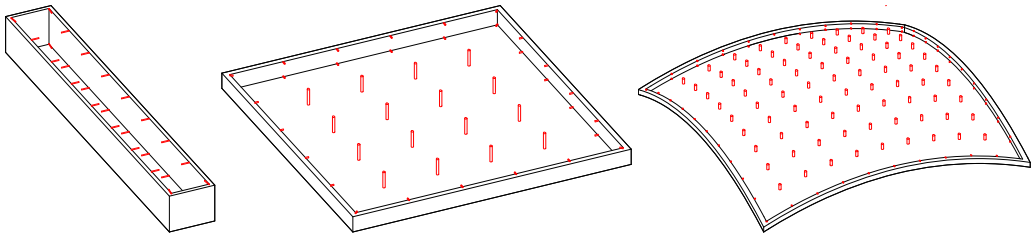
Strut-and-tie models are discrete stress fields use to design concrete structures as a set of compressive struts and tensile ties for the given support and load conditions. Their justification is based on the lower-bound theorem of plasticity. While concrete plays the role of the compressive struts, the reinforcements act as tensile ties. Structural analysis of the strut-and-tie model provides the stresses and the necessary cross-sections of tensile reinforcement. This model can include any combination of lines connecting the winding points in the formwork system, which can all be built using filament winding.

In this combinatorial design space of tensile ties, some layouts are more efficient and therefore require less reinforcement. The search through this space of feasible layouts is performed using layout optimisation [16, 17]. Such methods minimise the amount of material, which is equivalent to the total load path LP, which is the sum of the force F_i times the length L_i in each edge i over the entire set of edges E:

$$LP = \sum_{i \in E} |F_i| L_i$$

.

Minimising the amount of tensile reinforcement is equivalent to minimising this load path, when the location, magnitude and direction of the external forces is the



(a) Beam (b) Plate (c) Shell

Figure 2. Formwork system with winding points, using elements in red to anchor and deviate the flexible filament.

same. Indeed, according to Maxwell's theorem [18], the algebraic load path, which comprises the tensile part T and the compressive part C, only depends on the applied loads:

$$\sum |F_T| L_T - \sum |F_C| L_C = \sum \underline{\mathbf{P}} \cdot \underline{\mathbf{r}},$$

with $\underline{\mathbf{P}}$ the external loads and $\underline{\mathbf{r}}$ their position vectors from any arbitrary reference point. Since the algebraic load path is constant for a given set of loads, decreasing the total volume of material decreases in equal volume the compression material and the tension material.

Therefore, global layout optimisation provides the minimum reinforcement.

After optimisation, the discrete cross-section A_f of the filament must be included. For each tensile element, the force F_T is retrieved to find the necessary number n of filament passes that must constitute this element to take this force, based on the filament tensile strength f_f:

$$n = \left\lceil \frac{F}{A_f \cdot f_f} \right\rceil.$$

The lower the filament cross-section, the lower the loss of material due to the rounding up and oversizing, but the higher the number of passes and the production time.

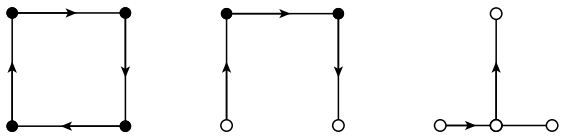
As the initial ground structure was informed by the location of the winding points in the formwork, the resulting structurally-optimised layouts include only passes that can be realised by the filament. Even though significant post-processing is not necessary, a rationalisation step is required to obtain a continuous path through the tensile reinforcement layout. This specific continuity requirement prevents from multiple interruptions of the filament-based fabrication process, whether manually or robotically wound.

2.3 Fabrication rationalisation

From the optimised layout, a continuous path for filament winding must be computed that respects the required number of passes per tensile element. From this continuous path, a robotic trajectory is generated that winds the reinforcement around the winding points of the formwork.

However, the existence of such a continuous path is not guaranteed for any graph of nodes and edges. Here, the graph consists of the winding points as nodes and the tensile elements as edges. Since some edges require multiple passes to achieve the necessary filament cross-section, the algorithm is applied to a multi-graph, where multiple edges can connect the same pair of nodes. For each pair of nodes requiring n passes, n edges connect the pair of nodes in the graph.

Figure 3a shows an Eulerian graph with a closed circuit, marked with arrows, that visits each edge of the graph exactly once. This strong constraint of a circuit can be relaxed to an open path, as the wound filament does not need to close. Such a graph is called a semi-Eulerian graph, as in Figure 3b with path extremities marked with white nodes. However, some graphs do not have such paths nor circuits, such as the one in Figure 3c.



(a) (b) (c)

Figure 3. Eulerian properties of graphs: (a) an Eulerian graph with a cycle, (b) a semi-Eulerian graph with a path and (c) a graph without path visiting each edge exactly once.

The problem of finding a path can be solved with Eulerisation algorithms, which convert graphs into Eulerian graphs, which have the property of containing a circuit, or closed path, that visits each edge of the graph exactly once. The Eulerisation problem is also called the Chinese Postman Problem (CPP) [19]. The CPP searches for edges to add to obtain a circuit. In Figure 4, Eulerisation of the graph yields two Eulerian graphs. To minimise the amount

of material for needed reinforcement, the one that corresponds to a minimal length of added edges is retained. This algorithm is adapted to perform semi-Eulerisation to find a continuous path by considering different path extremities, highlighted in white in Figure 5, resulting in more semi-Eulerian graphs, with fewer edges added due to rationalisation.

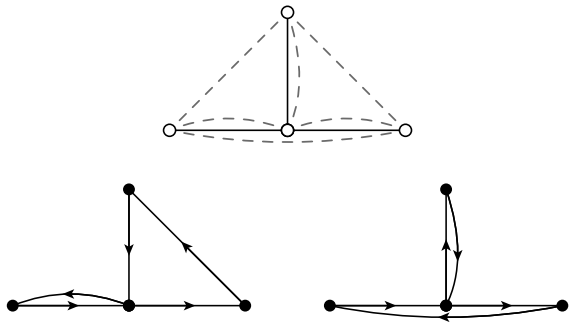


Figure 4. Eulerisation of a graph by adding edges to find a closed circuit.

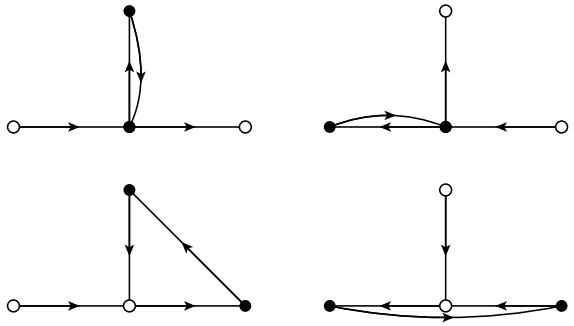

Figure 5. Semi-Eulerisation of a graph by adding edges to find an open path.

However, because the tensile parts can form disconnected graphs, and because other edges in the ground structure represent other potential winding passes, the Rural Postman Problem (RPP) [20] is used, which is a generalisation of the CPP. The RPP, also called priority-constrained CPP, finds a circuit that visits each required edge exactly once and potentially visits optional edges of the graph to form a circuit or path. Here, the required edges are the tensile edges and the optional edges are all the edges of the ground structure.

While the CPP is NP-complete, the RPP is NP-hard. Therefore, multiple algorithms exist to solve this problem based on heuristics. Here, the sub-paths are found for each disconnected component first, using a CPP algorithm. Then, as shown in Figure 6, these sub-paths, simplified as black edges, are iteratively connected in a greedy approach by adding the shortest optional path, highlighted in red, among all the possible ones, until they form a general path that connects all the sub-paths.

As a result, a continuous path is found through the tensile part of the optimised strut-and-tie model, taking into account the number of passes per edge.

From the continuous path, a trajectory for robotic winding around the formwork points is obtained.

The bulk of the formwork elements informs the offset of the lines connecting the axes of these elements. The orientation of the offset takes into account the relative positions of the elements along the winding path. Figure 7 shows how from a path, in black, connecting winding elements, in white, the trajectory, in red, alternates on the right- and left-hand sides based on the successive path turns. The trajectory passes by the opposite side of the next element: winding from element $i-1$ to i, the filament goes to the right-hand side of the path at the element i if the next element $i+1$ is on the left-hand side, and vice versa.

Vertical sliding along the elements is assumed to be prevented.

The robotic trajectory computation completes this automated workflow to obtain an optimised layout to wind reinforcement in concrete structures around formwork points.

3 Structural application

This automated workflow is applied to a classic plate as a benchmark, though more complex shapes can be considered, as long as winding points are provided during the fabrication process.

3.1 Parameters

The plate is a 5m x 5m square, has a thickness of 20cm, is supported vertically at its bottom four corners and is loaded at the top surface with a uniform downward vertical load of 5 kN/m^2. The concrete is considered to be C30/37 with a compressive strength f_c=30MPa. The filament is considered to be Fibre-Reinforced Polymer with a tensile strength f_f=1500MPa and a cross-section A_f=4.3mm^2 [21]. The winding points in the formwork are organised in a 6 x 6 x 2 array of 72 nodes, corresponding to a spacing of 1m in-plane and 0.2m vertically, as shown in Figure 8 with the results of the automated workflow.

3.2 Results

The ground structure, shown in grey in Figure 8a, connects all the pairs of the 72 winding points, highlighted as white dots, to each other, representing all the $\binom{72}{2}$=2556 edges that can be potential filament paths. Only edges shorter than 3m are shown for clarity.

The optimised strut-and-tie model in Figure 8b shows the support reactions in green, the external loads in orange,

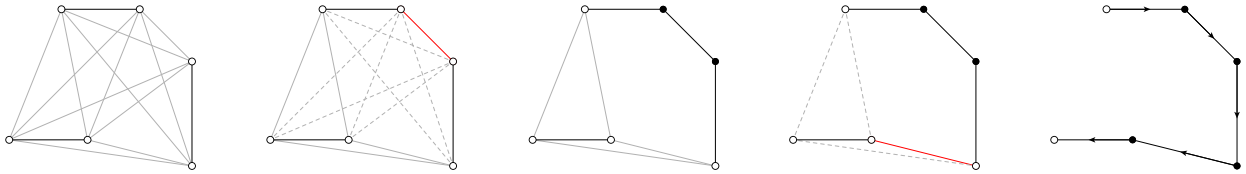

Figure 6. Semi-Eulerisation of a disconnected graph by finding first sub-paths, in black, and then connecting them with the shortest optional paths, in red.

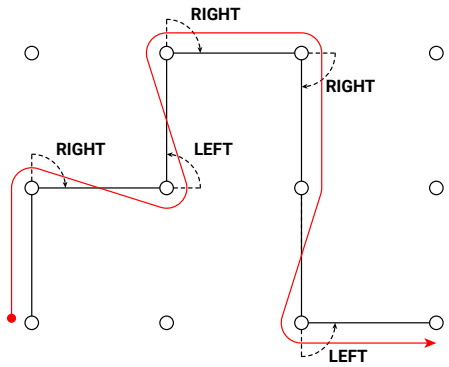

Figure 7. Winding trajectory, in red, from the filament path, in black, alternating between the right- and left-hand sides.

the compressive struts in blue and the tensile ties in red. The cylindrical elements are sized based on the internal forces and corresponding material strengths. The tensile load path amounts to 3266kN.m, or a theoretical material volume of CFRP of 0.00218m^3. A grid of winding points with an XY spacing of 50cm gives 3004kN.m, or 8% less, and an XY spacing of 25cm gives 2870kN.m, or 12% less, but also more than 3 times and 12 times the number of formwork elements, respectively. These results are summarised in Table 1.

Table 1. Tensile load paths for different densities of formwork winding points

winding node spacing [cm]	tensile load path [kN.m]	nb. of winding nodes [-]
100	3266 (100%)	72
50	3004 (92%)	242
25	2870 (88%)	882

Once computed the number of passes per tensile element, the filament volume is 0.00241m^3, an increase of 11%, for a total filament length of 561m. The graph in Figure 8c illustrates the continuous filament path generated after semi-Eulerisation. The colours and thicknesses illustrate the number of passes per edge, ranging from thin green edges with 1 pass to thick red edges with 10 passes. The filament volume is then 0.00246m^3, an additional increase of 2%, for a total filament length of 572m that can be wound in one go. Eventually, the total increase of material volume from the initial, optimal strut-and-tie model including the winding points to the filament path amounts to 13%. Table 2 summaries the material quantities at the different steps of the optimisation and rationalisation workflow.

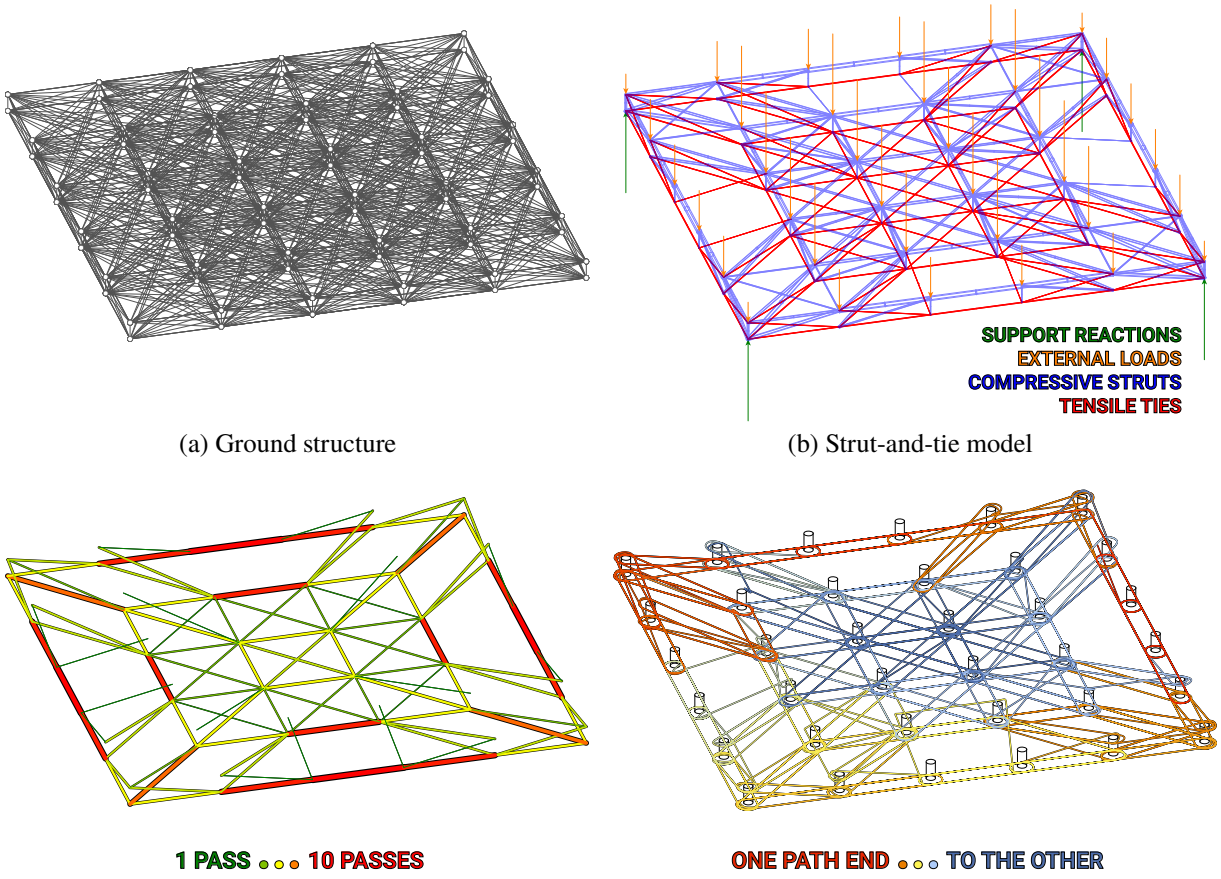
The continuous curve in Figure 8d represents the path of the extremity of the robot end-effector winding the filament around the formwork elements. The path time is plotted as a colour gradient from red to blue, from an extremity to the other of the job. The material increase due to the bulkiness of the formwork elements is not taken into account.

Table 2. Reinforcement material quantities after each step of the optimisation and rationalisation workflow

step	volume [m^3]	increase [-]
layout optimisation	0.00218	-
discrete sizing	0.00241	+11%
graph eulerisation	0.00246	+2%
total		+13%

3.3 Discussion

This case study shows the application of a digital framework for the optimisation of structurally-sound and fabrication-informed reinforcement layouts. The numerical results predicting the material quantities highlight the trade-offs between the theoretical optimal design and the feasible sub-optimal design. The waste of material due to winding (2%) is low compared to the waste due to using a limited number of winding points in the formwork (around 10%) and compared to oversizing due to the use of a single cross-section for the filament (11%). These parameters, number of winding points and discrete filament cross-section, also have an impact on the production time, due to assembly/disassembly time of the formwork and winding time of the robot, respectively. A physical prototype of a structural element with a specific formwork system will allow the evaluation of this impact. The specific setup will introduce additional constraints, related to



(a) Ground structure

(b) Strut-and-tie model

(c) Connectivity graph

(d) Winding path

Figure 8. Automated optimisation and rationalisation of a reinforcement layout suitable for robotic filament winding applied to a concrete plate of 5m x 5m x 20cm.

reach possibilities and the collision risks, which will need to be integrated into this automated workflow.

4 Conclusion

Advanced fabrication technology should enable the production of optimised reinforcements, instead of resorting to standardised and inefficient cages or mats, which significantly contribute to the environmental impact of reinforced-concrete structures. This paper presented an automated framework for the design of optimised reinforcement layouts for concrete structures that are suitable for robotic filament winding. Its application to a reinforced-concrete slab highlight the impact of the rationalisation steps and some of their parameters. Further work consists of:

- parametric studies on the spacing of the formwork points for winding, the filament cross-section, as well as layout simplification, to reduce the production time with controlled deviation from the optimal tensile reinforcement;
- physical prototypes with detailing of the formwork system and its winding points, exact generation of the robotic tool-path and inverse kinematics that prevents clashes, with the sequencing of the winding from the bottom layer to the top layer of the reinforcement layout;
- material and structural testing to understand the behaviour of this system, including the bonding between concrete and reinforcement; and
- life-cycle assessment to compare the whole-life cost of this approach with traditional methods, as comparing only embodied material can be misleading, without taking into account production waste and energy.

Abstract –

Delivering energy-efficient buildings or settlements has become a popular topic amongst architects, engineers, and building engineering physicists. There are many methods for improving building energy performances, both for new build projects and for retrofitting existing buildings. However, the construction industry faces some profound challenges to satisfy the increasing demand for energy-efficient buildings or other solutions and to be able to offer them at an affordable cost. A holistic approach has been adopted to validate whether automation robotics and off-site manufacturing technologies can yield positive changes in the delivery of energy-efficient buildings. This paper emphasizes the potential transformations and possible impacts on the design, construction, and installation process of an energy-efficient building once the advanced technologies are implemented. This paper also highlights case studies in multiple on-going or past European Union (EU) Horizon 2020 research projects as well as private projects to demonstrate the applicability and technical feasibility of the proposed solution. The scenario proposed was used to demonstrate how to apply the proposal in a large-scale residential building project. In addition, the findings from this study will serve as proof of the concept of a larger research project, or as an inspiration for the construction industry to execute energy-efficient building projects in the future.

Keywords –

Prefabrication; Construction robotic; Energy-efficient building

1 Introduction

At present, and in the near future, the build environment has many implications for peoples' lives in Europe. The construction industry consists of a complex value chain and supply chain yet is also one of the major contributors to CO2 emissions and consumes a substantial amount of energy. Building activities consumes up to 40% of the total EU energy usage [1]. Recently, decarbonisation has become a popular topic so new policies and research initiatives are aiming to improve the overall energy consumption rates in new builds and existing building stocks. Many building activities belong to a construction project and the energy consumption rates differ between each activity across the entire building life cycle. For instance, the building operational phase consumes the most energy, which is why it is the area researchers and the extended industries are focused most. However, due to the complexity and fragmentation of construction tasks, it is very challenging to improve the overall performance of an energy-efficient building if it only addresses the operational phase and ignores the others. This paper provides a comprehensive insight into how prefabrication, construction automation, and technology integration have the potential to enhance entire segments of an energy-efficient building value chain from the design stage to the end of the building life cycle. The paper features several EU Horizon 2020 research projects that validate the proposed solutions. These proposed solutions are an emphasis on the design, energy product integration, and construction processes in both new build and renovation projects. Introducing innovative methods and technologies to the construction industry requires cross-disciplinary collaboration between stakeholders, allowing interdisciplinary interaction and promoting collaborative work throughout the building life cycle. In addition, the featured solutions for energy-efficient building construction or renovation can be used as a proof of concept (PoC) for a larger research project within the respective parties [2].

2 Energy-efficient building construction strategy

It is difficult to form a definition that would easily summarize the building construction process, let alone an energy-efficient building construction project. Building construction consists of various phases and tasks; each task involves specific skill sets, tools, and methods.

Buildings are designed, constructed, or located in different styles, materials, locations, respectively, and also sometimes have different functions. Occupants also change over the entire building life cycle. Ultimately, an energy-efficient building should consume less energy yet retain the same performance for as long as possible. To achieve maximum adaptability and flexibility, a building should be designed as a system rather than a collection of individual parts, which creates high levels of inefficiency. More flexibility in design also means the building can easily adapt to potential changes in requirements and demands. The designer should consider all the building phases regarding building energy consumption and evaluate how the energy performance could be influenced by each construction phase throughout the building life cycle.

In general, the building life cycle consists of four stages, including the planning stage, the building stage, the operational stage, and the decommissioning stage. The planning stage includes building site selection, obtaining a building permit, a regulation submission, building material selection, and general organization. The building stage involves logistics, site preparation, construction, site clearance, and building commissioning. Each construction method will have distinct energy requirements and the choice of construction method can instantly influence many aspects within the building phase, such as the selection of construction tools, management method, scheduling, and cost structure. The operational phase consists of usage, repair, maintenance, and upgrades of the building. Based on research, the operational phase uses up to 36% of the total energy consumption in the building life cycle. Moreover, a building should be designed to accommodate the selected technologies as well as to ease the repair and maintenance processes [3]. The decommissioning phase covers disassembly, large-scale alteration, demolition, and recycling. The waste generated by the construction sector is astronomical. In terms of an energy-efficient building, the building should be ungraded and reutilized rather than disposed of in a landfill site. Moreover, to achieve an energy-efficient design, the designer should take into account the embodied energy in the building lifecycle, which means being aware of the energy consumption associated with each building process, i.e., production, design, construction, operation, maintenance, and repair [4].

A reduction of building energy consumption in building construction as well as in existing building stock is a vital part of the EU sustainable development strategies. Thus, the European Commission has set up relevant policies and directives that are aimed towards supporting energy-efficient buildings. For instance, Energy Performance of Buildings Directive (EPBD) was set up in 2002 [5], an Energy Policy for Europe was announced in 2007 [6], Energy 2020 was enacted in 2009, and Energy Performance of Building Directive was published in 2010 [7]. Due to building processes involving many stakeholders, implementing innovative building technologies requires an extensive cross-disciplinary approach along with strong public-private-partnerships in order to develop a feasible roadmap and applicable solutions for developing an energy-efficient building.

3 Challenges and barriers

The energy-efficient building development has been divided into the following stages: design, building structure, building envelope, construction process, end of life, integration, and cross-disciplinary collaboration. This section will evaluate the challenges and barriers imposed by each of these stages.

The main challenges during the design stage are how to involve every key stakeholder from the earliest phase of the project as well as how to enhance interactions of the stakeholders to achieve cost-effective solutions. The main barrier associated with these challenges is a lack of a holistic approach for organizing construction tasks related to energy-efficient buildings. There are ample opportunities for miscommunication or a lack of communication between key stakeholders. Many stakeholders are reluctant to adopt Information and Communication Technology (ICT) tools and many of the regulations regarding energy-efficient building are complex and varied across the EU. The challenges that relate to the building structure stage are reducing the overall level of embodied CO2 level in all buildings and utilising building structures more effectively. The barrier associated with these challenges is how difficult it is to integrate innovative energy production products with existing building structures. Regarding improving the performance of the building envelope, the main challenges are improving the building envelope energy performance in both new builds and existing buildings, interconnecting innovative materials and technology with the existing envelope, complying with the regulations, and easing the installation process by using alternative construction methods, such as prefabrication. The barriers associated with the building envelope stage are fourfold. First, there is a lack of development in energy-efficient building envelopes. Second, most of the commercialized products are driven by local building code and investments. Third, there are high costs involved in industrialized systems and they are still not wildly accepted. Finally, the compatibility between the innovative technology and the existing building envelope is low. The main challenges and barriers related to the construction process include labour-intensiveness, inadaptability, and lacking innovation and a skilled

workforce. The construction sector is slow in adopting prefabrication and the initial investments for implementing an innovative construction method are high [8]. Understanding what the most feasible solution is for transferring the industry from traditional building demolition to deconstruction, upgrading, reusing, and recycling is the main challenge for a building's end of life management. The main barriers with these are a lack of innovative recyclable construction material, the costs of building material recycling being high, and limited institutional, as well as technological, support for deconstruction. The next section summarizes numerous on-going or past European Union (EU) Horizon 2020 research projects to investigate the practicable solutions for the aforementioned challenges. The selected projects also inspired the design of the proposed systems that shall be described in the later section.

4 Methods

Developing energy-efficient buildings or settlements still faces many challenges so it is essential to transform the barriers associated with each challenge into innovation opportunities for the designer to consider during each construction stage. The selected case studies provide a comprehensive insight into technology integration, prefabrication, and automated installation technology, and are focused on either new builds or renovations of a residential building, see Figure 1.

4.1 Case studies

4.1.1 Zero-Plus

The ZERO-PLUS project was commissioned by the European Union's Horizon 2020 Research and Innovation Programme under Grant Agreement No. 678407 [9]. In brief, the overall aim of the ZERO-PLUS project is to achieve near-zero and positive energy settlement by using innovative and cost-effective energy production products in Europe. The project consists of four case study countries: the United Kingdom (UK), Italy, France, and Cyprus, which cover various climatic regions in Europe. In the Cyprus case, the Freescoo system is an innovative desiccant evaporative cooling air conditioning system developed by SolarInvent in Italy. According to the structural features of the case study building, an installation wall was developed to simulate the installation processes of the Freescoo system, which can be installed either externally or integrated into the building envelope. The installation wall is comprised of galvanized strut channels, fixture profiles, roof panels, insulation panels, HPL stratified laminated cladding panels, and a maintenance access door. The installation wall components were prefabricated in Italy and then shipped to Cyprus, and the installation took three days to complete. There were two main lessons learned from the Freescoo case study. First, the system was too heavy for manual handling so the optimum method would be integrating the system with the wall element and hoisting it into place using a crane. Second, the installation time was slow due to many smaller loose parts, which could impose challenges when installing the system at extreme heights or while standing on a suspended working platform. Nevertheless, the ZERO-PLUS demonstrates that energy technology can be integrated with a building façade and that prefabrication technology could potentially improve product quality as well as improve installation processes incrementally.

4.1.2 BERTIM

BERTIM was also funded by the European Union's Horizon 2020 Research and Innovation Programme under Grant Agreement No. 636984 [10]. The objectives of the project were to enhance a building retrofitting process by deploying an integrated timber frame façade module system and to develop an efficient manufacturing method for the timber façade. The timber façade module uses prefabricated windows, heating, ventilation, and air conditioning (HVAC) systems, and insulation materials were integrated ingeniously. The design, manufacturing, installation, and life cycle management systems were supported by an advanced Building Information Modelling (BIM) application. One of the challenges when installing an additional layer of the façade element on an existing building was that the installation surface was not completely flat or level. To solve this issue, an innovative interface design was proposed, which consisted of three components: one part connected to the surface, another part fastened with the façade module, and a middle piece sandwiched between the two parts. An existing building, located in one of the Tecnalia's testing facilities in Derio, Basque Country, Spain, was used as the pilot project to validate the logistics, the installation process, and the thermal performance of the BERTIM project. The project demonstrates the benefits of using prefabrication technology in a renovation project. In addition, the innovative interface connectors developed during the project enabled accurate installation results and revealed the potential of implementing automated installation methods by using construction robotics.

4.1.3 Hephaestus

Hephaestus was also founded by the European Union's Horizon 2020 Research and Innovation Programme under Grant Agreement No. 732513 [11]. The key objective of the project was to improve the glazing wall installation process by adopting an innovative Cable-driven parallel robot (CDPR). The CDPR consists of five components, which include the

CDPR structure, the CDPR body, the modular end-effector (MEE), the loading bay, and the control station. The CDPR can be installed on a roof structure or on a floor level that can support the weights and force of the system, respectively. The optimal installation location of the CDPR varies and depends on the individual building's load-bearing structure. The CDPR enjoys great manoeuvrability across the vertical plane of the building due to the eight winches and pulleys located on the top and ground levels. The MEE is divided into upper and lower sections. The upper MEE enables the system to detect rebar positions, drill, install fixtures, and fasten the fixtures in the correct position. The lower MEE is equipped with a vacuum system that is used for picking and placing the curtain wall element as well as the stabilization system. The pilot project was carried out from late December 2019 to early January 2020 at the Tecnalia facilities in Derio, Basque Country, Spain. During the pilot project, the overall performance of the CDPR was evaluated, but because the project isn't over yet, there are still some challenges that have to be solved (i.e., calibration time, size of the different components, etc.). Hephaestus has greatly inspired the proposed design that will be described in the later section. First, the project is a useful starting point case that can be augmented by adopting automation and robotic technologies. Second, the project provides a systematic approach and features applicable integration of software, sensors, and hardware in the context of the curtain wall installation. Third, the project demonstrates that CDPR is able to pick up and position large, heavy building components and is relatively highly accurate.

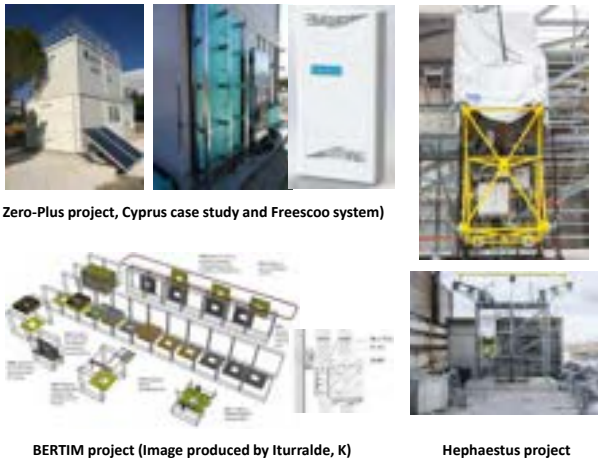

Figure 1. Top left: Zero-Plus, Bottom left: BERTIM, and Right: Hephaestus

5 System development

The demand for energy-efficient buildings are increasing in Europe and fulfilling the demand must be done either through new build projects or renovations of existing housing stocks. Conventional construction activities associated with new build project or renovation projects, however, are often inefficient, labour-intensive, and impose a high level of health risks to the workers. A novel construction system that focuses on the construction of a low-rise residential building by using prefabricated building components and assembled by automated on-site construction system is proposed in this section. Energy production technology is merged with the prefabricated façade module to ease the installation and maintenance processes by using construction robotic technology that was inspired by the aforementioned projects.

A prefabricated, fully assembled building system was used as a case study building for developing the proposed on-site assembly factory. The system is commercialized in China and it consists of the precast foundation system, structural frames, steel bracing system, precast external wall panel, precast internal wall panel, precast floor panel, precast canopy, precast roof panel, and precast stairwell. The prefabrication rate of the system is over 95% and, during on-site assembly, scaffolding is no longer required.

The proposed semi-automatic construction system features an on-site factory equipped with CDPRs that could travel on preassembled rails. The proposed on-site factory consists of ten key parts, see Figure 2.

1. On-site factory structural frame: the structural frames will arrive on-site as steel components and will be assembled by a spider crane.
2. Cable robot structure: the cable robot structure supports winches, pulleys, and cable routing systems and there are two branches of the structure that support two connecting planes.
3. Winches and pulleys: the winches and pulleys are installed on the cable robot structure and the lower supporting structure and in principle, the payloads should be more than 2.5 tons.
4. CDPR: there are two sets of CDPRs installed on either plane of the on-site factory that are equipped with a vacuum platform that is able to hold and position the precast external wall panels.
5. Lower supporting system: the lower supporting system supports the lower winches and pulleys and is equipped with a rotating set of rail wheels that is similar to the system used on trams or trains while the dimension of the wheels will be determined by the specification of the track gauge.
6. Temporary rail: the temporary rail track will be laid in a similar manner as traditional railway tracks but will depend on ground conditions, project budgets, and time as to whether the rail track will be laid on wooden sleepers or precast concrete track supports.
7. Gantry crane: the function of the overhead gantry

crane is to hoist and position precast floor and roof panels, but it is retractable, so it can reach out to the picking area.

8. Control room: the control room contains the main electrical cabinet, control units, power supply, and operator stations and is fully waterproof and highly mobile.
9. Temporary stabilization pillar: the stabilization pillar consists of two parts, the underground precast concrete footing, and over-ground pillar and he on-site factory structure will be connected to the over-ground pillar while it is in operation.
10. Temporary horizontal stabilizer: the horizontal stabilizer is used to provide additional strength of the on-site factory structure, but it can be disassembled and exchange to the working plane where the CDPR is not installed.

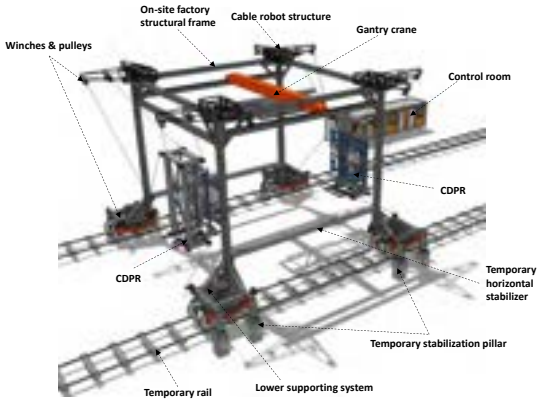

Figure 2. The proposed CDPR

The site will be prepared according to the construction plan. Once the location is confirmed, the precast concrete footings will be installed and the steel structure of the building will be assembled manually with assistance from the spider crane. Meanwhile, the precast external walls, floor panels, internal walls, and roof panels will be delivered and stored on-site. The on-site factory structure will arrive on-site partially assembled. The entire on-site factory structure, winches and pulleys, cable robot structure, and gantry crane will then be assembled and the temporary stabilization pillar is to be connected to the precast concrete footings. At this point, the on-site factory is stabilized and the CDPR can be installed and calibrated. Then the precast external wall panels are picked up from the picking position. The CDPR positions the wall panel at the correct installation position. The worker will carry out the final positioning and fastening task while the precast floor panels and internal wall panels are installed by using the overhead gantry crane. Figure 2 and Figure 3 demonstrate how the CDPR would operate at the front elevation of the building. Once the front wall panel is installed, the CDPR will be dismantled and reassembled on the side plane of the on-site factory. To cope with various weather conditions, the roof opening of the on-site factory can be covered with a waterproofing material. The direction of the temporary rail depends on the construction site configuration, but can be longitudinal or transversely. In addition, once the assembly task has been completed, the on-site factory shall be towed by the lorry to the next assembly location. The visualization of the building and the settlement are shown in Figure 3.

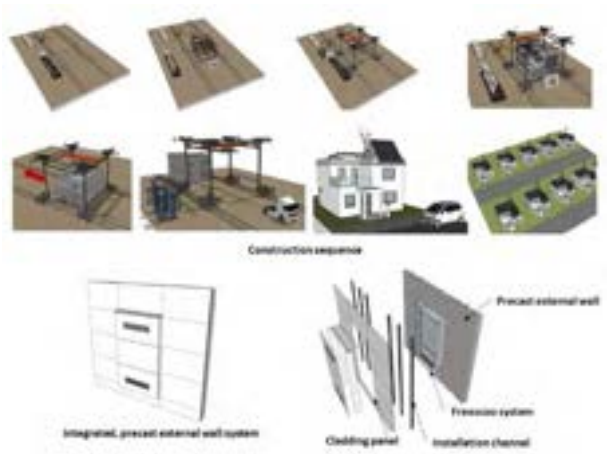

Figure 3. The construction sequence and the integrated precast external wall system

The proposed system features an integrated, precast external wall system, which is integrated with the energy production products. To demonstrates the design, the Freescoo system is utilized as an example. The integrated external system consists of four components, including the precast concrete wall panels, the Freescoo system, the installation channels, and the cladding panels. In the proposed scenario, the integrated wall system is installed by the CDPR and the installation channels along with the cladding panels are installed by the worker once the building structure is completed. The design provides proof that to ease repair and maintenance activities, a building should be designed as sequential parts and components. Energy production systems and mechanical systems can be integrated with the building envelope so as to be accessed, disassembled, and serviced separately.

At the time of this writing, the design presented in this scenario has been developed only as a conceptual idea to demonstrate the overall concept. The drawbacks and specific issues that need to be taken into consideration while continuing to develop the conceptual idea are:

- The construction site needs to be relatively level. If the slanted level of the site is too great, the site is not suitable to adopt the proposed design.
- The temporary rail requires additional groundworks, (i.e., increased construction time and costs) so

achieving economy of scale is key.
- The on-site factory might take significant time to assemble and calibrate, therefore the time spent on assembling the on-site factory needs to be taken into consideration when planning the project.
- New health and safety legislation is required when introducing human-robot collaboration for on-site assembly tasks.

6 Future work and recommendations

The outcomes from the Hephaestus project demonstrated the potential of implementing automation and robotic technologies for improving the overall performance of a specific construction task. The results from the BERTIM and Zero-Plus project indicate that the adoption of prefabricated façade elements and the integration of energy production technology can improve the installation process as well as renovation tasks over the building lifecycle. The proposed system in the paper encapsulated the outcomes of the three projects to embrace building prefabrication and construction automation in the context of energy-efficient settlement construction. To continue developing the PoC, there are still many obstacles and challenges. First, building prefabrication technology has not been wildly accepted by the conventional construction industry. Second, initial investments are high and the operation might be limited geographically. Third, the construction task involves many stakeholders and the construction industry is known to be one of the most fragmented industries, making the adoption of a new building method, material, or technology extremely challenging, highlighting the significance of cross-disciplinary collaboration. An energy-efficient building should be designed as an open building system rather than a single-use permanent structure to be disposed of once the building life runs out. The initial costs of construction automation may be high, nevertheless, the embedded costs over the building life cycle will decrease incrementally due to higher construction quality and easier repair and maintenance procedures [8]. To further develop the proposed concept requires financial assistance, policy incentives, and institutional support from the construction industry and government bodies. Furthermore, the proposed design shall serve as a foundation for a larger research project in the future, when the design, production, installation, management, operation, and human-robot collaboration can be validated through lab testing and pilot projects.

7 Conclusion

The paper proposed an innovative semi-automatic construction system in conjunction with an integrated, precast external wall system with an aim to improve construction efficiency and quality and to enhance building performance throughout the entire building life cycle. The proposed system was inspired by investigating several selected European Union (EU) Horizon 2020 research projects. Each project provided specific insight on how to implement prefabrication and construction automation technology in the context of energy-efficient settlement construction. The proposed construction system is based on the concept developed in the Hephaestus project. The system incorporates a CDPR equipped with a concrete vacuum end-effector, overhead gantry crane, and control room, supported by a structural frame. The system functions like an on-site construction factory, and moreover, it travels on temporary rails that follow a pre-planned construction master plan. Unfortunately, there are also challenges imposed by the industry to further developing the PoC. Some of the issues and barriers cannot yet be verified, such as the construction industry's reluctance to change, the lack of development in the energy-efficient building envelope and integration methods, the lack of skilled labour, and awareness of cross-disciplinary knowledge. Furthermore, using the proposed concept to inspire the construction industry and focusing on solving energy-efficient buildings with innovative, practical, and feasible approaches could bridge the gap between academia and the construction industry.

Abstract –

With a growing number of high-rise buildings, glass curtain walls are widely used. In the long-term service of such curtain walls, the safety problems arise, such as cracks and spontaneous breakages of glass. Therefore, they need regular inspections to prevent accidents. Current inspection work for glass curtain walls in high-rise buildings mostly depends on manpower and conventional tools such as ropes and gondolas, which exhibit poor performance and safety risks for the workers to operate in the high-elevation working environment. Thus, there is an urgent need for inspection robots to improve efficiency and reduce safety risks. As a preceding work for the development of an inspection robot for glass curtain walls, this paper investigates the existing publications of the robots for the façade works and analyzes the implementation mechanism of an inspection robot for glass curtain walls.

Keywords –

Inspection robot; High-rise building; Glass curtain wall; Work mechanism

1 Introduction

In recent years, the number of the world's high-rise buildings is growing rapidly. Glass curtain walls are widely used in high-rise buildings because they can enhance the appearance of the buildings by creating a beautiful façade, as well as allow the filtration of natural light into the building. For example, in 2018, the annual output of tempered glass in China was about 470 million square meters and more than 40% are used in glass curtain walls [1]. However, the wide usage of glass curtain walls also brings safety risks. The glass curtain wall system has the potential of failure, which may lead to falling of glass fragments. Since most high-rise buildings with glass curtain walls are located in downtown areas with large people and traffic flow, the accidents of glass falling would be devastating. Therefore, the glass curtain wall inspection of high-rise buildings is necessary.

The conventional method of glass curtain wall inspection in high-rise buildings mainly depends on manpower with ropes, gondolas and winch systems. However, it is costly and inefficient with safety risks for workers in high-elevations.

In a broader range, the interest in wall inspection of high-rise buildings is increasing in recent years and there have been studied exploring automatic methods to replace human workers to conduct the inspection work, such as developing inspection robots. These studies can be divided into two categories:

(1) Unmanned Aerial Vehicles (UAV) with visioning methods to detect visible cracks. For example, Liu et al. [2, 3] developed a bat-like inspection robot with abilities of flying and adhesion to save power and prolong the time of endurance. Bulgakov et al. [4] proposed control algorithms to stabilize the UAV for high quality captured images. However, photography by UAVs is not allowed in many cities around the world, which limits the applications of the research results based on UAVs.

(2) Wall climbing robots with visioning methods for wall inspection. For example, Muthukumaran and Ramachandraiah [5] developed a pneumatics based wall-climbing robot for façade inspection. The robots in this category have both technical feasibility and the potential of applications. However, there is only a small number of studies in this category and many of them deal with the bonding situation of the wall tiles rather than the quality of glass curtain walls. Besides, many studies only focused on the development of mechanical parts, without an in-depth analysis of the inspection method and the user demands.

Therefore, this paper aims to focus on the inspection robots based on wall climbing platforms and systematically analyze and summarize their implementation mechanisms for glass curtain wall inspection in high-rise buildings. The remainder of the paper is organized as follows. Section 2 introduces the method of this study. Section 3 proposes the requirements of an inspection robot for glass curtain

walls based on an analysis of the glass curtain wall failure. Based on the requirements, Section 4 analyzes the implementation mechanisms according to the existing literature and discusses their features for the implementation of an inspection robot for glass curtain walls. Finally, the paper is concluded in Section 5.

2 Method

In this study, a literature review was conducted firstly in two aspects: (1) the essential information of the working environment of inspection robots and the knowledge of safety inspection of glass curtain walls. (2) the development of related robotic systems in both academic research and existing products in the market.

As the number of studies on wall climbing-based inspection robots is small, the literature retrieval in the second step was not limited to inspection robots but also expanded to other robots for façade works. First, since this study focuses on wall climbing-based inspection robots, the literature related to wall climbing robots also needs to be reviewed. Second, since wall-climbing robots can also be used for other façade maintenance works in high-rise buildings, particularly for façade cleaning and in most cases, the key technologies of a façade inspection (or cleaning) robot include climbing mechanisms and inspection mechanisms (or cleaning mechanisms) [6], hence the experience of façade cleaning robots can be a reference for inspection robots, so the literature of façade cleaning robots is also reviewed.

The literature retrieval was conducted in both Scopus and CNKI (China National Knowledge Infrastructure). The two databases were selected because Scopus covered a large range of literature in the field of construction robotics [6] and CNKI is the largest database of Chinese literature. The search keywords included “high-rise”, “robot*”, “curtain wall”, “façade”, “safety”, “inspection”, “climbing”, “maintenance”, and “cleaning” (in both English and Chinese). The asterisk (*) is a wildcard character that denotes a fuzzy search. Then a preliminary screening process was conducted successively to exclude the papers from irrelevant areas (e.g., biology, medicine, agriculture, etc.). By reading the titles, we successively filtered out unrelated papers and finally obtained 91 papers, including 71 ones about robot development and 20 ones about glass curtain wall inspection. Then we read the abstracts of each paper and selected the most related and important content for further reading.

Besides, we also referred to some Chinese national standards and industry standards for basic concepts of the glass curtain wall such as Terminology for Curtain Wall (GB/T 34327-2017), Standard for Testing of Engineering Quality of Glass Curtain Walls (JGJ/T 139-2001), and Test Method for the Defects of Glass – Photoelastic Scanning Method (GB/T 30020-2013).

The investigation of existing products in the market was also conducted by searching on the Internet with search engines including Google and Baidu. As a result, 15 products were found, which are all façade cleaning robots.

Both the analysis on the requirements and that on implementation mechanism are very much crucial for developing an inspection robot for glass curtain walls. Thus, the former is conducted based on the results of (1) because it needs our knowledge on both the related robotics and the inspection of the glass curtain wall. The latter is conducted based on the result of the former with the help of the results of (2) because it is a feasible way to build the implementation mechanism instead of building it from scratch.

Due to space limitation, this paper focuses on the following two points, i.e., requirement analysis of the inspection robot for glass curtain walls and analysis on its implementation mechanisms.

3 Requirement analysis of the inspection robot

3.1 Working environment of the inspection robot

The working environment of the inspection robot depends on the surface conditions of the glass curtain walls. A glass curtain wall system of a high-rise building consists of glass panels and a supporting system. The supporting systems are usually metal frames, such as aluminum frames and steel frames. According to the exposure of the supporting frames, the glass curtain wall systems can be categorized as exposed framing glass curtain wall, hidden framing glass curtain wall, and semi-exposed framing glass curtain wall, i.e., the horizontal/vertical frames are exposed and the frame in the other directions are hidden [7]. Besides, there are also other types of supporting systems, such as glass rib supporting curtain walls and point-supported glass curtain walls [7]. However, these supporting systems have no ledges at the external side of the curtain walls. For the climbing robots working on the façades of the buildings, the exposed frames are larger obstacles and the seams between glass panels are smaller ones, which need to be considered in the design of the climbing mechanisms.

In some cases, the façades of the buildings are not flat but curved. However, the glass panels are still flat but the panels are connected with small angles [8]. Therefore, in these cases, the climbing mechanism should be specially designed for the robot to cross from one panel to another.

3.2 Failure of glass curtain walls

The failure of the glass curtain walls on the high-rise buildings can be divided into two categories [9]: (1) Failure I is the partial failure of the aging components, including the spontaneous breakage of the glass under temperature stress or installation stress, the bonding failure because of the aging of the seals, the corrosion of metal fittings, etc. The most common one is the spontaneous breakage of the glass under temperature stress or installation stress. The characteristics of this failure type are as follows: the failure points cannot be easily found; the failure has a high probability to lead to accidents; the accidents caused by this type of failure will lead to serious damages and casualties without warning to people on the ground. (2) Failure II is the failure of the entire structure after large impacts from external forces such as typhoons, earthquakes, and fires. In these cases, one or more materials of the curtain wall reach their bearing capacity. This type of failure is caused by force majeure in a short time with great damage and low probability.

The prevention of accidents caused by Failure II depends on structural reliability, which is decided by design, construction and usage according to the standards. However, the prevention of accidents caused by Failure I depends on management and maintenance. In fact, most accidents of glass curtain walls were caused by Failure I. Therefore, this paper focuses on the inspect tasks on the detection of Failure I.

The spontaneous breakage of the glass (Failure I) can be explained as follows [1, 10]. Tempered glass for curtain walls has many internal defects, which are formed in production, processing, installation, and application. These defects will lead to stress concentrations. When these stress concentrations are combined with other environmental loads such as wind loads, vibration loads, and temperature loads, the local strength of the glass might exceed the capacity and the glass might break spontaneously. Although it is difficult to detect the defects, the stress concentrations can be detected with a specific instrument.

Some studies mentioned about using the visioning technology in inspection robots to detect visible cracks on the building façade [5, 11]. However, these studies are aimed at the cracks on other materials rather than glass panels. Actually, for the tempered glass, the spontaneous breakage happens before visible cracks are formed.

Therefore, the inspection robot needs the ability to detect the stress concentration of the glass panels.

3.3 Requirement analysis

Based on the above analysis and the usage scenarios of the inspection robot for glass curtain walls, the basic requirements include the following five points. Moreover, requirements 1-4 are for wall climbing and requirements 5-6 are for inspection.

1. Safe and reliable climbing mechanisms on the surface of the glass curtain wall. The climbing robot should attach to the glass panels safely with reliable protection methods. It should have the ability to move horizontally and vertically on the glass so that it can cover all the working areas.
2. Identification of the surrounding environment and obstacles. Multiple sensors and an intelligent control system are needed to identify the situation of the environment, especially the obstacles. Most obstacles are predictable ones such as the frames of the curtain wall, the information of which needs to be input preliminarily into the control system. Meanwhile, the control system also needs to consider the unpredictable obstacles that the robot might meet and the corresponding identification algorithms.
3. The ability to cross or avoid obstacles. After the detection of obstacles, the robots should have the corresponding methods to cross them safely and quickly. If there is an unpredictable obstacle that cannot be crossed, the robot should avoid it and record the situation and corresponding position.
4. Motion control. To realize the movement and cross the obstacles, motion control needs to be precise and instant to ensure safety. Besides, the sensors need to detect deviations and the control system needs to correct the motion direction.
5. Efficient inspection methods. Sensors are needed to identify the internal stress concentration of the glass panels.
6. The ability to record and export the inspection results. After the inspection on each panel of the curtain wall, the robot should record the results, especially the problems and the corresponding positions. When the inspection work is finished, the results need to be export to a computer.

4 Analysis on the implementation mechanisms of the inspection robot

The inspection robot should contain two parts, i.e., the climbing part and the inspection part. The most critical issue for developing it is to design the mechanism for each part.

4.1 Climbing mechanism

After reading the abstracts and important content of the 71 papers about robots of wall climbing, cleaning, and inspection in high-rise buildings, as well as the introduction materials of the 15 products of façade

cleaning robots, we found the climbing mechanisms of façade cleaning robots are most valuable references to this study. The reasons are as follows: (1) as mentioned in Section 1, the number of papers on glass curtain wall inspection robots is small and many of them are based on UAVs or deal with wall tiles rather than glass panels; (2) although the research on wall-climbing robots proposed various mechanisms such as legged robots, biomimetic robots, and robots with dry adhesive materials on the footpads, they are still at the stage of laboratory prototype with low practicability.

Based on an analysis of the related robots for façade works, they can be divided into two categories, i.e., robots with and without built-in guide rails, which have different climbing mechanisms.

For robots with built-in guide rails, the climbing mechanism is based on the guide rails. For example, Lee et al. [12] proposed a robotic system for façade cleaning (Figure 1), which consists of a horizontal-moving robot (HMR) performing cleaning, a vertical-moving robot (VMR) for transporting the HMR to each floor, and a winch module to move the VMR to the target floor. Both the HMR and VMR are connected with the rails and move on the building façade by gliding along the rails. A communication network is built for information transmission among the robots and the monitors. The power source of the system is DC batteries installed on the robots.

For robots without built-in guide rails, the core mechanism of climbing mainly includes the techniques of adhesion to the wall and that of locomotion.

There are two most commonly used adhesion techniques that have the maturity to be implemented in on-site prototypes. One is using suction cups. As shown in Figure 2, the suction cups can not only provide adhesion but are also "feet" of the robot, which can be organized into several groups. The groups of suction cups can adhere to the glass and release alternatively and the released ones can retract and move on to the next position so that the robot can realize locomotion and cross the obstacles. Another method is using vacuum fans to extract the air to create a vacuum between the robot and the wall surface for adhesion, as shown in Figure 3.

Various types of locomotion were designed for climbing robots and the common ones implemented in on-site prototypes include footed/legged, wheeled, and cable-driven. The footed/legged robots usually use suction cups for adhesion as mentioned above. The wheeled and cable-driven ones can work with suction cups or vacuum fans for adhesion, as shown in Figure 3-5. For cable-driven robots, the cables can provide different functions. For example, in Figure 4, the robot can move in all directions based on the cables. In Figure 5, the robotic system consists of a robot and a rooftop gantry, which are connected with cables. In this system, the cables are only responsible for the vertical movement and the horizontal movement is realized by the rooftop gantry moving along the pre-installed tracks. The cables can also transfer data and provide power.

Figure 1. A robotic system with built-in guide rails [12]

Figure 2. A robot with suction cups [13]

Figure 3. A wheeled robot with a vacuum fan [14]

Table 1 summarizes the climbing mechanisms mentioned above and compares their advantages and disadvantages. The guide rail-based robot has high efficiency because it can cover a large area and the motion path is very clear. It also has high safety and robustness because the connection between the robot and the guide rail is reliable. However, it is not versatile because it is based on the built-in guide rail of the

building and its dimensions depend on the design of the building. The footed/legged robot with suction cups is flexible to cross obstacles by releasing and retracting the feet/legs alternatively. However, it needs a more complicated design of the gait and corresponding algorithms for movement. Wheeled and cable-driven robots with suction cups or vacuum fans are both easy to control and agile in movement but incapable of crossing large obstacles. The cable-driven robot has higher safety because the cables can protect the robot from falling once the adhesion fails. However, its versatility is limited by auxiliary tools such as pre-installed pulleys and rooftop gantry. Besides, it is difficult to deal with curved façades.

Figure 4. A cable-driven robot [15]

Figure 5. A robot with a rooftop gantry [16]

Table 1. Comparison of the basic climbing mechanisms

Climbing mechanism	Advantages / Disadvantages
Guide-rail based	High efficiency High safety and robustness
	Limited versatility
Footed/legged with suction cups	Flexible to cross obstacles
	Complicated design of gaits and moving algorithms
Wheeled with suction cups or vacuum fans	Easy to control Agile in movement
	Hard to cross large obstacles
Cable-driven with suction cups or vacuum fans	Easy to control Agile in movement High safety
	Hard to cross large obstacles Limited versatility

4.2 Inspection mechanism

According to the analysis in Section 3.2, the critical part of glass curtain wall inspection is the detection of stress concentrations.

The instrument to detect stress concentrations already exists and is named photoelastic scanner, as shown in Figure 6 [17]. In manual inspection, the photoelastic scanner is handheld and placed close to the surface of the glass. Then the photoelastic image of the glass will be transmitted to a computer through a wireless communication network. When a photoelastic scanner is placed close to the surface of the glass, it can take images based on the reflection of polarized light on the glass surface. Since the glass is a photoelastic material, which is isotropic in general but anisotropic at the positions of stress concentrations, the stress concentrations in the glass will result in spots in the image, which can be easily observed by people or identified by image processing [18]. Thus the photoelastic scanner can be implemented in inspection robots for glass curtain walls. A robotic device with a sensor for distance detection should be designed on the robot to move the photoelastic scanner and place it close to the glass surface for inspection.

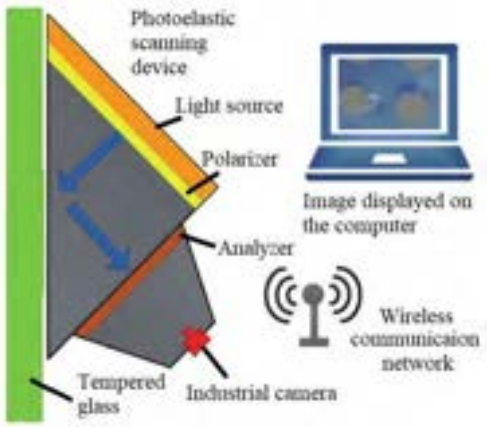

Figure 6. A photoelastic scanner for tempered glass inspection [17]

5 Conclusion

With a growing number of high-rise buildings, the glass curtain wall is widely used and its safety problem is concerned. To improve the safety and efficiency of glass curtain wall inspection, inspection robots are needed. As a preceding work of the robot development, this paper investigates the existing publications of the robots for the façade works. Based on the essential information above, six requirements of the inspection robot were proposed, in which four requirements are for wall climbing and the other two are for inspection. Then

based on a literature review, the climbing mechanisms of a glass curtain wall inspection robot were summarized and compared. The inspection mechanism based on a photoelastic scanner and its potential to be implemented in the inspection robot were analyzed.

The results of this paper can be a valuable reference for further development of glass curtain wall inspection robots, as well as other robots for façade maintenance.

Abstract –
For thousands of years, the human construction process was mainly done by hand. In an era when automation technology is so mature, although some components of building components can be produced industrially, on-site construction and special component production still require a lot of manpower. But no matter how skilled the workers are, more or less mistakes will occur during the construction process, which wastes a lot of material waste and energy waste, especially when dealing with increasingly complex digital designs. Using a robot instead of manually completing the construction process will be the solution to these problems. Currently, most ideas for robot construction are dealing with non-standard components in the field, this will cause a lot of problems, first of all, it will extend the construction cycle, and secondly, it will generate a lot of waste. This article proposes a new construction workflow using standardized timbers. Spatial information for each piece of wood is communicated directly to a robot fabricator. The robot, equipped with various tools, can accurately position and assemble timbers. This workflow has the potential to improve the sustainability, time, cost, and quality of construction.

Keywords –
Robotic Fabrication; Parametric Design; Standardized Timber; Spatial Structure

1 Introduction

Fukuda Building Technology Lab and iSMART Qingdao were able to leverage their previous research into mass standardized timber and robotic fabrication, combining expertise across laboratory in two month effort. Fukuda Building Technology Lab and iSMART Qingdao fabricated a wooden arch in modules(using 840 pieces of timber and 3155 nails) at Qingdao University of Technology iSMART Robotic Center, used over 26 hours to fabricate 8 parts of the structure and were then shipped and assembled at the exhibition venue where it stole the show with its complex structure and huge volume, topping out at 2.25 meters tall and 4*4 meters wide.

The success of the wooden arch marks a major step forward for automation construction application and sustainable application of robotic fabrication. Because it shows the possibility of applying standardized timber to complex spatial structures, and the use of wood allows for a sustainable, renewable material to displace concrete or steel to reduce carbon footprint. The use of robotics simplifies the construction process, allows to constructed faster and precisely. Designed construction process and use of standardized timber simplifies the works of workers allows the undergraduates who have only received simple construction training and complete safety training to easily complete the construction work.

In the future, iSMART and Fukuda Lab seeks to optimize these workflows and implement into their projects, ensuring a better solution of robotic construction.

1.1 Problem Statement

Robotic is an old and new field in architecture industry. The importance of developing technology to increase the productivity of the construction industry has been proposed in the late of 20th century[1-3]. Over the decades, many studies have also emphasized the necessity of implementing robotic technology.[4] Whether in China or Japan the population aging and declining labor force have become a serious problem, the aging workforce and the increasing complexity of construction shows that traditional construction methods have gradually shown inadequacies [5]. Although many studies have been implemented and various of technologies have been developed but application of robotics still limited and behind other industries. High cost, unskilled worker and lack of research funding make robotic technology not widely used in the construction industry.

Considering application of Robotic Timber Construction(RTC)research is still in initial stage, and

high cost and high construction difficulty is the main problem. Fukuda Lab and iSMART used uniform standardized timber to displace customized wood and optimized the man-machine collaboration workflow. Significantly reduced costs and the skill requirements of workforce.

2 Robot Setup

A 6-axis KUKA kr30/60/HA robot applied in this experiment. The robot is operated at a speed of 2 meters/s, vertical range of activity from +35° to -135° and large turning range of 185˚ in both directions.

2.1.1 Tool Setting

In order to optimize the construction process 3 tools are equipped, those tools are mounted to one shared base to allow for rapid positioning. These tools include(Fig 1):

- A customized pneumatic suction sucker for gripping wood with a maximum payload of 8kg.
- A customized laser emitter for locating the nailing point and glue area of each piece of wood.
- A customized pneumatic suction gripper for fixing the wood to allow the workers can finish the glue and nailing.

A pneumatic calibration table is set next to the reclaimer to recalibrate the position as each timber is processed.

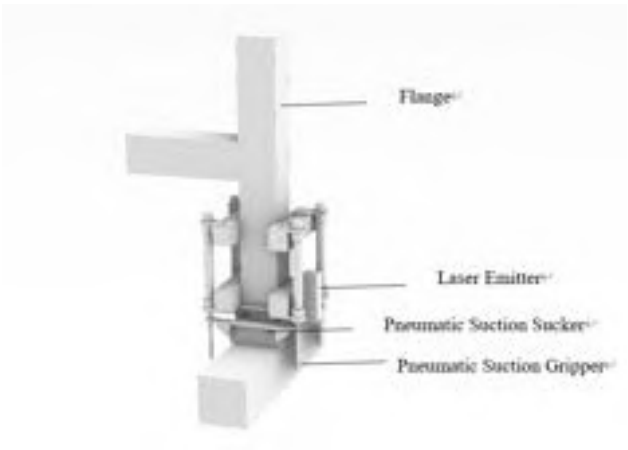

Figure 1. Customized Tools

2.1.2 The Robot Work Area

The work area measures 2.35 meters wide by 2.5 meters long and by 3.56 meters tall dictating the maximum construction area of robot. Laid out in a sector fashion, the area has two parts, the first being for material stacking and the other for construction. Each part is linked with safety control system of the robot and activates an emergency stop if limit or error occurs during robot operation. A safety operator is configured with the smart pad during each construction operation for collaborative operation(Fig 2). If an emergency occurs, the machine can be manually stopped. Positioned next to the material stacking area, a positioning frame is resting in a appropriate allows reposition each piece of wood to ensure that the center coordinates of them are accurate.

Figure 2. Safety Operator

2.1.3 Wood selection

A series of investigations in attempt to select suitable wood for RTC process. After comparing all kinds of the timber in Qingdao and Fukuoka lumberyards, our solution was to side on a low-cost approach using Japanese Hinoki as it is a popular construction material and it is reliable and easily machined. We use (50*100*650 mm) wooden bricks as construction material, the uniform size reduces processing costs and allows stacking without sorting, reducing construction difficulty.

2.2 Design program

A 4-sided symmetrical wooden arch were explored within the 5*5 meters area of the booth at the exhibition hall, with the basic theme of two sets of symmetrical construction units(Fig 3). Grasshopper was used to divide those 4 units into 8 construction team and divide the surfaces in to the center plane of timber, modeled in Rhinoceros 3d into its individual elements and generate.

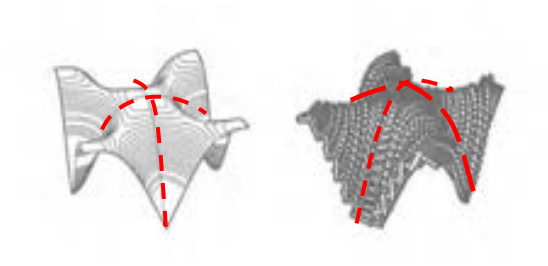

Figure 3. Model of the design

a nailing-gluing pattern needed to connect them. The positioning of nailing points and glued range of the digital model was automated using the custom script for Grasshopper. The nailing points and the glued area are mapped to the joints of the wooden blocks in the form of point coordinates. Primary parameters of divided surface geometry script, used to adjust the position of the nailing point and the size of the glue area:

- Timber Thickness
- Timber Length
- Timber Width
- Timber Rotation Angle

Using the custom script for Grasshopper, surfaces of the construction team are divided into polyline contours every timber thickness along the y axis (The default y direction in the software three-dimensional space.). Polylines are divided into lines based on timber length. According to the timber width and timber length, rectangular profiles are extruded along the resulting linear. Using KUKA|plc plugin for Grasshopper provide input data by design output subsequently by assembly. These input data include:

- Timber Thickness
- Timber Center Plane
- Timber Center Lines
- Nailing Points Plane
- Gluing Area Line
- Press Points Plane

Rotate the whole structure 90 degrees along the y-axis as the construction form. Timber geometry organized by construction order.

Using the Grasshopper Gluing area script, the overlapping area of the two layers of timber are offset inward by 15mm to generate the glued area. Primary parameters of Grasshopper Nailing points script, used to generate the nailing points planes:

- The Maximum Diameter of The Glue Range
- Nail Collision Radius
- Nail Length
- Glue Range Center Points

Using the Grasshopper gluing area script, glue range are showed visible, adjusting timber length and rotation angle to optimize the glue area to a suitable size and a suitable shape (quadrilateral), 4 terminal points of glue range are identified for primary rail and laser emitter, moved by the order of endpoints along the length from both endpoints. All endpoints are assigned to geometry and organized by construction order as glue range. Two nail points are selected by the maximum distance between the glue area minus the upper and lower nail collision range (to avoid conflicts) and assigned to each primary rail. All nails are assigned to geometry and organized by construction order as nail-points. The center points of two glue range center points which on the same timber are assigned to each primary rail as the press points (Fix the wood for nailing and gluing).

Figure 4. Geometry nailing points and gluing range

2.3 RTC Process

The KUKA|plc plugin is applied to transform outputs from the design script into construction process and outputting robotic commands for execution. The Softwire used for RTC process are:

- Rhinoceros 3D (modelling)
- Grasshopper(scripting)
- KUKA|plc Plugin (robot communication and simulation)

An accurate simulation of RTC was created for a visual understanding of work process of the RTC, and adjust main parameters in time according to simulation results.

OBJECTIVE	ROBOT MOVEMENT	IMAGE
1. Get Timber From Stack	· Select Timber in Order · Turn on Air Pump · Get Timber from Stack	2. Calibrate Timber	· Place Timber on Calibrator · Calibrate Timber · Pick up Timber	3. Place Timber on Site	· Place Timber on Site · Release Air Pump · Move to Safe Distance	4. Draw Gluing Range With Laser	· Move to Gluing Start Point · Turn on Laser · Transform Robot Speed to 0.2m/s · Move Along Endpoints · Turn off Laser	5. Draw Nailing points With Laser	· Move to First Nailing Point · Turn on Laser · Move to Second Nailing Point · Turn off Laser · Transform Robot Speed to 2m/s	6. Fixe Timber	· Move to Center Point · Turn on Gripper · Nail and Glue Timber · Turn off Gripper	
The script generates whole process of RTC. Standardized Timber allows the stacks don't need order, using the calibration device also allows the wood place unprecise, reduced the difficulty of placing stacks. Output construction data is oriented and centered to build site, that gives the designer a visual understanding of the structure which will be built. A series of subroutines are programmed outlining the overall construction process.

2.4 On-site Assembly

Limitation of robot arm length, manual handling, transportation and assembly logistics were factored which limited the size of each construction part could be. The constraints are that every part should be its longest length not greater than 2 meters and its height not greater the 1.5 meters. That ensured that every part fabricated by the robot could be lifted and moved by 6 people into a moving truck and erected on site. Every part was drawn a crossover line with neighbouring part, that aided in precisely aligning modules together. This simple modular technique was designed to allow for non-skilled worker to easily assemble complex structure with basic tools.

3 Result

Using the parametric workflow was necessary to managing the mass data of 840 individual timber with 3155 nails. The relation of the digital model allowed for this big data to be flexible, changing as the tests affirmed or rejected our initial setting. After completing the construction work, 4 construction units (Fig 5) were moved and assembled in the exhibition hall (Fig 6). The overall appearance is a smooth arch, consistent with expectations. The strong visual impact made by the huge volume. Using standardized timber placed along a hyperbola allowed audiences to visually obtain surface information.

Figure 5. One construction unit

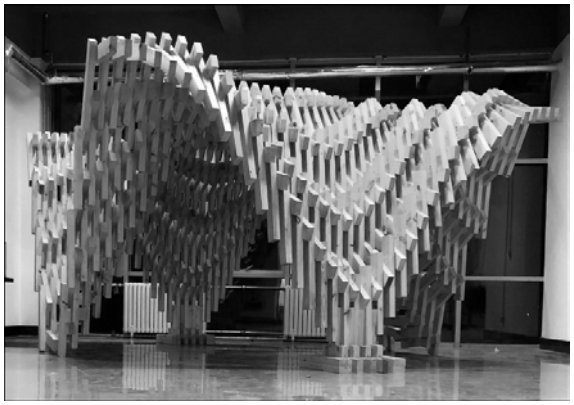

Figure 6. Construction Result

3.1 Speed of Construction

Every steps of the construction were gradually sped up to maximum capabilities without affecting performance and quality. Each step of pick up the timber to nailing it in place would take per 1 minutes 42 seconds. For the total of 840 members, total construction time amounted to 24 hours, and it takes 2 hours to assemble.

3.2 Human-Robot Coordination

Despite the automated nature of the RTC process, there were a few manual processes involved during fabrication and post fabrication. 840 standardized timber supplied from the lumber yard came in size of 50*100*650 millimeter stacked on site. 3115 nails nailed by non-skilled labour. with the nail-points and glue-range marked by robot, the work of nailing and gluing were very easy and non-skilled labour can finish the work with simple training.

3.3 Calibration

Every tool was carefully measured in and calibrated of optimal performance to untilize the high precision of the robot. Integration tool's TCP (Tool Center Point) was measured in with an accuracy of 0.01mm-0.05mm. The sucker went through a series of optimizations, gripping vacuum pressure and crawl speed reached the expected value. As for the Laser, adjusted the distance from the timber surface to 5mm which is the best focal distance to burning wood surface for mark the nail-points and glue-range. The speed of laser process was running to 0.2m/s, provided clear marking (Fig 7).

Figure 7. Mark of glue-range and nail-points

4 Conclusion

The success of the wooden arch marks a major step forward for application of robotics. Because it used the standardized timber to construct a complex hyperbolic structure. The use of standardized timber allows for a widely available, renewable material to displace steel and concrete to reduce a building carbon footprint, in the same time, allowed to reduce the material cost and processing cost. The use of robot allows the resulting optimized with millimeter precision. Human-Robot coordination allows non-skill labour involved in construction, alleviated the social problem of shortage of experienced workers. The communication between the digital model and the robot allows for a seamless translation from design to constructed on-site.

5 Future Research

Fukuda Lab and iSMART will seek ways to implement this workflow into real projects. Due to time and technology limitations, nailing and gluing process have not been automated in this experiment, the project used generous tolerances to finish within the deadline. Future research will optimize workflow, automate and integrate the nailing and gluing process into the current process.

In the future, iSMART and Fukuda Lab seeks to optimize these workflows and implement into their projects, ensuring a better solution of robotic construction.

Abstract –

The participation of robots in building construction is already a global trend. Compared with the actual construction with a large number of manual participation at this stage, the stability of the robot construction process will greatly affect construction efficiency and construction accuracy. As a future material carrier for building industrialization, robot construction has promoted the realization process of customized production and intelligent on-site construction. How to coordinate the robot platform, tool end development, building materials, construction tasks and on-site environment for the complex on-site construction environment and mass production needs The relationship between the optimization of robot construction technology will become an important step in the future development of building industrialization.

This paper focuses on the actual case, through the simulation of a built-in residential reconstruction, from the design process, the actual construction process to the final result, exploring the possibility of robots participating in the construction of residential buildings. It is hoped that the construction performance of the on-site construction will be improved through the participation of robots.

1 In Situ Fabrication

1.1 Application Status of Robotic in Architecture

Since the construction industry has begun deploying robotic technologies for digital fabrication processes, this direction has mostly been focused on integrating industrial-type robots into off-site prefabrication processes [1]. By contrast, no enabling robotic technology exists today that allows robotic systems to be integrated into in situ construction processes right on the building site. This is mainly because in comparison with robotic prefabrication, robotic in situ fabrication faces fundamental technological challenges.

First, buildings are large in scale. In contrast to prefabricating sub-assemblies of a building with stationary robotic systems off-site, in situ robotic systems must be able to fabricate large-scale assemblies at their final location.

Second, building sites are poorly structured. As opposed to operate within structured factory conditions, in situ robotic systems must be able to accurately fabricate large-scale assemblies irrespective of the uncertainties prevalent on-site.

At the same time, the construction site has a strong dynamic, the task and the surrounding environment are prone to system changes, in a large, unstructured on-site environment, robot also face fundamental challenges of mobility and robotic manipulation. The accompanying questions of locomotion, planning, self-localization, workpiece-localization, mapping as well as guaranteeing accuracy and repeatability are only partially solved to date [4].

The in situ construction project aims to bring robotic fabrication out off the laboratory environment directly to the construction sites. The long-term goal is to use context-aware, collaborative mobile robotics to manufacture the high-accuracy fabrication of large-scale building structures [4,5].

Integrating in situ fabrication into architectural planning and building construction workflows can ensure constant information exchange between the design and the construction processes. Ultimately, the goal is to develop an adaptable and accurate fabrication process for building components on site and enable a novel digital fabrication system.

This paper will focus on the possibility of implementing robot construction in actual construction and compare it to traditional construction methods to

explore the advantages and disadvantages of different construction methods.

At the same time, this paper uses two different types of construction robotics for on-site construction simulation: stationary robotic and mobile robotic, and analyzes their different focuses, advantages and disadvantages.

1.2 Type of the Robotic System

The challenge of accuracy in robotic in situ building construction directly correlates with the type of robotic system used. The construction robotics has two main types: stationary robotic systems and mobile robotic systems [5]. And mobile robotic systems also have three types. this division is irrespective of the robotic system's customisation for tasks-specific operations, or the material system used [3].

The fabrication of building components usually requires the absolute positioning of the end electronic components of the robot in a global workspace. This allows the material to be deposited in absolute positions, thereby keeping the fabricated components consistent with the CAD model. Therefore, depending on the type of robot system used, there are various methods to deal with the challenges of absolute positioning [5].

This paper will use two types of construction robots to simulate the construction of the target building, and then compare the advantages and disadvantages of the two types of robots through the construction method and construction efficiency.

1.3 Mapping, Alignment and Localization

The construction site is an uncertain environment induced from multiple sources. The building site, localization and materially induced uncertainties [4].

Regarding the various uncertainties on the construction site, the robotic system used for on-site construction must perform sensing tasks at multiple levels before and during the ongoing fabrication process. The process are as follows:

The first step is mapping and alignment. Before the fabrication, the building site needs to be mapped by the robot from a central location. the corresponding robot's sensing system must obtain a set of measurement values for the entire construction site environment or certain entities therein. Then, these acquired data are fused to construct a 3D reference map of the measurement space. In the one-time calibration step, the reference drawing is aligned with the CAD model of the construction site, and the transformation between them is estimated based on this.

Then is localization. During the fabrication process, the robot must sense and estimate its position on the construction site. For this localization process, the reference mapping created in the previous mapping step serves as a source of information. This known map is used as a reference to estimate the transformation of the robot pose respectively.

The last step is fabrication survey: During the fabrication process, the robot must also check the structure being built. Since the fabrication survey is local, it is always performed with the currently estimated robot pose [5]. This survey allows the robot to perceive uncertain material behavior and record the geometric deviation from the fabricated structure relative to its reference geometry.

Mapping, alignment and localization largely guarantees the accuracy of the robot's in situ fabrication process. Especially for mobile robotics, the relative changes in the robot's position during the construction process can easily cause errors in the construction results. Therefore, mapping, alignment and localization is particularly important throughout the construction process. In the following experiments, the mapping, alignment and localization process needs to be considered during the construction process using mobile robotic.

2 Application of KUKA robot in wooden structure architecture

2.1 Research Purposes

The target building is a wooden house that has been designed and built by students. Here we will study how to use robots to replace part of the manual to build a building when facing the same target building. Finally, through the comparison of the number of participants, construction efficiency, construction accuracy and construction difficulty, the difference and the advantages and disadvantages between the two construction methods are finally obtained.

2.2 Overview of the Building

This is a two-story building constructed by wood construction, covering an area of 32.1 square meters (see Fig.1).

Previous studies have planned complex plans for free-form modeling. Previous studies have planned complex plans for free-form modeling. The construction will use 105mm timber, which is not designed for free-form design as previously studied.

Therefore, in order to improve the constructability and research constructability at the time of design, the plan is set as a simple form, and the module is set to 105 mm timber multiple (105 x 9 = 945 mm) for overall design.

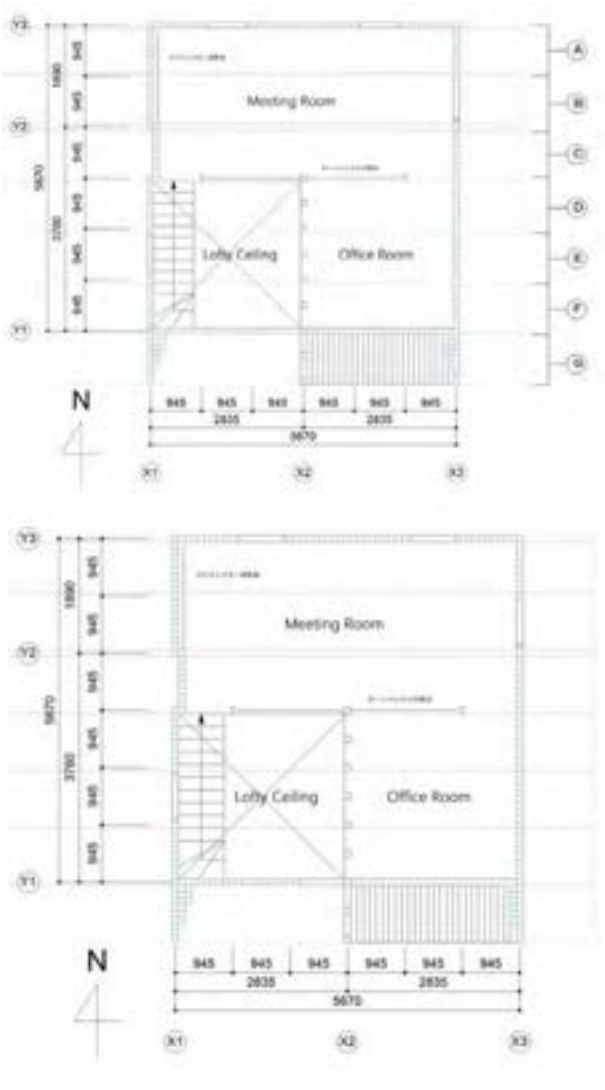

Figure 1. First and second floor plan of the wooden building.

2.3 Design Methods

The parametric design software RHINO is used as the design platform, and the simulation is built using the grasshopper on it. Most importantly, Kuka | prc software [3] of the KUKA robot can run on the grasshopper platform, effectively converting the design graphics into a language that the robot can recognize. At the same time, compared with traditional design software, the digital design platform can effectively improve the design efficiency in the design stage. Especially for modular residential buildings, digital modeling can more effectively formulate the rules between modules, which is convenient for modeling and later modification.

2.4 Construction Procedure

The human construction building was completed by students by hand. Construction efficiency is affected by many factors when building by manual work. Because the construction depends on manual work, the constructor has a decisive influence on the construction efficiency. First of all, the construction efficiency largely depends on the construction experience of the constructor. Secondly, construction difficulty of construction objects will also affect efficiency. Since the construction work is located outdoors, the construction efficiency is also affected by the weather.

For robot construction, two types of robots, stationary robotic and mobile robotic, are used. The KR90-KR150 R3700K KUKA robot is used in both constructions (see Fig.2).

The two types of robots in this construction are this KUKA robots equipped with a span of 3.7m, plus a Y-axis slide and the other equipped with a mobile base.

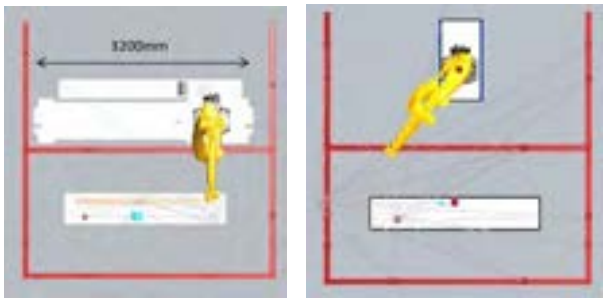

Figure 2. KR90-KR150 R3700K KUKA Robot with Y-axis slide and with a mobile base.

2.5 Robot Building Process

2.5.1 Comparison of Unit Assembly

These three construction methods are different in the construction unit assembly. In comparison, the number of units when the fabrication with mobile robot is the smallest, which simplifies the overall assembly steps after the completion of the later unit construction.

The completed unit, like unit A of Figure 3, is first erected perpendicular to the ground. The other units take the same action. Then, the completed unit B is connected with the unit A, and then the unit C is connected to the unit B in turn, and so on, until the units are spliced together. The building finally uses the crane to erect the units and erect them, then fixes the erected units to the anchor points of the foundation.

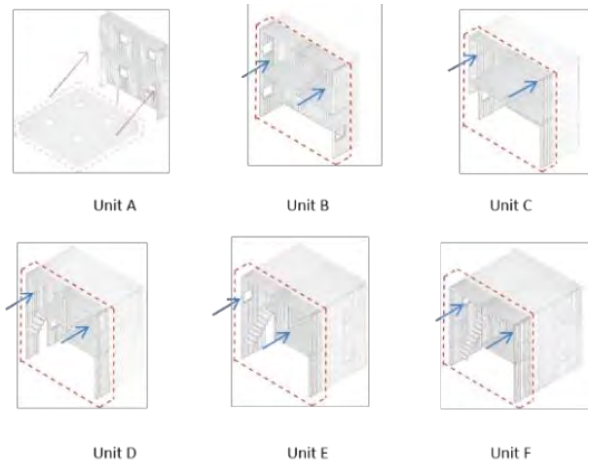

Figure 3. Unit assembly of human construction building

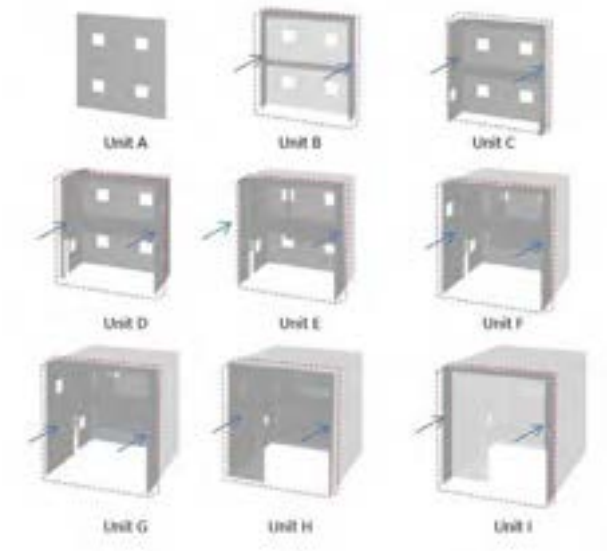

Figure 4. Unit assembly of stationary robotic construction building

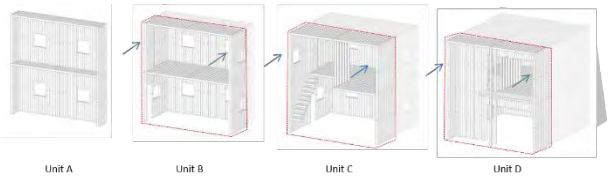

Figure 5. Unit assembly of mobile robotic construction building

For stationary robotic construction (see Fig.4), each unit is composed of eight layers during construction. The robot moves directionally through the y-axis slide, and a complete unit can be built each time. During the construction of mobile robotic construction (see Fig.5), each unit is built in two parts, so that the robot can complete the construction of sixteen floors in one positioning, and the construction of each unit needs to be displaced once.

The specific construction of each building unit, the construction mode of the stationary robotic construction and mobile robotic construction are also different (see Fig.6 and Fig.7).

Figure 6. Unit composition of stationary robotic construction building

Figure 7. Unit composition of mobile robotic construction building

2.5.2 Comparison of Construction Procedure

Construction efficiency is affected by many factors when building by manual work. Because the construction depends on manual work, the constructor has a decisive influence on the construction efficiency. The construction efficiency largely depends on the construction experience of the constructor. Also, the construction difficulty of construction objects will also affect efficiency. Since the construction work is located outdoors, the construction efficiency is also affected by the weather (see Fig.8).

Figure 8. Live photos of human construction building

The purpose of using robots in the construction field is to minimize the amount of manual use in the construction process.

So first of all, we will see which construction steps are replaced by robots in the reconstruction of the target building (see Fig.9 and Fig.10).

Grab timber: In the robot construction step designed with grasshopper software, the robot operation step begins with grabbing timber from the timber stacking

point. First of all, how to select the timber stacking point is very important. The appropriate starting point for grabbing should be at an appropriate position between the robot and the building object. Considering the length of the timber, it should be ensured that the stacked timber will not affect the operation of the robot, nor will it collide with the subsequent building.

Glue: The joint method of this construction mainly adopts an adhesive connection. Each of the intersecting timbers is coated with an adhesive. This process of applying the adhesive is also done by the robot. A glue tank is arranged between the timber stacking place and the building object, and the glue tank is provided with a glue roller. When the timber contacts and moves, the glue in the glue tank can be automatically applied. After the robot arm grabs the timber from the timber stacking place, it stops at the beginning of the glue tank and then descends and brings the timber into contact with the glue roller. And then drag the timber to move, so that the contact surface of the timber is coated with glue. Similarly, the setting of the position of the glue tank also ensures the continuity of the robot's operation.

Timber construction: After completing the steps of grabbing and applying the glue to the timber, the robot arm then places the timber in the designated position of the design. This is also the most critical step in the entire construction process. In order to ensure the smooth construction process, in the design stage, the order of the robot construction should be considered. Compared with manual construction, the construction method operated by the robot arm greatly improves the accuracy and precision of the construction.

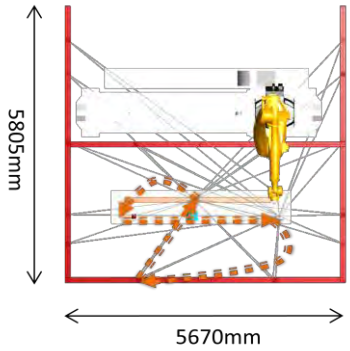

Figure 9. A process diagram of stationary robot construction

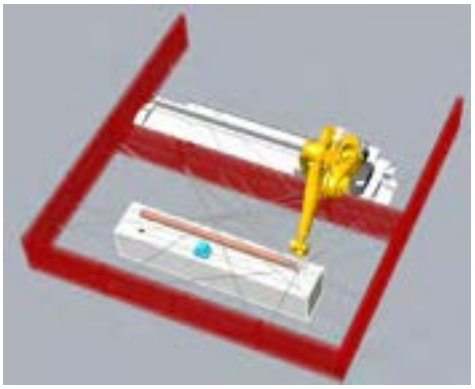

Figure 10. Schematic diagram of stationary robot work

For the construction process of mobile robots, a displacement of the robot is also included in the construction process of each unit, and each movement of the robot requires a localization (see Fig.11 and Fig.12). For this purpose, the robot is equipped with an end effector consisting of a vacuum gripper for pick and place routines and a laser range finder for sensing.

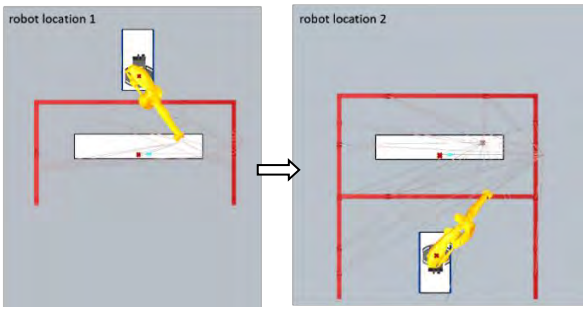

Figure 11. Fabrication sequence for mobile fabrication

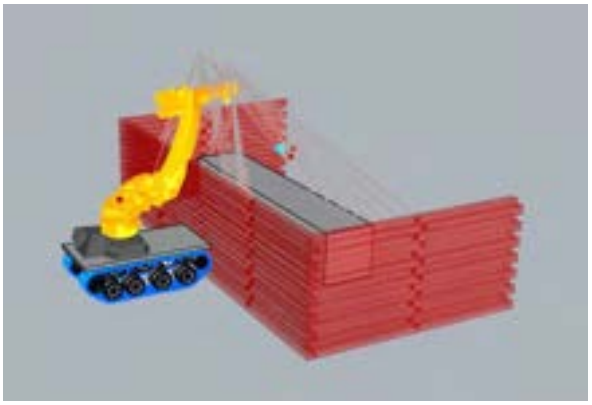

Figure 12. Schematic diagram of mobile robot work

3 Construction Evaluation

The construction evaluation is the focus of this comparative test. It aims to compare the advantages and

disadvantages of the two ways of building a wooden house by comparing the human construction with the robot construction. Next, the efficiency of both parties is evaluated mainly from the aspects of time efficiency evaluation, human efficiency evaluation, and construction quality evaluation.

Time efficiency is an important manifestation of the efficiency of a project, so time efficiency evaluation is the focus of this comparison. When the other conditions are the same, the time is shortened, which means that the overall efficiency of the project is increased, thereby greatly shortening the construction period, saving time and labor costs. This makes sense for any building project.

The first is the efficiency evaluation of human construction building.

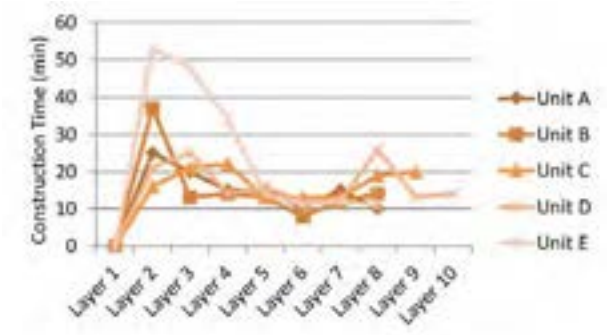

Figure 13. The layer construction time of each unit by human construction building

In the production of each unit (see Fig.13), the shortest production time is the sixth layer of unit B, about 8 minutes. In addition, the longest production time is the second layer of unit E is 53 minutes, as shown in figure 10. One of the reasons for this difference is the number of people working. There are 8 people in unit B, 2 in the first half of the work in Unit E, and 3 in the second half of the work in unit E. This is the reason for the difference in working hours. The number of people involved in the construction will directly affect the construction time.

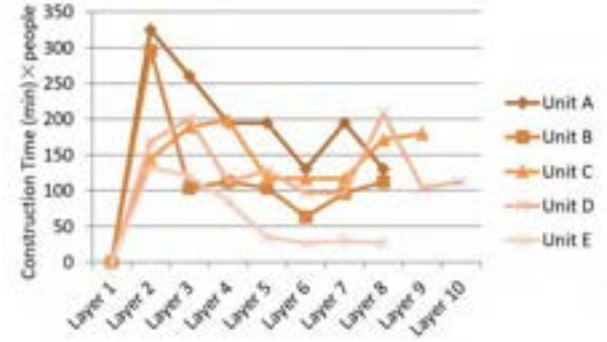

Figure 14. The layer construction time × people of each unit by human construction building

Compared with unit E, unit A has the lowest efficiency and unit E has the highest efficiency (see Fig.14).

First, it can be concluded that in this construction, each unit does not need too many people, and three people work at the same time with the highest efficiency.

Secondly, unit A is the first group of construction units, and the construction workers are unfamiliar with the construction process, resulting in inefficiency.

This proves that in the manual construction, the factors of the workers have a great influence on the construction efficiency.

Then is the efficiency evaluation of stationary robot construction building.

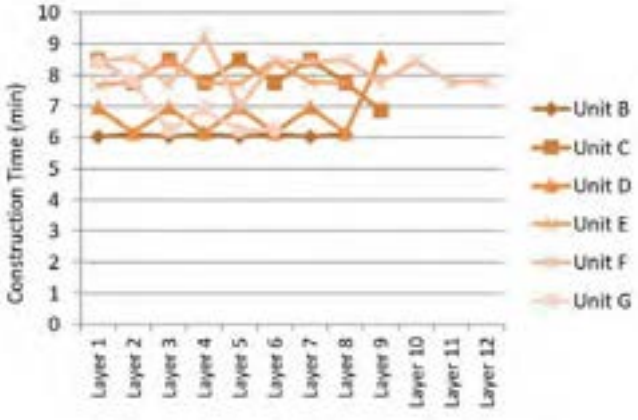

Figure 15. The layer construction time of each unit by stationary robot construction building

In the design of the grasshopper, every step of the whole process of the construction has been considered, so the time required for the robot to build can be directly calculated by the program.

The efficiency of the robot construction is stable, and the difference in construction time is only because the number of timbers that need to be built on each layer is different.

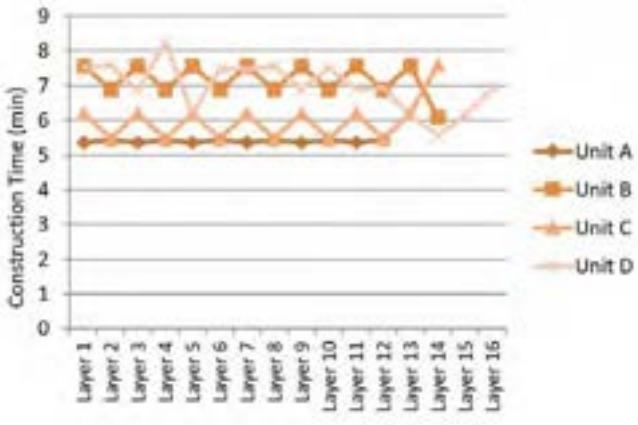

Figure 16. The layer construction time of each unit by mobile robot construction building

The comparison shows that the robot construction time is shorter than the human construction time, the efficiency is higher, and it is more stable and will not be affected by the number of people.

The difference in the time of each layer between the two robot construction methods is mainly caused by the different robot construction steps (see Fig.15 and Fig.16).

Here, the construction time of each layer of the mobile robot does not include the time required for the displacement and repositioning of the robot during the construction of each unit.

Table 1. Each unit and production time by human construction

Time(min)	Unit A	Unit B	Unit C	Unit D	Unit E
Total Time	115	111	137	153	183
Average Build Time Per Layer	14.38	13.88	14.63	15.75	22.88
Per Layer Builds Time	16.3				

Table 2. Each unit and production time by stationary robot construction

Time(min)	Unit B	Unit C	Unit D	Unit E	Unit F	Unit G
Total Time	49	72	61	63	98	42
Average Build Time Per Layer	6.07	7.98	6.78	7.92	8.17	6.97
Per Layer Builds Time	7.31					

Table 3. Each unit and production time by mobile robot construction

Time(min)	Unit B	Unit C	Unit D	Unit E
Total Time	86	100	84	112
Average Build Time Per Layer	5.36	7.16	5.98	7.00
Per Layer Builds Time	6.38			

The comparison clearly shows that the robot construction time is nearly 1/2 less than the human construction time, as shown from Table 1 to Table 3. Therefore, the construction of robots has a significant effect on the improvement of construction time efficiency.

4 Conclusion

stationary robots and mobile robots are usually suitable for different construction environments. For the target building, two sets of different types of robot simulation construction are designed to verify that facing a medium-sized wooden residential building, under the existing conditions, the simulation can be carried out by both stationary robots and mobile robots, and the two types of robots Construction, its efficiency and accuracy are much higher than manual construction. stationary robots and mobile robots are usually suitable for different construction environments. The construction of the two ways of robotic construction under the existing simulation conditions also has advantages and disadvantages. In future research, it is equally important to find conditions suitable for the construction of different types of robots.

The focus of this research is to compare the advantages and disadvantages of the same wooden structure, human construction and robot construction in software modeling, construction, and construction results. It is hoped that the construction performance of the on-site construction will be improved through the participation of robots. From the comparison results, the construction time efficiency evaluation, human efficiency evaluation, and construction quality evaluation of the robot construction are significantly improved compared with the human construction. Therefore, it is considered practical to study the use of robots in the field of building construction.

Compared with stationary robots, mobile robots have more advantages in actual building construction. And for the in situ processing tasks of various functions to further optimize the mobile robot, future research must target real-time sensing and complex dynamic overall control methods.

Towards 3D Perception and Closed-Loop Control for 3D Construction Printing

Xuchu Xu, Ruoyu Wang, Qiming Cao, Chen Feng

Tandon School of Engineering, New York University, Brooklyn, NY 11201, USA

{xuchu.xu, ruoyuwang, qimingcao, cfeng}@nyu.edu

Abstract -

With the expanding size of additive manufacturing products, research pioneers start to explore 3D printing in the construction field. For 3D construction printing, quality means safety, cost, and efficiency. However, it is challenging to ensure quality via defect detection and deviation correction during the construction printing process. Conventionally, defect and deviation still rely on the quality check after printing is completed or on-site manual monitoring, which could cause either a waste of material and time to abort printing or lagging adjustment for printing settings after obvious defect appeared. To overcome these challenges, we propose a point-cloud-based approach for real-time 3D construction printing defect detection using a 3D camera and cloud-to-plane distance to evaluate printing layer integrity and compare printing results with CAD models. We also define different types of defects and deviations that can cause printing failure. Additionally, we feedback detection output into a closed-loop controller for updating the printhead motion. Our experiments show this joint printing and detection process handling various defects and deviations.

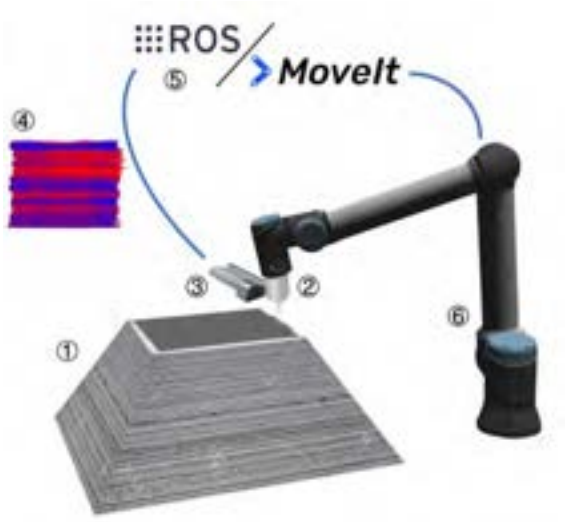

Figure 1. Illustration of our setup. 1. Concrete printing model. 2. Print head. 3. 3D perception sensor. 4. Color-coded printing error. 5. Control system. 6. Robot arm. During the printing process, the 3D perception sensor updates error feedback to the control system for defect and deviation correction.

1 Introduction

During the last several decades, additive manufacturing (AM), also widely known as 3D printing, demonstrated an incredible ability to assist designers and engineers prototype and produce rapidly. Recently, the study of 3D construction printing has rapidly risen as a new active area in the AM communities. A key challenge in 3D construction printing is monitoring the output quality and in real-time automatically adjusting the printhead control to reduce deviation and avoid structure collapse. To achieve this, 3D perception should to be tightly coupled into the printing process, since we need to evaluate not only each layer's integrity but also the evolving structure's shape deviation from the CAD model.

To acquire 3D shape data, traditional sensors, like multi-beam Lidar [1, 2], firmly occupy the high-end manufacturing and research of 3D perception. Although it could provide highly accurate point cloud data, a notable drawback of this type sensor is the excessive cost. Another limitation of this sensor in 3D printing is the difficulty of point cloud segmentation in post-processing due to their spare coverage on the printing output. To overcome these drawbacks, a different approach is to combine Time-Of-Flight (TOF) sensor with RGB camera. Microsoft Azure Kinect (Kinect) benefit from its high resolution TOF sensor, which has a balanced cost and performance. Kinect could provide precise and densely distributed point cloud data with RGB information that help us extract useful points while easily excluding the insignificant background. Moreover, we can observe the printer's extruder from Kinect's RGB camera in real time, which monitors material without interrupting the printing process.

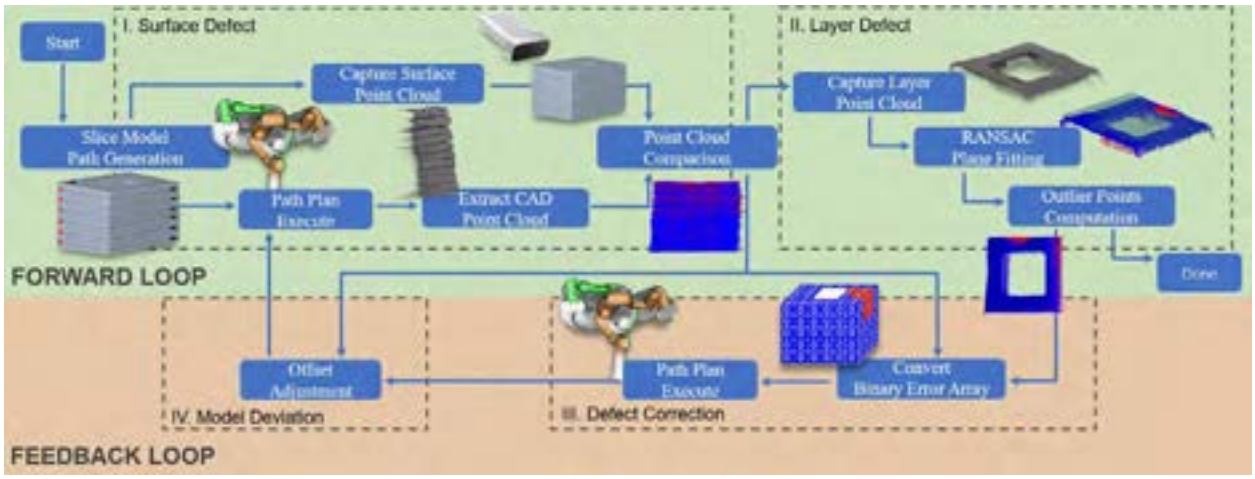

Figure 2. Our workflow. I. Simultaneous surface defect detection and 3D printing. II. Defect detection after printing the current layer. III. Error feedback. IV. Error adjustment from the current to the next layer.

With dense RGB point cloud data, we will measure surface defect and shape deviation compared with the corresponding point cloud which is generated from the CAD model. Cloud-to-plane (C2P) [3] distance is the error metric we adopt for measuring the difference between two point clouds. By projecting error vectors along the unit normal vector of the local plane, this metric could evaluate shape deviation and trigger with preset tolerances the online printing correction through feedback control.

In this paper, we propose an online approach for increasing the quality of 3D construction printing using a 3D camera and feedback control. To this end, we designed two experiments testing several different types of defects and deviation. Due to COVID-19 pandemic and facility closure, one of our experiment, closed-loop 3D printing, was only conducted in the simulation environment. The following are our main contributions in this paper:

- We define three types of printing error in 3D construction printing, includes layer defect and deviation, surface defect, and model deviation.
- We propose a novel approach for closed-loop 3D construction printing that could help us correct defects during the printing process.
- We implement a cloud-to-plane shape deviation error assessment between the point cloud captured by the 3D camera and that generated from the CAD model.
- We design two experiments to demonstrate our approach under different printing error scenarios.

2 Related Works

Our approach is mainly involved in three major research domains: 3D construction printing, defect detection and closed-loop control printing. As our previously mentioned, point cloud matching algorithm employed to find corresponding points between two point clouds and help us to calculate the error rate between them. Therefore, we will expand to discuss related research and approaches in these three areas.

3D Construction Printing. Different from other 3D printing types, construction 3D printing needs more consideration in product transportation, material property, printing quality and even aesthetic requirement. Crump et al. [4], as inventor of fused deposition modeling (FDM) technology, opened the gate of 3D printing. His method slices 3D objects to 2D layers and prints by CNC based machine. Although his approach initially used polymer filament, this method is also applicable to use other materials in different regions, such as AM with concrete material. Contour crafting [5, 6], present by Khoshnevis, is one of approach which employed for 3D construction printing. This approach sets a side trowel on the side of the extruder to smooth the apparent finish texture produced by the printing process. Buswell et al. [7] proposed the concept of Freeform Construction, which brings 3D printing into mega-scale rapid manufacturing. He aims to divide the building into a mega-scale section that could rapidly produce in the factory and assemble at the construction site. Recently, Keating et al. [8] demonstrated a mobile printing platform called Digital Construction Platform (DCP). DCP used a KUKA robot arm to research the printing position instead of the gantry-base fixed platform. Also, the author of DCP uses two-component polyurethane closed-cell foam to ensure printing material curing in a short period of time. 3D construction printing is not only a popular topic in the research area but also favored by the construction industry. WinSun [9], a Chinese 3D print-

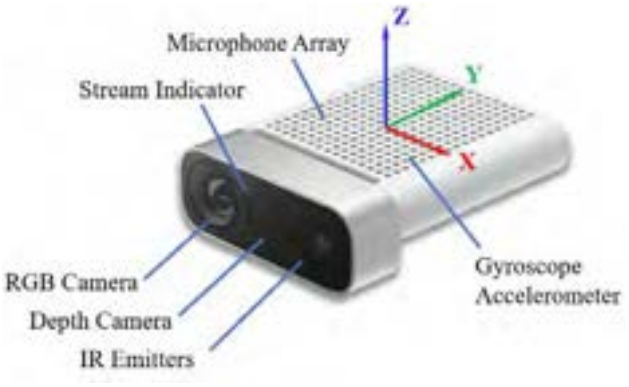

Figure 3. Microsoft Azure Kinect. We use RGB camera, Depth camera and Gyroscope in the following experiments.

ing industry leader company, developed multiply property material and successfully applied 3D printing to the construction field. Therefore, we need to explore a reliable method to real-time monitor the quality of 3D printing.

Defect Detection. Currently, defect detection methods of 3D Printing fall in two different domains, scanning based and vision based. Scanning based methods usually use a TOF sensor or with additional auxiliary equipment. Benefit form scanning whole model, these type methods could inspect detailing defects, such as tiny surface crack and local deformation. One of the obvious drawbacks is time-consuming, that these methods required a screening window to scan each layer during the printing process. Moreover, the calibration and preciseness of auxiliary equipment will directly affect the final accuracy. Lin et al. [10] used a sliding window to detect filling situations by a laser scanner, which attaching with printer extruder. Liu et al. [11] used a camera to measure the target surface assisting with a line laser and linear translation stage. Image based methods only rely on different types of cameras. Holzmond et al. [12] demonstrated real time defect monitor system that compares layer point cloud with a model cross section by using a dual camera under different light sources. Shen et al. [13] proposed a feature based surface defect detection approach by contour comparison. There are also some vision based methods combined with neural network [14, 15]. The downside is that these methods require a large amount of data, especially labeled data for supervised learning. Moreover, most of the methods above are implemented in polymer FDM 3D printing. Either point cloud of one single layer is too sparse or model defects is difficult to be accurately captured online. Therefore, all of the above methods only detect defects after printing and can not correct error during printing process.

Closed-loop Control Printing. Nowadays, researchers have not only focused on developing new 3D printing technology, but also hoped to improve the quality and automation level of 3D printing, which reducing the degree and impact of human factors. Different types of 3D printing have disparate limitations and drawbacks which need to overcome. For the ink-jet printer, Lu et al. [16] proposed a feedback controller for finding the best droplet location to minimize the edge shrinkage effect. Guo et al. [17] incorporated feedback measurements to a predictive control algorithm for avoiding edge shrinking, unreliable dimensions and uneven surfaces. Altın et al. [18] developed a spatial iterative learning control framework that involves discrete Fourier transforms and iterative learning control to improve part's build quality from a single layer toward the relationship between two layers. For laser metal deposition (LMD) printing, Sammons and his colleagues [19] present a stabilizing layer-to-layer controller to track and compensate for the deposition process. When we ask why closed-loop control is so important in 3D printing, especially used in manufacturing, we need to understand that the nature of 3D printing is repetitive motion. The quality of the current layer is highly dependent on the previous layer, such as integrity, flatness and support structure.

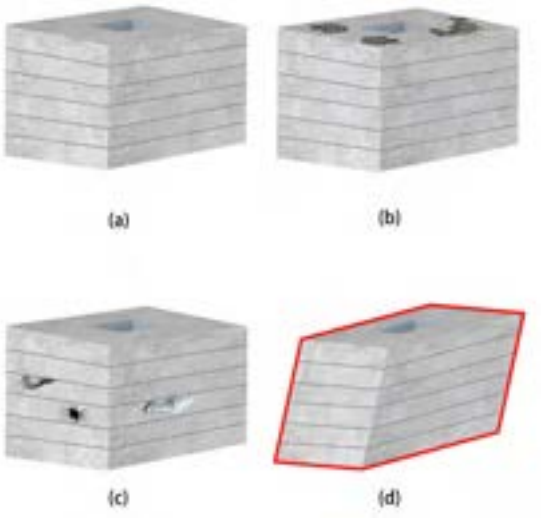

Figure 4. Defect and Deviation Diagram: (a) Ground Truth; (b) Layer Defect and Deviation; (c) Surface Defect; (d) Model Deviation.

3 Method

As shown in Figure 2, the entire 3D printing processing workflow is divided into four phases. Phase 1 is mainly composed with the regular 3D printing process and surface defect detection, which also includes layer deviation detection. Phase 2 includes our original steps, which are layer defect detection after each layer printing. Phase 3 aims to integrate the error output of phase 1 and 2, then following to repair the model. The goal of phase 4 is to

compensate for model shape deviation by adjusting offset. The detail of the explanation and discussion will present in section 3.2.

3.1 Hardware Platform

Perception Sensor. Microsoft Azure Kinect, Figure 3, is a fusion sensor that provides an RGB camera, infrared sensor, depth sensor, gyroscope with accelerometer and microphone array. The reason why we chose Kinect as perception sensor in our approach is that it preset synchronization and calibration-free transformation between each sensor. The depth sensor model in our research is set as WFOV 2x2 binned. The nominal range accuracy of Kinect is less than 11mm in the distance range of 0.25-2.88m [20]. It provides 512x512 resolution with 0.5m to 5m operating range and 120 degrees field of interest in the dual-axis, accurate and dense enough for our purpose.

3D Printing Platform. Universal Robot 10e (UR10e) [21] is a 6-DOF collaborative robot arm that could handle up to 10 kg payload in a 1.3 meters radius and 360 degrees workspace. We designed a concrete print head with a center mixer and attachment for Kinect. The center mixer could rotate clockwise to feed material and the opposite direction to block material. We prepared fast setting mortar mix as our printing material.

Control and Simulation Environment. In order to better observe printing process, ensure safety environment and prevent hardware damage, we use ROS [22] with Moveit [23] in the Gazebo environment to simulate the printing path. Moreover, we use Gazebo simulation world and physics engine for simulating and demonstrating the closed-loop control experiment in section 4.3.

3.2 Defect and Deviation Detection.

When the failure of the 3D printing model occurs, defect and deviation will appear in some places of our model. Therefore, we need to clarify what is defect and what is deviation. In this paper, we define a defect as missing the integrity of the printing layer or material overfill and underfill on the printing model surface. Similarly, the deviation is defined as the contour or shape error.

We divide the defect and deviation generated in 3D construction printing into the following three categories:

Layer Defect and Deviation. Since the printing model is stacked up by multiply concrete layers, it is necessary to check the defect and contour deviation of each layer. The cause of layer defect is either the interruption of feeding material or the impurities contained in the material, such as air bubbles. Layer deviation is caused by path planning error or robot arm control accuracy and noise.

We use RANSAC to fit a plane, $\hat{P}_L$, based on the points in the point cloud, S_L, captured from the Kinect sensor.

$$\begin{aligned} S_L &= \{(x, y, z)\} \\ \hat{P}_L &= \{(x, y, z) | \hat{A}x + \hat{B}y + \hat{C}z + \hat{D} = 0\} \end{aligned} \tag{1}$$

By calculating the point to plane distance, d_i, of each points in the point cloud, we uses an error index array, $e(d_i)$, to record those outliers which compare with the preset tolerance, λ.

$$d_i = \frac{|\hat{A}x_i + \hat{B}y_i + \hat{C}z_i + \hat{D}|}{\sqrt{(A^2 + B^2 + C^2)}} \tag{2}$$

$$e_L(d_i) = \begin{cases} 1 & |d_i| \geq \lambda \\ 0 & |d_i| < \lambda \end{cases} \tag{3}$$

Surface Defect. The surface of the 3D printing model is formed by stacking the sides of the layer. Hence, the obvious layer texture can be observed on the model surface. During the printing process, due to changes in the print head's motion speed or angle rotation, it will cause the material to accumulate at some particular positions, thus forming a class of overfill defect. Unlike overfill, underfill is happened at the gap between roaster path and contour path. Additionally, the local collapse by lacking support will also cause surface underfill.

In order to slice the CAD model for outputting each layer's outer surface, we export the CAD design file to STL format. During printing operation, we subscribe ROS message which present Kinect's position in global coordinate system by calculating robot's forward kinematics. After that, we use this position to map points cloud into Kinect coordinate system. By applying Iterative Closest Point (ICP) algorithm, we identify corresponding point, p_i, for each point, $\hat{p}_i$, between CAD point cloud and scanning point cloud respectively. We minus p_i and $\hat{p}_i$ to get error vector. Then we project the error vector along the unit norm vector N_p on point p_i in reference point cloud P. Therefore, the C2P error distance, d_i, is finally computed as,

$$d_i = \min_{\forall p_i \in P_s} (|\hat{p}_i - p_i| \cdot N_p) \tag{4}$$

Once we have the C2P error distance, we apply (3) to compute point cloud error array.

Model Deviation. Even our printing model avoiding previous errors, we may still fall short of our printing results. The shape deviation we discuss here refers to the misalignment between layers. To provide misalignment bias to feedback control system, here we choose absolute error distance instead of error index array in (3).

$$e_M(d_i) = \begin{cases} d_i & |d_i| \geq \lambda \\ 0 & |d_i| < \lambda \end{cases} \tag{5}$$

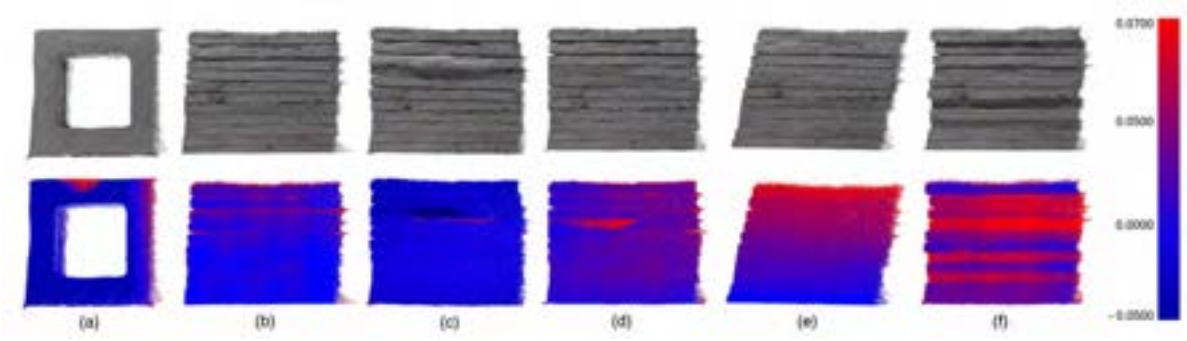

Figure 5. Task 1 results: (a) Layer Defect; (b) Surface without Defect and Deviation; (c) & (d) Surface Defect; (e) & (f) Model Deviation. Top: RGB point cloud captured by Kinect. Bottom: visualization of C2P error between scanned point cloud and CAD. Signed error is color coded from red (positive) to blue (negative).

3.3 Closed Loop Control

As we mentioned in the beginning of this section, we explain and discuss in detail for the each phase setup and process below:

Phase 1. First of all, we directly export the design model from CAD drawing software and save it in STL format. Then we send this STL file to ROS Additive Manufacturing (RAM) for 3D slicing and path generation. We import each layer path from RAM output into ROS MoveIt! to perform path planning. This step helps us to ensure UR10e avoiding self-collision. Once MoveIt! does not detect any collision, it will send the trajectory to UR10e and execute.

At the same time, our point cloud comparison algorithm is also working as a ROS node during the printing process. By subscribing pose message, ROS transfer the position of UR10e's end effector to point cloud generation. In our algorithm, we compute the Kinect observation frame and generate the reference point cloud under the current frame. On the other side, the Kinect sensor continuously captures depth images of the layer surface and transmits it back to our algorithm in real-time. When UR10e completes printing each layer, our approach will go through the ICP algorithm to register the scanning point cloud to reference point cloud and calculate the C2P distance to output the error-index array.

Phase 2. During exporting error-index array in phase 1, UR10e move forward to the next phase, which set Kinect to capture the top view of each layer. By converting RGB to HSV color space, we able to easily segment layer's points from the scanning point cloud. Subsequently, we apply the RANSAC algorithm to fit a plane from those layer's points and output as the planar equation format. The manipulation of the planar equation can help us check multiple layer defects. We check the layer's level corresponding to the horizontal datum. We also find the outlier compare with our preset distance to find the defect position

Figure 6. Task 1 results. Left: RGB point cloud captured by Kinect. Right: visualization of Layer Deviation between scanning point cloud and CAD file. Signed error is color coded from red (positive) to blue (negative).

on the layer plane. The same as phase 1's last step, the algorithm outputs the error-index array to provide feedback information.

Phase 3. In the previous two phases, we got error-index arrays. In the feedback loop, we first convert them into binary error-index arrays to indicate the makeup position for MoveIt! path planning. During MoveIt! execute the trajectory path, we able to correct layer deviation before concrete curing by setting the different angles of side trowel. Moreover, for those defect positions, the print head will re-feed concrete with adjusted side trowel.

Phase 4. Benefit from error array provided in phase 1, the final phase is able to estimate the offset between the current layer and previous layers on each axis direction. In this step, we regard the previous layer as an integral base and only discuss the relationship between the current layer and the base. Applying compensation could help us avoid systematic bias, even compensates control noise for certain special position.

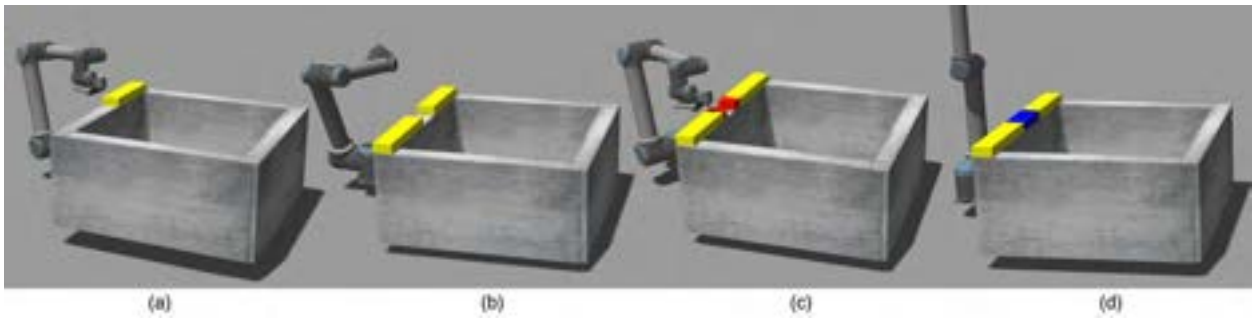

Figure 7. Task 2 experiment process: (a) Normal Printing without Defects; (b) Printing Complete; (c) Mark Defect Area; (d) Complete Defect Correction.

4 Experiments

Our experiment is designed as two tasks, static detection test, and simulation of 3D construction printing. The first task, static detection, aims to demonstrate our approach worked as normal defect detection in a static environment. We will show the three different defects and deviations, which defined in section 3.2. For the second task, we will present our complete approach including defect detection with feedback control during real-time printing. Due to research facility closure and limited available equipment, this experiment will be present in the simulation world by Gazebo.

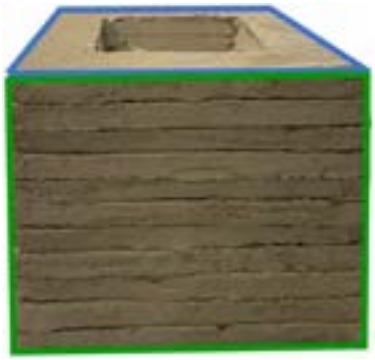

Figure 8. Eleven-layer concrete cubic. Top (Blue): Layer without defect and deviation. Front (Green): Surface without defects.

4.1 Experiments Setup

In Task 1, we are looking for a model that would demonstrate errors as mentioned in section 3.2. For better simulate the product of 3D construction printing, including material property and texture, we made serval half inches concrete planes by concrete-water mixture in a ratio of 9:1. We superimposed these concrete planes to build a cubic shape model. Here, each concrete plane represents corresponding layer in the real printing process. Therefore, we finally got a cube that is 6.5 inches high and 8.5 inches in both depth and width. Each concrete plane has two sides of fixed length and 90 degrees angle, the same as our CAD design. The other two sides are designed to contain different deviation and defect, such as material overfill or layer deviation. We can simulate the errors under various situations by adjusting the placement and order of concrete planes, just like we designed in advance.

In Task2, we setup a UR10e robot with a combination of a simple print head an kinect in Gazebo's simulation environment. To prevent the robot arm hitting the ground, we set the UR10e on a 0.7m high box. Similarly, the printing platform also raised 0.4m accordingly. In this task, our goal is to use the Kinect to capture the layer defect caused by interrupt feeding material during the printing process. Since there is no fluid setting in Gazebo, we made a plugin that will follow the print head position to place thin yellow boxes from the waiting area to the target location in real time. We randomly deleted one segment of materials in the waiting area. Therefore, UR10e will interrupt printing even robot arm is still moving. By using the depth camera plugin, we convert the depth image to a point cloud and use it as the feedback input of our approach. After the printing complete, our plugin will mark the defect position in red first and turn blue after defect correction.

4.2 Defect and Deviation Detection

Figure 5 and Figure 6 present the experiment results in task 1. For Figure 5, RGB point cloud images in the top row demonstrate the concrete cubic that we see in the real world. The images in the bottom row show the difference between printing model and CAD design by presenting in heat map. As scale bar shows, the red regions represent the shrinkage of the model, which means that these regions do not meet the designed size. Similarly, the dark blue areas tell us that the printing exceeds CAD design. As mentioned in section 3.2, tolerance is always a necessary consideration in the engineering world. We set 0.5cm as

the tolerance, λ, in (3) and (5).

The images in column (a) are captured by Kinect from top to bottom after completing each layer. We can see that there are only slight traces in the top image, even it will not be noticed, if the observer does not look closely. However, after generating RGB point cloud, we can easily segment our target, concrete cubic, from the background by color space change. The heatmap below makes us more intuitive to see the defects that are difficult to detect with naked eye or image based detection approaches. There is a shrinkage area at the top of the model. In the actual printing process, the reason of causing this type failure could be the interruption of feeding material. Furthermore, we can also determine the layer deviation at the same time. In Figure 6, the red area presents layer deviation exceeding the boundary of the CAD design model.

Column (b) in Figure 5 shows an ideal 3D printing model that we can see that the entire point cloud is the blue color. Columns (c) and (d) simulate two types of surface defects, overfill and underfill, respectively. In the top image of column (c), we can see a prominent material overflow part in the middle of our printing model. When we applied our method, the dark blue zone is the detection of the overfill area. The note that the underfill depth in column (d) is only 0.7 cm, but our approach still can accurately detect it. For model deviation detection, we simulate two types of control error, columns (e) and (f), that cause to misalignment between neighbor layers. Column (e) simulates the printing drift, which usually occurs in the control systems with accumulated errors. We choose random noise for offset error and make the detection in column (f).

4.3 Closed-loop Control Printing

As Figure 8 shown, our goal is to print a 1 meter cubic. The initial experiment randomly deletes material for an arbitrary length. After confirming that our experiment plan is feasible in the simulation environment, we change the range of the interrupted material to check the limitation of our approach. Starting from 20cm, we found, when the length is less than 2.4cm, our method cannot detect surface defects. Note that we follow the specs entirely from the Microsoft Kinect website to set the parameters in Gazebo depth camera plugin.

5 Conclusion

In this paper, we proposed a front-end closed-loop control approach for 3D construction printing. We also explored the feasibility of using point cloud based defect defection for the construction size printing model. Comparing to other methods, our approach demonstrates a high performance defect detection method with a cost-effective sensor. As the experiments we showed, we believe that our proposed approach has great potential in the field of 3D construction printing.

Limitations and Discussions. An obvious limitation of our approach is that the detection accuracy will significantly decrease as a shrink of the printing model size. Generally, a smaller model will require higher performance and resolution of the 3D perception sensor to detect detail defects. Since the model size of 3D construction printing is large enough, and even a single layer could be easily captured by Kinect. Therefore, this is the main reason why we propose our method for defect detection in 3D construction printing.

Future Work. Our future work is aiming to bring out the real 3D printing product by using our approach. Furthermore, we believe that our work can ultimately help construction workers improve their safety and construction quality, help customers achieve their ideal designs, and reduce material waste to protect our environment.

Abstract –

Exact development progress estimation has been demonstrated to be basic to the accomplishment of a structure venture. The techniques for robotized development progress estimation proposed in past examinations have certain constraints in light of fragmented informational collections. The principle target of this research was to create a precise, basically completely mechanized strategy for development progress estimation utilizing a 360□ cameras and 3D information with LiDAR technology to detect site plan by remote-detecting innovation. The cameras at that point select the parameter settings that best fulfill the relegated contending solicitations to give high goals perspectives on the stage accomplishments. We propose using robotic scanning with AI analytics to tackle the plaster stage and the camera parameter determination issues continuously. The adequacy of the proposed framework is approved in both reproduction and physical test. The consequences of the proposed progress estimation technique can be utilized as contribution for development progress representation and enhance the inspections timeframe.

1 Introduction

Robots and mobile platforms have recently begun to solve many of the goals for remote sensing. Mobile laser scanning devices have enabled the identification and classification of roadside objects [1].

Human-mounted solutions, like backpacks equipped with laser scanners, allow for human-in-the-loop navigation of indoor spaces [2]. These mobile solutions afford operators access to previously inaccessible regions that stationary systems cannot sense.

Autonomous and semi-autonomous mobile remote sensing platforms, including robots, further improve the flexibility that mobile sensing offers. Robotic agents can operate without the need of constant human presence and input [3][4]. Therefore, environments can be remotely sensed without involving or endangering humans, making surveying safer and more efficient. Many robotic platforms outperform their human counterparts in similar sensing and mapping tasks as well [5], which increases the reliability and accuracy of produced geospatial intelligence. This process of simultaneously localizing a robot in its surroundings and mapping these surroundings is known as Simultaneous Localization and Mapping (SLAM). The fine level details and autonomy afforded by SLAM robots have contributed to the ubiquity of these platforms as mobile and adaptable exploration solutions.

One result of the increased use in robotic remote sensing platforms is a greater portfolio of environments and spaces that can be explored. Urban and subterranean environments pose a unique challenge because they typically feature tight spaces and are often poorly lit. Additionally, underground caves are often rocky and difficult to traverse. Nonetheless, robots have been produced to explore these spaces. Urban-focused robots use three-dimensional (3-D) lidar to scan areas due to the high failure rate of visible-light dependent cameras [6][7]. As a result, robots can produce highly detailed maps for the precise environments for which they are selected, including deep mines and archaeological sites [8].

The goal is to provide the warfighter a cost-effective solution that provides situational awareness, in near real-time, of building interiors and Subterranean (SubT) environments. In order to address the gaps listed above, merging a mapping technology with a robotics platform that has limited computational and power resources will need be done successfully.

However, most commercially available LIDAR systems are designed for use outdoors, specifically for

high-resolution aerial imaging and mapping applications. As a result, they tend to be large, heavy, power-hungry, data bandwidth intensive, and expensive and not suitable for integration on a robotics platform. Also, the amount of data collected is quite large (gigabits) and requires post-processing (days). In the last few years, the automotive industry's push for autonomy has resulted in a number of industries producing SWaP-C sensors that should be suitable for a robotics platform and still be capable of surveying and mapping underground structures and the interior of buildings.

This capability would provide the warfighter with data intelligence to develop situational understanding and support troop maneuverability. Utilizing these commercial off the shelf (COTS) low-power sensors to provide a near real-time solution has yet to be implemented, and the benefits provided when compared to their larger, expensive, and power-hungry counterparts are unrealized.

In regards to the robotics platform, the Maneuver Center of Excellence (MCoE) SubT equipment list has a variety of robot platforms, including the Firstlook and Packbot 510. Both of these robots are equipped with cameras, but neither system generates point clouds of the environment. In addition to the cost of the robotics platform, additional revenue is also required for mapping sensors (i.e., GeoSLAM ZEB-REVO or Carnegie Robotics Multisense). However, these sensors merely sit atop the robotics platform and do not leverage the robot's on-board sensors for enhanced positioning and localization. The robotics platform that is being leveraged for this report is the Army Ground Vehicle Robot (GVR-BOT) Gen 1.1 platform. This platform is the reference design standard for Project Manager (PdM) Unmanned Ground Vehicle. By combining the robot's localization and positioning sensors with the mapping solution, highly accurate data can be generated.

2 Literature Review

2.1 Robotics Surveillance

The construction industry is known to be a major economic sector. However, it is also dealt with different types of inefficiencies as well as low productivity. Robotics autonomous surveillance is a solution that has the potential to address such types of shortcomings. Delgado stated that robotics and subsequent automated systems can revolutionize and also provide several advantages to the overall construction industry [9]. Construction is considered to be a labour-intensive sector. Nonetheless, it can also be stated that the Robotic System automation can help to become very effective in other sectors as well for labour cost reduction and at the same time, look for productivity and quality improvement.

2.2 Robotics Automation

Different types of Construction Robotics exist in the construction industry. These can be group into 4 general categories. This include off-site prefabrication systems, on-site automated and robotic systems, drones and autonomous vehicles, and exoskeletons. The adoption of such robotic mechanisms can be largely attributed to the successful use of robots in the automotive manufacturing industry of Japan. Construction works need to be completed soon as significant financial matters are involved. However, this process can be automated as Artificial Intelligence (AI) can consider proper measures that will improve the situation related to robotics involvement in construction [9].

2.3 Factors of Robotics Automations

This is evident that there is a cost for the client for robotics adoption in their whole process. Governments are considered to be the major clients of all the construction and infrastructure companies. Furthermore, the public spending amount in the infrastructure can have a big influence as well in terms of adopting new technologies. The construction companies operate in a highly competitive market. If we consider that price is the only criteria for selection, then the construction companies can significantly consider reducing the overall profit margins in an aggressive manner. This type of manner will increase confrontational behaviour as well as restrict those people from alternative thinking [10].

2.4 Technical Factors

There is also case where different practical factors can limit the overall robotics related implementation. These factors can be attributed to the technical limitations that reside within the current technologies and also some other work-related factors.

The challenge in this case is the high complexity that remains within the construction tasks which also have effects on the usability and effective of the robotic automated solutions [9]. Construction robotics, with the help of AI detection and internal mapping, can consider construction automation and inform about completion. This type of autonomous inspection will bring results within a short period of time. To improve the quality of such inspections, it is preferred to have inspections enhancements in place [9].

A construction work consists of many stages. With AI detection and other latest technologies, it is possible to know about construction automation and completion period. The progress will help the stakeholders to make relevant decisions that will have an impact at the direct workflow.

2.5 Adaptation Process

There is a certain level of complexity in the overall construction process and hence, sufficient preparation is necessary for adaptability. All the participants who work in the construction process needs to be considered in the overall adaptation process. The autonomous inspection will help time and cost for the companies and help them focus on the core issues. The adaptation process of the robotic automation can take place through step by step process [11].

2.6 Robotics in Construction Automation

The robotic technology performance is on the rise rapidly and therefore, this can complement the construction process's automation and completion progress monitoring. Nonetheless, to conduct the operations flawlessly, workers need to have mechatronic and robotic training as well as qualifications [9]. The stakeholders and the decision makers can think about automation and integration of different advanced technologies in the construction field. This can be done when the guidelines are properly followed and considered into the thinking process.

Robotics can work in different forms and it has also been considered for augment abilities. There are working exoskeleton available which will not only help to enhance the wearer's mobility but also make them much stronger. This will make those people less prone towards any type of work-related injuries. These wearables eliminate major stress as well as damage that can result from being involved in physical labor too often [11].

Robotics and automation play a crucial role in the construction sector. It is also to be noted that there should be high technology of Research & Development to be used because of the dynamic and unstructured nature of the overall construction environment. There are several robotics automations which are used in the construction area and they include- fireproofing spray robot, wall finishing robot, steel beam positioning manipulator, spray coating robot, and ceiling panel positioning robot. In terms of the civil work, there are also the use of different types of robot, such as- semi autonomous robot, concrete crusher, demolition robot, robot for all jobs etc. Each of these robots have different purposes that they serve [12].

2.7 Robotics in Construction

The primary role of automated techniques in the construction sector is to develop a multidimensional as well as a comprehensive costs and benefits analysis which is related to some certain robotic application. The success in this regard can be analysed through the process of technical as well as economic feasibility. The technical feasibility is an ergonomic evaluation of the steps that help to complete the given work task. It also considers the analysis related to the robot control and process monitoring requirements [9].

Through the process of Robotics and Automation, we have also seen an increase in the overall occupational safety issue. Using robotics and its automation help especially in the case of dangerous zones. There are several automated systems which may help in working for the dangerous zones for the humans. This type of automation helps to reduce the labour related injuries and also keep company cost at a minimum. There is an increase in quality that is evident as well because of the robotics autonomous surveillance algorithms. These operations are carried out with less variability in comparison to the human workers [13].

The automation system possesses a greater control towards the whole production process. We are able to detect the problems easily and for different stage as well. Through this process, it gets easier to understand if there is a correct functioning of the system happening or not. The robotics automation gives greater control towards the final result and this can be controlled in an efficient way by look at the steps of the overall process individually.

3 Research Methodology

3.1 Lidar Automation

The method of simultaneous localization and mapping (SLAM) using a light detection and ranging (LiDAR) sensor is commonly adopted for robot navigation. However, consumer robots are price sensitive and often have to use low-cost sensors. Due to the poor performance of a low-cost LiDAR, error accumulates rapidly while SLAM, and it may cause a huge error for building a larger map. To cope with this problem, this paper proposes a new graph optimization-based SLAM framework through the combination of low-cost LiDAR sensor and vision sensor. In the SLAM framework, a new cost-function considering both scan and image data is proposed, and the Bag of Words (BoW) model with visual features is applied for loop close detection. A 2D map presenting both obstacles and vision features is also proposed, as well as a fast relocation method with the map.

Experiments were taken on a service robot equipped with a low-cost LiDAR and a front-view RGB-D camera in the real indoor scene. The results show that the proposed method has better performance than using LiDAR or camera only, while the relocation speed with our 2D map is much faster than with traditional grid map.

Localization and navigation are the key technologies of autonomous mobile service robots, and simultaneous

localization and mapping (SLAM) is considered as an essential basis for this. The main principle of SLAM is to detect the surrounding environment through sensors on the robot, and to construct the map of the environment while estimating the pose (including both location and orientation) of the robot.

3.2 SLAM Detection

LiDAR can detect the distance of the obstacles, and it is the best sensor to construct a grid map, which represents the structure and obstacles on the robot running plane. The early SLAM research often used LiDAR as the main sensor. Figure 1 shows the obstacles near the robot, marked in red dots. SLAM has the ability to detect moving objects as well. Table 1 shows the angle and distance from the obstacle shown in figure 1.

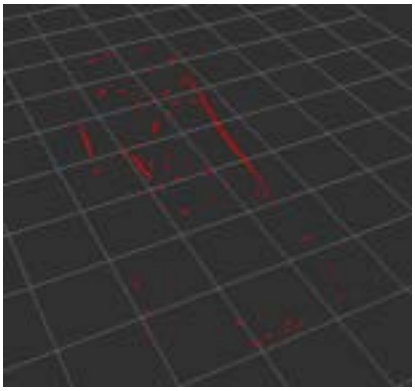

Figure 1. Obstacles Detection

Table 1. Angle and Obstacles

Angle	Distance
-179	2.691
-143	2.124
-107	0.901
-71	0,655
-35	2.679
1	1.872
36	0.963
72	0.643
108	0.703
144	1.344
180	0.729

Extended Kalman filter (EKF) was applied to estimate the pose and of the robot, but the performance was not ideal. For some strong nonlinear systems, this method will bring more truncation errors, which may lead to inaccurate positioning and mapping. Particle filter approaches were introduced because they can effectively avoid the nonlinear problem, but it also leads to the problem of increasing the amount of calculation with the increase of particle number. In 2007, Grisetti proposed a milestone of LiDAR-SLAM method called Gapping based on improved Rao-Blackwellized particle filter (RBPF), it improves the positioning accuracy and reduces the computational complexity by improving the proposed distribution and adaptive re-sampling technique.

As an effective alternative to probabilistic approaches, optimization-based methods are popular in recent years. In 2010, Kurt Konolige proposed such a representative method called Karto-SLAM, which uses sparse pose adjustment to solve the problem of matrix direct solution in nonlinear optimization. Hector SLAM proposed in 2011 uses the Gauss-Newton method to solve the problem of scanning matching, this method does not need odometer information, but high precision LiDAR is required. In 2016, Google put forward a notable method called Cartographer by applying the laser loop closing to both sub-maps and global map, the accumulative error is reduced. Figure 2 shows the map generated using hector slam. This map is saved and then used in navigation to avoid the walls. The dark black boxes shown in figure 2 shows the room boundaries.

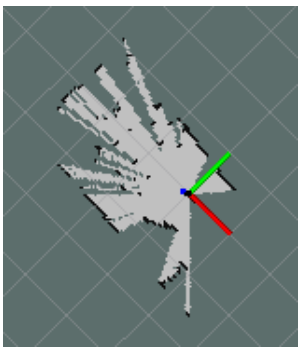

Figure 2. Map generated using Hector SLAM

3.3 Traditional Grid Map

Occupy grid map is wildly used in LiDAR-SLAM, it is a simple kind of 2D map that represents the obstacles on the LiDAR plane:

$$Mgrid = \{mg(x, y)\},$$

where mg(x, y) denotes the possibility if the grid (x, y) is occupied. Generally, the value of mg(x, y) can be 1 (the grid (x, y) is occupied) or 0 (the grid (x, y) is not occupied).

Feature map is another kind map generated by most feature-based Visual-SLAM approaches; it can be represented as:

$$Mfeature = \{f(x,y,z)\},$$

where f(x,y,z) denotes that on the world position (x,y,z), there is a feature f(x,y,z), for real applications, f (x, y, z) could be a descriptor to the feature in a dictionary like BoW.

As a result, a feature map is a sparse map which only has value on the position which has features. This makes a feature map is reliable for localization, but not good for navigation and path-planning.

3.4 360 degree Cameras

In photography, a 360-degree camera is a camera with a visual field of the entire sphere or simply a camera with the ability to capture a 360-degree field of view in the horizontal plane. Such cameras are a highly appreciated in instances when large visual field coverage is desired, such as in robotics or panoramic photography.

Most cameras have a field of view that ranges from a few degrees to almost 180 degrees or sometimes slightly larger than this. It implies that such cameras have the ability to capture the light falling onto their focal points through a sphere. On the contrary, a 360-degree camera covers a full sphere and has the ability to capture light falling from all directions onto the focal point. In actual application, however, most 360 degrees cameras can cover almost a full sphere along the equator, but with the exclusion of the bottom and top of the sphere. Should they cover the full sphere, including the top and the bottom, the rays will not meet at a single focal point.

3.5 Robotic Computer Vision

360-degree cameras are used in robotics to solve simultaneous localization and mapping as well as for visual odometry. With the ability to capture a 360-degree field of view, the 360-degree cameras lead to better optical flow, feature matching and feature selection in robotics.

The 360-degree camera would be used to take pictures of the rooms constructed. That will be used later on to determine the stage the wall is in. It can take the picture of the whole room in one go, and then the program can differentiate different walls in the room.

Figure 3. 3 stages of construction

After taking the picture, the program will use AI to determine the stage the wall is on and then evaluate the progress of the construction. Figure 4 shows the three stages of construction that are Blocks, Plaster and Primer. After determining the stage of all walls in the house, the program can evaluate the progress of house completion.

4 Results & Findings

For each classified scene, a confusion matrix was generated, used to examine commission and omission errors, the accuracy of the producer, and the classification in general. In turn, the K was calculated, which computes the agreement between the classified image and the observed reality due solely to the accuracy of the classification, deleting the agreement that would fit simply wait by chance. How much is K close to 100% how much is the classification accuracy good.

Table 1 below provides a detailed information from the used images in the training and testing with each results classification accuracy.

Table 2. Learning Model Classifications Accuracy

Dataset	Amount	Confusion Matrices	Classifier Behaviour Testing
Training	Class plaster 540	Class one-one 99%	Class with plaster 98%
		Class one-two 1%	Class without plaster 99%
	Class without plaster 540	Class two-two 100%	
Testing	Class plaster108	Class one-one 100%	Class with plaster 100%
		Class one-two 100%	
	Class without plaster 108	Class two-two 0%	Class without plaster 100%

Abstract -

Boom cranes are among the most common material handling systems due to their simple design. Some boom cranes also have an auxiliary jib connected to the boom with a flexible joint to enhance the maneuverability and increase the workspace of the crane. Such boom cranes are commonly called knuckle boom cranes. Due to their underactuated properties, it is fairly challenging to control knuckle boom cranes. To the best of our knowledge, only a few techniques are present in the literature to control this type of cranes using approximate models of the crane. In this paper we present for the first time a complete mathematical model for this crane where it is possible to control the three rotations of the crane (known as luff, slew, and jib movement), and the cable length. One of the main challenges to control this system is how to reduce the oscillations in an effective way. In this paper we propose a nonlinear control based on energy considerations capable of guiding the crane to desired sets points while effectively reducing load oscillations. The corresponding stability and convergence analysis is proved using the LaSalle's invariance principle. Simulation results are provided to demonstrate the effectiveness and feasibility of the proposed method.

Keywords -

Knuckle Cranes; Robotics; Oscillation Reduction; Underactuated Systems; Nonlinear Control

1 Introduction

Cranes are material handling machines which are used in different industries (i.e., construction, manufacturing, shipbuilding and freight handling) for transporting heavy materials that humans cannot handle. Cranes have the capability of moving the load vertically and horizontally, either along a straight or a curved path. Nowadays, most cranes are manually operated by skilled operators. In this paper we focus on the design of an effective automatic control to obtain accurate positioning and reduce the swing of the load.

Cranes come in various sizes and designs to perform different tasks. Depending on their dynamic properties they can be classified as gantry cranes and rotary cranes. Gantry cranes can be further classified into overhead cranes and container cranes. Rotary cranes can be classified into tower cranes and boom cranes [1].

In this paper we will focus on a so called 'knuckle boom' crane which is one of the most common type of boom crane. Boom cranes are characterized by a first boom that can rotate around two orthogonal axes (e.g. slew and luff motions). From the free end of the boom, a payload is suspended using a hoisting rope. The length of the hoisting rope can be driven using a winch. A boom crane can move the payload in the 3D space using the luff and slew movements of the boom and the hoisting of the payload. Such cranes are commonly used in construction sites [2]. Boom cranes can also have more than one boom. Common variant of the boom crane has an auxiliary jib connected to the boom to enhance the maneuverability. Such boom cranes are the knuckle boom cranes (see Fig. 1). In this paper we present for the first time a complete mathematical model for this kind of crane which takes into account not only the three main rotations (e.g. luff, slew, and jib movement), but also the cable dynamic and the payload oscillations.

As all cranes, knuckle cranes are nonlinear systems with complicated underactuated dynamics. Underactuated systems [3] are commonly found in several areas and applications, such as robotics, aerospace systems, marine systems, flexible systems, mobile systems, and locomotive systems. The condition of underactuation refers to a system with more DoF (number of independent variables that define the system configuration) to be controlled, than actuators (input variables). This restriction implies that some of the configuration variables of the system cannot be directly commanded, which highly complicates the design of control algorithms. In particular for the proposed model of knuckle crane the non-actuated variable are the swing angles of the payload, whereas the four actuated variable will be the three main rotation (i.e. luff, slew, and jib movements) and the length of the cable.

Cranes can be controlled using different control laws depending on their operations, which usually involve the process of gripping, lifting, transporting the load, lowering, and releasing the load. A damping capacity of the system plays a significant role towards the precision motion

performance. The control schemes developed for cranes can mainly be categorised into open loop and closed loop techniques [4]. Control schemes based on a combination of open and closed loop techniques have also been proposed. Input shaping is one of the most used open loop techniques, mostly based on a linearized system, that can be applied in real time, mainly for control of the oscillations of the payload. Anti-swing crane controls using input shaping have been widely implemented in the literature [5]-[6]. Concerning closed loop techniques, Proportional Integral Derivative (PID) control laws have been proposed for instance in [4], where the authors proposed a position control of a gantry crane system. A state feedback controller has been implemented in [7] for a boom crane system in order to control the load sway angles in the vertical and horizontal boom motions, as well as in the vertical and horizontal boom angles. In [8] the authors present a constrained control scheme based on the ERG framework for the control of boom cranes. In [9] a model predictive control (MPC) approach was used for a boom crane in order to reduce the swing angles as much as possible.

Compared with the other kinds of cranes like boom cranes, the study of knuckle cranes is still at an early stage with much less reported control strategies. In [10] the authors focus on controlling mobile electro-hydraulic proportional valves to move the crane to a desired position. In [11] the authors solve the problem of controlling knuckle crane through the inverse kinematics without take into account the dynamic of the cable and the payload. In [12] an anti-sway control is shown which is performed by simplifying the dynamic model and assuming that the tip of the crane can be controlled directly.

To the best of our knowledge, no research has been carried out to develop a detailed mathematical model and develop a control strategy taking into account the strongly nonlinear nature of this type of crane. In this paper we advance the state of the art of the knuckle crane by introducing for the first time a complete mathematical model in which we takes into account all of the degrees of freedom (DoF) that characterize this type of system (i.e. the three rotations, the length of the rope and the payload swing angles) and proposing novel control strategy designed directly on the nonlinear model.

The rest of this paper is organized as follows. In Section 2, the dynamic model of the knuckle crane and the control objectives are provided. In Section 3, the proposed controller is designed, and the corresponding stability analysis is provided in detail. Section 4 shows the results of the simulations regarding the proposed control strategy.

Figure 1. Model of a knuckle crane [1].

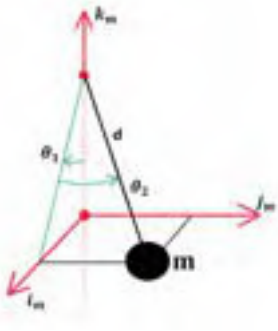

Figure 2. Payload swing angles.

2 Dynamic Model

A schematic view of knuckle crane is shown in Fig.1. The knuckle crane consists of a first boom of length l_b and mass m_b connected to the tower with one revolute joint. The auxiliary jib of length l_j and mass m_j is linked to the first boom by a revolute joint. For the sake of simplicity in this paper, both of these two links are considered to be rigid. The cable is supposed to be massless and rigid, thus the lifting mechanism can be represent as a prismatic joint. The payload of mass m can be represented as lumped mass. The two swing angles of the payload are represented in the Fig.2.

The configuration of the crane can be represented by six generalized coordinates, in which, α is the slew angle of the tower, β is the luff angle of the boom, γ is the luff angle of the jib, d is the length of the rope, θ_1 is the tangential pendulation mainly due to the motion of the tower and θ_2 is the radial sway mainly due to the motion of the boom.

To simplify the ensuing analysis, the following abbreviations are used: $S_\alpha \triangleq \sin(\alpha), S_\beta \triangleq sin(\beta), S_\gamma \triangleq \sin(\gamma), S_{\theta_1} \triangleq \sin(\theta_1), S_{\theta_2} \triangleq \sin(\theta_2), C_\alpha \triangleq \cos(\alpha), C_\beta \triangleq \cos(\beta), C_\gamma \triangleq \cos(\gamma), C_{\theta_1} \triangleq \cos(\theta_1), C_{\theta_2} \triangleq \cos(\theta_2)$.

The dynamic model of the knuckle crane is obtained by using the Lagrange method [13]. Firstly, we need to express the system kinematic energy $T(t)$, which consists of three parts, the boom kinematic energy $T_t(t)$, the jib

kinematic energy $T_j(t)$, and the payload kinematic energy $T_p(t)$. Then, the system potential energy $U(t)$ consists of the boom gravity energy $U_t(t)$, the jib gravity energy $U_j(t)$, and the payload gravity energy $U_p(t)$. Next, the Lagrange function is constructed as

$$\begin{aligned} L(t) &= T(t) - U(t) \\ &= T_b(t) + T_j(t) + T_p(t) - U_b(t) - U_j(t) - U_p(t), \end{aligned} \tag{1}$$

where

$$\begin{aligned} T(t) = \frac{1}{8}(m_B((l_B C_\beta S_\alpha \dot{\alpha} + l_B C_\alpha S_\beta \dot{\beta})^2 + (l_B C_\alpha C_\beta \dot{\alpha} \\ -l_B S_\alpha S_\beta \dot{\beta})^2 + l_B^2 C_\beta^2 \dot{\beta}^2)) + \frac{1}{2}(m_J((l_B C_\beta S_\alpha \dot{\alpha} + l_B C_\alpha S_\beta \dot{\beta} \\ +\frac{1}{2}(l_J C_\gamma S_\alpha \dot{\alpha}) + \frac{1}{2}(l_J C_\alpha S_\gamma \dot{\gamma}))^2 + (l_B C_\alpha C_\beta \dot{\alpha} + \frac{1}{2}(l_J C_\alpha C_\gamma \dot{\alpha}) \\ -l_B S_\alpha S_\beta \dot{\beta} - \frac{1}{2}(l_J S_\alpha S_\gamma \dot{\gamma}))^2 + (l_B C_\beta \dot{\beta} + \frac{1}{2}(l_J C_\gamma \dot{\gamma}))^2)) \\ +\frac{1}{2}(m((C_{\theta_2} S_\alpha S_{\theta_1} \dot{d} - C_\alpha S_{\theta_2} \dot{d} + l_B C_\beta S_\alpha \dot{\alpha} + l_B C_\alpha S_\beta \dot{\beta} \\ +l_J C_\gamma S_\alpha \dot{\alpha} + l_J C_\alpha S_\gamma \dot{\gamma} - C_\alpha C_{\theta_2} \dot{\theta_2} d + S_\alpha S_{\theta_2} \dot{\alpha} d \\ +C_\alpha C_{\theta_2} S_{\theta_1} \dot{\alpha} d + C_{\theta_1} C_{\theta_2} S_\alpha \dot{\theta_1} d - S_\alpha S_{\theta_1} S_{\theta_2} \dot{\theta_2} d)^2 + (l_B C_\beta \dot{\beta} \\ -C_{\theta_1} C_{\theta_2} \dot{d} + l_J C_\gamma \dot{\gamma} + C_{\theta_2} S_{\theta_1} \dot{\theta_1} d + C_{\theta_1} S_{\theta_2} \dot{\theta_2} d)^2 \\ +(S_\alpha S_{\theta_2} \dot{d} + l_B C_\alpha C_\beta \dot{\alpha} + l_J C_\alpha C_\gamma \dot{\alpha} \\ -l_B S_\alpha S_\beta \dot{\beta} - l_J S_\alpha S_\gamma \dot{\gamma} + C_\alpha S_{\theta_2} \dot{\alpha} d + C_{\theta_2} S_\alpha \dot{\theta_2} dv \\ +C_\alpha C_{\theta_2} S_{\theta_1} \dot{d} + C_\alpha C_{\theta_1} C_{\theta_2} \dot{\theta_1} d - C_{\theta_2} S_\alpha S_{\theta_1} \dot{\alpha} d \\ -C_\alpha S_{\theta_1} S_{\theta_2} \dot{\theta_2} d)^2)) + \frac{1}{2} I_{tot} \dot{\alpha}^2 + \frac{1}{2} I_B \dot{\beta}^2 + \frac{1}{2} I_J \dot{\gamma}^2, \end{aligned} \tag{2}$$

$$\begin{aligned} U(t) = gm(l_B S_\beta + l_J S_\gamma - C_{\theta_1} C_{\theta_2} d) + gm_J(l_B S_\beta \\ +\frac{1}{2} l_J S_\gamma) + \frac{1}{2} g l_B m_B S_\beta, \end{aligned} \tag{3}$$

The equations of the motion of the crane are derived using the Lagrange's equation

$$\frac{d}{dt}\left(\frac{\partial L(q,\dot{q})}{\partial \dot{q}}\right) - \frac{\partial L(q,\dot{q})}{\partial q} = \zeta, \tag{4}$$

where $\mathrm{q} = [\alpha, \beta, \gamma, d, \theta_1, \theta_2]^T \in \mathbb{R}^6$ represents the system state vector, and $\zeta = [u_1, u_2, u_3, u_4, 0, 0]^T \in \mathbb{R}^6$ represents the control input vector.

The dynamic model of a knuckle crane (see Fig. 1) can be written as:

$$M(q)\ddot{q} + C(q,\dot{q})\dot{q} + F(\dot{q}) + g(q) = \begin{bmatrix} I_{4x4} \\ 0_{2x2} \end{bmatrix} u. \tag{5}$$

The matrices $\mathrm{M(q)} \in \mathbb{R}^{6x6}$,$C(q,\dot{q}) \in \mathbb{R}^{6x6}$,$F(\dot{q}) \in \mathbb{R}^6$ and $\mathrm{g(q)} \in \mathbb{R}^6$ represent the inertia, centripetal-Coriolis, air dynamic friction [14], and gravity. The system matrices (see Appendix for the detailed description) are defined as follows:

$$M(q) = \begin{bmatrix} m_{11} & m_{12} & m_{13} & m_{14} & m_{15} & m_{16} \\ m_{21} & m_{22} & m_{23} & m_{24} & m_{25} & m_{26} \\ m_{31} & m_{32} & m_{33} & m_{34} & m_{35} & m_{36} \\ m_{41} & m_{42} & m_{43} & m_{44} & 0 & 0 \\ m_{51} & m_{52} & m_{53} & 0 & m_{55} & 0 \\ m_{61} & m_{62} & m_{63} & 0 & 0 & m_{66} \end{bmatrix}, \tag{6}$$

$$C(q,\dot{q}) = \begin{bmatrix} c_{11} & c_{12} & c_{13} & c_{14} & c_{15} & c_{16} \\ c_{21} & c_{22} & c_{23} & c_{24} & c_{25} & c_{26} \\ c_{31} & c_{32} & c_{33} & c_{34} & c_{35} & c_{36} \\ c_{41} & c_{42} & c_{43} & 0 & c_{45} & c_{46} \\ c_{51} & c_{52} & c_{53} & c_{54} & c_{55} & c_{56} \\ c_{61} & c_{62} & c_{63} & c_{64} & c_{65} & c_{66} \end{bmatrix}, \tag{7}$$

$$g(q) = \begin{bmatrix} 0, g_2, g_3, g_4, g_5, g_6 \end{bmatrix}^T. \tag{8}$$

$$F(\dot{q}) = \begin{bmatrix} 0, 0, 0, 0, f_1, f_2 \end{bmatrix}^T, \tag{9}$$

Although the equation of motion (5) is quite complicated, it has several fundamental properties that can be exploited to facilitate the design of the controller. The two main properties that will be exploited in the next section are:

Property 1. The matrix

$$\frac{1}{2}\dot{M}(q) - C(q,\dot{q}),$$

is skew symmetric which means that

$$\zeta^T \left[\frac{1}{2}\dot{M}(q) - C(q,\dot{q})\right]\zeta = 0, \quad \zeta \in \mathbb{R}^6$$

Property 2. The gravity vector (8) can be obtained as the gradient of the crane potential energy (3), i.e., $g(q) = \frac{\partial U(q)}{\partial \dot{q}}$.

2.1 Control objective

The aim of the control is to move the crane to the desired position and to dampen the swing angles of the load as much as possible.

The control objective can be described mathematically as

$$\begin{aligned} \lim_{t\to\infty}[\alpha(t), \beta(t), \gamma(t), d(t), \theta_1(t), \theta_2(t)] = [\alpha_d, \beta_d, \gamma_d, d_d, 0, 0], \\ \lim_{t\to\infty}[\dot{\alpha}(t), \dot{\beta}(t), \dot{\gamma}(t), \dot{d}(t), \dot{\theta_1}(t), \dot{\theta_2}(t)] = [0, 0, 0, 0, 0, 0], \end{aligned} \tag{10}$$

where $\alpha_d, \beta_d, \gamma_d, d_d$ are the desired references for the actuated states.
In our development we will consider the following reasonable assumptions.

Assumption 1 *The payload swings satisfy the following inequality* $|\theta_{1,2}| < \frac{\pi}{2}$.

Assumption 2 *The cable length is always greater than zero to avoid singularity in the model (5):* $d(t) >, \forall t \geq 0$.

3 Control Design and Stability Analysis

The control strategy proposed in this paper consists of a nonlinear control law based on energy consideration. The corresponding stability and convergence analysis is demostrated by using the LaSalle's invariance principle.

In order to develop our control law, we started to considered the energy of system (2)-(3), wich is

$$E(t) = \frac{1}{2}\dot{q}^T M(q)\dot{q} + mgd(1 - C_{\theta_1}C_{\theta_2}), \tag{11}$$

where the first term is the kinetic energy of the crane, whereas the second term represents the payload potential energy. Based on (11), we can define the following Lyapunov function candidate:

$$\begin{aligned} V(t) = &\frac{1}{2}\dot{q}^T M(q)\dot{q} + mgd(1 - C_{\theta_1}C_{\theta_2}) \\ &+\frac{1}{2}k_{p\alpha}e_\alpha^2 + \frac{1}{2}k_{p\beta}e_\beta^2 + \frac{1}{2}k_{p\gamma}e_\gamma^2 + \frac{1}{2}k_{pd}e_d^2, \end{aligned} \tag{12}$$

where $e_\alpha, e_\beta, e_\gamma, e_d$ are the error signals defined as:

$$e_\alpha = \alpha_d - \alpha, \quad e_\beta = \beta_d - \beta, e_\gamma = \gamma_d - \gamma, \quad e_d = d_d - d. \tag{13}$$

Differentiating the equation (12) with respect to the time and using (5) we obtain

$$\begin{aligned} \dot{V}(t) = &\dot{\alpha}(u_1 - k_{p\alpha}e_\alpha) \\ &+\dot{\beta}(u_2 - k_{p\beta}e_\beta - gl_B C_\beta(m + \frac{1}{2}m_B m_J)) \\ &\dot{\gamma}(u_3 - k_{p\gamma}e_\gamma - gl_J C_\gamma(m + \frac{1}{2}m_J)) \\ &+\dot{d}(u_4 - k_{pd}e_d + mgC_{\theta_1}C_{\theta_2} + mg(1 - C_{\theta_1}C_{\theta_2})) \\ &-d_{\theta_1}C_{\theta_2}^2|\theta_1|\,\dot{\theta}_1^2 - d_{\theta_2}|\theta_1|\,\dot{\theta}_2^2. \end{aligned} \tag{14}$$

In order to cancel the gravitational terms and keep $\dot{V}(t)$ non-positive, the following controller is designed:

$$u_1 = k_{p\alpha}e_\alpha - k_{d\alpha}\dot{\alpha}, \tag{15}$$

$$u_2 = k_{p\beta}e_\beta - k_{d\beta}\dot{\beta} + gl_B C_\beta(m + \frac{1}{2}m_B m_J), \tag{16}$$

$$u_3 = k_{p\gamma}e_\gamma - k_{d\gamma}\dot{\gamma} + gl_J C_\gamma(m + \frac{1}{2}m_J), \tag{17}$$

$$u_4 = k_{pd}e_d - k_{dd}\dot{d} + mg, \tag{18}$$

where $k_{p\alpha}$, $k_{p\beta}$, $k_{p\gamma}$, k_{pd}, $k_{d\alpha}$, $k_{d\beta}$, $k_{d\gamma}$, $k_{dd} \in \mathbb{R}$ are positive control gains.
Substituting (15)-(18) into (14), one obtains

$$\begin{aligned} \dot{V}(t) = &-k_{d\alpha}\dot{\alpha}^2 - k_{d\beta}\dot{\beta}^2 - k_{d\gamma}\dot{\gamma}^2 \\ &-k_{dd}\dot{d}^2 - d_{\theta_1}C_{\theta_2}^2\dot{\theta}_1^2 - d_{\theta_2}\dot{\theta}_2^2 \leq 0, \end{aligned} \tag{19}$$

The following theorem describes the stability property of the crane using the proposed control law (15)-(18).

Theorem 1 *Consider the system (5)-(9). Under Assumptions 1-2, the controller (15)-(18) makes every equilibrium point (10) satisfying Assumptions 1-2, asymptotically stable.*

Proof: As already seen, the derivative of the Lyapunov function candidate (12) is (19) which is negative semidefinite.

At this point let Φ be defined as the set where $\dot{V}(t) = 0$, i.e.

$$\Phi = \{q, \dot{q} | \dot{V}(t) = 0\}. \tag{20}$$

Further, let Γ represent the largest invariant set in Φ where the Assumptions 1-2 are verified. Based on (19), it can be seen that Γ is the set such that:

$$\begin{aligned} &\dot{\alpha} = 0, \dot{\beta} = 0, \Rightarrow \ddot{\alpha} = 0, \ddot{\beta} = 0, \\ &\dot{\gamma} = 0, \dot{d} = 0, \Rightarrow \ddot{\gamma} = 0, \ddot{d} = 0, \\ &\dot{\theta_1} = 0, \dot{\theta_2} = 0, \Rightarrow \ddot{\theta_1} = 0, \ddot{\theta_2} = 0, \\ &\dot{e}_\alpha = 0, \dot{e}_\beta = 0, \Rightarrow e_\alpha = \phi_1, e_\beta = \phi_2, \\ &\dot{e}_\gamma = 0, \dot{e}_d = 0, \Rightarrow e_\gamma = \phi_3, e_d = \phi_4, \end{aligned} \tag{21}$$

where $\phi_{1,2,3,4}$ are constants to be determined.
Combining (21) with (15)-(18) and (5), we obtain the conditions:

$$\begin{aligned} k_{p\alpha}e_\alpha &= 0, \\ k_{p\beta}e_\beta &= 0, \\ k_{p\gamma}e_\gamma &= 0, \\ -gmcos\theta_1 cos\theta_2 &= -mg + k_{pd}e_d, \\ gmdcos\theta_2 sin\theta_1 &= 0, \\ gmdcos\theta_1 sin\theta_2 &= 0. \end{aligned} \tag{22}$$

From the first three equations of (22),we will have that

$$k_{p\alpha}e_\alpha = 0 \Rightarrow e_\alpha = 0 \Rightarrow \phi_1 = 0 \Rightarrow \alpha = \alpha_d, \tag{23}$$

$$k_{p\beta}e_\beta = 0 \Rightarrow e_\beta = 0 \Rightarrow \phi_2 = 0 \Rightarrow \beta = \beta_d, \tag{24}$$

$$k_{p\gamma}e_\gamma = 0 \Rightarrow e_\gamma = 0 \Rightarrow \phi_3 = 0 \Rightarrow \gamma = \gamma_d. \tag{25}$$

From the last two equations of (22), due to Assumption 2, one can be obtained that:

$$\begin{aligned} cos\theta_2 sin\theta_1 = 0, \\ cos\theta_1 sin\theta_2 = 0, \end{aligned} \tag{26}$$

The following conclusion can be achieved:

$$\theta_1 = \theta_2 = (k\pi) \vee \frac{(2k+1)}{2}\pi, \quad k \in \mathbb{Z}. \tag{27}$$

However, due to Assumption 1, the only acceptable solution will be:

$$\theta_1 = \theta_2 = 0. \tag{28}$$

By inserting the (28) in the forth equation of (22), one can conclude that:

$$k_{pd} e_d = 0 \Rightarrow e_d = 0 \Rightarrow \phi_4 = 0 \Rightarrow d = d_d, \tag{29}$$

□

Remark 1 *Other types of cranes such as overhead cranes, boom cranes, tower cranes etc, have similar dynamic characteristics to a knuckle cranes. Accordingly, the controller proposed in this paper may be adapted to all these underactuated system.*

4 Simulation Results

In order to demonstrate the effectiveness of the proposed strategy, in this section we simulate the knuckle crane in Fig. 1. The practical performances of the proposed control approach are compared with a linear quadratic regulator (LQR) obtained by linearization.The physical parameters are selected as follows: $m_b = 2kg$, $m_j = 3kg$, $m = 1k$, $l_b = 5m$, $l_j = 4m$.
The parameters for the control law (15)-(18) are the following:$k_{p\alpha} = 30, k_{p\beta} = 10, k_{p\gamma} = 10, k_{pd} = 1, k_{d\alpha} = 50, k_{d\beta} = 30, k_{d\gamma} = 50, k_{dd} = 10$.
For the LQR control approach, first, the crane dynamics is linearized around the equilibrium point, and then, the following weight matrices have been chosen to stabilize the plant: $Q = diag\{25, 400, 450, 200, 1, 1, 1, 1, 1, 1, 120, 120\}$ and $R = diag\{0.1, 0.1, 0.1, 1\}$.

As one can see in Figg. 3-4-5 both controllers successfully move the crane towards the desired angular positions. Although the LQR controller moves the first three degrees of the cranes (tower, boom, and jib angles) slightly faster than the method presented in this paper, one can notice that our method produces much less oscillations of the load (see Figg.7-8) and of the cable (see Fig. 6) , resulting in an overall faster and safer stabilization of the load. It is worth noting that in both methods, the input profiles and maximum values are almost similar. This values are well within the typical limits of the crane actuators.

5 Conclusion

This paper proposed a nonlinear control scheme for the control of knuckle crane. The main contribution of this article is that for the first time a detailed mathematical model is shown where the complexity of this type of sys-

tem emerges. Furthermore, the proposed control is based directly on the nonlinear system avoiding linearization. Despite the complexity of the model, the proposed control scheme is able to guide the crane towards a desired reference and ensuring that the non-actuated variables (i.e., θ_1 and θ_2) go to zero in a fast way.

Appendix

The nonzero entries of the system matrices $M(q)$, $C(q,\dot{q})$, $F(\dot{q})$ and $g(q)$ are define as follows:

$$m_{11} = I_{tot} + d^2m + A_1C_\beta^2 + A_2C_\gamma^2 + A_3C_\beta C_\gamma$$
$$+2A_4dC_\beta S_{\theta_2} + 2A_5dC_\gamma S_{\theta_2} - d^2mC_{\theta_1}^2C_{\theta_2}^2$$
$$m_{22} = A_1 + I_B \quad m_{33} = A_2 + I_J \quad m_{44} = m$$

Abstract -

Fast and accurate inspection of elevated structures is imperative for sustaining the increasing traffic flow o n deteriorating bridges. Despsite their importance, today's inspection processes still require dedicated equipment, impact traffic flow, a nd e xpose i nspection p ersonnel t o s afety concerns. The advent of Unmanned Aerial Vehicles (UAVs) and the ability to position a camera close to elevated highway structures presents an opportunity to perform inspections quickly, safely and effectively. Towards this goal, we present an end-to-end system for robotic bridge inspection. Our system is structured around integrated methods to (a) create UAV flight m issions; (b) e valuate a ccuracy a nd completeness of data collection plans; (c) generate 3D models of the structures of interest; (d) detect surface distresses in 3D; and (e) generate inspection reports in compliance with the requirements of highway agencies. We present results on validating each algorithm and the system as a whole. We also share lessons learned from an owner's perspective on deploying this system for bridge inspection in Japan particularly around procedures for documenting, communicating, and following up on bridge inspectors' recommendations.

Bridge Inspection; Deep Learning; Structure from Motion; Aerial Robots; Computer Vision

1 Introduction

The discovery of fractures in steel members of Kisogawa Ohashi Bridge and Honjo Ohashi Bridge in 2007, yet again raised alarms about the deterioration and fragile state of the infrastructure in Japan. By March 2019, deficient or functionally obsolete bridges constitute 9.6% of all the 700,000 road bridges in Japan [1]. Japan's geography creates additional risks associated with natural disasters. Thus, evaluating as-is conditions of Japan's bridges and infrastructure assets is more important than many other places around the world.

Today's bridge inspection practices are expensive and can be disruptive to ongoing traffic. Onsite documentations are also time-consuming and assessments can be inconsistent. This means additional data collection may be necessary in many cases, while resource allocation is always challenging. The advent of agile aerial platforms with the ability to carry digital cameras, along with a greater awareness of the technology has created an cost-effective alternative to conduct bridge inspection in a quick, safe and effective manner. Application of aerial platforms resolves issues of access and traffic disruptions. Also, cloud-based analysis lowers the need for onsite engineer visits, reducing cost associated with inspection. As such, the Ministry of Land, Infrastructure, Transport and Tourism (MLIT) in Japan launched an initiative in 2015 with the aim of leveraging advanced robots and artificial intelligence technologies to improve productivity in construction and infrastructure inspection tasks.

Because of the MLIT initiative as well as similar ones in the United States, a large body of work has emerged from the industry and academia which focuses on computer vision and visualization methods to process, analyze and share inspected drone data. Much of these efforts has focused on improving one step in the process, rarely offering an insight or recommendation on how various techniques can be applied in an integrated manner to streamline the data collection, analytics, and reporting in an end-to-end fashion. While there are promising computer vision methods such as 3D reconstruction, image classification, object detection and semantic segmentation that can been applied to bridge inspection processes, yet their adaptability as part of an end-to-end system has not been investigated.

To address the existing gaps in knowledge, we present an integrated end-to-end system for robotic bridge inspection consisting of five integrated methods: (a) creation of flight missions for data collection; (b) evaluation of flight missions based on requirements of inspection and visual quality of collected data; (c) 3D reconstruction of elevated structures; (d) automated detection and localization of surface distresses in 3D; and (e) report generation in compliance with owner requirements. We validate each underlying algorithm and the end-to-end system as a whole. We also share best practices on documentation, communication and following up on bridge inspection recommendations based on deploying our system on 30 bridge inspection projects in Japan and the United States.

2 Related Work

A large body of work in the literature has focused on robotic infrastructure inspection. In this section, we discuss the most recent methods and their gaps in knowledge:

2.1 Model-driven Data Capture using UAVs

Visual data collection with the UAVs has many applications including surveying, inspections, safety and progress monitoring. Based on whether models are used as *a priori*, these methods can be categorized into two classes: (1) Conventional methods that focus on ensuring minimum overlap between collected images to generate complete 3D point clouds; and (b) model-driven methods which use 3D CAD or BIM as *a priori* to simulate and evaluate the 3D visual coverage of structures and in turn reduce safety risks associated with the UAVs. Flight plans with waypoints sampled at a safe offset distance from the structure [2] and the utilization of 4D BIM for path planning in construction monitoring use-cases [3] are examples of these model-driven approaches. Our method builds on these model-driven path planning methods, but it also enables verifying and planning for requirements such as preserving line-of-sight to UAVs, or orthogonality of camera viewpoints against the structure during data capture.

2.2 Image-based 3D reconstruction

Structure from Motion (SfM) and Simultaneous Localization and Mapping (SLAM) algorithms have been widely used as 3D reconstruction techniques to generate high fidelity 3D point cloud and mesh models using images or videos collected with aerial robots. These techniques allow for better organization of collected data by identifying locations and viewpoints of images relative to 3D models. While these techniques have matured over the past decade, nevertheless they can still result in *incomplete* and *inaccurate* models. To address these issues, recent efforts such as [4] propose simulators or empirical metrics to examine quality of data collection and their impact on 3D reconstruction. Nonetheless, these studies have been validated in contexts which are not relevant to data collected from varying heights and viewpoints relative to elevated structures. Tools that can generate elevation or under-deck orthoviews are also required for inspection reports, however current 3D reconstruction pipelines do not produce such deliverables.

2.3 Metrics for visual quality assurance

The percent overlap between collected images, the resolution of bridge elements in each image, and the quality of 3D reconstruction are three key parameters that influence the accuracy of automated condition assessment system. Model-driven flight paths have been deployed to improve the quality of collected visual data [2] but these methods lack quality assurance capabilities. [5, 6] show parameters such as proximity of camera to the bridge elements and orientations of the collected images, which can impact accuracy of defect detection and appearance-based classification of structural components. To evaluate accuracy of 3D reconstruction in simulation environments, metrics such as (a) visibility per element and (b) redundancy in visibility have been introduced by [7]. Metrics such as Ground Sampling Distance (GSD) have also been employed to guarantee resolution of 3D reconstruction before image capture is conducted [8]. In this study, we build upon previously studied visual quality assurance metrics and investigate new metrics focusing on defect detection such as perpendicularity of image viewpoints while achieving a specific GSD per inspection target.

2.4 Defect Recognition, Severity Assessment and Mapping

Computer vision methods can be used on site images to detect and classify surface defects such as crack, spalling, exposed rebar, efflorescence and corrosion. Particularly, deep learning-based approaches have shown promising results in the recent years. Deep Convolutional Neural Network (CNN) architectures such as VGG, AlexNet, ResNet and MetaQNN for single and multi-class defect classification [8] have resulted in exceptional results (e.g., VGG architecture achieved 70.61% for multi-class defect classification) but these method do not predict defect regions and at best, they only focus on a Single-class defect detection. [9, 10, 11, 12] in among the few works that has investigated feasibility of an end-to-end framework for bridge inspection, however no previous work has considered multi-class defect detection and localization within a 3D context. Localizing defect in 2D and 3D is essential for assessing seriousness of defects and to prioritize maintenance operations.

2.5 Virtual inspection and report generation

There is plenty of work in the literature on generating 3D point clouds of bridges and detection of multiple type of defects; nevertheless there are still many components missing to enable an end-to-end robotic inspection; i.e., (a) Comparative views of point clouds and images over time, (b) interactive orthoviews generated automatically, and (c) ability to view images overlaid on 3D point clouds through an interactive interface, similar to ones implemented for project controls [13], are much needed. 3D measurements and annotations could also be enabled through a visual interface for defect severity assessment purposes. These tools and systems can automate and significantly improve how owner-compliance reports are generated. The work in

[9, 14] demonstrate methods to generate reports utilizing BIM of bridges. However, creating BIM from point clouds is not a trivial task and is often cost-prohibitive for large number of bridges in need for inspection.

In the following, we present an end-to-end solution that addresses these gaps in knowledge. Our solution has been deployed by the MLIT in Japan and other bridge owners and operators in the United States.

3 Method

We propose a new end-to-end system for robotic inspection (see Figure 1). Each step in our system's is discussed in the following sections:

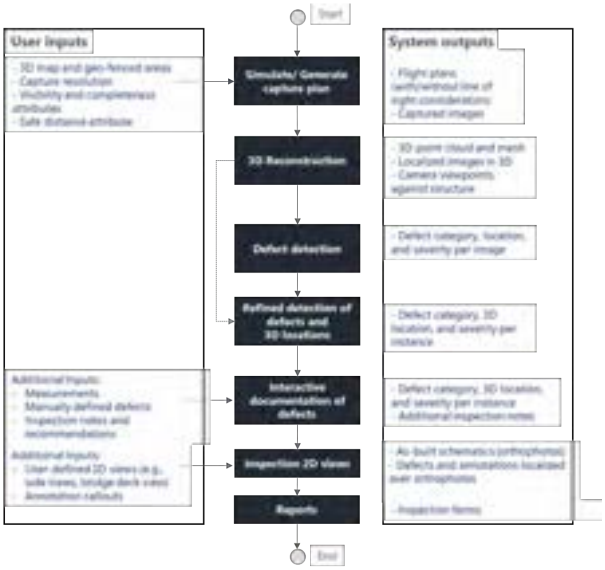

Figure 1. A new end-to-end system of bridge inspection, with relevant user inputs and expected outputs.

3.1 Model-driven Visual Data Inspection

Automatic visual data collection is the first step in our end-to-end bridge inspection system. To achieve this, we developed a web-based virtual environment with client-server architecture for fast and easy access to aerial data collection missions and automatic 3D flight plans generation. The user sets the inspection region with a 2D satellite map and specified the data collection parameters to generate the 3D flight p lan. The p arameters c onsidered the requirements of the data collection, such as altitudes of bridge deck underside and topside, waypoints offset distance from the structure, drone and camera settings, the field of view to keep line-of-sight during flight execution and the required overlap between image frames. The generated flight p lan i s s liced i nto m issions t o a ccount for line-of-sight requirements and the drone's battery life.

The 3D virtual environment is used to render the flight mission alongside BIM/reality models of the bridge for evaluation and communication. This allows adjustments to the flight mission parameters for improving visual coverage and safety. Execution is supported via an iOS mobile application adapted from a previous study [3].

3.2 Quality Evaluation and Feedback on Data Collection Plan

We developed four metrics to define the visual quality of bridge inspection data with regards to the requirements of bridge inspection data: (1) visual coverage completeness of inspection region; (2) redundancy of observations of bridge elements across images needed for accurate 3D reconstruction; (3) target pixel resolution or GSD needed for precise defect detection; and (4) canonical orientation of camera against bridge elements for minimal distortion and required pixel resolution. Redundancy in observations is used for cross-referencing detection across images, which improves detection reliability.

A priori 3D model needs to be generated to perform the flight mission simulation. Without previous capture, we perform a 3D reconstruction from synthetic images extracted from 3D terrain map platforms to create *a priori* model. Using this model, the simulation can estimate: (1) the visibility of each element in each data frame; (2) redundant visibility of elements across all data frames; (3) the average pixel resolution of each element in every frame; and (4) the relative orientation of each element to each frame. The elements are rendered in the virtual environment by a simulated camera with the parameters of the actual camera used for data collection. In the evaluation of visibility and redundant visibility of elements, an element ID color-coding scheme is implemented, and an element's visibility is determined by whether the number of back-projected pixels of the corresponding color exceeds a user-defined threshold in a frame.

A similar approach is applied to estimate pixel resolution of an element in each frame with color-coding based on the depth of the element. The relative orientation of each element to each data frame is estimated in the final simulation. We utilize the surface normal shader to render elements' surface normals as RGB colors. The results of the simulation are provided to the user visually for flight plan adjustment.

3.3 Image-based 3D modeling

We developed different 3D reconstruction methods to address the issues that appear more frequently for bridges. These issues include incompleteness, misregistration, and curvature (drift). The 3D reconstruction pipeline follows an extension of previous studies [15], which include Structure from Motion (SfM) algorithm, patch-based multi-

view reconstruction and mesh modeling steps. However, point cloud misregistration often occurs in bridges due to the repetitive bridge structures in typical SfM process. To resolve the ambiguity in the feature matching process, we introduced a feature clustering mechanism that utilizes GPS coordinates extracted from image metadata to reduce the misregistration. To mitigate point clouds curvature caused by the radial distortion ambiguity, we implemented the camera model [16] that estimates the intrinsic matrix including the distortion coefficient. In the final mesh modeling process, a *digital depth model* is generated to allow users to create orthographic views from any user-defined view necessary for inspection (e.g., under the deck view or side view). The *digital depth model* is presented in the form of a raster image with pixels representing depth value arranged in rows and columns. The images are stitched together along the seam lines with the correction of radial and depth distortion utilizing the digital depth model.

3.4 Damage Detection, Localization and Mapping

We use the Faster-RCNN architecture [17] and present a new algorithm to detect, localize, and determine the 3D spatial mapping of each type of damage. The detection output is a predicted label with its bounding box and score. In our new method, these outputs are projected into the 3D point clouds and back-projected to all related images to analyze intersected area and then fed into the 3D spatial mapping algorithm to determine final labels for each fragment in the 3D point cloud (Fig. 2).

Faster-RCNN includes a Region Proposal Network (RPN) and an object detection network Fast-RCNN, which shares a backbone CNN to form a unified network. The backbone CNN architecture is initialized with a pretrained network (e.g., VGG, Alexnet, ResNet) and fed with input images to extract feature maps. The RPN utilizes the feature maps to generate region proposals by sliding a network with fully-connected $n \times n$ spatial windows, which are output as a lower-dimensional (512 for VGG, 1024 for Resnet) vector and fed into box-regression and box-classification layers. Translation and scale-invariant outputs are achieved using k anchor boxes set as a grid, and k regions are predicted simultaneously. Anchors are associated with three scales and three aspect rations and are generated at the center of the sliding window. Loss function for training of RPN is computed using eq. 1 with a binary class label assigned to each anchor box, where positive labels have Intersection over Union (IoU) over 70% with ground truth. The Feature Pyramid Network (FPN) utilizes deep CNN pyramidal feature hierarchy to build a semantically rich feature pyramid from low to high levels to both learn local and spatial features.

$$L\{d_i\},\{t_i\} = \frac{1}{N_{cls}} L_{cls} d_i, d_i^* + \lambda \frac{1}{N_{reg}} d_i^* L_{reg} t_i, t_i^* \quad (1)$$

where, i is the index of the anchors, d_i the corresponding predicted probability and the ground truth label d_i^* the binary classification of the anchor. t_i is the coordinate of the bounding boxes where t_i^* denotes the ground truth box associated with the positive anchor. L_{cls} is the classification loss and L_{reg} is the regression loss, while these two terms are normalized to N_{cls} and N_{reg} by batch size and total anchor locations.

3.5 3D Spatial Mapping

The 3D spatial mapping developed in this study helps eliminate the annotation and prediction inconsistencies. We utilize computer graphics techniques and camera projection matrices estimated in 3D reconstruction to localize the same damages. All defect bounding boxes from each data frame are projected to 3D space and back-projected to any images that contain the corresponding region. Ideally, all such back-projected boxes should perfectly align with the same defect, but due to errors in projection and defect detection, that is not the case. To address such errors and increase detection precision, we present an algorithm to identify the most probable back-projected boxes for each defect.

Three user-defined parameter thresholds are used for this purpose. An IoU threshold is used to identify bounding box clusters within a user-defined 3D spatial distance to limit reprojection error. Clustered bounding boxes over a threshold count are then processed by performing a greedy Non-maximum suppression (NMS) to choose the most probable box. This approach is first applied to the ground-truth bounding boxes obtained from annotations and then to the predicted detection bounding boxes. Ground-truth bounding box clusters with lower box count than the threshold are kept, and detection box clusters with lower box count than the threshold and lower IoU than the threshold are removed. Similar approach is also applied to the detection process.

3.6 Interactive Web-based Viewers for Inspection

The interactive web-based viewer is extended from [13] with added components specifically developed for the purpose of bridge inspection. In our system, the octree structure stores a point cloud in different hierarchical levels of detail for efficient rendering. The system automatically loads the points inside the user's field of view via a lazy scheme to reduce the loading speed.

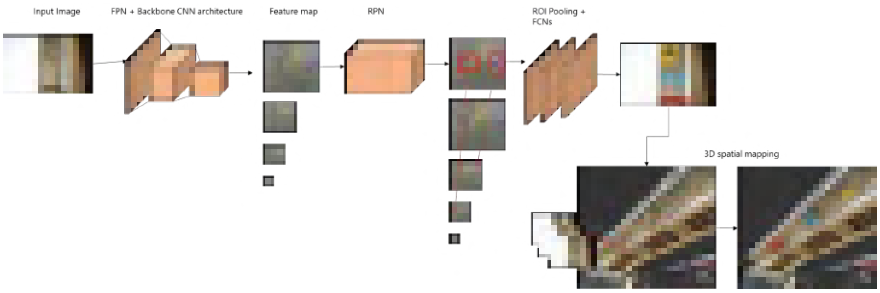

Figure 2. The network architecture. Feature maps extracted from backbone Resnet50, FPN are input to RPN. Bounding boxes with labels and scores as output from classifier mapped in 3D environment is re-injected to finalize prediction.

In addition to visual data collection planning and capture quality evaluation, the virtual walkthrough provides the necessary measurement capabilities for inspection. The image-based measurement tools utilize raycasting to find the closest point and backproject the point using the camera intrinsic, extrinsic to the image. We improved the raycasting accuracy by implementing a cylindrical ray with a radius r to get accurate results when the point cloud is sparser with varying depth. The web-based viewer also provides a non-linear transformation from 3D point clouds to 2D orthophoto using feature matches, estimated depth, and gravity direction from 3D reconstruction. A 4D (3D+time) point cloud timeline is formed chronologically by the capture date with the images, point clouds. Side-by-side or overlaid image comparison interface over time is also enabled by finding the closest image and transform it into the same coordinates using McMillan & Bishop warping method.

Per-pixel distance values are used to warp pixels to their correct location for the current camera position. Side-by-side or overlay views enable observation of defect progression over time and severity assessment for the inspectors.

3.7 Report Generation

Bridge inspection results are summarized in necessary reporting forms that (a) present schematic views of various bridge components and relative location and severity of defects; and (b) defect images as well as their associated inspection info. Our process leverages defect information and associated attributes already mapped in the 3D point cloud to speed up the generation of such reports. An image with a pin is automatically attached to the reports with associated information. These are exported as excel sheets with hyperlinks to the 3D location in the viewer. The related information includes properties such as severity, notes, inspector's name, and GPS location. Inspectors can easily access all the information that needs to be used to assess the defect from these excel sheets that follow owner reporting guidelines (fig. 3).

Our surface mapping tool creates 2D orthophoto from different viewpoints, facilitates the schematic drawing creation with more information than the traditional. The 2D orthophoto with the analysis of the inspected structure provides the overall status of the bridge in a short glance.

Figure 3. Examples of inspection forms (left) that require bridge elevation view to illustrate defect location and (right) detailed description of each defect with additional notes

4 Technical Validation

We validated the developed end-to-end system through 30 bridge inspection projects in Japan and the United States. In this section we present a couple of these projects for the purpose of demonstrating our results, mainly we show the qualitative and quantitative findings of deploying the new system to two Japanese bridge inspection projects. For each of the later projects, we focused on automatic defects detection for one of the bridge's spans covering the underside and lateral sides of the inspection region. Accordingly, detailed results for each stage of the inspection workflow are presented as follows.

4.1 Data Collection

The first step of bridge inspection system is using the developed web-interface to select the inspection region for each of the bridges, such region is selected by navigating a 2D map to the project location and using satellite images to define the boundary of the region. Next we set the data collection parameters as discussed in the method section, for instance, we provide an example of the parameters set for one of the bridges in Table 1.

Table 1. Flight plan parameters

Parameter	Value
Top offset	6 m
Bottom offset	3 m
Sides offset	4 m
Images overlap	80%
Drone battery life	20 mins
Drone speed	25 kph
Line-of-sight FOV	90°
Aerial platform	DJI Phantom4

The developed flight planning interface automatically generates a 3D flight plan with missions covering the top, lateral and under sides of the bride structure. The total flight distance and flight-time for the plan are 2,200 meters and 79 minutes respectively. We provide a visual representation for the later flight plan in Figure 4 which shows the 3D missions along with as-is point cloud model of the bridge.

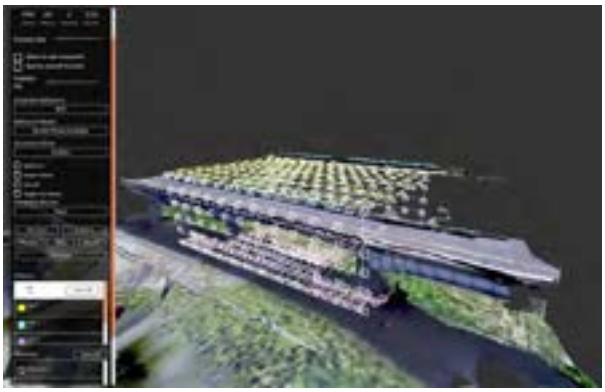

Figure 4. Generated 3D flight plan with top, bottom and one of the side missions visualized in unique colors.

4.2 Visual Quality Evaluation

Feedback for the visual quality of the data collection plan is presented in Figure 5 which provides an example of the visual feedback for visibility, resolution and orientation evaluations. For such task, the bridge mesh was divided into fine fragments that are color-coded to show the visual quality value for each fragment.

The visual evaluation criteria are set according to the requirements for bridge inspection, the later criteria and results of the evaluation feedback are shown in Table 2. 13 fragments found to be outside the acceptable criteria which happen to be on the ground and outside the inspection scope. In future iterations of the tool, we plan to remove these elements from the resolution evaluation process, thus, revisions and further modifications to the flight plan were not needed.

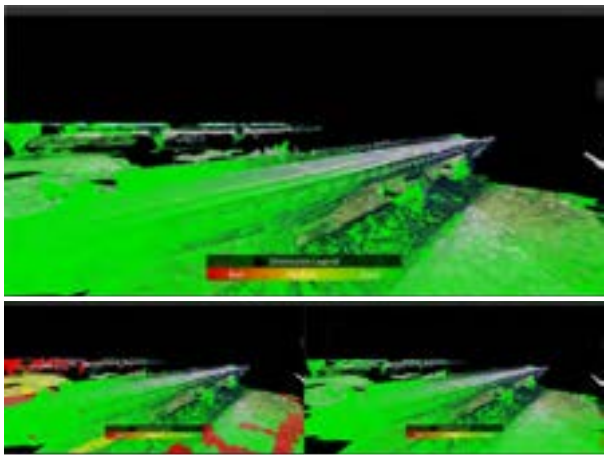

Figure 5. Color-coded visual feedback for data collection plan. (top) visibility evaluation, (bottom-left) resolution evaluation, and (bottom-right) orientation evaluation. The red region, being outside scope of evaluation, is ignored.

Table 2. Flight plan evaluation results

Metric	Criteria	# of elements	% of elements
Visibility	Not met ($<$ 3 observations)	13	16.88%
	Acceptable ($3-8$ observations)	3	3.90%
	Satisfactory ($\geq$ 8 observations)	61	79.22%
Resolution	Not met ($>$ 0.01 m/pix)	11	14.29%
	Acceptable ($0.005-0.01$ m/pix)	0	0.00%
	Satisfactory (≤ 0.005 m/pix)	66	85.71%
Orientation	Not met ($>45°$)	1	1.30%
	Acceptable ($15-45°$)	2	2.60%
	Satisfactory ($\leq 15°$)	74	96.10%

4.3 Damage Localization, Detection and Mapping

4.3.1 Dataset preparation and annotations

The image dataset was created from inspection images captured for the two bridges, the defects in these images were labelled into five common defect classes, namely: crack, spalling, efflorescence, corrosion stains and exposed rebar. For the annotation process, we extended Computer Vision Annotation Tool (CVAT) by integrating the collected dataset and specifying new labels. The inspection images were annotated by experts and validated by two reviewers per each annotation job following the quality assurance/control process in [18]. A total of 30 engineering experts served as annotators and reviewers in this study. Attributes of the resulted dataset are detailed in Table 3. For defect detection, the dataset was split into training and testing datasets with the 80/20 convention. A total of 653 images with 14,302 defect instances were used for training and 89 images with 4804 object instances for testing.

Table 3. Results from the annotation process and detection

Defect Class	Number of annotations	AP (%)	w/Mapping AP (%)
Spalling	5,013	84.6	85.3
Exposed rebar	1,545	84.5	85.2
Corrosion stains	3,310	74.1	74.9
Efflorescence	1,944	57.6	61.1
Crack	5,779	49.2	53.2

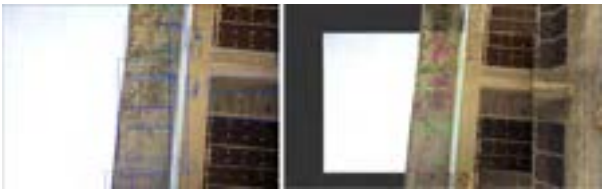

Figure 6. (Left): Results of the localization bounding-boxes for defects in green with projected boxes from other frames -generated through 3D mapping process- colored in blue; (Right) the final localized bounding boxes -after 3D mapping process- overlaid on registered image in 3D point cloud context.

4.3.2 Experimental Results and Discussions

FasterRCNN architecture was implemented using pytorch framework and was fine-tuned with MS-COCO object detection model to expedite initial training with six object classes including defects mentioned earlier and the background. The model was trained from scratch for each layer with the Stochastic Gradient Descent (SGD) optimizer. The learning rate was set using cosine annealing schedule cycling between 1e-5 to 1e-2 in every 10 epochs to avoid local minimum and overfitting. Results of the detection are shown in Fig. 6.

Average Precision (AP) is then calculated by dividing count of true positive detections over all positive detections and is used to evaluate the detection results. The average precision values from the detection are summarized in Table 3. NMS removes some detection boxes not meeting threshold earlier defined leading to reduced total detections. NMS parameters were fine-tuned to balance trade-off for best result.

3D spatial mapping was found to increase the AP for crack and efflorescence by more than 4% with improvements in all defect types (Table.3). Detection results are also continuously improved through user inputs provided through the interactive web viewer such as verification of correct defects and adding missing detections for documentation and reporting by expanding dataset and detection model retraining.

4.4 Web-based Viewer and Inspection Reports

We adopted Charette test method [19] to evaluate the user's feedback about the web-viewer and report generation process. The validation works by evaluating *effectiveness*, *repeatability*, and *reliability* of our method, which measure productivity improvement, performance of system under different inspection conditions and users. These were measured qualitatively through interviews and observations from MLIT practitioners interacting with the system. We have provided training and guidelines for bridge inspectors, transportation professionals and civil engineers to perform virtual inspection tasks. Users expressed through the training that time required for defect localization and creating reports using corresponding images was significantly reduced. Users also expressed that the output generated can be easily transformed to actionable format which is vital for effective bridge maintenance.

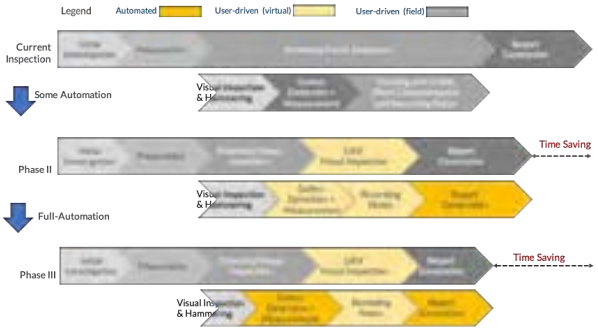

Figure 7. The MLIT in Japan has outlined a three-phase path towards a fully automated bridge inspection process, where more automation is introduced one step at a time. Currently, Phase II is in full testing mode with the solution presented in this paper.

5 Discussion - Gradual Transition to a Fully Automated System

The components of the presented system were deployed on bridge inspection projects in Japan and the United States. Based on discussion and interviews with bridge inspectors, Japan MLIT has decided to engage in a gradual transition from their current workflow to full automation, due to the many components, bridge owners, and engineering personnel involved. Fig. 7 shows MLIT's plan and perceived benefit from this transition.

In the current workflow, inspectors spend significant time measuring, capturing and organizing damages and related information. Phase II will involve automating data collection and report generation processes consisting of the robotic solutions that collect and process the data in the web-based system. The system will also actively improve the automatic defect detection through (a) user input of correcting and adding missing detections, and (b) retraining of detection model on a timely basis over more massive ground truth datasets. Phase III will introduce automated pre-analysis of bridge condition, 3D reconstruction, defect

detection, and report generation. Analyzed data will be used for verification of condition and to perform physical examinations on the field. Full adaptation of automation by Phase III is expected to cause substantial time savings (30% based on Charettes) and cost-savings in the inspection process. A reliable defect detection component is an essential step towards Phase III.

We have shown in this study that the data collection process improves the visual quality of collected data to meet MLIT inspection and report generation requirements. Future work will focus on improvements of the flight plan optimization by eliminating user manual inputs, the evaluation process by removing simulated fragments that are not in the inspection scope, the detection model by phased rollouts of improved models, and expansion of ground-truth dataset with a generalized distribution of defect shapes, colors and incorporating 3D geometry information in the detection process.

6 Conclusion

We presented an end-to-end system to automate robotic bridge inspection process with integration of flight mission generation, assessment of visual quality of collected data, ensuring accuracy and completeness of reconstructed reality model, 3D reconstruction for elevated structures, automated detection and localization of damages and report generation. Our proposed system shows the connections between components and how robotic bridge inspection solutions can be streamlined systematically and gradually. We introduced the phase-based implementation of detection models that enables continuous improvement and active learning over time through dataset expansion and user input. Our holistic approach through the proposed end-to-end system connects the dots between the components of robotic bridge inspection for the MLIT in Japan. We plan to implement this system across 100s of bridges in the coming year.
