Foreword

The International Association for Automation and Robotics in Construction (IAARC) and the Local Organizing Committee are pleased to present the Proceedings of the 42nd International Symposium on Automation and Robotics in Construction (ISARC 2025). This year's symposium draws inspiration from the vibrant spirit and cultural diversity of its host city—Montreal, an international hub of innovation and creativity. ISARC 2025 was held from July 28–31, 2025, proudly hosted by Concordia University.

The 42nd edition of ISARC demonstrated continued growth, with remarkable participation: a total of 272 papers were submitted, marking a 24% increase from the previous year. After a rigorous multi-step peer-review process, including a rebuttal phase, 211 papers (78% acceptance rate) were ultimately selected and included in the proceedings. In total, 1038 authors and co-authors representing 123 universities, research labs, departments, and companies from 27 countries/regions across Asia, Eurasia, the Middle East, North America, Oceania, South America, and Western Europe submitted their work.

The review process was strongly supported by an expanded and diverse group of 32 Area Chairs, representing institutions across various continents, including previously underrepresented regions such as South America and Oceania. Area Chairs actively coordinated the review efforts, providing critical insights across the eight technical areas of interest within IAARC, including "Decarbonizing the Construction Industry," a theme proposed by the Local Organizers. A total of 258 reviewers participated, providing 590 comprehensive reviews. Each submission received at least two reviews, with 77% of papers receiving two reviews, 22% receiving three reviews, and 1% undergoing four reviews.

Building upon the successful innovations introduced by the Technical Committees of previous years, this year’s Technical Committee solidified and integrated these advancements into ISARC’s curation process. The review procedure included pre-screening, two rounds of formal reviews, and a rebuttal phase, which have become fundamental elements within the ISARC review framework. This rigorous process was further structured and rubricated this year by enhanced guidance provided to Area Chairs and reviewers, including streamlined guideline documents, step-by-step cue cards, short instructional videos, systemized regular communication among editorial board members, and a tailored submission system.

The ISARC 2025 symposium featured three keynote presentations, eight plenary sessions, and 200 parallel and poster sessions. We hope you find this year's proceedings engaging and the included papers insightful and inspiring. Enjoy your reading!

Table of Contents

K - Keynote talks

GPR-Former: Context-Aware Moisture Detection 1

Kevin Lee, Chen Feng

Dynamic Analysis of a Six-Cable Parallel Robot for Automated Panelized Building Retrofits 9

Yifang Liu, Nolan Hayes, Diana Hun, Bryan Maldonado

Semantic-based behavioral decision-making method for construction robots in worker-robot collaboration 17

Xiao Lin, Hongling Guo, Ziyang Guo

P - Plenary talks

Neural Network-Based Estimation of Rebar Deflection for Robotic Rebar Installation of Vertical Structures 26

Hongjie Cai, Rongbo Hu, Ser Tong Quek, Soungho Chae, Justin K.W. Yeoh

Mobility-added multi tool end-effector for picking and nailing applications in robotic timber assembly 34

Mauricio Arredondo-Soto, Paolo Pancho-Ramirez, Rafiq Ahmad

Learning-based 6 DOF Camera Pose Estimation Using BIM-generated Virtual Scene for Facility Management 42

Thai-Hoa Le, Ju-Chi Chang, Wei-Yi Hsu, Tzu-Yang Lin, Ting-wei Chang, Jacob J. Lin

Slate detection in orthophotos of building roof panels 49

Jiajun Li, Frédéric Bosché, Chris Xiaoxuan Lu, Lyn Wilson, Boan Tao

A Large Language Model as an Assistant for Software-Independent Structural Analytical Model Review and Editing 57

Justin S. Lee, Ghang Lee

Roadmap for Exoskeleton Adoption in the Construction Industry: Leveraging Standard Tests and Minimum Criteria 65

Malcolm Dunson-Todd, Mazdak Nik-Bakht, Amin Hammad

Feasibility of an EEG-based dynamic suboptimal cognitive monitoring for field neuroergonomics....73

Eren {M.} Shahrokhi, S. Nizam Ahmed, Gaang Lee, SangHyun Lee

Tracking algorithm for hazardous area in construction sites using PTZ cameras....81

Jaehwan Seong, Hyung-soo Kim, Hyung-Jo Jung

A - Automated/robotic machines, devices, and end-effectors

Dynamic Hand-Signal Recognition and Prediction Framework for Crane Operations Using Deep Learning....89

Zhihao Wei, Ghulam Muhammad Ali, Xinming Li

Adaptive Fractal Quadtree Approach for Efficient Drone-Based Construction Site Safety Inspection....97

Marvin Cheng, Ci-Jyun Liang, Hugo Camargo

Demonstration of a robotic system for remote control of the end-hose during concrete pumping 105

Mathias Haage, Robert Larsson

Adaptive Hazard Zone Model for Improved Safety in Highway Work Zones 113

Ayenew Yihune Demeke, Moein Younesi Heravi, Israt Sharmin Dola, Inbae Jeong, Youjin Jang

Advanced Sensor Integration for Enhanced Flight Control in UAV-Based Construction Automation....122

Tianyu Ren, Xiayu Zhao, Houtan Jebelli

BIM-Driven Robotic Disassembly for Resource Recovery in End-of-Life Buildings 130

Jeehoon Kim, Christopher Rausch

The Development of a Low Code-based Planning Interface System for Coordinated Work of Multiple Construction Machines....136

Sheng Lian, Fumiya Matsushita, Ryosuke Yajima

From BIM to Autonomous Navigation: Using BIM Models to Enable Autonomous Navigation and Localization in Construction Environments 143

Jörg Husemann, Maximilian Kunz, Marcel Suiker, Karsten Berns

Case study: Robotic Underwater Inspection of Concrete Dam Face Prior to Refurbishment 151

Frédéric Nadeau, Marion Nourry, Guillaume Boivin, Eric Boudreault, Carmin Drolet

Robotized tower crane: Simulation and high-level action planning system 155

Mohammad Reza Kolani, Stavros Nousias, André Borrmann

Senser Fusion and Hierarchical Inspection Strategy for Aerial-Ground Multi-robot System 163

Xiayu Zhao, Tianyu Ren, Yizhi Liu, Houtan Jebelli

Vision-Guided Camera Pose Estimation for Robotic Rebar Tying 171

Shaopeng Xu, Huiguang Wang, Xiaoyi Lv, Lu Deng, Bo Jin, Jingjing Guo

Reinforcement Learning with Vision-based State Estimation for Generalized Robotic Assembly.....179

Mark Trovinger, Leonel Giacobbe, Tanner Grantham, Chuangchuang Sun, Jingdao Chen

Enhancing Robotic Vision through Deep Learning Techniques: From Detection to Construction 187

Yusuf Aykin, Hans Sachs, Nikolai Gerzen

Automated Helmet Detection in Construction Sites using UWB and Machine Learning 195

Amir Shahbazi Ojghaz, Sayeh Bayat, Farnaz Sadeghpour

Advanced Vision-guided Robotic Tying with 6-DoF Rebar Pose Estimation 202

Mi Liu, Jingjing Guo, Lu Deng, Xiaoyi Lyu, Linzhen Nie

Adaptive Kinematic and Dynamic Control for Hexapod Robots in Complex Construction Environments 210

Xiayu Zhao, Houtan Jebelli

Drone-Assisted Progress and Quality Tracking for Surface Finishing in Construction.....218

Tianyu Ren, Houtan Jebelli

Path tracking of bucket edge using a hydraulic excavator with a built-in angular velocity controller 226

Daisuke Endo, Genki Yamauchi, Takeshi Hashimoto, Yoshiaki Tsutsumi, Shinjiro Yamamoto, Kenta Furuuchi, Shinya Imura

Interoceptive Robotic Agents for Shared Control and Learning in Collaborative Construction Work.....234

Xiaoshan Zhou, Carol Menassa, Vineet Kamat

Evaluation of an Autonomous Driving Dumper using a Robot Evaluation Framework.....242

Tim Bernhard, Yuan-Jen Huang, Anne Fischer, Cynthia Brosque, Johannes Fottner

LLM-PCPP: A novel robot prioritized coverage path planning approach for complex environments.....250

Zhaofeng Hu, Ci-Jyun Liang

Remote Physical Control for Upgrading Heavy Construction Equipment 258

Meta Soy, Jiaming Fu, Yifu Wu, Jiansong Zhang, Dongming Gan, Jin Wei-Kocsis, Byung-Cheol Min

Robot-to-Human Construction Tool Handover Grasp Prediction for 6-DOF Robotic Arm with Parallel Gripper 264

Yu Lun Kuo, Guan Yong Xiong, Jacob J Lin, Ci Jyun Liang

Automated Decision-Making Tool for Optimal Long-Term Scheduling of MRR Strategies: A Case Study on Bridges 272

Mohammed Alsharqawi, Saleh Abu Dabous, Tarek Zayed

Integration of a real-time orientation measurement system for a real-time evaluator (RTE) to measure the position and orientation of crane-lifted components 280

Balaji Selvakumar, Nolan W Hayes, Yifang Liu, Bryan P Maldonado, Mengjia Tang, Diana Hun

Robot-Assisted 3D Scene Reconstruction Using Fixed FOV LiDAR-Based Depth Camera 288

Vincent J.L. Gan

New collision avoidance algorithm approach based on social sciences 296

Shuntaro Tamura, Masahide Horita

Enhancing Robotic Path Planning in Industrialized Construction: A Novel Benchmarking Approach 304

Amirpooya Shirazi, Aladdin Alwisy

Exploring Extreme 3D Printed Clay Overhangs with Integrated Active Hot Air Drying System on Robotic Arm 312

Mohamed Abdelaziz, Ilija Vukorep, Deena El-Mahdy

Automation of the Pneumatic Caisson Method - Optimization of Excavation Using the Greedy Algorithm - 318

Hiroki Harada, Kiichiro Ishikawa, Taichi Terui, Yusen Inagawa, Kiyoshi Nakamura, Shinichi Tachibana, Shingo Tsugawa, Kotaro Nagahama, Koji Terada

Human-Inspired Inverse Reinforcement Learning for Autonomous Excavator Operations in Lunar Environments 326

Minguk Kim, Youngjib Ham

Safe Reinforcement Learning for Objects Manipulation in Safety-Critical Coordinated Tasks 334

Fawad Khan, Wei Feng, Zhiyong Wang, Tianlun Huang, Liu Xiao, Asad Ali Shahid, Weijun Wang

CoNav Chair: Design of a ROS-based Smart Wheelchair for Shared Control Navigation in the Built Environment 342

Yifan Xu, Qianwei Wang, Jordan Lillie, Vineet Kamat, Carol Menassa

Advancing Automated Building Inspection: A BIM and GSD Integrated Framework for UAV Applications 350

Emadaldeen Benshaaban, Po-Han Chen, Shahinuzzaman

Towards Agent: LLM-based Framework for Robotic Construction by Leveraging IFC 358

Song Du, Yan Gao, Wei Tong, Yiwei Weng

Advances in the Development of a Custom End Effector for Construction Automation 366

Dax Pimentel, Mario Cervantes, Jiansong Zhang, Luis C Félix-Herrán

Exploration of Sustainable Beam Design Using Voronoi Patterns in Concrete 3D Printing 374

Gokul Santhosh S, Benny Raphael, Manu Santhanam

Design and Development of a Remote User Interface for Multi-Robot On-site Component Inspection 381

Juan Carlos Cruz Rivera, Mohsen Navazani, Ibukun Awolusi, Ao Du, Jiannan Cai

SatAOI: Delimitating Area of Interest for Swing-Arm Troweling Robot for Construction 389

Jia-Rui Lin, Shaojie Zhou, Peng Pan, Ruijia Cai, Gang Chen

Real-time 3D Perception System of Construction Equipment for Autonomous Mobile Robots 397

Duho Chung, Seunghun Im, Yohan Kim, Hyoungkwan Kim

Dynamics Model of an Excavator in an Open Source Physical Simulator for Developing Autonomous Construction 405

Taro Abe, Yosuke Matsusaka, Daisuke Endo, Genki Yamauchi, Takeshi Hashimoto

Personalized Emotion-Adaptive Robot Control Strategy for Human-Robot Collaboration in Construction 413

Francis Baek, Leyang Wen, Gunwoo Yong, SangHyun Lee

GPU-Accelerated Collision-Free Path Planning for Multi-Axis Robots in Construction Automation 421

Ilija Vukorep, Rolf Starke, Arastoo Khajehee, Nicolas Rogeau, Yasushi Ikeda

Investigating the Evolving Robot-Building Relationship via a Past-Present-Prospect Model 428

GPR-Former: Context-Aware Moisture Detection

Kevin Lee[1] **and Chen Feng**[1,2]

[1]Building Diagnostic Robotics, Inc., USA
[2]Tandon School of Engineering, New York University, USA

k.lee@nyu.edu, cfeng@nyu.edu

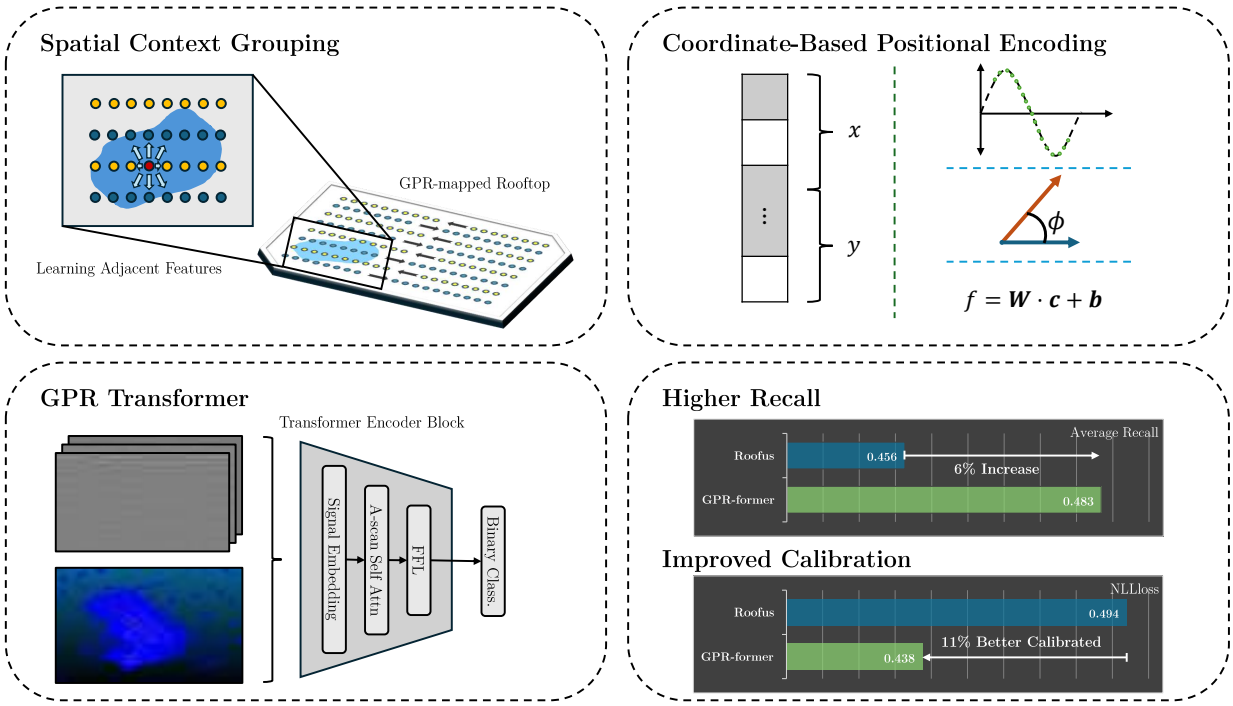

Figure 1. **Overview of GPR-former.** We take inspiration from the complex patterns in which moisture propagates and design a 2D coordinate-based spatial context grouping strategy to more effectively detect the presence of moisture damage on building rooftops. Compared to our previous method, GPR-former demonstrates superior performance in key metrics such as Average Recall as well as having better calibrated outputs.

Abstract -

Moisture damage in roofing systems poses a significant challenge to building operation and maintenance, with far-reaching implications for energy efficiency, structural integrity, health, safety, and sustainability. This study introduces *GPR-former*, a novel transformer-based architecture designed to leverage spatial context in ground-penetrating radar (GPR) data, enhancing the accuracy of moisture detection. Unlike our previous approach that analyzes isolated B-scans, GPR-former incorporates spatial groupings of A-scans with coordinate-based positional encoding, enabling the model to detect complex, nonlinear moisture patterns. Comprehensive experiments across diverse roofing materials demonstrate that GPR-former outperforms our previous method by up to 6% across performance metrics and achieves improved calibrated results. These findings highlight the potential of GPR-former as an improved, transformative tool for sustainable building maintenance, contributing to embodied carbon reduction and extending roof lifecycle management.

Keywords -

Moisture detection, ground-penetrating radar, transformers, spatial context, sustainability

1 Introduction

Moisture damage in roofing systems is a critical issue that impacts energy efficiency, structural safety, and repair costs. It also undermines sustainability efforts by increasing the embodied carbon footprint of buildings through both premature and overdue replacements. Early and ac-

curate detection of moisture damage is essential to mitigate these impacts, support lifecycle management, and enable circular economy initiatives in building renovation and maintenance.

Using GPR to detect moisture in roofing materials presents unique challenges:

- **Signal Obfuscation:** GPR signals are inherently affected by environmental noise, material heterogeneity, and structural interference, making it difficult to identify moisture-related patterns with high confidence.
- **Complex Moisture Patterns:** Moisture often propagates nonlinearly, driven by factors like capillary action and material saturation, complicating interpretation when relying on isolated scans.

Recent advancements in deep learning for GPR [1, 2, 3], particularly the use of transformers and attention mechanisms for B-scan analysis [4, 5, 6], have demonstrated the potential of neural networks in GPR data interpretation. Moreover, progress in the development of mobile robotic systems for GPR data acquisition and processing [4, 7] motivates the development and integration of these technologies. However, methods like our previous approach [4] typically operate within localized linear windows, limiting their ability to leverage spatial relationships critical for identifying moisture patterns across adjacent scans. This gap underscores the need for models that integrate spatial context and enable holistic analysis of GPR data.

To address these challenges, we propose **GPR-former**, a transformer-based architecture that introduces the following key contributions:

- **Spatial Context Grouping:** A novel grouping mechanism that aggregates A-scans based on spatial proximity, providing a richer contextual understanding of moisture propagation.
- **Coordinate-Based Positional Encoding:** A mechanism to encode spatial coordinates directly into the model, allowing GPR-former to effectively map relationships between grouped scans.
- **Comprehensive Evaluation:** Extensive experiments across diverse roofing materials validate the efficacy of the proposed approach.

2 Related Work

2.1 GPR-Based Moisture Detection

Ground-penetrating radar has been widely applied in various domains for moisture detection. For example, [8] employs a drone-mounted GPR sensor to map soil moisture across agricultural fields, demonstrating the versatility of GPR in remote sensing applications. Similarly, [9] integrates GPR with thermal imaging to detect moisture in building walls, highlighting the potential of GPR-based moisture detection specifically in the domain of building diagnostics and maintenance.

In the context of roofing systems, our previous work [4, 10] establishes a foundation for GPR-based moisture analysis. [10] explores self-supervised learning to extract semantically meaningful features from GPR A-scans, enabling downstream tasks like moisture detection with minimal reliance on labeled data. Our investigation indicates the possibility of accurately identifying and isolating GPR scans taken over moisture saturated surfaces, but fails to produce a scalable and robust classifier. Building on this, Roofus [4] applies supervised learning as well as the transformer architecture to classify moisture in real-world rooftop environments using a large-scale labeled dataset of GPR B-scans. Although effective, Roofus focuses on localized analysis within sample B-scans, failing to account for broader spatial relationships that may be critical for detecting moisture propagation across B-scans.

2.2 Transformers in Coordinate-Based Applications

Transformers [11] have gained prominence in tasks requiring spatial reasoning, with positional encoding enabling the modeling of spatial relationships in structured data. In medical imaging, for instance, [12] employs coordinate-based embeddings to enhance transformer-based models for spatially aware tasks. Similarly, CoordFormer [13] introduces a Coordinate-Aware Attention module to encode spatial-temporal coordinates, preserving dependencies critical for analyzing video and image datasets. Li et al. [14] investigates the efficacy of explicit positional encoding by concatenating 2D positional coordinates to the end of each token's embedding dimension among other strategies. Despite these advancements, the application of transformers to specifically GPR data remains underexplored, leaving untapped potential for leveraging spatial relationships in GPR-based analysis.

2.3 Limitations of Existing Approaches

Existing GPR-based methods, including Roofus [4], primarily analyze localized B-scans and overlook the spatial propagation of moisture across adjacent scans. This limitation often results in the model struggling when encountering strongly reflective objects like horizontal rebar. Similarly, while transformers with positional encoding have been effectively applied to coordinate-based tasks, their use in GPR data analysis lacks exploration. Addressing these gaps requires a model capable of capturing the unique spatial relationships inherent in GPR datasets to identify complex moisture diffusion patterns in real-world

rooftop environments.

3 Model Overview

3.1 Task Definition

The primary goal is to classify Ground Penetrating Radar (GPR) A-scans into binary categories indicating the presence or absence of moisture. Formally, given a collection of A-scans grouped by spatial proximity, denoted as $\{S_1, S_2, \ldots, S_\omega\}$, where each scan $S_i \in \mathbb{R}^{655}$ represents a feature vector derived from radar signals, the task is to output a binary prediction $P_i \in \{0, 1\}$ for each scan S_i. Here, $P_i = 1$ signifies the presence of moisture, while $P_i = 0$ indicates its absence.

Binary classification is particularly suited for the application domain, where client-facing diagnostic reports prioritize actionable outcomes. While additional insights such as moisture depth or severity could enrich the analysis, this study focuses on binary classification as a practical first step. The detection of moisture ingress typically necessitates remediation regardless of severity, aligning with the goal of actionable and interpretable results.

Unlike previous approaches that process A-scans or B-scans in isolation, GPR-former leverages spatial context by analyzing grouped A-scans across multiple B-scans. This strategy enhances sensitivity to obfuscated or diffuse moisture signals, which are often missed by single-scan models like Roofus.

3.2 Spatial Context Grouping

Intuition. Moisture in roofing materials seldom manifests as isolated points; instead, it propagates radially or irregularly due to dynamics like capillary action and absorption as illustrated in Figures 1 and 2. These patterns often form clusters or saturate adjacent regions. To capture such propagation behaviors, GPR-former organizes A-scans into spatially coherent groups using x, y coordinates obtained from LiDAR data, enabling the model to recognize subtle or diffuse moisture patterns that elude traditional methods.

Group Sampling Procedure. A straightforward K-D Tree-based algorithm is used to group A-scans according to spatial proximity. We use the K-D Tree for its simplicity and performance. The procedure is outlined as follows:

1. Construct a K-D Tree using the x, y coordinates of all A-scans from a rooftop dataset.
2. Arbitrarily select an A-scan as the seed for a group and identify its $\omega - 1$ nearest neighbors.
3. Form a group of ω A-scans and remove them from the K-D Tree.
4. Repeat steps 2–3 until the K-D Tree is empty. Discard any group with fewer than ω A-scans.
5. Ensure that all groups are formed strictly from A-scans belonging to the same rooftop to prevent erroneous mixtures of scans from different sites.

Algorithm 1: Generate Groups using K-D Tree

Input: GPR Data D, group size ω
Output: Groups G

Initialize D copy: $D_0 \leftarrow D$;
Initialize empty groups: $G \leftarrow \emptyset$;
while *size*$(D_0) \geq \omega$ **do**
  Construct K-D Tree tree $\leftarrow$ `KDTree`(D_0);
  Select the first sample as seed: seed $\leftarrow D_0[0]$;
  Query nearest neighbors:
    neighbors $\leftarrow$ `query`(tree, seed, $k = \omega - 1$);
  Form group: $G \leftarrow G \cup \{\text{seed}, \text{neighbors}\}$;
  Remove group from D_0:
    $D_0 \leftarrow$ `delete`$(D_0, \{\text{seed}, \text{neighbors}\})$;
end
return G

This procedure ensures spatial coherence by grouping A-scans strictly from the same rooftop. Groups with fewer than ω A-scans are discarded to maintain consistency. Although this procedure may not be the most computationally efficient, it is sufficiently effective for handling our large rooftop datasets in practice.

An important hyperparameter to consider is the group size ω. An ω that is too small inhibits the algorithm's capability to span the gaps between B-scans, nullifying the benefits of inter-scan context that we propose. If ω is too large, undesirable artifacts like spatial discontinuity in group membership may occur. Figure 3 provides an illustration describing such phenomenons. In our study, we explore the effects that these situations can have on performance and we investigate the optimal ω in our ablation.

3.3 Coordinate-Based Positional Encoding Strategies

Overview. Positional encodings are essential for embedding spatial relationships among grouped A-scans, enabling the model to leverage spatial context effectively. To achieve this, we explore three different strategies for encoding the positional information into each A-scan representation:

- **Sinusoidal Absolute Encoding:** Employs fixed periodic functions to encode absolute signal feature positions.
- **Rotary Encoding:** Encodes relative positional relationships within groups by applying rotational transformations to the embeddings.
- **Learned Encoding:** Learns position embeddings directly from the data via a linear layer.

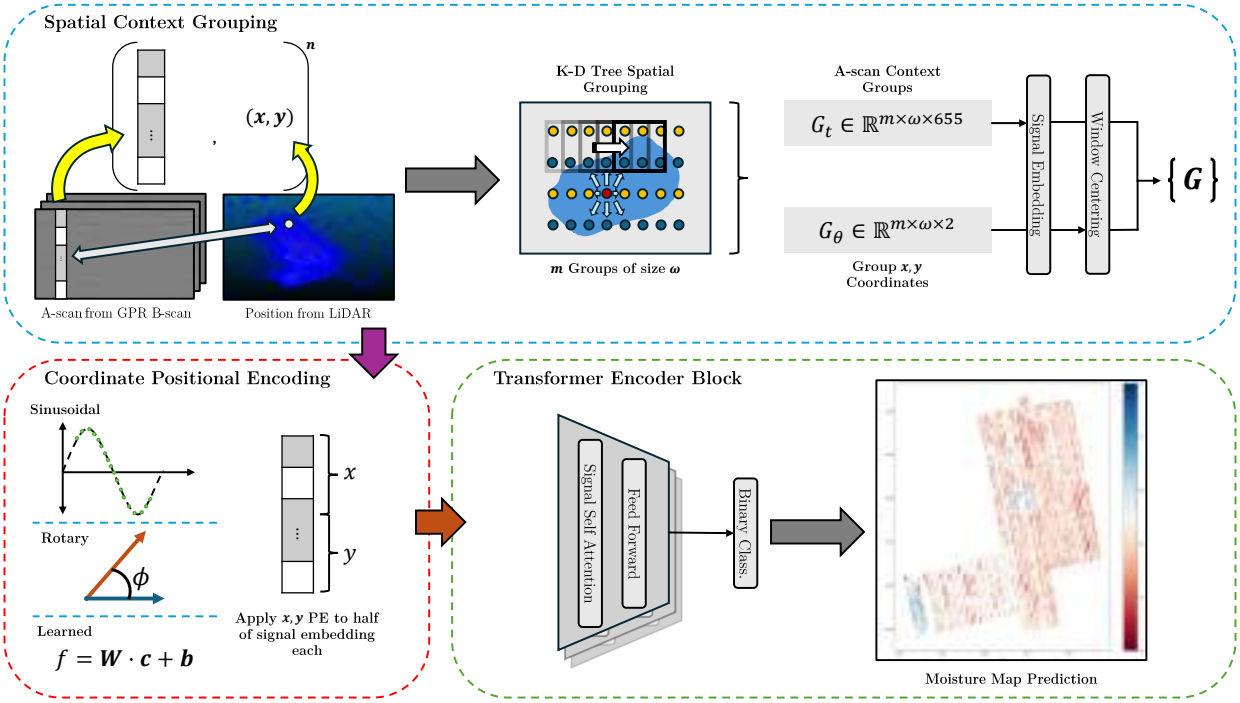

Figure 2. **GPR-former aggregates A-scans into groups of size ω using a K-D Tree sampling procedure.** These grouped scans are processed by a transformer encoder, which incorporates coordinate-based positional encodings to capture spatial relationships and contextual dependencies.

Implementation Details. To account for variability in rooftop layouts and scan alignments, the x, y coordinates are normalized relative to the group's mean position before encoding. This normalization ensures that encodings are invariant to the absolute coordinate system, allowing the model to generalize across diverse rooftop environments.

Each encoding method maps the normalized x, y coordinates to feature embeddings, with half of the embedding dimension allocated to each axis for the Sinusoidal Absolute Encoding and Rotary Encoding. The specific formulations are detailed below:

Sinusoidal Absolute Encoding. We borrow the encoding scheme used in the implementation of the Masked Autoencoder [15], where half of the feature embeddings are dedicated to the x position and the remainder to the y. This particular approach encodes x and y positions using sine and cosine functions of varying frequencies, defined as:

$$\begin{aligned} PE_x[i] &= \sin(x \cdot \beta[i]), \quad PE_x[i+1] = \cos(x \cdot \beta[i]), \\ PE_y[i] &= \sin(y \cdot \beta[i]), \quad PE_y[i+1] = \cos(y \cdot \beta[i]), \end{aligned} \tag{1}$$

where $\beta[i] = \frac{1}{10000^{2i/d}}$, d is half the embedding dimension, and i indexes the frequencies.

Rotary Encoding. We utilize a similar approach as the Sinusoidal encoder with the Rotary encoder, where the encoding transforms feature embeddings to encode relative positions using rotational transformations on x and y embeddings:

$$\begin{aligned} \mathbf{x}_{\text{rot}} &= \mathbf{x} \odot \cos(\theta) + \text{Rot}_{90}(\mathbf{x}) \odot \sin(\theta), \\ \mathbf{y}_{\text{rot}} &= \mathbf{y} \odot \cos(\theta) + \text{Rot}_{90}(\mathbf{y}) \odot \sin(\theta), \end{aligned} \tag{2}$$

where θ is derived from scaled positional values, and $\text{Rot}_{90}(\cdot)$ rotates the second half of the embedding vector by 90 degrees. This method emphasizes spatial relationships by directly modifying feature representations in embedding space.

Learned Encoding. This method learns position embeddings directly through a linear layer:

$$PE = \mathbf{W} \cdot \mathbf{c} + \mathbf{b}, \tag{3}$$

where $\mathbf{c} \in \mathbb{R}^2$ represents the input coordinates, and $\mathbf{W} \in \mathbb{R}^{d\times2}$, $\mathbf{b} \in \mathbb{R}^d$ are trainable parameters. This approach adapts the encoding to dataset-specific requirements but risks overfitting in low-data scenarios.

Practical Considerations. Unlike static encodings in image-based transformers, the dynamic nature of grouped

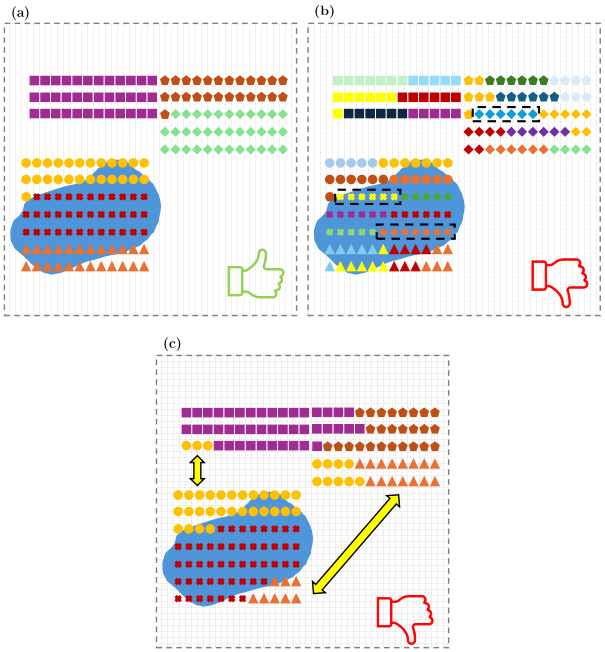

Figure 3. **Comparison between the effects that different groups sizes can have on group semantics and composition.** An ideal group size (a) has sufficiently large groups to just enough cover pertinent regions like puddles. A group size that is too small (b) has difficulty spanning the gap between B-scans, making it no different than previous methods like Roofus [4]. Groups that are too large (c) may introduce unwanted artifacts such as discontinuity and noise.

A-scans in GPR data necessitates real-time encoding computation. However, we find that the real-time computation adds minimal overhead in practice across various large-scale rooftop datasets.

While Sinusoidal Absolute Encoding efficiently captures global structure, Rotary Encoding and Learned Encoding emphasize local spatial patterns and task-specific adaptability, respectively. These differences highlight trade-offs in flexibility, interpretability, and computational requirements for each encoding scheme.

3.4 Transformer Architecture

In GPR-former, we adopt a vanilla transformer architecture similar to the design introduced by [11]. This transformer is central to our approach as it models the contextual and spatial dependencies among grouped A-scan features. Each transformer layer block is comprised of multi-head self-attention, a feed-forward network, residual connections, and layer normalization. After the transformer encoder, the resulting feature vector is passed through a final linear layer followed by a sigmoid activation to yield a binary classification probability.

Figure 2 illustrates the summarized approach of GPR-former.

4 Experiments

Implementation. GPR-former employs a transformer encoder architecture with a binary classification head as shown in Figure 2. Training is conducted using Focal Loss to address the inherent dataset imbalance (it is typical to expect moisture signals to be less frequent than dry signals), with a learning rate of 1×10^{-5} on a cosine annealing schedule. Weighted binary cross-entropy was also tested but yielded suboptimal results compared to Focal Loss, likely due to the latter's ability to emphasize difficult samples more effectively. We use the AdamW optimizer and train on an Nvidia RTX 8000 GPU with a batch size of 64.

Three versions of GPR-former are developed: **GPR-former-B** (base), **GPR-former-L** (large), and **GPR-former-H** (huge). These versions differ in the number of attention heads, layers, and representation dimensions, with GPR-former-B containing a total of 44.6M parameters, GPR-former-L containing 84.7M parameters, and lastly GPR-former-H containing 118.9M parameters. For reference, the architecture used for Roofus contains 302M parameters, making GPR-former noticeably light-weight in comparison. The exact details of each configuration is described in Figure 1. The architectures share a common classification layer, ensuring consistency across the comparison. Hyperparameters were optimized through grid search, with specific focus on dropout, learning rate, and batch size. All GPR-former models in our main evaluation use Sinusoidal positional encoding and a group size $\omega = 1024$. We provide the justification in our ablation analysis in Section 4.2.

Dataset. The dataset is sourced from the same building complex used in the Roofus investigation [4], a 46.5K m^2 retail complex with diverse roofing materials, including modified bituminous membranes, EPDM rubber, and TPO. It contains hundreds of thousands of A-scans spanning a wide range of roofing conditions and damage levels. Labels were manually annotated and cross-validated against reference moisture maps provided by a third-party partner. These reference maps were generated using established rooftop moisture detection techniques, including infrared thermography, electrical capacitance testing, and nuclear moisture gauges.

The dataset is divided into distinct sections, labeled Section 1 through Section 10, with Section 7 excluded due to scanning errors. Section 6 is reserved exclusively for testing, while the remaining sections are used for training and validation with an 85/15 split. This division ensures

Models	Hyperparameters			# Parameters
	# Heads	# Layers	Representation Dim.	
Roofus	16	24	1024	302M
GPR-former-B	4	8	768	44.6M
GPR-former-L	8	10	1024	84.7M
GPR-former-H	16	10	1280	118.9M

Table 1. **Design differences between the different sizes of GPR-former, with the tested version of Roofus included for comparison.** The different sized models vary in the number of attention heads and layers as well as their representation dimensions.

Models	Quantitative			Qualitative
	AR ↑	F2-Score ↑	AUROC ↑	NLLloss ↓
Roofus	0.4563	0.7158	0.8240	0.4940
GPR-former-B	0.4563	0.7267	0.8386	0.4465
GPR-former-L	0.4730	0.7174	0.8296	0.4443
GPR-former-H	**0.4834**	**0.7277**	**0.8436**	**0.4376**

Table 2. **Comparison of GPR-former variations and Roofus across evaluation metrics on the test set.** GPR-former-H appears to be better fit to take advantage of the additional spatial information through the increased number of encoder layers and attention heads.

that the model is evaluated on unseen data, reflecting real-world deployment scenarios.

Prior to input into the models, the GPR B-scans are pre-processed using a linear gain down the time domain. The data is then standardized by the mean and standard deviation values calculated from the training set. Additionally, we apply a random horizontal or vertical flip of the x, y coordinates with a separate probability of 0.5 for each flip during training.

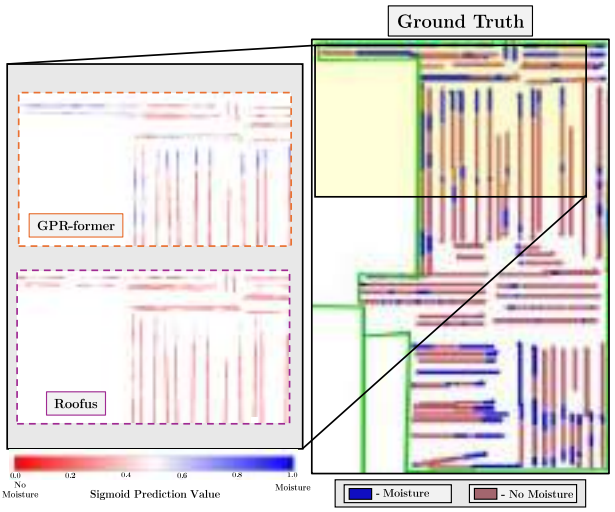
Baseline. To benchmark the performance of GPR-former, we compare it with our previously developed Roofus model. Roofus also employs a transformer-based architecture but operates on GPR B-scans, treating A-scans within a window as sequential data without incorporating spatial context beyond individual B-scans. Roofus was retrained on the current dataset using the same training regimen as GPR-former, with adjustments where necessary to accommodate its architectural differences.

Evaluation Metrics. Given the critical need to identify all potentially damaged roofing areas, **recall** is selected as the key evaluation metric. While precision is valuable, prioritizing recall ensures minimal false negatives, which is essential for identifying areas that might require repair. In roofing diagnostics, conservative predictions often lead to better outcomes, as even marginally damaged areas are typically repaired along with severely damaged sections.

To capture this priority, we use metrics such as Average Recall (AR) and F2-score, with F2-score weighted more heavily toward recall. The Area Under the Receiver Operating Characteristic (AUROC) is also included to provide both consistency with our previous investigation with Roofus as well as further insights into the trade-off between true positive and false positive rates. F2-scores are calculated using the optimal threshold identified during the final validation step.

4.1 Main Results

Quantitative. Table 2 presents the performance of GPR-former variants compared to Roofus. The results show that the largest model, GPR-former-H, using $\omega = 1024$ and the Sinusoidal positional encoding, achieves the highest recall, F2-score, and AUROC, demonstrating the benefits of incorporating spatial context into the model. The slight underperformance of GPR-former-L compared to GPR-former-B in F2-Score and AUROC is an unexpected result, potentially due to overfitting or architectural inefficiencies. Further analysis of this phenomenon is left for future work.



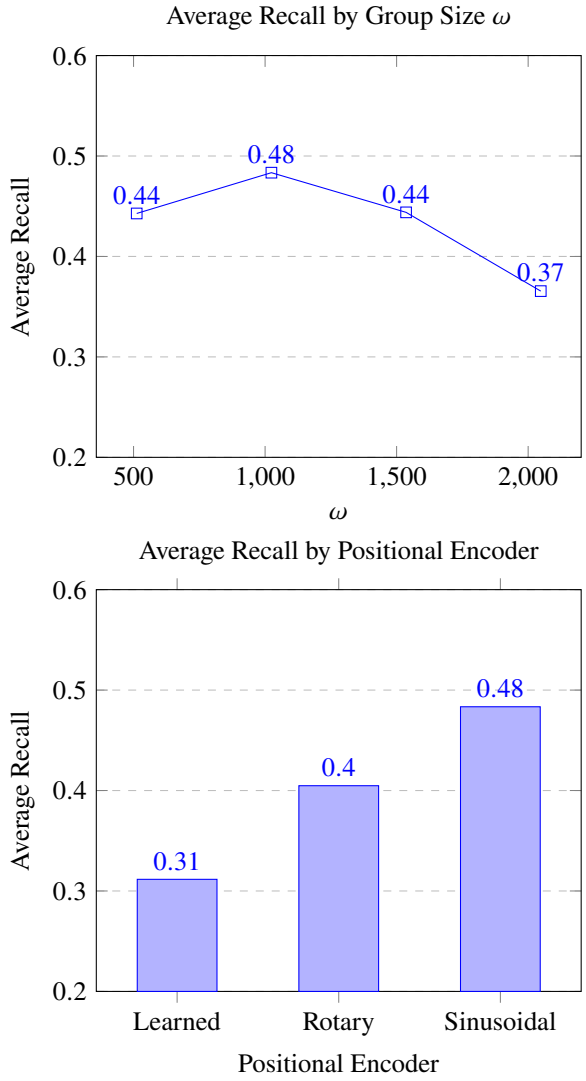


Figure 4. **Qualitative comparisons against the ground truth labels of the un-thresholded moisture predictions generated by GPR-former and Roofus [4].** The example highlighted region clearly illustrates the improvement in the calibration of GPR-former is over its predecessor.

Qualitative. Despite being hidden from client-facing reports, the un-thresholded predictions can provide additional insights into how well-calibrated the models are and the uncertainty present in them. Figure 4 illustrates the raw model outputs prior to thresholding for GPR-former and Roofus. GPR-former exhibits a wider distribution of prediction scores, indicating higher confidence in its classifications. To quantify uncertainty, we compute the negative log-likelihood loss as shown in Table 2, reveal-

ing that GPR-former produces more calibrated predictions compared to Roofus.

4.2 Ablation

Group size ω. As discussed prior, the group size ω determines the spatial context provided to the model. Larger groups introduce additional spatial information but risk incorporating irrelevant or noisy data, while smaller groups may lack sufficient context. To strike a balance, we tested group sizes of $\omega = 512, 1024, 1536, 2048$. Results indicate optimal performance at $\omega = 1024$, beyond which performance declines, likely due to grouping artifacts or interruptions in data continuity. Overlapping groups or advanced sampling methods may address these limitations in future iterations.

Positional Encoding. As previously mentioned, the three encoding schemes were evaluated: sinusoidal absolute positional encoding, a rotary positional encoder, and a learned positional encoder. Contrary to expectations, the sinusoidal encoder outperformed the rotary encoder, possibly due to the relative encoder's complexity relative to the dataset size. The poor performance of the learned encoder underscores the importance of carefully designed encoding schemes in spatial transformers, especially in low-data scenarios.

5 Discussions

Limitations. This study shares limitations with prior work [4], including the need for an expanded dataset with additional roofing material types and environmental conditions to generalize the model's applicability. Artifacts in the sampling procedure, such as large gaps between group members, can lead to discontinuities in spatial context. Furthermore, the current approach is unable to quantify the severity of damage or localize the damage beneath the surface, which somewhat limits the practical utility of the predictions.

Conclusions. The experiments validate the effectiveness of incorporating spatial context in transformer-based architectures for GPR data. GPR-former outperforms our previous model Roofus across key metrics, demonstrating the advantages of spatially aware processing.

Future Work. Directions for future research include developing advanced methods for constructing groups (e.g., overlapping groups or clustering-based sampling) and increasing the dataset size through scanning and labeling more rooftops to enhance diversity and saturate the capabilities of relative positional encoding. Investigating the applicability of self-supervised learning may also address the difficulties in large-scale data collection and annotation. Exploring the prediction of moisture depth or damage severity could further improve the practical value of the system in real-world diagnostics.

Abstract -

Cable-Driven Parallel Robots (CDPRs) are highly suitable for automated panelized building retrofits, thanks to their compact footprint and high payload-to-weight ratio. A common CDPR configuration featuring eight cables, where the anchors form a rectangular prism in front of the building facade, offers a large wrench feasible workspace and good control versatility. However, installing upper anchor points requires additional support structures, such as towers or beams, increasing setup complexity and posing logistical challenges in construction settings. To mitigate these challenges, we propose a six-cable CDPR model specifically designed for automated panelized building retrofits. Although the feasible workspace is limited, our analysis shows that the proposed CDPR adequately covers the critical areas required for panel installation. To validate that the six-cable system can effectively transport the end effector to the desired installation pose, we calculated optimal trajectories based on a constrained dynamic model. The simulation results of the six-cable CDPR demonstrate promising potential for automated panelized building retrofits, effectively balancing simplicity, cost-effectiveness, and functionality.

CDPR; Panelized Envelope; Construction Robotics; Trajectory Optimization

1 Introduction

Building retrofits using panelized prefabricated envelopes substantially enhance the energy efficiency of a building. Traditional methods for installing panels in multi-story buildings typically rely on manual labor or crane hoisting, with panels being placed by hand [1]. However, these approaches are often hindered by labor shortages, high costs, and panel installation errors. Automating this process with robotics offers a promising solution to enhance efficiency, improve quality, and reduce the overall installation cost. Cable-Driven Parallel Robots (CDPRs) are well-suited for handling heavy payloads while maintaining a compact footprint. These attributes make them particularly effective for automated building retrofits using prefabricated panelized systems.

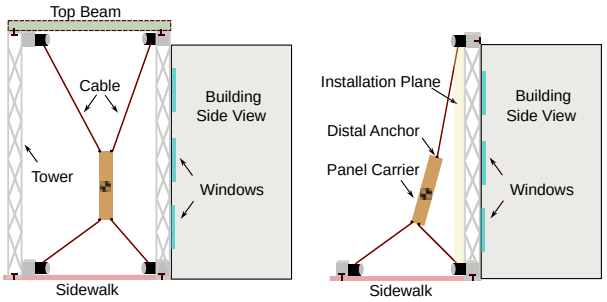

Figure 1. Side views of eight-cable (left) and six-cable (right) CDPRs for panelized building retrofits

CDPRs are highly versatile robotic systems used in various applications, including 3D printing [2], material handling [3], and prefabricated panel installation [4]. Many CDPR designs utilize an eight-cable configuration supported by rigid external elements surrounding the workspace [5]. This setup, with four anchor points on the ground and four positioned mid-air, offers a large wrench feasible workspace and high control versatility. However, installing the upper anchor points requires additional support structures, such as towers, cantilever beams, or bracing (left plot of Figure 1), which significantly increases setup complexity and presents logistical challenges in construction environments.

To address these issues, this paper introduces a novel six-cable CDPR model designed specifically for panelized building retrofits. As shown in the right plot of Figure 1, the proposed system uses six cables, with four anchors on the ground and two near the roof. By removing the anchor points that need to be suspended mid-air, this configuration simplifies setup process and mitigates logistical complexities. When the end-effector is away from the facade, the

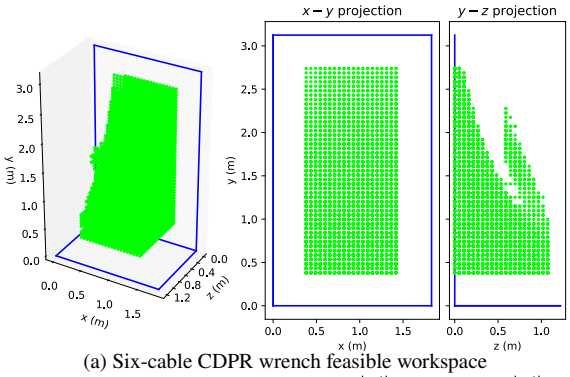
system operates as a spatial (three-dimensional) CDPR. However, as the center of mass of the end effector aligns with the installation plane, the bottom two cables furthest from the facade begin to sag, transitioning the system into a planar (two-dimensional) configuration. A key focus of this study is evaluating if the model is capable to transport the end effector from a starting feasible pose away from the facade (e.g., at the end of the sidewalk) to a desired pose at the installation plane near the facade. Using a dynamic model of the six-cable CDPR, a trajectory optimization problem was formulated to demonstrate the feasibility of the proposed design. Simulation results showed that the six-cable CDPR can successfully pick up a panel at a given pose and manipulate it to achieve the desired plumb and level panel position on the installation plane. To the best of our knowledge, this is the first six-cable configuration that is used for panelized building retrofits. This streamlined configuration aims to enhance feasibility and efficiency while maintaining sufficient operational control for panelized building retrofits.

The remaining sections are arranged as follows. Section 2 presents the state of the art in CDPRs for construction applications. Section 3 describes the benefits and challenges of a six-cables CDPR system. Section 4 defines the dynamic model used and the trajectory optimization problem to be solved. Section 5 demonstrates the simulation results. Section 6 concludes the paper and outlines directions for future work.

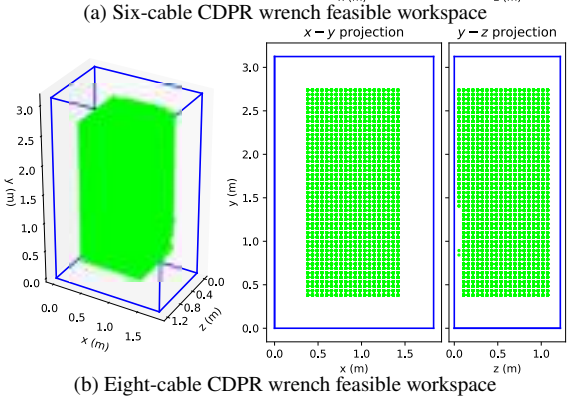
2 CDPRs in Construction Applications

Recently, CDPRs have gained attention across various fields and applications. Due to their desirable characteristics, such as scalability, reconfigurability, compact design, and high payload-to-weight ratio. They are widely investigated in construction applications such as bricklaying [6], 3D printing [7, 8], and solar power plant assembly [9]. Murphy *et al.* developed a planar CDPR for cooperative modular manipulation, enabling CDPRs to assist in construction tasks and gap-crossing scenarios [10]. For building envelope applications, Izard *et al.* explored the use of eight-cable CDPRs for inspecting building facades [11]. In addition, Iturralde *et al.* designed and implemented an eight-cable CDPR model for modular curtain wall installation in real-world applications [5]. Their work examined whether CDPRs could achieve sufficient accuracy for installing curtain wall modules and reduce manual installation time. In the context of automated panelized building retrofits, our previous work investigated the wrench feasible workspace for various cable configurations, with a primary focus on four-cable planar models and eight-cable 3D models [4]. CDPRs designed for building envelope applications have predominantly focused on eight-cable models, leaving the potential of a six-cable CDPR configuration unexplored.



3 Six-Cable CDPR for Panelized Systems

To achieve control over the six degrees of freedom (DOF) of the end effector, an eight-cable configuration is commonly used, especially when a large workspace is required. Among the eight proximal anchor points, two need to be placed away from the building facade and away from the ground. This setup usually requires additional support structures, such as vertical towers and/or top beams, as illustrated in Figure 1. Support towers provide a simplified setup by providing the necessary rigidity for the system while minimizing dependency on the building. In this case, if a CDPR with eight cables is needed, then four towers are required to attach all anchor points. Although top beams or bracing are not strictly mandatory, they become essential when a highly rigid support structure is needed. However, constructing four towers with beams and bracing presents logistical challenges and adds considerable expenses.



In contrast, some systems, such as Hephaestus [5], use only two welded-steel cantilever structural beams fastened to the roof of the building, with each beam element supporting two anchor points. While this approach reduces setup complexity, it is not universally applicable, particularly for older buildings where additional load-bearing capacity of the structure may be limited. The feasibility of relying solely on roof-mounted structures depends heavily on the building's age, structural integrity, and availability of attachment points. For such cases, a structural assessment is necessary to ensure that the building can support the CDPR system, which adds additional complexity and cost for retrofitting. To address these limitations and improve system robustness, we propose avoiding roof-mounted structures entirely, so that the CDPR design can be largely independent of the building's architecture.

Therefore, the tower-based setups, i.e. the combination of towers, top beams, and bracing, ensures a rigid and reliable system while minimizing dependence on the building structure itself to support the robot. Many existing multifamily residential buildings have sufficient space adjacent to the facade to accommodate the tower-based setups, which provides a suitable condition for retrofitting projects using CDPRs.

To further simplify the installation process and reduce costs, this paper investigates the feasibility of using a CDPR with only six cables for panelized building retrofits. This approach aims to maintain functionality while significantly minimizing the structural and logistical requirements associated with the traditional eight-cable configurations. The six-cable configuration offers several notable advantages. As illustrated in Figure 1, unlike the eight-cable setup that requires four top anchors, the six-cable

(a) Six-cable CDPR wrench feasible workspace

(b) Eight-cable CDPR wrench feasible workspace

Figure 2. Wrench feasible workspace of the six-cable CDPR and an eight-cable CDPR. Green dots represent feasible positions of the end effector's center of mass. Blue lines represent the CDPR frame. Left: 3D view; Middle: $x - y$ projection; Right: $y - z$ projection. Further details on the calculations can be found in Section 5.2.

system requires only two anchors located near the top of the building. This reduces the number of towers needed from four to two. Additionally, a six-cable CDPR system uses only six actuator systems, further lowering costs. The reduction in cables and towers minimizes material usage and overall expenses. These adjustments simplify the setup process and reduce installation complexity. However, this approach also introduces technical challenges. Unlike the eight-cable system, the six-cable configuration cannot provide sufficient control to achieve the same level of mobility for the end effector. This limitation reduces the workspace (see Figure 2), causing more than 30% of the wrench feasible area in the eight-cable CDPR to become wrench-infeasible. Additionally, it increases sensitivity to external disturbances and adds complexity to control and trajectory optimization. For example, in the eight-cable CDPR, when the end effector is at the pickup location, a wide range of initial orientations are wrench-feasible. However, for the six-cable CDPR, most of these initial orientations are no longer feasible. Additionally, determining

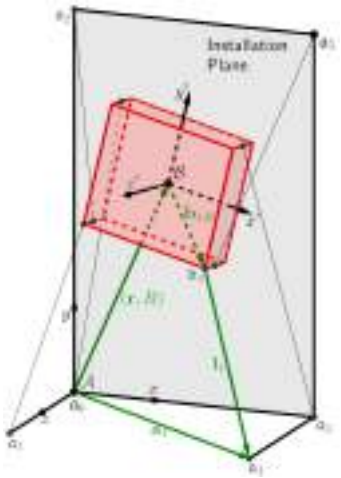


Figure 3. Geometric and dimensional definition of the six-cable CDPR model for building retrofits.

a feasible initial trajectory between a given starting position and target pose presents a significant challenge. This paper addresses these issues by proposing solutions to enhance the practicality and reliability of a six-cable CDPR. By overcoming these challenges, the six-cable configuration can serve as a promising alternative for certain retrofit applications, offering a balance between simplicity, cost-effectiveness, and functionality.

4 Modeling and Trajectory Optimization

We will start by describing the CDPR dynamic model and then formulating the trajectory optimization problem for bringing a panel from a starting pose to a desired pose.

4.1 CDPR Dynamics

The six-cable CDPR model studied in this paper is illustrated in Fig. 3. Note that in this setup, the installation plane is parallel to, but distinct from the building facade. The building facade is located on the negative side of the z axis. The fixed (black) frame of size $\boldsymbol{F} = \begin{bmatrix} F_x & F_y & F_z \end{bmatrix}^T$ sets the dimensions of the CDPR in the world coordinate system $\mathcal{A}$. The CDPR manipulates the (red) end effector of size $\boldsymbol{P} = \begin{bmatrix} P_{x'} & P_{y'} & P_{z'} \end{bmatrix}^T$, which defines the dimensions of the panel in the rotating coordinate system $\mathcal{B}$. Note that in real-world panel installation using CDPRs, the end effector serves as the panel carrier and may be bigger than the panel itself. Finally, $n = 6$ massless cables connect the panel to the frame. The cable end connected to the frame runs through pulleys and cable drums to facilitate the winding and unwinding of the cable. However, in this study, we will not model the geometry or dynamics of

the winding mechanism. Consider the following vectors for $i \in \{1, \ldots, n\}$, according to Figure 3:

- The constant vectors $\mathbf{a}_i$ denote the proximal anchor points $\mathfrak{a}_i$ in the frame with respect to $\mathcal{A}$.
- The constant vectors $\mathbf{b}_{i,\mathcal{B}}$, denote the distal anchor points $\mathfrak{b}_i$ in the panel with respect to $\mathcal{B}$.
- The pose $(\boldsymbol{r}, R)$ is defined by the location of the panel's center of mass $\boldsymbol{r} = \begin{bmatrix} r_x & r_y & r_z \end{bmatrix}^T$ relative to $\mathcal{A}$, and the orientation of the panel's frame $\mathcal{B}$ relative to $\mathcal{A}$, denoted by the rotation matrix $R \in SO_3$.
- The cable vectors $\boldsymbol{l}_i = \mathbf{a}_i - (\boldsymbol{r} + R\mathbf{b}_{i,\mathcal{B}})$ which are functions of the panel pose calculated relative to $\mathcal{A}$.
- The cable forces $\boldsymbol{f}_i = f_i \boldsymbol{l}_i / \|\boldsymbol{l}_i\|$ with $f_i \geq 0$ tension acting on the cables ($\|\cdot\|$ denotes Euclidean norm).

The translational motion of the panel is defined in terms of the acceleration of its center of mass, which is measured from the inertial frame of reference $\mathcal{A}$. Therefore, the Newton equations of translational motion are [12]:

$$\frac{d}{dt}\boldsymbol{r} = \boldsymbol{v} \tag{1}$$

$$\frac{d}{dt}\boldsymbol{v} = \boldsymbol{g} + \frac{1}{m}\sum_{i=1}^{n} f_i \frac{\boldsymbol{l}_i}{\|\boldsymbol{l}_i\|} - \frac{\mu_{\boldsymbol{v}}}{m}\boldsymbol{v}. \tag{2}$$

Here, $\boldsymbol{v}$ is the velocity of the panel's center of mass, $\boldsymbol{g}$ is the acceleration due to gravity, m is the panel's mass, and $\mu_{\boldsymbol{v}}$ is a linear friction coefficient to provide damping. Since the coordinate system $\mathcal{B}$ moves with the panel, the rate of change in orientation and Euler equations of motion written with respect to the coordinate system $\mathcal{B}$ are [12]:

$$\frac{d}{dt}\boldsymbol{\Phi} = T\boldsymbol{\omega}_{\mathcal{B}}. \tag{3}$$

$$\frac{d}{dt}\boldsymbol{\omega}_{\mathcal{B}} = -I_{\mathcal{B}}^{-1}\left(\boldsymbol{\omega}_{\mathcal{B}} \times I_{\mathcal{B}}\boldsymbol{\omega}_{\mathcal{B}}\right) + I_{\mathcal{B}}^{-1}\sum_{i=1}^{n} f_i \left(\mathbf{b}_{i,\mathcal{B}} \times \frac{R^T\boldsymbol{l}_i}{\|\boldsymbol{l}_i\|}\right) - I_{\mathcal{B}}^{-1}\mu_{\omega}\boldsymbol{\omega}_{\mathcal{B}}. \tag{4}$$

Here, $\boldsymbol{\Phi} = \begin{bmatrix} \varphi & \theta & \psi \end{bmatrix}^T$ denotes the Euler angles of the panel. The composition order $R = R_z(\psi)R_y(\theta)R_x(\varphi)$ was adopted for the elemental rotations to compute the rotation matrix. Then, the transformation matrix is [13]:

$$T = \begin{bmatrix} 1 & \sin\varphi\tan\theta & \cos\varphi\tan\theta \\ 0 & \cos\varphi & -\sin\varphi \\ 0 & \sin\varphi\sec\theta & \cos\varphi\sec\theta \end{bmatrix}. \tag{5}$$

In addition, $I_{\mathcal{B}}$ is the panel's inertia tensor (solid rectangular cuboid of dimensions $\boldsymbol{P}$), $\boldsymbol{\omega}_{\mathcal{B}}$ is its angular velocity observed from the rotating reference frame $\mathcal{B}$, and μ_{ω} is another friction coefficient. Equations (1)–(4) define the CDPR dynamics under gravitational, friction, and cable tensile forces. Let $x = \begin{bmatrix} \boldsymbol{r}^T & \boldsymbol{\Phi}^T & \boldsymbol{v}^T & \boldsymbol{\omega}_{\mathcal{B}}^T \end{bmatrix}^T$ be the combined state and $u = \begin{bmatrix} f_1 & \cdots & f_n \end{bmatrix}^T$ the control input. Then, the nonlinear model can be written as $\frac{d}{dt}x = h(x, u)$.

4.2 Trajectory Optimization

A general trajectory optimization problem can be formulated as minimizing a cost function while satisfying a set of constraints, including dynamics constraints, path constraints, as well as initial and terminal conditions. Consider the following cost function, formulated as the sum of the control effort and two regularization terms that ensure the smoothness of the generated motion:

$$J = \int_0^{t_T} \frac{\alpha}{N}\|\ddot{x}\|_{W_x}^2 + \frac{\beta}{N}\|\ddot{u}\|^2 \, dt. \tag{6}$$

Here, the coefficients α and β are nonnegative, N is a scaling constant equal to the number of samples observed during the trajectory, $W_x = \mathrm{diag}\begin{pmatrix} 0, & 0, & \mathbb{I}, & \mathbb{I} \end{pmatrix}$ is used for the weighted squared norm, and t_T is the terminal time. The constraints for the optimal control problem $\min_u J$ are:

Dynamic Constraints: Equations of motion

$$\frac{d}{dt}x = h(x, u), \text{ for } t \in (0, t_T) \tag{7}$$

Force Bounds: Lower bound ensures the cables only pull (sagging is allowed), while the upper bound maintains the cable tension below the rupture limit.

$$0 \leq f_i \leq f_{\max}, \forall i \in \{1, \ldots, n\} \tag{8}$$

Path Constraints: Maintain the panel inside the CDPR frame and limit both the linear and angular velocities.

$$0 \leq \boldsymbol{r} + R\mathbf{b}_{i,\mathcal{B}} \leq \boldsymbol{F}, \forall i \in \{1, \ldots, n\} \tag{9}$$

$$-\Phi_{\lim} \leq \boldsymbol{\Phi} \leq \Phi_{\lim} \tag{10}$$

$$-v_{\lim} \leq \boldsymbol{v} \leq v_{\lim} \tag{11}$$

$$-\omega_{\lim} \leq \boldsymbol{\omega}_{\mathcal{B}} \leq \omega_{\lim} \tag{12}$$

Initial Conditions: Equality constraints to ensure that the trajectory starts from $(\boldsymbol{r}_0, R_0)$ at a stationary state $\boldsymbol{v} = \boldsymbol{\omega}_{\mathcal{B}} = 0$. Let $\boldsymbol{l}_{i,0}$ be the cable vectors at $t = 0$. Then, stationary of the Newton-Euler equations (2) and (4) at the initial pickup pose becomes:

$$x_0 = \begin{bmatrix} \boldsymbol{r}_0^T & \boldsymbol{\Phi}_0^T & 0 & 0 \end{bmatrix}^T \tag{13}$$

$$0 = \begin{bmatrix} \dfrac{\boldsymbol{l}_{1,0}}{\|\boldsymbol{l}_{1,0}\|} & \cdots & \dfrac{\boldsymbol{l}_{n,0}}{\|\boldsymbol{l}_{n,0}\|} \\ \mathbf{b}_{1,\mathcal{B}} \times \dfrac{R_0^T\boldsymbol{l}_{1,0}}{\|\boldsymbol{l}_{1,0}\|} & \cdots & \mathbf{b}_{n,\mathcal{B}} \times \dfrac{R_0^T\boldsymbol{l}_{n,0}}{\|\boldsymbol{l}_{n,0}\|} \end{bmatrix} u_0 + \begin{bmatrix} m\boldsymbol{g} \\ 0 \end{bmatrix} \tag{14}$$

where x_0 and u_0 are the initial state and control. Eqn. (14) can be written in a compact matrix-vector form as $0 = A_0^T u_0 + w_\text{p}$, where A^T is referred to as the structure matrix and w_p is the stationary wrench [14].

Terminal Conditions: Equality constraints to ensure that the robot comes to a complete stop at the target pose $(\boldsymbol{r}_T, R_T)$ at time t_T. Static balance guarantees that when the robot ceases movement, the motors experience minimal stress during the stopping process:

$$x_T = \begin{bmatrix} \boldsymbol{r}_T^T & \boldsymbol{\Phi}_T^T & 0 & 0 \end{bmatrix}^T \tag{15}$$

$$0 = A_T^T u_T + w_\text{p}. \tag{16}$$

Here, x_T, u_T, A_T^T are the terminal state, terminal control, and structure matrix evaluated at t_T, respectively.

5 Simulation Results

In this section, we begin by assigning numerical values to the model parameters for simulation. Next, we present the six-cable wrench feasible workspace. Finally, we discuss the optimized trajectories for transporting the panel from a starting position to the desired final pose.

5.1 Simulation Parameters

We used a 1/3 scaled model of a three-story residential building for our simulations. The simulated cable configuration is illustrated in Figure 3. The initial and terminal poses were defined based on the expected real-world scenario. The panel was picked up from a lower height of the workspace $\boldsymbol{r}_0 = \begin{bmatrix} 0.9 & 1.0 & 0.6 \end{bmatrix}^T$ m with a pre-calculated initial orientation and zero angular and linear velocities. The panel was then held stationary at its final position at the top of the facade, fully plumb and level ($\boldsymbol{\Phi}_T = 0$). Two final positions were tested: $\boldsymbol{r}_T = \begin{bmatrix} 0.8 & 2.2 & 0 \end{bmatrix}^T$ m, and $\boldsymbol{r}_T = \begin{bmatrix} 0.8 & 2.3 & 0 \end{bmatrix}^T$ m. Here, we assume that the robot has sufficient cable length, and the cable length remains positive at all times. Other parameters and constraints are listed in Table 1. CasADi [15] was used as the numerical optimizer with a sampling time of $\Delta t = t_T / N$.

5.2 Wrench Feasible Workspace

To estimate the wrench feasible workspace $\mathcal{W}$, a set of M positions $\mathbf{r}_{j \in \{1,\ldots,M\}}$ was selected from a discretized grid. The following optimization problem was formulated to determine the optimal orientation $R_j(\boldsymbol{\Phi}_j)$ that minimizes the force vector u_j at each corresponding position:

$$\begin{aligned} \min_{\boldsymbol{\Phi}_j} & \|u_j\|^2 \quad \forall j \in \{1, \ldots, M\} \\ \text{s.t. } & 0 = A_j^T u_j + w_\text{p}, \\ & \text{Equations (8) to (10).} \end{aligned} \tag{17}$$

Table 1. Model parameters and constraints

Variable	Value	Description
m	13.6 kg	Panel mass
$\boldsymbol{F}$	$[1.83, 3.12, 1.22]^T$ m	Frame dimensions
$\boldsymbol{P}$	$[0.76, 0.76, 0.25]^T$ m	Panel dimensions
$\mu_{\boldsymbol{v}}$	100 kg/s	Linear friction coefficient
$\mu_{\boldsymbol{\omega}}$	3500 kg · m^2/s	Angular friction coefficient
f_max	1200 N	Cable maximum force
$\boldsymbol{\Phi}_\text{lim}$	90 deg	Euler angle limit
$\boldsymbol{v}_\text{lim}$	0.2 m/s	Linear velocity limit
$\boldsymbol{\omega}_\text{lim}$	2 deg/s	Angular velocity limit
t_T	20 s	Terminal time
N	2000	Samples per trajectory

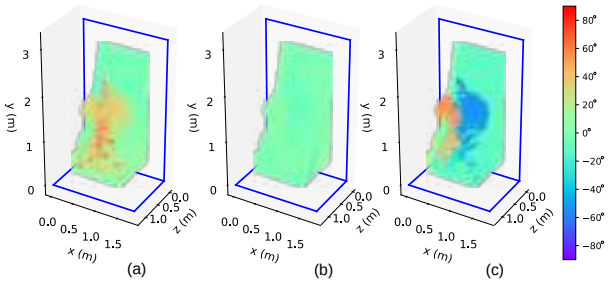

Figure 4. Plots (a), (b), and (c) represent the optimal Euler angles $\boldsymbol{\Phi}_j = [\varphi_j \quad \theta_j \quad \psi_j]^T$, respectively.

If the optimizer converges to a solution, the pose $(\mathbf{r}_j, R_j)$ is wrench-feasible. Figure 4 illustrates the optimized Euler angles $\boldsymbol{\Phi}_j$. The main region of $\mathcal{W}$ resembles a wedge shape and the majority of angles fall within [-20°, 20°]. Note that $\mathcal{W}$ connects the facade installation plane with the assumed pickup panel locations (away from the facade and close to the ground). Thus, there should exist feasible continuous trajectories that can transport the end effector from its starting pose to the installation plane within $\mathcal{W}$. Moreover, we can find trajectories that satisfy certain optimal criteria to minimize installation time and effort.

5.3 Optimized Trajectories

Given the start position $\mathbf{r}_0$ and the final desired pose $(\mathbf{r}_T, R_T)$, we use the trajectory optimization method described in Section 4.2 to compute the optimal force trajectory for the CDPR to follow in simulation. In trajectory optimization, finding a suitable initial trajectory is critical for accelerating the convergence of the optimizer. For the six-cable configuration, finding a suitable initial trajectory is particularly challenging. Firstly, achieving an initial plumb and level orientation $\boldsymbol{\Phi}_0 = 0$ is generally infeasible for most points in the workspace. In contrast, for the eight-cable CDPR, the end effector can be assumed to start in a plumb and level position or with small random rotations.

Consequently, determining an appropriate initial orientation for a given starting position is nontrivial and requires a dedicated optimization process. Selecting an improper orientation—even if wrench-feasible—can lead to convergence failure during optimization. Secondly, generating a practically feasible initial trajectory from the given starting pose to a position near the goal is another significant challenge. The trajectory should ideally satisfy feasibility criteria while avoiding abrupt discontinuities in inputs or states. Unlike in the eight-cable CDPR, where the initial trajectory can be directly obtained using inverse dynamics, the six-cable system requires a more intricate approach to ensure smooth and feasible motion. We address these two challenges in the following paragraphs.

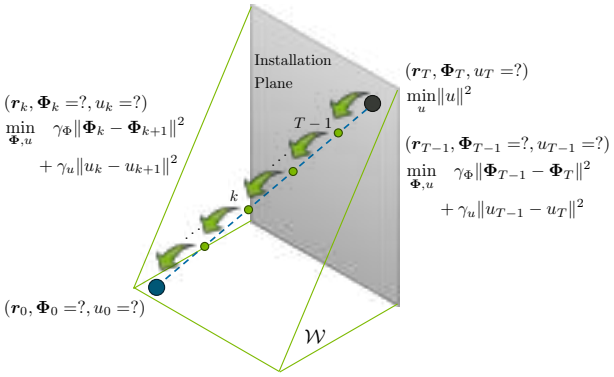

Figure 5. Backwards optimization for finding initial orientation $\boldsymbol{\Phi}_0^*$ and force trajectory $\{u_0^\dagger, \ldots, u_T^\dagger\}$

5.3.1 Determining the orientation of the starting pose

To determine the orientation of the starting pose, we first generate a linear static trajectory connecting the initial and terminal positions: $\{\boldsymbol{r}_0, \boldsymbol{r}_1^\dagger, \ldots, \boldsymbol{r}_k^\dagger, \ldots, \boldsymbol{r}_{T-1}^\dagger, \boldsymbol{r}_T\} \in \mathcal{W}$. At the goal pose $(\boldsymbol{r}_T, \boldsymbol{\Phi}_T)$, an optimization routine similar to Eqn. (17) can be done to find the optimal input force $u_T^\dagger$ by solving $\min_u \|u_T\|^2$. Then, starting from the goal pose and moving backwards along the position trajectory, the optimal orientation $\boldsymbol{\Phi}_k^*$ and input force $u_k^\dagger$ at the k-th ($0 \leq k < T = N-1$) pose is calculated using the constraints in Eqn. (17) and the following cost function:

$$\min_{\boldsymbol{\Phi},u} \gamma_\Phi \|\boldsymbol{\Phi}_k - \boldsymbol{\Phi}_{k+1}\|^2 + \gamma_u \|u_k - u_{k+1}\|^2. \tag{18}$$

Here, γ_Φ and γ_u are weighting factors. The cost function was designed to ensure continuity in both orientation and control input. This optimization is performed position by position, progressing backward until the starting position is reached, as depicted in Figure 5. The resulting optimal continuous quasi-static force trajectory $\{u_0^\dagger, \ldots, u_T^\dagger\}$ is shown at the top plot of Figure 6. Note that the final force values of two cables are zero (cables 1 and 4 start sagging), signaling the transition from a six-cable 3D CDPR system to a four-cable 2D CDPR system. The optimized $\boldsymbol{\Phi}_0^*$ is then set as the orientation for the starting pose.

5.3.2 Generating initial trajectories for the optimizer

Having a well-defined initial trajectory is crucial for accelerating the convergence of the optimizer. Using the starting pose $(\boldsymbol{r}_0, \boldsymbol{\Phi}_0^*)$, static conditions $\boldsymbol{v} = \boldsymbol{\omega}_\mathcal{B} = 0$, and quasi-static force trajectory $\{u_0^\dagger, \ldots, u_T^\dagger\}$ as inputs, we applied the system dynamics in Eqn. (7) to compute the dynamic state trajectory. The bottom plots in Figure 6 compare the dynamic trajectory (solid line) with the quasi-static trajectory (dashed line) used in the backwards optimization. Note that the final pose of the dynamic state trajectory does not coincide with the desired target pose. This occurs because the backward optimization was performed using static instead of dynamic constraints. This simplification impacts the results accuracy, as it fails to account for changes in velocity and acceleration. This dynamic state trajectory was used to initialize the optimizer.

In practice, two routing strategies can be used to generate the initial trajectory. The first method, directly connecting the start and end positions, was described in Section 5.3.1. However, this approach does not guarantee that Eqn. 18 will converge at every point along the trajectory. To address this issue, we propose a second approach that divides the process into two phases. In the first phase, the end effector is moved to a position on the installation plane, which can be selected near the initial position (similar heights). Once the end effector reaches the plane, cables 1 and 4 are slackened, transforming the system into a 2D planar configuration. Each phase's trajectory is optimized separately, and the two optimized segments are concatenated to form the initial trajectory. This trajectory is then used by the optimizer to find the final optimal trajectory from the true starting position to the desired pose.

5.3.3 Final optimized trajectories

Figure 7 illustrates two optimal trajectories originating from the same starting position but with different initial orientations. In the left plot, the trajectory used to initialize the optimizer directly connects the start and end positions. In contrast, the right plot demonstrates an initial trajectory that first guides the end effector to the installation plane before moving upwards along the plane. The reason for splitting the trajectory in the second example is that the optimizer failed when attempting to conduct the backwards optimization to find the optimal orientation for the initial position. As a result, the initial trajectory for the second example first brings the end effector to the position $\begin{bmatrix} 0.8 & 1.2 & 0 \end{bmatrix}^T$ m, before continuing to the final goal

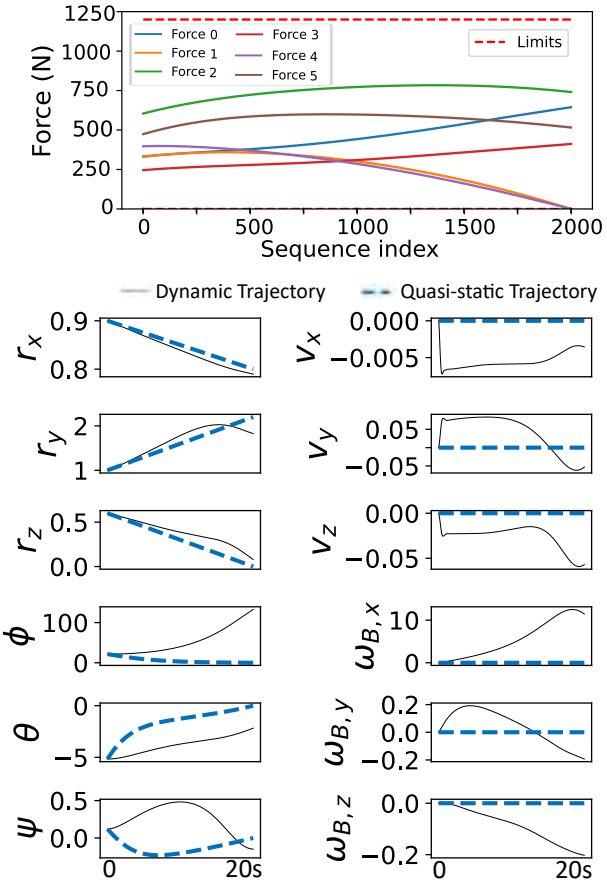

Figure 6. Example of calculated initial trajectory. Top: quasi-static force trajectory calculated using backward optimization. Bottom: comparison between quasi-static and dynamic trajectories. Positions are measured in meters and angles in degrees.

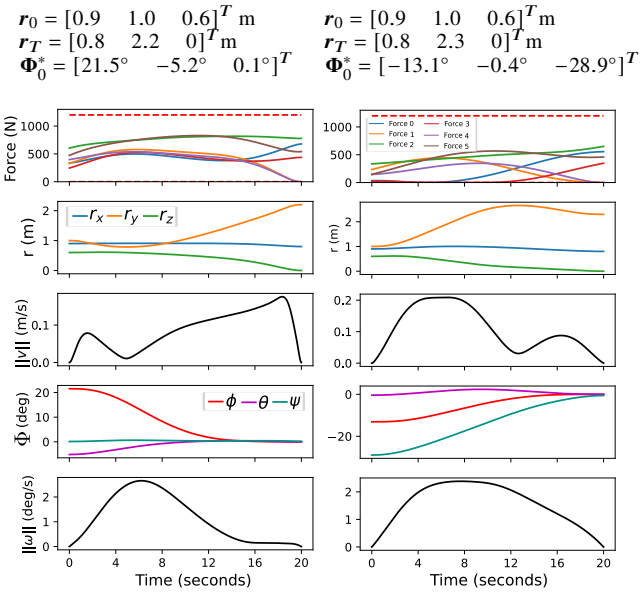

Figure 7. Two optimized trajectories starting from the same position with different initial orientations.

pose.

Although the left plot in Fig. 7 shows a shorter Euclidean distance between $\boldsymbol{r}_0$ and $\boldsymbol{r}_T$ compared to the right plot, the CasADi optimizer achieved only an acceptable level of convergence in the left case, while it successfully reached the optimal solution in the right case. This may explain why the linear velocity profile in the right plot is smoother than that in the left plot. After the optimizer converges, both methods lead to smooth force input trajectories $\{u_0^*, \ldots, u_T^*\}$. The top plots of Fig. 7 show the optimal input force. In method one (left plot), all six cables are used until the end effector reaches the installation plane, then only four cables are used. On the other hand, method two (right plot) achieves the same goal with a lower average input force, as it tends to sag at least one cable throughout most of the trajectory. Although splitting the trajectory into two phases requires running the trajectory optimization process three times: first to bring the end effector to the installation plane, then to travel within the plane, and finally to optimize the trajectory for the final pose, the process proves more practically feasible as it is more robust and converges faster.

6 Conclusion and Future Work

This paper investigated the feasibility of employing a six-cable CDPR for panelized building retrofits, with the goal of simplifying the robot installation and setup process, reducing costs, and simultaneously maintaining the essential functionalities required for building retrofits. Through simulation, we examined one specific cable arrangement, evaluated its wrench feasible workspace, and optimized trajectories within this workspace to transport the end effector from a starting position to the desired goal pose. Given the initial panel pickup position $\boldsymbol{r}_0$, desired panel position $\boldsymbol{r}_T$, and assuming that the panel will be installed plumb and level $\boldsymbol{\Phi}_T = 0$, the proposed method determines the optimal pickup orientation $\boldsymbol{\Phi}_0^*$ and computes the optimal continuous input force trajectory $\{u_0^*, \ldots, u_T^*\}$ that minimizes cable force, maintains the system within safe boundaries, and achieves the desired terminal pose.

This work primarily focuses on studying the feasibility of the six-cable CDPR in a construction setting, specifically investigating whether a dynamically feasible path exists to transport the panel from the bottom to the top. However, we do not address other real-world challenges, such as partial observability or external disturbances, which can significantly impact system performance. These aspects require further exploration and will be our future work.

Additionally, this study did not consider cable-to-cable collisions. Future research will address this limitation by exploring methods to adjust the positions of the anchors in order to avoid such collisions. Moreover, in the six-cable model, two cables must sag as the end effector nears the installation plane. Moving forward, we aim to investigate the sagging mechanism to better understand its effects on system stability and performance. Furthermore, We also plan to explore how the system can be adapted to handle larger-scale applications and more complex scenarios.

ACKNOWLEDGMENT

This research was supported by the DOE Office of Energy Efficiency and Renewable Energy (EERE), Building Technologies Office, under the guidance of Sven Mumme, and used resources at the Building Technologies Research and Integration Center, a DOE-EERE User Facility at Oak Ridge National Laboratory. Abstract –

Worker-robot collaboration (WRC) can enhance the efficiency and performance of construction robots in complex tasks and dynamic environments. The behavioral decision-making capabilities of robots are critical for them to effectively interact and collaborate with workers. This research presents a behavioral decision-making method for automatic construction robots. First, a semantic world model is introduced to represent the on-site WRC state with graph data structures. Then, a Learning from Demonstration (LfD) method is utilized for robots to acquire behavioral policy through worker demonstrations. Finally, behavioral decision-making for construction robots is achieved using graph-matching algorithms. The proposed method was tested and validated in a virtual reality environment through panel installation tasks. The results show a 90% success rate in extracting feasible and reproducible robot behavioral policies on a single demonstration. The proposed method is promising for enhancing the intelligence of construction robots and improving the safety and efficiency of on-site WRC.

Worker-robot collaboration; Construction robot; Behavioral decision-making; Semantic understanding

1 Introduction

Construction robots can address urgent issues in the construction industry, including low productivity, worker shortages, and occupational health concerns. However, the ever-changing nature of construction sites presents significant challenges for the effective deployment of construction robots on-site [1]. Worker-robot collaboration (WRC) can enable robots to adapt to dynamic construction environments by introducing workers' flexibility to help robots overcome the complexity and unpredictability of construction sites [2].

Recent studies are focusing on on-site WRC with automated construction robots collaborating with workers as teammates. These collaboration tasks include common activities such as welding [3], wall painting [4], and wooden structure assembling [5]. In WRC, construction robot needs to decide what to do and when to act to ensure both safety and the smooth progress of the collaboration. However, most construction robots in existing research rely on direct commands from workers and lack the flexibility and intelligence to boost productivity [6].

To enhance the efficiency and safety of WRC, it is essential for construction robots to possess behavioral decision-making capabilities. This involves selecting appropriate actions from their built-in skills based on the situation they perceive themselves to be in, which is crucial in dynamic environments [7]. Nevertheless, several challenges remain unaddressed for construction robots: first, how to establish a structured representation of the WRC situation; and second, how to map the WRC situation to appropriate behaviours.

The objective of this research is to propose a behavioral decision-making method for construction robots in on-site WRC. A semantic world model is proposed for WRC's scene understanding. Based on the model, behavioral policies can be learned from demonstrations and embedded into construction robots' knowledge base, ultimately supporting their behavioral decision-making. The remainder of this paper is structured as follows. A literature review is first made in Section 2. Then, the proposed method is introduced in Section 3, and experiments and results are discussed in Section 4. Finally, a conclusion is drawn in Section 5.

2 Literature Review

2.1 World model of robots in WRC

A world model refers to the information the robot has about the world around it, and that needs to be shared between several activities [8]. A well-defined world model is not only crucial for the robot to understand the scene and make behavioral decisions but also enhances its explainability [9].

Syntax-based world model interprets a scene as a sequence of events driven by the behaviors of agents. For instance, Pan et al. [10] developed a scene understanding method for construction robots utilizing syntax to outline

construction progress such as “Base setup” and “Framework setup.” Markov models are used to describe state transitions. Cunha et al. [11] adopted predicate symbolic representations to describe scenes and used a short-term memory layer to model state transitions.

A semantic world model analyzes a scene by leveraging the semantic relationships among entities to deduce the context. Niccolò et al. [12] modeled the assembly task with semantic descriptions, where assembly tasks are defined by the spatial relationships among components. This model was expanded into an enriched event chain model to describe state transition processes[13]. A semantic world model can also be used to guide robots in performing safe operations [14]. Markov processes and other stochastic models are used to describe state transitions within a semantic world model [15]. The semantic world model significantly outperforms the syntax-based world model in terms of reusability and scalability. However, existing semantic world models cannot characterize elements unique to the on-site WRC environment. Moreover, the transition path representations in current world models fail to account for the modeling of the concurrent operations of multiple agents, making them unsuitable for supporting construction robots' decision-making in WRC.

2.2 Behavioral policy for robots in WRC

A policy is a set of rules mapping the optimal behavior to the current state [15]. If an explicit world model is not provided, reinforcement learning (RL) is applied, allowing the robot to learn optimal policy through repeated interactions with the environment, guided by a defined reward function [16]. Nevertheless, designing a reward function for WRC is challenging, as it must account for factors related to both efficiency and safety. Additionally, RL-based decision-making is difficult to explain and may disrupt workers in WRC.

In scenarios where the decision-making process cannot easily be scripted or optimized, robots can learn the decision-making process from human demonstration [17]. The policy learned from the demonstration can be either probabilistic or deterministic. Probabilistic policy learning methods, such as Markov networks [18] and Bayesian networks, output a distribution of behaviors rather than deterministic actions. However, when demonstration data is limited, robots can only learn a deterministic behavioral policy. In these cases, the robot's policy can be represented using a finite state machine or a decision tree [19]. However, previous research rarely considers robot policies in WRC. On one hand, most world models are not designed for WRC scenarios that involve concurrent behaviors from multiple agents, making them unsuitable for supporting the robot's decision-making in on-site WRC. The other challenge is how to acquire demonstration data and learn behavioral policies from limited demonstration data for construction robots. These are the two central questions that need to be addressed in this research.

3 Method

The proposed robot’s behavioral decision-making method begins with the introduction of a semantic world model to represent the on-site WRC process. The world model abstracts unstructured WRC scenes and processes into structured data, enabling robots to establish semantic-based scene understanding and policy learning foundations. To facilitate behavioral policy learning from demonstrations, a virtual reality (VR) platform is developed to simulate the WRC environment, where workers demonstrate the robot’s behaviors through intuitive interaction. The behavioral policy is subsequently extracted from the demonstration data structured by the world model. Using the policy learned from the demonstration, construction robots can make behavioral decisions by matching their observation of the current WRC scene to the WRC state stored in the policy, thereby reasoning and determining their behaviors accordingly. The framework of the method is illustrated in Figure 1.

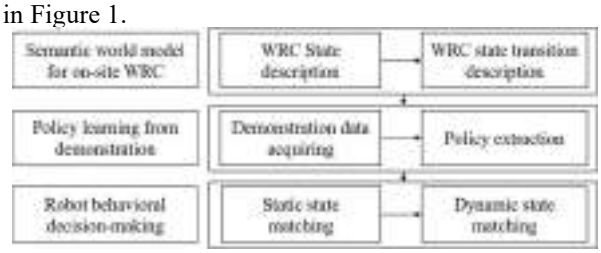

Figure 1. The framework of the proposed method.

3.1 Semantic world model for on-site WRC

3.1.1 Description of WRC state

The state of a static WRC scene is semantically described by the entities and their relationships within the environment. The entities involved in on-site WRC are identified and classified into three categories:

- **Agents**: Agents can proactively interact with other entities and drive the progress of on-site WRC, including workers and construction robots.
- **Movable objects**: Movable objects are entities that can be manipulated and relocated, including construction materials, tools, containers, etc.
- **Static Objects**: Static objects are entities that cannot be moved by agents or other objects, such as walls and floors.

Spatial relationships and kinematic relationships are defined to describe interactions between entities. A spatial relationship exists between entities that are in

spatial contact, whereas a kinematic relationship denotes movement constraints between entities (e.g., a tool being held by a worker). Since multiple semantic relationships can coexist between the same entities, a multi-graph is employed to model the static scene as $G_s = (V_s, E_s)$, where the nodes V_s represent the entities and the edges E_s represent the semantic relationships. An example of the semantic state description of a WRC scene is showcased in Figure 2, where the robot is holding a tube while the worker is touching it.

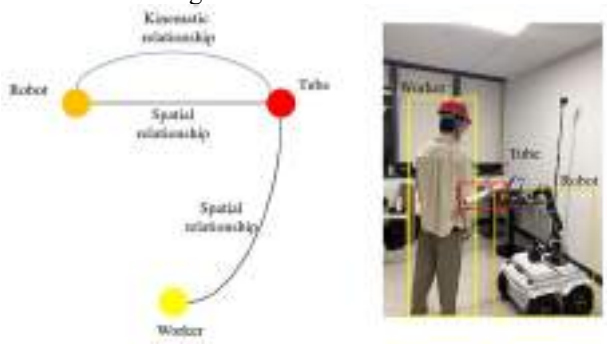

Figure 2. The semantic description of a WRC scene.

3.1.2 Description of WRC state transition

The description of WRC state transitions defines the evolution rules from one state to the next in the WRC process. The extended semantic event chain (ESEC) is introduced to describe the WRC process with concurrent agents' behaviors. ESEC models a WRC process as a quatrain (S, B, V, T), where:

- S is the set of semantic graphs representing WRC states.
- B is the set of agents' behaviors.
- V is the set of variables to be monitored during the WRC process.
- T is the set of transitions among WRC states within the WRC process.

A transition is defined by four parameters, denoted as (s, b, g, s'), where:

- s is the semantic graph before the transition.
- b is the behavior involved in the transition.
- g is the guardian condition, which determines whether the behavior can be executed.
- s' is the semantic graph after the transition.

To model a WRC process using ESEC, the WRC states in the process are serialized with an initial state and a final state identified as s_s and s_e respectively. Except for the final state, each state should have at least one associated transition to the next state. The end of a WRC process is signified by reaching the final state.

3.2 Behavioral policy learning from demonstration

A robot's policy is a mapping function that projects the state to the behavior, denoted as $s \rightarrow b$. This mapping relationship is explicitly defined in the ESEC model as a transition (s, b, g, s'). To learn the behavioral policy $s \rightarrow b$ from collaboration demonstration samples, the demonstration process is first abstracted using ESEC model to significantly reduces the state space of WRC. The behavioral policy is then extracted from the structured demonstration data.

3.2.1 Demonstration data acquiring

In the demonstration, the construction robot is controlled by a human operator, who invokes the robot's built-in behavior interfaces to collaborate with other workers. Essentially, the robot needs to replicate the behaviour policy adopted by the operator.

VR is considered a valuable tool for acquiring demonstration data due to its advantages in safety, cost-efficiency, and customization. This research creates a VR-based demonstration platform. The Unity engine is utilized to create a WRC environment with realistic physical effects. The OpenXR framework enables workers to move and interact with objects freely using controllers in the VR environment. The virtual construction robot is controlled by the Robot Operating System (ROS). Movable objects and static objects are modelled with necessary interaction functions to respond to the agents' behaviors. Semantic relationships are modeled according to their definition: a contact between two bounding boxes indicates a spatial relationship between the corresponding entities, while kinematic relationships are modeled with fixed joints between objects. The creation and deletion of the semantic relationships are controlled by specific events triggered by agents' behaviors.

During the collaboration demonstration, the following data will be recorded frame by frame: 1) entities and their relationships in the VR environment, 2) monitored variables, and 3) the virtual robot's behavior invocation events. The data will be stored along with timestamps in JSON format.

3.2.2 Policy extraction

To extract the policy from the demonstration data, the demonstration data is first processed into serialized key semantic graphs. Initially, entities and relationships in each frame are processed into semantic graphs. In two consecutive frames, if the semantic map of the latter frame undergoes any changes, it is extracted as a key semantic map. It should be noted that during the demonstration, the WRC state may undergo a rollback: for instance, a worker might pick up an object and immediately put it back down. The rollback state will

then be integrated with the historical state. Finally, the key semantic graphs are serialized into a tree structure based on their temporal order, as shown in Algorithm 1.

Algorithm 1 Key semantic graphs serializing

Input: $list_G = [G_0, G_1, G_2, \dots, G_n]$
  Initiate: $node_c = G_0$
  foreach G in $list_g$ **do**
    if $G = node_c$ **then**
      continue
    else if $G = node_c.parent$ **then**
      $node_c = node_c.parent$
    else
      if $\exists child = G, G \in node_c.children$ **then**
        $node_c = child$
      else
        add G to $node_c.children$
        $node_c = G$
      end if
    end if
  end if
Output: Serialize key semantic graphs

Furthermore, the transitions are defined based on the invoke records of the robot's behaviors to create an ESEC model. For each robot behavior b, the timestamp at which the behavior begins is used to find the preceding key semantic graph s and the succeeding key semantic graph s'. If multiple robot behaviours correspond to the same preceding and succeeding key semantic graph, this indicates that these behaviours are adjacent and can be considered as one combined behaviour. Lastly, guardian conditions are manually set, typically considering the WRC safety requirements [20]. The collection of all transitions $\{t_r\}$ that include robot behaviors constitutes the robot's behavioral policy.

3.3 Robot behavioral decision-making

With the policy learned from the demonstration, the construction robot needs to recognize the WRC state to map its behavior. Due to sensor limitations and the dynamic movement of agents and movable objects, entities and their semantic relationships may not be fully recognized. To address this issue, this section develops static and dynamic state-matching algorithms to match incomplete observation results into the WRC state.

3.3.1 Static state matching

To simplify the discussion, several assumptions about the robot's observations are made as follows:

- The entities presented in the ESEC model are perceptible.
- The observation result for an entity is binary: the entity is either observed or not.
- Some semantic relationships between entities are perceptible (e.g., all spatial relationships), referred to as R_p; the remaining semantic relationships are undetectable due to the limitations of the robot's perception method, denoted as R_u.
- The observation result for a semantic relationship is binary: the relationship is either observed or not.

The above assumptions are made based on the current state of robotic perception technologies and methods, including computer vision, LiDAR, force sensors, etc. For a given WRC state s, its semantic graph is denoted as $G_s = (V_s, E_s)$, and the corresponding observation result is represented as $G_o = (V_o, E_o)$. Based on these assumptions, the observed graph is reasoned to be a subgraph of the actual WRC state semantic graph, i.e. $V_o \in V_s, E_o \in E_s$. The observed graph is then matched to all candidate WRC state graphs from the ESEC model according to Algorithm 2.

Algorithm 2 Static graph matching

Input: $G_0 = (V_o, E_o)$, $\{S\}$
  Initiate: $\{S_m\} = \emptyset$
  foreach $s \in S$ **do**
    $G_s = (V_s, E_s)$
    match_flag = True
    foreach $v_o^i \in V_o, v_o^j \in V_o, e^{ij} = (v_o^i, v_o^j)$ **do**
      if ($e^{ij} \in E_s$ **and** $e^{ij} \in E_o$) **or**
      ($e^{ij} \notin E_s$ **and** $e^{ij} \notin E_o$) **or**
      ($e^{ij} \in E_s$ **and** $e^{ij} \notin E_o$ **and** $e^{ij} \in R_u$) **then**
        continue
      else
        match_flag = False
        break
      end if
    end for
    if match_flag = True **then**
      add s to S_m
    else
      pass
    endif
  end for
Output: Candidate matched states $\{S_m\}$

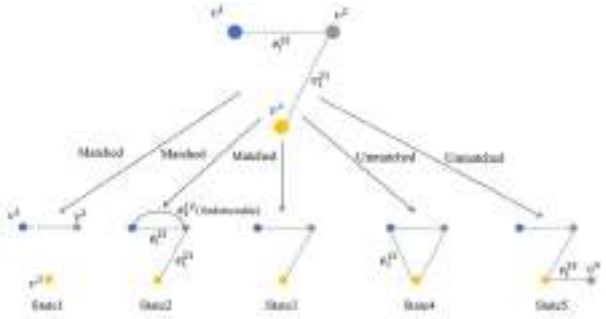

Figure 3. The static state matching process.

3.3.2 Dynamic state matching and behavior decision-making

The construction robot can reason from its historical observations to further narrow down the candidate WRC states. For two semantic graphs G_1 and G_2, their semantic difference is defined as the symmetry difference of their edge sets, i.e. $D(G_1, G_2) = E_1 \triangle E_2$ Consider two adjusted observed semantic graphs $G_o^{i-1} = (V_o^{i-1}, E_o^{i-1})$ and $G_o^i = (V_o^i, E_o^i)$, their static state match results are S_m^{i-1} and S_m^i. The following conditions must be satisfied for matching a state pair s^{i-1}, s^i to the observation pair G_o^{i-1}, G_o^i:

- $s^{i-1} \in S_m^{i-1}, s^i \in S_m^i$;
- $D(G_o^{i-1}, G_o^i) = D\left(G(s^{i-1}), G(s^i)\right)$;
- A transition exists from s^{i-1} to s^i.

Figure 4 depicts a dynamic state match example, where the observed semantic graph G_o^i is statically matched to s_2 and s_5, and G_o^{i-1} is statically matched to s_3 and s_4. According to the dynamic match rules, G_o^i is only dynamically matched to s_5 since no transition exists from s_3 or s_4 to s_2. If the dynamic matching results filter out all static matching results, dynamic matching will not be performed in the next keyframe.

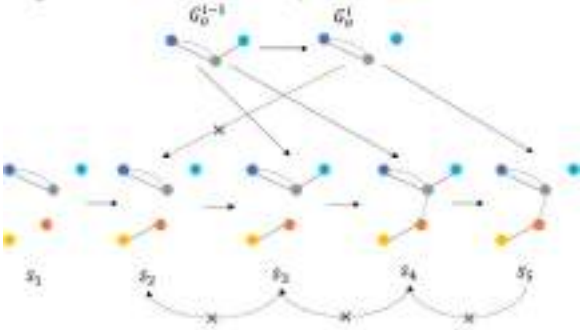

Figure 4. The dynamic state matching process.

Finally, the construction robot decides its behavior based on the matched possible WRC states and its policy. If only one WRC state is matched, or if multiple WRC states are matched but mapped to the same behavior, that behavior will be the decision-making result. Otherwise, if the candidate WRC states map to multiple behaviors, the default waiting behavior is adopted to avoid any risks.

4 Experiment and Results

An experiment was conducted to validate the feasibility of the proposed method. A typical WRC scenario was simulated in a VR environment, replicating a wall panel installation task. Wall panel installation is a common and representative task in decoration construction, which requires the worker to move the panel to the designated place on the wall and fix it using nails. Adopting a WRC method, the construction robot acts as a collaborative teammate, responsible for moving and positioning the panel to reduce manual labour and mitigate safety risks.

The experiment scene is illustrated in Figure 5. The panels and a nail gun are placed on a worktable. Workers can pick up these items and use the tools using VR controllers. The construction robot employed in the experiment is configured as a classic mobile manipulator with a suction cup serving as its end-effector. The construction robot has three built-in skills: 1) controlling the suction cup to attach or release the panel, 2) moving the robotic arm to a designated configuration, and 3) driving the chassis to a designated location. The installation place is assumed to be known by the robot.

Figure 5. The experimental setup.

The experiment consists of two phases. In the first phase, a demonstration experiment is conducted, where the construction robot's behavior is controlled by an operator. In the second phase, the construction robot collaborates automatically with the worker using the behavioral policy learned from the demonstration to perform an identical task.

10 subjects were invited to participate in both the demonstration experiment and the collaboration experiment, while an additional 20 subjects were invited to participate in the collaboration experiment. None of them had prior experience in collaborating with construction robots. Before the formal experiment, the subjects were given the opportunity to practice in the VR environment to ensure they understood the collaboration objectives and could use the VR devices correctly. After the experiment, the participants were interviewed to gather their feedback on the demonstration process and their experience in collaboration with the robot.

4.1 Demonstration results

In the demonstration experiment, each subject was required to perform two demonstrations to ensure that sufficient demonstration data was collected. Collectively, the 10 subjects contributed to 20 demonstration processes. The general WRC workflow is as follows: the subject

first grabs the panel and hands it over to the robot. The robot then moves the panel to the designated installation spot on the wall. Once in place, the subject uses a nail gun to secure the panel with four nails, one at each corner.

Even though the process appears intuitive, subjects still collaborated with the robot in a variety of ways, leading to significant diversity in the number of states within the ESEC models. The ESEC models of these demonstrations contained up to 28 WRC states and at least 14 WRC states. For example, some subjects chose to grasp both the panel and the nail gun simultaneously to avoid repeatedly picking up the nail gun. During the fixing stage, some subjects nailed all four nails before commanding the robot to release the panel, while others nailed two nails first and secured the remaining two after the robot released the panel and moved away. While either approach is feasible to complete the task, this flexibility poses a challenge for the construction robot to understand the variant WRC process.

In contrast to the diversity observed in collaboration, the construction robot consistently exhibits four distinct behaviors across various collaborative demonstrations. These four behaviors are defined as grasp, position, release, and reposition. Using the ESEC model, these behaviors and their corresponding prerequisite WRC states can be extracted. While the strategies derived from different demonstration data vary, a representative example is analyzed below and depicted in Figure 6.

- Grasp: Grasping creates a kinematics relationship between the robot and the panel. The pre-state of grasp requires the spatial relationship between worker and panel, robot and panel, and a kinematics relationship between worker and panel, which means that the worker is holding the panel while it is touching the robot.
- Position: Positioning includes moving the robotic arm to the installation posture and moving the chassis to the installation position. The pre-state of positioning requires a kinematic relationship between the robot and the panel, but no spatial or kinematic relationship exists between the worker and the panel.
- Release: Releasing removes the kinematic relationship between the robot and the panel. In most demonstrations, the pre-state of releasing requires four nails establishing a kinematic relationship with the panel and the work surface.
- Reposition: Repositioning includes moving the chassis to the receiving position and moving the robotic arm to the receiving posture. The repositioning behavior typically follows adjacently the releasing behavior.

The feasibility of demonstrated behavioral policies will be further validated in the collaboration experiment.

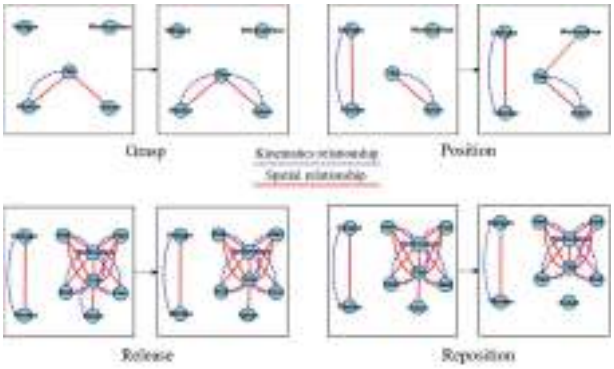

Figure 6. The behavioral policy of the construction robot learned from the demonstration.

4.2 Collaboration results

The collaboration tasks in the experiments were scaled from installing one single panel to four panels to test the robustness of the demonstrated behavioral policy. In this setup, the robot autonomously collaborates with subjects based on its observations and behavioral policies demonstrated. To simulate the construction robot's observation, a virtual camera is deployed. The camera's view follows the robot's end-effector, as illustrated in Figure 7. Entities not within the field of view along with their associated relationships will be ignored. A simulated force sensor provides information on whether a panel is attached to the robot's end-effector, indicating the kinematic relationship between the robot and the panel.

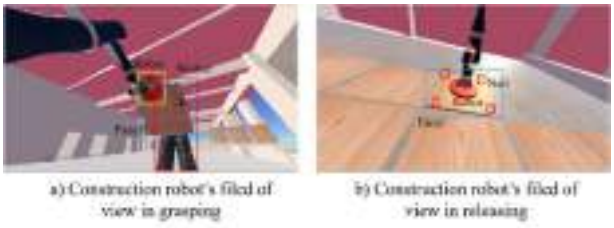

Figure 7. Construction robot's field of view in collaboration.

The 10 subjects who participated in the demonstration experiments were once again invited to participate in the collaboration experiment to validate the feasibility of the policies they demonstrated. The results of the collaboration experiment revealed that 18 out of the 20 policies were feasible, enabling the robot to successfully collaborate with the workers. However, in the remaining two unfeasible policies, the prerequisite states for some of the robot's behaviors were not correctly represented in the semantic graph. For instance, a subject demonstrated the positioning behavior while remaining close to the robot, resulting in an erroneous spatial relationship

captured in the semantic graph as the prerequisite state for the behaivor. This inconsistency hindered the robot's ability to align its observations with the appropriate WRC state during the collaboration experiments.

Excluding the two unfeasible policies, among the remaining 18 collaborations with feasible policies, the tasks were successfully completed on the first attempt in 16 instances, with the two failures resulting from human error. From these feasible policies, a representative behavior policy was adopted by the robot to collaborate with the additional 20 subjects. The success rate on the first attempt was 70%, lower than the 89% observed among the 10 subjects who had participated in the demonstration experiments. Through repeated trials, all subjects ultimately completed the tasks successfully.

Since the ESEC model is explicit, the robot's behavioral decision-making process is transparent. While the construction robot's observation is often incomplete due to limitations in its field of view and the lack of detection methods for most kinematic relationships, static and dynamic matching enable the robot to match its observation to the correct WRC states. Static matching first matches observed semantics with candidate WRC states, while dynamic matching further filters the matched states. Figure 8 illustrates the behavioral decision-making process during a collaboration.

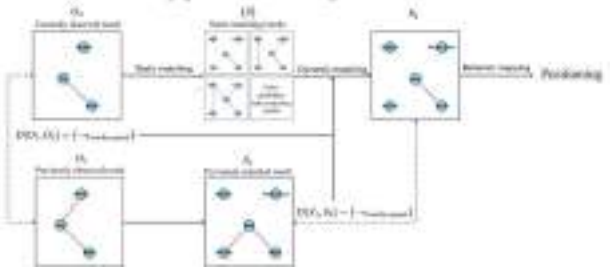

Figure 8. The behavior decision-making process in the collaboration experiment.

4.3 Discussion

The experiments utilize VR environments in both demonstration and collaboration experiments, simulating a complex and dynamic WRC task, wall panel installation. This task involves both spatial and temporal interactions between the worker and the robot, with the workflow being highly diverse and dependent on the strategies employed by the collaborating worker.

To validate the effectiveness of the proposed method, a series of measures have been implemented to ensure that the VR environments replicate real-world WRC conditions as closely as possible, including 1) utilizing the same control logic for the virtual robot as its real-world counterparts, 2) immersive VR perspectives and physical interaction logic for the participants, and 3) virtual sensors that emulate the functions and limitations of real sensors. The primary distinction from the real world lies in the simplification of the robot's perception process. In reality, the robot's detection methods (e.g. computer vision) may not always be accurate, potentially leading to mismatches between observations and correct states. In the VR environment, however, the robot's observations are always accurate. While it is reasonable to expect that the robot's observations will be accurate in most cases, establishing error recovery and correction mechanisms for behavioral decision-making may be essential for real-world construction robots.

The experiments also emphasize the flexibility of the proposed method in on-site WRC applications. In most cases, the participants need only perform a single successful demonstration to construct the robot's behavioral policy. Although the behavioral policy learned from demonstrations is task- and robot-specific, as workflows and built-in skills may vary across WRC tasks and robots, the ESEC model itself is task- and robot-agnostic. This enables the demonstration and learning process to be generalized to various construction works (such as bricklaying and welding) and construction robots (humanoid robots, etc.), allowing for the rapid establishment of corresponding behavioral policies in WRC.

The demonstration itself also provides additional benefits to on-site WRC. First, all subjects reported that the VR-based demonstration was intuitive and user-friendly. Second, subjects who engaged in the demonstration indicated that it helped them better understand the robot's behavior and intentions, thereby enhancing their sense of safety and performance in the collaboration experiments. This suggests that the proposed method holds promise for improving both safety perception and performance when applying on-site WRC.

5 Conclusion

This research proposes a behavioral decision-making method for constriction robots in on-site WRC. The proposed method comprises three main components: a semantic world model for on-site WRC, behavioral policy learning from demonstration, and a robot's behavior decision-making algorithm. The validation of the proposed framework was conducted in a virtual reality environment, exemplified by a panel installation task. The experimental results demonstrate that the framework effectively supports the robot's comprehension of complex and dynamic WRC processes, enabling accurate behavioral decision-making during autonomous collaboration with workers. Additionally, the results show that the demonstration process enhances workers' understanding of the robot's behavior and increases their sense of safety during collaboration.

The limitations of this research are summarized as follows. Firstly, the proposed method is only validated in a VR environment with simulated robots and sensors, where the impact of perception on robot decision-making may have been underestimated. Future research will focus on testing the decision-making method in real-world settings to assess the influence of environmental disturbances. Secondly, the framework currently lacks support for collaborative recovery in the event of unforeseen and erroneous WRC states. Future research can aim to integrate recovery mechanisms into the robot's policy. Finally, the experiments only involve a single worker and one robot. While the framework theoretically supports collaboration among multiple agents, the complexity of collaboration increases exponentially with the number of entities involved in the WRC process. Therefore, it is vital to validate the framework's accuracy and operational efficiency in on-site WRC scenarios involving more workers or robots.

Abstract -

In construction, most existing research on rebar placement focuses on guardrail system for large-scale planar slabs or multi robot arm system for off-site rebar cage assembly, frequently utilizing gantry systems. However, their substantial setup time and spatial requirements greatly reduce their suitability for smaller-scale or more spatially constrained settings. This limitation is particularly pronounced in on-site application where the rebar installation of vertical structural elements occurs in fragmented and restricted workspaces, limiting the applicability of existing guardrails or multiple robotic systems. To address this gap, this study investigates the feasibility of employing a single arm robotic system to grasp and position rebar for vertical structural components. One critical challenge in this context is to account for rebar deflection during rebar placement operations. Moreover, existing analytical equations do not provide sufficiently accurate deflection estimates. To address this problem, a neural network model was developed to predict rebar deflection across a range of sizes and lengths, allowing the robot to adapt its position dynamically according to the target location. The proposed model achieved an R^2 accuracy of 0.9714 and outperformed other models in both the ±0.01m and ±0.092m thresholds, demonstrating its effectiveness in providing precise deflection estimates. This level of precision facilitates efficient robotic rebar placement using a single-arm system.

1 Introduction

The construction industry has long been recognized as a labor intensive and inherently hazardous field, characterized by physically demanding tasks, challenging work environments, and a high risk of injuries [1]. Over the years, researchers and innovators have directed significant efforts toward addressing these challenges through the development and deployment of construction robots. Such technologies promise to mitigate labor shortages, enhance workplace safety, and boost operational efficiency.

However, despite these advancements, the widespread integration of construction robots remains limited, particularly in structural work, an essential component often found on the project's critical path. Reinforcement bar (rebar) placement, specifically, is a crucial structural activity directly influencing the structural integrity, durability, and safety of reinforced concrete structures. Manual rebar placement can be labor-intensive, prone to errors, and subject to variable quality. Automating rebar placement presents significant opportunities for improving industry-wide efficiency, precision, and safety, marking it as a high-priority area for innovation.

Most existing research has focused on horizontal structures such as planar slabs and precast panels, while vertical structures have received far less attention. Yet vertical components which are on-off or low-repetition require in-situ casting, such as soil-retaining walls and water tanks that common in housing and infrastructure project. For infrastructure projects in particular, most of vertical elements are also cast in situ, because most of them are designed as one-off components. Moreover, Many existing robotic solutions for rebar placement are complex and space-intensive (e.g. gantry with multi-arm), requiring extensive setup and wide, unobstructed work areas that typical construction sites cannot provide. To address these shortcomings, this study investigates the feasibility of a single-arm robotic system for rebar placement in vertical structures.

In horizontal assemblies, rebar deflection is limited to the lifting phase and is naturally resolved upon placement. However, for vertical structures, deflection remains a critical factor that must be addressed throughout the placement process. Existing research primarily focuses on deflection in reinforced concrete or steel beams, with no attention given to the deflection behavior of standalone rebars. Furthermore, existing formulas are inadequate for accurately predicting rebar deflection due to the irregular shape of rebar. Therefore, the primary objective of this study is to identify an effective method to estimate deflection under cantilever conditions, providing a foundation for single-arm robotic rebar placement in vertical structural components.

2 Literature Review

2.1 Robotic or automation for rebar placement

Some rebar palcement system have been explored and developed over the past few decades, for example the IronBot [2] was used for bridge deck rebar installation and the multi-manipulator gantry system described by Mahdi Mo-

meni et al. [3] for prefabricated rebar cages, are effective in controlled factory or open-site environments. However, their extensive setup time, large footprint, and need for clear working envelopes limit their practicality on most housing and many infrastructure projects, where sites are fragmented and space constrained

Additionally, Zhang et al. [4] use a off-the-shelf kuka robot arm for tasks like rebar picking, transportation, and placement. However, the study used short rebars for demonstration, allowing deflection to be ignored, and was limited to planar mesh construction. Dörfler et al.[5] presented the Mesh Mould system, an innovative mobile robotic setup capable of fabricating vertical freeform structural wall on site. However, the system relied on short steel wire segments rather than the long rebars conventionally employed in typical construction practices.

In summary, existing automated rebar placement systems primarily focus on planar slab construction, often using short rebars that do not account for deflection. Currently, no research explores the use of a single-arm robotic system for long rebar placement in vertical structures.

2.2 Estimation of deflection of beam

The Euler–Bernoulli beam theory is a fundamental method for analyzing beam deflection. It assumes linear elastic behavior, small deflections, and negligible shear deformation, making it suitable for long, slender beams under relatively small loads [6]. The relationship between bending moment and curvature is expressed in Equation 1:

$$M = EI\frac{d^2w}{dx^2} \tag{1}$$

where M is the bending moment, E is Young's modulus, I is the moment of inertia, and w is the deflection.

Elementary beam theory neglects the square of the first derivative in the curvature formula, making it unsuitable for scenarios involving large deflections. In contrast, large deflection theory considers both initial and deformed configurations of the beam axis [7], capturing phenomena like significant rotational effects in flexible structures. Due to the mathematical complexity of these nonlinear equations, analytical solutions are often impractical, and numerical methods—such as Finite Element Analysis (FEA) tools like ANSYS and ABAQUS—are widely used. For instance, Yuan et al. [8] applied numerical methods to analyze steel beams with octagon-web designs, achieving improved accuracy in deflection predictions.

While beam deflection theories are well-studied in structural engineering, most research focuses on composite structures like reinforced concrete or steel beams with larger moments of inertia. However, there is a notable lack of investigation into the deflection behavior of rebar as an individual structural element. This gap highlights the need for focused research in this area.

3 Methods

3.1 One-arm robot for rebar placement

In this study, a single robotic arm is used for rebar placement, with an RGB-D camera detecting the position and intersection of the rebar. Figure 1 shows two cases of rebar gripping and placement: in the top diagram, the robotic gripper holds the rebar at its center, causing the ends to bend downward; in the bottom diagram, the gripper holds the rebar at one end, allowing the opposite end to deflect freely. The dashed red line indicates the target position, and the solid green line represents the actual deformation when gripped.

The workflow is outlined in Figure 2. After receiving the rebar's target size and location, the robot retrieves the rebar and moves it to the intended position. Using vision-based detection, the system calculates the error between the actual and target positions. If the error exceeds 10 mm, feedback is sent to adjust the rebar's position until it falls within the fluorescence zone, ensuring accurate placement.

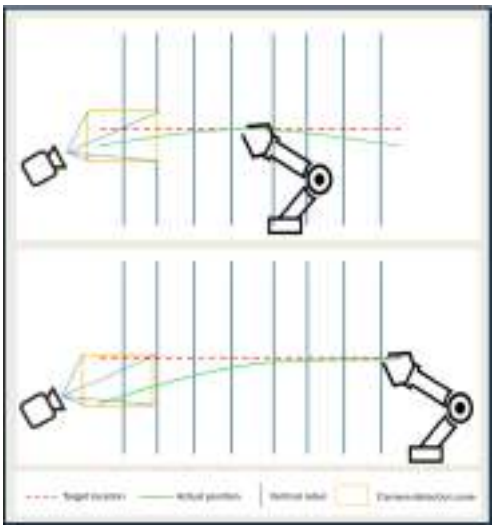

Figure 1. Two scenarios of one robot arm rebar placement system

Accurate deflection estimation is crucial for two reasons: 1) keeping the intersection point within the camera's detection range ensures proper operation, and 2) improved estimation increases the likelihood of errors being within the 10 mm threshold, reducing repositioning.

The Intel RealSense D435 camera, with a horizontal FOV of 69° and vertical FOV of 42° is used [9]. The detection zone can be calculated using Equation 2 [10]:

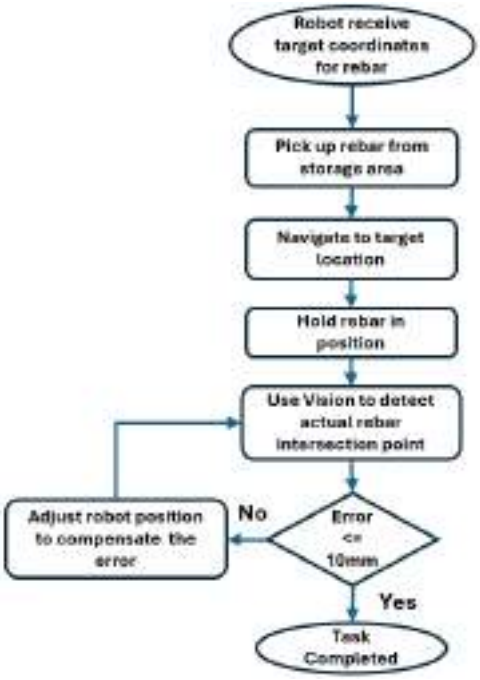

Figure 2. Flow chart for rebar placement

$$\text{Dimension} = 2 \times \text{Distance} \times \tan\left(\frac{\text{FOV}}{2}\right) \quad (2)$$

Where dimension is either Width (using Horizontal FOV) or Height (using Vertical FOV).

For example, as shown in Figure 3, positioning the camera 0.30 m from the target yields a viewing window of roughly 0.41 m × 0.23 m. After restricting analysis to the central 80 % region of interest (ROI)[9], permitting detection of deflections up to about 0.092 m below the target binding point; larger sag will lie outside this effective window. Moving the camera farther back can enlarge the coverage area but at the cost of potential loss of image fidelity [11].

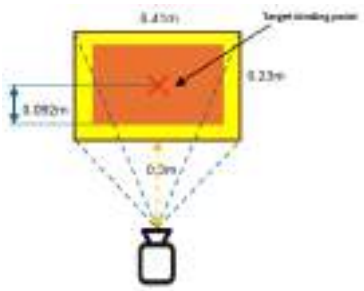

Figure 3. Illustration of camera detection zone

While no specific tolerance for rebar spacing is stated in Eurocode or Singapore Standards, common practice in Singapore allows a tolerance of ±10mm from the designed spacing. In the United States, according to ACI 117-10 [12], the tolerance for wall thicknesses between 4 to 12 inches is ±3/8 inch (approximately 10mm). Thus, ensuring the rebar deflection estimation remains within 10mm of the target location could significantly minimize the need for repeated repositioning of the robot gripper and improve operational efficiency.

3.2 Estimation of rebar deflection

In this study, four different models were developed to predict deflection behavior: two theoretical models—the Euler-Bernoulli equation and large deflection theorem conducted in ANSYS, and two data-driven models—a nonlinear regression model and a neural network model—built using empirical data from experimental testing.

Model accuracy was judged by the coefficient of determination (R^2), which measures the proportion of variance in the dependent variable explained by the independent variables, and the mean absolute error (MAE), the average magnitude of prediction errors. Additionally, two threshold - ±0.092 (camera detetction zone) and ±0.01 m (construction tolerance) were also applied to verify the performance of the predictions stayed within practical limits.

For the purposes of this study, it was assumed that the rebar is firmly grasped by the robotic gripper, simulating a cantilever boundary condition. The estimation process utilized two input variables: the length and diameter of the rebar, with the output being the deflection of the rebar. Common material properties were applied across all techniques, including an elasticity modulus of 200 GPa, a density of 7850kg/m3, and a gravitational acceleration of 9.81m/s2.

3.2.1 Theoretical and numerical estimation

Initial deflection estimations were conducted using two primary approaches: the Euler–Bernoulli beam theory and the finite element method (FEM) performed in ANSYS. The Euler–Bernoulli beam theory was first employed, providing a theoretical framework based on assumptions of linear elasticity and small deflection behavior. The maximum deflection $\delta_{\max}$ under self-weight was calculated using the equation 3:

$$\delta_{\max} = \frac{\omega L^4}{8EI} \quad (3)$$

where ω is the distributed load, L is the length of the rebar, E is the modulus of elasticity, I is the moment of inertia.

To address potential geometric non-linearity, the large deflection theorem was applied. This approach considers

large displacements and provides more accurate predictions for long rebars. The large deflection analysis were performed using ANSYS to supplement the theoretical models and provide a computational perspective on deflection behavior (Figure 4).

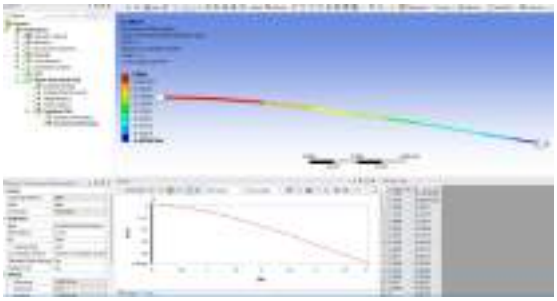

Figure 4. ANSYS analysis of rebar deflection

3.2.2 Experimental data collection

To validate the theoretical predictions and provide data for subsequent nonlinear regression analysis and neural network training, an experimental study was conducted. Rebars of varying lengths and diameters were tested under self-weight in a cantilever setup, where one end was securely fixed to a workbench using two clamps, and the other end was left free to deflect, as illustrated in Figures 5. Deflections at the free end were measured using laser displacement sensors (Leica DISTOTM X4).

Figure 5. Rebar deflection experiment set up

The experiment involved a total of 27 rebars, with diameters ranging from 10mm to 32mm and lengths ranging from 2.5m to 4m. Each rebar was tested multiple times (4-6 trials) at different cantilever lengths, resulting in a total of 154 data points. These measurements served as the foundation for evaluating the accuracy of the theoretical models and for developing data-driven predictive methods.

3.2.3 Training of Nonlinear Regression Model

To predict rebar deflection, a nonlinear regression model was developed using experimental data. The relationship between the key inputs—rebar length (L) and diameter (d) of the rebar—and the deflection $\delta_{\max}$ was modelled using the "`curve_fit`" function from Python's SciPy library. This regression analysis aimed to find the best-fit equation by minimizing the residual error between the predicted and observed values, producing a model that accurately reflects real-world behavior. The dataset was randomly split into 70% for training and 15% for testing using the "`train_test_split`" function from Python's scikit-learn library. The training set and testing set are the same for both nonlinear regression model and neural network model. The remaining 15% is validation set, which is only used in neural network model training.

The equation for maximum deflection is expressed in the general form:

$$\delta_{max} = aL^b d^c \tag{4}$$

where a, b, and c are coefficients of the regression.

Considering the mechanics of deflection, it is influenced by the rebar's self-weight (proportional to its density) and length, while being inversely proportional to material stiffness and cross-sectional properties. Incorporating these relationships, the equation is refined as:

$$\delta_{\max} = e\frac{\rho g L^f}{E d^h} \tag{5}$$

Where ρ is density of the material, g is the gravitational acceleration, E is the modulus of the elasticity. and e, f, and h are coefficients to be determined through regression.

This refined equation links deflection to fundamental physical parameters, ensuring the model aligns with theoretical expectations. By determining the values of e, f, and h through regression analysis, providing a practical equation for estimating rebar deflection under self-weight.

3.2.4 Training of Neural Network Model

The predictive model for estimating deflection employs a neural network architecture designed to capture the relationship between two primary input features: Diameter and Length. As shown in Figure 6, the network consists of a single hidden layer with 256 neurons, utilizing the ReLU activation function to learn complex, non-linear relationships. The final output layer contains a single neuron without an activation function, suitable for regression tasks.

The hyper-parameter tuning process was conducted to optimize the neural network architecture for deflection prediction. Various configurations were evaluated, including single-layer and multi-layer architectures, with a single hidden layer selected for its simplicity and performance. The number of neurons was varied from 64 to 512, with 256 neurons chosen as the optimal configuration. Regularization methods such as L2 regularization (0.01 to 0.0001) and dropout (0.01 to 0.5) were tested but excluded in the final model as they did not improve performance. The Adam optimizer and mean squared error (MSE) loss function ensured efficient convergence.

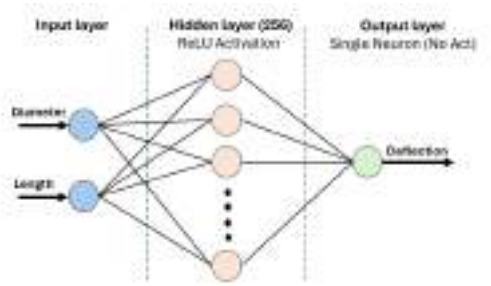

Figure 6. Neural Network Architecture

4 Results

4.1 Results of different models

The graph in Figure 7 illustrates the deflection of seven different rebar diameters under self-weight in a cantilever boundary condition, as predicted by the Euler–Bernoulli equation, FEA (large deflection), non-linear regression model, neural network model, and the actual experimental measurements. For the non-linear regression and neural network models, data from only the first trial run are presented in the graph. Trend lines are included for each model to improve visualization and facilitate a clearer comparison of accuracy among the four predictive models.

In addition, comprehensive evaluations were conducted across various diameters and length ranges using all available data points. Metrics including R^2, MAE, and the percentages of predictions falling within two accuracy thresholds (±0.092 m and ±0.01 m) were computed for each method—the Euler-Bernoulli equation, the non-linear regression model, and the neural network model. These results are summarized in Tables 1 and 2, with the best-performing method in each category highlighted in bold. However, the FEA was excluded from this detailed analysis due to the significant computational time required to run simulations. Running simulations for all 154 combinations of diameters and lengths to calculate comparable values was deemed impractical.

For both the non-linear regression and neural network models, training, validation, and testing datasets were randomly assigned. To ensure robustness, additional five trial runs were conducted for each model, using identical datasets across both models in each run. This approach also helps to verify that if the result in Table 1 was representative of the overall models' performance. The data presented here is derived from the testing dataset, providing a more reliable basis for comparison between the non-linear regression and neural network models. A detailed summary of these results is provided in Table 3.

4.2 Regression equation of non-linear model

To develop the regression model, parameters e, f, and h were estimated for each trial, and the ressult were listed on Table 4. These parameters define the model's ability to relate the input variables to the target output. The average values of these parameters were used to construct the regression equation, which is expressed as Equation 6.

$$\delta_{\max} = 10\frac{\rho g L^{3.61}}{E d^{1.75}} \tag{6}$$

4.3 Model fitting of neural network

Figure 8 shows the training and validation loss curves, which are closely aligned, indicating that the model generalizes well to unseen data. Both loss curves drop sharply

5 Discussion

5.1 Analysis and comparison of model results

Figure 7 shows that both the Euler–Bernoulli and large deflection models closely match the actual deflection values for shorter rebar lengths. However, as the rebar length increases, these models increasingly underestimate deflections, resulting in conservative predictions.

In contrast, the non-linear regression and neural-network models both sustain high predictive quality over the full span of rebar diameters and lengths: their trendlines track the measured deflections closely, confirming their superior accuracy and robustness in modelling deflection behaviour for a wide range of geometries.

Detailed numerical comparisons are presented in Tables 1 and 2. Both the neural network and non-linear regression models generally achieved higher R^2 values than the Euler–Bernoulli equation across every diameters and lengths. Diameter-wise, the non-linear regression model

has a slight edge over the neural network for several sizes, whereas length-wise the neural network leads in all categories except the 3–3.5 m interval.

In terms of MAE, the neural network consistently produced the lowest values across both diameter and length ranges, , except for the 3-3.5 m, indicating its superior absolute accuracy. The non-linear regression model also consistently performed better than the Euler–Bernoulli equation, highlighting the inherent limitations of linear-elastic assumptions for predicting complex deflection behaviors.

Most importantly, when evaluating performance based on practical accuracy thresholds (±0.01 m and ±0.092 m)—a key focus of this study—the neural network and non-linear regression models clearly outperformed the Euler–Bernoulli equation. Under the stringent ±0.01 m criterion, the neural network delivers the highest within-tolerance rate for almost all lengths and diameters. With the more lenient ±0.092 m threshold, both data-driven models achieve near-perfect accuracy, far surpassing Euler–Bernoulli—particularly for the longer bars.

A notable discrepancy is observed for parameters of 10 mm diameter and 3–3.5 m length, where the neural network model underperforms relative to the nonlinear regression model, despite its otherwise comparable or superior performance. This exception is likely a training-specific artefact: the particular network realisation appears to have missed one or two points in that band. To test whether this weakness is systematic, we retrained both models five times on identical, randomly drawn training–testing splits and compared with non-linear regression model with same testing set in each run.

As Table 3 shows, across the five runs, each model sustained an average testing R^2 values of approximately 0.97. The neural network further lowered the MAE by about 4.5 mm relative to the non-linear regression. For the broader ±0.092 m threshold, both models achieved similarly high accuracy, with the neural network slightly ahead (99.17%) compared to the non-linear regression model (98.33%). However, for the stricter ±0.01 m threshold, the neural network significantly outperformed the non-linear regression model, achieving nearly double the percentage of accurate predictions (54.17% vs. 28.33%). This substantial difference highlights the neural network model's greater capability in capturing subtle variations in rebar deflection, and the earlier 3–3.5 m anomaly is a model-realisation outlier rather than an inherent limitation.

In summary, both the non-linear regression and neural network models demonstrate superior robustness in predicting rebar deflection and consistently outperform the numerical models in all metrics. However, the neural network model excels in fine-grained precision, making it the most effective approach for accurate rebar deflection estimation.

5.2 Factors influencing rebar deflection

One possible explanation for the increased deflection is the fact that rebar is not perfectly round. The rebar used in the test complies with the BS4449:2005 standard (Grade: B500B) and features transverse and longitudinal ribs on its surface, which are designed to enhance the bonding between the concrete and the rebar [13]. However, these ribs are not accounted for in the estimated mass or cross-sectional area when using the nominal diameter, as the actual core diameter is slightly smaller than the nominal diameter. This discrepancy is illustrated in Figure 9 [14]. The irregular shape is likely a primary factor contributing to the larger deflection observed compared to theoretical predictions based on simulations or calculations assuming a regular, perfectly round steel bar. The irregularities in the shape lead to a non-uniform distribution of material. The effective moment of inertia will likely be lower than that of the nominal circular shape due to the reduced symmetry and possible loss of material at certain points.

Figure 9. Actual cross section of rebar

Additionally, Orientation or gripping point may also influence deflection, but consistent orientation is impractical on site, so bars were randomly oriented for testing. The measured deflection data, presented in Figure 7, were obtained from rebars of varying sizes and orientations. Although some variation exists, the data points consistently follow a similar trend, indicating that orientation is not a critical factor influencing deflection.

In conclusion, irregularities in rebar geometry pose significantly challenges for accurate prediction of deflection using numerical models, as indicated by the consistently large MAE observed across different rebar sizes. These results underscore the necessity for developing more advanced predictive models that effectively account for geometric irregularities.

5.3 Impact to the robot rebar palcement

With the improved accuracy in rebar deflection estimation, the use of a single robotic arm for rebar placement

becomes a viable solution. The higher prediction accuracy increases the likelihood of maintaining deflection within the required tolerance, minimizing the need for repeated intersection detection and position adjustments. This enhancement streamlines construction workflows, improving both efficiency and precision.

Additionally, accurate prediction of rebar deflection plays a critical role in other stages of rebar handling. For example, the motion planning of the robotic arm must consider predicted deflection to avoid collisions with objects during movement. Deflection estimation is also essential when determining the optimal gripping points, ensuring effective handling of the rebar.

6 Conclusion

This study emphasizes that managing rebar deflection during placement is a significant challenge when utilizing single robotic arm systems for rebar placement in vertical structural elements.

It also underscores the limitations of existing theoretical models, which fail to accurately predict standalone rebar deflection under real-world conditions. By integrating experimental data, the development of a neural network model effectively addresses these gaps, achieving nearly 100% likehood of fall within the camera's field of view and over a 50% likelihood of placing the rebar within 10mm of the target location. This advancement provides a more reliable and practical predictive tool for robotic rebar placement applications.

However, certain limitations should be acknowledged. For instance, further research is necessary to comprehensively identify and evaluate factors that lead to larger deflections, including rebar geometry and environmental influences such as corrosion and temperature variations. Moreover, this study is limited to the initial rebar intersection placement, leaving the complexities associated with subsequent intersections unaddressed. Exploring these challenges represents a valuable direction for future work.

Abstract -

Robotic timber assembly applications, such as nailing, often require the simultaneous execution of multiple tasks, necessitating the use of multiple devices and large working spaces. This poses a challenge for the development of transportable robotic manufacturing cells, which aim to bring the benefits of controlled environments closer to construction sites. Addressing this issue requires the design of manufacturing cells that optimize robotic resources and space by enabling multiple tasks to be performed simultaneously. In this work, the concept of Mobility-Added Multi Tool (MAMT) end-effector is introduced. Specifically, a MAMT end-effector designed for picking and nailing operations is proposed to eliminate the need for additional external devices during timber nailing processes. This end-effector is based on closed-loop linkages driven by linear actuators, providing ease of control, high force transmission, and structural stability. To demonstrate their practicality, application examples involving two-robot collaboration are presented and animated, illustrating the usability of the proposed end-effector in real-world scenarios. Future work includes the development of linkage kinematics and dynamics, as well as the exploration of alternative mechanisms to introduce additional mobility features, enabling the same robot to perform a broader range of tasks during the timber assembly process.

1 Introduction

Timber assembly plays a vital role in the construction industry. Timber is one of the most widely used construction materials globally and serves as the primary material in countries such as the United States and Canada [1, 2]. The construction industry is gradually transitioning towards greater automation, although at a slower pace compared to other industries [3, 4]. However, significant steps are being made in this direction. Among various construction processes, timber assembly is particularly well-suited for robotic fabrication due to the material's lightweight nature, flexibility, and ease of manipulation.

Currently, robotic timber assembly is predominantly carried out in off-site facilities, where robots are working collaboratively with other robots [5, 6] and automated devices such as stationary disc saws and CNC machines [7, 8, 9] to perform tasks like pick-and-place [10, 11], cutting [12], milling [13], drilling [14], screwing [15], and nailing [16]. These operations facilitate the prefabrication of small individual elements [17, 18] as well as larger products, such as complete building sections and facades [19, 20, 21].

While off-site timber assembly factories are advancing toward full automation, there is an urgent need to develop robotic manufacturing solutions closer to construction sites. Such solutions would retain the advantages of controlled factory-like environments while avoiding logistical challenges, such as transportation. Transportable and reconfigurable manufacturing cells have emerged as a promising solution [22]. To ensure portability and efficiency, these cells must optimize robotic and spatial resources, often relying on just one or two stationary robots equipped with the necessary capabilities to execute the entire manufacturing process, even for large timber products.

A significant challenge in timber assembly lies in the wide range of tasks required to complete a fabrication process. These tasks can lead to delays and increased human intervention for tool and material handling. To address this, additional automated devices have been incorporated into manufacturing cells for robot use [23]. Furthermore, robots have been equipped with the ability to perform multiple tasks by employing tool changers [24] or multi tool end-effectors [25, 26, 7]. While these innovations have improved timber assembly efficiency, they also present challenges. Adding more automated devices increases spatial and control system complexity, while tool changers and multi tool end-effectors often reduce robotic mobility. Crucially, these approaches fail to address the fundamental issue of performing multiple tasks simultaneously with a single robot. In many cases, tools remain fixed relative to the robot's end-effector, relying entirely on robot motion for operation.

Simultaneous task execution often requires multiple devices, such as robots or other automated tools, equal to the number of tasks involved. This is particularly problematic for applications like nailing, where at least two timber elements are joined using a nail, thus requiring the use of up to three devices during a single nail process. As a result, robotic nailing is challenging to implement with one or multiple robots. Currently, robotic nailing often involves a table—sometimes automated and equipped with additional Degrees of Freedom (DoF)—to hold timber elements while a robot performs the nailing operation [22, 27, 28, 29]. However, this approach limits manufacturing capabilities to the table's size and the robot's range of motion. Consequently, most robotic nailing applications are restricted to producing smaller products, such as panels and pallets, and transportable manufacturing cells are similarly limited to fabricating small-sized items.

In this work, the concept of Mobility-Added Multi Tool (MAMT) end-effector is introduced. This end-effector enhances robotic capabilities by providing additional mobility, enabling simultaneous execution of multiple tasks while optimizing resources, space, and time. The proposed MAMT end-effector allows a robot to hold a timber element and perform nailing simultaneously, with the ability to vary the nail's position and orientation. The MAMT end-effector is designed using closed-loop linkages driven by linear actuators, which enable precise adjustments to the nail gun's position and orientation. Additionally, these linkages provide high force transmission and structural integrity, which are characteristics of this type of linkages, meeting the demands of construction materials and processes. This paper describes the design and motion principles of the proposed MAMT end-effector. Furthermore, application examples involving collaborative tasks performed by two robots are presented to demonstrate their usability in real-world scenarios.

The remainder of this paper is structured as follows: Section 2 details the proposed MAMT end-effector and their mobility principles. Section 3 presents three application examples of timber nailing processes using the MAMT end-effector. Finally, concluding remarks are summarized in Section 4.

2 MAMT end-effector description

The general structure of the proposed MAMT end-effector is shown in Figure 1. This design is intended for installation on an industrial serial robot, specifically the KUKA® KR 250 R2700, as illustrated in Figure 1(a). The MAMT end-effector consists of four primary modules, depicted in Figure 1(b):

1. **Gripping module** (Module 1) for gripping timber studs.
2. **Linear translation module** (Module 2) for horizontal nail gun movement.
3. **Rotation module** (Module 3) for angular adjustments.
4. **Height variation module** (Module 4) for vertical positioning and nail gun triggering.

The main objective of this section is to present the MAMT end-effector concept and its operational principles without delving into detailed technical analyses. Synthesis, kinematic, and dynamic studies are beyond the scope of this work; however, key dimensions of the model are provided for reference.

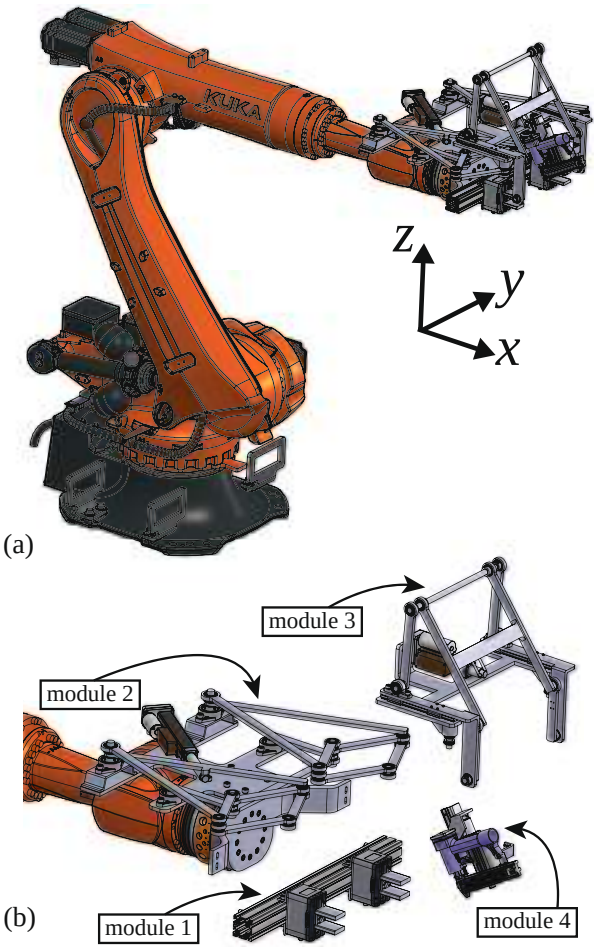

Figure 1. Proposed MAMT end-effector: (a) installed on a robot KUKA® kr 250 r2700, and (b) modules.

2.1 Module 1 - gripping

Module 1, shown in Figure 2, consists of two grippers symmetrically positioned along the end-effector's y-axis. This module enables the end-effector to pick and securely

hold timber studs during the nailing process. The grippers' tips are fixed at a distance w_1 from the center of the robot's final link. Distances h_1 and v_1 can be adjusted by repositioning the grippers. The dimensions used in the computational model are listed in Table 1.

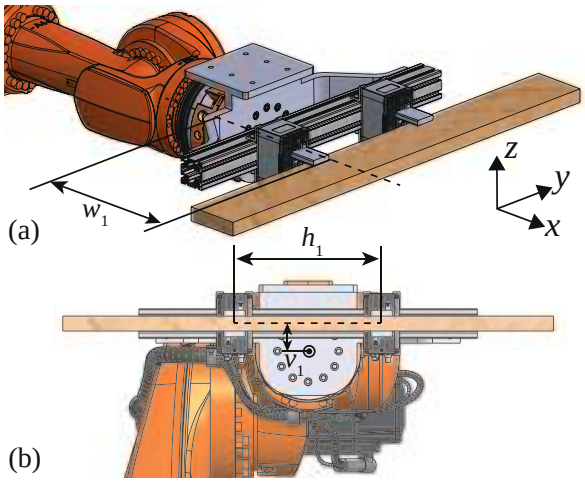

Figure 2. Module 1 - gripping: (a) isometric view, and (b) front view.

Table 1. Dimensions of Module 1 - gripping

Element	Dimension [mm]
h_1	300
v_1	56
w_1	447

2.2 Module 2 - linear translation

Module 2, shown in Figure 3, utilizes a double Peaucellier planar mechanism mounted in a plane parallel to the xy-plane of the robot's end-effector. The Peaucellier mechanism, a classic straight-line generator, comprises eight links and six revolute joints, resulting in one degree of freedom (DoF). Connecting two Peaucellier mechanisms, as shown in Figure 2(a), not only generates straight-line motion but also achieves straight-line body translation. This setup enables the nail gun to move linearly (parallel to the y-axis) over the gripped timber stud without undesired rotations, as illustrated in Figure 3(b).

The entire linkage maintains a single DoF and allowing to be driven by a single linear actuator. The Peaucellier mechanism's link dimensions are listed in Table 2. This double mechanism architecture provides a linear displacement d_1 of 700 mm with an output/input ratio of 3:1, meaning the nail gun moves three times the displacement of the linear actuator.

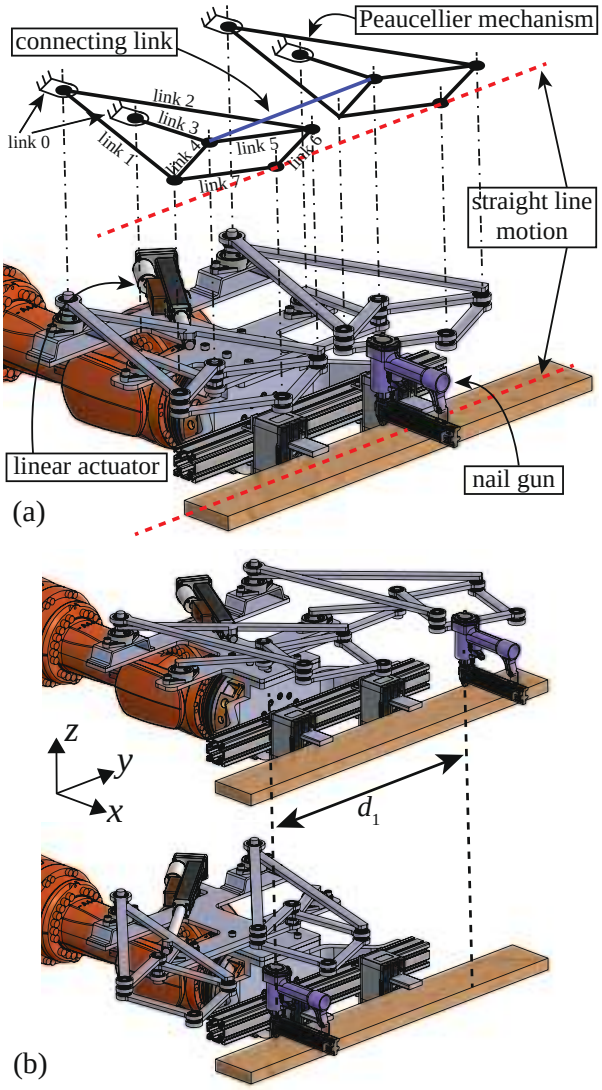

Figure 3. Module 2 - linear translation: (a) base linkage, and (b) displacement range. Modules 3 and 4 that physically connect module 2 with the nail gun are not included for better visualization of the base linkage.

Table 2. Dimensions of Module 2 - linear translation

Element	Dimension [mm]
link 0	200
link 1	530
link 2	530
link 3	200
link 4	210
link 5	210
link 6	210
link 7	210
connecting link	450

2.3 Module 3 - rotation

Module 3, shown in Figure 4, is based on two parallel four-bar planar mechanisms. Two design variants, to be used independently, are proposed:

1. **Variant 1** (Figure 4(a)): Mechanisms placed in planes parallel to the xz-plane of the robot's end-effector.
2. **Variant 2** (Figure 4(b)): Mechanisms placed in planes parallel to the yz-plane.

Each four-bar mechanism comprises four links connected by four revolute joints, resulting in one DoF, making it suitable for actuation by a single linear actuator. In these mechanisms, links 1 and 3 rotate about fixed axes. The nail gun is attached to link 3 in both variants, allowing rotation about axes parallel to the y and x, respectively.

The nail gun tips are positioned along these axes at a distance w_2 from the robot's last link. This distance can be adjusted using carriage and rail systems that enable translation along the x-axis between Modules 2 and 3. The link dimensions of the four-bar mechanism are listed in Table 3.

Module 3 provides a rotation range θ of 50° to 120° for variant 1 and 40° to 140° for variant 2. The rotation range of Variant 1 is shown in Figure 4(c).

Table 3. Dimensions of Module 3 - rotation

Element	Dimension [mm]
link 0	306
link 1	220
link 2	350
link 3	150
w_2	460

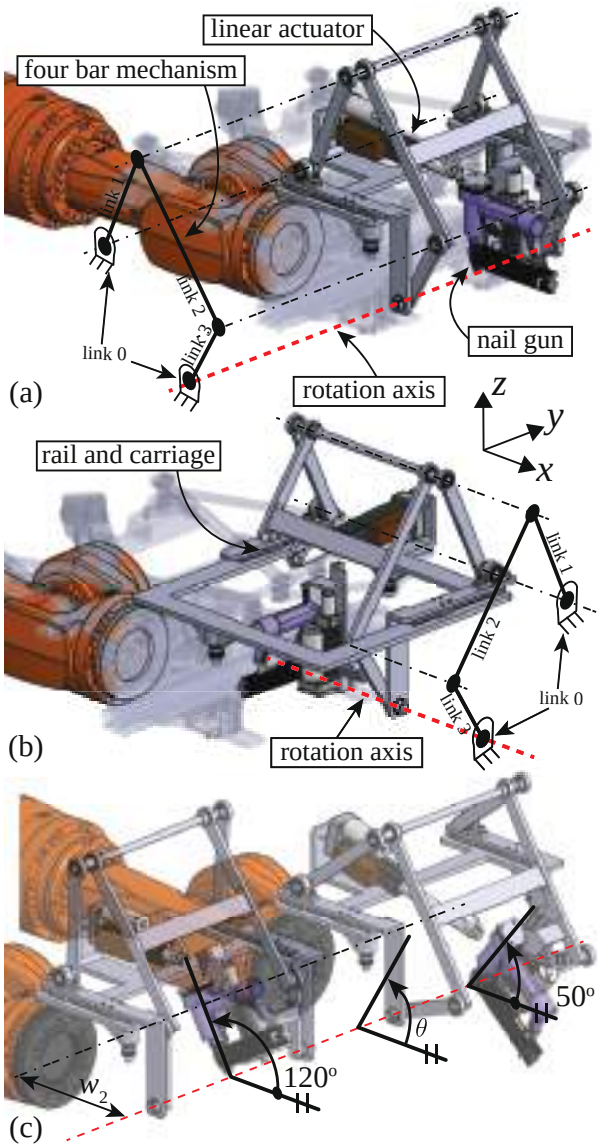

Figure 4. Module 3 - rotation: (a) base linkage of variant 1, (b) base linkage of variant 2, and (c) rotation range.

2.4 Module 4 - height variation

Module 4, shown in Figure 5, includes the nail gun and a linear actuator connected via a linear track. This module enables direct adjustment of the nail gun's distance d_2 relative to the gripped timber stud. In the initial position, as described in Section 2.3, the nail gun tip aligns with the rotation axis of Module 3.

Module 4 is rigidly attached to link 3 of Module 3, ensuring that any displacement produced by Module 4 moves the nail gun tip along an axis intersecting the rotation axis of Module 3. This functionality allows precise positioning of the nail gun tip close to the timber stud surface, regardless of the position and orientation defined by Modules 2 and 3. Additionally, Module 4 can trigger certain nail guns by moving the gun tip until it contacts the timber stud.

3 Application examples

This section provides visual demonstrations of the MAMT end-effector functionality in real timber nailing processes. Two robots in collaboration, each equipped with the proposed MAMT end-effector, were 3D modeled and animated to fabricate three types of timber-nailed structures:

1. **Straight on-plane structure**.
2. **Rotated on-plane structure**.
3. **Rotated off-plane structure**.

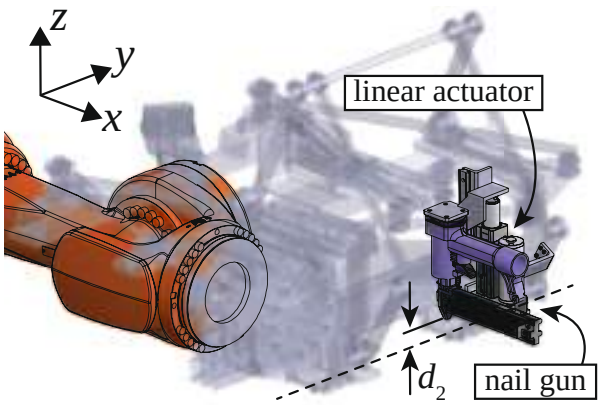

Figure 5. Module 4 - height variation.

The dimensions and configurations of these structures are illustrated in Figure 6.

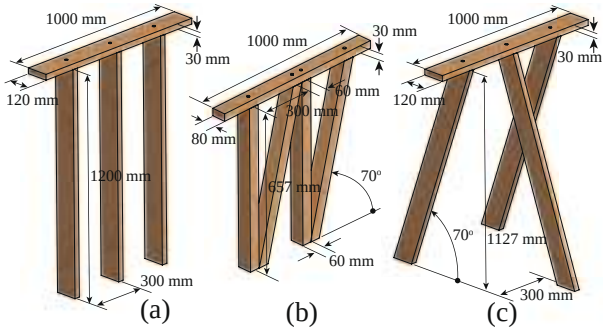

Figure 6. Timber structures: (a) straight on-plane, (b) rotated on-plane, and (c) rotated off-plane.

The fabrication process begins with Robot 1 picking the base timber stud and holding it horizontally at a height of 1797 mm, as shown in Figure 7. Simultaneously, Robot 2 picks the additional timber studs and aligns them with the base stud for subsequent nailing. This process of Robot 1 holding the base stud while Robot 2 places additional studs is repeated for the entire assembly of the three timber structures.

The initial steps of the fabrication processes for the three timber structures are depicted in Figure 8. The procedures for each structure are described as follows:

Straight On-Plane Structure (Figure 8(a)): i) Module 3 fixes the nail gun at 90°, Module 2 translates the nail gun 300 mm along the negative y-axis from the center, and Module 4 lowers the nail gun to join the two timber studs. ii) Module 4 raises the nail gun, Module 2 translates the nail gun 300 mm along the positive y-axis to align with the next stud placed by Robot 2, and the nailing process is repeated.

Rotated On-Plane Structure (Figure 8(b)): i) Module 2 translates the nail gun 300 mm along the negative y-axis, Module 3 (Variation 2) rotates the nail gun to 90°, and Module 4 lowers the nail gun to join the two timber studs. ii) Module 4 raises the nail gun, Module 2 translates the nail gun 300 mm along the positive y-axis to align with the next stud placed by Robot 2, Module 3 rotates the nail gun to 70°, and Module 4 lowers the nail gun to repeat the nailing process.

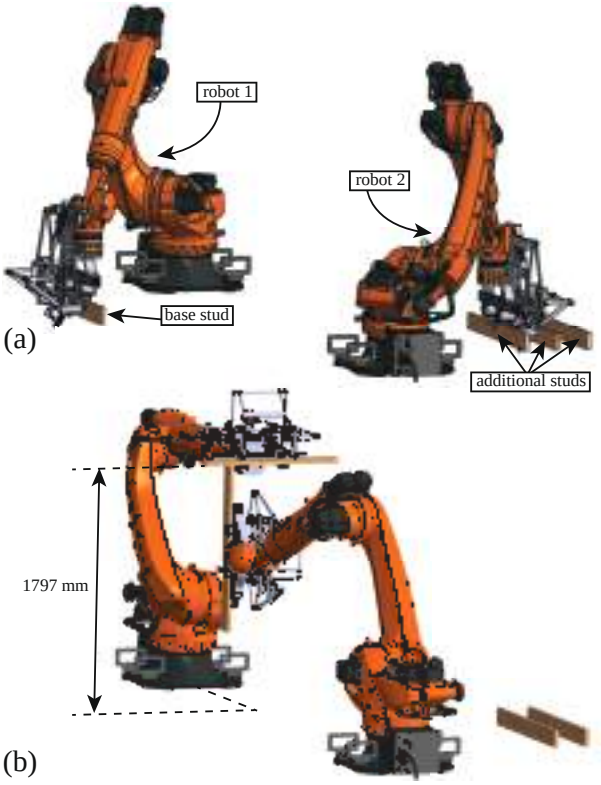

Figure 7. First stage of the timber nailing process with the robot team: (a) picking the timber studs, and (b) placing the timber studs.

Rotated Off-Plane Structure (Figure 8(c)): i) Module 2 translates the nail gun 300 mm along the negative y-axis, Module 3 (Variation 1) rotates the nail gun to 70°, and Module 4 lowers the nail gun to join the two timber studs. ii) Module 4 raises the nail gun, Module 2 translates the nail gun 300 mm along the positive y-axis to align with the next stud placed by Robot 2, Module 3 rotates the nail gun to 110°, and Module 4 lowers the nail gun to repeat the nailing process.

An animated video illustrating the assembly processes for all three timber structures is available at the following link [1].

4 Discussion

Timber assembly is one of the most widely robotized construction processes due to the favorable characteristics of timber, which makes it highly suitable for robotic manipulation. However, specific operations such as nailing remain particularly challenging because of the wide range of tasks involved. This poses a significant obstacle to the development of compact and transportable manufacturing cells that can be deployed near construction sites.

This research introduces the concept of MAMT end-effectors for robotic timber assembly, addressing the need for more efficient and versatile solutions in nailing operations. By enabling robotic systems to perform multiple tasks simultaneously, the proposed MAMT end-effectors optimize space, time, and robotic resources.

The MAMT end-effectors leverage closed-loop linkage mechanisms driven by linear actuators, which provide high force transmission and structural stability essential for timber construction processes. Additionally, the mechanisms are easy to control, making them suitable for seamless integration into industrial robotic systems. The design includes four specialized modules: a gripping module for holding timber studs, a linear translation module for precise straight-line motion, a rotation module for angular adjustments, and a height variation module for accurate positioning and triggering of the nail gun.

The effectiveness of the MAMT end-effectors was illustrated through application examples, where collaborative two robots successfully fabricated three distinct timber-nailed structures: straight on-plane, rotated on-plane, and rotated off-plane. These examples showcased the system's ability to perform complex tasks with minimal reliance on external devices and within compact working spaces.

By eliminating the need for additional external devices during nailing, the MAMT end-effectors enable a more streamlined and efficient approach to robotic fabrication. Their modular and compact design enhances the adaptability and versatility, making them particularly valuable for applications where space and resources are limited. Furthermore, the linkage-based mechanisms ensures precise, robust, and reliable operation, even in demanding construction scenarios.

Some limitations of the proposed MAMT end-effector include the manual pre-setting of parameters h_1 and v_1, which requires prior knowledge of the timber stud dimensions. Additionally, the end-effector does not allow active translation of the nail gun along the x-axis. However, the nail position relative to the timber studs in this direction can be slightly adjusted by varying the portion of the timber stud grasped by the grippers.

While this work presents the feasibility and functionality of the MAMT end-effectors, further research will focus on conducting comprehensive technical analyses, including position synthesis, kinematic and dynamic modeling, and Finite Element Analysis simulations. Fabrication and experimental validation of physical prototypes are also planned as future work. Additionally, exploring alternative mechanisms to enable additional tasks such as cutting

and milling is also planned as part of ongoing research.

5 Conclusion

The concept of MAMT end-effectors represented in this paper goes beyond the additional mobility seen in many existing robotic end-effectors. It emphasizes equipping the end-effector with the necessary capabilities to perform tasks independently of the robot's motion. This independence significantly advances the automation of timber assembly, offering a compact, efficient, and versatile solution for robotic systems. By bridging the gap between off-site prefabrication and on-site manufacturing, the MAMT end-effectors have the potential to address critical challenges in the construction industry, paving the way for more sustainable, scalable, and adaptable processes.

Abstract –
Image-based indoor localization is a promising approach to enhancing facility management efficiency. However, ensuring localization accuracy and improving data accessibility remain key challenges. Therefore, this research aims to automatedly localize images captured during facility inspections by matching the viewpoint of the camera with a corresponding viewpoint in a Building Information Modeling-based (BIM) simulated environment. In this paper, we present a framework that generates photorealistic synthetic images and trains a deep learning model for camera pose estimation. Synthetic datasets are generated in a simulation environment, allowing precise control over scene parameters, camera positions, and lighting conditions. This allows the creation of diverse and realistic training data tailored to specific facility environments. The deep learning model takes RGB images, semantic segmented maps, and corresponding camera poses as inputs to predict six-degree-of-freedom (6DOF) camera poses, including position and orientation. Experimental results demonstrate that the proposed approach can enable indoor image localization with an average translation error of 5.8 meters and a rotation error of 69.05 degrees.

Keywords –
Synthetic data; Image localization; Pose estimation; Facility management; BIM

1 Introduction

In facility management, accurate camera pose estimation is crucial for tasks such as building surveying, indoor navigation, and asset tracking. Within indoor built environments, reliable positioning data is the foundation for numerous location-based services. By determining the precise orientation and location of the camera, facility managers can automate the detection of structural changes, schedule efficient maintenance, and enhance occupant safety. Additionally, camera pose estimation enables advanced applications like augmented reality guidance and remote inspections, ultimately improving the overall efficiency and effectiveness of facility operations.

A traditional approach to getting a camera pose from a given 3D model of the scene is to match 2D image features with their corresponding 3D points using an n-point pose solver in a RANSAC loop [1]. Another common method is reconstructing a 3D scene via Structure-from-Motion (SfM), in which 3D points are triangulated from multiple local features and can be associated with the corresponding image descriptors [2, 3]. In recent years, the integration of SfM with Multi-View Stereo (MVS) has transformed 3D reconstruction by making data collection and processing more broadly accessible [4]. By capturing and computing multiple overlapping images, it is possible to derive 3D information without relying on knowing camera poses, camera calibration, or surveyed reference markers in the scene. However, in construction, capturing ordered photo collection typically follows a strict schedule and is implemented at predetermined intervals. Furthermore, reconstructing a reality model is time-consuming, and its quality may decrease if random photos are taken at different times. On the other hand, deep learning approaches have demonstrated strong capabilities in providing reliable and real-time image localization [5, 6]. Deep learning-based methods can automatically learn discriminative representations that are robust to large variations in scene appearance and viewpoint changes. Their ability to handle complex environments, varying lighting conditions, and scene dynamics leads to improved accuracy and efficient inference speeds,

making them suitable for real-time deployment [7].

Nowadays, Building Information Modeling (BIM) model is commonly available in the project, and it serves as a rich source for generating synthetic imagery of the scene. By rendering the model from multiple viewpoints, synthetic data can be produced to augment or replace labor intensive image capture. Such synthetic datasets are particularly beneficial for training deep learning–based (e.g., CNN-based) localization models, as they provide diverse examples of the scene without requiring extensive onsite photo documentation. Especially this approach can work with a low level-of-detail BIM model [8], thereby reducing the required time for the indoor camera pose regression process.

In this paper, we present a deep learning-based image localization approach that is suitable for dynamic and complex construction indoor environments. The framework includes two main phases: synthetic data generation and image localization.

2 Related Work

2.1 Traditional Approaches for Camera Pose Estimate

The goal of camera pose estimation is to estimate 6 degrees of freedom (DoF) of a given camera, including 3D translations and 3D orientations. Classical methods for camera pose estimation primarily rely on geometric principles and feature-based matching. Techniques such as Perspective-n-Point (PnP) solvers, including Direct Linear Transform (DLT) [9], EPnP [10], and advanced variants like UPnP and OPnP [11, 12], estimate camera pose from 2D-3D correspondences with improvements in efficiency and robustness. Feature-based approaches, like Structure-from-Motion (SfM), reconstruct 3D scenes by detecting and matching local features (e.g., SIFT, SURF), performing triangulation, and refining camera pose and 3D structures through bundle adjustment [3]. Multi-view geometry techniques, such as essential or fundamental matrix estimation, recover relative camera motion between image pairs. Additionally, model-based methods align 2D image features with known 3D models, while marker-based systems, using fiducial markers like ARTag or AprilTag provide reference points for simplified pose estimation [13, 14]. These methods then form the theoretical foundation for modern deep learning solutions in camera pose estimation.

2.2 Deep Learning-based Image Localization

Compared to traditional methods, which rely heavily on geometric principles, recent advancements in deep learning have transformed the field, offering robust and scalable solutions. A comprehensive overview of state-of-the-art methods for deep learning-based image localization, particularly in indoor environments, is presented in the work of [15], showing numerous benefits of using convolutional neural network (CNN) models for camera pose estimation. CNNs trained on large datasets have demonstrated exceptional capability in learning feature representations. Pose regression can be performed using RGB-D images, which incorporate depth information to encode the 3D location of each pixel within the scene relative to a known environment. Pair-wise registration is a common method in which corresponding 3D key points between consecutive frames are utilized to estimate the relative camera pose [16]. However, depth cameras are not as popular in construction as ordinary cameras, leading to limitations for using RGB-D photos. Deep learning-based approaches using RGB images only, such as PoseNet and its variants, have become prominent in the construction domain. PoseNet directly regresses the camera's 6-DOF (degrees of freedom) pose from an input image, bypassing the need for explicit feature extraction and geometric matching [17]. Variants of PoseNet further enhance accuracy and robustness by introducing loss functions tailored to pose regression, attention mechanisms, or incorporating spatial constraints [8, 18, 19]. Data augmentation is also used to increase fine-tuning samples [20, 21]. Deep learning-based localization methods not only improve the robustness and scalability of image-based localization systems but also adapt well to diverse application domains. By leveraging neural networks' ability to learn feature representations directly from data, these approaches overcome many limitations of traditional methods, such as sensitivity to occlusion, lighting variations, and large-scale environments.

2.3 Synthetic Data for Model Training

Recent advances in synthetic data generation have significantly impacted various computer vision applications, including image localization and camera pose estimation. Synthetic datasets, created through graphics engines or procedural modeling, allow researchers to overcome the challenges posed by limited real-world data, expensive annotation processes, and environmental variability. In construction, synthetic data generated from BIM models can be useful for training CNN models for different tasks, including image localization. Acharya et al. [8] introduced a pose estimation approach to determine the 6-DOF camera pose, which can serve as an initial location input for techniques like PDR, SLAM, and visual odometry. A deep Bayesian recurrent CNN is fine-tuned with synthetic image sequences generated from a BIM model to predict the poses of real image sequences [22]. Hong et al. [23] proposed an image retrieval method for

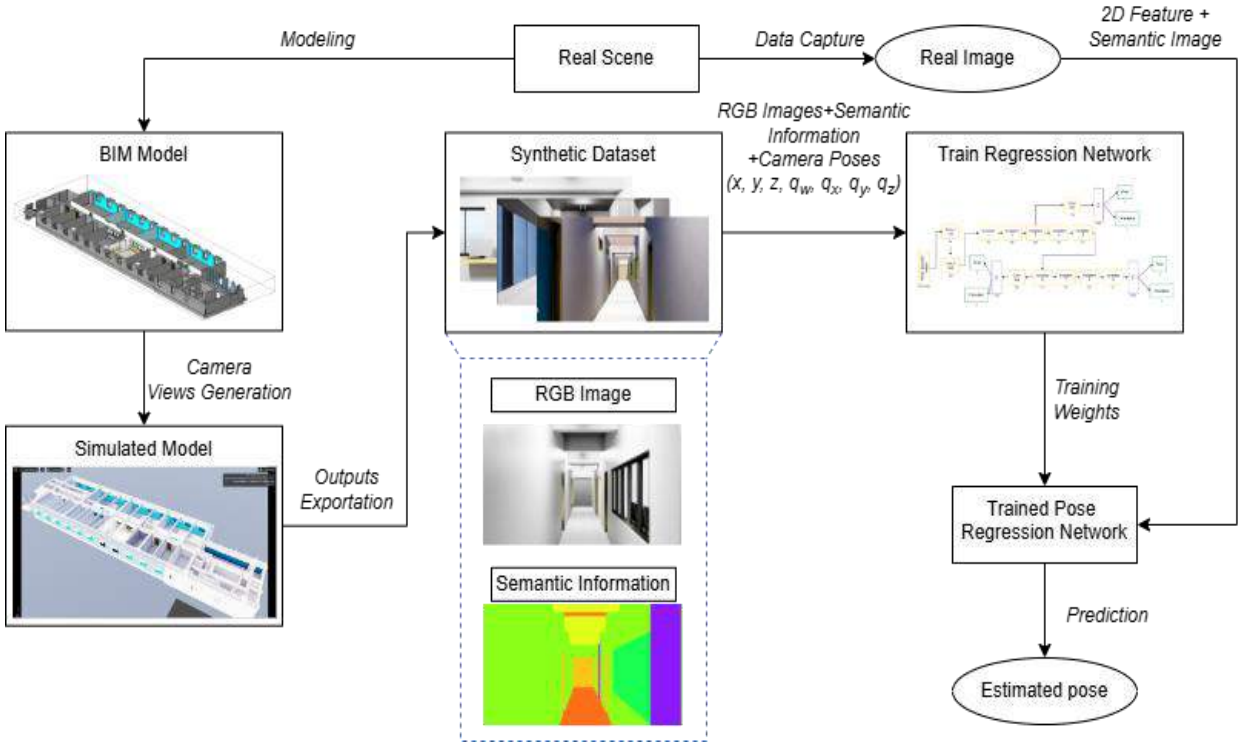

Figure 1. Overview of the framework for CNN-based image localization in this study

achieving coarse indoor localization utilizing BIM. It can be said that synthetic data has emerged as a flexible source for supplementing building image datasets and enhancing the performance and reliability of learning-based visual localization frameworks. The effectiveness of deep learning models trained on synthetic images may be influenced by the reality gap, which refers to discrepancies in color and texture between synthetic and real-world images [24].

In our framework, we combine different platforms to render photorealistic images with similar appearances to real-world images. The rendered outputs are used to train a PoseNet-based CNN model for image localization. The contributions of this study include: (1) propose an automated BIM-based localization for indoor inspection images, and (2) apply cross-domain feature integration to train a deep learning model to improve the indoor image localization.

3 Methodology

3.1 Framework of the CNN-based image localization

Figure 1 indicates our framework for CNN-based image localization, which combines synthetic data generation and deep learning to achieve accurate and robust image localization in dynamic construction scenarios. The BIM model is the basis of real-world environment simulations, including geometric, material, and spatial information, which are necessary to generate a synthetic dataset comprising images rendered from multiple viewpoints under diverse conditions. Furthermore, BIM software provides essential functionalities, such as its API, which allows automated creation and manipulation of camera poses within the model environment. These capabilities enable the efficient generation of diverse camera views, facilitating the development and testing of camera pose estimation techniques. The BIM model is then exported to an advanced simulation platform to generate the required synthetic dataset. This dataset is used to train a deep learning-based pose regression network, which learns to estimate the camera pose directly from input images. Real images captured from the construction scene are fed into the trained network, producing pose predictions.

3.2 Synthetic Data Generation

In this research, camera poses are generated from a 3D model in Revit by defining the positions and orientations of cameras to ensure the coverage of inner spaces in the building. A set of camera poses, as illustrated in Figure 2, is the result of our developed algorithm in Revit API. The process in Revit API begins by setting key parameters such as offset distance and camera position spacing. A transaction is started to

handle model modifications, and room boundaries are identified. For each room, the algorithm extracts boundary segments and generates viewpoints along the offset segments. It then determines valid points for camera placement and assigns viewpoints accordingly. Each viewpoint is processed to compute the camera's position and orientation.

In facility management, the inspectors often need to capture numerous images following a specific path. Thereby, camera poses should be determined on such a camera path that simulates the actual inspection path. After that, the model with camera poses is exported to Nvidia Isaac Sim to add more textures of objects and simulated lights and adjust the camera's parameters. The export process from RVT file in Revit to USD file in Isaac is directly supported by the NVIDIA plugin in Revit, ensuring optimal model preservation. Figure 3 shows the simulated environment in Isaac Sim software, in which camera parameters can be adjusted to match the real camera parameters. Other adjustments can also be executed, such as adding realistic materials and changing light intensity. Using this simulation is necessary because the current camera setting in Revit lacks customized functions to simulate the different cameras. The simulation environment in Isaac Sim is then used to render outputs, including RGB images, depth maps, and instance segmentation maps, which were saved with filenames corresponding to the camera names and timestamps for traceability. This process enabled the generation of high-fidelity visualizations of the architectural model, with realistic camera perspectives derived from the Revit-defined poses. Simultaneously, the position (x, y, z) and orientation (in quaternions) of the virtual cameras are exported into a CSV file as preparation for our CNN model training.

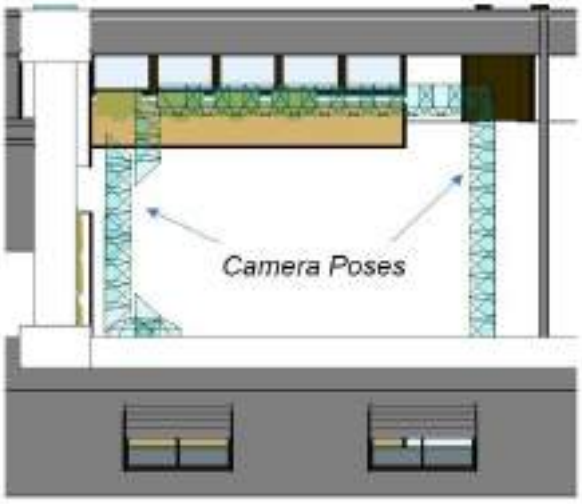

Figure 2. Camera poses defined in Revit

Figure 3. Simulated environment with generated camera poses in Isaac Sim

3.3 Image Localization

The localization of the camera pose is performed using a PoseNet-based CNN network, which has been proposed in our previous research [21]. This network is designed with 22 layers in its deep neural network architecture (Figure 4). In this study, the dataset used for training includes RGB and semantic images generated by Isaac Sim software, as well as their relevant 6-DOF poses. The poses are stored in a CSV file and linked to the relevant input images.

At first, the images are resized to 224×224 pixels and normalized using ImageNet-specific mean and standard (mean = [0.485, 0.456, 0.406] and standard = [0.229, 0.224, 0.225]) as required by the pre-trained GoogLeNet. The encoder, which includes convolutional layers and inception modules, extracts features from input images. This module uses pre-trained weight from the original GoogLeNet. An illustration of the inception module can be found in Figure 5. Each inception module captures a deeper level of abstraction from the input data. Originally in GoogLeNet architecture, the final layer of the network, representing the highest level of abstraction, along with

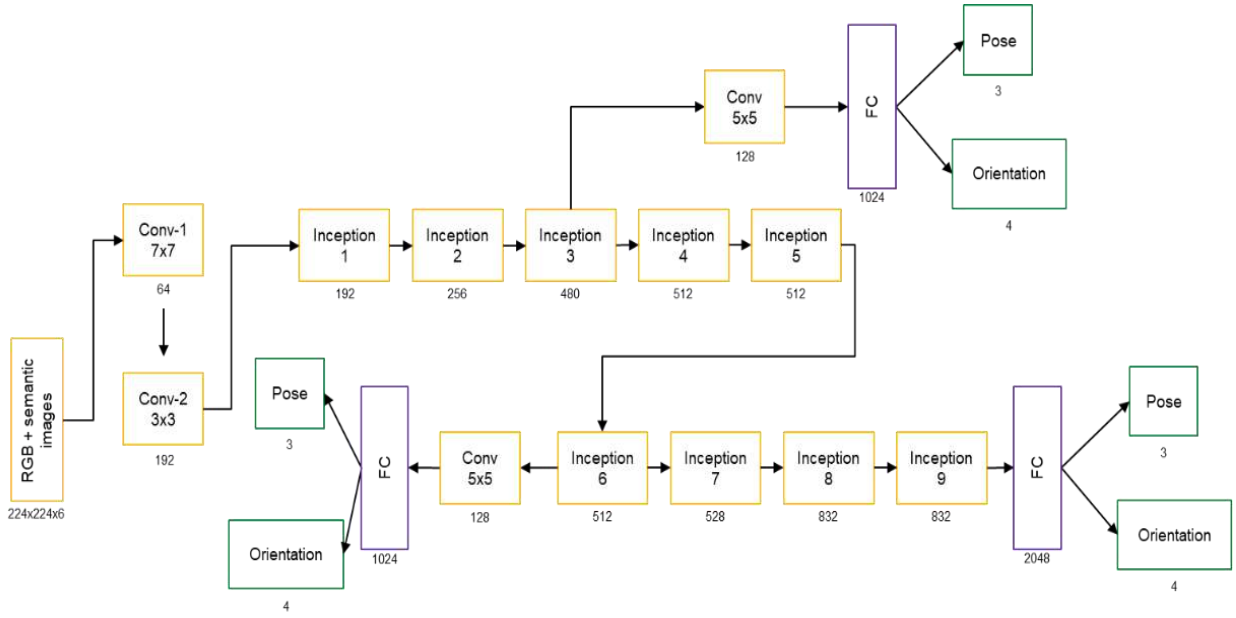

Figure 4. The architecture of CNN-based pose regression network

two intermediate abstraction levels, is passed to fully connected and Softmax layers to classify the objects.

PoseNet, however, replaces the Softmax classifier with two parallel fully connected layers with 3 and 4 units, respectively. These regressors output a 7-dimensional vector representing the camera's 6-DOF pose, which includes the 3D position $\hat{X}_c$ and orientation $\hat{q}_c$ in quaternion format. The network is trained using a loss function that minimizes the position error $\|\hat{X}_c - X_c\|$ and the orientation error $\|\hat{q}_c - q_c\|$ with a balancing hyperparameter to ensure optimal performance. Xc and qc are the ground truth position and orientation of the input camera poses, respectively.

$$Loss(I) = \|\hat{X}_c - X_c\|_2 + \beta\|\hat{q}_c - q_c\|_2 \qquad (1)$$

The hyperparameter β is used to balance the weights of position and orientation losses, keeping them with in a similar range. Since position errors and orientation errors are measured in different units and magnitudes, directly optimizing them together may lead to an imbalance, where one dominates the loss function. Thereby, β acts as a scaling factor that adjusts the relative contribution of orientation loss compared to position loss. If β is too high, orientation accuracy improves at the cost of position accuracy, and vice versa. Previous experiments suggest that β is typically assigned values between 250 and 2,000 [17]. The closest camera pose is determined by calculating the distance in position (Euclidean distance) and angular difference in orientation (quaternion angular distance) for each camera pose in the dataset

4 Initial Result and Discussion

In our study, an academic building model was used, containing different offices and a long hallway. The synthetic dataset generated by Isaac Sim includes 1922 RGB images and 1922 semantic images. Each camera position has five different orientations. These images' poses are controlled by creating camera paths offset from the room walls. These camera paths simulate the tracks when implementing inspections for facility management. The integration of Revit for camera pose generation, and Isaac Sim for advanced rendering provides an effective workflow for applications such as architectural visualization, training datasets for AI models, or construction progress monitoring. The resulting outputs demonstrate the feasibility of leveraging a combined pipeline for precise and visually rich simulation data.

When preparing the dataset, 80 percent of the images were used to train the pose regression model. Testing and validation used 10% of the data relatively. The testing results show an error of 5.81 meters in translation and 69.05 degrees in orientation. This section aims to evaluate the accuracy of our network for single-image localization using only synthetic images. The goal is to analyze the network's performance when trained exclusively on synthetic data and tested directly on real images without employing any techniques to bridge the domain gap.

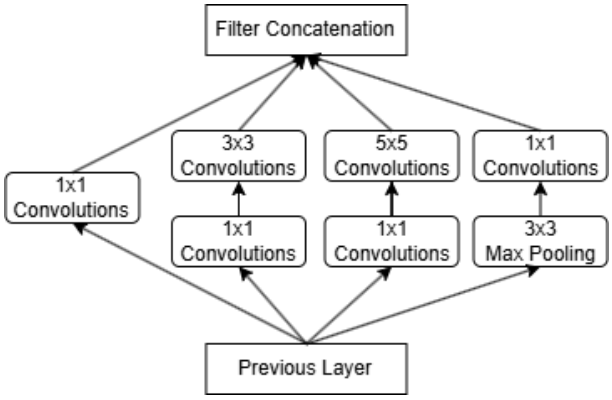

Figure 5. The inception module based on [17]

The test result can be considered acceptable in predicting the pose of an actual image, especially when the model was trained with a small dataset (less than 4000 images compared to other common models). Some causes can be listed for this result. At first, only images of the virtual environment and semantic information were used to train the mode. It is noticeable that there is a vast difference between the simulated environment and real-world space, including the furniture and objects in the scene. We acknowledge the complexity of the environment captured in the real image, including different finishing materials and furniture. Therefore, the images in our synthetic dataset subsequently lack features compared to the images captured in the real world. When using the pre-trained GoogLeNet backbone, the convolutional layers learn to recognize lines and geometric patterns as part of the training process. These features do not exist in the images in the synthetic dataset, thereby issuing challenges for the network. Furthermore, the network's ability to estimate the camera's rotation is less accurate, likely due to the complexity of capturing fine-grained orientation details. Without refinement techniques, the network struggles to bridge this gap, leading to suboptimal performance on real-world data.

For future work, additional features should be utilized to train the regression model. The simulation software Isaac Sim can generate depth information from images, which is essential for predicting spatial details. This input will support the prediction process. On the other hand, PnP and RANSAC algorithms are preferred for refining the poses predicted by the CNN in the earlier stage. The process will use a set of virtual images taken from the initial predicted poses, which serve as the starting point for the pose refinement process. The PnP algorithm leverages 2D-3D point correspondences to estimate the camera's position and orientation, minimizing reprojection error. In detail, it solves the transformation between a set of 2D image points and their corresponding 3D points in a known reference model such as a 3D point cloud. Then, PnP estimates the projection matrix, which aligns the image features with their 3D world coordinates. However, the presence of mismatched or noisy correspondences can degrade accuracy. This is where RANSAC becomes essential, as it ensures that only inliers contribute to the pose estimation. The algorithm repeatedly selects small random subsets of point matches to estimate the pose using PnP and evaluates the consistency of the remaining points. By using RANSAC, mismatched feature correspondences or erroneous keypoints are rejected, ensuring that only inliers contribute to the final pose estimation. As validated in our previous study [21], PnP and RANSAC enhance the robustness and precision of camera pose predictions, making them particularly effective for scenarios involving noise or incomplete data.

5 Conclusion

In conclusion, this study introduces an automated method for creating photorealistic synthetic images of BIM scenes depicting building interiors. In addition, a deep learning-based framework for image localization tailored to challenging and dynamic construction environments has been presented. The proposed framework includes two stages: the first stage involves synthetic dataset generation using BIM software and an advanced simulation platform; the second is a CNN-based pose regression. The pose regression model can use inputs, including RGB images and semantic images for prediction. The findings demonstrated that currently, using only a synthetic dataset generated in advanced simulation software can be reliable for training a CNN-based pose regression model. The network performs well for the initial coarse localization. However, in order to improve the performance of localizing a real-world image, implementing pose refinement will be the next step in our research. Future work will improve this initial prediction by matching the query image with virtual images generated from the BIM model, using geometric pose optimization methods such as PnP and RANSAC. The refined poses ensure higher accuracy, enabling the alignment of real images with the virtual model. This combination of synthetic data, deep learning, and geometric optimization creates a robust pipeline for localizing images in complex and evolving construction environments.

Abstract -

Traditional roof inspection methods rely heavily on manual labour, which poses challenges in efficiency and safety. In this paper, we propose an overall approach and 4 specific methods for slate detection in orthophotos of building roof panels, using edge detection by Canny detector (Method 1), SAM (Segment Anything Model) (Method 2), SAM with bounding box prompt (Method 3), and edge detection on original SAM masks (Method 4). The methods are developed using a dataset composed of 4 sample roof segments and 3 complete orthophotos from real roof panels. Method 4 reaches the best results (overall results for all slates: mIoU = 0.67, Recall = 0.81) with Method 1 also performing well (mIoU = 0.57, Recall = 0.74). Such performance demonstrates the potential of the proposed approach and these methods to provide a robust foundation for slate detection and subsequently classification tasks.

1 Introduction

Roof systems are a critical building fabric element serving to protect interior spaces and inhabitants against the elements (in particular rain). Slated roof systems are common type of roofs in both historic and modern buildings, requiring monitoring and timely maintenance to prevent damages, including structural damages. This is being made increasing challenging by climate change. As global weather patterns become increasingly erratic, slated roofs are subject to more frequent and severe fluctuations in temperature, moisture, and wind intensity. These environmental stressors can exacerbate the natural vulnerabilities of slates, a metamorphic rock that, while durable, has specific material properties—such as its anisotropic nature and inherent brittleness—that make it susceptible to damage under variable climate conditions [1, 2]. Besides, the nails used to secure slates can rust and fail. As a result, slated roofs often experience a range of deterioration issues, including broken, displaces, or detached (missing) slates.

The repair and maintenance of slated roof necessitate a targeted approach due to the localised nature of damage. Given that damage typically affects individual slates rather than large sections of the roof, restoration efforts often focus on a slate-by-slate basis. This time-saving and cost-effective approach is essential, not only to maintain the structural integrity and aesthetic quality of roofs but also to extend the lifespan of overall roofing systems. Therefore, a meticulous analysis of each individual slate is warranted to assess the type (if any) and extent of deterioration.

Current research on roof defect detection methods has advanced from manual inspection towards automation. For flat roofs, visual inspection by skilled experienced professional, with auxiliary means by sensors such as electric and ehermohygrometric methods, is the dominant method for non-destructive testing [3]. But, to capture data from buildings without the need for human access provision, Unmanned Aerial Vehicle (UAV)-based close-range sensing is increasingly used [4]. With the development of Artificial Intelligence (AI), deep learning models such as U-Net and HRNet are being developed to detect and categorise flat roof defects from aerial images, such as hollows, swellings, etc. These defects show continuous and large-area features [5]. In studies targeting at generic roof types, Mostafa et al. [6] apply Convolutional Neural Networks (CNNs) to classify roof damage types, achieving high accuracy in prioritising repairs.

However, during the evaluation and repair process of pitched roofs, workers must locate, assess, and restore individual slates at elevated heights, posing safety risks and inefficiencies. This further underscores the importance of precisely identifying the position and defect status of each slate to enable targeted physical intervention. As a result, pitched roofs, especially traditional pitched roofs, present unique challenges for automated and remote inspection: 1. Different from flat roofs, defects (mostly structural damages) of slated roofs are linked to single slate units. Therefore, defect detection should ideally start with slate mapping. 2. The complexity of slate arrangement and the variability in appearance, alongside variations in lighting and occlusions in roof images, further complicates automated analysis. 3. Defect categories of flat roofs differ

from those of pitched roofs, making existing defect detection model inapplicable. Addressing these challenges necessitates an advanced methodology capable of detecting individual slates and evaluating their condition in a robust and scalable manner.

Using UAV-based photogrammetric reconstruction, Digital Twin -based data processing, and Artificial Intelligence have been shown to be useful to automated slated roof monitoring Li et al. [7], from orthophoto generation for each roof panel [8] to roof sub-component segmentation [9]. These processes realise the gradual deconstruction of roof in a more measurable and analysable way. To further detect slate defects, one approach can be to first detect each individual slate in the roof orthophotos, and then classify each detected slate according to its condition, supporting high-precision diagnostics that can automate and streamline the repair process. This study proposes and compares a few methods of detecting individual slates, such as using traditional image processing in edge detection, the innovative Segment Anything Model (SAM).

2 Related work

2.1 Object detection using construction images

Image processing has emerged as a cornerstone of construction informatics, facilitating automated analyses for tasks like defect detection, progress monitoring, and material classification. Among them, object detection is the most common application. Simple yet effective techniques such as thresholding (e.g., Otsu's method) and filtering, are commonly applied in crack detection [10]. Canny edge-detector and watershed transformation are used in building component (column) detection [11]

With the advent of deep learning, modern models are built for object detection, like convolutional neural networks (CNNs), transformer-based vision architectures or more advanced zero-shpt SAM. For example, CNN refine input data for edge detection, making it easier for the network to learn spatial features. Such integrations enable applications like real-time construction site monitoring, where drones capture data that is processed for safety analysis [12], equipment detection [13]. While SAM-related research enables provide more accurate and comprehensive results [14]. Image processing in construction not only enhances operational efficiency but also addresses challenges like labour shortages and the need for faster project delivery, making it indispensable for modern construction workflows.

Based on object detection, segmentation helps further clarify the boundary of each object. To realise precise segmentation, edge detection-based methods and direct segmentation methods can be considered.

2.2 Edge detection -based methods

Traditional edge detection -based methods focus on explicitly identifying intensity discontinuities in images, often marking the boundaries of objects. These methods typically involve gradient-based techniques, such as:

1. *Canny Edge Detection* combines Gaussian smoothing, gradient calculation, non-maximum suppression, and hysteresis thresholding to produce clean and precise edges [15].
2. *Sobel and Prewitt Operators* compute gradients in horizontal and vertical directions to highlight regions with high intensity variation, making them ideal for detecting straight lines or simple contours [16, 17].
3. *Laplacian of Gaussian (LoG)* identifies edges by detecting zero-crossings in the second derivative of the image, providing robust results for blob-like structures [18].

Recent advancements in deep learning have significantly enhanced traditional edge detection methods, shifting from purely gradient-based approaches to data-driven, learning-based frameworks. Modern edge detection methods leverage convolutional neural networks (CNNs) and other architectures to achieve robust and adaptive performance in diverse scenarios. For instance, models like Holistically-Nested Edge Detection (HED) use deep CNNs to learn hierarchical edge features, allowing for precise edge maps with context-aware refinement [19]. Transformer-based approaches, such as DETR (DEtection TRansformer), implicitly model edge-like information by attending to boundary regions during object localisation and segmentation tasks [20].

2.3 Segment Anything Model (SAM)

Segment Anything Model (SAM) is a groundbreaking zero-shot learning model designed for universal image segmentation. It is trained using segmentation dataset with over 1 billion masks on 11M images. Unlike task-specific models, SAM employs a flexible prompting mechanism, enabling it to generalise across diverse image types and tasks without fine-tuning. It accepts various prompts such as points, bounding boxes, and even textual descriptions, making it adaptable to many domains. For example, SAM can segment complex natural scene images with minimal human intervention, showcasing its versatility [21].

Traditional edge detection methods offer efficient, lightweight solutions for extracting structural details, especially in scenarios where computational resources are limited, while deep learning approaches excel in capturing complex patterns and contextual information through data-driven feature learning. SAM adds a high-level semantic understanding to segmentation tasks, enabling precise object delineation across diverse and challenging vi-

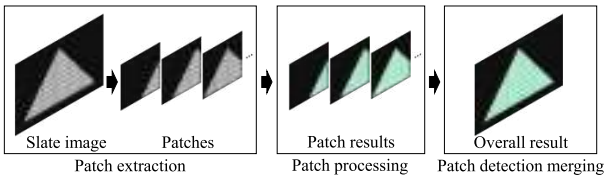

Figure 1. Approach overview

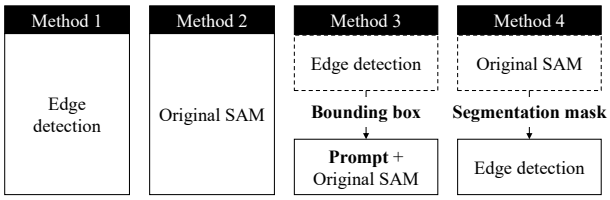

Figure 2. Method development of slate detection

sual contexts.

3 Approach overview

Roof panels, and consequently roof panel orthophotos come in various sizes. Since the performance slate detection algorithms is dependent on the size of the slates in the processed image, it is necessary to process each roof panel orthophoto in patches representing roofs at similar scale. As a result, the overall pipeline for slate detection in roof panel orthophotos includes the following three steps (fig. 1):

1. **Patch extraction**: the image is split into an overlapping set of patches;
2. **Patch processing**: slates are detected in each patch; and
3. **Patch detection merging**: all detections are merged in the original image.

Sections 4 to 6 detail those three steps.

4 Patch extraction

Small fixed-size patches (200×200 pixels) are extracted from the complete slate images using a sliding window approach. Square patches are the best option for inputting in SAM model to prevent distortion. The step size is 25% of the window size (i.e. 50 pixels), creating overlapping patches. This ensures that each slate will appear fully in at least one patch. The mask of the slated area in the orthophoto is also a known input from the orthophoto generation theory [8].

5 Slate detection

Four slate detection methods are investigated in this study (see fig. 2). They are developed according to the following logic: **Method 1** is developed based on traditional image processing using edge detection. Thanks to the well-developed AI model by meta, SAM, **Method 2** is developed by using SAM as is. However, as will be shown, **Method 2** shows lower performance than **Method 1**. As a result, Methods 3 and 4 are investigated. **Method 3** uses the bounding boxes obtained using **Method 1** as prompt to SAM. **Method 4** employs the same detection strategy of **Method 1** but applied to the SAM segmentation map. The 4 methods are described in more detail in the following sub-sections.

5.1 Method 1: Edge detection by Canny detector

The process of the application of **Method 1** to each patch is as follows:

1. *Noise removal*: Gaussian blur is applied to the patch (or the overall image) to reduce noise.
2. *Edge detection*: The Canny edge detector is applied to the patch, followed by oriented horizontal edge detection using Sobel.
3. *Slate row detection:* Probabilistic Hough Transform-based line detection is applied to the edge map to identify horizontal slate rows in the image. Only lines where the absolute difference between the y-coordinates of the two endpoints is less than 10 are retained. The most common distance between neighbouring lines — which should correspond to the roof panel *exposure*, also called *margin* — is calculated, and any line whose distances to neighbouring lines are smaller than the exposure is discarded. Similarly, lines are added between pairs of lines whose distance is twice (or three times) the exposure. The final set of lines is used to split the image into strips, with each strip expected to contain one slate row.
4. *Slate detection*: For each slate row, the average vertical grayscale value is computed across the strip, and valleys in this resulting 1D signal are assumed to correspond to the locations of vertical boundaries between slates in the strip, and the strip is segmented correspondingly into boxes defining initial slate boundaries, The slates boxes detected across all strips are gathered in the patch.
5. *Slate detection filtering*: Boxes that contain more than 90% black pixels (i.e. background pixels in the orthophoto that are not part of the roof panel) are discarded as noise.
6. *Slate detection adjustment*: Because slates may not be laid in a strict horizontal direction, each slate box is slightly resized by locally adjusting their top and bottom edges to better match the local minimum average grayscale along the edges. The resizing is restricted

Figure 3. Method 4 pipeline, left to right: grayscale image - SAM segmentation mask - line extraction based on Hough Transform - strip extraction - strip valley calculation - box visualisation - box shifting.

within a distance set to 30% of the slate exposure.

5.2 Method 2: Original SAM

In **Method 2**, the original SAM is used without any other input to generate the probability map of segments, followed by a segmentation mask by setting the threshold as the median value of the entire probability map. Bounding boxes are then generated by extracting the largest connected components after removing noise (small objects, pixel count < 25) and smoothing edges. Due to the transition area from slate to slate gap, segments by SAM tend to be smaller than the actual slates. Therefore, a two pixel extension is added to the four boundary sides to make the boxes closer to reality and touch each other. Theoretically, this approach may be able to better generalise than **Method 1**, since SAM offers strong generalisation capabilities and high-level semantic understanding.

5.3 Method 3: SAM with bounding box from edge detection as prompt

In **Method 3**, the original SAM is used with the bounding box information from **Method 1** used as prompt, with the aim of increasing the probability of a slate segment inside the box while retaining the theoretical capability of SAM to detect slates that may not have a rectangle appearance. The detection box refinement steps of **Method 1** are then applied the same way.

5.4 Method 4: Edge detection by original SAM mask

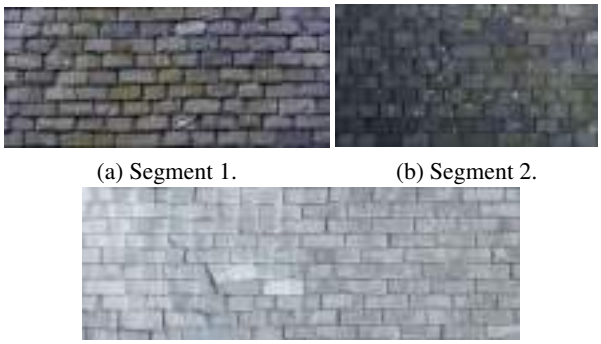
Because we noticed that the segmentation masks produced by SAM have clear slate boundaries, possibly clearer than in the original grayscale image, in **Method 4** SAM is applied to the grayscale image, outputting a probability map indicating pixel-level segmentation confidence. By setting the threshold as the median probability value, a segmentation mask is generated to which the Canny edge detector of **Method 1** is applied. The detection box refinement steps of **Method 1** are then applied the same way.

6 Patch slate detection results merging

All slate detections from all patches are gathered in the overall roof panel orthophoto. The resulting set of detections contains redundant detections from overlapping detections as well as boxes with abnormal sizes (noise). To merge and filter those results, the following steps are applied:

1. *Boundary boxes*: Boxes located on the boundary of overlapping patches are discarded.
2. *Small boxes*: Boxes whose height or width is $< 0.5 \times exposure$ are discarded, but only if $> 90\%$ of the area of the orthophoto covered by the box is already covered by another box.
3. *Redundant boxes*: Non-Maximum Suppression (NMS) is used to discard redundant (overlapping) boxes. When boxes are overlapping, NMS keeps the most significant one based on a predefined Intersection-over-Union (IoU) threshold (0.3). However, like above, a box is discarded only if $> 90\%$ of the area of the orthophoto that it covers is already covered by another box.

7 Experimental results



7.1 Dataset

The dataset used in the study is a set of orthophotos obtained from real slated roof panels using the method in [7]. The orthophotos are of roof panels with different shapes and deterioration conditions (see fig. 7) . Panel A and B are expected to be easier due to their smaller size, while Panel C is much larger and has the highest deterioration level. The three panels collectively contain 5,386 slates. Ground Truth (GT) labelling for each slate is done manually with axis-aligned bounding box (even though some slates are not rectangular). The results are presented for sample images first and then for the overall roof panels.

7.2 Performance evaluation metrics

Recall and Intersection over Union (IoU) are widely used metrics for evaluating object detection and segmentation tasks. Recall helps evaluate how well a model identifies all objects in an image, while IoU provides a robust measure of spatial overlap between predicted and ground truth (GT) regions[22]. Slate detection performance is thus evaluated here using both Recall and IoU. Note that each predicted box is matched to the GT box with highest IoU, and classified according to the IoU value as summarised below:

- *TP (True Positive)*, if $IoU >= 0.5$.
- *FP (False Positive)*, if $0.1 <= IoU < 0.5$. It is further classified into:

(a) Segment 1. (b) Segment 2.

(c) Segment 3.

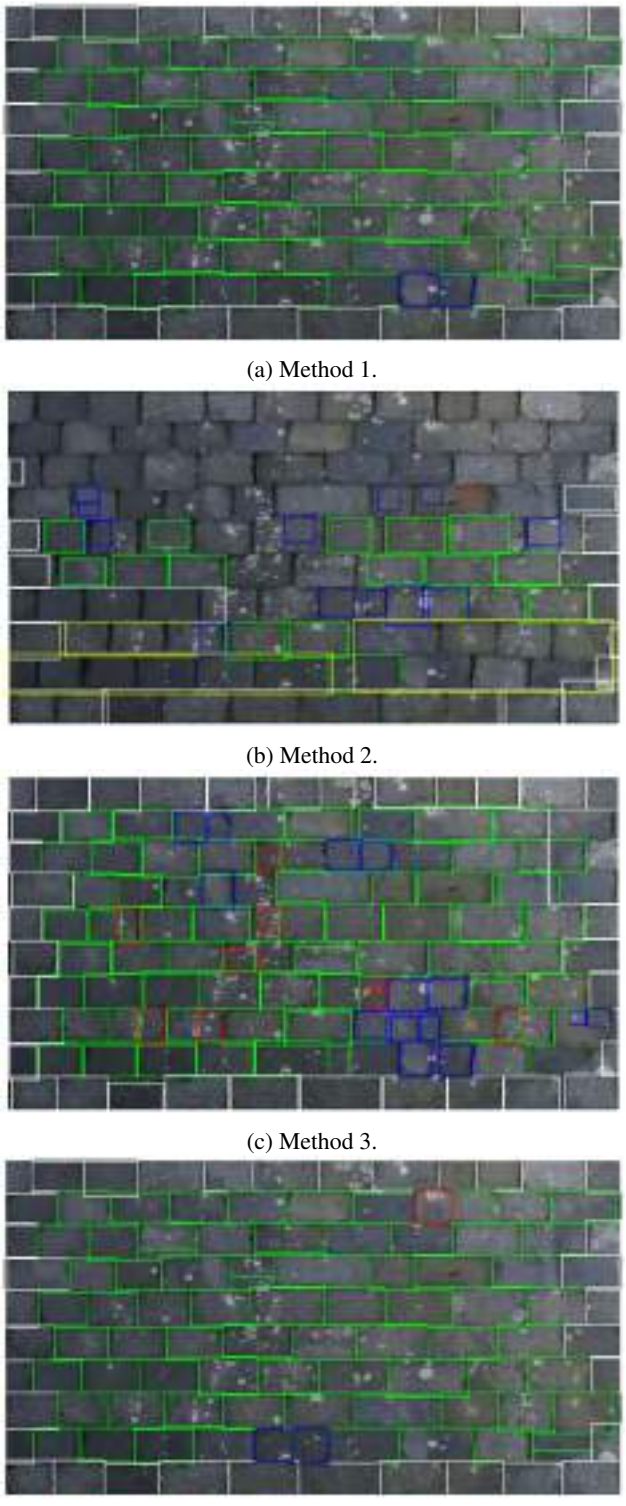
Figure 4. Three segments extracted from the three roof panels.

Method	mIoU	Recall
1	0.86	0.97
2	0.62	0.65
3	0.76	0.89
4	0.86	0.97

Table 1. Performance (mIoU and Recall) of the four slate detection methods applied to the three sample orthophoto segments.

  - *FP - Over segmented*, if GT box size > Prediction box size.
  - *FP - Under segmented*, if GT box size < Prediction box size.
- *FN (False Negative)*, if $IoU < 0.1$.

Overall performance is evaluated using:



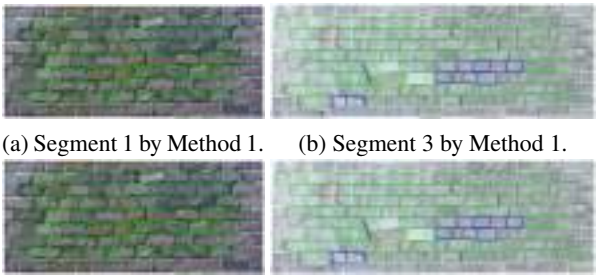
- *mIoU*, the mean IoU values;
- *Recall*, the proportion of slates correctly detected.

7.3 Detection results on sample roof segment

Results using the 4 different methods were first obtained for three roof segments extracted from the three panels, shown in fig. 4. The results for the three segments are summarised in table 1, and results can be visualised for one segment in fig. 5.

Note that the slates located at the boundaries of the segments are typically incomplete, and should thus be discarded from the performance analysis. The three segments collectively contain 202 non-boundary slates, and 114 discarded boundary slates, and the results in table 1 are obtained by considering only the non-boundary slates.

The first observation is that **Method 1** clearly outperforms **Method 2**. **Method 2** performs poorly because some its segmentation map sometimes includes small connections between the detecting areas of neighbouring slates leading to the detection of one large (that is subsequently filtered out) instead of two slates.



(a) Method 1.

(b) Method 2.

(c) Method 3.

(d) Method 4.

Figure 5. Slate detection results obtained by the four methods on Segment 2 (White: Boundary; Green: TP; Blue: FP - Over Segmented; Yellow: FP - Under segmented; Red: FN).

(a) Segment 1 by Method 1. (b) Segment 3 by Method 1.

(c) Segment 1 by Method 4. (d) Segment 3 by Method 4.

Figure 6. Visualisation of results obtained with Method 4 for Segments 1 and 3.

Method	Panel	Non-boundary		All slates	
		mIoU	Recall	mIoU	Recall
1	A	0.72	0.89	0.68	0.85
	B	0.57	0.78	0.54	0.73
	C	0.57	0.75	0.56	0.73
	Overall	0.58	0.77	0.57	0.74
4	A	0.78	0.93	0.76	0.91
	B	0.63	0.83	0.59	0.78
	C	0.69	0.83	0.67	0.81
	Overall	0.69	0.84	0.67	0.81

Table 2. Comparison between different segmentation methods in raw slate images.

The results of **Method 3** demonstrate an obvious improvement compared to **Method 2**. The bounding box prompt helps increase the probability of segments inside each prompt bounding box, making **Method 3** distinguish individual slates more robustly than **Method 2**.

Method 4 performs even better, to a similar level to **Method 1**. However, because of the mechanism behind the two methods (Canny detector and SAM segmentation mask), they differ in their sensitivity to edges, resulting in both methods seemingly failing in different locations.

fig. 6 show the results obtained with **Method 4** on the remaining two segments.

7.4 Detection results on complete slate images

The results obtained for the three orthophoto segments in section 7.3 clearly show the superiority of **Method 1** and **Method 4**. Therefore the performance on the complete orthophotos is now evaluated for only those two methods. The results are summarised in table 2 and those obtained with **Method 4** can be visually explored in fig. 7. Note that the analysis distinguishes the performance with and without *boundary* slates, that are the slates whose GT box intersects the slate mask, i.e. intersect the orthophoto background of black pixels. The reason for this distinction is that boundary slates typically present a greater range of shape (e.g. truncated) and appearance (e.g. presence of leadwork pixels), which may challenge the detectors.

Overall, **Method 4** performs best, with $mIoU = 0.67$ and $Recall = 0.81$. The better seems because the SAM segmentation map demonstrates clearer slate boundaries than the Canny edge detector. Such advantage is more obvious in the complete orthophotos that include a broader range of complex shape and conditions (e.g. boundary slates, holes, etc.).

However, **Method 4** still makes a number of errors. For example, there are a lot of noisy bounding boxes generated in areas containing biological growth (see the upper and right part of Panel C). The uneven brightness in the bottom part of Panel A also affects the vertical slate edge detection, leaving some non-boundary slates undetected. The unclear slate boundary in the top part of Panel B results in more slates detected in FP (Under segmentation) status.

The comparison of the results for all slates and non-boundary slates shows a drop of 2 percentage points in the performance for all slates. As noted above, a drop was expected due to the fact that boundary slates tend to have a greater range of shapes and appearance. However, the drop appears to be only minor.

8 Discussion

The results of **Method 1** and **Method 4** already demonstrate promising results, with mIoU=0.67 and recall=0.81 for **Method 4** and mIoU=0.57 and recall=0.74 for **Method 1**, which can form the basis for defect assessment of individual slates, e.g. through classification. However, the orthophoto quality noticeably influences the accuracy, especially in Panel B where the slates at the bottom of the panel are not as clear. This motivates further work to improve data collection and orthophoto generation. Besides, FPs are noticed to be common in areas where there is the presence of biological growth. Therefore, methods should be explored to better discriminate slate boundaries from biological growth in the image input to the Hough Transform-based line detection (from Canny edge detector or SAM segmentation map).

We note that the proposed slate segmentation approach is designed for typical traditional slated roofs (laid in in horizontal rows) and does not require any roof-specific parameters. The approach is thus applicable to most slated buildings. However, slated roofs may at times have different patterns, with slates cut and laid in other ways (e.g. fish scale patterns). For those roofs, **Method 1** and **Method 4** would not be applicable, but **Method 3** could prove suitable.

Finally, while SAM is shown to be able to highlight edge features, some alternative deep learning model for image segmentation (and slate detection) could be explored.

(c) Panel C.

Figure 7. Visualisation of complete slate image results obtained by Method 4.

9 Conclusion

This study proposed an overall approach and 4 specific methods for slate detection in orthophotos of building roof panels, comparing: edge detection by Canny detector (**Method 1**), SAM (**Method 2**), SAM with bounding box prompt from **Method 1** (**Method 3**), and edge detection on the original SAM mask (**Method 4**). All four methods were first evaluated on three cropped orthophoto segments, and **Method 1** and **Method 4** stood out with similar and high mIoU (0.86) and Recall (0.97). The two methods were then further evaluated on complete roof panel orthophotos, on which **Method 4** showed superior performance. The results highlight the encouraging levels of performance of **Method 1** and **Method 4**, but also their difficulty in areas containing significant biological growth and their sensitivity to roofs acquired in poorly lit conditions. Their distinct performance in different areas also suggest that future research could — alongside evaluating the methods on more extensive datasets — possibly explore integrating their results.

Abstract

While structural analysis software facilitates the modeling of complex structures, it requires significant effort to master these tools. With advancements in large language models (LLMs), this study explores the potential of leveraging an LLM as a software-independent assistant for reviewing and editing structural analytical models. The proposed framework was tested using GPT-4o and an analytical model from Midas Gen, focusing on tasks such as model information extraction and editing. The results demonstrated the framework's potential, achieving an accuracy of 91% when a system prompt with model data ontology information was used, compared to a 20% accuracy without the use of any prompt engineering.

Keywords –

Analytical Models; Structural Models; LLM; System Prompt; Code Interpreter

1 Introduction

Computer based structural analysis has become an indispensable part of the structural engineering profession. The emergence of structural analysis software has enabled engineering designs of much higher complexity and greater scale. However, even with the evolution of structural analysis software over the years, the general modeling approach has not evolved dramatically – they still rely heavily on heuristics and trial-and-errors which makes the structural design optimization a human-centric process [10]. In this task, the extent of the engineer's ability to efficiently control the analytical model constructed within the analysis software becomes an important factor. Especially for engineers who perform designs for multiple industries or regions, they may be required to obtain proficiency in multiple structural analysis software which is no small feat. Furthermore, even if adequate software proficiency is reached, engineers are usually limited to the native features of the software. This lack of flexibility in analytical model control leads to tasks with high interaction cost, especially when dealing with complex models.

Large language models (LLMs) have made great strides in recent years. With carefully designed prompts, LLMs demonstrate great performance on textual classification, information extraction, and summarization [11]. Considering the building blocks of any structural analytical model are simple textual and numeric arrays, an LLM based user interaction method for analytical model control can potentially provide much more freedom in communicating the engineer's intent to the structural analysis software. In addition to this already powerful textual processing abilities, multimodal LLMs allow for amalgamation of diverse set of data types [9].

This study aims to lay the foundation for developing a software-independent structural analytical model review and editing method using an LLM for future research endeavors. To perform a structural analysis, a structural model and its properties must be prepared, reviewed, and adjusted for the targeted analysis. The process of establishing a structural model frame can be broken down as shown in Figure 1. This study focuses particularly on the last two steps: review and editing steps. For the review step, the ability to select specific groups of elements and extract various information about them is evaluated. For the editing step, the capability to adjust element attributes, such as section types or boundary conditions, for a specified group of elements is assessed.

Selecting a specific group of elements within the modeling software, or filtering, is an essential feature in performing review and editing steps of any structural analytical model. Filtering is generally done with natively offered basic filter options. There are software packages that allow users to build custom filters such as SAP2000 and its advanced filter features using a

structural query language (SQL); however, while such approach widens the types of filters that can be used, it still does not offer enough flexibility to cover all possible scenarios and are often time consuming to build, test, and deploy when needs arise. For example, if a user needs to filter beams that are not directly connected to any columns to select all sub-beams or joists, such filtering would generally not be covered by native software filters. This element selection via filtering must be followed by the ability to apply edits to the element attributes, if necessary, completing the review and editing process.

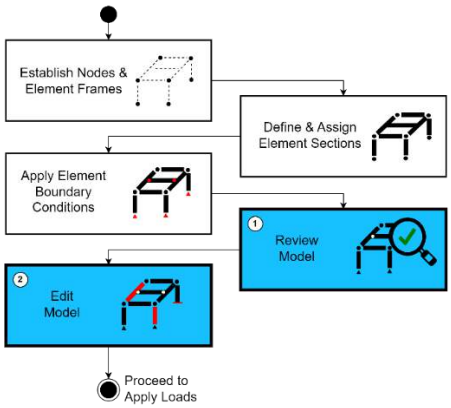

Figure 1. Review and editing steps of structural analytical modeling process

For testing, the geometric and element feature data of an analytical model from the most widely used structural analysis software in South Korea, Midas Gen, was uploaded to ChatGPT-4o along with a system prompt and model data ontology information to enhance its performance. Then, a series of tasks were given as user prompts where corresponding results were evaluated.

2 Related Studies

This section of the study consists of two parts: The first part will review literature on LLM applications in architectural design process where the primary focus will be LLM augmentation on design software. The second part will be an overview of artificial intelligence (AI) applications in structural engineering where model generation and design optimization will be discussed.

2.1 LLM Augmentation on Design Software

Natural language (NL) based user expressions allow for much more complex forms of queries to be used in software control. One application strategy is to extract user's intentions via LLM and map specific functions or features of the design software. For instance, an NL query to search for a specific element or additional information about the element from a building information modeling (BIM) entity, such as a Revit model, has been proposed [11]. In this literature, the NL query is first processed by the LLM to map its intent to the corresponding parameters and value dictionaries. Then, the appropriate search functions are called to interact with the application programming interface (API). However, this approach limits its focus on element searching and does not account for design generation or information management.

Jang et al. expands the prompt-based user interface concept to handle Revit element manipulation with their proposed framework Natural-language-based Architectural Detailing through Interaction with AI (NADIA) [4]. In this framework, the user request via the task prompt is first categorized based on its task type and relevant component type. Then, the necessary BIM authoring is executed to generate, modify, retrieve, or delete the relevant Revit object. This functionality more closely resembles the analytical model control which will be discussed in this study; however, the main difference will be that the geometric data and some of the element feature data will be entirely transferred to LLM for this study where analytical model data will be manipulated directly by LLM without any reliance on existing software functions or features.

2.2 AI Application in Structural Engineering

Design optimization is expectedly a popular topic of interest in many recent studies involving AI and structural engineering. As per most engineering design problems, structural design problems involve a large set of input variables and also many output variables to be optimized. Structural optimization problems can be categorized into cost, performance, environmental impact, and multi-objective optimization (MOO) problems [8]. For example, reinforced concrete section design is an MOO problem that is an excellent candidate for an optimization method using an artificial neural network (ANN). ANN can be used to explore various pareto curves to flexibly optimize what would traditionally be a computationally expensive problem with much less effort [2]. However, design process optimization, including user-software interaction, unfortunately falls outside of the purview of this popular view of engineering optimization.

Although it is not an optimization method, generative AI presents new opportunities for structural topology generation. AI models can be used to extract patterns from a large design dataset and reproduce resembling structural layouts accordingly [7]. Generative Adversarial Network (GAN) can be used to generate column and beam models based on 2D images [6], furthermore, physical rules can be implemented alongside GAN to enhance the quality of the generated structural topology [1]. Although these novel strategies

contribute to enhancing the qualities of the AI generated analytical models, the need for structural engineers to closely review and edit these models still remains.

3 Proposed Method

3.1 Analytical Model Data

For most commercial structural analysis software, such as Midas Gen or ETABS, analytical model data is typically stored in a series of 2D arrays or tables. Analytical model data composition for Midas Gen is summarized in Table 1. These tables reference each other – for example, the element table does not contain the coordinates of these elements explicitly, but rather they specify the two nodes each element is connected to. A part of the "Elements" table from Midas Gen is shown in Table 2.

Table 1. Midas Gen model data tables

Table Name	Contents
Elements	Element Number / Material / Section / Orientation / Node Connectivity
Nodes	Node Numbers / Coordinates
Materials	Material Number / Name / Type / Sub-type
Supports	Node Assignment / Translation & Rotation Release
Sections	Section Number / Name / Shape / Sizes

Table 2. "Elements" table from Midas Gen

Element ID	Material	Section	Beta Angle	Node 1	Node 2
1	1001	101	90	1	10
2	1001	103	0	1	11
3	1001	101	90	2	11
4	1001	103	0	3	11
5	1001	101	0	3	12

Compared to typical architectural models, structural analytical models are much simpler and hold vastly less information as they are based on directional stick-and-node graphs. This simpler and smaller model data can be uploaded to ChatGPT-4o for more direct control of the model data without relying on any built-in software functionalities for model manipulations. To ensure that ChatGPT-4o properly understands the data structure, an ontology representation file was created with Protégé as shown in Figure 2.

Figure 2. Midas Gen model data ontology

3.2 Data Processing

When tabular data, such as CSV files, is uploaded to ChatGPT-4o, it is stored in its memory as DataFrames which is a table-like data format provided by the Python library pandas. When the user prompts inquire about the information stored in the DataFrames, ChatGPT-4o then writes and executes its own Python codes to extract and edit the data (Figure 3). This functionality of ChatGPT-4o is called Code Interpreter. These codes are then immediately available to the user with the response. An example of the code generated by ChatGPT-4o is shown in Figure 4 in pseudo-code for clarity.

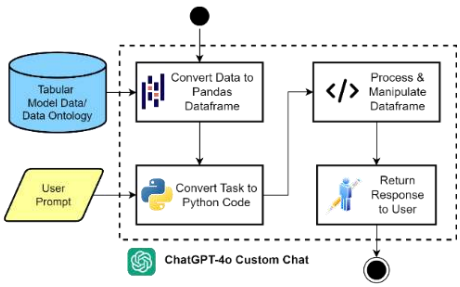

Figure 3. Tabular data processing of ChatGPT-4o

Figure 4. ChatGPT-4o generated code for the task 'How many columns are on the first floor?'

Because the analytical model review and edit assistant proposed in this study relies on ChatGPT-4o to correctly interpret the user tasks and successfully extract and manipulate the relevant information, the system heavily depends on ChatGPT-4o's ability to write effective Python codes.

3.3 System Prompt

The system prompt was developed through a trial-and-error approach, iteratively refining its content based on errors until ChatGPT-4o could visualize the analytical model successfully. After several iterations, the following three main components were selected to be included in the textual part of the system prompt: general role, geometric context, and element definitions as shown in Table 3. The general role explains the expected role of ChatGPT-4o followed by the descriptions of the CSV model data files and the data ontology file. The geometric context explains the contextual meaning of the coordinate system, for example, z = 0.0 means ground level. Finally, the element definitions describe the definitions of various structural components in terms of their nodal coordinates. The element definitions component of the system prompt is important because the user is expected to refer to the elements by the element types, such as beams or columns; however, ChatGPT-4o, in its native state, was not able to identify these element types solely based on the model data.

Followed by the textual portion of the system prompt, the data ontology file was attached to the system prompt of ChatGPT-4o; however, the CSV model data files were not uploaded with the system prompt for two reasons: first, the proposed framework needed to work with any model data, not just one set of CSV files. Second, ChatGPT-4o was unable to keep and recall all the information properly when textual system prompt, the ontology file, and the CSV files were all uploaded within the system prompt at once. In other words, ChatGPT-4o was unable to process multiple instructions and files all under one request as LLMs generally struggle with queries with multiple objectives and perform better when interrelated tasks are provided separately [3].

3.4 Framework Assembly

The analytical model review and edit framework is assembled using the custom chat feature of ChatGPT: The system prompt is first inserted in the instructions window, followed by uploading the data ontology file (.rdf format) prepared using Protégé. This custom chat is saved and initiated as an instance, expecting to receive the analytical model CSV files extracted from Midas Gen. For this study, the CSV files were directly uploaded to ChatGPT-4o's web interface. Once CSV files are processed, it is then ready to take on the user tasks. The overall flow of this framework is shown in Figure 5.

Table 3. The textual portion of the system prompt

Category	Contents
General Role	• You are a virtual assistant to help review and edit an analytical structural model. The model data is stored in several CSV files. These files reference each other. You can combine these files referencing an ontology (.rdf format) file which I will provide also. Let me give you the ontology file first.
Geometric Context	• Ground level is first floor (z = 0.0m). • The second floor is one story above the first floor. • Roof level is the highest level.
Element Definitions	• Columns are vertical elements (change in ONLY 'z' coordinates). • Beams are horizontal elements (no change in 'z' coordinates between nodes). • Braces are diagonal elements (change in ('x' or 'y') coordinates AND 'z' coordinates). • 'Beta_angle' means local orientation, not global.

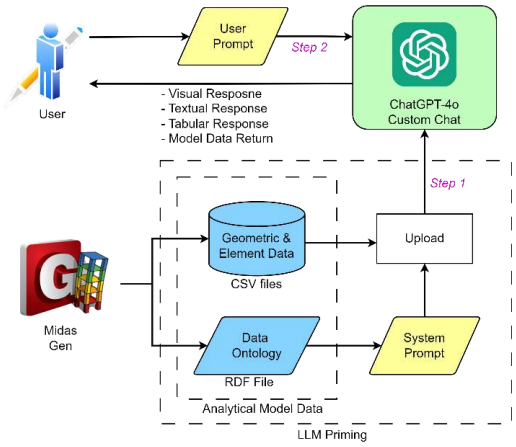

Figure 5. Structural analytical model review and edit framework

4 Validation

To evaluate the analytical model review and edit framework, this study focused on its ability to accurately execute user queries. A diverse set of tasks, including visualization, review, and editing were designed to

evaluate the key capabilities of the framework. The task set and the descriptions are summarized in Table 4.

4.1 Test Subject

A modified version of the American Society of Civil Engineers (ASCE) benchmark structure from the Earthquake Engineering Research Laboratory at the University of British Columbia (UBC) [5] was modeled in Midas Gen. Minor modifications were introduced to this model to add more geometric complexity and incorporate additional section types.

Table 4. Validation Task Set

Task Type	Task Sub-Type	Description
Visualization	Create 3D view	Render a 3D view of the model.
	Color by element type	Show beams, columns, braces and support nodes in assorted colors.
Extraction for Review	Single table reference	Inquire about information accessible from a single table.
	Multiple table reference	Inquire about information that requires accessing multiple tables that reference each other.
Extraction and Editing	Based on prompts	Edit model data based on user prompts.
	Based on images	Edit model data based on user prompts and image files.

4.2 Evaluation Task Categories

4.2.1 Visualization Tasks

The purpose of the visualization task category is to verify that the custom chat initialization has been correctly performed. Although these tasks do not simulate any potential user inquiries, for the validation of the study, it is a key step to ensure that the framework is able to assemble the model data correctly. The geometric assembly is validated by the 3D render task and the element classification is validated by the element color assignment task (Figure 6).

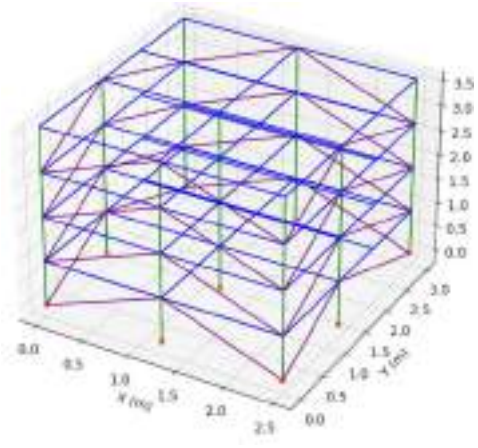

Figure 6. A successful visualization task result

4.2.2 Extraction for Review Tasks

The extraction for review task category is to simulate the user inquiries to extract model information for the purpose of reviewing various model attributes, such as element quantities, section types, material types or connection types. This task category includes basic filtering tasks to ensure that the LLM based approach can effectively replace the basic filters offered by most modeling software as well as more challenging tasks such as boundary condition-based filtering and filtering based on neighboring element types such as adjacency with columns.

For the single table reference tasks, the requested information is directly accessible from one of the DataFrames, while for the multiple table reference tasks, ChatGPT-4o must utilize the data ontology to reference multiple DataFrames to process and generate the appropriate response. An example of a multiple table reference task would be an element length calculation task where the element node numbers refer to the nodes table where the coordinates are stored. The coordinates are then used to calculate the Euclidean distance between the two nodes to evaluate the element length. An image file containing grid label assignment is also uploaded at this stage of testing.

4.2.3 Extraction and Editing Tasks

The extraction and editing task category consists of two important steps: firstly, the framework needs to understand the user request to extract element attributes and make changes to the model data stored in its memory, then secondly, it needs to return CSV files back to the user in a format that is consistent with the original model data. The second step is crucial to allow the CSV files to be loaded back to Midas Gen for an uninterrupted workflow.

The extraction and editing task based on images is to simulate a scenario where structural elements need to be

updated in accordance with drawings, either from architectural or structural design changes. For this task, an image (.png format) file containing a plan view with revised section type labels is uploaded along with the user prompt.

5 Results

A total of 11 tasks were tested 5 times each. In addition, to see the effects of the system prompt containing the textual instructions and the data ontology file, the same set of tests were repeated without any initialization (ChatGPT-4o in its vanilla state) and with the system prompt. In total, 110 task trials were conducted for this study. The test results are summarized in Figure 7 and detailed results along with the task prompts are shown in Table 5.

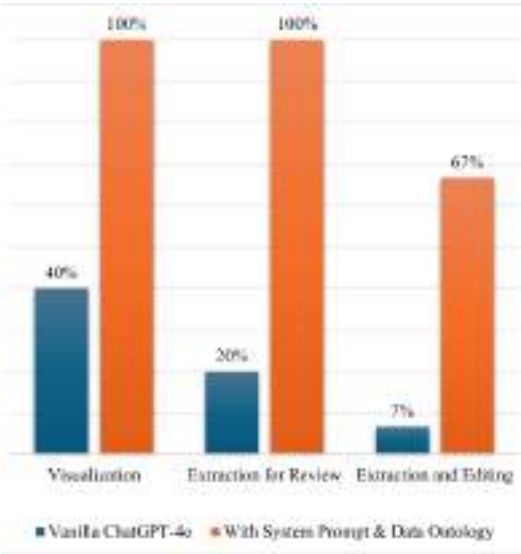

Figure 7 Test results summary

5.1 Results by Task Categories

5.1.1 Visualization Tasks

ChatGPT-4o was able to successfully perform the 3D visualization task 4 out of 5 times even without any assistance from the system prompt; however, it was not able to classify different element types, such as beams, columns, or braces. Although ChatGPT-4o has access to general definitions of what each of those element types are, it was not able to semantically connect the dots between element definitions and geometric orientations in the cartesian coordinate system.

When initialized with the system prompt that contains detailed element definitions in the context of the model geometry, both 3D visualization and color coding by element type tasks were performed perfectly.

5.1.2 Extraction for Review Tasks

The overall success rate of the extraction for review tasks without the system prompt was 20%. A notable result was when asked to check if all beams that are not directly connected to columns also pin connected, the correct response (‘yes’) was given 3 out of 5 times even without the system prompt. To ensure the successful responses were not ‘false positive’ answers, an additional inquiry was made to identify the relevant element numbers for confirmation. With the system prompt, all the tasks were performed perfectly for all trials.

5.1.3 Extraction and Editing Tasks

ChatGPT-4o was able to return the edited CSV files in the correct column arrangements (to allow for direct import back to Midas GEN) even without the system prompt; however, it was able to perform the requested edits correctly for only 1 out of the 15 trials. The most common errors were edits being applied to too many elements around the correct target elements. Prompt-based editing tasks were perfectly performed with the system prompt. Image-based editing tasks could not be performed successfully even with the system prompt as the target elements were always misidentified.

6 Discussion

Recent LLM driven BIM software control studies have generally relied on the software’s natively built-in functionalities for model control. This study demonstrates that leveraging ChatGPT-4o’s code interpreter feature to more directly control analytical model data is a feasible strategy, with one important caveat: the framework requires an elaborate system prompt, including detailed textual instructions along with data ontology information, to function effectively.

6.1 Limitations

While this study provides new insights into a prompt-based analytical model review and editing framework that is free of any predefined software functionalities, there are limitations that must be addressed.

The proposed framework was evaluated using the ASCE benchmark model, which is significantly less complex than most real-world engineering examples. This limitation restricts the generalizability of the results, as the structural simplicity of the ASCE model may not adequately represent the challenges encountered in practical engineering scenarios. In addition, the validation process was conducted with a relatively small and narrowly defined set of tasks, further constrained by a limited number of repetitions.

Table 5. Task user prompts and test results

Task Type	Task Sub-type	User Prompt	Success/Fail: Vanilla ChatGPT-4o	Success/Fail: With System Prompt & Data Ontology
Visualization	3D View of Model	a. Create a 3D visualization of analytical model.	4/5	5/5
		b. Show support nodes in red, and color beams, columns, and braces differently.	0/5	5/5
Extraction for Review	Single table reference	a. How many columns are there on the first floor?	1/5	5/5
		b. What are the element numbers of beams on the ‘roof level’ along grid X1?	0/5	5/5
		c. Give me the element numbers of beams that are not connected to columns.	0/5	5/5
	Multiple table reference	a. Give me the element lengths of all the beams on the third floor.	1/5	5/5
		b. Give me the element numbers and section names of beams that are on the third floor and beam end released	1/5	5/5
		c. Are all the beams that are not directly connected to columns also beam-end-released?	3/5	5/5
Extraction and Editing	Based on prompts	a. Replace all beam sections on the roof level to 'section 101'. Apply this change and return the element CSV in its original column format.	0/5	5/5
		b. Remove all beams with beam end released on the second level. Apply this change and return the element CSV in its original column format.	1/5	5/5
	Based on images	a. Apply beam section changes as per the uploaded PNG on the ‘roof level’. Select the section number according to the section name in the PNG file. Apply this change and return the element CSV in its original column format.	0/5	0/5
		Overall Success Rate	20%	91%

The framework's performance depends entirely on ChatGPT-4o's ability to generate effective Python code for manipulating model data. Also, heavy reliance on an LLM can lead to unreliable reproducibility. As demonstrated by the test results, variations were observed in the responses generated, even when identical input conditions were provided.

Failure to perform image-based tasks is a crucial drawback of this framework. Drawing based structural analytical model revision is a common and time-consuming task, and it would be an invaluable functionality to be implemented to this framework.

6.2 Future Work

Further testing with structural models that more closely resemble the size and complexity of real-world engineering examples with greater number of repetitions will be conducted. A more unified pipeline will also be developed for the proposed framework for proper testing and further development.

For the upcoming research efforts, the effects of the data ontology representation independently from the system prompt will be explored to better quantify its impact on the performance of the proposed framework.

Image-based task performance must be addressed by exploring new strategies such as few-shot learning or more refined system prompt designs.

7 Conclusion

This study explored the potential of LLMs as analytical model review and editing assistants for structural analysis. By using an LLM-driven approach, it demonstrates new ways to improve user interaction beyond traditional tools like rule-based filters. The results showed the framework’s potential, achieving an accuracy of 91% when a system prompt with model data ontology information was used, compared to a 20% accuracy without any prompt engineering.

Key limitations include evaluation with the relatively simple ASCE benchmark model with limited validation task set and repetitions, an overreliance on ChatGPT-4o's capability to produce effective Python code and difficulties in managing image-based model edit tasks. Future work will focus on more rigorous validation and developing a unified pipeline for seamless integration with industry-standard tools. The image-based task performance will also be addressed by exploring few-shot learning and more refined system prompts.

Abstract –

Occupational exoskeletons (OEs) offer significant potential to reduce the incidence and severity of musculoskeletal disorders (MSDs) in the construction industry. Despite this potential, OE adoption remains low due to unique challenges in this industry. By addressing the limitations of previous OE adoption frameworks and roadmaps, this paper proposes a framework to guide OE design, evaluation, and implementation specifically for the construction industry. The novel elements of the framework are: (1) incorporating sets of general and trade-specific standard OE test methods, and (2) incorporating trade-specific criteria for minimum OE design requirements, sufficient evidence of OE efficacy, and sufficient evidence of OE effectiveness. A roadmap is extrapolated from the proposed framework that recommends future research on trade-specific standard test creation and trade-specific stakeholder surveys to inform minimum criteria. Finally, the results of a pilot field study on a back-support OE for reinforcing ironworkers are linked to the framework as an example of its utility. The goal of this research is to define a process for generating a comprehensive body of scientific evidence that can support large-scale OE adoption in the construction trades.

Keywords –

Occupational Exoskeleton; Construction

1 Introduction

Trade workers in the construction industry suffer from work-related musculoskeletal disorders (MSDs). MSDs in the United States construction industry in 2016 were higher than the average of all other industries combined [1]. 46% of United States construction workers in 2019 self-reported MSD symptoms [2, 3]. Research in Québec, Canada in 2024 suggested that occupational exoskeletons (OEs) had the potential to have addressed 50% of all MSD cases that were observed in a large construction contractor's work force over the three-and-a-half-year study period [4]. The adoption of OEs by the construction industry, however, remains low.

Previous research has investigated the necessary elements for successful industry adoption for any type of occupation intervention. Van der Beek et al. [5] proposed a general roadmap for the adoption of occupational interventions which involves six steps: (1) Quantify MSD incidence and severity, (2) Identify the risk factors associated with MSDs, (3) Investigate the underlying mechanisms relating risk factors to MSDs, (4) Develop an intervention, (5) Evaluate the intervention, and (6) Implement the effective intervention. Step 5 returns to Steps 2, 3, or 4 if there is no evidence of an intervention's effectiveness when evaluated, thereby making the roadmap iterative. Step 6 returns to Step 1, ideally showing a reduction in MSD incidence and severity in a population of workers, making the roadmap circular. As an example-use of their roadmap, Van der Beek et al. [5] presented the hypothetical development of an intervention for bricklayers: change in workstation height.

As the interest in adopting OEs at a large scale has grown since the mid-2010s, frameworks have been proposed specifically for the design, evaluation, and implementation of OEs [6–12]. Pesenti et al. [6], De Bock et al. [7], and Golabchi et al. [8] categorized measures of an OE's effects as either muscular, biomechanical, metabolic, functional, or subjective, and recommended task-specific and posture-specific evaluations. De Bock et al. [7] proposed technology readiness levels (TRLs) to guide the choice of test environments, including laboratory efficacy studies, field effectiveness studies, and simulation studies. Balancing comprehensive evaluation with practicality, Hoffmann et al. [11] recommended standardizing evaluation methods and consolidating measures of OE effects. This has since been exemplified by standard test methods from the ASTM Committee F48 on Exoskeletons and Exosuits (ASTM F48).

To realize such frameworks, roadmaps towards the goal of large-scale OE adoption have also been proposed. Crea et al. [13] proposed a roadmap to facilitate OE adoption in any industry, e.g., manufacturing, logistics, or construction. The goal of the authors was to provide a path toward a holistic body of scientific evidence that is necessary for large-scale OE adoption [13]. A limitation,

however, of this roadmap, and of all the above frameworks, is the lack of specific mechanisms or processes by which to generate such a body of scientific evidence.

Clear processes for OE adoption may be especially important for the construction industry because of the unique challenges it faces. Zhu et al. [14] and Nnaji et al. [15] found that, compared to the manufacturing and logistics industries—where OE design and evaluation is more mature—the construction industry is unique because of the inherent variability and intensity of the tasks and conditions that construction workers face within each trade, and because of the variability between trades. These challenges complicate OE adoption in the construction industry [14, 15].

Previous work has attempted to addressed these unique challenges in construction by proposing realistic evaluation methods towards the development of standard tests, including the research from Kopp et al. [16] on the welding and timber framing trades. Similarly, Dunson-Todd et al. [17] proposed a realistic test method for evaluating back-support OEs for reinforcing ironworkers (rebar workers), towards a standard test that can be used to generate sufficient evidence of OE efficacy, safety and acceptance, as recommended by [11]. The question remains, however, of how these standard tests for the construction industry can fit within a larger framework for generating the holistic body of scientific evidence required for OE adoption, as proposed by [13].

Informed by the previous work discussed above, the current paper proposes such a framework and uses it to extrapolate a roadmap for future research required in the construction industry. The framework addresses the specific challenges inherent in the construction trades while providing a comprehensive path towards OE adoption. To provide insights into the utility of the proposed framework, the results of a pilot field study on a back-support OE for rebar workers are discussed. The pilot field study is a continuation of previous work toward a standard test for the rebar trade [17]. Examples of real-world construction OE challenges found from the pilot field study are linked to the framework to demonstrate its value. Section 2 presents the framework for OE adoption in the construction industry and the roadmap to realize it. Section 3 presents the results of the pilot field study.

2 Framework and Roadmap for OE Adoption in the Construction Trades

Informed by the previous research described in Section 1, Figure 1 shows the proposed framework for OE adoption in the construction industry. The framework is divided into Steps 1 to 4, and sub-steps, e.g., 2(a), 2(b), etc. Much of the framework has been adapted from previous research: Step 2, Design, is adapted from Van der Beek et al. [5], and Step 3, Evaluation, is divided into short-term and long-term laboratory and field evaluation, as proposed in previous frameworks and roadmaps, e.g., [13]. By convention, long-term can be defined as a study period greater than 3 months, as in [18]. Short- and long-term simulation have been included in Steps 3(a) and 3(b) of the framework. Simulation has been used to estimate an OE's immediate effects on the biomechanical system of the body in previous research, e.g., [19]. Although no methods exist for simulating the long-term effects of an OE, future longitudinal field testing may generate evidence that can be used to verify simulations of an OE's long-term effects.

Two elements of the framework are novel: (1) proposing a set of general and trade-specific realistic standard laboratory tests for each trade, and (2) proposing three minimum requirement decision points informed by a trade-specific industry stakeholder survey, further referred to in this paper as a trade-specific survey (TS). These novel elements are outlined with a bold border in Figure 1. The framework, and a roadmap to realize it, are described in detail in the following subsections.

2.1 OE Design

Van der Beek et al.'s [5] proposed framework for designing an intervention rested on an evidence-based understanding of the mechanisms behind MSDs in a population of workers. As shown in Figure 1, this has been adapted as follows: Step 1, looking to statistics to understand MSD incidence and severity in a construction trade population, (e.g., as in [4]); Step 2(a), conducting epidemiological observational studies to identify the MSD risk factors present in a given trade; Step 2(b), conducting laboratory and field studies to identify the etiological mechanisms linking risk factors to MSDs; and Step 2(c), a research and design process that targets these mechanisms to develop a new OE or modify an existing OE for the benefit of a specific construction trade.

2.2 Set of General and Trade-Specific Standard Laboratory Tests

As recommended by Gutierrez et al. [20], controlled laboratory studies that simulate construction tasks and environments will help identify the most appropriate situations to implement OEs. The Delphi survey from Mahmud et al. [21] identified seven potential solutions regarding policy and regulatory barriers to OE adoption, two of which were (1) scientific data to drive regulation and policy development, and (2) forming industry standard practices. These solutions can be achieved by collecting benchmarking data from a set of both general and trade-specific standard tests.

As an example, the welding trade would benefit from

a general standard test to evaluate OE capabilities in confined spaces, and ASTM F48 has already published such a test method: F3523 − 21 [22]. The trade-specific requirements of an OE for a welder, however, cannot be fully met by a set of general standard tests. A realistic trade-specific standard efficacy test for welders, as proposed by Kopp et al. [16], can be used in combination with general standard tests to generate sufficient evidence for OE efficacy. In this case, "sufficient" can be defined by the results of a TS for the welding trade, as will be described in Section 2.3. As a second example, a candidate for a general test method is the evaluation of an OE design's heat retention, which is especially applicable to all construction trades that work in outdoor and non-temperature-controlled environments, such as the rebar trade. The proposed trade-specific test method from Dunson-Todd et al. [17] could be used in combination with general standard tests, including a general test on heat retention, to build a set of test methods that comprehensively evaluates an OE design for the rebar trade.

The challenge of creating useful standard efficacy tests is in balancing the comprehensiveness of a set of measurements and conditions with the practicality of implementing them [11]. An example of balancing comprehensiveness of experiment conditions with implementation practicality comes from De Vries et al. [23]. The authors limited the scope of their evaluation for plasterers to three main ceiling and wall plastering activities. In this way, the authors limited test complexity while still capturing most of the ergonomic risk in the

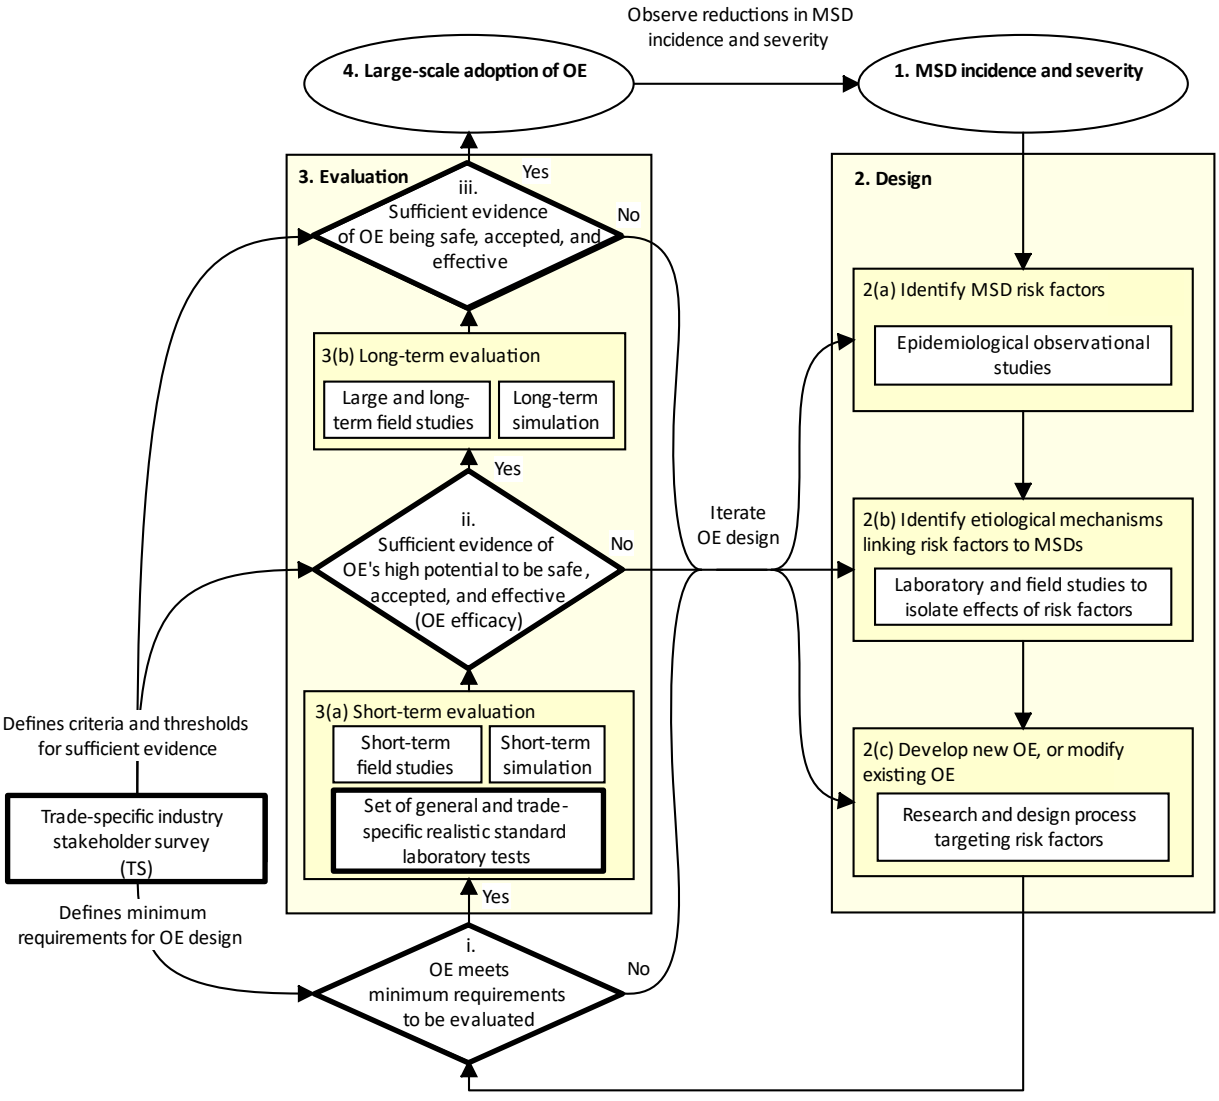

Figure 1. Framework for OE adoption in a specific construction trade

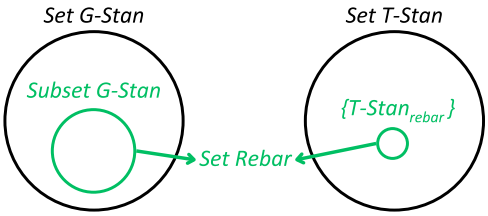
plastering trade. Moreover, the conditions captured the task variability inherent to the trade: results showed a significant reduction in perceived effort during overhead tasks but no significant reduction while applying gypsum to walls, likely due to the variable nature of the latter task. Future work can learn from this example of synthesizing the most important features of the environments and activities of a trade into a realistic efficacy test.

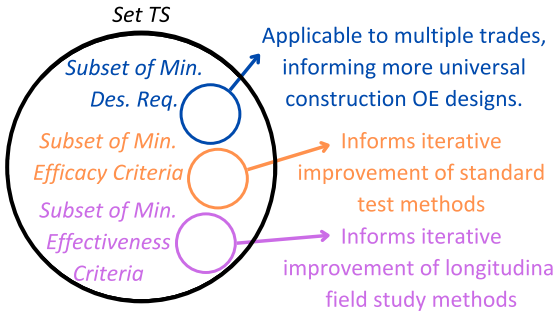
2.3 Trade-Specific Surveys to Define Minimum Criteria Decision Points

The framework shown in Figure 1 includes three decision points: (i) Does the OE meet minimum design requirements to be evaluated? (ii) Is there sufficient evidence of the OE's high potential to be safe, accepted, and effective (i.e., of OE efficacy)? (iii) Is there sufficient evidence of the OE being safe, accepted, and effective? Because of the variation of construction tasks and environments between each construction trade, the criteria for meeting each of these decision points will vary between trades. The criteria for passing each decision point in the framework may therefore be most readily determined through a TS that includes all relevant stakeholders for a given trade. Previous research (e.g., [20, 24, 25]) involved conducting industry surveys to collect construction stakeholders' perspectives. Various survey methods have been used, including Delphi, as in Nnaji et al. [15], in which a panel of experts come to a consensus agreement regarding questions that are important to the construction industry. Similarly, a Delphi TS can be used to inform criteria for passing each decision point in the proposed roadmap in Figure 1.



The roadmap from [13] recommended incorporating all stakeholder perspectives into the design and evaluation of an OE and included the following groups to encompass all OE stakeholders: (1) workers, (2) unions and worker associations, (3) corporate management and corporate decision makers, (4) health professionals, including but not limited to ergonomists, kinesiologists, and occupational medical doctors, (5) insurance companies, (6) policy makers, and (7) certifying bodies and standards development organizations (SDOs), e.g., ASTM F48. For the construction industry, two additional stakeholders are trade school instructors and students. These stakeholders can be added for inclusion in a Delphi TS, as they have a strong influence on the future of any major construction trade.

To further leverage the use of minimum criteria for design requirements, and for sufficient evidence of efficacy and effectiveness, a useful tool for OE adoption may be a minimum criteria labeling system. Labels that signify an OE's adherence to minimum design, efficacy, or effectiveness criteria would accelerate OE adoption in the construction industry, shifting the burden of finding suitable OEs away from individual contractors to the evaluation process outlined in Figure 1. This labeling system could be administered by an SDO to provide the industry with clear indicators of the suitability of any given OE for a specific trade.



Labels may also be useful for market-neutral OE evaluation. The idea of market-neutral reporting used by Kopp et al. [16] promotes participation in the authors' proposed and implemented *Exoworkathlon*. The authors' reporting of aggregate results from multiple OEs, however, relied on the OEs being relatively similar passive shoulder-support designs with similar torque profiles [16]. This method of market-neutral reporting would therefore be impossible for a group of OEs that have significantly different designs and biomechanical effects. With defined criteria of sufficient OE efficacy and effectiveness—(ii) and (iii) in Figure 1, respectively—multiple disparate OE designs can achieve efficacy and effectiveness labels. Labels could thereby provide market neutrality while encouraging OE design diversity.

2.4 Roadmap Toward Standard Tests and Minimum Criteria

To realize the framework for construction OE adoption shown in Figure 1, a roadmap, the goals of which are shown in Figure 2, is proposed as follows.

(a) Goal of standard testing research effort.

(b) Goal of TS research effort.

Figure 2. Roadmap goals toward OE adoption

As outlined in the introduction, previous research has designed OEs for construction trades and has evaluated their efficacy in laboratory studies. In coming years, ongoing longitudinal field studies on construction OEs may be published. The non-novel steps of the framework

(without a bold outline in Figure 1) have therefore been touched upon by previous or ongoing research, with varying degrees of success, and for a limited number of construction trades. Future research may increase the probability of success for construction OE adoption by focusing on the novel components of the framework, which are outlined in bold in Figure 1 and described in Sections 2.2 and 2.3.

The set of general standard tests (*G-Stan*) and trade-specific tests (*T-Stan*) described in Section 2.2 can be represented visually, as shown in Figure 2(a). A set of standard tests for each construction trade can come from the union of a subset of tests from *G-Stan* with a subset of tests from *T-Stan.* As an example for the rebar trade, Figure 2(a) shows *Set Rebar* as the union of multiple general tests, *Subset G-Stan*, and one trade-specific test, $T\text{-}Stan_{rebar}$.

Set G-Stan, *Set T-Stan*, and *Set Rebar* can also be represented as equations, as shown in Equations (1), (2), and (3), respectively:

$$Set\ G\text{-}Stan = \{G\text{-}Stan_1, G\text{-}Stan_2, \dots, G\text{-}Stan_n\} \quad (1)$$

$$Set\ T\text{-}Stan = \{T\text{-}Stan_1, T\text{-}Stan_2, \dots, T\text{-}Stan_{nt}\} \quad (2)$$

$$Set\ Rebar = Subset\ G\text{-}Stan \cup \{T\text{-}Stan_{rebar}\} \quad (3)$$

In Equation (1), *n* is the total number of general standard tests. In Equation (2), *nt* is the total number of construction trades. Zhu et al. [14] classified 16 separate construction trades and their potential for OEs. An *nt* greater than 16 may be necessary, however, as some trade categories from publicly available occupational statistics are too broad. For example, "ironworker" encompasses rebar assembly and steel beam assembly—arguably two sub-trades involving significantly different tasks, environments, and ergonomic risk factors.

The set of trade-specific industry stakeholder surveys (*Set TS)* described in Section 2.3 can also be represented visually, as shown in in Figure 2(b). *Set TS* would provide a benchmark for minimum OE design requirements and useful measures of an OE's efficacy (i.e., evidence for Decision Point ii in Figure 1), and effectiveness (i.e., evidence for Decision Point iii in Figure 1). As represented in Figure 2(b), subsets of *Set TS* can be used as benchmarks to guide the design of future OEs that optimize capabilities and features to meet the requirements of multiple trades. Research conducting TSs would therefore support the development of OEs that are more universally applicable in the construction industry.

Set TS can also be represented as an equation, as shown in Equation 4:

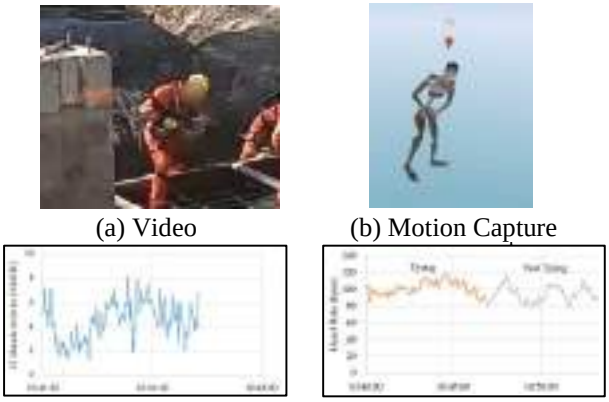
$$Set\ TS = \{TS_1, TS_2, \dots, TS_{nt}\} \quad (4)$$

As in Equation (2), *nt* in Equation (4) is the total number of construction trades. To efficiently use the resources dedicated to researching OEs for the construction industry, the largest construction trade populations with the highest MSD incidence and severity should be prioritized in the pursuit of the goals shown in Figure 2.

3 Pilot Field Study on Rebar Installation

As discussed in Section 2.2, Dunson-Todd et al. [17] proposed a realistic trade-specific efficacy test method for evaluating back-support OEs for rebar workers. The proposed test method from [17] is currently under review by ASTM F48 to potentially contribute to a new standard. Following this research, a pilot field study was conducted to evaluate the same OE as in [17] in field conditions.

Three male construction workers participated in the pilot study, with an average (standard deviation) age of 45.7 (4.0) years, and an average (standard deviation) of 21.0 (2.6) years of experience in construction. The Research and Ethics Unit at Concordia University approved all ethics documents and surveys. The participants constructed a reinforced concrete slab foundation over the course of five days at an electrical substation construction site. Their tasks included assembling rebar, assembling formwork, and pouring and consolidating concrete. Figure 3 shows the construction site conditions and an example of a participant tying rebar while wearing the Biolift back-support OE. Although the sample size of participants was small, the pilot field study was aimed primarily at providing suggestive results on challenges regarding OE design and evaluation in construction. To that end, the following subsections discuss insights from the pilot field study regarding the utility of the design and evaluation framework proposed in Section 2.



(a) Construction site (b) Tying task

Figure 3. Pilot field study conditions.

3.1 Challenges with Measuring OE Effects

As in Dunson-Todd et al. [17], electromyography (EMG) was used to record muscle activity of the lower back, electrocardiography (ECG) was used to record heart rate as a measure of physiology, and inertial measurement units (IMU) were used to record full-body motion capture (i.e., joint angles and segment positions). Figure 4 shows the three sensor data types synchronized to video reference of a participant tying rebar.

(a) Video (b) Motion Capture

(c) Lower-Back EMG (d) Heart Rate

Figure 4. Synchronized sensor data from the pilot field study.

Although the small number of participants and quantity of objective data was too low to be statistically significant, insights were gained regarding using these measures of OE effects in the field. The lack of control over when and for how long each task was performed created challenging conditions for collecting data in both the control (No OE) and intervention (With OE) conditions for each participant.

Data collection was also challenging due to environmental conditions, where hot days delayed construction, induced noise in muscle activity data, and made frequent readjustment of sensor placement necessary due to the participants sweating. Future field studies would benefit from more practical measures, and from measures that are more directly correlated with safety, acceptance, and effectiveness. The criteria created by a TS for the rebar trade could provide insight into what is sufficient evidence of efficacy and effectiveness, and therefore, what objective measures of an OE's effects are required.

3.2 Iterative Design Process

As examples of the iterative design process shown in Figure 1, the OE manufacturer has implemented design improvements informed by [17] and by internal studies, including: (1) providing a suitable replacement for a rebar worker's tool belt, (2) lowering the position of the lower-back pad and dividing it into two pieces on either side of the spine to improve comfort, and (3) providing more secure thigh strap fixtures to prevent strap misalignment.

The pilot field study exposed other potential OE design requirements that were not anticipated in the study from Dunson-Todd et al. [17]. Figure 5 shows participants' responses to a 5-point Likert survey adapted from [17]. Although opinions on support and on balance in the steep environment were positive, all participants found the heat retained by the OE uncomfortable. As discussed in Section 2.3, low heat retention—achieved through integrated cooling, low contact area, or other features—is a promising minimum design requirement for many trades.

Two unanticipated design requirements stemmed from the concept of OE acceptance: (1) A design that allows for both men and women to use the restroom without removing the OE, and (2) A design that allows for maintenance to be possible in field conditions without the need for specialized tools. Two additional design requirements stemmed from the safety measures necessary at an electrical substation: (1) fire resistant materials, and (2) covering all metal parts to eliminate the risk of electrical arcing. A further unanticipated design requirement was the OE's compatibility with a kneeling posture while tying, as one participant commented they were uncomfortable while kneeling with the OE activated. This difficulty, however, may stem from the pilot study's ad-hoc conditions. The design of the OE [26] evaluated in the pilot field study was informed by subjective feedback from experienced rebar workers on large slab construction sites, collected with surveys internal to the manufacturer. The pilot study field conditions were fundamentally different compared to large-slab construction sites, as the conditions involved a relatively small concrete slab with no need to carry rebars. Moreover, although the participants were experienced construction workers, they did not specialize in the rebar trade. As noted in [17], difference in experience in the rebar trade is correlated with significant differences in posture while tying.

The above observations highlight the challenge of designing OEs that accommodate a wide range of workers and use cases, and the challenge of ensuring field conditions that provide generalizable results. Identifying useful minimum design requirements, as described in Section 2.3, can help strike a balance between OEs that are versatile enough to support diverse trades while remaining cost-effective for widespread adoption.

4 Summary and Conclusions

Improving the design and metrology of construction OEs can accelerate the successful adoption of OEs in the construction industry. Informed by previous research, this paper provides a framework by which the OE research community may generate the holistic body of scientific evidence required for OE adoption while addressing the unique challenges faced by the construction industry. By aligning OE design and evaluation processes with trade-specific requirements, incorporating comprehensive stakeholder input, and by leveraging standard tests and minimum criteria, the roadmap offers a specific pathway for accelerating the adoption of safe, accepted and effective OEs.

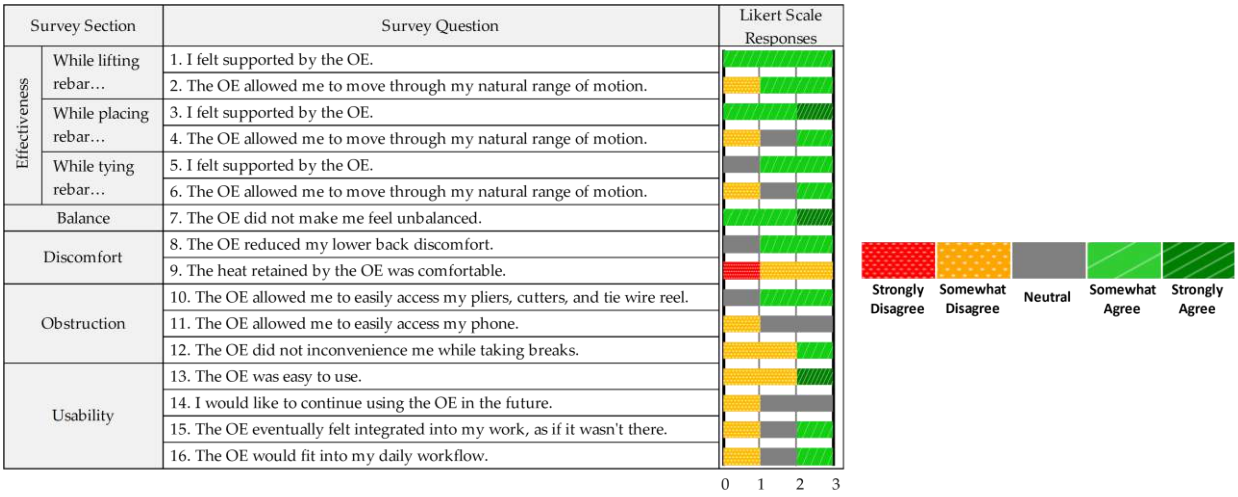


Figure 5. Subjective data from the pilot field study.

The framework outlines significant research initiatives, and this paper argues that investment in these initiatives is justified by the benefits they may bring to the construction industry: mitigating the unique challenges of OE design and evaluation which prevent large-scale OE adoption. To demonstrate the value of the framework with real-world examples of these design and evaluation challenges, the paper presented a pilot field study on a back-support OE for construction workers. The challenges identified in the study included choosing suitable measures for field evaluation, choosing representative field conditions in which to evaluate an OE, the difficulty of accounting for minimum design requirements in unpredictable environments, and other specific design challenges like heat retention. All these challenges can be mitigated by insights gained from a trade-specific industry stakeholder survey, and by this survey informing the other novel aspects of the proposed framework.

As described in the roadmap in Section 2.4, future work can focus on conducting trade-specific industry surveys to establish a consensus on the criteria for each decision point in the framework, eventually leading to benchmarks for minimum design requirements and useful measures of OE effects.

Acknowledgments

This research represents a joint effort with Hydro-Québec and Biolift Technologies, and the authors sincerely thank them for this collaboration. The authors would also like to thank the study participants for their enthusiasm and good humor throughout the research.

Abstract

Suboptimal cognitive states among construction workers significantly impact safety and productivity, with mental workload playing a key role in triggering these states. Determining if the mental workload fluctuation is leading to an error is challenging as the relationship between mental workload and suboptimal cognitive states is complex and non-linear, with traditional theories failing to map their fluctuations effectively. Recently, a two-dimensional space has been introduced to theoretically map mental workload fluctuations and suboptimal cognitive states using task engagement and arousal. However, there is currently no framework in place to continuously apply this theoretical knowledge in practical settings. To address this gap, this study investigates the feasibility of EEG-based frameworks for classifying four different cognitive states, namely comfort zone, mind wandering, effort withdrawal, and inattentional blindness, based on mental workload fluctuations. EEG signals were collected from 10 participants using a headset with dry electrodes, processed to extract relevant features, and classified using Support Vector Machine (SVM) and Artificial Neural Network (ANN) models. The ANN achieved superior performance in k-fold and leave one period out validation methods, though accuracy declined in leave one subject out validation. These findings underscore the potential of EEG-based differentiation of cognitive suboptimalities to enhance safety and productivity in construction by providing crucial information about when construction workers are most likely to make cognitive errors, which is essential for timely and appropriate interventions. Also, the low subject independent accuracy emphasizes the need to address individual differences in EEG signals for broader applicability.

Keywords

EEG, Wearables, Biosensors, Neuroergonomics, Construction safety

1 Introduction

Managing workers' mental workload is a critical aspect of construction management [1]. The dynamic nature of construction sites often subjects workers to varying levels of mental workload, ranging from excessively low to overly high. These suboptimal cognitive states increase the likelihood of unsafe or erroneous work behavior, making it essential to monitor and manage mental workload for both safety and productivity.

Traditionally, mental workload monitoring has been conducted through self-assessment methods, such as questionnaires and interviews [2,3]. However, these methods are highly subject to individuals' recall bias and sporadic due to their invasive nature, making them unsuitable for continuous and dynamic monitoring, which is critical for understanding the dynamics of mental workload oscillation during the ongoing task. To address these limitations, neuroergonomics, which is a field of research to study human brain function in the workplace [4], has been integrated with various wearable-based techniques capable of continuous monitoring and assessing the mental workload. These studies have applied different wearable biosensors, such as electrocardiogram (ECG) [5], electroencephalogram (EEG) [6], photoplethysmography (PPG) [7], and Electrodermal activity (EDA) [8], to measure individuals' mental workload levels during their ongoing tasks.

The previous efforts have enabled the monitoring of changing mental workload levels. For example, [9] applied EEG to quantify the construction workers mental workload and the findings suggest that Gamma band activity of specific EEG channels strongly correlates with tasks with high mental demands. However, challenges

remain in distinguishing problematically low or high levels—those that involve suboptimal cognitive states, such as mind wandering and blindness, and increased susceptibility to cognitive errors—from acceptable/appropriate levels during ongoing field tasks. The current literature does not establish thresholds for problematic mental workload, leaving no clear reference for identifying activities that may induce suboptimal cognitive states in workers. This limitation hinders the operationalization of biosensor-based mental workload monitoring to improve workers' cognitive states by identifying and addressing problematic moments and environmental factors likely to cause suboptimal cognitive states.

A recently introduced framework [10] has shown potential not only in addressing this limitation, but also in enabling the differentiation of different suboptimal states for interventions, by characterizing problematically low and high mental workload in relation to neurophysiological states. The framework, proposed by Dehais [10] and his team, reconceptualizes mental workload as a transactional interaction between an individual and a task's cognitive demands, influenced by intra-individual factors (e.g., emotional states, fatigue) and inter-individual variability (e.g., skill levels, personality). It categorizes neurophysiological states along with their associated suboptimal cognitive states and their symptoms that emerge when mental workload becomes problematically low or high. Specifically, an individual's neurophysiological state, depending on their mental workload, can be mapped onto a two-dimensional space defined by task engagement (the cognitive and emotional effort invested in achieving task goals) and arousal (the physiological readiness to respond to goals and external task demands, influenced by inherent traits and situational factors). This two-dimensional space is divided into four regions: three suboptimal cognitive states—Mind Wandering, Effort Withdrawal, and Mind Blindness—and one optimal cognitive state (Figure 1).

Mind Wandering occurs when mental workload is excessively low, leading to boredom and a lack of focus on the task. Effort Withdrawal and Inattentional Blindness, on the other hand, arise from excessively high mental workload levels, representing two distinct suboptimal states characterized by reduced task engagement and diminished awareness of unexpected stimuli, respectively. Differentiating these three mental workload-related suboptimal cognitive states not only enables the detection of problematic mental workload, but also provides insights for "state-specific" interventions, thereby significantly contributing to the field application of the wearable biosensor-based neuroergonomic approach. This framework takes a more detailed look at mental workload by considering both the intensity and quality of cognitive engagement. It offers a clearer way to understand how individual cognitive states influence performance on complex tasks.

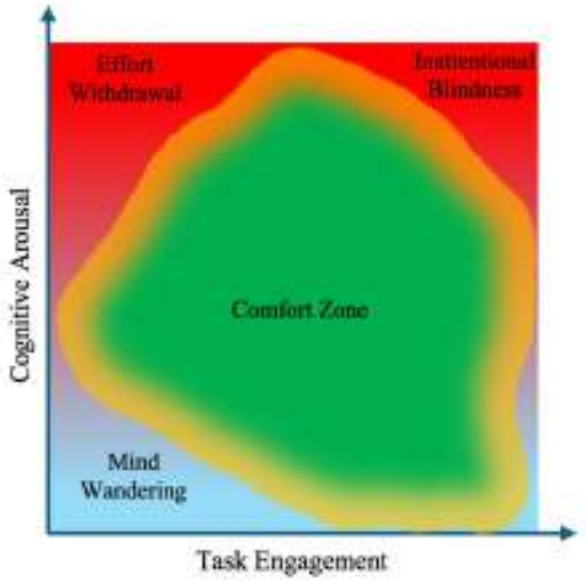

Figure 1. Dehais's framework characterizing mental workload-related suboptimal states [10]

To effectively implement this sophisticated framework in practical settings, an equally advanced method of analyzing the collected neurophysiological data is essential. In the field of neuroergonomics, traditional approaches to analyzing the signals collected during cognitive monitoring typically employ either post-hoc analysis or machine learning methods. While post-hoc analysis has been valuable for in-depth, after-the-fact evaluations, it does not facilitate the continuous and dynamic adjustments needed for ongoing cognitive state monitoring. Therefore, the integration of machine learning analysis and the new perspective on mental workload shows significant potential for effective and dynamic monitoring of field works. Despite this potential, the feasibility of this framework in accurately identifying distinct cognitive states remains untested. This gap signifies a crucial missed opportunity for enhancing operational efficiency, safety, and worker well-being through state-specific cognitive interventions. To address this knowledge gap, this study aims to investigate the feasibility of developing an EEG-based machine learning model that can differentiate between four cognitive states derived from the novel perspective on operationalized mental workload.

2 Methods

To achieve the research objective, a machine learning model was developed for classifying different suboptimal cognitive states (i.e., Mind Wandering, Effort

Withdrawal, and Mind Blindness), along with the optimal. To this end, an in-lab data collection was structured incorporating the characteristics of the suboptimal cognitive states stated in Dehais's framework and conducted. Following this, the data preprocessing techniques were employed to ensure the EEG signals were clean and reliable. The focus then shifted to the feature extraction process, which is crucial for preparing the data for effective machine learning analysis and classification model development.

2.1 Data collection

2.1.1 Participants

Data were collected from 10 participants aged 20 to 39 years, comprising 5 females and 5 males. All participants reported being in good physical and mental health, with no history of neurological disorders. To minimize confounding factors, participants were instructed to abstain from alcohol for 24 hours before the session. Each participant completed only the data collection session, with no additional activities scheduled before or after. The study protocols were approved by the University of Alberta's Research Ethics Board (Reference: Pro00135533), and participants provided informed consent via an electronic form before starting.

2.1.2 Tools

The study employed the DSI-24 dry-electrode EEG headset from Wearable Sensing for data acquisition. This device was chosen for its practical advantages, including reduced setup time, stable signal quality without the need for conductive gel, and comfort during extended use. In addition, the patented common-mode follower technology in this headset offers near immunity to electrical and motion artifact signals during data collection [11]. The headset features 19 channels based on the 10-20 system, a sampling rate of 300 Hz, and an active shielding system to filter environmental noise. Wireless data collection ensured flexibility and minimized interference during the session.

The data collection session was designed using the PsyToolkit platform [12,13], while the iMotion platform was utilized to integrate biosensors and stimuli for improved synchronization. This setup enabled the efficient execution of complex data collection designs.

2.1.3 Procedures

The data collection session involved three cognitive tests, each designed to target specific suboptimal cognitive states characterized by Dehais's framework [10]. First, an adapted Task-Switching test was used to induce inattentional blindness [14]. Participants alternated between rules for responding to stimuli, such as letters and numbers in a grid, under time constraints. The frequent rule changes introduced cognitive demands, simulating real-world multitasking challenges. Participants had only 4 seconds to respond to each stimulus; failing to do so triggered an error message. This setup required participants to concentrate intensely at the beginning of each block to apply the newly presented rule effectively and perform well. The intense focus and task engagement accompanied with high cognitive arousal due to time constraints, can lead to Inattentional blindness and deafness as shown in Figure 1. Each participant completed six Task-Switching sessions, each lasting 2.5 minutes, with randomized rules for each session. Breaks were allowed between sessions if needed.

The second test was the n-back task [15], designed to induce effort withdrawal. Participants were required to identify matches in a sequence of stimuli presented a specific number of steps (n) earlier, with task difficulty increasing incrementally from 1-back to 7-back. When the number of steps is higher than 5 the task looks impossible to individuals [16] and discourages them from fully engaging in the task since achieving the goal seems very unlikely. This procedure can induce Effort Withdrawal behavior among participants. Four n-back tasks were administered, each lasting 2.5 minutes, with no breaks between levels to maintain cognitive load and push participants toward a mental breaking point.

The third test was the Sustained Attention to Response Task (SART) [17], conducted to induce mind-wandering. Participants responded to any digit from 1 to 9 while withholding responses to an exception, the digit "3". Participants had 0.9 seconds to respond to the digits, and since the target digit was infrequent, they frequently had to respond to other stimuli. Over time, this repetitive response to non-target digits could become an automatic process requiring minimal attention, potentially allowing their freed-up focus to drift to other tasks. This cognitive shift increases the likelihood of Mind Wandering. Five SART sessions were presented toward the end of the session, leveraging reduced cognitive arousal after the more demanding preceding tasks. Each session lasted 4 minutes.

Upon arrival, participants were introduced to the biosensors and provided informed consent before setup. The tests were conducted in a quiet, isolated room to minimize distractions. The entire data collection session, including setup and breaks, lasted between 1.5 and 2 hours. This duration was carefully optimized to minimize fatigue while ensuring sufficient data quality and variability for the machine learning model.

2.2 Data preprocessing

EEG data were continuously recorded throughout the session without interruptions. To prepare the data for analysis, a 60 Hz notch filter was first applied (to account for the powerline frequency in Canada), followed by

bandpass filtering between 0.5 Hz and 50 Hz to reduce extrinsic artifacts. Despite these preprocessing steps, the data remained prone to noise from intrinsic artifacts such as eye blinks and muscle movements. To mitigate these, Independent Component Analysis (ICA) was employed to isolate and remove artifact-related components, enhancing the overall signal-to-noise ratio.

After preprocessing, the data were prepared for labelling. Since no self-reported measurements were used, the labelling strategy was based on the design and cognitive mechanisms of the tasks, supported by previous research. Each section's labelling was validated separately to ensure the tasks effectively induced the intended cognitive suboptimalities.

For Task Switching, it was hypothesized that participants initially struggle with new rules under time constraints but adapt as the session progresses, feeling more at ease. Therefore, first 30 seconds of each new trial was labelled as inattentional blindness. For effort withdrawal, the Task Engagement Index (TEI) was calculated during the 1-back, 3-back, 5-back, and 7-back tasks. The TEI increased from 1-back to 5-back but significantly dropped for the 7-back task, reflecting a state of effort withdrawal as participants found the task too demanding to complete effectively. Hence, the 7-back task data were used as effort withdrawal data.

For SART, errors were captured using a setup where an error message was displayed alongside a white box with a photodetector attached to the screen. This system pinpointed the exact moments when participants made errors. Following the methodology of previous studies [18], the 5 seconds preceding each error were labeled as mind-wandering states. After the error message appeared, participants were prompted to refocus and attempt better performance, and these moments were labeled as focus states.

2.3 Feature Extraction

After labeling the data, features were extracted from the EEG signals to prepare inputs for the machine learning model and analyze signal patterns linked to various suboptimal cognitive states. An effective window size for EEG data segmentation in cognitive state classification is typically determined through trial and error and generally ranges from 1 to 12 seconds [19]. The optimal window size in this study was found at using a 2-second window with a 25% overlap to ensure sufficient temporal resolution.

Feature extraction is a critical step in developing robust EEG-based machine learning models for classifying cognitive states. Selecting features that effectively capture the underlying neural dynamics is essential for accurate and meaningful classification. From the literature, features derived from both time and frequency domains, as well as non-linear analyses, have demonstrated their effectiveness in distinguishing between mental states and cognitive processes. Specifically, power spectral features, such as Alpha, Beta, Theta, and Delta Power, offer insights into the brain's frequency-specific activities related to relaxation, focus, drowsiness, and disengagement, respectively. Complementing these, non-linear and time-domain measures, such as Higuchi Fractal Dimension and Hjorth parameters (Activity, Mobility, and Complexity), provide valuable information on neural complexity, brain activity levels, cognitive flexibility, and adaptability. Together, these features encapsulate the multifaceted nature of brain activity, making them a suitable choice for the classification of various cognitive states [20].

A total of eight features were computed for each EEG channel: alpha, beta, theta, and delta power bands; Higuchi fractal dimension; and Hjorth parameters (activity, mobility, and complexity). With 19 channels in the EEG system, this resulted in 152 features (8 features × 19 channels) being extracted for each window. A summary of the selected features, along with the rationale for their selection and their significance in EEG signals, is presented in Table 1.

Table 1. Summary of feature selection

Feature	Description
Alpha Power	Represents relaxed but wakeful states and reduced sensory input, typically decreasing with increased cognitive load
Beta Power	Linked to focus, problem-solving, and sustained attention, often increasing with cognitive effort
Theta Power	Associated with drowsiness and working memory, helpful in identifying low vigilance or mental fatigue
Delta Power	Indicates low-frequency activity often tied to relaxation or cognitive disengagement in awake individuals
Higuchi Fractal Dimension (HFD)	Captures neural complexity, with higher values reflecting increased cognitive processing
Hjorth Activity	Reflects overall brain activity levels, useful for assessing mental workload or stress
Hjorth Mobility	Represents frequency variability, linked to cognitive flexibility
Hjorth	Indicates adaptability and mental engagement, highlighting the temporal

Complexity	intricacy of brain activity

These features provide a comprehensive representation of brain dynamics, enabling the model to differentiate between distinct cognitive suboptimalities effectively.

2.4 Multiclass classification of suboptimal cognitive states

After completing the feature extraction and labelling stages, a feature matrix and a target matrix were constructed to train machine learning models for classifying various suboptimal cognitive states: Mind Wandering, Effort Withdrawal, Inattentional Blindness, and the Comfort Zone.

In this study, Support Vector Machines (SVM) and Artificial Neural Networks (ANN) were utilized to classify EEG-based cognitive states due to their complementary capabilities in processing complex, high-dimensional data. SVM was employed for its effectiveness in identifying nonlinear decision boundaries and its suitability for smaller datasets, leveraging kernel functions to map EEG data into higher-dimensional spaces for enhanced separability. Fully connected ANN was selected for its capacity to model intricate patterns and automatically learn features from EEG signals, accommodating the data's non-stationary and multivariate characteristics. Both models were trained and evaluated on preprocessed EEG data to compare their classification performance across different cognitive states.

In machine learning research, validation methods play a crucial role in assessing the generalizability of models to unseen data [21,22]. Among the commonly used approaches is K-Fold Cross-Validation (KFCV), which splits the dataset into k equal-sized subsets or "folds." The model is trained on k-1 folds and tested on the remaining fold, cycling through until each subset has been used for testing. While this method is efficient and widely applicable, it assumes independence between data points. This assumption can lead to overestimation of model performance, particularly when applied to time-series or biosignal data, where neighboring data points are inherently correlated. The result of this validation method is used as a benchmark to compare the developed model with existing studies since this validation method is frequently used in the current literature [19,23].

The second method, Leave-One-Period-Out Cross Validation (LOPOCV), is designed to evaluate the generalizability of machine learning models across different environmental or contextual factors. In this approach, the dataset is divided so that data from one specific context—such as a particular environmental condition, task type, or experimental setup—is completely excluded during training and reserved for testing. This process is repeated iteratively, with each context taking a turn as the test set, ensuring that every context is evaluated independently.

Finally, Leave-One-Subject-and-Context-Out Cross-Validation (LOSCOCV) [24] was used to ensures both subject and context independence. By excluding data from one subject and one context during training and using them for testing, LOSCOCV provides a more stringent evaluation of generalizability. This method is particularly suited for biosignal research, where both individual and contextual variability significantly influence the data. Incorporating these three validation methods into the methodology ensures a comprehensive evaluation of model performance and generalizability under varying conditions.

To optimize performance, hyperparameter tuning was conducted for both the SVM and ANN models. The holdout method was employed for this process, with 8 subjects used for training and 2 set aside as the validation dataset. Models were trained and tested on this subset to identify the best hyperparameters, which were subsequently applied to the full dataset of 10 subjects. The selected hyperparameters ensured the models achieved robust performance across all validation methods.

3 Results

The classification models were trained using the SVM and ANN algorithms, with hyperparameters optimized to achieve the best performance. The implemented ANN has a fully connected architecture with 3 hidden layers and 2 drop out layers. The hyperparameters were determined using a grid search method. Final architecture and hyperparameter setting of SVM and ANN are presented presented in Table 2.

Table 2. Hyper parameter tunning results

Model	Hyperparameter and Architecture
SVM	Kernel: RBF
	C: 10 / Gamma: 0.1
ANN	Input layer: 152 neurons
	1st Hidden layer: 100 neurons
	1st Dropout layer: 15 percent
	2nd Hidden layer: 100 neurons
	2nd Dropout layer: 15 percent
	3rd Hidden layer: 75 neurons
	Output layer: 4 neurons

Model performance was evaluated using three validation methods—KFCV, LOPOCV, and LOSCOCV—and the results are presented in Table 3. The ANN outperformed the SVM across all validation methods, achieving the highest accuracy in both KFCV and LOPOCV validations. These results align with

previous studies that differentiate between levels of specific cognitive suboptimalities, providing benchmarks for comparison. Importantly, this study highlights the challenge of achieving high accuracy in LOSCOCV models, a critical area for future research and practical applications.

Table 3. Accuracy of different models for each validation method

Model	Validation method					
	KFCV		LOPOCV		LOSCOCV	
	Acc	F1	Acc	F1	Acc	F1
SVM	0.62	0.62	0.58	0.59	0.24	0.10
ANN	0.72	0.71	0.68	0.65	0.27	0.24
* ACC: classification accuracy						

4 Discussion

Traditional approaches to mental workload have faced challenges in distinguishing various suboptimal cognitive states, as the relationship between mental workload and cognitive errors induced by these states remained unclear. Recently, new perspectives have emerged, focusing on measuring task engagement and arousal to map suboptimal cognitive states related to mental workload, opening new opportunities to enhance field applicability. This study explores the feasibility of this approach by employing a neuroergonomic framework to map suboptimal cognitive states resulting from excessive mental workload. A machine learning model was developed to classify four distinct cognitive states using features extracted from EEG signals.

The study classifies cognitive comfort zone, mind wandering, inattentional blindness, and effort withdrawal with acceptable accuracy. Given that the task involves a 4-class classification, accuracies above 0.7 can be considered promising. Both classification accuracy and F1-scores were reported to mitigate the effects of data imbalance and validate the performance of the models. Among the models tested, the ANN trained with extracted features outperformed the SVM, achieving the highest accuracy. This result aligns with expectations, given the ANN's ability to handle the high number of features and capture complex relationships between input data and cognitive state labels. While the SVM demonstrated reasonable performance, its simpler architecture limits its ability to manage the intricacies of the dataset compared to the ANN.

Accuracy decreased as validation methods introduced greater independence across time periods or subjects, highlighting the challenges of generalization. However, the ANN demonstrated robust performance under LOPOCV, showcasing its potential for generalization within the same participant group. This validation method ensures that testing occurs on unseen time periods and data collection sessions, meaning the model can differentiate classes with acceptable precision even when the participant remains the same but the data collection setup changes. However, the accuracy for LOSCOCV was notably low across all models, underscoring the difficulty of achieving generalizability across different individuals. This limitation highlights the need for additional labeled data from new subjects to train models effectively, a process that is both time-consuming and inefficient.

This study demonstrates the feasibility of using machine learning combined with EEG-extracted features to classify cognitive states, including both the comfort zone and cognitive suboptimalities. This framework holds significant potential for continuous, dynamic monitoring of construction field workers with minimal invasiveness and without disrupting their tasks. Its neuroergonomic foundation enhances reliability by leveraging data directly from the central nervous system.

The benefits of such a framework are multifaceted. It enables timely interventions to mitigate risks associated with cognitive suboptimalities, thereby reducing cognitive errors and enhancing worker safety and performance. Furthermore, it offers indirect applications, such as integration with geographic information systems (GIS) or eye-tracking data for hotspot analyses. This integration can help identify areas or environmental factors where cognitive suboptimalities frequently occur, facilitating targeted interventions to improve workplace conditions.

This study sets a benchmark for multiclass classification of cognitive suboptimalities but has some limitations that need further exploration. First, the tested framework shows low generalizability across different subjects, which means there is a need to individualize the model for each user or increase the dataset diversity by data augmentation. Second, the proposed technique requires extensive labelled data collection eliciting cognitive suboptimalities, highlighting the need for a combination of improved protocols and techniques that reduce the reliance on learning from scratch to quickly build more reliable datasets. This prolonged data collection process means the developed model may require many hours of data acquisition and hyperparameter tuning whenever a new user is introduced, significantly increasing implementation time and effort. Third, as the models were developed and tested with data collected in a controlled environment, the additional finetuning and/or validation might be required in more realistic work scenarios to examine the field applicability.

Given the lack of a clear solution in the current literature for developing a generalizable model across individuals and the absence of a comprehensive dataset

with sufficient representation from diverse demographic groups, future research should explore strategies to simplifying the data collection and hyperparameter tuning process for new users. Reducing the time required for these tasks would enhance the framework's cost-effectiveness and scalability, opening new possibilities for industrial applications.

Addressing this technical challenge is crucial because the practical use of current EEG-based models is hindered by their limited subject independence. Future studies need to focus on enhancing subject independence to facilitate wider use and real-world implementation of these models.

5 Conclusion

This study demonstrates the feasibility of using mobile EEG-based machine learning models to detect and classify suboptimal cognitive states, highly relevant to construction workers' cognitive errors in the field. By leveraging neuroergonomic principles and advanced validation methods, the proposed framework successfully differentiates between four distinct cognitive states: mind wandering, inattentional blindness, effort withdrawal, and the comfort zone. Among the models tested, the ANN consistently outperformed the SVM in classification tasks, demonstrating superior capability in handling high-dimensional EEG data and capturing complex relationships. The findings underscore the potential of EEG-based frameworks for real-time and continuous monitoring of cognitive states in demanding environments like construction, with minimal invasiveness and without disrupting workers' tasks.

Despite its success, the study also identifies significant challenges, particularly in achieving generalizability across individuals. Accuracy decreased when validation methods introduced greater independence across subjects or contexts, highlighting the need for extensive retraining with new user-specific data. This limitation points to a critical area for future research: enhancing model generalizability to enable broader applicability without compromising accuracy. Additionally, the time-intensive process of collecting labeled data and tuning model hyperparameters further underscores the necessity of more efficient protocols and comprehensive datasets representing diverse demographics.

The implications of this work are both immediate and far-reaching. In the short term, the framework offers a robust tool for identifying cognitive suboptimalities in real-time, enabling timely interventions to mitigate risks, reduce cognitive errors, and improve worker safety and performance. In the long term, its integration with other technologies, such as GIS or eye-tracking systems, could provide actionable insights into environmental factors that contribute to cognitive errors. This integration could facilitate targeted interventions to optimize workplace conditions and enhance overall productivity.

Future research should focus on addressing these limitations by improving data collection, developing generalizable models that work across individuals and contexts, and validating the framework in larger and more diverse populations. Expanding its practical applications to other industries and refining its usability for real-world conditions could further enhance its impact. This study establishes a critical foundation for EEG-based neuroergonomic frameworks, advancing our ability to monitor and manage mental workload dynamically and effectively in the field settings.

Abstract

This paper proposes a PTZ (Pan-Tilt-Zoom) camera-based solution to enhance construction site safety, particularly for small to medium scale projects and those in the early or late stages of development. Traditional sensor-based methods often face challenges related to cost, installation time, and adaptability, limiting their suitability for dynamic construction environments. In contrast, the proposed system leverages PTZ cameras and deep learning techniques specifically Visual Place Recognition (VPR) and Monocular Depth Estimation (MDE) to dynamically redefine hazardous areas in real time as the camera's view changes. The system integrates multiple tracking strategies, including feature-based tracking, scene re-identification, depth-driven adjustments, moving object detection, and image stabilization, to adapt to diverse site conditions. Experimental validation in both virtual and real-world settings demonstrate high accuracy, achieving an average IoU of 0.8627 in virtual sites and 0.7463 in real sites, despite the increased variability in actual conditions. The virtual environment, developed using a game engine, enabled precise simulations of site dynamics such as lighting, weather changes, and object movements. Real site tests further validated the system's practical applicability, highlighting its potential for broader deployment in construction safety management. By enhancing hazard identification and monitoring capabilities, this approach contributes to more effective and comprehensive safety management in construction projects.

Keywords

Safety Management; Computer vision; Real-time hazardous area tracking; Pan-Tilt-Zoom (PTZ) cameras

1 Introduction

The construction industry has long been recognized as a sector with a high risk of occupational accidents due to several intrinsic factors: the use of large-scale equipment, complex processes, collaboration among various stakeholders, and prolonged project durations often conducted outdoors. These characteristics have continually drawn global attention to construction site safety, prompting sustained efforts toward improvement. According to the U.S. Occupational Safety and Health Administration (OSHA), there were 1,075 fatalities in the U.S. construction sector in 2023, accounting for over 20% of all workplace deaths, with falls representing the most frequent cause [1]. In China, data from the Ministry of Housing and Urban-Rural Development (MOHURD) show that between 2012 and 2019, approximately 4,100 accidents claimed 5,011 lives in the construction sector, with falls constituting 52.83% of these incidents. These statistics suggest that accidents frequently occur around static hazard areas (e.g., foundation excavations, edges, openings), underscoring a persistent risk in such environments [2]. Similarly, in Korea, there were 26,829 injuries reported in 2023, accounting for over 20% of all occupational accidents in the construction industry. Small-scale sites often lack systematic safety management measures, leading to a high incidence of falls and collapses [3].

A noteworthy aspect is that many of these fatal incidents occur in relatively predictable "static hazardous areas." That is, certain spatial features such as openings or edges of structures pose an inherent and constant risk throughout the construction process. When this latent hazard is compounded by managerial or technological limitations, the likelihood of accidents increases [4, 5]. As a result, continuously and efficiently monitoring static hazardous areas and detecting unauthorized entries into these areas in real time has emerged as a key priority for global construction safety management.

Against this backdrop, recent research in construction safety management has actively explored the use of computer vision (CV)-based technologies. Traditional manual surveillance in construction sites is labor-intensive, time-consuming, and susceptible to human judgment errors and observer fatigue. By contrast, computer vision technologies employ automated algorithms to analyze targets such as workers, equipment,

and structural conditions and have demonstrated utility in various applications, including worker safety monitoring, detecting facility defects, ergonomic posture assessments, and process monitoring [6-10]. Recently, approaches aimed at the real-time recognition of and intrusion detection into static hazardous areas have also emerged, such as the work by Mei et al., which proposed a more clearly defined hazardous area identification model based on computer vision [11]. Their system uses object detection to locate workers in each video frame and then determines the level of risk by checking whether the detected position falls within a polygon that represents a predefined hazardous area on the camera image.

However, most existing detection techniques for static hazardous areas rely on images from fixed cameras, requiring manual designation of these areas. The manually designated area is defined based on the image coordinates of the camera, and when the camera moves, the dangerous area is distorted and the worker's entry into the wrong area is detected. This approach presents significant constraints when applied in real-world scenarios. Nowadays construction sites are vast, and observation points change frequently as the project progresses, making it challenging to comprehensively monitor all areas through a static viewpoint. While the use of Pan-Tilt-Zoom (PTZ) cameras with adjustable fields of view is on the rise, each camera movement necessitates redefinition of the static hazardous area, a process that is both inefficient and lacking in adaptability as shown in Figure 1. In other words, current methods suffer from limited dynamic adaptability to changes in camera orientation, undermining both the reliability and practicality of real-time hazard monitoring.

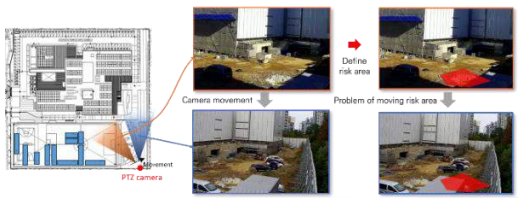

Figure 1. Problem of moving to a hazardous area

To address these limitations, this study proposes a safety management framework that estimates the pose of a PTZ camera using image data alone and automatically reconfigures predefined static hazardous areas according to camera movements. The key contribution lies in extracting spatial information solely from image input, without relying on additional sensors (e.g., IMUs), and using this information to dynamically map static hazardous areas in response to camera adjustments. As a result, the system can continuously track previously defined static hazard areas and determine whether intrusions occur, regardless of the camera's position and viewing angle. This approach is anticipated to improve both the operational flexibility of camera usage and the accuracy of monitoring in practical environments, thereby advancing real-time safety management systems that focus on static hazards. By applying the system proposed by Mei et al. to the tracked risk area, workers' access to the hazardous area can be detected. Moreover, by expanding the applicability of CV-based construction safety monitoring, this research may ultimately provide a practical method for managing various forms of risks across diverse project scales and processes in the future.

2 Proposed Framework

Construction sites are operated over extended periods, during which camera imagery is subject to significant variability due to equipment and worker movement, changes in workflows, illumination fluctuations, and weather conditions. To reliably track predefined hazardous areas under such variability, it is necessary to utilize robust algorithms against various factors such as camera motion, lighting changes, object rearrangements, and weather fluctuations. In this study, we propose a framework that, using only the footage captured from a PTZ (Pan-Tilt-Zoom) camera, estimates the camera pose and automatically reconfigures a predefined static hazardous area according to changes in the camera's viewpoint (see Figure 2).

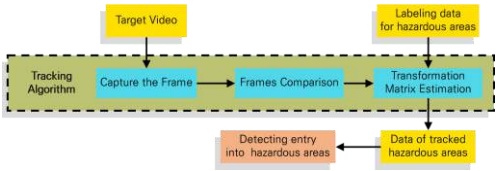

Figure 2. Framework of tracking algorithm for hazardous area

The proposed framework consists of three key stages:

1. **Camera poses estimation:** Using feature points extracting and matching technique, a transformation matrix between two viewpoints is computed. This method ensures real-time capability while maintaining relatively stable features matching under various environmental changes.
2. **Site verification based on Visual Place Recognition (VPR):** A VPR network is employed to determine whether the current image is from the same site where the hazardous area was previously defined. This allows for temporarily halting hazardous area tracking whenever the camera angle or position changes causes a completely different location to be captured, preventing safety incidents due to wrong identification.
3. **Robustness enhancement using depth information (MDE):** Depth information estimated

from a single image by a Monocular Depth Estimation (MDE) network is integrated into the tracking process. This approach enables stable background feature extraction despite lighting changes or temporary occlusions, thereby offering more robust adaptation to environmental changes when tracking the actual hazardous area.

2.1 Overview of the Framework

Figure 2 shows the overall structure of the proposed framework. First, features are extracted from images at two different points in time, then matched to estimate a transformation matrix. Traditional methods such as SIFT, SURF, and ORB are relatively easy to implement but are vulnerable to lighting changes and often struggle with speed-accuracy trade-offs. In contrast, the lightweight deep learning-based approach (XFeats) proposed by Potje et al. enables a better balance between real-time processing and accuracy [12]. By estimating camera pose changes between frames using this method, the static hazardous area is reprojected onto the image according to camera movements, enabling continuous tracking.

However, relying solely on feature matching can lead to erroneous matches caused by environmental changes (fog, rain, occlusion, changes in wall layout), ultimately resulting in incorrect hazardous area projections as shown in Figure 3. To mitigate this, the VPR network is employed to determine whether the captured footage is from the same site. If it is not, hazardous area tracking is suspended to prevent safety issues stemming from erroneous tracking. In addition, MDE is utilized to strengthen the structural understanding of the background beyond mere image-based features. By integrating depth information obtained from a single image, the framework achieves greater robustness against environmental changes during feature matching and VPR.

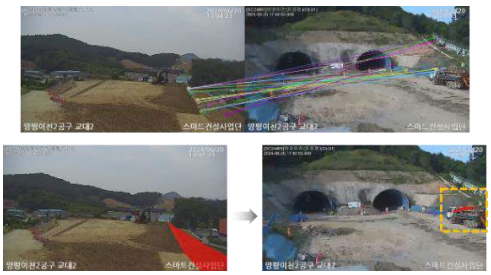

Figure 3. Failure of tracking due to PTZ camera operation (red area)

2.2 Estimation of Relative Camera Pose

Camera poses estimation is based on feature extraction and matching. Traditional methods (e.g., SIFT, SURF, ORB) are human-interpretable and easy to implement, but are sensitive to lighting and scale changes, and present a trade-off between speed and accuracy. Following Melekhov et al. CNN-based feature extraction and matching techniques have been explored [13]. Potje et al. introduced a lightweight approach, XFeats, combining real-time performance with accuracy [12]. In this study, XFeats is adopted to ensure stable tracking under diverse environmental changes in large-scale construction sites. Using the estimated transformation matrix, the camera pose is continuously updated, and the static hazardous area is reconfigured in real-time.

2.3 Visual Place Recognition (VPR)

VPR is a core component for identifying whether the captured images are from the same site where the hazardous area was previously defined. Traditional feature-based methods are highly vulnerable to changes in lighting (day/night) and weather (clear/rain/snow), resulting in misinterpretations that consider the same site as a completely different space. To address this issue, this study references the latest CNN- and Transformer-based VPR approaches [14, 15]. By employing the MixVPR method, high-dimensional features are mixed to generate a global descriptor. The similarity between global descriptors allows robust determination of whether the current site matches the previously defined hazardous area location.

Using the VPR results, the proposed framework maintains hazardous area tracking if it is the same site or suspends tracking or updates the reference images if not, preventing safety management issues caused by erroneous matches. The incorporation of MDE-derived depth information assists in robustly capturing background structures, further enhancing resilience to weather changes or temporary occlusions and improving overall recognition performance.

2.4 Monocular Depth Estimation (MDE)

Monocular Depth Estimation (MDE) is a technique that estimates the distance to each pixel in an image using only a single RGB camera input. It can be leveraged to acquire three-dimensional environmental information from construction sites without expensive equipment or complex installations, effectively serving as a substitute for RGB-D cameras. By employing an encoder-decoder neural network architecture, spatial features are extracted, and depth is predicted from the input image. Incorporating LSTM can capture temporal features, enabling more stable depth estimation. In addition, training on ground-truth depth maps that incorporate physical constraints ensures that the estimated depth is robust to environmental changes such as lighting variations, weather conditions, and occlusions.

In this study, a Monocular Depth Estimation (MDE)

network with a DINOv2 encoder and a DPT decoder is employed. We use a model pretrained on large-scale unlabeled data as demonstrated by Yang et al. [16]. This provides effective depth estimation, which, when integrated into feature matching and VPR, enhances the stability and accuracy of hazardous area tracking in construction sites.

3 Experiments

This chapter explains the preparations and approaches used in the experiments for the proposed PTZ camera-based static hazardous area tracking algorithm. It also defines the evaluation indicators that will be used to interpret the experimental results presented in Section 4. To overcome the challenges of collecting and labelling video data from actual construction sites while minimizing safety management burdens, a virtual construction site environment was developed using the Unity game engine. This approach enabled the simulation of realistic variables, including camera operations (pan, tilt, zoom), weather, and lighting changes, while ensuring accurate labelling information and controlled hazardous area configurations. The final performance was verified by applying the approach, which showed the highest performance in the virtual construction site, to the actual field.

3.1 Implementation Details

Section 3.1 describes the implementation details of the algorithms used in the experiment, the configuration of the virtual environment, and the process of labeling hazardous areas.

3.1.1 Virtual Construction Site Implementation

A virtual construction site was built using Unity as shown as Figure 4, incorporating various architectural elements (structures, equipment, terrain features, etc.), changes in lighting over time (day/night transitions), weather variations (rain, fog), and object movements. A PTZ (Pan-Tilt-Zoom) camera was set up to mimic actual site operations by randomly altering camera poses. Objects, such as equipment and workers, moved unpredictably, reflecting the dynamic nature of active construction sites.

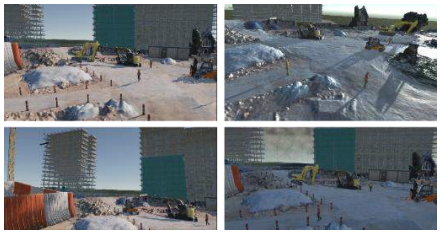

Figure 4. Virtual construction site

Camera operation times along a virtual timeline were categorized into four segments: less than 10 seconds (brief), 10 to 30 seconds (short), 30 seconds to 1 minute (mid), and over 1 minute (long). This categorization aimed to evaluate tracking performance over extended periods.

3.1.2 Hazardous Area Labeling and Ground Truth Generation

Within the virtual environment, certain areas were predefined as “static hazardous areas” and used as ground truth. As the camera moved, the projective representation of these hazardous areas changed. The proposed algorithm continuously reprojects these areas in real-time based on camera movement. The lighting environment was shifted over a 100 s day/night cycle, and intermittent rainfall was introduced to replicate weather-induced visibility changes. The ground truth information was utilized in subsequent evaluations (see Section 3.3 for evaluation metrics).

3.1.3 Detail Parameter of Applied Model

Feature extraction and matching for localization and tracking are performed using XFeats, a CNN-based feature extraction and matching model designed for real-time operation in resource-constrained environments. XFeats employs a lightweight CNN backbone that maintains a low number of channels, optimizing computational efficiency while preserving high-resolution feature representations. The model was pretrained on a combination of the Megadepth dataset and synthetically warped images from COCO to enhance its robustness. To further improve structural feature representation, MixVPR, a CNN-based descriptor specifically designed to handle severe illumination and weather variations, is utilized. MixVPR was pretrained on the Pitts30k-train dataset, and its encoder is employed to extract descriptors that capture the structural characteristics of each image. The cosine similarity between these descriptors is then used to assess structural similarity across images, enabling the determination of on/off states for risk area tracking. Additionally, for monocular depth estimation (MDE), a pretrained model was adopted following the approach proposed by Yang et al., as discussed in Section 2.4.

3.2 Experimental Setup and Approaches

This section outlines various approaches used to implement the proposed tracking mechanism. These include frame-to-frame comparison techniques, the use of a reference image, VPR (Visual Place Recognition) methods, and strategies for flexible hazardous area activation/deactivation by incorporating MDE-based depth information. Five approaches were proposed, and the structure of each is illustrated in Figure 5.

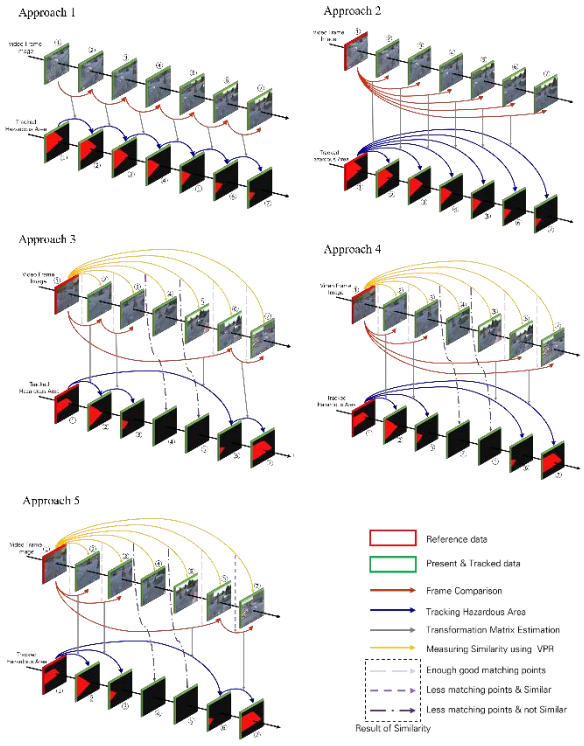

Figure 5. Architecture of each approach

3.2.1 Simple Transformation Approaches (Approaches 1 & 2)

Approach 1 (Continuous Frame Comparison) involves estimating the transformation matrix between consecutive frames for hazardous area tracking. This approach, commonly used in SLAM, effectively handles small incremental changes but suffers from cumulative errors over time, presenting challenges for long-term tracking.

Approach 2 (Reference Image-Based) defines the first frame as a reference and directly estimates the transformation matrix between the current frame and the reference frame for reprojection. This approach avoids long-term error accumulation but may face difficulties when the scene differs significantly from the reference image, making direct matching challenging.

3.2.2 VPR for Scene Change Adaptation (Approaches 3 & 4)

In construction sites, the camera may capture different scenes where the previously defined hazardous area no longer applies. To address this, 2 types of VPR methods were applied. Type 1 determines similarity based on feature points, while Type 2 integrates image descriptors with depth information from MDE. By evaluating whether the current frame and the reference frame depict the same location, the hazardous area can be deactivated when shooting a different site, mitigating tracking errors caused by scene changes. Approach 3 is a method of introducing the VPR plan based on Approach 1, and Approach 4 is a method of introducing the VPR plan based on Approach 2

3.2.3 Hybrid Approach (Approach 5)

Approach 5 overcomes the limitations of Approaches 1–4 by dynamically selecting between reference image-based tracking and VPR-guided results. If enough matching points are extracted, reference image-based tracking (Approach 2) is used; otherwise, previous-frame-based tracking (Approach 1) is employed. At the same time, VPR results guide the deactivation of hazardous areas when the scene changes. The integration of VPR and MDE enables stable activation and deactivation of hazardous areas, even under varying environmental conditions.

3.3 Evaluation Indicators

In this section, we define the quantitative evaluation metrics for interpreting the experimental results presented in Section 4.

3.3.1 Intersection over Union (IoU)

The accuracy and stability of hazardous area tracking are evaluated using various indicators. The performance of hazardous area tracking is quantitatively assessed using the Intersection over Union (IoU) metric and several supplementary indicators. First, the IoU (see Equation (1)) is the most representative indicator of similarity between the actual hazardous area (R_t) and the tracked hazardous area (R_g). When comparing the tracking results and the actual hazardous area in each frame.

$$IoU = \frac{R_t \cap R_g}{R_t \cup R_g} \quad (1)$$

An IoU value closer to 1 indicates a higher overlap between the two areas, signifying a closer match between the tracked and actual hazardous areas. However, to comprehensively evaluate performance across the entire video, a single frame value of IoU is insufficient. Therefore, the following additional indicators are employed to assess overall tracking performance and reliability. This metric evaluates the similarity between the ground truth hazardous area and the area reprojected by the tracking algorithm. It represents the ratio of the intersection to the union of the two areas, and a higher IoU value indicates greater tracking accuracy. Through the average IoU across all frames ($\overline{IoU}$), the ratio of frames where $IoU \geq 0.80$ (IoU_{80}), and the ratio of frames where $IoU \geq 0.95$ (IoU_{95}) the tracking performance can be evaluated from multiple perspectives.

3.3.2 Accuracy of Activation and Deactivation

When applying the VPR algorithm, changes in the scene can require the hazardous area to be deactivated; AoD measures the accuracy of deactivation in such cases. Conversely, in situations where the hazardous area should remain active, AoA indicates how accurately it remains activated. These metrics allow for an assessment of scene change adaptability and overall reliability in real-world site management.

3.3.3 Long-term Operational Stability

The degradation of the $\overline{IoU}$ based on the length of the video (brief, short, mid, and long) provides a view of the long-term tracking stability. We imply that the approach that does not significantly degrade the $\overline{IoU}$ for long videos compared to brief videos is the approach to maintain consistent performance in long-time operations. Therefore, the approach that does not significantly degrade for long videos compared to brief videos is more advantageous for construction site applications that require real-world long-term operations. These complementary metrics are used to compare and evaluate the performance of the proposed tracking Approaches (Approaches 1-5). Specific performance figures and comparison results are discussed in detail in Section 4.

4 Results

4.1 Results at Virtual Construction Site

4.1.1 Comparison of Basic Tracking Methods

Based on the $\overline{IoU}$, Approach 2, which tracks using a reference frame, showed a slightly better performance than Approach 1, which compares consecutive frames. In short and mid-length video scenarios, Approach 2 outperformed Approach 1. However, in long videos, both approaches exhibited similar performance, while in brief videos, Approach 1 performed slightly better. Overall, Approach 2 holds an advantage in terms of $\overline{IoU}$, but each approach comes with its own strengths and weaknesses when examining additional indicators. The performance of Approach 1 and Approach 2 is shown in Table 1 and shown as Figure 6.

4.1.2 Effect of Introducing VPR

Approaches 3 and 4 improved the $\overline{IoU}$, IoU_{80} and IoU_{95} compared to their respective counterparts, Approaches 1 and 2. Notably, Approach 4 demonstrated superior overall performance compared to Approach 3. However, in both approaches, AoA was observed to be significantly degraded compared to Approach1.

When comparing VPR types (Types 1 and 2), Type 1 accurately identified deactivation timing but often excessively deactivated hazardous areas, reducing its AoD value. In contrast, Type 2 achieved a higher AoA value, allowing for more reliable detection of actual worker access. However, since neither directly accounts for transformation inaccuracies, there are some limitations in determining the precise deactivation timing. The performance of each approach is detailed in Tables 2 and 3 and shown as Figure 6.

Table 1. Performance by tracking Approach 1 and 2

Tracking Method		Approach 1	Approach 2

4.1.3 Performance of the Hybrid Approach

Approach 5 is a hybrid approach that dynamically decides whether to use the reference frame based on the number of matching points and relies on VPR results for activation and deactivation. When combined with descriptor-based VPR, this method achieved the highest $\overline{IoU}$ and most stable performance metrics overall. Approach 5 recorded top scores in most of the evaluated indicators. This highlights that integrating depth

information and adopting a flexible reference-frame selection strategy significantly improves long-term stability and accuracy in hazardous area tracking, especially under the complex, dynamic conditions of construction sites. Detailed performance results for each method can be found in Table 4 and shown as Figure 6.

Table 4. Performance by tracking Approach 5

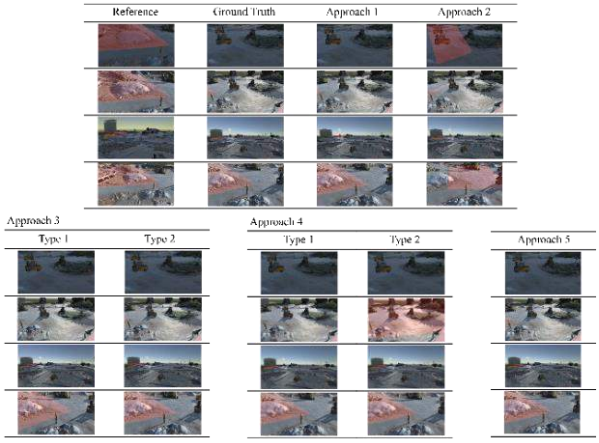

Figure 6. Tracking result at the virtual site

4.2 Results at Real Construction Site

The proposed algorithm (Approach 5 which is the highest performance method in virtual sites, illustrated in Figure 7) was validated using a PTZ camera at an actual construction site. For 20 videos collected from the PTZ camera at 13 sites, the initially set hazardous area and the hazardous area moved after the PTZ camera operation were manually labeled. In 20 videos, the hazard areas were manually defined based on the first frame, and the ground truth for the final tracking results was also manually established using the last frame. To evaluate the tracking performance, we calculated the IoU between the ground truth and the hazard areas tracked by the proposed method.

Performance was measured by comparing the hazardous area tracked by the algorithm with the ground truth of the hazardous area after PTZ camera operation. The tracking algorithm achieved average performance score of 0.7463 across 20 videos, with detailed results illustrated in Figure 8.

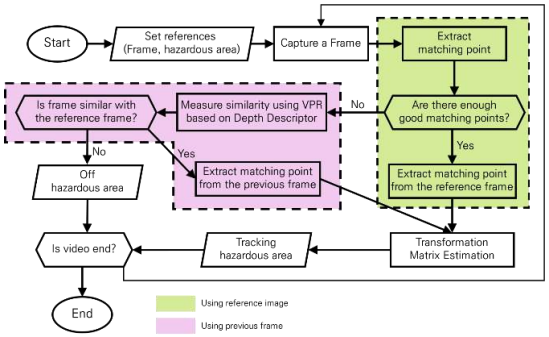

Figure 7. Flow chart of algorithm to track the hazardous area for PTZ camera

The complexity of real sites that was not considered in the virtual sites resulted in a lower result than the performance in the virtual sites. In general, segmentation models evaluated using the IoU metric are considered highly accurate when mean IoU exceeds 0.7. Based on this standard, our proposed algorithm appears sufficiently robust for hazard zone tracking in construction sites. However, from a safety management perspective, further improvements in tracking accuracy will be necessary for more precise hazard detection.

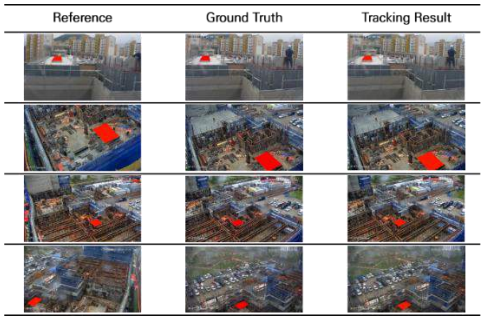

Figure 8. Tracking result at the real site

5 Conclusion

In this study, a hazardous area tracking algorithm was developed for PTZ cameras operated at construction sites. The tracking algorithm's performance was validated in both simulated and real-world construction site environments. The proposed algorithm was implemented by extracting well-matched point pairs from the reference image, deciding on reference image usage for transformation estimation, and activating hazardous areas based on descriptor cosine similarity. The proposed algorithm was verified at a virtual construction site and actual construction.

The proposed system achieved a tracking performance score of 0.8627 and an IoU_{80} of 87.12% in

virtual construction site simulations. In addition, by applying the estimation algorithm to actual construction sites, the average IoU was 0.7463, confirming that it could be properly applied to the actual site. As a result, a smart safety system that can detect construction workers' access to hazardous areas can be applied to PTZ cameras, thereby enhancing the safety of construction sites. The system is also expected to enable the projection of virtual object information for construction site safety management without requiring separate control points or sensors, thus contributing to more efficient site management.

This study focused solely on tracking methods for 2D objects. However, hazardous areas at actual construction sites often appear in the form of 3D, and it is necessary to implement the tracking function for 3D objects in subsequent studies. Additionally, while the hazardous area tracking algorithm was implemented, future research should evaluate its accuracy in detecting worker access to hazardous areas at real construction sites, especially when integrating previously proposed access detection algorithms.

Abstract –

The study proposed a real-time sensor-based hand gesture signal classification framework to address communication challenges between signalmen and crane operators on construction sites. The system collects data from a 3-axis accelerator, 3-axis gyroscope, and three flex sensors installed on gloves to recognize and predict dynamic hand signals. A dedicated data structure is developed to capture temporal characteristics of gestures by combining five consecutive time step sensor data, making sure that the deep learning model can differentiate between complex, sequential gestures. A hybrid CNN-LSTM deep learning model is employed for gesture recognition, and an LSTM-based model is used for predicting sensor data for subsequent signals, helping crane operators improve operation accuracy. The proposed framework successfully classifies 18 predefined crane operation hand signals with 98% overall accuracy, and the prediction process achieves a R^2 0.872. For the real situation test, the framework achieves a correct classification rate of 95.72%. These results demonstrate the effectiveness and robustness of deep learning models with dynamic data structure in addressing communication challenges and improving work safety in crane operations.

Keywords –

Crane operations; Deep learning; Sensor-based systems; Safety in construction.

1 Introduction

Cranes have become indispensable tools on construction sites, especially with the growing adoption of prefabricated components and modular construction techniques. In crane operations, effective communication is vital to ensuring safety and efficiency. Traditionally, hand signals and two-way radios are used for communication, with crane operations being entirely dependent on the signalman's instruction.

However, the complexity of construction sites makes signal communication challenging. The main barriers include low visibility caused by obstructions of large size prefabricated modular components and weather conditions, as well as low clarity of radio communication caused by excessive construction site noise, low signal stability, and diverse workers accents. These difficulties increase the likelihood of miscommunication and the failure to execute instructions correctly. For crane operations, even the slightest error can result in fatal consequences. In fact, miscommunication between crane operator and signalman is a major factor in the high rate of fatalities in the construction industry [1]. According to the US Bureau of Labor Statistics 2017, the average number of fatalities in crane operations is 42 per year in the past 7 years [2]. Furthermore, a study [3] found that 34% of crane-related fatalities are caused by signalman and operator errors, with miscommunication accounting for 11% of these cases.

The alarming statistics highlights the need for a smart system to capture real-time signalman hand-signal to enhance existing communication methods and improve worker safety. In the presented study, we address this gap by proposing a real-time sensor-based hand signal classification framework for crane operations. A detailed deep learning algorithm to improve the classification accuracy of dynamic gesture recognition is developed and validated, while data with comprehensive temporal information, collected from HandCoMM glove set, is used to train the model. Additionally, a prediction process is also implemented for providing crane operators with more reaction time, enabling them to make the correct decisions and operations.

The proposed system can recognize signals, as illustrated in Figure 1. It is worth noting that an additional gesture, "*standby/activate*," is used to initialize the system proposed in this study. This gesture is performed with the forearm vertical and the index and middle fingers pointing upward. However, it is not shown in Figure 1.

Figure 1. Hand signal for hoist and crane operations

2 Literature Review

2.1 Internet of Things (IoT) in crane operation

Internet of Things technology has been developed, tested, and used in crane operation in construction sites. For instance, IoT technologies such as RFID [4] and GPS [5] positioning are used to integrate crane resources, which can reduce latency and improve efficiency in construction sites. Automation in crane operations is also a hotpot of IoT applications, X. Li et al. [6] used laser scanner and 4G communication to realize automatic crane operation for a prefabricated part. With AI-decision implementation, an automatic crane operation model has been achieved in a digital simulation model [7].

Sensor-based wearable devices represent another promising development direction. By integrating sensors into workers' personal protective equipment (PPE) rather than mounting them on crane arms or hooks, IoT systems can enable faster responses and provide more accurate hazard warnings [8], signal transmission [9], and other functionalities.

2.2 Deep Learning (DL) in crane operation

In crane operations, computer vision is one of the most widely applied deep learning technologies. Plenty of DL models, like YOLO (You Only Look Once), CNN (Convolutional Neural Network), are applied to achieve automation and intelligentization. CNNs are particularly effective in computer vision tasks, as they excel at capturing spatial features and local dependencies within image data. Some gesture recognition tasks rely on CNN-based architectures [15], while others use CNNs to extract combined feature representations from sensor data [14]. In addition, Long Short-term Memory (LSTM) model is crucial technology for processing time-series data. Many LSTM-based models are employed to achieve specific functions in construction sites. Wang et al. [10] used an optimized LSTM to achieve real-time and precise locating of the crane hook. LSTM is also applied to monitor and predict crane movement path [11], ensuring efficient crane operation planning and real-time adjustment.

2.3 Hand gesture recognition

With the widespread development of IoT technology and deep learning, more advanced systems for hand gesture recognition have further integrated to enhance the safety and efficiency of crane operations. Among these studies, vision-based sensors are the one of the most widely applied, with many efforts dedicated to combining visual signal with deep learning networks to achieve efficient hand signal recognition. Wang et al. [12] conducted a comparative study on different DL architectures, including ResNeXt-101 and Res3D + ConvLSTM + MobileNet, to evaluate their performance in image-based hand gesture recognition tasks in construction site. In addition to visual sensors, IMU sensors have been widely used to capture dynamic hand motion information. Mansoor et al. [1] integrated IMU sensors with traditional machine-learning algorithms and LSTM-based deep learning models for crane hand signal classification. Their study successfully demonstrated the feasibility of using wearable glove-based sensor layouts for reliable gesture recognition. Many other types of sensors have been selected to adopt to gesture recognition on under different conditions. EMG [13] helps to reduce restrictions on finger movement, flex sensors [9] improve the recognition of complex finger movements. LiDAR [14] minimizes the influence of lighting condition. Another effective approach is multimodal hand gesture recognition, by combining eye-tracking and IMU sensor [15], and adding context-aware sensing [16], researchers achieved more efficient the hand signal communication.

Building on these prior studies, this paper optimizes the use of accelerometers, gyroscopes, and flex sensors, while introducing a custom time-series data structure to better capture the temporal dynamics of hand gestures. Furthermore, we develop a CNN-LSTM hybrid model for precise gesture classification and incorporate an LSTM-based prediction module to anticipate future hand signals. This predictive capability extends the crane

operator's reaction time, enabling more accurate and timely execution of commands, ultimately enhancing operational safety and efficiency.

3 Research Methodology

The methodology for this study has been structured into three main parts: system design, data structure and preprocess, and deep learning model and implementation.

The overall workflow in the study is illustrated in Figure 2:

Step 1: Data is collected by sensors installed in the glove and transmitted to the central device.

Step 2: The data undergoes auto labeling, preprocessing and data structure management.

Step 3: The hybrid CNN-LSTM recognition model and LSTM prediction model are trained and tuned using processed data.

Step 4: The trained and fine-tuned models are deployed on the central device to enable real-time gesture signal recognition and prediction.

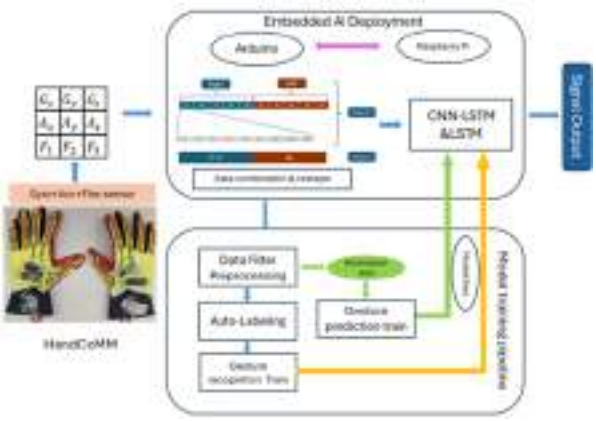

Figure 2. Dynamic crane signal recognition and prediction workflow.

3.1 System Design

The system consists of two main hardware components: the HandCoMM glove set, and a central device mounted on a belt. The glove set is responsible for collecting gesture signal data, while the central device handles data preprocessing for deep learning model and serves as the host for the deployed deep learning model using the preloaded weighted model file.

As shown in Figure 3, three flex sensors are strategically positioned on the thumb, index finger, and middle finger to precisely detect finger bending. As the ring and pinky fingers tend to move together with the middle finger, their bending pattens can be inferred from the flex sensor on the middle finger. This simplification not only reduces sensor complexity while maintaining high accuracy in gesture recognition but also lowers the communication burden and minimizes transmission delay. An Arduino development board, integrated with an accelerometer and gyroscope, is securely mounted on the back of the glove near the wrist. This configuration enables the system to monitor a wide range of hand movements, including hand pitch, wrist rotation, arm rotation, and the overall direction, speed, and acceleration of the hand. The battery and related accessories are securely fixed at the base of the glove.

The central device comprises an Arduino development board, a Raspberry Pi, and related supporting accessories etc. battery and power management unit. The gloves communicate with the central device via the Bluetooth protocol, while the Raspberry Pi and Arduino exchange data through a serial connection. These components are integrated and mounted on a belt to ensure the signalman's comfort during wear.

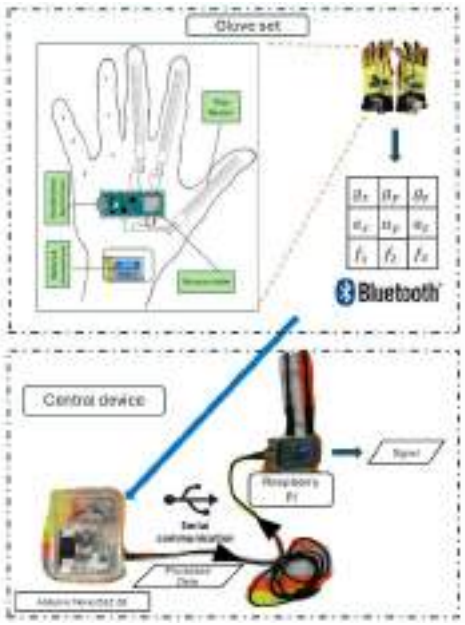

Figure 3. Layout of HandCoMM glove [17], [18] and system setup.

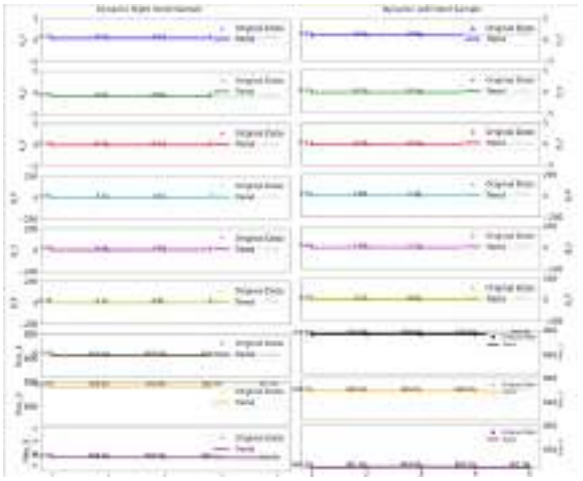
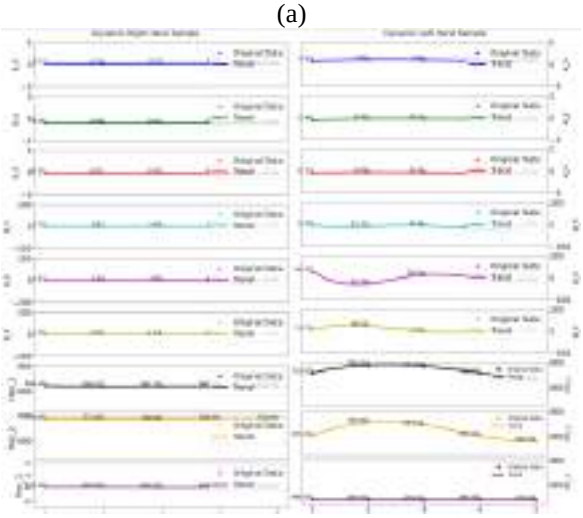


In this study, all devices are worn by the signalman. The gloves collect data from the accelerometer, gyroscope, and flex sensors, which are then transmitted via Bluetooth 5.0 Low Energy (BLE) to an Arduino development board for integration and preprocessing. This data transmission method ensures real-time performance and stability over short distances. The maximum Bluetooth packet size per transmission is 247 bytes, while the study's data size is approximately 200 bytes per packet, resulting in a transmission delay of just 1-2ms, depending on the communication mode. With a continuous communication interval of 7.5ms, this delay

is negligible compared to the 4-6Hz frequency of hand movements (150ms-250ms per motion cycle), ensuring smooth and uninterrupted communication. Although Bluetooth communication has a typical range of 10 meters, the actual distance between the gloves and the central device during operation is less than 1 meter, further enhancing the stability and reliability of the connection. The prepared data is subsequently sent to the central device (Raspberry Pi) via serial communication for deep learning inference, where gesture signals are generated and transmitted.



3.2 Data Structure and Preprocess

The dataset is designed to capture the temporal dynamics of hand gestures, essential for distinguishing complex dynamic gestures. Unlike static gestures, dynamic gesture signals require temporal context to represent transitions and movements. For example, the "*Boom up*" signal involves making a fist with the thumb raised, while "*Boom up hoist down (Option 1)"* requires sequentially bending four fingers while maintaining the thumb's position. Since these gestures share certain hand positions, single time-point data cannot differentiate them effectively. To address this, each sample integrates data from five consecutive time points, encoding the gestures' temporal characteristics. In Figure 4, the structural differences in sensor data between the two types of hand gesture signals are illustrated.

Each glove records nine types of data per time point: gyroscope readings (G_x, G_y, G_z), accelerometer readings (A_x, A_y, A_z), and flex sensor readings from the index finger, middle finger, and thumb (flex_1, flex_2, flex_3). Combining five consecutive time points results in a 45-dimensional feature vector per glove, and merging data from both gloves produces a 90-dimensional dataset per sample. With a sampling frequency of 30 Hz, the system captures samples at 6 Hz after combining five time points, ensuring efficient data processing and remaining gesture nuances. The selection of five-time steps in this study is determined by multiple factors. Research on human motion sensor sampling frequencies has shown that a sampling rate between 20Hz and 40Hz [19] provides a more accurate representation of human movements. Based on this, a baseline sampling frequency of 30Hz was adopted in this study. Additionally, studies on hand movement frequencies indicate a range of 1Hz to 4.5Hz [20], [21]. Considering the time required for data transmission, the effective sampling frequency was set to 6Hz, leading to the choice of five consecutive time steps. Furthermore, selecting a longer time window would increase communication time, as there are limitations on the data packet size per transmission. Exceeding this limit would require data segmentation, significantly increasing communication latency. As shown in Figure 4(b), five-time steps sufficiently capture the transition from finger bending to extension, including the two noticeable gyroscope fluctuations caused by the full bending and straightening of the fingers, as well as the rise and return of flex sensor values for the index and middle fingers.

(a)

(b)

Figure 4. Dynamic feature of sensor data comparison. (a) Gesture "*Boom up*". (b) Gesture "*Boom up Hoist down (Option 1)*"

For prediction tasks, due to the significant differences in absolute values among different sensor data, additional scaling is required to enhance the accuracy of the model's predictions. The gyroscope and accelerometer data possess directional properties, meaning their values can be both positive and negative; therefore, they are normalized within the range of (-1, 1). In contrast, the flex sensor measures resistance values, which are always positive, so it is normalized within (0, 1). The normalization process was conducted using the following formula:

$$x' = a + \frac{(x - x_{min})}{(x_{max} - x_{min})} \cdot (b - a)$$

Where x represents the original sensor value, x_{min} and x_{max} are the minimum and maximum values of the data, a and b are the lower and upper bounds of the target range, x' is the normalized value. Then generated data by the model could be reversed to its true value for analysis and practical applications.

Each dataset sample is labeled with one of 18 predefined crane signaling gestures. Stringent quality control measures were applied to ensure the data's integrity, removing incomplete or corrupted samples. The labeled data is stored in CSV format for accessibility and structured analysis.

The dataset includes contributions from six volunteers, reflecting diverse crane signaling experiences. This diversity ensures the dataset represents realistic variations in hand gestures. The final dataset comprises 13,514 samples, providing a robust foundation for developing deep learning models capable of recognizing dynamic gestures accurately in real-world scenarios.

3.3 Deep learning Model and Implementation

In the present study, deep learning is employed to achieve two critical objectives: gesture recognition and gesture prediction. Based on the data from flex sensors and IMU mounted on gloves, deep learning model will extract the features and time sequence characteristics to recognize different hand signal and generate sensor data at time step t+1. The section provides the details of deep learning models and implementation used in the proposed paper.

3.3.1 Model architecture and implementation: gesture recognition

To achieve robust gesture recognition, a combined CNN-LSTM model is employed. This architecture takes advantage of the strengths of CNNs in spatial feature extraction and LSTM in modeling temporal dependencies. Below, the model components and their functionalities are outlined:

- 1D-CNN Module

The 1D-CNN layers are designed to extract spatial features from the input sensor data, capturing correlations among the mounted sensors at each time step. This means CNN can identify static patterns. For example, if G_x and G_y increase together, it may signal a clockwise rotation. Through convolutional and pooling operations, the module reduces the dimensionality of the data while retaining its essential features. The first convolutional layer employs 64 filters with a kernel size of 3, followed by batch normalization to stabilize and accelerate training, max-pooling for dimensionality reduction, and dropout for regularization. A second convolutional layer, consisting of 128 filters, further enhances the model's ability to extract complex spatial features.

- LSTM Module

The LSTM module processes the sequence of features extracted by the CNN module to capture temporal dependencies and dynamic patterns in the sensor data. A single LSTM layer with 100 units is implemented, allowing the model to learn both short-term and long-term dependencies across time steps. To mitigate overfitting and improve generalization, a dropout rate of 0.5 is applied.

- Implementation

A Global Max Pooling layer was used to retain the most critical temporal features, followed by a dense layer with 256 units and ReLU activation to capture high-level representations. The final output layer employed SoftMax activation to classify the data into 18 predefined gesture categories.

The model was trained using the Adam optimizer with a learning rate of 1×10^{-3} and categorical cross-entropy loss. An early stopping mechanism with a patience of 10 epochs was employed to prevent overfitting, and the best weights were restored after training. The dataset was split into 80% training and 20% testing subsets, with a batch size of 64 and a maximum of 300 epochs.

3.3.2 Model architecture and implementation: Gesture Prediction

The predictive model employs an LSTM-based architecture designed to forecast sensor data for the next time step. The model consists of a single LSTM layer with 50 units, followed by a dense layer to generate predictions. Optimized using the Adam optimizer with a learning rate of 1×10^{-5}, the model minimizes Mean Squared Error (MSE) during training. Early stopping and model checkpointing are implemented to prevent overfitting and ensure optimal performance, with the best model weights saved for future use.

The hyperparameters of both models are summarized in Table 1, including architecture, training, and regularization settings selected for optimal performance.

Table 1. Summary of parameters of model structure and training details for task recognition and task prediction.

Aspect	Gesture Recognition	Gesture Prediction
Model type	CNN-LSTM hybrid	LSTM
LSTM Units	100	50

LSTM layers	1 LSTM Layer	1 LSTM Layer
Dropout Rate	0.5	Not Applicable
Optimizer	Adam	Adam
Learning Rate	1e-3	1e-5
Loss Function	Categorial Cross-Entropy	Mean Squared Error (MSE)
Activation Function	ReLU (Dense Layer), SoftMax (Output Layer)	Linear (Output Layer)
Batch Size	64	32
Epochs	Maximum of 300	Maximum of 20000
Early stopping Patience	10	10
Metrics	Accuracy	MSE
Output	Gesture Classification (18 classes)	Predicted Sensor Data

4 Result

The results of this study demonstrate the effectiveness of the proposed deep learning models and dedicatedly designed data structure for gesture recognition and prediction.

4.1 Gesture recognition

The CNN-LSTM model achieved a high accuracy of 98% on the testing dataset, which was derived from a split of 20% (2703 samples) of the entire dataset, in classifying 18 predefined crane signal gestures.

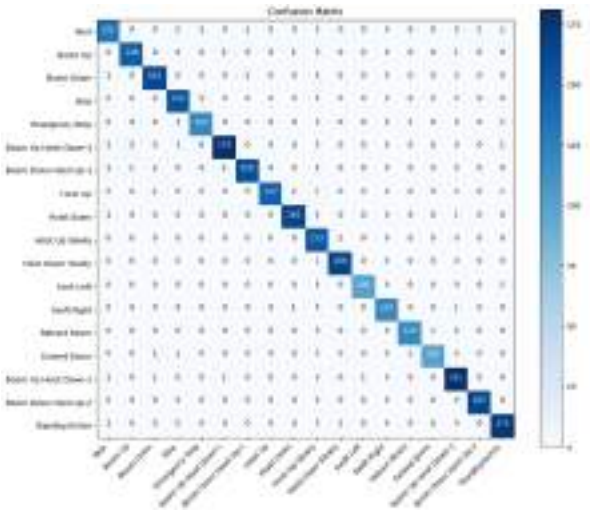


Figure 5. Confusion matrix of CNN-LSTM model for task gesture recognition.

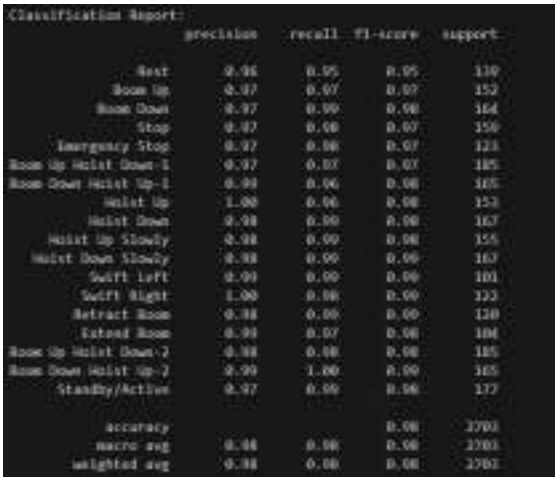
In real situation test, a volunteer was instructed to wear the gloves and perform all 18 predefined gestures. The model successfully detected the correct signals with an accuracy of 95.72% (179 out of 187 samples), demonstrating its strong generalization ability and effectiveness in recognizing both dynamic and static gesture signals. In Figure 5, the confusion matrix provides a comprehensive view of the model's classification performance across all gestures. Figure 6 displays the detailed classification report. In the report, precision measures the proportion of correctly predicted positive observations out of all predicted positive observations, recall (or sensitivity) measures the proportion of correctly predicted positive observations out of all actual positive observations, F1-score is the harmonic mean of precision and recall, and support represents the total number of true instances for each class.



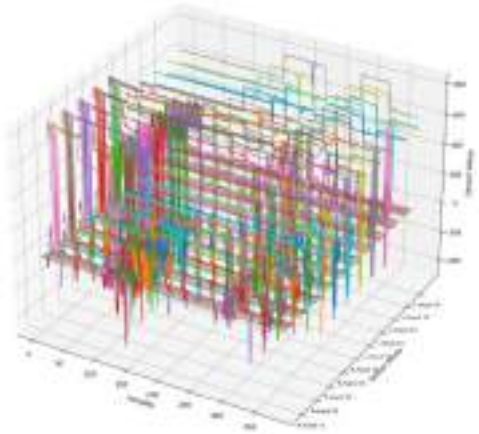


Figure 6. Classification report for gesture recognition

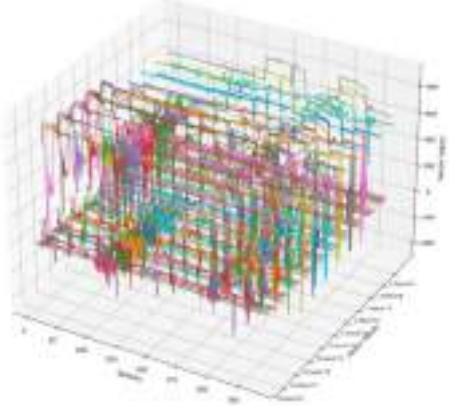
4.2 Gesture prediction



The LSTM model effectively predicted sensor data with an overall R^2 of 0.872, demonstrating reliable accuracy. Here, R^2 measures the proportion of variance in the data explained by the model. With values closer to 1 indicating better predictions. The mean squared error (MSE) quantifies the average squared difference between predicted and true values. The root mean squared error (RMSE) represents the average prediction error in the same unit as the data.

Table 2. Summary of Sensor Prediction Performance

	R^2	MSE	RMSE	Scope
Accelerator	0.924	0.030	0.172	-4.0 - 4.0
Gyroscope	0.789	759.019	27.550	-481.81 - 618.84
Flex sensor	0.903	2557.124	50.568	0 - 843

(a) True sensor values

(b) Predicted sensor values

Figure 7. Comparison between the true values and predicted values

For individual sensors, the accelerator achieved R^2 = 0.924, MSE = 0.030, and RMSE = 0.172 within a range of -4.0 to 4.0, indicating precise predictions. The gyroscope data showed R^2 = 0.789, MSE = 759.019, and RMSE = 27.550 over a broader range of -481.81 to 618.84. The flex sensor achieved R^2 = 0.903, MSE = 2557.124, and RMSE = 50.568, spanning 0.0 to 843.0. The detailed prediction performance indicators are shown in table 2. These results confirm the model's robust performance across diverse sensor types, reliably supporting crane operation safety and decision-making.

From the overall perspective, the prediction results essentially reflect the data characteristics, including the temporal dynamics and distribution patterns of the real data. The comparison between the true value and the predicted value is shown in Figure 7, (a) is the true value, (b) is the predicted value.

The predicted value will be reinput the CNN-LSTM model, the gesture recognition model, to get a predicted signal, so that the operator has an expectation of the next operation and more reaction time to perform correctly.

5 Conclusion and Future work

In the proposed system, the gloves, equipped with multiple sensors (accelerator, gyroscope, and flex sensors), are used as both data collection devices and personal protective equipment (PPE). A dedicated dynamic data structure, combining five consecutive time steps, ensures the preservation of temporal features in signal recognition. This is particularly important for differentiating dynamics signals like "*Boom up*" and "*Boom up hoist down (Option 1)*", where sequential motion is essential for correct classification.

The hybrid CNN-LSTM deep learning model successfully recognizes 18 predefined signals with 98% accuracy on test dataset and 95.72% accuracy in real situation test. Considering the high accuracy, the model performance is effective and robust. In addition, an independent LSTM model is employed for forecasting sensor data for the next time step. The predicted sensor data will be re-input the recognition model to provide crane operators with the oncoming signals. This enables operators to have an expectation for the oncoming instructions, which can help them have longer reaction time and increase the possibility of making correct operations. In turn, operation losses caused by miscommunication and accidents will be minimized.

Future work will focus on continuous data collection and online learning, allowing the system to adapt new data from different users and continuous improvement through real-world usage; enhancing the signal transmission process, which will ensure that correct signals are reliably passed between signalmen and crane operators; improving hardware reliability and standardization, which will prevent equipment damage during use and ensure consistent system performance. Finally, integrating the system with crane control systems, which will enable semi-autonomous or fully automated crane operations, further improving efficiency and safety.

Abstract –

This study presents a novel approach for optimizing the flight paths of multiple drones during construction site inspection and monitoring by leveraging image compression techniques, specifically the fractal quadtree method. Traditional path planning methods often fail to account for varying levels of complexity across the construction site, leading to inefficiencies in energy consumption and scanning time. By applying the fractal quadtree approach, we dynamically adapt grid sizes based on the complexity of the initial captured site images, allowing drones to prioritize more intricate areas while minimizing focus on simpler regions. Simulation results demonstrate that this method efficiently reduces the number of required scans compared to conventional approaches, significantly improving the overall efficiency of construction site inspections. The integration of this adaptive path planning strategy provides a scalable and time-saving solution for hazard identification and site monitoring, ensuring more efficient use of drone resources.

Keywords –

Path planning; Safety; Drones; Fractal Algorithm

1 Introduction

Many construction companies are increasingly recognizing the benefits of incorporating drones and unmanned aerial vehicles (UAVs) into their operations [1, 2]. These devices are used to monitor construction progress [3] and inspect structural conditions of civil infrastructures [4] based on 3D reconstruction models. They can also be used to identify hazardous conditions on-site, such as missing personal protective equipment for work at height, and to generate safety warnings for workers [5]. Timely information about nearby hazards is essential for construction workers to ensure their safety. Therefore, drones and UAVs that can quickly and thoroughly scan the entire construction site are crucial [6]. However, deploying a fleet of drones and designing efficient flight paths across construction sites has posed challenges. Existing drone monitor and inspection methods are focused on how to identify the best flight path based on user's experience and 3D reconstruction model quality [3], [4]. Optimizing flight paths is crucial to saving time and energy; for example, Yang et al. [7] proposed an ant colony optimization approach to determine the flight path for digital terrain model reconstruction based on user-defined area, image overlap, and battery limit. In addition, existing methods usually do not consider multiple-drone scenarios in optimization process and assume using a single drone. Traditional flight pattern design methods, such as zigzag or grid-based approaches [8], apply uniform scanning across the entire site and do not account for the varying complexity of different areas. As a result, they can lead to inefficient resource utilization, redundant scans, and even missed critical safety hazards in more complex regions.

In contrast, applying image compression techniques, such as the fractal quadtree method [9], provides a more efficient solution for drone path planning during surface monitoring of construction sites. This approach has been successfully used in adaptive path planning for scanning microscopes [10], [11] robot path planning [12], and trajectories for aerial coverage [13], enabling effective scanning of both complex and simple geometric shapes with different resolutions. By dynamically adjusting the grid sizes based on the visual complexity of different regions, this approach focuses the drones' efforts on areas that require more detailed scanning. Consequently, by dynamically adjusting grid sizes based on the complexity of surface conditions, the proposed fractal quadtree approach (FQA) may allow for better resource allocation, faster coverage, and improved accuracy, as the drones can spend more time in high-risk or complex areas while minimizing redundant scans in simpler zones.

2 Safety Inspection with Drones

To effectively utilize drones to assess safety risks in construction, they must be equipped with high-resolution cameras, GPS for precise localization, and an optimized

angle of view to capture fine details across varying site conditions. The clarity of these images primarily depends on two factors: the resolution of the camera and the drone's Ground Sampling Distance (GSD) above the target area. These variables determine the number of pixels captured per unit length in site imagery, which may vary across different areas of interest. However, high-resolution footage is not always required uniformly across all zones; in areas with minimal construction activity, less detailed scrutiny is sufficient compared to zones with intense building operations.

2.1 Flight Altitude and Resolution of Camera

Drones used for hazard inspection on construction sites should be equipped with two cameras: a forward-facing camera for navigation and a downward-facing camera for capturing site images (Figure 1). These cameras can be combined using a gimbal mechanism to reduce the number of sensors the drone needs to carry.

To examine the relationship among the map resolution of the acquired images, the drone's altitude, or ground sampling distance (GSD), and the resolution of the camera used, a geometric relationship can be applied. As illustrated in Figure 1, the visible range of the camera can be easily derived from this geometric configuration. In this setup, the downward-facing camera's field of view (FOV) angle determines the number of pixels per unit length and area based on its resolution at various GSDs. The drone's visible range at a given GSD is determined by the camera's FOV angle, while the pixel density per unit length is governed by the camera's physical resolution as well as GSD. Given the camera resolution and flying altitude, the visible range of each image can be calculated, allowing the total coverage of the construction site to be determined and divided into a grid. Table 1 provides the visible ranges and image resolutions at specified GSDs.

Table 1 Covered visible ranges and image resolutions on the targeted area at specified GSDs.

Camera resolution			720p	1080p
FOV	GSD (m)	Visible range (m)	Pixels / meter	Pixels / meter
90°	10	20 m	36	54
	20	40 m	18	27
	30	60 m	12	18
	40	80 m	9	13.50
120°	10	34.64 m	20.78	31.18
	20	69.28 m	10.39	15.59
	30	103.92 m	6.93	10.39
	40	138.56 m	5.20	7.79

3 Resolution Adjustment and Flight Path Planning of Swarming Drones

Swarming drones involve multiple drones working collaboratively and autonomously in a coordinated manner to perform tasks. To ensure that drones gather useful information across an entire construction site, their visible range and flight pattern had to be defined. In this study, three approaches were examined. Two of the approaches required the drones to maintain a fixed resolution for the captured images, including: 1) random walk approach [14], and 2) zigzag flight path planning. The third approach used an adjustable resolution based on a fractal quadtree approach (FQA). This section explores each approach and outlines the corresponding flight paths.

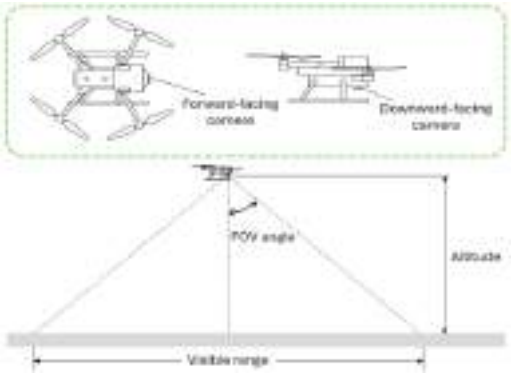

Figure 1. Geometric relationship between FOV angle, altitude, and visible range of the downward-facing camera used by a drone.

3.1 Random Walk Approach

One of the simplest methods for controlling drone behavior is to allow the drones to swarm randomly within a designated map, navigating in various directions across the targeted construction site. The primary advantage of the random walk approach is that the drones only need to communicate for collision avoidance, eliminating the need for coordinated communication or pre-programmed flight paths, which simplifies the overall operation. The images captured by the drones can be stitched together to identify potential hazards. However, this approach can be time-consuming for the drones to cover the entire area, as random flight patterns may result in insufficient coverage and overlap, leading to delays before the full site is scanned. Additionally, since the drones are not coordinated, some areas may receive more attention than necessary, while others might be underexplored. The starting location of the drones, whether random or fixed, does not significantly affect the total time required to complete the scan, but the overall efficiency remains lower compared to more structured flight patterns.

With the random walk theory, the flight pattern can be modeled as a two-dimensional random walk on a grid or a continuous space. Figure 2 demonstrates the possible movements using the random walk method. Each drone makes a series of steps, where each step is determined by

a random direction. We assume that the drone's movement direction follows a uniform distribution in the random walk approach, with random starting positions. Figure 3 illustrates the flight paths of two selected drones (out of a total of 50 drones in the simulation) navigating a 100 × 100 grid area during the process of a full scan.

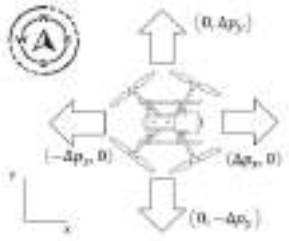

Figure 2. Flight pattern of random walk approach.

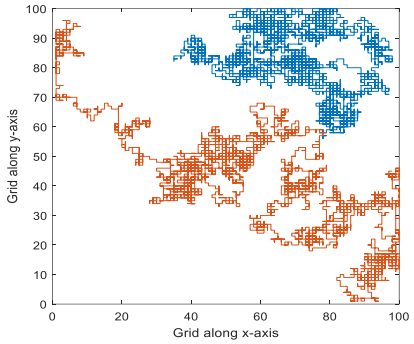

Figure 3. Flight trajectories of two selected drones using random walk approach (50 drones deployed in an area with 100 × 100 cells).

3.2 Zigzag Flight Path Planning

To ensure the image of the targeted construction site can be captured within a predictable timeframe, the zigzag approach can be a versatile option. In this approach, the area is divided proportionally among the total number of drones, allowing the time required to cover the entire site to be easily estimated. By following predefined zigzag paths, the drones systematically sweep through their assigned zones, ensuring full coverage.

In the zigzag approach, the construction site is divided into equal sections for each of the N_D drones, with each drone responsible for scanning a designated portion of the total area, A_S. The total area can be represented as a rectangle or grid of dimensions $L \times W$, where L is the length and W is the width of the site. Thus, the area each drone must cover can be calculated as

$$A_{drone} = \frac{A_S}{N_D} = \frac{L \times W}{N_D}. \quad (1)$$

In this case, the path for each drone is defined by a series of horizontal or vertical zigzag motions across their respective areas.

The path length for each drone depends on the shape of its assigned area. Assuming that the drone moves in a horizontal zigzag pattern, the path length per section for a drone covering an area of $L_{region} \times W_{region}$ is determined by the number of back-and-forth passes required to cover the width of the area. The total length of the path l_{drone} for each drone can be approximated as

$$l_{drone} = \left(L_{region} + 1\right) \cdot \frac{W_{region}}{\Delta p}. \quad (2)$$

where L_{region} is the length of the area each drone covers, W_{region} is the width of the area each drone covers, Δp (Δp_x or Δp_y) is the distance between consecutive passes in the zigzag path. One advantage of the zigzag method is its efficiency. With clearly defined paths, drones can avoid redundant overlap, minimizing wasted time and ensuring that each section of the site is inspected. This structured approach also allows for better time management and straightforward coordination between drones. Moreover, the predictable nature of this method simplifies post-processing, as the images can be stitched together more seamlessly. However, the effectiveness of the zigzag pattern is influenced by the starting positions of the drones. If the drones are not deployed from optimal locations, some may need more time to reach their designated zones, leading to uneven coverage and potential delays. Additionally, the rigid path planning might be less adaptable to irregularly shaped construction sites or areas with obstacles, reducing flexibility compared to more dynamic flight patterns. Overall, the zigzag approach offers a reliable and efficient solution for structured environments, making it a preferred choice when speed and predictability are critical.

3.3 Fractal Quadtree Approach

As noted in the previous section, the visible range of a drone changes with its altitude, affecting the grid sizes used for mapping the targeted area. Image processing techniques using FQA offer a way to dynamically adjust these grid sizes based on the complexity of the construction site surface. Instead of applying a uniform grid across the entire site, this technique adapts the grid resolution according to the visual details captured in lower-resolution images. In areas with lower complexity, such as inactive or open zones, larger grid sizes are used for faster scanning. In contrast, regions with higher complexity, such as those with active construction, are subdivided into smaller grids to capture finer details.

3.3.1 Iterated Function System

In a fractal process, the theory of iterated function systems (IFS) is applied, serving as the foundation for fractal processing techniques [9]. In the application for a construction site, IFS employs affine transformations to capture the relationships between different sections of the image S of the target construction site captured by the downward-facing camera. By using the transformations,

it can define and represent areas with complex structures efficiently. Affine transformations are combinations of rotation, scaling, and translation applied to coordinate axes in *n*-dimensional spaces. A transformation is denoted by q, with $q(S)$ representing the transformed set of points S. The general form of an affine transformation can be expressed as

$$q(p_x, p_y) = \begin{bmatrix} a & b \\ c & d \end{bmatrix} \begin{bmatrix} p_x \\ p_y \end{bmatrix} + \begin{bmatrix} e \\ f \end{bmatrix} = \begin{bmatrix} a \cdot p_x + b \cdot p_y + e \\ c \cdot p_x + d \cdot p_y + f \end{bmatrix}. \quad (3)$$

In this transformation, the coefficients a, b, c, d, e, and f are real numbers that define the parameters. If the translation, scaling, and rotation associated with the mapping q are predetermined, the values of these coefficients are given as

$$a = u\cos\theta,\ b = -v\sin\varphi,\quad c = u\sin\theta,\ d = v\cos\varphi, \quad (4)$$

In this context, u represents the scaling factor along the x-axis, v is the scaling factor along the y-axis, θ is the rotation angle about the x-axis, φ is the rotation angle about the *y*-axis, e and f represent the translations along the x- and y-axis, respectively.

To define an IFS, the concept of contractivity is introduced as following:

Definition 1 (Contractivity) [9] Let S be a metric space with metric f_q. A mapping $q: S \to S$ is said to be Lipschitz with a Lipschitz factor s if there exists a positive real value s such that

$$f_q\big(q(\mathbf{p}_1), q(\mathbf{p}_2)\big) \le s \cdot f_q(\mathbf{p}_1, \mathbf{p}_2) \quad (5)$$

for all $\mathbf{p}_1, \mathbf{p}_2 \in S$. If the Lipschitz factor satisfies $s < 1$, then q is considered contractive with contractivity s.

An IFS consists of a finite collection of contractive affine transformations. This collection of transformations W defines a mapping from the original image S to the transformed image $Q(S)$, which can be expressed as

$$Q(S) = \cup_{i=1}^{n} q_i(S_i). \quad (6)$$

It is important to note that the contractive affine transformation q_i operates on a subset of the original image S, referred to as block S_i. Consequently, $Q(S)$ is formed as a union of these individual contractive transformations. Each transformation q_i is associated with a predetermined property that determines the significance relative to the other transformations.

To establish a systematic method for identifying the affine transformation that generates the IFS encoding of a desired image, the following two theorems are introduced: the collage theorem and contractive-mapping fixed-point theorem.

Theorem 1 (Collage Theorem) [15] Let S be a complete metric space and $q: S \to S$ be a contractive mapping with a contractivity factor s for any pixel $\mathbf{p} \in S$. Then, the following inequality holds:

$$f_q\big(\mathbf{p}, q^n(\mathbf{p})\big) \le \tfrac{1}{1-s} f_q\big(\mathbf{p}, q(\mathbf{p})\big), \quad (7)$$

where $q^n(\cdot)$ represents the n^{th} iteration of the affine transformation.

Theorem 2 (Contractive-Mapping Fixed-Point Theorem) [15] Under the assumption of the collage theorem, there exists a unique point $\mathbf{p}_f \in S$ such that for any point $\mathbf{p} \in S$,

$$\mathbf{p}_f = q\big(\mathbf{p}_f\big) = \lim_{n\to\infty} q^n(\mathbf{p}). \quad (8)$$

This point $\mathbf{p}_f$ is referred to as the fixed point or the attractor of the mapping q.

For a contractive affine mapping, the distance $f_q(\mathbf{p}, q^n(\mathbf{p}))$ between the original points and their mapped counterparts decreases with each iteration. Similarly, for an input image S, it can be demonstrated that the error between the original point and the mapped point remains below a certain bound after n iterations. This is established through repeated application of the triangle inequality and the contractivity of q [9]. If the mapped image $q(S)$ exhibits lower complexity than the original image, then q can be viewed as a lossy encoding of S. We refer to such a transformation w within S that satisfies (5) and (6) as a fractal code for the original image S, indicating that S is self-transformable under q. The process exemplifies a common method for constructing fractal objects.

3.3.2 Partitioned Iterated Function System

In the fractal processing approach used in this study, a key requirement is that the width and length of the target area must be equal, with the side length of the scanned image being a power of 2. Once these conditions are met, the partitioned iteration function system (PIFS) can be applied, which generalizes the standard IFS method. In a PIFS, the original image is divided into numerous non-overlapping square blocks of two different sizes, creating a two-level square partition, commonly referred to as quadtrees. The large blocks of the original image, measuring $L_p \times L_p$, are designated as parent blocks, while the smaller ones, measuring $L_p/2 \times L_p/2$, are termed child blocks. Each parent block can be partitioned into four non-overlapping child blocks that correspond to its four quadrants.

During the transformation process, a segment of the original image S, denoted as S_i^q, is transformed into a corresponding section of the reproduced image, represented as R_i, through the mapping q_i. Here, S_i^q is referred to as a domain block and R_i is called a range block. The collection of domain blocks $\{S_i^q\}_{0\le i<n}$ is termed the domain pool. The decisions to split a parent block occurs during the encoding of individual image blocks. A metric that measures the difference between the original block and the transformed block is essential for determining whether a split is necessary. This process is repeated until the difference between the original and the approximated image is below a predefined threshold.

Based on this recursive approach, given an image S of the construction site and a collection of n contractive

mappings q_1, q_2, …, q_n, the representation of the transformed image of the site can be written as

$$Q(S) = q_1(S) \cup q_2(S) \cup \cdots \cup q_n(S) = \cup_{i=1}^{n} Q_i(S). \quad (9)$$

The partition created in this manner is dependent on the specific image taken from the construction site being processed. This technique enables the encoder to utilize larger blocks in less complex regions of the image while employing smaller blocks to capture finer details in more complex areas.

3.3.3 Fractal Encoding Procedure of FQA

The proposed FQA partitioning algorithm assumes that the images captured from construction sites exhibit fractal characteristics. A key aspect of fractal image processing is minimizing the difference between the original image and its processed result. The goal PIFS encoding process is to identify a set of mappings that reduces this difference between partitioned results and original site conditions with a predefined threshold. The encoding procedure is governed by two main parameters: the tolerable deviation e_t between the original image and the approximated result and the depth (or the finest resolution) r_{min} of the quadtree. The tolerable deviation e_t defines the acceptable deviation between the encoded partitions and the actual image captured at the construction site. The depth of the quadtree determines how much detail is preserved in the transformed partitions, allowing for adaptive grid size based on the visual complexity of different areas.

The coarse image, captured from the construction site, is initially divided into several sections based on a predefined minimum number of grid cells. This quadtree partitioning method represents the image as a hierarchical structure, where each node corresponds to a square section (parent block) of the image, which can be further subdivided into four sub-sections (child blocks). The encoding process begins at the root node, which represents the entire initial image. The relationships among these nodes are structured in a tree-like format, where each node in the branches corresponds to a part of the processed image, or a range block.

After partitioning the image, the range blocks (nodes) are compared with domain blocks from a predefined domain pool $\{S_i^q\}_{0 \le i < n}$. An affine transformation is applied to find the best match that minimizes the difference between the range block and its corresponding domain block. Each domain block, consisting of four non-overlapping square blocks, is four times the size of the range block. To compare them, the pixels in the domain block are averaged in groups of four, reducing the domain block to match the size of the range block.

If the difference between the range block and the domain block exceeds the preset error threshold e_t and the distance between adjacent pixels is larger than the defined minimum resolution r_{min}, the range block is further subdivided into four child blocks, and the process repeats. If the difference is within the acceptable threshold, the affine transformation q_i is stored for that domain block. This collection of all such transformations $Q = \cup q_i$ forms the encoding process of the targeted area, allowing for adaptive grid resolution across different sections of the site based on visual complexity.

Once the area is partitioned into blocks, drones can be deployed accordingly: larger grid blocks correspond to higher flight GSDs, while smaller grids represent lower flight altitudes. Drones are assigned to these grids based on altitude requirements. The blocks, varying in size, are sorted by their proximity to optimize the drones' flight paths. As a result, the flight trajectories at different altitudes can be determined. Taking this into account, the number of drones N_D can be determined and allocated to the appropriate altitudes. Figure 4 illustrates the deployment of drones at different altitudes, tailored to the resolution needed for the partitioned blocks. This approach significantly reduces the number of high-resolution images required, thereby speeding up the overall scanning process for the targeted construction site.

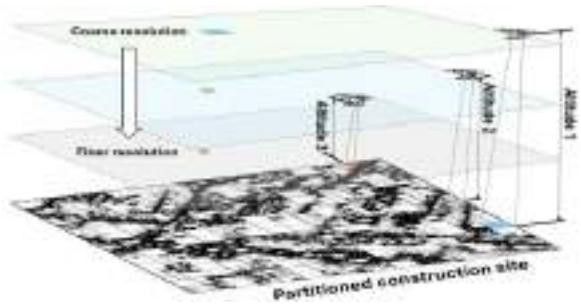

Figure 4. Partitioned construction site and its corresponding drone flight altitudes.

4 Simulation of Different Approaches

To evaluate the performance of the three approaches, a real construction site image covering an area of 64 m × 64 m, as shown in Figure 5, was used to develop a simulated test case. The target resolution was set to a 2 m visible range, based on the downward-facing camera equipped on the drone. This resolution allowed the construction site to be divided into a grid of 32 × 32 cells for both the random walk and zigzag methods.

4.1 Random Walk Approach

In the random walk approach, the number of steps required to fully scan the entire targeted area can vary significantly due to the drone's unpredictable movements. To assess the variability, simulations were conducted using both one drone and two drones. Each scenario was simulated over 200 trials to ensure that the results

exhibited Gaussian distribution. The simulated outcomes are presented in Table 2. The random walk method proved to be highly inefficient. A single drone required over 26,000 steps to cover all 1,024 cells of the 32 × 32 grid at least once. Even with two drones working in tandem, the required steps remained high, exceeding 13,000 to ensure full coverage of the grid. These results demonstrate that, while multiple drones can reduce the total steps, the random walk approach is still suboptimal and time-consuming for large-scale site inspections.

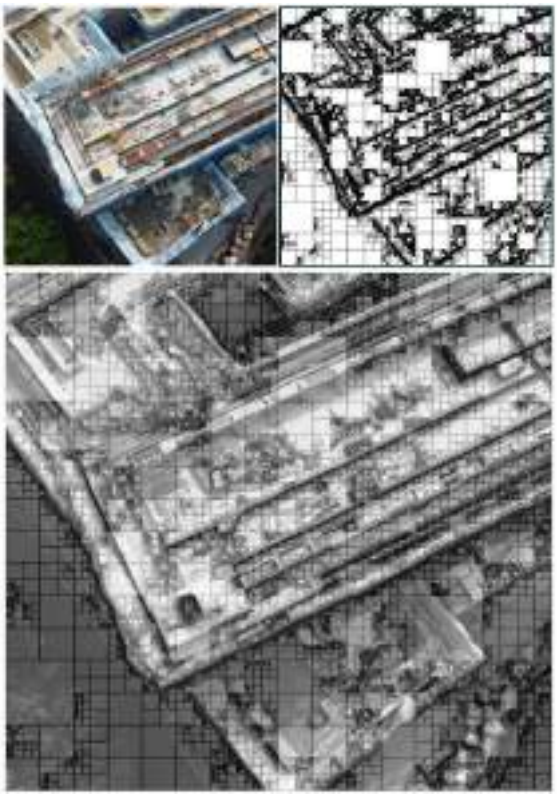

Figure 5. The acquired image of the construction site and the partitioned result (e_t = 10% of the maximum and minimum grayscale values).

4.2 Zigzag Flight Path Planning

Of the simulated approaches, the zigzag approach was the most efficient method for completing a full scan with a fixed resolution. A single drone covered the entire 32 × 32 grid in 1,024 steps, much fewer in comparison to the random walk method. When two drones were deployed, the required steps were halved to 512 for full coverage (with the drones positioned at specific initial locations within the partitioned blocks). This positioning ensures that the zigzag trajectories in each block can be completed systematically and without overlap. Table 3 presents the required steps for areas partitioned into varying grid sizes, highlighting the efficiency and predictability of the zigzag approach compared to the random walk method. This structured deployment helps to ensure optimal utilization of drone resources while maintaining comprehensive coverage.

Table 2 Required steps for a complete scan on the targeted area using random walk method (32× 32 cells).

	Number of drones			
	1		2	
Completed area	Average steps	Standard deviation	Average steps	Standard deviation
50%	2479.6	716.8	1110.1	412.9
70%	4371.8	1066.1	1987.7	678.0
95%	10612	2493	5594.8	1596.7
100%	26502	8901	13585	4479

Table 3 Required steps for a complete scan on the targeted area using zigzag method.

	Number of drones		
	1	2	4
Gridded cells	Required steps	Required steps	Required steps
32 × 32	1024	512	256
64 × 64	4096	2048	1024

4.3 Quadtree Approach

In FQA simulated approach, the number of cells that required drones to visit and acquire images varied, depending on the complexity on the site surface.

4.3.1 Parameters of Fractal Quadtree Approach

To evaluate the performance of the proposed fractal-based path planning approach, images of the College of Liberal Arts Building construction at the National Taiwan University were again used. The area, measuring approximately 64 m × 64 m, was captured, as shown in Figure 5. Before deploying the drones to scan the site and assigning specific flight paths, a preliminary image of the construction site was taken to determine how the area should be partitioned. Once the image was obtained, it was first converted from color to grayscale, a necessary step for FQA. For this test, the construction site was initially divided into 64 blocks, each measuring 8 m × 8 m, to ensure that no portions of the site were scanned without adequate pixel-per-meter resolution. The tolerable deviation e_t was set at 10% of the maximum and minimum grayscale values in the image. Using this threshold, the fractal quadtree approach was applied to generate the partitioned grids for flight scanning, ensuring an optimized balance between resolution and scan efficiency.

4.3.2 Partitioned Blocks Using FQA

The results showed that a simulated construction site could be efficiently partitioned into grids to plan drone flight paths, as demonstrated in Figure 5 and Figure 6.

Initially, the site was divided into very fine grids with a 0.25 m visible range. The original image of the construction site had a resolution of 8 pixels per meter. When partitioned into 8 m × 8 m blocks, the resolution increased to 64 pixels per meter. Doubling the resolution to 128 pixels per meter requires the blocks to be 4 m × 4 m. For this study, the blocks were divided into 2 m × 2 m to achieve the desired resolution of 256 pixels per meter. After merging, the final partitioning resulted in six 8 m × 8 m blocks, 44 blocks sized 4 m × 4 m, and 784 blocks of 2 m × 2 m. This totaled 834 blocks that needed to be scanned and imaged by the drones. In comparison, a traditional zigzag approach for the same area would require scanning 1,024 locations with a single drone, meaning the FQA reduced the total imaging time (no flight time) by approximately 18.75%, requiring only 81.25% of the zigzag approach's locations to be visited.

If the visible range is further refined to 1 m × 1 m blocks, the zigzag approach would require scanning 4,096 locations, while FQA reduces this number to 2,647, or 64.6% of the total grids. At even higher resolutions, 0.5 m × 0.5 m blocks, the FQA covers only 47.91% of the total grids, significantly reducing the imaging effort compared to the zigzag flight path planning method.

Table 4 provides a comparison of the required number of blocks for different visible ranges. Results show that as the resolution becomes finer, FQA substantially reduces the number of locations that need to be scanned, showcasing its efficiency over the zigzag approach. This reduction in the number of required blocks is the key advantage of the FQA, particularly when fine visible range is essential.

Table 4 Comparison of visited blocks and ratios across different tolerable deviations and visible ranges.

e_t	10%			15%		
Visible range	# of blocks	Ratio (%)	PSNR	# of blocks	Ratio (%)	PSNR
2 m × 2 m	832	81.3	24.08	778	76.0	22.84
1 m × 1 m	2647	64.6	25.59	2305	56.3	25.85
0.5 m × 0.5 m	7849	47.9	28.44	6283	38.4	26.04

The quality of the acquired images at different GSDs can be assessed using peak signal-to-noise ratio (PSNR) during the reconstruction of the site image by stitching all partitioned images. To ensure acceptable image fidelity, the PSNR value should typically remain above 25 dB [10]. In this study, the PSNR exceeds 25.59 dB when the compression ratio is kept below 65%, indicating minimal loss of critical visual details.

4.3.3 Synthesis of Flight Paths Using FQA

In FQA, the construction site was partitioned into grids of varying sizes based on the complexity of the acquired images, with smaller grids indicating more detailed areas and larger grids representing fewer complex regions. Once the partitioning was completed, the flight paths for the drones were generated by assigning drones to fly at corresponding altitudes, where the altitude was correlated with the size of the grids. These results indicate that drones flying at higher altitudes can cover larger, less complex areas represented by the bigger grids, while drones flying at lower altitudes can be tasked with scanning smaller, more detailed areas. This adaptive use of altitude ensures that drones are optimally deployed according to the resolution requirements of each specific region within the site.

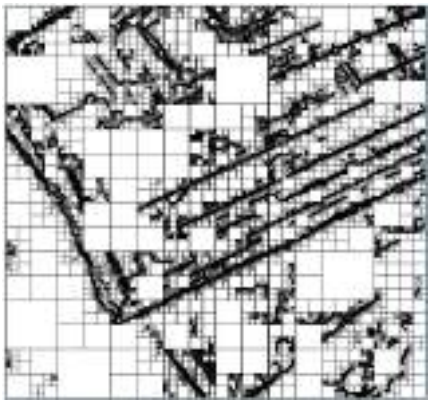

Figure 6. The partitioned result of the construction site ($e_t = 15\%$ of the maximum and minimum grayscale values).

The key advantage of the FQA approach is its efficiency. Drones at higher altitudes can scan large sections of the site in less time, as the lower level of visual detail in these areas requires fewer images. By covering more ground per flight, these drones reduce the total number of paths needed to fully scan the site. Meanwhile, drones operating at lower altitudes can focus on areas that require a higher resolution due to their complexity, ensuring that detailed information is captured where necessary. This distribution of tasks allows for a balanced and scalable operation, where drones can be deployed in the most efficient manner possible based on visual complexity of different zones.

By leveraging the flexibility of flying at different altitudes, FQA may reduce the overall time needed for site scans compared to the two traditional methods. Drones do not need to uniformly fly at low altitudes across the entire site, which can be time-consuming and inefficient. Instead, they can be selectively allocated to specific altitudes, aligning their flight paths with the partitioned grid sizes. This not only reduces the total number of flight paths but also minimizes redundant scanning, allowing for faster coverage of the site without compromising the quality of the images in critical areas. As a result, the overall scan time for the construction site can potentially be reduced, maximizing both the efficiency and precision of the hazard inspection process.

5 Conclusion

The proposed FQA approach offers an efficient and scalable solution for drone-based construction site inspections. By dynamically adjusting grid sizes based on the complexity of acquired images, the FQA approach allows for optimized flight path planning and reduces the time required to scan large areas without sacrificing image quality in critical regions. The adaptive nature of the fractal quadtree technique also enables drones to be deployed at varying GSDs, further enhancing the efficiency of the scanning process by aligning drone altitude with the complexity of the targeted area. This approach not only outperforms traditional approaches such as zigzag and random walk flight patterns but also provides greater flexibility in handling diverse site conditions. Ultimately, the fractal-based grid partitioning method presents a robust and practical solution for improving hazard identification and monitoring on construction sites, facilitating efficient inspections.

Abstract

Placing concrete using a truck-mounted pump is a common construction method, enabling pouring of large volumes of concrete in a highly efficient way. However, the method is associated with unfavorable working conditions due to the need for manual handling of the end-hose. The hose-man are exposed to hazardous and poor working conditions. This paper reports on efforts to develop a robotic system for wireless remote control of a concrete pump's end-hose. The idea is to replace the need for manual handling of the end-hose. The robotic system is comprised of four pneumatic actuators (so called pneumatic muscles) attached to the pump's end-hose by two light-weight fixtures, and a control system. The proposed system offers improved safety and working conditions for concrete crew members. The robotic device was tested both in laboratory and in real conditions during concrete pumping.

Keywords – Construction robotics, concrete pumping, end-hose, robotic system, pneumatic actuator.

1 Introduction

Concrete is one of the most used materials in construction projects worldwide. The material properties provide important structural functionality in a wide range of applications such as in buildings, bridges, dams, tunnels etc. About 30 billion tons of concrete are used globally each year and the consumption is estimated to increase to about 44 billion tons in 2050 [1].

Due to the heavy weight of concrete (about 2.4 tons per cubic meter) in combination with large volumes normally used in a construction project, there is a great need for an efficient distribution method on the construction site. The idea of transporting concrete using a pump was introduced almost a century ago. Since then, concrete pumps have technically evolved and today, it is an obvious choice of placement method in many construction projects [2]. The pump enables pouring of large volumes of concrete in a shorter time compared to other existing methods such as using a crane-lifted concrete skip [3]. Today, in some countries more than 50% of annual concrete volume is poured using truck-mounted pumps [4].

A truck-mounted concrete pump consists basically of a piston pump, a foldable boom arm, and a flexible end-hose. The boom arm consists of multiple articulated elements whose movements are controlled by hydraulic actuators. The elements are unfolded at the construction site enabling vertical and horizontal reach.

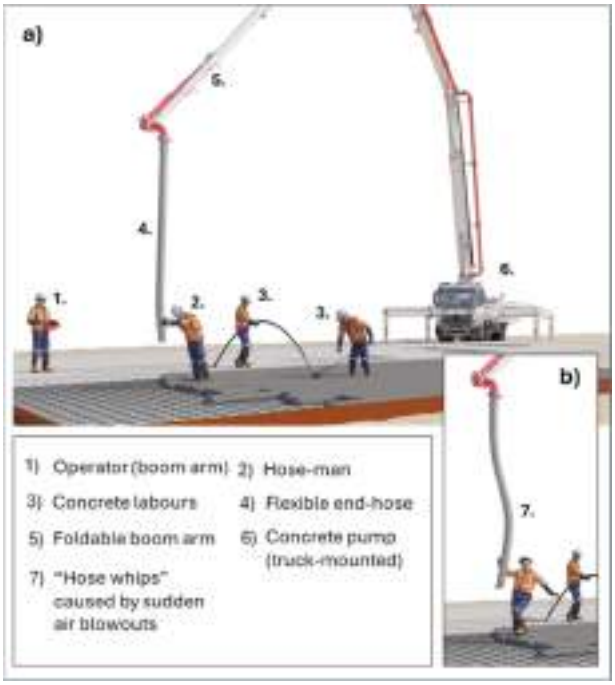

Figure 1a) Truck-mounted pump and concrete crew during placement of concrete. 1b) Sudden blow-outs may cause serious injuries to the hose-man and other workers close to the end-hose.

Concrete is pumped under high pressure (up to 85 bar) through a conveying pipe attached along the boom arm and is sprayed out at the end of the flexible hose [5]. The overall position of the boom arm is controlled remotely by an operator, but the precise position of the end-hose is manually directed by concrete laborer (so called hose-man). The hose-man directs the flexible hose close to the point where concrete is sprayed into the formwork. This is heavy work, but also associated with personal risk due to risk of unexpected buildup of compressed air voids in the conveying pipe systems, resulting in sudden blowouts forcing the hose into uncontrolled movements. This can cause severe injuries to the hose-man or anyone else that are close to the swinging end-hose. To eliminate risk of severe injuries to concrete laborers, this paper describes the efforts to develop a robotic system for remote control of the flexible end-hose. The paper focuses on describing the proposed robotic system and the main findings from a field test under real conditions at a construction site during pumping.

The paper is structured as follows; first a review of previous research is described, then work methodology and the robotic system is presented. Thereafter, results of the tests are provided followed by conclusions and suggestions on future work.

2 State of the art review

2.1 Concrete pumping method

A typical truck-mounted pump and the concrete crew involved during concrete pumping is presented in figure 1 (a and b).

The operator controls the movement of the foldable boom arm using a radio remote control. Another important task for the operator is to control pumping pressure and position of the truck. During concrete pumping, the hose-man handles the flexible end-hose during pumping and the other concrete crew members perform vibration and levelling of the pumped concrete. Handling of the end-hose is a heavy task due to the weight of the flowing concrete, but also hazardous due to the risk of blowouts. Blowouts are caused when air is sucked in the piston pump and compressed in the pipe system. When the compressed air reaches the end-hose it can cause strong and sudden movements of the flexible hose. These “hose whips” can cause serious injuries for laborers who are hit by the end-hose. Typical injuries are broken bones, head injuries, eye damages, but also more severe injuries have been reported resulting in death of the labor worker [6]. The risk of serious accidents increases when pumping is performed at elevated working areas, e.g. pouring slabs in multistorey buildings.

2.2 Review of previous research

During the last two decades, boom arms have been designed to be as light as possible to enable an increased operating reach [7]. However, light-weight boom arms are more vulnerable to vibrations which make them more difficult to control. Accurate control of the boom arm is essential to enable a safe and efficient pumping process, but also to enhance the level of automation of the concrete boom arm. Understanding the dynamic properties of modern boom arms are important. Accordingly, several research attempts have focused on the mechanical and dynamic behavior of the boom arm during concrete pumping.

Zhang et al. used dynamic modeling to study the behavior of a boom arm [8]. The model described the boom arm as a system of several linked sub-structures accounting specifically for the stiffness and dampening of the hydraulic cylinders. The model was compared with a test rig and the results showed that the model could predict displacements and vibrations. Ren et al. studied the displacements and forces subjected to a concrete pump boom arm. Rigid and flexible simulation models were developed and compared with a test rig. It was concluded that a model accounting for flexible behavior is necessary [9]. Schramm et al described a multibody simulation model along with the use of transmission elements to simulate the dynamic behavior of a concrete pump boom arm [10]. It was shown that the model can generate a motion control algorithm that reduce the elastic effects of the boom arm during a typical maneuver. Other researchers have focused on developing a scheme to enable automatic spray of concrete using the boom arm [11]. A simulation model that accounted for the flexible behavior of the boom arm was used to develop the algorithm for automatic control of the end-hose. Simulation results confirmed that the proposed algorithm could control the movement of the boom arm along a narrow pathway. Fan et al reported on their efforts on the design of a new 3-DoF concrete pouring robot along with an autonomous path planning system [12]. The robot was designed to be stationary at a construction site but with a flexible operational reach due to a moveable truss arm. The path planning system included a simplified obstacle algorithm based on reinforced learning. The feasibility of the obstacle avoidance algorithm was demonstrated by simulation and prototype experiments.

Another approach was introduced by Hudelmaier where a mechanical device was attached onto the flexible hose and by using muscle-like actuators (cylinders), the hose could be forced into a desired direction [13]. The cylinders were suggested to be controlled by a handheld remote control eliminating the need for manual handling of the end-hose. The invention was described in a patent document that has expired, and any documentation of realization could not be found.

2.3 Summary of state of the art

Several research attempts have focused on developing control algorithms for precise control and path planning of the boom arm to enable automatic placement of concrete. However, precise control of the boom arm is very difficult to achieve due to the inherent mechanical properties of the boom arm (combination of rigid and flexible parts), vibrations caused by the pulsating flow of concrete, and from varying wind loads acting on a fully stretched boom arm. Moreover, these attempts have not addressed how to control the flexible end-hose where the concrete is sprayed. Therefore, this paper reports on the efforts to develop and test a robotic system for remote control of the end-hose. The system is based on the idea introduced by Hudelmeier but has been updated and modified with recent technologies when it comes to pneumatic actuators and control systems. This paper presents findings of a first-in-kind prototype of a robotic controlled flexible end-hose tested in real environment during concrete pumping.

3 Methodology and setup

The work was initiated by conducting a pre-study, followed by laboratory tests, and finally a field test. The pre-study started with a review of previous research, review of industry reports, and a search of patent databases. A workshop with experts in concrete pumping was also conducted. The purpose of the workshop was to identify functional requirements of a robotic system for controlling the end-hose. Based on findings from the workshop, a design proposal of the robotic system was developed involving experts in robotics and mechanical engineering. After some modifications, a physical prototype was finally manufactured. The system is described in sections 3.1-3.3.

3.1 Description of robotic system

A schematic illustration of the robotic system is outlined in figure 2. The system consists of four pneumatic actuators (so called air muscles) which are attached to a flexible rubber hose by two light-weight fixture plates (top and bottom). The pneumatic cylinders can be manipulated using compressed air which are supplied or released from the air muscles forcing them to change in length. Depending on which cylinders that are filled or released with air, it will force the hose to flex in a certain direction. A valve connected to each cylinder controls the supply and release of air. Compressed air is supplied by the compressor unit of the truck-mounted concrete pump. However, in this version of the robotic system, an external mobile compressor unit is used.

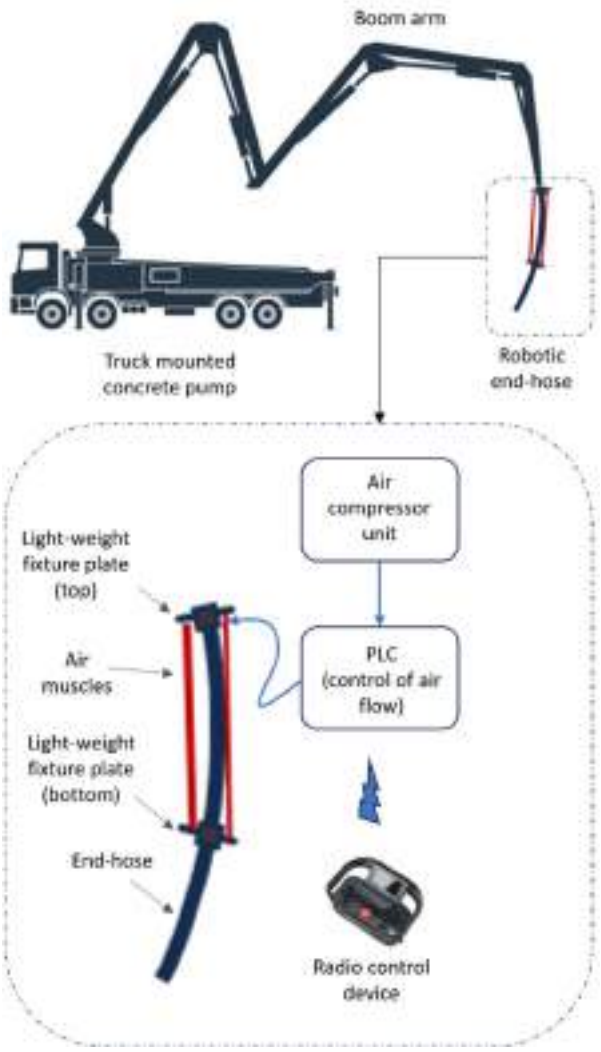

Figure 2. Schematic layout of the robotic system.

A control system comprised of a PLC unit and a wireless radio control device is used to control the movements of the end-hose.

3.2 Mechanical components

The mechanical components of the robotic system are the flexible end-hose, four air muscles (pneumatic actuators), and two light-weight fixture plates. Figure 3 shows a layout of the mechanical components.

The end-hose is a standard concrete hose made of rubber-based material. The hose is available in different standard dimensions, e.g. 3-5 inches in diameter. In this configuration, the end-hose is 4 inches in diameter with a total length of 4 meters.

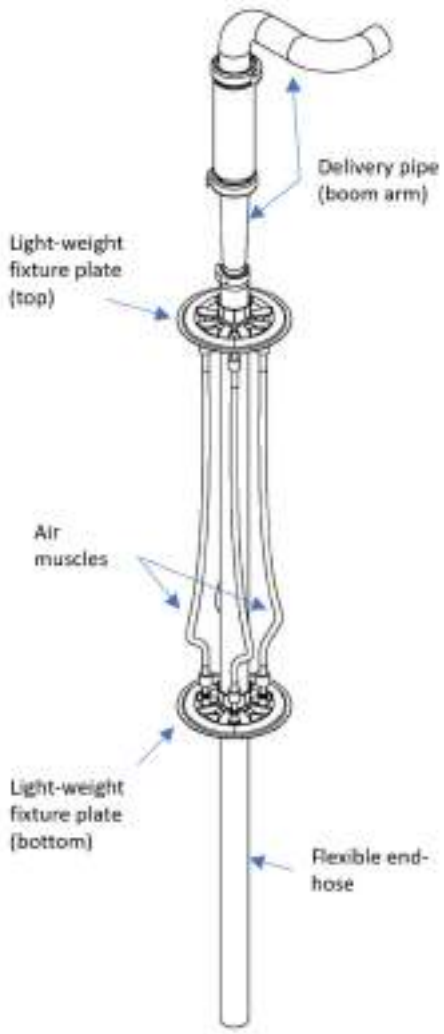

Figure 3. Mechanical components of the robotic end-hose device.

The air muscles are tensile actuators from Festo[1]. Each air muscle consists of a contractible tubing made of a rubber sheath and appropriate connectors. The muscle expands lengthways when it is subjected to an external force, but when pressurized, the muscle contracts, i.e. its length decreases. The air muscles are available in different sizes, e.g. diameter and length.

The air muscles are attached at each end to light-weight fixture plates made of carbon fiber. The upper fixture plate is attached to the end of the boom arm using a standard clamp.

The bottom fixture plate is attached to the flexible end-hose using a standard clamp. This allows for manipulation of the end-hose by controlling the air flow to and from the air muscles.

Figure 4. The wireless joystick control device used for remote control of the end-hose[2].

3.3 Control system

The air muscles are controlled by a programmable logic controller (PLC), as recommended by Festo. The PLC is integrated with programmable pneumatic valves with built-in pressure sensing and equipped with analog and digital I/O for integration with external sensors and control units.

For the field test a wireless industrial joystick was integrated as control unit with the PLC, see Figure 4. Steering programs for muscle control using joysticks were then developed in preparation for the field test.

The joystick device enables control of the end-hose based on two different principles, 1) position-based, or 2) velocity-based. Position-based mode means that when the operator releases the grip of the joystick, the end-hose will return to its neutral position, i.e. straight vertical direction. On the other hand, when the operator releases the grip of the joystick, the end-hose will stay fixed in its current position, e.g. in a position where the end-hose is bent pointing towards a specific direction.

3.4 Laboratory tests

Prior to the field test, prototype development and testing took place in laboratory settings, kindly hosted by facilities at the company Composite Design AB[3] and the Center for Construction Robotics at Lund University[4].

The robotic end-hose prototype was mounted vertically with pneumatic muscles connected to a control PLC through 10 meters of 10 mm air hoses, one for each

[1] www.festo.com
[2] https://akerstroms.se/
[3] https://www.composite-design-sweden.com/
[4] https://robotics.lth.se/research/center-for-construction-robotics/

muscle. This setup enabled systematic experiments where different sub-systems could be tested and evaluated in a controlled environment. The aim was to perform assembly of the prototype and to evaluate the remote control of the pneumatic muscles and the corresponding response of the end-hose. The target was as easy and fast remote handling of the hose as during manual handling, to be evaluated at the field test.

3.5 Field test

A field test was carried out where the robotic system was tested under real conditions, i.e. during concrete pumping. Details about the field test are given in table 1.

Table 1 Details about the field test.

Field test items	Specifications
Construction type and dimensions	Foundation slab (8x12x0.2 m)
Total concrete volume	19 m^3
Concrete type	C35/45, slump range: 100-150 mm
Truck-mounted concrete pump	Putzmeister M36
Boom arm reach	36 m

The aim was to evaluate the performance of the robotic system. More specifically, the evaluation focused on two areas: 1) Remote control, 2) On-site handling and performance of the robotic end-hose. An experienced concrete pump operator from Swerock[5] was used as a test pilot for remote control of the end-hose during concrete pumping. It was considered important to select a test operator with experience of the concrete pumping procedure as well as being used to handle remote controls similar to the one used in this setup. Vibration, levelling, and surface treatment were done by three concrete labor workers. Prior to the start of concrete pumping, the test pilot person was instructed in how to use the remote control. The evaluation was carried out by analysis of video recordings and an interview with the test operator after completion of the pouring. The results were also presented in a workshop after completion of the field test. The workshop involved 9 experts in concrete pumping technology and the aim was to discuss and evaluate the robotic system and the findings from the field test. Special attention was on safety aspects when introducing a robotized pumping method.

[5] www.swerock.se (Swedish ready-mix concrete producer).

4 Results from field test

Here, the findings from the field test are presented. In Figure 5, a schematic illustration of the pouring scheme is shown. The pour units denoted S1-S18 indicate the approximate working area of the robotic end-hose. The boom arm with its end-hose was positioned close to the center of the first pour unit (S1). From here, the end-hose was remotely directed to enable distribution of concrete over the whole area of the pour unit. Thereafter, the boom arm is moved to the next position (center of S2) where the end-hose is used to spray concrete into this area. This procedure was repeated for all successive pour units. In parallel to the concrete placement, labor workers performed tasks such as vibration, level control, and

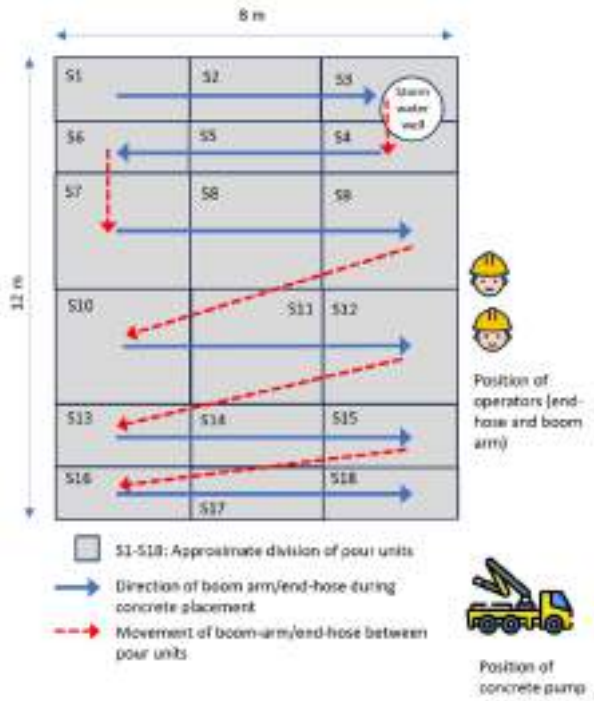

Figure 5. Schematic layout of the pour units and direction of concrete placement.

surface levelling. In Figure 5, the blue arrows indicate the principal direction of the boom arm and end-hose during concrete placement.

The red dotted arrows indicate the movement of the boom arm with its end-hose between concrete pours. Within pour units S3 and S4, a well for storm water is located requiring careful placement of concrete to prevent the well from being filled with concrete.

The truck-mounted concrete pump was positioned near the slab allowing for the boom arm to reach the whole slab without moving the truck.

Table 2. Lead Times (LT) for remote control and manual control of end-hose during concrete placement.

Pour unit	LT Remote placing [sec]	LT Manual placing [sec]	LT Total [sec]
S1	125	0	125
S2	100	0	100
S3	50	85	135
S4	0	67	67
S5	35	18	53
S6	50	0	50
S7	111	0	111
S8	122	5	127
S9	133	0	133
S10	127	3	130
S11	65	0	65
S12	70	0	70
S13	67	0	67
S14	85	5	90
S15	85	0	85
S16	185	0	185
S17	102	3	105
S18	120	0	120

The test operator was standing along the long side of the slab together with the crane operator controlling the movements of the boom arm.

In table 2, lead times (LT) for each pour unit is presented based on video recording analysis. The table presents LT for remote and manual control respectively. Also, total LT is presented. Note that lead time is here defined as the time when concrete flows through the end-hose. Pausing of concrete pumping is not included in lead time.

As seen in table 2, LT:s vary between 50-185 seconds. Note that the sizes of the pour units are not exactly the same, even though it seems to be the case according to Figure 5. Other factors that influence LT are operator performance, need for more accurate control of spraying, interactions with labor workers performing parallel tasks.

The end-hose was remotely controlled for most pour units. In 11 of 18 pour units, concrete was poured using the remote control. Manual control of the end-hose was essentially needed in pour units S3 and S4 due to a more accurate placing of concrete around the storm water well. Also, in pour unit S5, the end-hose was manually handled even though it wasn't necessary. At pour units S8, S10, S14, and S17, only very limited manual handling was necessary to make quick adjustments of the end-hose.

Figure 6. a) manual control of end-hose, b) remote control of end-hose, c) end-hose in bended position, d) overview of robotic end-hose connected to boom arm.

In figure 6, photos from the field test are shown illustrating both manual and remote control of the robotic end-hose (figures 6a and b-c).

The total concrete volume poured was 19 m^3. The time for pouring, vibration, and surface finish was recorded to 60 minutes in total. With four labor workers (three plus one operator), the productivity rate was calculated to be 0.21 man-hours per cubic meter of concrete.

This is equal to the productivity rate used in Sweden for time estimation of manual concrete pumping of foundation slabs [14]. The test operator also confirmed, based on his experience, that the robotic method was equal to the manual method when it comes to concrete placement productivity. This clearly demonstrates that the proposed system provides added value when it comes to risk elimination and improved safety without lowering on-site productivity. In fact, this first test indicates that there is room for significant improvements in both safety and productivity aspects.

5 Discussion

Several aspects in the dimensioning of the robotic equipment turned out to be important. Specific requirements for mounting robotic equipment on an end-hose mounted on the boom arm of a concrete pump were specified by Swerock early on. End-hoses together with the concrete material flowing through them are subject to a tight weight budget. The weight allowance determined by the boom arm used. A typical number for the truck that was used in the field test is 160 kg. A standard 4-inch hose as utilized in our experiments weighs around 8 kg per meter, resulting in 30-35 kg payload for a 4-meter hose. The volume that can be filled with concrete in such a hose is approximately 0.03 m^3 weighing around 90 kg assuming a standard concrete density around 2.400 kg per m^3. Additional equipment, such as adaptors for inner diameter adjustment, limits weight allowance for the robotic equipment to around 20 kg to avoid implications on the hose's applicability.

Another reason for limiting the weight allowance of mounted robotic equipment was risk assessment. Preferably, a robotic end-hose should have a similar assessment as a regular hose to allow for manual handling without the need to dismount the equipment during a pumping session. During the field test it was seen that concrete laborers simply grabbed the hose and pushed it when deemed necessary. To enable ease of manual handling, the lower fixture plate was manufactured in composite material to keep the weight low.

To actuate the hose, four air muscles from Festo were selected. Air muscles are light-weight and therefore fit the weight requirement well. The Festo muscles need to be rather long for effective hose actuation. A typical muscle can contract around 20% of its total length. Some of this length needs to be reserved for slack when the opposite muscle is contracting, leaving an effective actuation of around 10-15% during operation. The muscles selected for the experiments were two meters in length. Considering the actuations of the hose in relation to the allowed 400 mm curvature radius of the hose, the length of muscles was appropriately chosen. Bending the hose has implications for its expected service life, where small bends are preferred over large bends.

An aspect to consider is that the air muscles are pull-only, with return motion dependent on factors such as permitted return air flow and the existence of actuating return forces on the muscle. In this setup, hose bends will act as a return force together with stretched muscle skin pressure. A hampering factor for the evacuation of pressure from a muscle is the length and surface area of the connection between the air muscle and the PLC valve units. During the field test the test operator observed that the equipment was slightly slower in motion than was preferred. Therefore, after the field test, our setup was simulated by Festo using their simulation software. The simulation results show that the tested field setup could get an increased return motion rate by a factor of two by mounting the valves close to the muscles. It is believed that such modification would meet the motion speed range preferred by the operator.

Another determining factor is the availability of air with a flow rate capable of sustaining continuous operation of the air muscles. A typical middle range air pump delivers around 200 liters per minute of 6 bar air, and this also seems to be what is mounted on the pump trucks and available at the tip of the boom arm. The current muscle setup requires more than this amount for sustained operation as noted during the field test. This issue could be solved by reducing the air volume needed by choosing smaller muscles (still strong enough to actuate the hose) or by adding silicon material inside muscles to decrease volume, as suggested by Festo.

During the field test the experienced operator made several observations. The first thing that was commented was alignment of the joystick with the perceived hose actuation directions for intuitive steering. During the field test this was achieved by switching air muscle to valve connections. In the future an alignment functionality in the steering system should be incorporated. There seem to be a learning curve involved in operating the hose remotely, as the operation of the hose became smoother towards the end of the field test. It should be noted though that there was no prior exposure of joystick remote operation to the test operator besides a short introduction right before pouring started. The slight lack of air flow for sustained operation was noted and seen as an inconvenience during the test. It was possible to steer the hose but with less capability as time progressed. When the boom arm was moving the hose between pouring units, the air volume recuperated though. A source of complaint was that the hose behaved differently due to the variation of mass in the hose. This variation was a result of varying amount of concrete flowing in the hose during pumping, e.g. full flow, partial flow, and no flow. The effect was not compensated for in the steering system used in the field test. Of the two

steering modes, the hold function in the velocity mode was preferred.

Overall, the general impression of the remote-control functionality was good. Communication between the boom arm operator, hose operator and concrete crew worked well during the field test, probably due to the experience of all involved. The remote control did not hamper the operation.

Assembly and disassembly of the robotic end-hose onto the boom arm of the concrete pump were done within five minutes by two labor workers. Disassembly and cleaning of end-hose was also done quickly and without any obstacles. In general, the on-site handling of the end-hose was conducted without any significant obstacles.

6 Conclusions and future work

The conclusion from the field test is that the setup worked well, especially considering this was a first of a kind test. There are considerations exposed from the field test, but those seem manageable to handle in a revision of the current setup. The remote steering did not hamper the operation, and the setup did not hamper end-hose handling and manual operation when perceived necessary. Though not performed in formal manner, there were no raised concerns on introduction of risk in the tested scenario.

For future work, we aim to do a revision of the current setup to address considerations exposed during the field test. A longer-term issue is the removal of the remote joystick for the end-hose, so that boom arm and hose operation are controlled through one joystick only.

Abstract

Highway work zones present hazardous conditions where worker safety is at constant risk due to interactions with construction equipment. In such environments, accurately defining hazard zones around equipment is vital for timely detection and prevention of incidents. Traditional static hazard zone models, often relying on simple geometric shapes, fall short as they cannot adapt to changes in equipment speed and movement, leading to either inadequate safety coverage or frequent false alarms. This study proposes a dynamic hazard zone model that leverages a probabilistic approach based on bivariate Gaussian distribution to generate adaptive and realistic hazard zones. Real-time data from GPS and inertial measurement unit (IMU) sensors enable the model to adjust hazard zone dimensions dynamically in response to equipment behavior, improving both accuracy and responsiveness. Simulations conducted in Webots software demonstrated that the proposed model achieved 93% accuracy in hazard detection, significantly outperforming the 60% accuracy of static circular zones tested in the same environment. The findings underscore the potential of dynamic hazard zone modeling to enhance safety in highway work zones, providing a practical and effective approach for reducing risks.

Keywords –

Highway work zones, construction safety, probabilistic modeling, real-time tracking, dynamic hazard zones

1 Introduction

Highway work zones are inherently complex and hazardous environments where the safety of construction workers and motorists is constantly challenged by active construction and traffic flows. The increased number of accidents and fatalities associated with these zones has led researchers and practitioners to focus on developing more effective safety measures [1], [2]. Accidents in these areas can result from a variety of causes, including but not limited to vehicular collisions, worker-equipment interactions, and improper management of traffic flow [3]. A significant number of these accidents happen due to worker-equipment interactions, making the prevention of near-miss incidents and collisions a critical issue [4].

Effectively mapping the hazard zone around equipment plays a pivotal role in this context, serving as a crucial mechanism for incident detection [5], [6]. Traditional approaches to hazard zone mapping typically employ static models, which use simple geometric shapes, such as circles, to define areas of danger around construction equipment [7]. These models could, however, fall short in adequately providing the necessary protection due to two main reasons. First, these hazard zones have fixed sizes and provide the same hazard area, even when the equipment moves at different speeds [8]. This would lead to either an insufficient zone that could not timely detect hazards for equipment moving at a higher speed, or too large zone, which would lead to unnecessary alarms for equipment moving at a low speed or a stationary piece of equipment [9], [10]. The second reason is related to the shape of the hazard zone. The use of simple shapes like circles will lead to the marking of relatively safer areas, such as the sides of a moving vehicle, as hazardous, which could lead to false alarms [11], [12]. These issues are especially relevant in congested areas such as highway work zones where workers on foot and equipment work side by side in a relatively small area [13]. In such situations, if the hazard zones are not carefully designed to efficiently detect true hazardous situations and avoid any false alarm scenarios, it will lead to either insufficient protection for workers or repetitive false alarms, which could result in work disruption and desensitization [8], [14].

To address these problems, this study proposes an adaptive hazard zone model that dynamically adjusts the

hazard boundaries in real-time based on equipment movement. The proposed model addresses the existing issues by creating a dynamic and more realistic hazard zone around the equipment, effectively mapping the real hazardous areas and avoiding safer areas. The study proposes a rigorous probabilistic approach to developing a mathematical hazard zone model that relies on equipment movement parameters to produce a hazard map with varying levels of safety around the equipment. Real time tracking of equipment movement is achieved by utilizing GPS and inertial measurement unit (IMU) sensors. The proposed model is validated in a simulated environment in Webots software, where several scenarios of realistic interactions between workers and construction equipment are evaluated.

2 Literature Review

Properly modelling hazard zones around construction equipment is essential for preventing near-miss and collision incidents between equipment and workers on foot. These zones must effectively detect and alert potential incidents, allowing both workers and equipment operators sufficient time to react safely. Additionally, the zones should be precise enough to avoid unnecessary alarms that could disrupt work or desensitize workers to genuine hazards. Various hazard zoning approaches exist in practice and in literature, each with its own advantages and limitations. The following sections discuss some of these methods.

2.1 Hazard Zone Models

Hazard zone modelling in construction and industrial environments traditionally relies on static models with fixed sizes, and typically utilizes simple geometric shapes to demarcate areas of danger around equipment. These static hazard zones have predefined danger areas around equipment that do not change shape or size in response to the equipment's real-time movement. Because static zones remain constant regardless of vehicle speed or direction, they can either overestimate or underestimate the true hazardous area in different scenarios.

Among the various static hazard zone approaches, the use of circular hazard zones is common in both practice and literature, with variations in how the circle's size and the number of hazard levels are determined. Wang & Razavi [6] proposed circular hazard and warning zones around a construction equipment. The warning zone represents the area where a warning should be issued when a worker breaches it while the hazard zone represents the actual dangerous area. Although the formulation in the study considered the speed and deceleration of the equipment for determining the braking distance, only typical values for a specific equipment were finally used to determine the dimensions of the hazard zone. Similarly, circular and rectangular hazard zones were explored in studies by Teizer et al. [7] and Luo et al. [15]. Jo et al. [14] also utilized circular hazard zones to represent hazardous areas around an excavator.

In an attempt to make circular zones more representative, Teizer & Cheng [11] proposed a hazard zone that considers only part of a circle, in the direction of the equipment's movement. The proposed hazard zone is also dynamic, adjusting its size based on equipment speed. Although the proposed hazard zone worked generally well, it was pointed out that there were missed hazards and false alarms during the experiment. A study by Shen et al. [5] proposed a standard procedure to come up with hazard zones with different shapes and sizes specific to the type and size of equipment. The procedure also uses typical equipment speed and deceleration values to determine the size of the hazard zone.

Although the studies mentioned above tried to consider several parameters to develop effective hazard zones, there is still a gap in providing a hazard zone model which both has a realistic representation of the actual hazardous area and adapts its size based on real-time equipment movement information. Park et al. [8] affirms this by stating that previous research has insufficiently investigated the variations in proximity sensing caused by different settings such as equipment types and approaching speeds. The study further recommends future research to focus on defining dynamic hazard zones based on factors such as approaching speeds.

Another key aspect to consider is the level of hazard that these zones represent. Many proposed methods provide a single hazard zone, which defines whether a worker is either inside or outside a hazardous area [11], [14]. In contrast, some methods suggest a multi-level hazard zoning approach, which establishes warning and alert areas to offer an additional layer of safety by distinguishing between moderate and critical risk levels [7]. Teizer [16] used three levels of hazard, corresponding to "warn," "slow," and "stop", during field experiment of a proposed magnetic field-based proximity detection and alert system.

Overall, previous literature highlights the need for a hazard zoning methodology where the hazard zone adjusts its size and shape in real-time based on equipment behavior. Such a model would significantly enhance the accuracy of detecting and preventing near-miss incidents. In addition, provision of multiple zones corresponding to varying levels of hazard would be beneficial to give early warnings before a more dangerous situation happens.

Probabilistic approaches are increasingly gaining traction in hazard zoning to improve risk estimation and adaptability in construction and industrial settings,

though there is limited research in applying them for modeling hazard zones around a vehicle. Studies have explored probabilistic risk assessments in construction and industrial environments to enhance safety performance. Park et al. [17] developed a sensor-based safety risk model that quantifies hazard exposure using probabilistic evaluation methods. Zhang et al. [18] applied stochastic processes to model safety risk in construction, demonstrating how probability-driven methods can improve accident prediction. Similarly, Abdrakhmanova et al. [19] proposed a probabilistic hazard analysis framework for industrial operations, incorporating dynamic exposure zones. While these studies demonstrate the benefits of probabilistic approaches in various domains, their application to highway work zones and to model vehicle hazard zones remains largely unexplored.

2.2 Recent Advances in Real-Time Location Systems

Implementing an adaptive hazard zone requires real-time tracking of equipment speed and acceleration. Recent technological advances, particularly in IoT-based applications, have significantly improved the feasibility of real-time data collection in construction environments. Real-time location systems (RTLS) are now frequently deployed in various industries to track the positions of workers, vehicles, and equipment. In construction, these systems could offer substantial benefits in various areas including safety improvements by monitoring proximity and movement in hazardous areas [20], [21].

RTLS employs a range of technologies, including GPS, IMU, radio frequency identification (RFID), Ultra-Wideband (UWB), and Bluetooth, to achieve precise location tracking. These technologies allow for real-time monitoring of assets and workers, enhancing situational awareness in complex, dynamic environments like highway work zones [22], [23], [24]. The use of these sensors allows accurate real-time tracking, which could be crucial for creating adaptive safety zones that adjust based on equipment speed and worker proximity [25].

With real-time data from IoT-based systems, it is now feasible to create hazard zones that expand or contract in response to movement, ensuring more precise safety measures than traditional static models. Such systems have been shown to improve both safety and efficiency on sites where real-time tracking of workers and equipment is crucial, as noted by Teizer et al. [26] in their study on LoRaWAN applications for tracking in construction environments.

3 Methodology

The aim of this study is developing an adaptive hazard zone model for construction equipment with a more realistic hazard zone area using a probabilistic approach. The use of probabilistic method enabled mapping the area around the equipment as a continuous zone with varying levels of hazard risk. The methodology used in this study generally included two main steps: theoretical derivation of a hazard zone model and testing in a simulated environment. In the theoretical derivation, the issues discussed in the previous sections, namely, having a more realistic hazard zone geometry, making it adaptive to equipment speed and direction, and providing zones for varying hazard levels, were addressed by utilizing a probabilistic approach.

3.1 Hazard Zone Model Development

A probabilistic approach with a bivariate Gaussian distribution is used to derive a hazard zone model. This resulted in a 3D graph that not only provides more representative elliptical hazard zones with adaptive major and minor axes but also allows to determine the probability of hazard at any location from the position of the equipment. A series of elliptical projections with the required probability of hazard can be extracted from the graph to represent varying levels of safety around the equipment (Figure 1). The colors of the ellipses in the figure represent an increasing level of hazard in moving towards the equipment, with the red color representing the highest level of hazard and the green one representing the lowest.

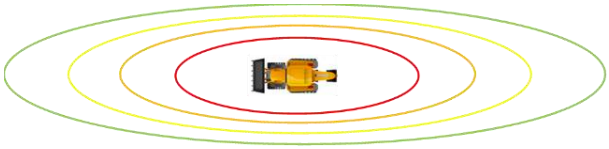

Figure 1. Elliptical projections from the proposed 2D Gaussian graph representing different hazard levels

The equation for a bivariate Gaussian distribution is given in Eq. 1, for independent variables x and y. The expression mainly involves four parameters: the mean and standard deviation values in both directions. The center of the distribution is taken to be at the center of the equipment and in line with this the mean values in both directions are taken to be zero. The standard deviation σ_x controls the spread along the x-axis while σ_y controls the spread along the y-axis. These standard deviations are made to be functions of the equipment's speed.

$$f(x,y) = \frac{1}{2\pi\sigma_x\sigma_y}\exp\left(-\frac{1}{2}\left[\frac{(x-\mu_x)^2}{{\sigma_x}^2}+\frac{(y-\mu_y)^2}{{\sigma_y}^2}\right]\right) \quad (1)$$

This study employs a six-step procedure to draw hazard zones around various construction equipment, as suggested by Shen et al. [5]. These procedures are generally followed to determine the necessary variables

used in the derivation, except for the last step, where a different formulation is used in this study.

1. **Equipment Footprint:** This parameter represents the overall dimensions of the equipment, which depend on the type of equipment. For this derivation, the length (L) and width (W) of the equipment are considered as variables, allowing for flexibility in applying the model to different types of equipment.
2. **Initial Safety Boundary:** The initial safety boundary, represented by S in this study, defines the hazard zone when the equipment is stationary and is also treated as a variable in this derivation.
3. **Equipment Function:** This step involves determining the required safety distance based on the function and type of movement involved in the equipment. For example, the hazard zone of an excavator will have a circular shape with a radius governed by the size of the rotating arm. This study focused on moving equipment such as wheel loaders and dump trucks, with a hazard zone governed by the speed of the equipment. Choosing the type and function of the equipment forms the basis for computing parameters that influence the size of the hazard zone such as the distance required for the equipment to stop once a hazard is perceived by the operator, which is addressed in steps 4 and 5.
4. **Operator Reaction Distance (D_R):** The reaction distance is the distance covered by the equipment between the moment the operator perceives the hazard and takes measure (Eq. 2). It is computed as:
$$D_R = vt \quad (2)$$
Where v is the speed of the equipment in m/s, and t is the reaction time. The reaction time t is recommended to be 2.5 seconds [6], [27]. Thus, the equation simplifies to:
$$D_R = 2.5v \quad (3)$$
5. **Braking Distance (D_B):** The braking distance is the distance the equipment travels between the moment the operator takes action, and the equipment comes to a full stop, as given in Eq. 4 [5].
$$D_B = \frac{v^2}{2a} \quad (4)$$
Where v is the speed of the equipment in m/s, and a is the deceleration of the equipment in m/s². The deceleration could be different depending on the type of equipment. For example, a deceleration value of 1.9 m/s²is taken in Wang & Razavi [6] for forklift. In this study, it is considered as a variable, so that appropriate value could be assigned for a specific type of equipment later.
6. **Determine Hazard Zone:** The final step involves determining the resulting hazard zone based on steps 1 through 5. As mentioned above, the hazard zone is taken to be elliptical in shape, following the projection of a bivariate Gaussian distribution with the major axis representing the direction of movement of the equipment. The lengths of the major and minor axis of the ellipse are computed based on the values in the previous steps as described in Eq. 5 to Eq. 7.

Major axis:
$$Major\ axis = L + 2S + 2D_R + 2D_B \quad (5)$$
Where L is the length of the equipment, S is the initial safety boundary, D_R is the reaction distance, and D_B is the breaking distance. Therefore,
Major axis:
$$Major\ axis = L + 2S + 5v + \frac{v^2}{a} \quad (6)$$
Minor axis:
$$Minor\ axis = W + 2S \quad (7)$$

To determine σx and σy, these values are equated with the equation of an ellipse for a typical projection of the proposed bivariate Gaussian probabilistic plot, taking the hazard zone to be the ellipse with a 70% probability of hazard. This could be done for different probability values to derive different safety boundaries for different levels of hazard.

For a bivariate Gaussian distribution, the equation for an ellipse representing a specific probability contour is given in Eq. 8.
$$\left(\frac{x-\mu_x}{\sigma_x}\right)^2 + \left(\frac{y-\mu_y}{\sigma_y}\right)^2 = k \quad (8)$$
Where k is a constant corresponding to a specific confidence level. For a 70% confidence level, the value is obtained from the chi-squared distribution table to be approximately 0.713.

For a bivariate Gaussian distribution, the major and minor axes of the ellipse can be expressed in terms of the standard deviations as in Eq. 9 and Eq. 10.
Major axis:
$$Major\ axis = 2\sigma_x\sqrt{k} \quad (9)$$
Minor axis:
$$Minor\ axis = 2\sigma_y\sqrt{k} \quad (10)$$

Equating Eq. (9) and (10) with the corresponding expressions obtained earlier for the major and minor axes will result in an equation for the standard deviations in terms of equipment parameters.
Major axis:
$$2\sigma_x\sqrt{k} = L + 2S + 5v + \frac{v^2}{a} \quad (11)$$
$$\sigma_x = C_1L + C_2S + C_3v + C_4\frac{v^2}{a} \quad (12)$$
Minor axis:
$$2\sigma_x\sqrt{k} = W + 2S \quad (13)$$

$$\sigma_y = C_5 W + C_6 S \quad (14)$$

Where C_1 = 0.592, C_2 = C_6 = 1.183, C_3 = 2.959, and C_4 = C_5 = 0.592 are the coefficients.

The final expressions for the standard deviations show that the size of the hazard zone along the major axis of the ellipse depends on the real-time speed and the deceleration rate of the equipment, while the size in the cross-sectional direction remains constant. If the equipment turns, the major axis will change direction accordingly keeping the hazard zone aligned with the equipment's direction of movement.

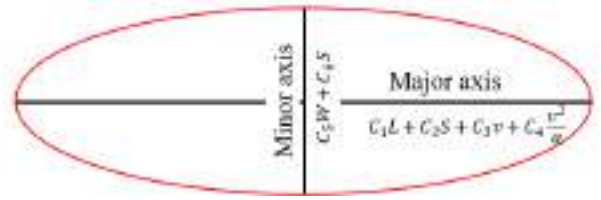

Figure 2. Hazard zone dimensions

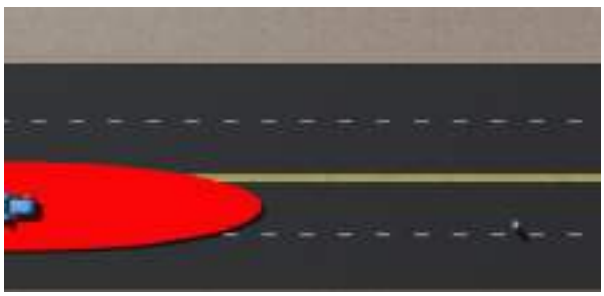
In practical applications, real-time GPS/IMU sensor data will be used to continuously track the equipment's location, ensuring that the center of the hazard zone remains properly aligned with its current position. Additionally, these sensors will provide velocity and acceleration measurements, enabling the dynamic adjustment of the hazard zone size using Equations (12) and (14). To enhance accuracy and mitigate sensor noise, efficient sensor fusion techniques should be employed to effectively integrate GPS and IMU readings.

3.2 Simulation Setup

The primary objective of the simulation was to evaluate the effectiveness of the proposed hazard zone model in correctly detecting near-miss incidents at the right time. The simulation was conducted in Webots R2023b, an open-source desktop application from Cyberbotics, primarily used for robot simulations. The software was chosen for its strengths in effectively creating realistic road and traffic environments [28].



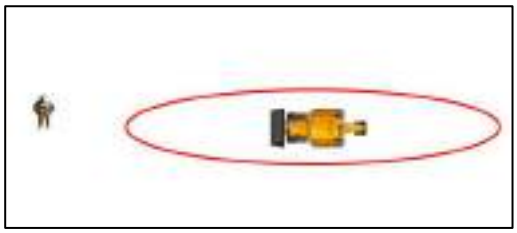


Figure 3. Simulation setup in Webots

The strategy involved driving equipment, equipped with GPS and IMU sensors, towards a worker positioned in front of it. A hazard zone was generated around the equipment, and when the worker entered the hazardous area, the equipment began decelerating, mimicking an operator's response upon being alerted (Figure 3). The equipment continued at its current speed for 2.5 seconds to simulate operator reaction time, then decelerated at the typical rate for the equipment in the simulation environment. The stopping position was evaluated to determine whether the hazard zone provided sufficient time for the equipment to stop. The simulation was conducted using the proposed dynamic hazard zone, and a static circular hazard zone for comparison (Figure 4).

(a)

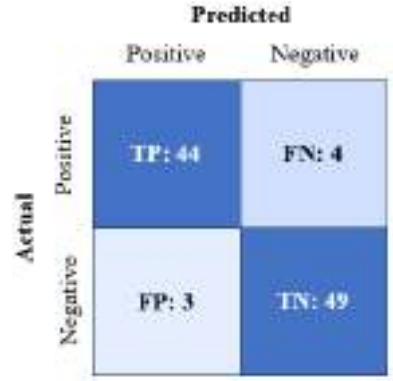
(b)

Figure 4. Model evaluation strategy (a) Proposed hazard zone (b) Static circular hazard zone

A total of 100 simulations were conducted for both hazard zones, with varying worker locations and equipment speeds. The worker's location was randomly varied both in the longitudinal and cross-sectional directions. To keep the location within a reasonable range, the location is kept within a 30 m range across the road, i.e. 15 m from the centerline of the equipment in both directions, and 100 m range along the road. The equipment speed was sampled from a normal distribution with a mean of 10 kph and a standard deviation of 5 kph. To ensure realistic speeds for construction equipment, the minimum and maximum speed values were set at 5 kph and 20 kph, respectively.

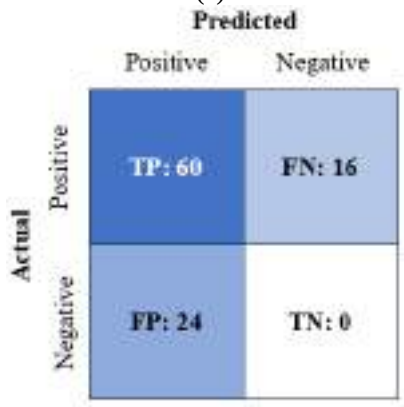
The proposed model has variables including equipment footprint, initial safety boundary, the speed of equipment, and deceleration rate of the equipment. These variables were set before running the simulation, except

for the speed of equipment which is variable. The equipment footprint was directly measured for the specific equipment used in the simulation to be 3 meters long and 1.7 meters wide. The initial safety boundary is taken to be 2 meters as is recommended by Shen et al. [5] and Wang et al. [6]. The deceleration rate, which is the rate at which the equipment decreases its speed when the brake is applied, was obtained to be 1.05 m/s^2 for the specific equipment used in the simulation.



3.3 Evaluation Criteria

After completing the necessary setup, the simulation was then run, and results were categorized into true positives, true negatives, false positives, and false negatives, with the following meanings:



- **False Negative (FN):** The equipment hits or dangerously approaches the worker, indicating a failure to alert in time. This indicates that the model couldn't timely recognize a positive case and gave a false safety, leading to a dangerous situation. A trial is classified as false negative if the equipment hits the worker or the worker comes within a 1-meter distance around the equipment footprint at any time during the equipment's movement or when the equipment finally stops.
- **False Positive (FP):** The equipment stops too far from the worker or passes safely, yet the system triggers an unnecessary alert. Previous literature provides little guidance on the appropriate distance between the worker and equipment to classify it as "too far". In a field experiment by Teizer et al. [7], equipment stopping at least 10 meters away from the worker was considered safe. This value is adopted as the criterion in this study to differentiate false positives from true positives, along the direction of equipment movement. However, applying the 10-meter threshold to the width of the equipment is deemed unreasonable, as it would be overly conservative and result in many false alarms being classified as true positives. Therefore, the width threshold is set at one standard lane width, i.e., 3.6 meters, from the equipment. Accordingly, a false positive occurs when the equipment stops while the worker is outside the 10 meters by 3.6 meters boundary.
- **True Positive (TP):** The equipment stops safely with the worker at a safe distance, indicating that the system correctly detected the danger.
- **True Negative (TN):** The worker is located at a safe distance from the equipment and no alert is issued, as expected.

4 Results and Discussion

Following the methodology described, a total of 100 simulations were conducted for both the proposed dynamic hazard zone model and a conventional static circular hazard zone. The simulations accounted for varying worker locations and equipment speeds, ensuring diverse scenarios for evaluation. The simulation results showed that the proposed hazard zone model classified 93% of trials correctly while the static circular hazard zone correctly classified 60% of trials. The total number of cases classified as true positives, true negatives, false positives, and false negatives are presented in Figure 5.

(a)

(b)

Figure 5. Confusion matrix (a) Proposed hazard zone (b) Static circular hazard zone

It can be clearly seen that the circular hazard zone struggled to identify negative cases and classified them as false positives. In addition, the static circular hazard zone was less efficient in detecting true positive cases, as it classified more cases as false negatives than the proposed hazard zone. This occurred because the static circular hazard zone used a fixed radius for varying equipment speed values, leading to false negatives at higher speeds and false positives at lower speeds. To further understand the performance of the proposed dynamic hazard zone model, the results were analyzed based on different speed ranges of construction equipment. The findings are summarized in Table 1.

Table 1. Breakdown of model performance across

different speed ranges

Speed Range	Hazard Zone	TP	TN	FP	FN	ACC
5–10 kph	Proposed	20	22	1	1	95.5%
	Static	37	0	12	0	75.5%
10–15 kph	Proposed	19	20	1	2	92.9%
	Static	17	0	9	12	44.7%
15–20 kph	Proposed	5	7	1	1	85.7%
	Static	6	0	3	4	46.2%

The results highlight the following key points:

- **Low Speeds (5–10 kph):** The proposed model demonstrated high accuracy (95.5%) with minimal false positives (1) and false negatives (1), effectively distinguishing between hazardous and safe scenarios. In comparison, the static model achieved lower accuracy (75.5%) due to a higher number of false positives (12).
- **Medium Speeds (11–15 kph):** At medium speeds, the proposed model maintained strong performance with an accuracy of 92.9%. The static model, however, exhibited significant performance degradation, with an accuracy of only 44.7% due to large number of false positives (9) and false negatives (12). This decline in performance is primarily because, despite the increase in speed, the static hazard zone remains unchanged, treating equipment moving at higher speeds the same as slower-moving equipment. As a result, the static model fails to account for the increased stopping distance and reaction time, leading to false negatives, where a real hazard is incorrectly classified as non-hazardous. This limitation highlights the advantage of the proposed model, which dynamically adjusts the hazard zone based on speed variations, ensuring more accurate hazard identification.
- **High Speeds (16–20 kph):** The proposed model achieved an accuracy of 85.7%, with a slight decrease compared to lower speeds. This indicates that the model still remains effective even at higher speeds. In contrast, the static model struggled significantly, achieving only 46.2% accuracy. These results reinforce the adaptability of the proposed model compared to static hazard zones.

While the simulation results demonstrate the proposed model's effectiveness, its validation in a controlled virtual environment limits generalizability to real-world conditions, where factors like unpredictable worker behavior, sensor inaccuracies, and environmental variables may influence performance. To address these challenges, field testing is essential to assess the model's accuracy and robustness under diverse, dynamic scenarios involving varying equipment types and operational conditions.

5 Limitations

While the proposed probabilistic hazard zoning model performs well in the simulated environment used in this study, several real-world challenges may affect its practical implementation. Real-world sensors are subject to noise and drift, which can introduce inaccuracies in position tracking and cause deviations in hazard zone boundaries. To mitigate this, effective sensor fusion techniques should be employed to enhance location reliability. Additionally, in highly dynamic environments such as highway work zones, unpredictable worker behavior and complex interactions between workers and construction equipment present further challenges. Adapting the proposed model for such scenarios will require future work focused on incorporating predictive techniques for worker movement patterns and worker-equipment interactions. Field validation through real-world deployments will also be essential to refine the model and optimize its parameters for practical applications.

6 Conclusion

This study developed a dynamic hazard zone model to address the limitations of traditional static circular hazard zones in highway work zones. By employing a probabilistic approach using a bivariate Gaussian distribution, the proposed model generates adaptive hazard zones that account for real-time changes in equipment speed and movement. The proposed model's effectiveness was validated through simulations, where it demonstrated superior performance compared to static circular hazard zones, achieving 93% accuracy in correctly classifying hazard scenarios. The findings highlight the significant potential of dynamic hazard zones in enhancing worker safety by accurately detecting true hazards and minimizing false alarms, even in highly dynamic environments. This approach not only reduces the risk of near-miss incidents and collisions but also minimizes disruptions caused by unnecessary alerts. Future work could focus on validation through field experiments and refinement of the model for more accuracy.

Abstract

In construction automation, several tasks such as surface finishing, material transport, and inspections typically rely on labor-intensive manual methods, which are inefficient, susceptible to human error, and expose workers to hazardous conditions. Drones have emerged as a solution to automate these processes, but maintaining precise navigation and stable attitude control in dynamic construction environments remains challenging. This paper presents a multi-sensor fusion and control framework to enhance UAV performance in dynamic and complex construction environments. The framework integrates multi-dimensional data from diverse sensing modalities, including geometric, visual, and inertial information, to achieve robust situational awareness and adaptive control. A Simultaneous Localization and Mapping (SLAM) model fuses multi-modal sensor inputs, including LiDAR point clouds, camera visual features, and inertial measurements, to generate precise environmental maps and perform accurate localization. The SLAM framework employs advanced loop closure techniques to minimize trajectory drift and optimize navigation paths in real-time. Additionally, flight stability under external disturbances is managed by a Deep Reinforcement Learning (DRL) algorithm, which models the UAV's control system as a Markov Decision Process (MDP). The DRL agent dynamically adjusts the UAV's flight parameters, such as thrust, roll, pitch, and yaw, based on real-time feedback from fused sensor data. The control strategy leverages a stability-based reward function to minimize deviations in position and orientation, ensuring rapid recovery from external disturbances. Simulation tests conducted in a Robotic Operation System and Gazebo simulation environment demonstrated mapping accuracy of 95.4%, localization errors under 2 cm, and rapid recovery from disturbances within 0.8 seconds.

Keywords – Construction Robotics, Reinforcement Learning, Unmanned Aerial Vehicle, Machine Learning

1 Introduction

The construction industry encompasses a wide range of tasks that are labor-intensive, repetitive, and often expose workers to hazardous conditions. Tasks such as material transport, structural inspections, and equipment monitoring demand precision and thorough coverage to meet stringent project standards and ensure site safety [1]. Material transport, for instance, frequently involves maneuvering heavy loads across uneven and challenging terrain, posing physical risks to workers and increasing logistical complexity [2]. Similarly, structural and visual inspections are critical for maintaining safety and quality but often require access to elevated or confined spaces that are difficult or unsafe for human workers. As construction projects grow in scale and complexity, there is an increasing demand for automation to enhance worker safety, improve operational efficiency, and uphold the high-quality standards required by large-scale projects [3].

To address these challenges, drones have emerged as a promising solution, automating tasks that traditionally require significant manual effort [4]. Drones offer numerous advantages, including rapid data collection, the ability to navigate hard-to-reach areas, and operational flexibility across diverse scenarios. Despite these benefits, achieving precise navigation and stable flight in dynamic construction environments remains a significant challenge. Construction sites are often cluttered and ever-changing, with complex layouts, sudden obstacles, and environmental disturbances such as wind gusts, debris, or equipment vibrations. Traditional drone systems frequently struggle to maintain steady flight paths, consistent altitude, and reliable navigation under these conditions, resulting in task inaccuracies, inefficiencies, and potential safety risks.

Advanced sensor integration in Unmanned Aerial Vehicle (UAV) systems has shown great potential to address these limitations by enhancing stability, navigation precision, and situational awareness [5]. Sensors such as Light Detection and Ranging (LiDAR), GPS, high-resolution cameras, and Inertial Measurement

Units (IMU) allow drones to collect comprehensive data about their surroundings. LiDAR provides precise distance measurements and environmental mapping, essential for spatial awareness in complex site layouts [6]. GPS offers high-level navigation strategies, while high-resolution cameras capture visual details critical for inspections and texture analysis. IMU sensors deliver real-time orientation and motion data to support stability during flight. By combining data from these sensors, drones can respond adaptively to real-time changes, improving their accuracy and operational efficiency across a range of construction tasks.

[7]However, current approaches to sensor integration often fail to fully utilize the potential of these technologies. Many systems process sensor data independently, leading to fragmented information, delayed responses, and limited adaptability to dynamic environmental changes [7]. Additionally, conventional flight control systems typically rely on basic algorithms, which struggle to capture the complex, non-linear relationships between diverse sensor inputs [8]. This results in suboptimal navigation, reduced stability, and inefficiencies in unpredictable construction settings.

To overcome these challenges, this paper proposes a multi-sensor fusion and control framework that integrates LiDAR, GPS, high-resolution cameras, and IMU sensors to significantly enhance UAV performance in construction automation. The proposed system employs a Simultaneous Localization and Mapping (SLAM) model to fuse multi-modal sensor data, generating accurate environmental maps and enabling precise localization. Additionally, a Deep Reinforcement Learning (DRL) algorithm refines flight control strategies, dynamically adjusting the UAV's responses to external disturbances such as wind gusts, vibrations, and near-miss collisions. Simulation tests conducted in a ROS-Gazebo environment validate the system's performance, and test the robustness of the designed system in various external disturbances.

2 Current Developments in Multi-Sensory Drone Flight Control for Automated Construction Tasks

2.1 Advancements in UAV Automation for Construction

In recent years, the integration of Unmanned Aerial Vehicles (UAVs) into construction workflows has accelerated, driven by the need to improve efficiency, safety, and precision across various operational tasks [9]. UAVs provide significant advantages over traditional manual methods, including faster data collection, the ability to reach hazardous or inaccessible areas [10], and reduced physical risk to human workers. These benefits have made UAVs invaluable tools in tasks such as material transport, aerial surveying, progress tracking, and structural inspection, where timely and accurate data collection is essential for effective project management [11]. Current applications primarily employ high-resolution cameras and LiDAR sensors to capture comprehensive visual and spatial data of construction sites [12], enabling tasks such as topographical mapping, structural monitoring, and site progress tracking. However, the potential of UAVs in construction automation remains largely untapped, with current systems often limited to basic applications due to challenges in achieving the level of control required for more complex, precision-oriented tasks.

2.2 Challenges in UAV Flight Control in Dynamic Construction Environments

Despite their advantages, UAVs face considerable challenges in maintaining stable navigation and precise flight control within dynamic and cluttered construction environments. Construction sites are characterized by rapidly changing conditions, including variable layouts, the presence of obstacles, and environmental disturbances such as wind and dust. These factors complicate UAV navigation, potentially causing navigation errors and inefficient task performance. In complex tasks that require close-range inspections or consistent altitude maintenance, such as detailed structural inspections, UAV stability becomes even more critical. However, most existing UAV control systems are built on basic sensor setups and simple algorithms, which struggle to adapt to environmental changes and cannot provide the required precision. As a result, UAVs may lack the stability and adaptability needed for more intricate construction tasks, where accuracy is paramount.

2.3 Sensor Integration and Advanced Control Algorithms in UAV Systems for Construction

To enhance UAV functionality in complex construction environments, the integration of multiple sensors has become crucial. This multi-sensor approach allows UAVs to collect detailed, varied data, increasing their situational awareness and enabling adaptive responses to real-time changes [13]. Key sensors such as LiDAR, GPS, high-resolution cameras, and infrared sensors each contribute uniquely to UAV operations [14]. LiDAR sensors generate 3D environmental maps and measure distances, aiding obstacle avoidance and altitude maintenance, while GPS supports broader site navigation, though it often lacks the precision required for dense or cluttered construction spaces. High-resolution cameras capture critical visual information for texture analysis,

defect detection, and adherence to specifications, providing UAVs with the ability to identify quality issues in structural elements. This diverse sensor data creates a richer environmental model, allowing UAVs to operate with improved accuracy, safety, and effectiveness.

The integration of such varied data sources has also driven advances in sensor fusion and control algorithms, addressing the limitations of traditional UAV systems that often process sensor data separately, leading to delays and lower precision in dynamic construction sites. Recent innovations in sensor fusion techniques unify data from multiple sensors to create a comprehensive environmental model, enabling more precise UAV control [15]. Deep Neural Network (DNN)-based models are particularly effective in this context, as they capture non-linear relationships between sensor inputs, enhancing UAV environmental mapping and control accuracy [16]. Techniques such as Simultaneous Localization and Mapping (SLAM), especially when combined with neural networks, further improve localization and trajectory planning by dynamically adjusting flight paths in real time [17]. Additionally, Deep Reinforcement Learning (DRL) algorithms allow UAVs to refine control strategies by continuously learning from environmental feedback, adapting to unexpected obstacles, wind disturbances, or other sudden changes while maintaining stable flight [18]. Together, these advancements provide a framework for UAVs to achieve greater accuracy, adaptability, and resilience, particularly in the unpredictable conditions of construction sites where conventional systems may struggle.

2.4 This Paper's Contribution for Enhanced UAV Control in Construction Automation

Despite notable advancements in sensor integration and flight control technologies, the application of these innovations in construction automation remains limited. Current research predominantly emphasizes UAV navigation and data collection, often neglecting the critical need for precise and stable flight control in scenarios requiring close-range accuracy, such as detailed structural inspections or dynamic obstacle avoidance. This gap underscores the potential of advanced sensor fusion, SLAM, and reinforcement learning techniques to address the unique challenges of UAV deployment in construction environments.

Therefore, this paper seeks to advance the state of UAV control in construction by presenting a multi-sensor fusion framework that integrates LiDAR, GPS, high-resolution cameras, and IMU sensors with advanced control algorithms. The SLAM system fuses multi-modal sensor data to generate accurate environmental maps and enable precise localization. Additionally, a Deep Reinforcement Learning (DRL) algorithm is employed to dynamically adjust flight parameters, allowing the UAV to maintain stability under external disturbances such as wind gusts, vibrations, and near-miss collisions.

3 Multi-Sensor Fusion and Control Framework

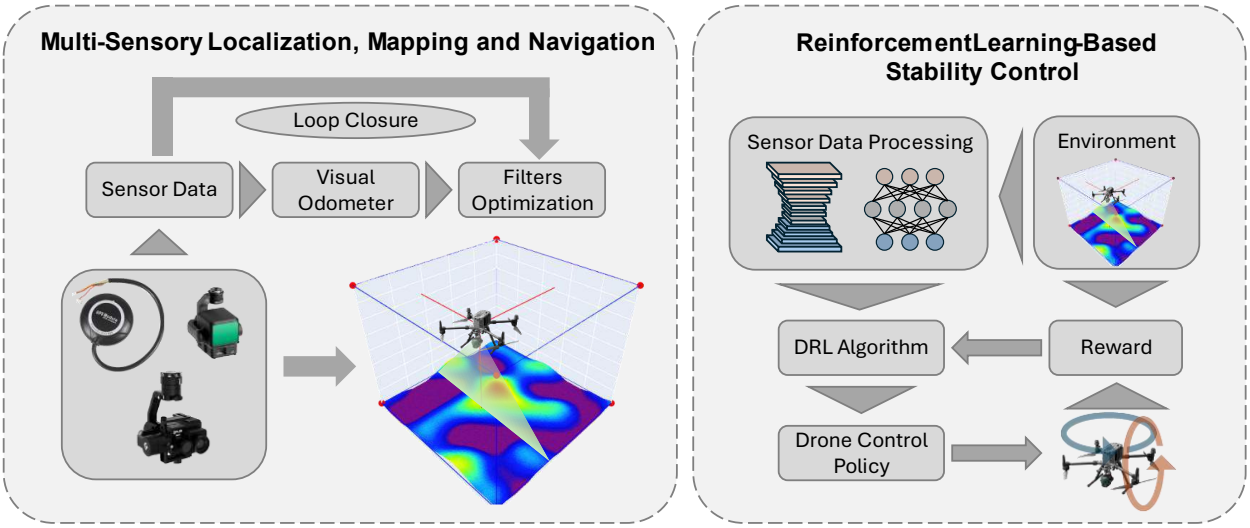

Figure 1. Multi-Sensor Fusion and Control Framework Method Overview

This framework is designed to enhance UAV flight control and stability for high-precision construction tasks by integrating advanced sensor fusion and control strategies as shown in Figure 1. The system consists of

two distinct modules: Multi-Sensory Localization, Mapping, and Navigation and Reinforcement Learning-Based Stability Control. Together, these modules enable the UAV to navigate complex environments, maintain balance under disturbances, and dynamically adapt to real-time changes. Each module is built on a combination of sensor data processing, algorithmic optimization, and machine learning techniques.

3.1 Multi-Sensory Localization, Mapping, and Navigation

Accurate environmental understanding and navigation are fundamental for UAVs operating in complex construction sites. This system integrates data from LiDAR, cameras, GPS, and IMU to construct a real-time, 3D map of the environment and provide reliable localization and navigation control.

3.1.1 Sensor Data Acquisition and Pre-Processing

The UAV is equipped with a suite of sensors that provide complementary data. LiDAR captures 3D point clouds, offering spatial awareness critical for obstacle detection and surface mapping. High-resolution cameras deliver RGB images for texture analysis and visual feature detection. The IMU provides angular velocity and acceleration for motion estimation, while GPS supplies coarse-grain global positioning for initial localization.

Raw data undergoes pre-processing to enhance accuracy and consistency. For LiDAR, a moving average filter is applied to reduce noise:

$$\widetilde{D}(i) = \frac{1}{N} \sum_{j=i-\frac{N}{2}}^{i+\frac{N}{2}} D(j) \quad (1)$$

where $D(j)$ represents the distance measured at point j and N is the window size. Given the need for rapid data processing and flight adjustments, the moving average filter presents a balanced trade-off between efficiency and accuracy.

3.1.2 Visual Odometry

Using pre-processed image data, the system detects and tracks visual features between consecutive frames. Pose estimation is calculated based on matched feature points, and IMU data is fused to refine these estimates:

$$\mathbf{T}_{k+1} = \mathbf{T}_k \cdot \Delta\mathbf{T}_{\text{vision}} \cdot \Delta\mathbf{T}_{\text{IMU}} \quad (2)$$

where $\mathbf{T}_k$ is the pose at time k, $\Delta\mathbf{T}_{\text{vision}}$ is the incremental pose estimated from visual odometry, and $\Delta\mathbf{T}_{\text{IMU}}$ accounts for short-term motion from IMU readings.

3.1.3 SLAM Framework

A Simultaneous Localization and Mapping (SLAM) algorithm optimizes the UAV's trajectory and generates a globally consistent map. The SLAM framework integrates LiDAR, visual odometry, and GPS data, estimating the UAV's position $P'(t)$ and orientation $\theta'(t)$ by minimizing localization error:

$$L_{\text{SLAM}} = \|P(t) - P'(t)\|^2 + \|\theta(t) - \theta'(t)\|^2 \quad (3)$$

where $P(t)$ and $\theta(t)$ are ground truth values. Loop closure constraints are incorporated to correct drift over time, ensuring trajectory accuracy.

The outputs from the SLAM framework guide the UAV's navigation system. Real-time path planning is performed using the fused environmental map, enabling obstacle avoidance and dynamic adjustments to environmental changes. The result is precise trajectory execution, even in highly cluttered and variable construction sites.

3.2 Reinforcement Learning-Based Stability Control

In addition to navigation, maintaining flight stability under disturbances such as wind gusts, airborne debris, or dynamic obstacles is critical for UAV operation. This system employs a Deep Reinforcement Learning (DRL) agent to adaptively adjust the UAV's flight parameters in real-time.

3.2.1 Sensor Data Processing

The stability control system uses fused data from the IMU, LiDAR, and cameras to define the UAV's state. The IMU provides orientation measurements (pitch, roll, yaw) and acceleration for disturbance detection, while LiDAR monitors altitude and proximity to surfaces. Cameras contribute visual feedback, which is particularly useful for fine-grained stability adjustments during precision tasks.

3.2.2 Markov Decision Process (MDP) Framework

The UAV's control system is modeled as an MDP, defined by the tuple (S, A, R, P), where:

State S: Fused sensor data, including position $P(t)$, orientation $\theta(t)$, and environmental features.

Action A: Control commands for thrust, roll, pitch, and yaw adjustments.

Reward R : A stability-based reward function penalizing deviations from reference position P_{ref} and orientation θ_{ref}:

$$R = -\alpha\|P - P_{\text{ref}}\|^2 - \beta\|\theta - \theta_{\text{ref}}\|^2 \quad (4)$$

where α and β are weighting factors.

Transition Probability P : The probability of

transitioning to a new state given the current state and action.

3.2.3 Deep Reinforcement Learning Algorithm

A policy gradient method optimizes the control policy $\pi(a \mid s)$ to maximize the expected cumulative reward:

$$J(\pi) = \mathbb{E}\left[\sum_{t=0}^{T} R(t)\right] \quad (5)$$

Through iterative training in simulated environments, the DRL agent learns to adapt to disturbances and maintain stable flight under various conditions.

In real-world deployment, the trained DRL agent dynamically adjusts flight parameters based on environmental feedback. For example, in the presence of wind gusts, the agent compensates by modulating thrust and adjusting orientation to minimize deviations from the intended trajectory. The system achieves rapid recovery from disturbances, maintaining consistent altitude and balance for precision tasks.

4 Implementations

The proposed framework was implemented and tested in a simulated ROS environment using Gazebo as the simulation platform. Gazebo provided a realistic simulation of construction site environments, including dynamic objects, complex terrains, and environmental physics. The testing process was divided into two stages: evaluating the UAV's environmental mapping and navigation capabilities, and assessing its stability control under various external disturbances.

4.1 Environmental Mapping and Navigation Testing

In the first stage, the UAV was tasked with collecting environmental data and navigating autonomously in a simulated construction site. The site included obstacles such as scaffolding, equipment, and uneven surfaces, emulating real-world conditions. The UAV's primary objectives were:

Environmental Mapping: Using LiDAR, cameras, and IMU sensors, the UAV generated a 3D map of the environment. The map's accuracy was evaluated using:

Mapping Accuracy: Intersection-over-Union (IoU) between the generated map and the ground truth.

Localization Error: Root Mean Square Error (RMSE) between estimated and true positions.

Navigation Performance: The UAV navigated predefined waypoints while avoiding obstacles. Navigation metrics included:

Path Efficiency: Ratio of the shortest path length to the actual path length.

Obstacle Avoidance Success: Percentage of successfully avoided obstacles.

Gazebo provided realistic physics for the environment, such as collisions, lighting effects for cameras, and terrain irregularities, enhancing the fidelity of the simulation.

4.2 Stability Control Testing Under External Disturbances

In the second stage, the UAV's ability to maintain stability and recover from disturbances was evaluated.

External disturbances relevant to construction sites were simulated in Gazebo, including: **Wind Gusts**: Random lateral forces were applied to mimic the effect of wind blowing through open or partially enclosed construction sites. The UAV was tested on its ability to maintain its trajectory and recover from sudden deviations caused by these forces. **Vibrations from Heavy Machinery**: Periodic oscillatory forces were introduced to replicate the effect of operating heavy equipment such as drills, concrete mixers, or excavators near the UAV. These vibrations tested the system's robustness to continuous destabilizing inputs. **Dynamic Load Changes**: External weights were dynamically added and removed from the UAV during flight, simulating scenarios where it might carry tools, sensors, or materials. This tested the system's ability to adapt to changes in payload and maintain stability. **Torsional Forces**: Rotational disturbances were applied to simulate uneven thrust distribution or sudden torque imbalances caused by dynamic construction operations. This tested the UAV's ability to quickly stabilize its orientation under unexpected rotational forces. **Near-Miss Collisions**: Fast-moving objects (e.g., scaffolding, cranes) were simulated to narrowly pass by the UAV. When encountering such a near-miss situation, the UAV was required to immediately halt its movement, stabilize itself, and correct any resulting disturbances. This scenario tested the drone's ability to rapidly switch to emergency stop procedures while ensuring stability post-disruption. **Dynamic Obstacles**: Moving objects, such as simulated workers or operational machinery (e.g., cranes), introduced additional challenges for stability and trajectory adjustment. These obstacles required the UAV to maintain stability and dynamically adjust its flight path in real-time to avoid collisions.

Gazebo's physics engine enabled precise simulation of these disturbances, ensuring realistic force dynamics and environmental interactions.

4.3 Metrics for Evaluation

The UAV's performance under disturbances was

assessed using: **Recovery Time**: The time taken for the UAV to return to stable flight after experiencing a disturbance. **Stability Deviation**: Standard deviation of orientation angles (pitch, roll, yaw) during and after disturbances

$$\sigma_\theta = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(\theta_i - \bar{\theta})^2} \quad (6)$$

where θ_i is the orientation angle at time i, and $\bar{\theta}$ is the mean orientation angle. **Trajectory Accuracy**: Deviation of the UAV's actual path from the planned trajectory. **Force Compensation**: Percentage of external forces effectively neutralized by the stability control system.

5 Results

The proposed framework was tested for 100 rounds in the ROS-Gazebo environment to evaluate its performance each in mapping/navigation tasks and stability control under simulated construction conditions. The results demonstrated the framework's capability to achieve accurate localization, robust navigation, and reliable stability in the presence of external disturbances.

5.1 Mapping and Navigation Performance

During the mapping and navigation tests, the UAV demonstrated its ability to collect detailed environmental maps and execute precise navigation tasks in the simulated construction site. The system achieved a high mapping accuracy, with an Intersection-over-Union (IoU) score of 95.4%, indicating substantial overlap between the generated map and the ground truth. Localization was also highly accurate, with a Root Mean Square Error (RMSE) of only 1.95 cm between the UAV's estimated and actual positions. In terms of navigation performance, the UAV showed efficient path planning, with a path efficiency ratio of 1.08, meaning the UAV's actual flight path was only slightly longer than the shortest possible path. Additionally, the system excelled in obstacle avoidance, successfully avoiding 96% of obstacles in its path. These results validate the effectiveness of the multi-sensory fusion system in enabling the UAV to navigate complex construction environments with precision and reliability.

For comparative evaluation, we benchmarked our SLAM-integrated fusion framework against conventional sensor fusion methods that independently process LiDAR, IMU, and visual data. Our results show that the proposed method improved localization accuracy by 22.5% and mapping accuracy by 17.8%, attributed to the integration of loop closure techniques that effectively mitigate trajectory drift. This enhancement demonstrates the robustness of our method in generating precise environmental maps under dynamic conditions.

5.2 Stability Control Performance

The stability control system was evaluated across six different disturbance scenarios, representing common challenges in construction environments. Each scenario was tested multiple times, and the UAV's ability to respond, recover, and maintain stability was measured using metrics such as recovery time, orientation deviation, and trajectory accuracy. Table 1 summarizes the performance results.

Table 1. Summary of Performance Metrics Under Different Disturbance Conditions

Disturbance	Recovery Time (s)	Orientation Deviation (°)	Trajectory Deviation (%)	Force Compensation (%)
Wind Gusts	1.3	2.8	3.40%	95%
Vibrations from Machinery	1.4	2.5	**0.60%**	97%
Dynamic Load Changes	1.8	3.1	1.10%	86%
Torsional Forces	1.5	2.9	2.60%	85%
Near-Miss Collisions	**0.8**	**2**	4.80%	97%
Dynamic Obstacles	1.6	3	8.20%	**98%**

The stability control system exhibited strong performance across various disturbance scenarios, effectively maintaining flight stability and compensating for external forces. Among the tests, vibrations from machinery demonstrated the best performance, with the UAV achieving a recovery time of 1.4 seconds, an orientation deviation of only 2.5°, and a trajectory accuracy deviation of just 0.60%, the lowest across all scenarios. This highlights the system's robustness against continuous oscillatory forces commonly encountered near heavy equipment.

Conversely, the dynamic obstacle scenario posed the greatest challenge. While the UAV achieved a high force compensation rate of 98%, its trajectory accuracy deviation reached 8.20%, the highest among all tests, due to the complex task of avoiding fast-moving objects

while maintaining stability. Despite this, the system's recovery time of 1.6 seconds and orientation deviation of 3.0° indicate its adaptability to highly dynamic environments.

The near-miss collision test highlighted the system's effectiveness in emergency scenarios. The UAV executed an immediate stop with a recovery time of just 0.8 seconds, the fastest among all disturbances, and managed a low orientation deviation of 2.0°. Although the trajectory deviation of 4.80% was higher due to the abrupt braking, the system compensated 97% of the external forces, demonstrating its reliability in handling rapid, high-stress situations.

To highlight the advantages of our reinforcement learning-enhanced flight control system, we compared its performance with a conventional PID-based control strategy. The proposed system demonstrated superior performance in maintaining stability under dynamic disturbances, reducing trajectory deviation by 35.2% and improving recovery time by 21.7%. These improvements are attributed to the reinforcement learning module's ability to adaptively adjust control parameters in response to real-time environmental changes, unlike PID controllers that rely on predefined gain tuning.

In addition to evaluating stability performance, we assessed the computational efficiency of the proposed framework to ensure its feasibility for real-time UAV applications. The system achieved a feedback rate of 10 Hz on an NVIDIA Jetson AGX Xavier, a commonly used edge computing device. This result highlights the framework's capacity to maintain real-time responsiveness in dynamic construction environments.

Overall, the UAV showed consistent recovery across most scenarios, with recovery times ranging from 0.8 to 1.8 seconds and orientation deviations remaining under 3.1°. The framework effectively balanced rapid stabilization and precision, making it suitable for complex construction environments.

6 Conclusions

This paper proposed a multi-sensor fusion and control framework to enhance UAV performance in dynamic construction environments. The integration of LiDAR, GPS, high-resolution cameras, and IMU sensors enabled precise environmental mapping, accurate localization, and robust stability control. The SLAM system provided reliable trajectory optimization and mapping, while a Deep Reinforcement Learning algorithm ensured adaptive responses to disturbances such as wind gusts and near-miss collisions. Simulation results demonstrated the system's effectiveness, achieving mapping accuracy of 95.4%, localization errors under 2 cm, and rapid recovery from disturbances within 0.8 seconds.

Despite these advancements, the framework's evaluation was limited to simulation environments, and real-world implementation is needed to assess its robustness under unpredictable site conditions. Future work will focus on addressing these challenges by optimizing computational efficiency, validating the framework in field conditions, and exploring the integration of collaborative multi-UAV systems to further enhance construction automation.

Abstract –

Deconstruction for resource recovery offers a sustainable alternative to traditional demolition practices. However, deconstruction remains labor-intensive and time-consuming compared to demolition of buildings. This study proposes a novel framework that integrates Building Information Modeling (BIM) with robotic systems to automate the recovery of building components. The BIM file is converted into a robot simulation environment, enabling precise disassembly planning by providing location and size information of recoverable resources. A case study on a BIM model of an exposed interior residential wall assembly unit demonstrates the methodology's effectiveness in automating resource recovery of end-of-life building components. The results validate the potential of the proposed framework to reduce manual labor and contribute to the circular economy of the building construction sector.

1 Introduction

The building construction sector plays a critical role in contributing to climate change. According to the United Nations Environment Programme (UNEP), the sector is responsible for approximately 37% of global energy-related carbon emissions [1]. Mitigating emissions within the construction supply chain requires transitioning from a linear economy to a circular economy. A circular economy in building construction emphasizes increasing reuse, recycle, reclaim of resources, thereby minimizing waste and resource production throughout the supply chain (Fig. 1).

Resource recovery from buildings at the end-of-life stage has garnered attention as a strategy to reduce the environmental impact of the building sector. As of 2022, the production of construction materials alone contributed 10% of global energy and process carbon emissions [2]. Additionally, the United States Environmental Protection Agency (EPA) reported that demolition activities in 2018 generated over 500 million tons of landfill debris in the U.S. [3]. By recovering resources through reuse, recycling, and reclamation, the volume of waste directed to landfills and the need for virgin materials can be markedly reduced.

Despite its environmental benefits, the deconstruction of buildings for resource recovery tends to be labor-intensive and time-consuming, requiring up to ten times longer processes compared to traditional demolition methods [4]. Improving the efficiency of resource recovery through automation offers a promising pathway to enhance the feasibility of a deconstruction process.

This study proposes a framework for planning automated resource recovery from end-of-life building assemblies using robotic systems. The approach leverages Building Information Modeling (BIM) enriched with resource information for each component. BIM files are converted into a simulation environment while retaining the resource information. This information is then used to plan robotic disassembly operations which can also be applied to physical world environments.

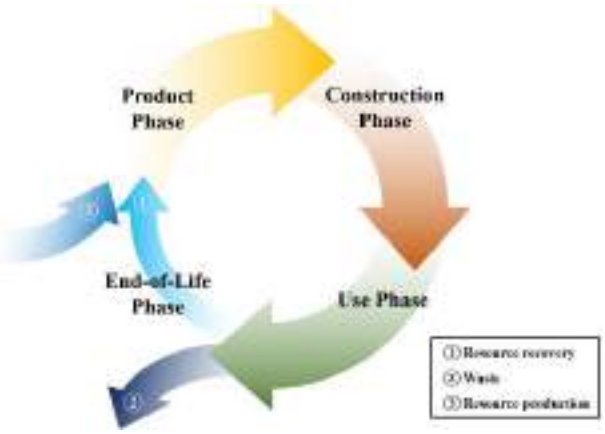

Fig. 1. Circular economy of building construction

2 Literature Review

Efforts to deconstruct buildings and effectively retrieve reusable resources have been widely studied. These approaches can generally be categorized into two main approaches: deconstruction planning up front during the design phase and planning once a building has reached its end-of-life phase.

Deconstruction planning during the design phase is commonly referred to as Design for Deconstruction (DfD). DfD involves incorporating strategies during the early design stages to simplify future resource recovery. These strategies include measures such as using bolted connections instead of adhesives [5], avoiding the use of toxic materials [6], and designing for offsite construction [7], among others. The primary goal of DfD is to streamline deconstruction efforts while minimizing the labor, cost, and environmental impact of the process.

Notable advancements in this field include the integration of BIM to simulate environmental and cost impacts throughout a building's lifecycle, enabling the optimization of designs to minimize these effects. For example, studies have developed BIM-integrated frameworks that enhance construction material management in the early design phase [8, 9]. These frameworks facilitate informed material selection and improve interoperability, ultimately supporting more efficient deconstruction and resource reuse planning at a building's end-of-life.

However, most modern buildings are not designed with deconstruction in mind [6]. Consequently, deconstruction planning often defers until the building reaches its end-of-life stage. In such cases, BIM serves as a critical tool for assessing a building's condition, resource properties, and reuse potential. Mollaei et al. [10] demonstrated the use of BIM's quantity take-off tools to extract material quantities and connection configurations. This data was then integrated into a multi-objective optimization model to evaluate various deconstruction strategies for different materials. Similarly, Sanchez et al. [11] proposed a semi-automated approach for selective deconstruction programming using BIM. Their approach optimized the deconstruction and reuse strategies by incorporating cost and environmental impact analysis.

While existing methods use BIM for deconstruction planning in the design phase or at the end-of-life stage, they often rely on manual processes that are labor-intensive and time-consuming. To improve the efficiency and scalability of deconstruction, researchers have explored the integration of automation and robotic systems. For instance, Lee and Brell-Cokcan [12] proposed a Human-in-the-Loop framework in which an operator defines high-level objectives, allowing robotic systems to execute deconstruction tasks with greater precision and efficiency.

However, deconstruction planning tailored for robotic systems remains largely unexplored. This study addresses this gap by introducing a novel approach that bridges BIM-based deconstruction planning with robotic execution. This method enables practitioners to directly extract information from a BIM model to plan and execute robotic resource recovery commands, enhancing efficiency in the deconstruction process.

3 Methodology

The proposed methodology involves converting a conventional BIM file (e.g., an Autodesk Revit file) into a Universal Scene Description (USD) format, which is compatible with robotic simulation environments (e.g., specifically Isaac SIM [13]). A USD file retains the resource information and hierarchy of the components, enabling the identification of recoverable resources in the simulation. This information is then used as input for robotic disassembly planning. Fig. 2 shows the proposed framework for robotic disassembly. Details of each step are explained in the following sections.

3.1 Converting BIM to USD

The BIM file containing information about the target structure is converted into a USD file. USD is a 3D scene representation file format designed to support complex 3D workflows including robotic simulations. This conversion is facilitated by the Nvidia Omniverse Revit Connector [14], which ensures that all subcategory information from the BIM file is preserved during the transition to the simulation environment. The resulting USD file retains critical resource specifications and hierarchical structural data necessary for accurate robotic simulations.

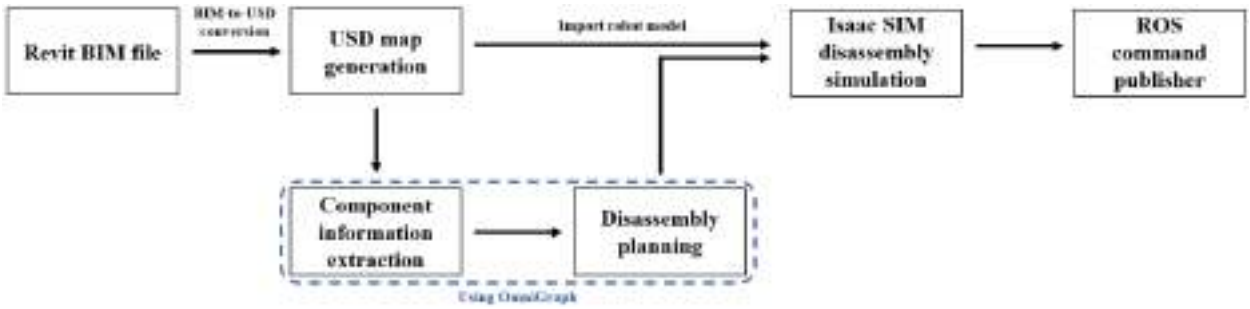

Fig. 2. Proposed framework for robotic disassembly using BIM information

3.2 Using Component Information for Disassembly Planning

The converted USD file is structured with elements defined as *prims* (short for primitives). A prim serves as a container for various attributes within any component in the USD scene, such as cameras, lights, objects, or robots. These prims are organized in a hierarchical structure, including the location and size information of specific components in their subcategories. Each object prim contains transformation coordinates and extent values. The transformation coordinate corresponds to the center of the component and the extent values define the min/max coordinates of the bounding box enclosing the component (Fig. 3).

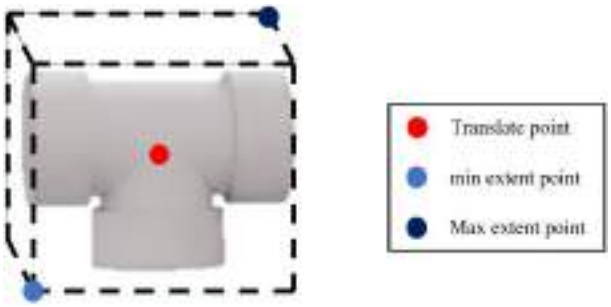

Fig. 3. Visualized example of component information in a prim

To plan and execute robotic disassembly, OmniGraph is used within the Isaac SIM environment. OmniGraph is a visual scripting language that enables dynamic control of robots [15]. It operates by connecting nodes, which perform specific tasks and contain input, output, and state attributes. These nodes are linked through connections, forming a network that controls robotic behaviors and interactions in the simulation. Action Graphs, a type of OmniGraph, define the execution of specific tasks, allowing for precise and flexible robot control.

Additionally, OmniGraph commands can be translated into ROS2 commands for physical world implementation. Isaac ROS2 nodes within the action graph enable the publishing of ROS2 messages, allowing the simulated actions to be executed by physical robots in real-world experiments.

4 Experiments

To demonstrate how the BIM-to-USD conversion process can support robotic disassembly planning, a small-scale experiment was conducted using an exposed interior residential wall assembly unit (Fig. 4(a)). The BIM file for the wall assembly unit was developed with an approximate Level of Detail (LoD) 300, providing detailed information about each component's size, shape, and location. The BIM file was then converted into a USD format and imported into Isaac SIM [13], a robotic simulation platform (Fig. 4(b)). A Franka FR3 [16] robot manipulator was incorporated into the simulation, mounted on a static platform to enhance its reachability during the disassembly process.

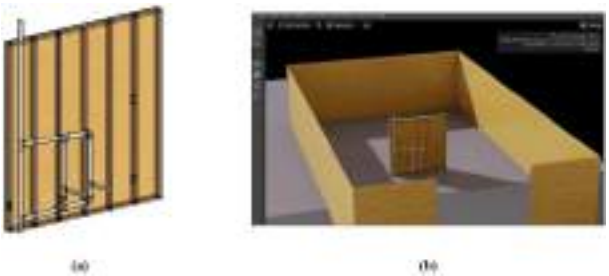

Fig. 4. Wall assembly unit: (a) LoD 300 BIM file and (b) USD file imported into Isaac SIM

Table 1. Recoverable resource attributes in wall assembly

Name	Mesh	Extent [min, max]	Translate	Material
Pipes 302099		[(-1.905,-1.905,-14.943), (1.905,1.905,14.943)]	(1213.926,252.986,38.882)	Plastic
Pipe Fittings 302081		[(-6.826,-6.826,-3.532), (6.826,3.532,3.532)]	(1236.335,252.930,105.643)	PVC
Electrical Fixtures 305293		[(-2.699,-5.080,-4.763), (2.699,5.080,5.414e^{-})]	(1233.557,141.838,33.020)	Steel

For this experiment, the primary objective was to utilize the resource information from the BIM model to demonstrate automated identification and recovery of reusable components. Table 1 shows an example of specific resources within the given wall assembly unit. As depicted in Fig. 3, the translate point indicates the center point of an object.

The disassembly task was executed using a combination of five OmniGraph action graph nodes (Fig. 5). The 'Pick and Place controller' node received inputs of the robot manipulator's joint movements, a target resource translate point, and a predefined placing point from the other four nodes. This combined algorithm enabled the robot manipulator to accurately pick up the center point of an identified resource and place it in a specified location.

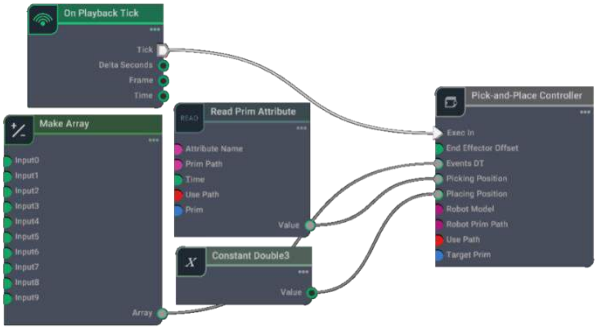

Fig. 5. OmniGraph node combination for resource pick and place task

The node combination automatically leverages the detailed positional data to perform precise disassembly operations (Fig. 6). The results show the potential of the proposed methodology in advancing resource recovery of end-of-life building components with a robotic system.

5 Conclusions

This study presents a new framework for automated resource recovery using a robotic system, addressing key challenges associated with deconstruction in the building construction sector. The methodology integrates BIM with robotic simulation tools by converting BIM files into USD format. The enriched data from the BIM model enables the detailed identification and retrieval of recoverable resources through robotic disassembly planning. A small-scale experiment demonstrates the potential of the approach, outlining the capability to utilize precise size and location information of components to retrieve target resources in the wall assembly unit. The results underscore how BIM-to-USD data conversion can directly support the potential of robotic systems as advanced disassembly tools. The proposed framework enhances the efficiency and feasibility of resource recovery and contribute to a more sustainable construction industry.

5.1 Discussion

While the RosBridge nodes of OmniGraph facilitate the conversion of simulated action graphs into ROS2 commands, significant challenges persist in replicating the simulation to physical world applications. A critical issue lies in the precise registration of simulated environments with their physical world counterparts. Addressing this challenge requires advanced machine

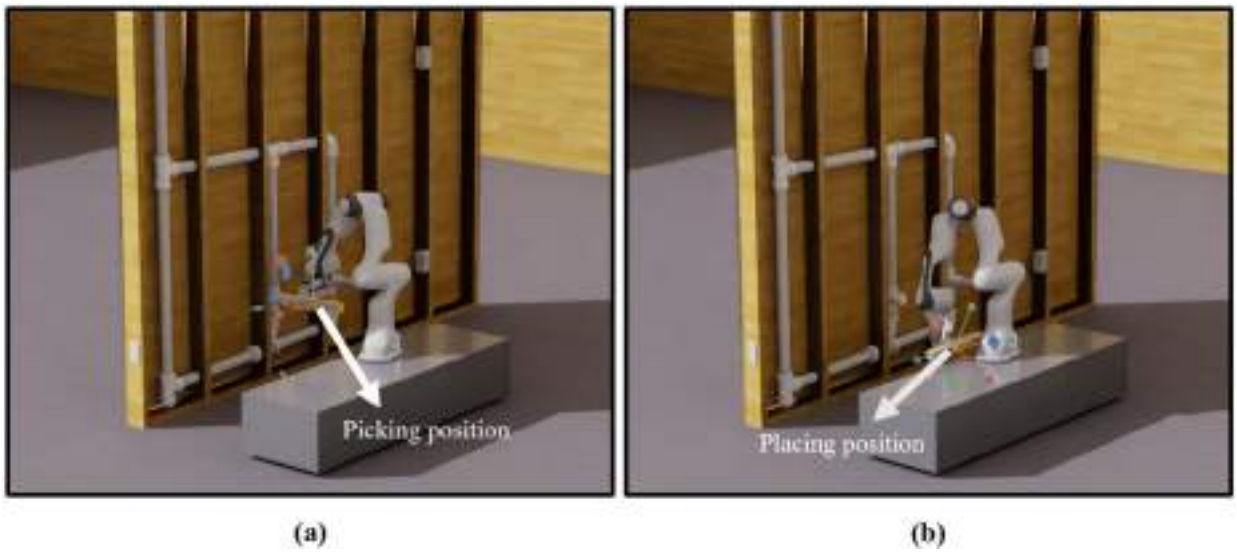

Fig. 6. Results of the robotic disassembly task: (a) picking the target object's translate point, and (b) placing the object at a specified point

vision systems capable of detecting fiducial markers (e.g., AprilTag [17] and QR code) or physical features of the building components to accurately align the simulation and physical world environments.

Future research should focus on determining the specific types and formats of building data that should be incorporated into BIM models to optimize robotic deconstruction processes. Accurate information modeling within BIM is essential for ensuring a seamless conversion to USD format using the Nvidia Omniverse Revit Connector. For example, it is critical to include compatible and detailed information identifying resources that are suitable and intended for robotic disassembly. Enhancing the fidelity of BIM-to-USD conversions should also be prioritized to ensure the accurate and comprehensive transfer of data into robotic simulation environments.

The current case study is limited to a small wall assembly unit in a simulation environment. Scaling this approach to larger, real-world applications will require addressing the complexities of diverse building materials with varying conditions. Unlike controlled simulation environments where material properties are predefined, physical structures comprise materials having different structural integrity, attachment types, and degradation levels. Developing adaptive robotic manipulation techniques capable of dynamically recognizing and adjusting disassembly strategies based on these variables is essential for maintaining efficiency. Furthermore, expanding the versatility of robotic systems is critical for addressing practical constraints (e.g., robot torque, reach, payload, and spatial maneuverability) [18]. Advancements that overcome these limitations will significantly enhance the effectiveness of the proposed framework.

Abstract -

The construction industry faces labor shortages due to an aging workforce, driving the need for construction automation to boost productivity. Despite recent advances in construction robotics in Japan, the complexity of construction tasks requires coordinated operations among multiple robots. This necessitates not only advanced automation but also a sophisticated planning system to align workflows with construction plans. This study introduces a low-code Planning Interface System (PIS) using the Node-RED platform, enabling civil engineers to design and manage robot workflows without extensive programming expertise. The PIS translates construction plans into executable operational logic, leveraging Robot Operating System (ROS) middleware and the *rclnodejs* package for seamless communication. A prototype demonstrates the ability of the PIS to coordinate an excavator and dump truck in a simulated environment, performing tasks such as navigation, excavation, and dumping through ROS topics and actions. This study highlights the potential of the PIS to facilitate coordinated operations between multiple construction machines, paving the way for more autonomous and streamlined construction workflows.

Keywords -

ROS; Construction automation; Multi-robot coordination; Low-code platform

1 Introduction

The traditional construction industry has long been characterized by its labor-intensive nature, where the majority of construction activities heavily rely on human labor and manual operations [1]. However, the industry is now facing a significant labor shortage due to an aging workforce and difficulties in attracting younger workers [2]. To address this issue, the Ministry of Land, Infrastructure, Transport, and Tourism (MLIT) in Japan launched the i-Construction initiative in 2016, aiming to fully leverage information and communication technology to enhance efficiency across all stages of the construction process, from survey and design to construction and maintenance [3]. Building on this foundation, i-Construction 2.0, which was announced in April 2024, sets an ambitious goal to achieve automation of construction sites and increase productivity by 30% by 2040, a critical target considering the projected 20% decline in the working-age population by that year [4].

One of the key solutions to achieve site automation is the adoption of automated and autonomous construction machinery. In Japan, both construction machinery manufacturers and general contractors have made significant progress in developing their own construction robots, with a primary focus on earthwork projects. Examples include automated hydraulic excavators [5], dump trucks [6], and vibration rollers [7].

However, in actual construction sites, the complexity of tasks often necessitates the coordinated operation of multiple construction machines, as no single robot can handle the entire workload independently. Effective collaboration between various construction machines is therefore essential for smooth project delivery. Achieving this requires not only advanced automation for individual machinery, but also a robust planning system that is capable of designing and managing workflows in alignment with the construction plan.

This study addresses the need by focusing on the integration of construction planning with multi-robot coordination, aiming to provide civil engineers with an intuitive interface to efficiently plan and execute coordinated operations between construction machinery.

2 Research background

2.1 The Role of Construction Planning

Construction planning involves organizing and coordinating all activities and resources needed to complete a project effectively, on time, and within budget. A well-structured plan serves as the foundation for successful project delivery, considering constraints such as contract requirements, site conditions, project duration, and financial limitations [8]. Several key decisions are made dur-

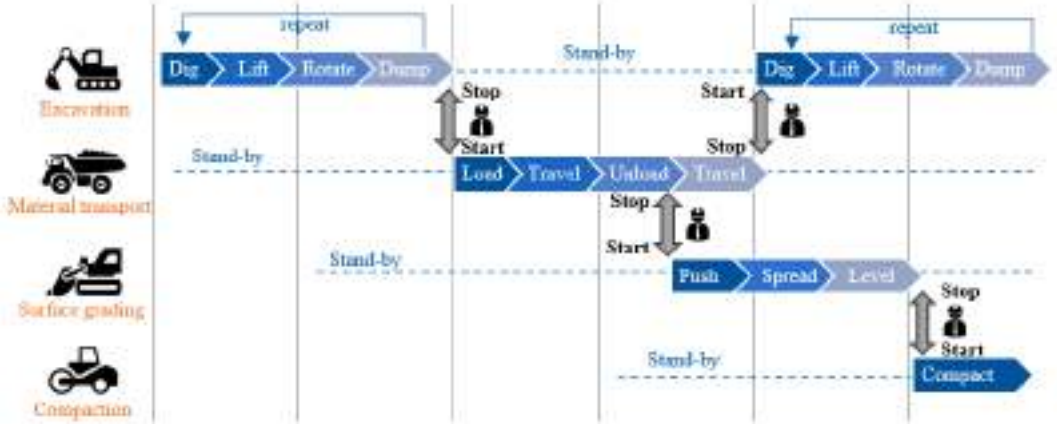

Figure 1. Conventional coordination of robot operations involving human intervention

ing this phase, including identifying specific construction tasks that need to be performed, determining the optimal number of construction machines required, and devising strategies for their arrangement and operation timings onsite. While construction robots have advanced in performing automated tasks such as excavation and material transportation, their operations often remain isolated rather than as part of an integrated construction workflow [9]. A construction plan, however, provides a framework for coordinating these robots to achieve more efficient task execution. By aligning construction operations with the overarching construction plan, isolated automated construction tasks can be transformed into a cohesive and collaborative workflow. This integration not only optimizes task execution but also facilitates smoother and more efficient project delivery.

2.2 Challenges in Multi-Robot Coordination

However, coordinating multiple robots poses significant challenges, as individual machines often lack awareness of others' positions and progress, making it difficult to determine their optimal operation timings. This limitation necessitates human intervention to monitor the overall status of construction and thus decide when to initiate or halt operations. As is demonstrated in Figure 1, in earthworks projects, construction machines such as excavators execute pre-programmed construction works (e.g., digging, lifting, dumping), but human intervention is still required to send "start" or "stop" signals for cooperative operation [10]. To achieve fully autonomous construction, robots must be able to exchange information and independently determine their operation timings. Existing methods often require complex code modifications involving conditionals, loops, and operators, demanding advanced programming expertise that civil engineers may not possess [11]. Therefore, there is a pressing need for an intuitive, accessible solution that allows engineers to define operational logic in a user-friendly manner, translating abstract ideas of collaborative robot operations into concrete, autonomous construction processes.

2.3 Objectives of This Study

The objective of this study is therefore to develop and prototype a Planning Interface System (PIS) that bridges the gap between construction planning and coordination of automated construction robots. The proposed system will allow civil engineers to translate construction plans into intuitive operational logic without requiring extensive programming skills. In addition, the PIS will provide comprehensive data visualization tools to enable civil engineers to monitor the status of construction activities and robot operations in real-time. Ultimately, this study aims to bring together all isolated automated construction tasks under a collaborative framework that aligns with the overarching construction plan, as well as to facilitate construction management process through real-time data visualization of the operational status of the site.

3 Specifications for PIS

3.1 System Requirements

The Public Works Research Institute of Japan has been advancing the Open Platform for Earthwork with Robotics and Autonomy (OPERA), an initiative designed to promote the development and social adoption of autonomous construction machinery [12]. OPERA achieves this by standardizing control signals for construction machinery, leveraging the widely adopted Robot Operating System (ROS) middleware to manage and transmit these signals. In light of the increasing trend among construction robots in Japan to adopt ROS-based control signals, it is essential that the proposed PIS is fully compatible with the ROS

framework to ensure seamless interoperability and integration. The following is a list of requirements that the proposed PIS should meet -

1. *Low-Code Visual Programming Interface:* The PIS should provide a low-code, flow-based visual programming environment to enable intuitive configuration of operational logic reflective of construction plans.
2. *ROS Integration:* The PIS must ensure compatibility with ROS middleware, enabling seamless integration with existing ROS-based robotic systems. This functionality must support the exchange of control commands and feedback data between the PIS and construction robots on-site.
3. *Data Visualization:* The PIS should provide comprehensive data visualization tools to help users monitor the status of construction activities and robot operations. Real-time dashboards and reports can assist in making informed decisions and optimizing workflows for construction management purpose.
4. *Scalability and Flexibility:* The system must be scalable to handle projects of varying sizes and complexities, while also offering flexibility to accommodate different types and manufacturers of construction equipment. It should allow users to control construction equipment in various combinations to suit specific tasks, ensuring adaptability to diverse workflows and site conditions.

3.2 Overall System Architecture

Figure 2 illustrates the overall system architecture, which comprises a construction planning system for defining detailed construction tasks, robot selection and operational instructions. This system interfaces with a centralized PIS that monitors overall vehicle statuses and issues control commands accordingly. Moreover, a group of automated construction robots are deployed at the construction site (i.e., the "edge"), where the operational data is generated and processed locally during task execution. Civil engineers utilize the PIS to translate construction plan details into operational logic that governs the collaborative behaviors of robots. By continuously acquiring and processing real-time data from edge robots regarding vehicle positions, conditions, and work progress, the PIS is able to gain a comprehensive understanding of the operational status of the site. This real-time insight allows the PIS to determine the optimal timings for each robot's tasks based on predefined logic. As a result, the PIS outputs a series of operational commands to individual robots, specifying task activation or deactivation, along with key operational parameters such as velocity and path trajectory for each robot. The output commands ensure a high level of coordination among various construction robots, aligning their operations with the overall construction plan.

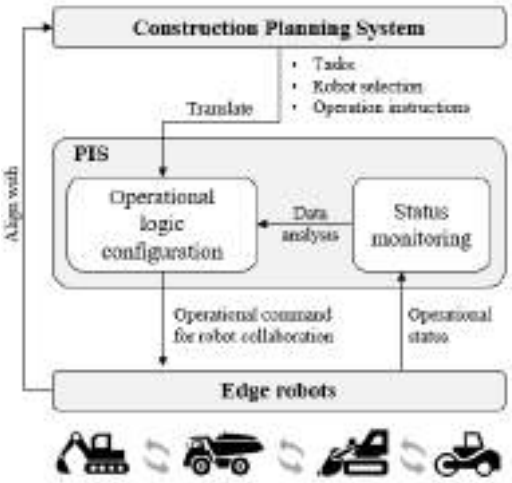

Figure 2. Overall system architecture

4 Prototype development

4.1 Platform Selection

Based on the system requirement in Section 3.1, Node-RED [13], an open-source, web-based visual programming tool, was selected as the development platform for the PIS to plan and control coordinated operation of construction robots. Its low-code, drag-and-drop interface enables civil engineers to design and configure operational logic without requiring extensive programming expertise. This allows civil engineers to focus on defining workflows that align with construction plans, efficiently translating project requirements into executable robotic behaviors.

Node-RED also excels in data visualization, providing a wide array of nodes to acquire, process, and display operational data. A node is an executable process that performs a specific computational task. By wiring up relevant nodes in Node-RED, users can quickly prototype dashboards featuring a variety of visual elements to monitor edge robots effectively and derive actionable insights into their operations. Additionally, the integration of Node-RED with ROS facilitated by the *rclnodejs* package [14] ensures seamless communication with ROS components such as topics, services, and actions. This capability allows users to visually develop and implement ROS-based control algorithms for multi-robot coordination. In this study, the proposed PIS leverages the Node-RED platform and an *rclnodejs*-based plugin software developed by EduArt Robotik [15] to directly interface with ROS.

4.2 Scenario Selection

The prototyping of the proposed PIS in this study focuses on automating the coordination of construction machines within earthworks projects, primarily due to the repetitive yet predictable nature of the workflow associated with earthwork construction. Earthwork operations, such as excavation, material transportation, and soil compaction, often require complex coordination among various construction machines, making them an ideal testing ground for collaborative automation. Additionally, the wide, open spaces with minimal external interference typical of earthwork sites further simplify the implementation of autonomous technologies, providing a controlled environment for testing and validation.

The workflow for earthworks construction can be broken down into a series of tasks, with the prototype in this study focusing on coordinating operations between an excavator and a dump truck using Node-RED and the relevant ROS client library. Figure 3 gives an example of the construction plan, specifying the detailed construction tasks involving the two machines, along with the timing as for each task to take place. To visualize and test their cooperative behavior in a controlled and risk-free environment, a Gazebo-based simulator was chosen for its simplicity and seamless integration with ROS. This ensures that the system's operational logic and coordination strategies are thoroughly validated prior to practical implementation in real-world construction scenarios.

	Scenario	Task	Trigger for the task
Task 1		**Dump truck**: Navigate to the excavation site **Excavator**: Stand-by	When the target position of dump truck is specified
Task 2		**Dump truck**: Stand-by **Excavator**: Digging, lifting, rotating, dumping (repeat)	When dump truck reaches its stand-by position at the excavation site
Task 3		**Dump truck**: Navigate to the dump site **Excavator**: Stand-by	When soil quantity reaches the weight limit of dump truck
Task 4		**Dump truck**: Soil dumping **Excavator**: Stand-by	When dump truck reaches the dump site

Figure 3. Example of a construction plan with detailed construction tasks and corresponding operation timings within an earthwork project

4.3 Prototype Development and Result Discussion

The prototype development thus involves translating the details of the construction plan above into equivalent flow-based operational logic that governs the work coordination of robots. Figure 4 shows the detailed communication flow between the Node-RED-based PIS and the edge robots. On the edge side, the robots execute high-level ROS control programs that govern their individual operations, such as navigation and excavation. Meanwhile, by incorporating the construction plan requirements into the operational logic, the PIS ensures the precise timing and conditions under which the edge control programs are executed, ensuring seamless collaboration among the machines. This operational logic is divided into three distinct parts: Part A, Part B, and Part C, each corresponding to a specific Node-RED flow, as illustrated in Figure 5. These parts collectively enable the PIS to orchestrate the coordination of tasks through intuitive flow-based programming. The following sections provide a detailed discussion of how the PIS facilitates task coordination.

4.3.1 Task 1 (Navigate to the excavation site)

Task 1 involves navigating the dump truck from its current position to reach a specified target position and orientation at an excavation site. This process implements path tracking control using the Pure Pursuit algorithm [16], which continuously calculates and adjusts the steering direction of the dump truck as it moves toward its target. This path tracking control is implemented using an action server–client communication framework in ROS. A ROS node on the edge robot initializes the action server that executes the Pure Pursuit algorithm and waits for goal requests from the Action Client a-1 in the PIS. The Action Client a-1 then sends the navigation goal to the running action server that triggers the navigation. The Node-RED configuration for this action client is detailed in Part A of Figure 5.

4.3.2 Task 2 (Excavation)

Task 2 automates the excavation process through a ROS node that integrates a subscriber and a publisher. The subscriber on the edge robot continuously monitors the **/flag_ex** topic to determine whether to proceed with excavation. Upon successful completion of Task 1 (the dump truck reaches its stand-by position at the excavation site), the action server sends the navigation result back to the PIS. This triggers the Publisher b-1 in the PIS to set the **/flag_ex** topic to "true", initiating the excavation process. The publisher as part of the excavation control program for Task 2 then sends joint position commands to control the excavator's movements. Simultaneously, the **/num_cycles** topic tracks the number of excavation cycles performed and thereby providing real-time feedback on the progress of the operation. The relevant Node-RED flow for coordinating Task 2 is shown in Part B of Figure 5.

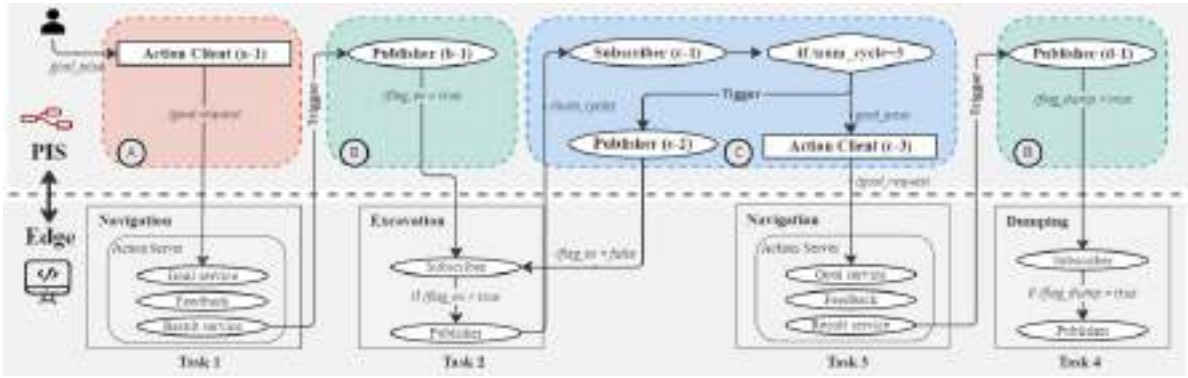

Figure 4. Overall communication flow between the PIS and edge side

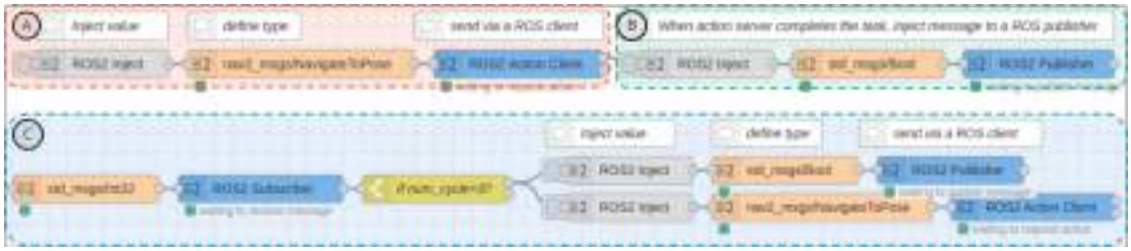

Figure 5. Node-RED flow configuration for work coordination

4.3.3 Task 3 (Navigate to the dump site)

Task 3, similar to Task 1, but this time involves navigating the dump truck to a designated dump site. In practice, excavation halts when the truck reaches its weight limit, whereas in the case of a simulated environment, this condition is approximated by counting the number of excavation cycles. The PIS sets up a Subscriber (c-1) to listen on the **/num_cycles** topic. After three cycles of excavation, the PIS triggers a Publisher (c-2) to set the **/flag_ex** topic to "false", effectively pausing the excavation work from Task 2. At the same time, the PIS sends a goal request via the Action Client c-3 to initiate the dump truck's navigation towards the dump site as per Task 3. This operational logic ensures that the dump truck starts moving only after the required amount of soil has been excavated, maintaining a smooth transition between the cessation of excavation and the initiation of material transportation. The detailed flow configuration for Task 3 is illustrated in Part C of Figure 5.

4.3.4 Task 4 (Soil dumping)

Task 4 oversees the soil dumping operation, managed by a ROS node to control the movement of the dump truck's vessel. On the edge robot side, the ROS node first starts a subscriber to monitor the **/flag_dump** topic to determine the timing for soil dumping, which then instructs the publisher to send joint control commands to the vessel actuator. Upon receiving the action results from Task 3, meaning when the dump truck has reached its designated position at the dump site, the PIS triggers the Publisher d-1 to set the **/flag_dump** topic to 'true' and hence initiates the dumping process. The setup for Publisher d-1, similar to Publisher b-1 and d-1, is detailed in Part B of Figure 5.

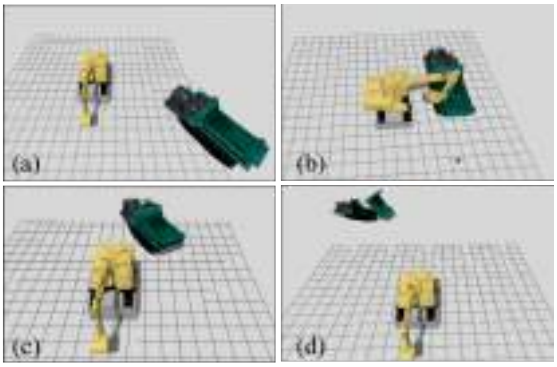

Figure 6. A snapshot of the cooperative behaviors of machines in Gazebo simulation: (a) Navigate to the excavation site; (b) Excavation and loading; (c) Navigate to the dump site; (d) Soil dumping

4.3.5 Validation of results in Gazebo simulation

Figure 6 provides a snapshot of the resulted machine behaviors in the simulation with respect to different tasks,

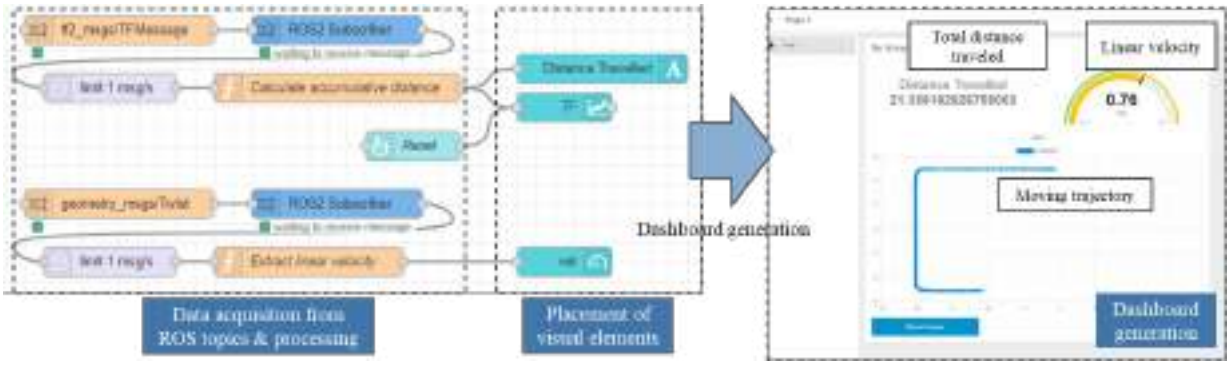

Figure 7. Sample Node-RED flow and its output dashboard for monitoring vehicle velocity, travel distance and trajectory

illustrating how the PIS orchestrates the excavator and dump truck to perform their respective tasks in a coordinated manner. The entire workflow from Task 1 (navigation to the excavation site) to Task 4 (soil dumping) is executed autonomously with no human intervention, with the PIS determining the optimal operation timings for each task based on predefined logic reflective of the construction plan. The simulation result demonstrates the potential of the PIS to design intuitive, flow-based operational logic for coordinating multiple construction tasks seamlessly.

4.3.6 Dashboard development

In order to facilitate the construction management process, a Node-RED dashboard was developed to provide real-time monitoring of the operational status of the construction machines throughout the task execution. By subscribing to relevant ROS topics, the system collects and processes data to generate insightful visualizations, offering a clear overview of machine performance. Figure 7 provides a simple example of the Node-RED flow and its corresponding dashboard, which tracks the linear velocity, travel distance and trajectory of the dump truck. By integrating with additional ROS topics, the dashboard is designed to expand its monitoring capabilities to include more construction management-oriented metrics, such as excavated soil quantity for tracking work progress and machine utilization rates for optimizing resource allocation.

5 Conclusion and future improvement

This study demonstrates the development of a low-code-based PIS leveraging Node-RED platform to integrate construction planning with the coordinated operation of multiple construction robots. The PIS simplifies configuration of operational logic for civil engineers through an intuitive drag-and-drop interface, reducing the need for extensive programming knowledge. By ensuring compatibility with ROS middleware through the *rclnodejs* package, the system enables seamless integration with existing ROS-based robotic systems. Additionally, the PIS provides robust data visualization capabilities, offering real-time insights into the operational status of construction activities and robot performance. The prototype demonstrated the coordination of excavator and dump truck operations in an earthwork scenario using ROS topics and actions. This showcases the PIS's ability to unify isolated automated tasks into a collaborative framework that aligns with the overarching construction plan with minimized human intervention.

Future work will expand the system to include a bulldozer for soil leveling and a vibration roller for compaction to allow for a more completed configuration of work coordination among all machines involved in earthwork operations. This will enable the PIS to handle more complex scenarios and edge cases that account for real-world construction scenarios. The dashboard will also be improved by integrating additional relevant ROS topics to monitor more construction management-oriented metrics for quality and quantity control. Additionally, a more advanced physics engine-based simulation environment will be adopted to accurately model soil properties, material interactions and machine dynamics, ensuring robust testing before field deployment. Finally, the PIS is expected to be deployed on actual construction machines to validate its effectiveness and practical applicability in real-world settings.

Abstract -

The automation of construction vehicles and digitization using building information modeling (BIM) are currently two of the most popular research topics in the area of construction. This work combines the two areas by utilizing the information from a BIM model to enable a vehicle to localize and navigate through a building autonomously. A robot equipped with an industry arm should receive marking tasks, which specify a position to navigate to and positions to mark with the robotic arm. These tasks should mimic typical tasks on a construction site, like drilling or cutting holes. The localization within the building is based on LiDAR data, which are compared to the structure of the building, which was received from a BIM model. The path planning uses the BIM model to find a path to the target area. The concept is first tested in a simulation using the Unreal Engine 5, which imports the BIM model and uses simulated LiDAR scanners. Furthermore, the concept is evaluated using a real robot and a building consisting of three rooms and an area of roughly 100 square meters.

Keywords -

autonomous navigation, localization, building information modeling

1 Introduction

Digitalization using Building Information Modeling (BIM) and advancements in automation of construction machines are currently two popular research topics. On the one hand, the advancements with BIM aim to have fully digital documentation of construction sites to monitor the worksite's progress continuously. On the other hand, research in autonomous construction machinery aims to reduce risks for construction workers and mitigate the effects of the shortage of skilled labor. While there is research in both fields, only a few works aim to try to use digital models to improve the processes of autonomous robots. This paper presents an approach in which a robotic platform equipped with a robotic arm should drive through a building imitating a drilling task by marking spots on the inside walls. A BIM model of the environment is used as a knowledge base to localize within the building and to find a path to navigate to given target positions. The localization is done using a LiDAR scanner and is performed in two steps. First, the current room is detected by detecting the outline of the current room and comparing it to the outlines of the rooms in the BIM model. For precise localization, a match between the current scan and a scan of the earlier detected room is compared. By calculating the offset between the two scans and taking the robot's odometry into account, a more precise location within the room is determined. The navigation algorithm uses an elastic band fusion algorithm to navigate the building. As the knowledge base for this algorithm, a grid map is created out of the BIM model. Out of the map, some initial waypoints are calculated using a flood fill algorithm. These points are given to the elastic band fusion algorithm, which coordinates the robot's navigation. The concept is implemented in the Finroc framework[1], which is a framework for intelligent robot[1][2].

Figure 1. Image of Baubot MRS5-1920 from Baubot equipped with an MOTOMAN HC20DTP produced by YASKAWA.

The experiments are executed using the Baubot MRS5-1920[2], a robotic platform equipped with a

[1]https://www.finroc.org/

MOTOMAN HC20DTP robotic arm produced by YASKAWA[3](Figure 1). The experiments aim to drive to a given position within the model and then do a marking on a specified position at the wall. Experiments are performed in both simulations and real scenarios. Unreal Engine 5 is used for the simulation. Here, the BIM model is directly imported as a test environment, and a 3D model of the robot is imported. Both navigation and localization are tested using simulated LiDAR data [3]. For the experiment on the real robot, a setup with three rooms and a size of roughly 100 square meters is built. In this environment, the robot is moving through several rooms to a given target location. After reaching the location, the robotic arm marks a set of points on the wall. The position marked are adapted based on the position of the mobile platform. By doing so, some inaccuracies of the navigation can be compensated during the marking process.

The paper is structured in the following way. Section 2 introduces some previous works utilizing BIM models in the scope of robotic tasks and other related aspects as localization. Then in section 3 our developed system is introduced including the localization, path planning algorithm and the navigation. Section 4 shows the experiments in the simulation environment and with the real robot. Finally the work is summarized in the conclusion 5.

2 Related Work

While there are many theoretical concepts on how the information saved in BIM models could be used to support the use of autonomous robots in construction, only very few works use these concepts in real applications. The most common application utilizing a combination of BIM models and autonomous vehicles is the scanning and monitoring of construction progress. In this area, Pietro et al.[4] proposes a concept to monitor the progress of a construction site. They propose a robotic platform with a sensor setup suitable for the application. A general idea of how a map can be created based on a BIM model and which sensors are needed to localize within the environment is sketched. To validate the concept, simulated tests in a simplified environment are run. The same domain is tackled in the approach of Park et al.[5]. They are using a Spot robot to scan the progress in an indoor environment. They utilize BIM models to plan and optimize the scan positions that the robot has to approach. The target is to minimize the number of static scans needed to cover the whole environment, thus minimizing the needed time to scan the whole building. In future works, the scans should also be registered automatically to achieve a fully autonomous process. A similar approach with a different application is presented by Hu et al.[6]. They present an approach to monitor the air quality in an office environment, documenting it inside a BIM model. An autonomous robot drives through an office environment, measuring the air quality. The measurements are incorporated into the BIM model to help identify problems with air conditioning. Their experiments state a precision of roughly 0.10 m using a Velodyne-16 LiDAR scanner mounted on a four-wheeled mobile platform. The information from BIM models can also be utilized to improve various aspects of robotics, such as localization. Zhao et al.[7] use BIM models to solve the wake-up problem in indoor environments. By detecting features of the environment and matching them with the features saved in a BIM model, they manage to find the robot's position in an indoor environment. If there are not enough features at the robot's current position, the environment is explored until the position can be verified. Depending on the environment, the robot had to travel between 15 m and 50 m until finishing the initial positioning. Doing so, they achieve a translational precision of 0.15 m – 0.21 m and a rotational precision of1 1.2° – 2.4°. Another approach in which an autonomous robot is navigating based on a BIM model is presented by Iqbal et al.[8]. The approach uses a small miniature robot to draw floor plans on a sheet of paper. While this work integrated information from a BIM model to an autonomous robot, the application is far from real scenarios since it uses a small robot with a pen to draw two-dimensional floor plans on a sheet of paper. There are also general concepts on how to use BIM models without a specific application. For instance, Chen et al.[9] present a concept of using BIM models to do global path planning within an indoor environment. They use an Industry Foundation Class (IFC) file of the environment as a knowledge base and generate a map from it. Then, they use a modified A* algorithm to plan a path. The experiments are performed in a simplified building simulation and a model of an example robot. While there are already various concepts on how the models can be used in different scenarios, only very few works show how an autonomous robot can participate in the building progress while utilizing the information saved in BIM models.

3 Localization and Navigation Approach

In this work, two major problems of autonomous locomotion are tackled by utilizing the information saved in a BIM model. First, the robot should localize within the building, which includes identifying the current room and then detecting the precise position of the robot within this room. Second, the model is used to create a map of the building, which is the basis for planning a path to the target position and then navigating it while adapting to the current situation within the environment.

3.1 Localization

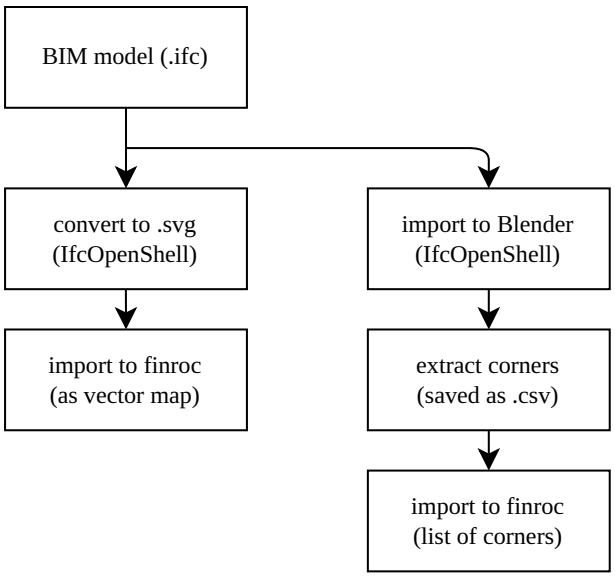

Figure 2. Processing pipeline to use the BIM model for the localization approach.

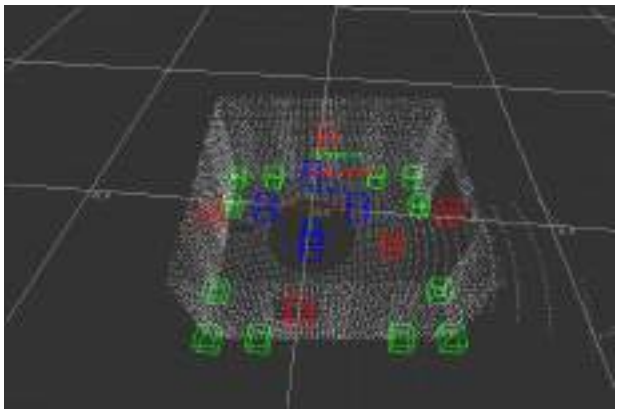

Figure 3. Visualization of feature extraction of a current LiDAR scan in the simulation. The green squares show the corners of the room together with the adjacent walls. The red squares represent the center of gravity of the wall depending on the number of points. The normals of every wall are visualized with the blue squares.

The foundation of our localization approaches is always the BIM model of the building we are currently in. We assume that the 3D model is up to date and contains all necessary components for localization and navigation. As explained in the introduction, we only utilize a LiDAR sensor to detect our environment, thus we are restricted to 3D geometries like walls and corners. We experimented with different pipelines for processing the BIM model stored in a .ifc file to generate a map we can use efficiently, resulting in the pipeline shown in Figure 2. In all of our approaches, we used the 3D modeling software Blender[4] which features an addon for visualizing, creating and working with .ifc files called BlenderBIM[5]. This allows us to use existing Blender features and export functionalities as well as writing our own python scripts inside Blender. Additionally, we made use of the open source IFC toolkit IfcOpenShell[6], e.g. for converting the .ifc file. For our first approach, we used the latter tool to export the BIM model as a .svg file. By doing so, we can interpret the basic geometrical shape of the rooms at a specific height and read the file into our Finroc framework. The downside of losing the Z dimension is neglectable since we extract the data at a specific height, only omitting the wall size. After having access to the building data, we can extract the corners with their corresponding wall normals. After we have created our map of the floor, we do the same for our current scan via the LiDAR sensor. A visualization can be seen in Figure 3. First, we filter the point cloud, then we extract the corners (green) and normal vectors of the wall (blue). As a result, we get a simplified point cloud consisting of corners and normals of the corresponding walls. We match this reduced room representation to our map of all corners using point cloud registration via RANSAC to get the estimated transform. This localization methods works well if we are in a relatively small room where we can see at least two corners. As a fallback, we use basic geometrical features in a similar matter. Similar to the approach by [10] we identify parallel and orthogonal walls since they are invariant to rotational changes and can be found both in the BIM model and the current LiDAR scan quite reliably. For the digital model, our preprocessing steps are similar to the ones we already explained. With the data in .svg format, we extract the walls, convert them into basic lines and extract orthogonal walls (corners) and parallel walls (corridors). In our current scan, we first filter the point cloud, project it to 2D and use the PCL library [11] to extract the walls. In the final step, we compare which features we currently see to what we have stored in the map and try to find the best match. The last influence of our localization is the position estimation based on odometry data we receive from the robot. For short distances, i.e. driving from one room to another, this data was accurate enough for our navigation. After reaching the middle of the room the other localization methods worked as a recalibration for the odometry error.

3.2 Navigation

The navigation approach consists of two parts. First, a map is generated from the BIM model. Then, the map is used to calculate a preliminary path, which points are used as initial guesses for an elastic band fusion algorithm.

3.2.1 Map Generation from BIM Model

For the navigation, the aim is to use the knowledge saved in the BIM model to create a map of the surroundings. In our scenario, we used the model to create a grid map with the basic structure of the building to be later enhanced with obstacles that can dynamically appear. To do so, some processing steps have to be performed. First, the BIM model available in the Industry Foundation Classes (IFC) format is converted to the Scalable Vector Graphics (SVG) format. The SVG format is usually used for vector graphics and is an efficient way to save geometries. The geometries of the SVG file are rendered to a two-dimensional matrix, which corresponds to the size of the grid map. The geometries' position relative to the BIM model's origin and the map's cell size are considered when mapping the geometries. Finally, the matrix is used to create a grid map in which each element intersecting with one of the geometries is marked as an obstacle in the map, and the other cells are marked as free. Figure 4 shows the BIM model of the test environment and the resulting gird-map. The small cell size for the grid map causes some issues during the calculation of the path planning algorithms. However, it is needed since the passages in the experiment environment are very narrow, considering the large size of the robot. Therefore, the small cell size is used to avoid further reduction of the available space by the map's resolution.

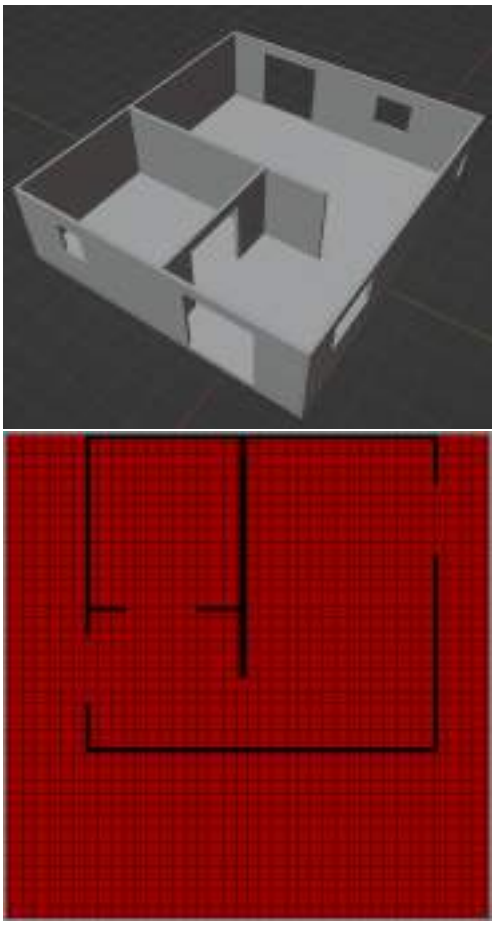

Figure 4. On top the BIM model of the test environment is shown. The image on the bottom shows the resulting grid map with a cell size of 0.06 m. Red indicates free areas and black indicates obstacles.

3.2.2 Elastic Band Fusion

For the actual driving, an elastic band fusion algorithm is implemented [12]. The elastic band method requires a path of target points, which finally leads to the target. Then, the robot always navigates to the next target point. The target points are adapted during navigation based on detected obstacles and the vehicle's position change. As soon as a point is reached, the next point is targeted. This procedure is done until the target is reached. In the case of the marking task, the robot turns to the correct orientation towards the wall after reaching the target point. To calculate the initial points for the algorithm, a flood fill algorithm [13] is used. The algorithm starts at the target pose and assigns to all neighboring cells the distance to the target, which is one in this case. Then, the algorithm iterates to all newly assigned cells and adds the previous cell's distance increased by one to the neighbors that do not have a distance assigned yet. After assigning a distance to the robot's current position, a path can be found by starting at the robot's position and always selecting a neighboring cell with a lower distance than the current one. Theoretically, each of the cells visited when selecting the path can be used as one initial point of the elastic bands algorithm. Since the cell size in our example map is extremely small, the number of points is too high for the algorithm. Therefore, only a subset of the cells is used as the initial target point. Therefore, using a simplified map for the flood fill algorithm, which has a larger cell size, is more meaningful.

The bubbles are created around the calculated target points and are later modified based on the robot's movement. Their size varies based on the critical obstacle, which is the closest obstacle to the bubble 5. The position of each intermediate bubble can be changed based on internal forces between neighboring bubbles, which represent the cohesion strength, and due to an external force, which pushes the point away from the critical obstacle.

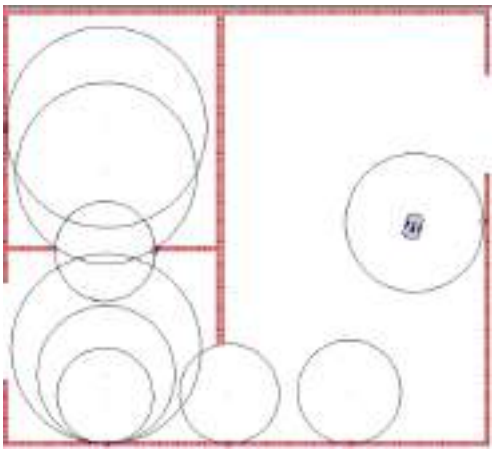

Figure 5. Initial points of the elastic bands fusion. The circles indicate the distance to the next obstacle. If the robots position changes or new obstacles are introduced to the map, the points adjust.

The internal force between two bubbles is defined in the following way

$$\vec{f}_{\text{int},ij} = \alpha_{\text{int}} \cdot \begin{cases} 0 & \text{if } ||\vec{c}_{bi} - \vec{c}_{bj}|| \leq \epsilon \\ \frac{\vec{c}_{bj} - \vec{c}_{bi}}{||\vec{c}_{bi} - \vec{c}_{bj}||} & \text{otherwise} \end{cases} \quad (1)$$

where c_{bi} and c_{bj} are the center points of the two adjacent bubbles. The external force is calculated based on the bubble's distance to the critical obstacle ($\vec{p}_i^*$).

$$\vec{f}_{\text{ext},i} = \alpha_{\text{ext}} \cdot \begin{cases} 0 & \text{if } r_{bi} \leq \epsilon \text{ or } r_{bi} \geq r_{\text{lim}} \\ \frac{r_{\text{lim}} - r_{bi}}{r_{bi}} \cdot (\vec{c}_{bi} - \vec{p}_i) & \text{otherwise} \end{cases} \quad (2)$$

The external force is only larger than zero if the critical obstacle is within the distance threshold r_{lim}. The only exceptions to this behavior are the first bubble, which is fixed to the robot, and the last one, which is fixed at the target position. The shift of a bubble c_{bi} in a discrete time step $t \rightarrow t+1$ is defined in the following way

$$\vec{c}_{bi,t+1} = \vec{c}_{bi,t} + \Delta\vec{c}_{bi} \quad (3)$$

where the delta is calculated based on the two internal forces between the bubble and its neighboring bubbles and the external force on the c_i. The delta is calculated by the sum of the two internal forces and the external force weighted with the value $\alpha_{tot,i}$.

$$\Delta c_{b,i} = \alpha_{\text{tot},i} \cdot \left(f_{\text{int},i,i-1} + f_{\text{int},i,i+1} + f_{\text{ext},i} \right) \quad (4)$$

Whenever the robot approximately reaches the next bubble, the reached bubble is removed, and the next one is chosen as the new target point. This procedure is continued until the bubble representing the target position is reached.

3.3 Marking

The marking task is performed by the robotic arm mounted on the platform. Due to the high precision achievable by the arm, it is responsible for compensating for inaccuracies in the platform's placement. During the marking task, the robot's base is not moving to avoid introducing additional errors. The general process of the marking task is simple. For the movement of the arm, the target positions are first transformed into the platform coordinate system and then into the local coordinate system of the robotics arm. Then, the TCP of the arm is moved to the desired positions. The movement of the arm is done by a function provided by the robotic arm, which is able to move the TCP to a desired local target position. Since only a global target position is given as input, the starting position of the marking progress is calculated to be 0.5 m in front of the marking position. Then, the arm is moved in small steps orthogonally towards the wall. In the target point calculation, the pose of the platform is considered to compensate for inaccuracies in its placement. Since there is no feedback from the arm indicating contact with the wall, a marking tool is used. This tool is equipped with a pen, which is pushed into the tool with a contact. A sensor indicates the contact of the pen. On contact, a new position is set on the arm, which is in front of the wall. As soon as this position is reached, the arm is either moved to the next marking point if another point is reachable from the current position, or the arm is moved back to the driving configuration to enable the platform to drive to the next position.

4 Experiments

To evaluate the concept, tests in simulation and a real test environment are performed. For both experiments, the same BIM model was used. For the simulated tests, the gaming engine Unreal Engine 5 is used. The real experiments are performed in an industry hall where an experimental building with three rooms is built. The setup of the two environments can be seen in Figure 6.

4.1 Hardware Setup

The mobile robot Baubot MRS5-19201 developed by the company Baubot[7] is used for the real experiments. The platform is equipped with the robotic arm MOTOMAN HC20DTP developed by Yaskawa. Additionally, the robot is equipped with an Ouster OS0 64 LiDAR scanner, which is used for perception, and an Intel NUC 13 pro as computing unit. The robot has a width of 1.26 m and a length of 1.88 m excluding the arm. Since the arm has a safety mechanism that is triggered whenever a specific torque

[7] https://www.baubot.com/

Figure 6. Test environment in the Unreal Engine simulation and the real test environment.

threshold is exceeded on the joint, the arm has to be placed in a specific driving position to avoid triggering this mechanism. Due to that, the length of the robot with the arm increases to roughly 3 m.

4.2 Simulated Experiments

A virtual environment based on the model is created for the simulated tests by importing the model into the simulation engine Unreal Engine 5 (Figure 6). Furthermore, a 3D model of the robot is used, which has the same properties as the real machine. Also, the sensors of the real machine are simulated, namely an Ouster OS0 64, the sensor of the marking tool, and the sensors measuring the inertial properties of the robot. In the simulated experiments, the parameters for the elastic band fusion algorithm are verified. Figure 7 shows the setup of the bubbles for a robot, starting in the small room and driving to the large one. The second image of Figure 7 shows the situation after the intermediate room is reached.

The resulting parameters are shown in table 1. The algorithm is also tested in larger environments proving the functionality.

Parameter	Value
r_{lim}	2.00
r_{robot}	0.90
α_{Int}	0.0001
α_{Ext}	0.0001
ϵ	0.050

Table 1. Parameter setup for the elastic band fusion algorithm

4.3 Experiments in Real Test Environment

In the experiments in the real building, the robot is placed in the small room, as also shown in the simulated experiments. Then, a position to drive to in the large room is selected, and a point to mark from this position. Then, the robot is enabled and starts driving to the target position. The initial localization is done using the LiDAR scanner. While driving mainly the odometry is used while resetting it from time to time with a new LiDAR position. The localization is done this way because the odometry is much more stable for short distances. In some places, especially while driving through a door, the LiDAR localization has large errors. Here, the odometry proved to be the best localization method. While driving through the doors, the navigation algorithm also tracks the robot's current room. By that, it is only needed to detect the current room in the beginning and track the current room afterward using the driven trajectory. In the real experiments, the elastic band failed in some cases. Those occurred due to the very narrow passages the robot has to drive. Because of that, fixed bubbles are generated within the middle of the doors and in front of the door in both connected rooms. By that, the robot was guaranteed to be approaching the door at an angle that enabled it to pass through. The most critical passage is shown in Figure 8. It can be seen that the margin for error while driving to the door is minimal, mainly because of the large length of the robot and the arm in the driving position. This issue only appeared in the shown passage. In the other cases, where the door is in the middle of the wall, the navigation is much easier since there is more space to maneuver the robot to pass through.

Figure 9 shows the two most relevant states of the marking process. The left image shows the inital position of the marker. Then the arm slowly moves perpendicularly towards the wall. Since there is very little room for the marker to move into the tool this movement was performed very slowly. As soon as the marker has contact to the wall as seen in the right image, the arm moves back to the driving position and the task is complete.

For obvious reasons, the main property of evaluating such a marking task is to check the accuracy of the marking position. During the process, there are multiple sources of

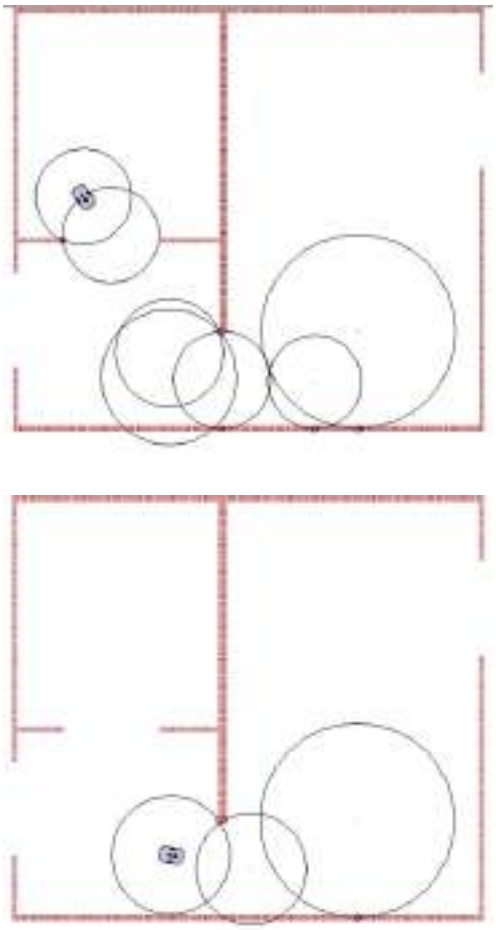

Figure 7. Bubbles of the elastic band fusion algorithm at the start and after driving half of the distance to the target position.

Figure 8. Robot driving through narrow passage in test building.

error, of which some can be optimized by the robotic platform, and some are introduced by the BIM model. During the test run, the precision of the marking varied between 0.2 m and 0.5 m. During the experiments, we found several error sources which have room for improvement. First, adjusting the arm movement to the possible imprecise positioning towards the wall introduced an error. This error grows with the difference between the desired perpendicular position and the actual position toward the wall. This can be either optimized by improving the precision of the driving of the platform or by improving the adaptation of the marking trajectory. The localization error introduces another issue. The quality of the LiDAR localization depends on the visual features as described in section 3. If the marking position is in an area with few features, the error increases. Another aspect that could improve the accuracies mentioned before would be to calibrate the sensors and the arm's position precisely. Currently, the positions are measured manually, which reduces overall precision. Those are the main error sources during our experiments. There are some smaller sources like the repetition accuracy of the arm, which can be up to 0.02 m, and the accuracy of the BIM model compared to the real building. While the accuracy is not yet suitable for real construction applications, improving the previously mentioned points could enable the robot to achieve much higher accuracy.

5 Conclusion

In this paper, an approach to using information from a BIM model to develop an autonomous robot for construction tasks is presented. The proposed concept uses the information to implement a localization approach based on point clouds and a planning and navigation approach. The aim is to navigate through a building while performing marking tasks with the robot's arm. The localization approach detects features of the current room to first identify the room the robot is placed in and then uses the features to precisely position itself within the room. For path planning, a grid map is created using the BIM model. Then, an elastic band fusion algorithm is implemented. A flood fill algorithm is used to find a suitable path to the target point. Then, this path is adapted based on the robot's current position and the LiDAR scanner's measured obstacles. Experiments in both a simulation and a real scenario evaluated the concept. The real tests are executed by a mobile

Figure 9. Robotic arm during the marking process. The left image shows the arm after moving into the initial position. The right image shows the arm after a contact before moving back to the initial position.

platform equipped with an arm. For these tests, a building with three rooms is constructed, and the robot navigates through this building to reach a target position. Then, it marks a given position with the arm. The experiments show that using the BIM model is sufficient for the localization and navigation tasks. Nevertheless, there is still room for improvement, especially regarding accuracy.

Abstract –

This case study examines the use of underwater robotic systems to assess cofferdam support faces prior to refurbishment. The inspection process employs a suite of specialized equipment, including a surface preparation robot, geometry measurement tools, and non-destructive testing (NDT) technologies for concrete delamination detection. The integration of these technologies enhances the accuracy and efficiency of structural assessments, ensuring comprehensive data collection and analysis while eliminating health and safety constraints for workers. The findings demonstrate the potential of robotic inspection systems to significantly improve the safety and effectiveness of dam infrastructure maintenance.

1 Introduction

Hydro-Québec has many hydroelectric generating stations and spillways, some of which were built more than 100 years ago. Our case study focuses on the La Gabelle dam (Figure 1) that celebrated its 100th anniversary in 2024. It has reached a point in its life cycle where some maintenances must be planned. To target the right intervention to restore the life of mechanical equipment and concrete structures, it is important to have quality data that is sufficiently representative of their condition.

In the case of the La Gabelle dam, spillway gates must be refurbished, thus requiring cofferdams to give dry access to workers. Before the cofferdams can be installed, piers' support faces must be inspected to ensure that the cofferdams will be adequately supported and offer appropriate watertightness.

Historically, divers conducted these inspections manually, leading to numerous operational and qualitative challenges. Among these, one can consider the health and safety risks for the divers associated with the dam's conditions (cracks, water infiltrations, etc.) and water currents. Additionally, significant doubt and uncertainty arise regarding the reliability of the measurements due to the following reasons:

- For measuring surface roughness, inspection is done visually using a ruler in turbid and turbulent water.
- For identifying delamination of concrete, inspection is done by manually hitting the concrete surface with a hammer and listening to the resulting sound wave through diving helmet.

To overcome these challenges, Hydro-Québec's Research Institute has developed robotic inspection solutions dedicated to the inspection of hydraulic dams and their features. This paper presents how these robotic solutions were used at La Gabelle to provide civil engineers with reliable measurements while avoiding the health and safety constraints associated with deploying divers in the water.

Figure 1. La Gabelle dam, upstream view of the concrete piers and inspection areas.

2 Surface Preparation

Before conducting laser measurement of geometry and concrete hammering, surface preparation must be conducted. The main purpose of this operation is to remove algae, mussels, and concrete parts weakly clinging on the surface. As shown in Figure 2, this is achieved using two cavitation cleaning domes mounted on a trolley, maneuvered by a multifunctional platform. The platform is shown in Figure 3. Rotating nozzles inside the domes create a strong suction force, ensuring the system remains in contact with the surface. The system can clean rough deposits like barnacles and mussels in up to 17 seconds per square meter, and for algae, it can clean a strip 0.89 meters wide at a speed of 0.5 meters per second.

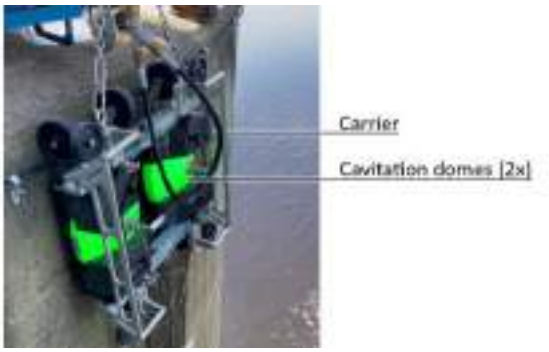

Figure 2. Cavitation cleaning system

The cavitation cleaning process involves water passing through specially shaped nozzles, generating millions of steam bubbles. These bubbles collapse upon hitting the surface, creating tiny pressure waves that remove scale and biofouling such as barnacles, algae, and mussels. This method is highly efficient, easy to integrate onto a carrier, and does not release any residue from the material itself.

Compared to other underwater cleaning technologies, cavitation cleaning is highly effective [1]. Ultrasonic and UV methods have limited capacity and slow efficiency in removing biofouling. Cavitation, bush rotary brushes and water jets achieves over 90% bio-fouling removal. Cavitation cleaning stands out with an efficiency range of 100-1500 m²/h, making it one of the most efficient methods available.

3 Geometry Measurements

Geometry measurements of the contact surfaces are required to evaluate the proper support and sealing of the cofferdams. Flatness and parallelism of the contacts will insure its proper operation. Geometry deviations may result from concrete swelling (e.g. alkali-aggregate reaction) or surface degradation. Erosion and spalling are often found within the tidal zone, where ice thrusts apply.

To assess the geometry, a survey team measured the contact surfaces on the dam, above and below the waterline. Surface digitization technologies are preferred. The resulting 3D point cloud data can be processed to generate vertical cross-sections and heat maps, effectively highlighting any deviation. Offering precision non-contact measurements, a Leica ATS-600 direct scanning laser tracker was used for measurement above the waterline.

Detecting damage on submerged structural elements is often challenging, especially when precision is required. To collect engineering-level three-dimensional measurements underwater, Hydro-Quebec developed the WireScan [2] [3], laser scanner for vertical surfaces that can achieve a ± 1mm accuracy in still water. The system is portable and deployed from the deck, eliminating the need for divers (Figure 3).

Figure 3. WireScan measurements on a spillway. Underwater scanning (top right). Modular multifunctional platform (left).

WireScan uses two plumb lines as vertical references, maintaining high precision over the range (10 meters at La Gabelle). Supported by its tether, the laser camera slides vertically along wires stretched by weights. Each scan covers approximately 400 mm wide and is positioned in the 3D space with reference spheres measured with the ATS-600.

As depicted in Figure 4**Erreur ! Source du renvoi introuvable.**, results show a large coverage of the top of both piers (with the ATS-600). Below the waterline, the scans focus on the narrow sealing surfaces. Surface damage is visible on the tidal zone just below the waterline.

From the 3D data, it is possible to measure:

- Verticality of the lifting plane
- Flatness defects on sealing surfaces
- Pier-to-pier width at the contact points

The results are shown in Figure 5. The left pier is deviated by +/-15mm around the vertical, while the right pier is deviated up to 60mm to the right. The

discontinuity on the left pier corresponds to the horizontal joint shown on the 3D scan.

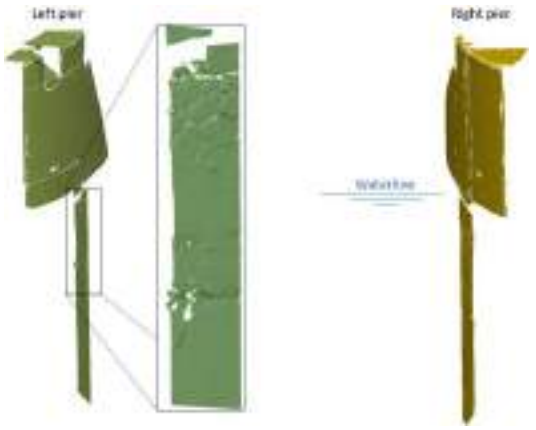

Figure 4. 3D scans of the cofferdam contact surfaces, La Gabelle.

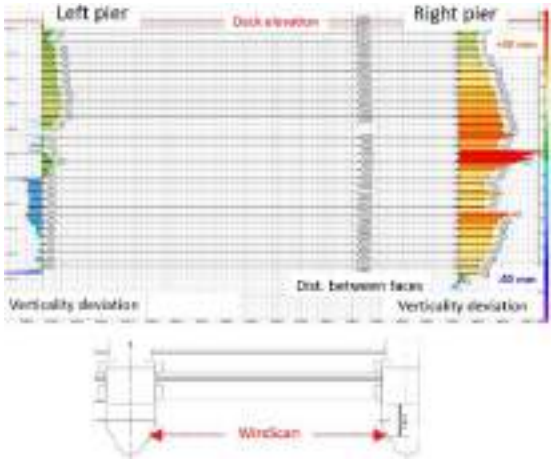

Figure 5. Measurement of the sealing surfaces, elevation view, La Gabelle.

4 Concrete Delamination Detection

To conduct delamination detection, we used an in house developed trolley, see Figure 6, equipped with a motorized hammer to perform impacts and with two hydrophones to acquire the resulting acoustic waves. Striking force consistency is improved compared to traditional methods by mounting the hammer on a shaft axially coupled to a servo motor. As the hammer rotates around the axis, it provides two impact points, 30 cm apart, enhancing inspection coverage. This setup allows precise control of the striking force and additionally offers insights such as the impact angle and the restitution factor. The impact angle can be used to detect surface imperfections, while the restitution force can help improve delamination detection and surface condition. Additional equipment has been mounted on the trolley: a camera and a line laser, allowing for detailed visual inspections and providing valuable information about the concrete's texture, and a vortex suction cup that keeps the trolley firmly attached to the concrete surface it is inspecting. The multifunctional platform mounted on top of the dam, shown in Figure 3, is equipped with a winch, and allows precise positioning of the inspection trolley over the concrete surface.

Figure 6. Hammering Trolley.

Hydrophones provide sound pressure resulting (in Pascals) of each impact. From there, we can calculate the sound exposure (see Equation (1)) where *p(t)* is the sound pressure reading from the hydrophone in respect to time t in seconds. Using Equation (2) & (3), we obtain the sound exposure level in a dB scale, sometimes referred as SEL_{SS} [4].

$$E = \int_{t_0}^{t_1} p(t)^2 \, dt \tag{1}$$

$$SEL_{SS} = 10 \log_{10} \frac{E}{E_0} \tag{2}$$

$$E_0 = 1 \cdot 10^{-6} \tag{3}$$

Sound exposure levels for each single strike, SEL_{SS}, are computed for each strike's respective duration, where $\Delta t = t_1 - t_0$ is approximately 80ms. In-air measurement would use a different reference level. E_0 and E are given in $Pa^2 \cdot s$.

System has been validated on a concrete block manufactured with known defects. We were able to determine with great accuracy the location of each defect embedded within the block. A software has been developed to map all the readings from an inspection into a heat map, see Figure 7. Our software enables the playback of each impact individually allowing reviewer to determine if a specific section if subject to

delamination. Further improvements could be envisioned such as use of Impact-Echo method [5]. However, surface roughness could pose a challenge in producing high-frequency compression wave.

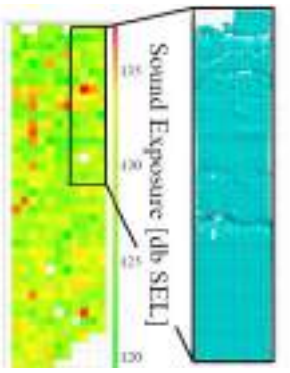

Figure 7. Hammer strike (left) vs WireScan (right).

When compared to measurements obtained from the WireScan, both inspection tools were able to find areas where wears and tears are present. The variation in sound exposure across the inspected surface (+/- 5 %) is not significant enough to correlate with delamination.

5 Conclusion

The adoption of robots in construction projects is anticipated to rise in the coming years, driven by their numerous benefits, including enhanced worker safety, consistency, and precision, among others. In this case study, we demonstrated how robotized inspection solutions developed at Hydro-Québec's Research Institute were successfully used to obtain surface roughness measurements and to assert presence of concrete delamination on concrete piers at the La Gabelle dam prior to the installation of cofferdams. The benefits expected from the use of robots were confirmed accordingly.

As a starter, all the operational constraints related to health and safety concerns over divers conducting inspections were eliminated. This should be sufficient to justify the robotic inspection project, as the health and safety constraints for divers are so restrictive that, at times, inspection phases of piers are completely abandoned, leading to cofferdam installation work being planned without data on the actual condition of the concrete, which has historically resulted in significant cost overruns.

Additionally, the inspection data that was delivered to the civil engineering team at Hydro-Québec provided unpreceded analysis capabilities. As compared with traditional inspection methods, which only provide maps with approximate areas that require attention, we provided millimeter precision surface roughness measurements, quantitative impact maps that reflect the state of concrete delamination, audio files for playback of all the impacts, and inspection videos. This valuable data will not only enable civil engineers to take more accurate decisions, reducing the risk of cost overruns, but also allow them to compare inspection data of different dams and at different moments of their lifespan, which will inevitably lead to a better understanding of concrete degradation mechanisms.

While the robotic inspection systems demonstrated significant advantages in terms of safety, precision, and data quality, there are still some limitations to consider. One major limitation is the requirement for easy and large access to the top of the structure directly above the inspection area. This can be challenging in certain dam configurations or when overhangs are present, which may obstruct the deployment of the inspection equipment. Additionally, the current system's effectiveness can be hindered by extreme underwater conditions, such as high turbidity or strong currents, which may affect the accuracy of the measurements and the stability of the robotic platforms. Future developments should focus on enhancing the adaptability of the robotic systems to various structural configurations and improving their performance in diverse underwater environments.

Abstract -

Tower cranes are essential in the construction industry and play a critical role in lifting and transporting materials. Despite significant advancements in the construction industry, a comprehensive framework for simulating tower crane operations and an Actions Management Node (AMN) to coordinate these operations effectively are currently lacking. This research presents a comprehensive framework that integrates a full-scale tower crane model with the Robot Operating System (ROS) and simulates its functionalities using a physics-based simulation. The framework not only facilitates operational-level control of a real-scale tower crane, but also incorporates the action management node that abstracts the complexity of crane functionalities. This abstraction enables users to provide a high-level control plan that the action manager executes with precise and efficient sequences of actions to lift and transport materials. The proposed framework, along with the action management node, is evaluated through a physics-based simulation in two different scenarios where construction components are transported from initial positions to designated target locations. The results demonstrate the framework's capability to effectively handle all crane operations, demonstrating its scalability and strong potential for real-world applications in tower crane automation.

1 Introduction

Rapid industrialization and urbanization drive a growing demand for housing, factories, and infrastructure as productivity in the construction industry remains stagnant [1, 2]. Tower cranes (TCs) are the most important equipment on construction sites and play a critical role in lifting and transporting structural materials such as steel beams and columns and concrete segments. In addition, TCs are used for the placement of prefabricated elements and heavy equipment, which is important for the assembly of structural frameworks and the installation of machinery. As a result, the overall productivity of construction projects is significantly influenced by the effective planning of crane operations. In addition, in industrial settings such as power plants, TCs are utilized to assemble heavy machinery and shipyards to transport containers and large equipment.

In practical scenarios, operations managers and planners often rely on their experience and subjective judgment to design lift plans, utilizing only 2D drawings or static 3D models [3]. Typically, planners evaluate crane accessibility to material pick-up and placement points and provide approximate estimations of lift task durations. However, these evaluations fail to consider the real movements and dynamics of the crane under operational settings on site [3]. These static planning methods can lead to inefficient and impractical plans for crane operations, compromising the effectiveness of the entire lifting process [4].

Therefore, the efficient operation of TCs on construction and logistics sites plays a critical role in reducing the time required for each load while maintaining safety standards for workers and operators. In this context, the robotization of TC and automation of its operations not only significantly enhance operational efficiency but also improve overall productivity, since the overall productivity of construction projects is heavily affected by the proper planning and operations of a TC [5]. Furthermore, this automation reduces human errors, operational risks, and enables precise load handling. Therefore, the capabilities of TCs make them crucial across various sectors, particularly in the construction industry, to improve productivity and efficiency, and robotization of TCs is an important step toward the envisioned robotized construction site [6].

Numerous studies have explored various aspects of tower cranes in planning, operation, control strategies, and automation techniques. In particular, several research studies investigate various aspects of tower crane controllers, highlighting advancements in control strategies [7–10]. A sliding mode control scheme was developed to enhance the control performance of 5-DOF TCs by precisely driving the trolley, jib, and hook to their target positions while suppressing payload swings caused by unknown payload masses, friction, and wind disturbances,

without relying on linearization techniques [10]. Another approach employed data-driven methods to reduce path tracking and positioning errors in automated TCs without permanently integrating additional sensors. This method used a regression model to predict path errors, enabling the computation of a compensatory hook path that ensures the measured trajectory closely aligns with the desired one [1]. Additionally, an offline trajectory planning algorithm was proposed to guide payloads along multiple straight connection lines formed by waypoints, with smooth transitions calculated at their intersections, further enhancing path planning precision [11].

In particular, significant research has been achieved in the field of robotic TCs to automate and improve crane operations [5, 12–16]. A motion compensation algorithm was developed for multi-step speed control to achieve the exact displacement based on dynamically optimizing the time duration at each planned velocity [13]. A re-planning module developed constitutes of a Decision Support System (DSS) and a Path Re-planner (PRP) based on a decision-making algorithm to enable near real-time collision-free path optimization [16]. To address operational challenges, an automated lifting path tracking system was developed to eliminate the 'blind spot' issue in tower crane operations [17]. This system incorporated laser devices to assess its feasibility across varying environmental conditions and dynamic payload swinging scenarios. Furthermore, [15] proposed an automated lift path planning method for tower cranes based on point clouds and utilizes an octree-based sampling strategy to generate a roadmap. However, existing planning approaches often do not consider lifting time considerations and face frequent infeasibility in planned paths. To overcome these limitations, [5] introduced a reinforcement learning (RL) algorithm that replicates human decision-making processes by determining actions based on visual inputs. This system employs a lidar sensor to detect surrounding obstacles, thereby preventing collisions and enhancing operational safety, like a human operator. Additionally, [12] developed time-varying linear quadratic regulators (LQR) for trolley and jib control employing a proportional-integral-derivative (PID) method. The proposed controllers were evaluated through the ROS framework and Gazebo simulator. In addition, a robotic truck crane system (RTCS) was developed in a simulation environment and was validated by a small-scale prototype of a truck crane [14].

To enhance productivity in the construction industry, a crucial step is the development of robotized tower cranes capable of transporting objects without the need for expert operators. However, achieving this level of automation requires prior simulation due to the safety risks and costs associated with real-world testing. Therefore, a framework that simulates TCs's operations in realistic scenarios in construction and logistic sites is the first step towards the automation of TCs. This framework should then provide various construction site scenarios and transportation tasks. These can provide better management of TCs and provide precise operation time per load, which can be used for real implementation. The simulation and automation of TCs have the potential to improve efficiency, ensure safer operations, and maximize productivity, especially in construction environments where multiple TCs are in use.

This study presents a comprehensive framework that emphasizes action handling and simplifies the complexities of operational-level commands. It achieves this through the development of an action management node, which translates user-provided high-level plans into precise instructions for the tower crane's controller, enabling the seamless execution of desired motions. The framework, built on the ROS [18], leverages its capabilities for robotic automation and machinery control. ROS provides the best middleware that enables seamless integration of various nodes, allowing for real-time communication between modules and efficient message parsing. To validate the proposed action management node and framework, we integrated them with the Gazebo simulator [19] and conducted simulations using various scenarios involving different objects. The results demonstrate the effectiveness of the framework in simulating tower crane operations with precision and reliability.

The rest of the paper is organized as follows: A detailed description of the tower crane model used in this research is presented in section 2. Following that, Sections 3 and 4 outline the design and implementation of the Action Management Node and the simulation framework, respectively. Section 5 presents the results, demonstrating the effectiveness of the proposed framework. Lastly, Sections 6 and 7 deliver a discussion of the results and conclude the study.

2 Tower Crane Modelling

A tower crane comprises several key components, including the ground base segment, body segment, climbing segment, cabin and motors, apex, counterweight segment, jib base, main and last segments, trolley, cables, and hook, as shown in Figure 1. These components collectively determine the operational workspace of the crane. Adjustments to the working space can be achieved by adding or removing body and jib segments, enabling customization to meet specific site requirements.

Tower cranes, particularly hammerhead tower cranes, are often modeled as five-degree-of-freedom (5-DOF) nonlinear dynamic systems [10]. Three DOFs are actuated—jib rotation, trolley movement, and hoisting cable operation—while two are unactuated, representing radial and tangential swinging. The generalized coordinates for the actuated DOFs are γ (jib rotation), x_t (trolley posi-

tion), and l_h (hoisting cable length). For the unactuated DOFs, the generalized coordinates are ϕ (tangential swing) and θ (radial swing). Figure 1 provides a schematic representation of a robotized tower crane, highlighting its structural components, jib segments, and trolley-hook assembly, which are responsible for its core functionalities.

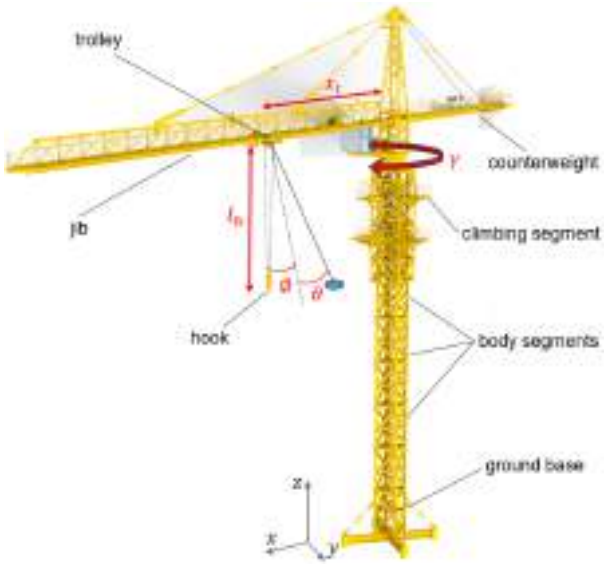

Figure 1. Schematic representation of the tower crane investigated in this study. The red color shows the DOFs of the tower crane.

This study focuses exclusively on the three actuated DOFs, treating the tower crane as a 3-DOF robotic arm. The unactuated DOFs, representing pendulum-like swings, are beyond the scope of this work. The jib, similar to a robotic arm, is mounted on the structural component (known as a mast) and driven by an electric motor coupled with a gear mechanism, allowing rotational motion. The trolley, which moves radially along the jib, is controlled by a cable-driven mechanism powered by a second electric motor. Finally, a pulley system operated by a third electric motor facilitates the vertical hoisting of loads.

The complete action functionalities of the three actuated DOFs are implemented and simulated in this study as part of a robotized tower crane model. This approach underscores the crane's operational capabilities while abstracting complexities related to the unactuated DOFs, ensuring a focused investigation of its robotic aspects.

The initial models of TCs are typically designed in formats such as .prt (Siemens NX) or .SLDPRT (SolidWorks). To integrate these models into robotics frameworks, they must be converted into formats compatible with simulation environments. This process involves modifying CAD files, converting their formats, and generating simulation-supported description files. These description files serve not only to define the crane's geometry but also to provide physical properties, including mass, inertia, joint limits, connections, and kinematics. In addition, modifying CAD files allows for minimizing the computational complexity of the simulation while preserving the operational and behavioral accuracy of the tower crane.

These steps are crucial, as they allow the ROS framework to effectively interpret the connectivity and relative motion of the crane's components, ensuring accurate simulation and control of the robotized tower crane.

3 Action Management Node

The main tower crane operations are gripping the load, lifting, transporting from one location to another, lowering, and releasing [12]. The Action Management Node (AMN) is responsible for handling all these operations by receiving high-level plans from users and converting them to low-level commands that can be used by the TC's planner and controller. The AMN incorporates all the functionalities of a TC within completely separate actions, enabling the transporting of objects from their initial positions to desired target locations. The AMN processes input data such as the object's name and the required sequence of operations, which are then transmitted to the planning and control nodes for the execution.

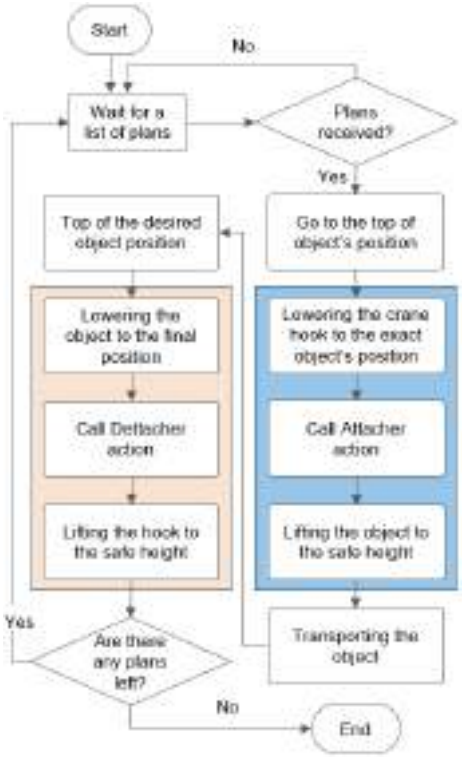

Figure 2. High-level flowchart illustrating the entire process of Action Management Node

The developed node provides continuous feedback to the user, enabling real-time tracking of the crane's status during execution. After completing the operation, the AMN sends a final status result to the user. Notably, the user can interrupt and cancel an operation at any stage of execution, ensuring flexibility and safety.

The workflow for a complete operation, from transporting an object from its initial position to its designated target location, is depicted in Figure 2. This process involves a series of sequential actions organized into three main phases: transportation, lifting (blue box), and placement (orange box). Each phase includes specific actions to ensure the precise and safe handling of materials during crane operations. The lowering action is for operational accuracy, while the lifting is critical for maintaining safety. The AMN incorporates a dedicated action to raise the hook to a predefined safe height, thereby minimizing the risk of collisions during transportation.

Given the assumption of a robotized tower crane, two additional actions, Attacher and Detacher, are introduced to perform tasks traditionally handled by human operators, securing the object to the hook and releasing it at the target location. These actions enable the system to autonomously handle objects, ensuring the same operation. When the tower crane hook reaches the object, the AMN executes the attach plan, securely attaching the object to the hook. At the target location, upon receiving the detach plan, the AMN releases the object. This automated workflow ensures efficient and reliable execution of tasks in an autonomous robotic tower crane system.

4 Simulation Framework

To simulate and control the tower crane, several core modules are essential, including the TC modeling, planning, control, and simulation, each composed of multiple sub-modules, as shown in Figure 3. These modules manage the entire process, from crane modeling to executing motion plans within the simulation environment. ROS [18], provides the best middleware that enables seamless integration of various nodes, allowing for real-time communication between modules and efficient message parsing. Furthermore, ROS's modular architecture supports scalability, enabling the addition of new functionalities or modifications to existing modules without disrupting the overall system's integrity. This enables continuous enhancement of the framework, ensuring its adaptability to various operational scenarios and evolving requirements in the construction industry.

Once the crane model is loaded into the system, the state publisher node continuously broadcasts the joint states and transformations of the crane, ensuring that its positions and orientations are consistently updated. This allows other modules, such as motion planning and control, to access

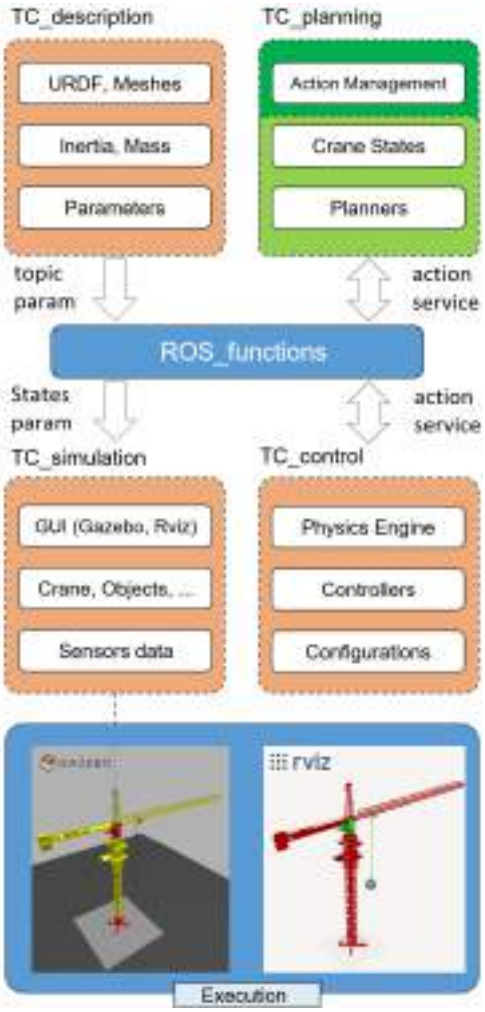

Figure 3. Flow diagram of the simulation framework

up-to-date kinematic data of the crane's current state.

A motion planning node was developed for transportation operations using MoveIt! [20], considering the crane's configurations and properties to ensure accurate and reliable motion planning. This node generates a trajectory consisting of a sequence of joint positions, defining the crane's motion from its initial state to the desired target position. Each joint position in the trajectory is associated with a specific timestamp, defining a time-parameterized trajectory. Once this trajectory is generated, a controller is required to drive the system's joint states to follow the planned positions at the corresponding timestamps.

A controller node was developed by adapting and enhancing existing control libraries originally designed for robotic manipulators. The control node ensures smooth and precise crane movements by implementing acceleration and deceleration profiles, optimizing motion dynamics for efficiency and accuracy. It interfaces with Gazebo

[19], a physics-based simulation environment, to simulate and execute planned trajectories. The controller operates as a closed-loop system, generating control commands for the crane model while continuously receiving real-time feedback to ensure accurate trajectory tracking and execution.

The action management node integrates this iterative feedback mechanism, enabling it to monitor the execution process and send the results to the user. This feedback loop continues until the controller either successfully completes the planned actions or sends an error message for the AMN. By incorporating this functionality, the AMN equips the tower crane with advanced action planning capabilities tailored to various construction scenarios.

5 Results

In this section, the simulation results of the tower crane operations using a physics-based simulation environment are presented. To evaluate the performance and effectiveness of the proposed framework, we utilized Gazebo, a widely-used simulation tool that allows for testing and validation in a virtual environment prior to real deployment. Gazebo simulates the dynamics of the crane, including the effects of gravity, friction, and other physical forces, such as wind and magnetic fields, which are crucial for accurate real-world operation. To validate the proposed framework, two transportation scenarios with different object types and different initial and target positions were evaluated within simplified construction sites. The simulation results presented here demonstrate the framework's ability to accurately replicate tower crane operations, validate motion planning algorithms, and assess the crane's performance in various dynamic conditions.

5.1 Conexes plan

Figure 4 shows the sequential steps involved in transporting conexes from their initial positions to their target locations. The process is systematically divided into six distinct stages for each conex. The detailed breakdown of these stages is as follows:

(a) Action Processing: The Action Management Node (AMN) receives and processes the user-defined plan and initiates the sequence of actions required to execute the operation.

(b) Initial Positioning: The conex is positioned on the ground, prepared for lifting. The AMN starts the plan, beginning with the "Picking" action. This step involves determining the exact initial position of the conex within the workspace.

(c) Object Attachment: The object is attached using the attachment action. To avoid potential collisions with surrounding components in the construction site, this step incorporates a controlled movement in the z-direction.

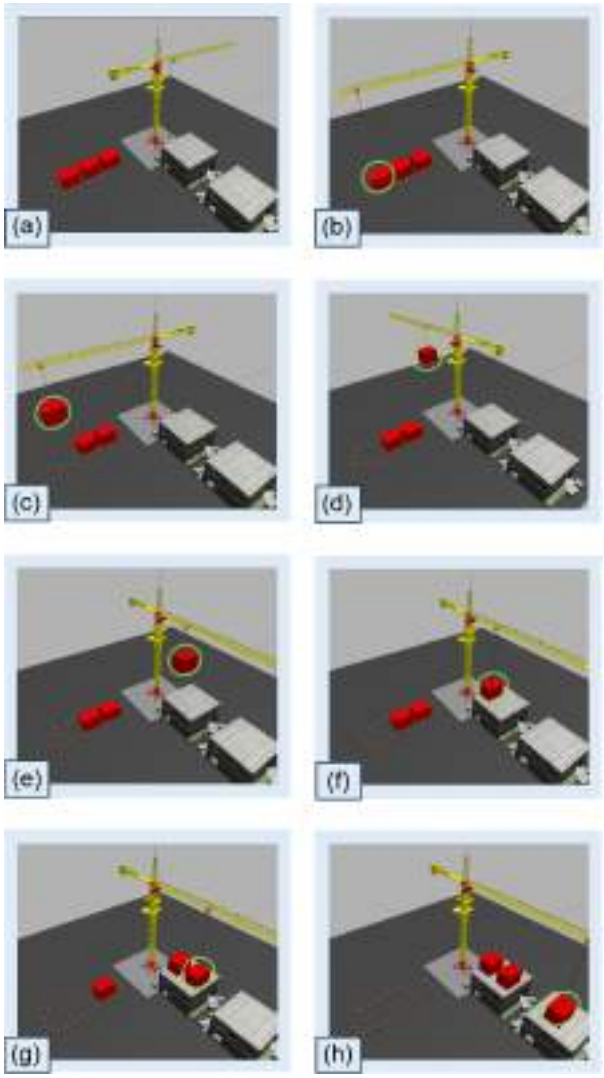

Figure 4. Objects transporting sequences: (a) home position, (b) picking position, (c) attaching the first object, (d) transporting the object, (e) placing position, (f) detaching the first object (g) placing the second object, (h) placing the third object

(d) Object Transportation: The system computes the optimal trajectory for transporting the conex from its initial position to a point directly above the target location, considering TC's working space and controller parameters. This step ensures collision-free movement.

(e) Object Placement: The conex is precisely placed at the target location. To avoid collisions, the AMN

employs accurate control for object placement in this step.

(f) Object Detachment: Finally, the conex is detached from the hook mechanism. Depending on the operational requirements, the crane either returns to its home state or proceeds with plans for the next objects.

(g) ,(h) Placement of the second and the third objects

This approach highlights the AMN's capability to efficiently manage complex transport scenarios while ensuring precision and safety throughout the operation.

5.2 Beams plan

Figure 5 shows another scenario for transporting construction material—beams, in this case—from source place to the destination. This transportation process includes several crane motions for each beam from precise lifting, transporting, and placing. Figure 5 shows: (a) the initial positioning of beams in the construction site, (b) the transportation phase where the crane is actively maneuvering the elements along trajectories, and (c) the final placement at the designated target positions.

Each stage is illustrated with detailed top-down views. The material source area, highlighted in blue, is located at the rear of the TC where beams are initially placed. These beams must be transported to the target area, highlighted in green, positioned at the top of the building within the construction site. The Action Management Node (AMN) executes the transportation plan sequentially for each beam, continuing the process until the entire plan is successfully completed or an error is encountered.

The evaluation scenarios involving conexes and beams validate the proposed AMN and the framework. These tests demonstrate the framework's ability to achieve precise positioning of materials and enable efficient crane operations. The results show the framework's potential to meet the operational requirements of real-world construction environments.

6 Discussion

This study introduces and evaluates a comprehensive framework for automating tower crane operations using robotic frameworks. The proposed system integrates TC functionalities within a physics-based simulation environment, supporting both operational-level control and high-level plans. By abstracting the complexities of crane operation, the framework allows users to control the TC without the need for an expert operator. In addition, the action management node demonstrated its effectiveness in two different scenarios, confirming its feasibility and robustness toward automation planning.

This study focused on controlling the actuated joints of the tower crane within a realistic simulation environment, excluding radial and tangential swings from its scope. The assumption is ideal, but the hoisting could experience swing and rotation due to wind or inertia of mass during object transportation. These dynamics are external to TC functionalities and are typically compensated through control strategies and algorithms. It is also important to note that robotic simulators, such as Gazebo, rely on rigid

body dynamics and do not natively support flexible or non-rigid structures. However, the flexibility of TC components, such as ropes, can be approximated by modeling them as chains of rigid links. While this approach closely replicates real-world dynamics, it significantly increases computational load on physics simulation.

Future research will address cable swings and tower crane structural deformation by integrating advanced mathematical models or sensor-based feedback control methods to enhance the accuracy and realism of the framework. Furthermore, we plan to deploy our framework to a scaled-down version of a tower crane in the future.

The modular and scalable nature of the framework allows for its extension to other crane types by providing their unique configurations, characteristics, and operational requirements. Additionally, the framework is built on the Robot Operating System (ROS), which facilitates seamless integration of distributed nodes through robust communication protocols and acts as a layer of abstraction on top of robotic hardware (actors and sensors) or simulation engines, such as Gazebo. Although the current implementation is optimized for Gazebo, the framework can be adapted to interface with other physics engines. However, this would necessitate additional development efforts to address differences in communication protocols and simulation interfaces.

Finally, this framework holds the potential to interface with real-world tower cranes in future applications, provided the cranes are equipped with suitable drivers to enable external connections. However, limitations and specific requirements should be considered when transitioning the framework to real-world operations to ensure reliability and accuracy in practical scenarios. These limitations include safety and compliance issues, as implementing a fully or semi-autonomous robotic crane in construction environments requires compliance with strict safety regulations and industry standards, which may impose additional design and operational constraints. Furthermore, sensor and localization challenges must be addressed, as precise localization of the crane and its load depends on sensor accuracy. External disturbances, and calibration errors could degrade performance, particularly in outdoor construction sites. Additionally, due to the increased communication between the framework and sensors, high-performance computing resources are required to handle real-time data processing and motion planning efficiently.

7 Conclusion

This research presents a simulation framework and action management node for planning and control of the jib, trolley, and hoisting using high-level information from the user and translating them to sequences of actions for the tower crane operations. The developed framework is validated on the physics-based simulator with a real-scaled tower crane model. The developed framework is scalable to a real TC as far as the desired data types are provided to the ROS framework.

Abstract –

Infrastructure inspection requires balancing coverage and detail for effective assessment. This paper presents a multi-robot inspection system combining aerial and ground platforms through a hierarchical approach. A hexacopter drone performs rapid site mapping, while specialized ground robots (hexapod and tracked variants) conduct detailed inspections. The system implements bidirectional learning where aerial mapping guides ground robot deployment, while ground inspection data refines aerial strategies. Multi-modal sensor data integration uses an Extended Kalman Filter framework to create unified structural health representations. Experimental results demonstrate 96.3% feature extraction accuracy, sub-millimeter registration between sensors, 3.2-second anomaly response time, and 99.7% collision-free operation. The system shows significant potential for inspecting large-scale infrastructure including bridges, industrial facilities, and power plants.

Keywords –

Multi-robot Inspection; Infrastructure Assessment; Sensor Fusion; Hierarchical Strategy; Bidirectional Learning.

1 Introduction

Infrastructure forms the backbone of modern society, enabling transportation, energy distribution, and industrial operations. Maintaining this critical infrastructure is essential for ensuring public safety, economic stability, and operational reliability. However, traditional manual inspection methods face significant challenges, including time constraints, labor intensity, and accessibility limitations, particularly in large-scale or hazardous environments [1,2].

Recent advances in robotic inspection systems have demonstrated promise in addressing these challenges through automation [3–5]. Single-platform solutions, such as autonomous drones or ground robots, offer improved efficiency and accessibility compared to manual methods [6–8]. However, these systems often struggle to balance comprehensive coverage with detailed examination. Aerial platforms excel at rapid site mapping but typically lack the resolution for detailed structural analysis, while ground robots provide high-fidelity inspection data but are limited by slower operational speeds and restricted mobility. Furthermore, existing robotic inspection systems typically operate with limited adaptability, following predetermined paths without the capability to dynamically adjust their strategies based on real-time environmental feedback [9]. This rigid approach can result in inefficient resource utilization and potentially missed critical areas, particularly in complex or evolving inspection environments.

This paper presents a novel multi-robot inspection system that addresses these limitations through a hierarchical strategy combining aerial and ground platforms. The system employs a specially equipped hexacopter drone featuring 30m-range LiDAR, 4K RGB imaging, and high-resolution thermal sensors for preliminary site mapping, working in concert with specialized ground robots - a hexapod capable of navigating 30° inclines and a tracked variant offering 0.1mm crack detection resolution.

A key innovation of our approach lies in its bidirectional learning mechanism, where inspection strategies are continuously refined through real-time data sharing between platforms. The aerial module efficiently generates preliminary site maps using RANSAC-based segmentation for feature extraction, while ground robots provide high-fidelity inspection data through contact-based sensors and close-range imaging. This collaborative approach is enhanced by a sophisticated sensor fusion framework that integrates visual, thermal, and LiDAR data through an Extended Kalman Filter, achieving sub-millimeter registration accuracy. The system implements a market-based task allocation strategy with token-based access control, enabling efficient coordination between platforms while preventing inspection conflicts. This coordination is

further optimized through a Q-learning based adaptation framework that continuously refines inspection strategies based on accumulated experience and environmental feedback. Experimental results demonstrate 96.3% accuracy in feature extraction and 3.2-second anomaly response time. The system maintains 99.7% collision-free operation while reducing overall inspection time, establishing new benchmarks for automated infrastructure assessment. These achievements suggest the potential for widespread adoption in various infrastructure maintenance applications, from bridge inspection to industrial facility assessment.

2 Related Works

Infrastructure inspection has evolved significantly from traditional manual methods to increasingly automated approaches. Manual inspection methods, while detailed, face substantial challenges including time constraints, labor intensity, and accessibility limitations [10]. These limitations become particularly acute in large-scale infrastructure inspection, where human inspectors often struggle to access critical areas safely and efficiently [11]. Recent advances in robotics have introduced various single-platform solutions for infrastructure inspection. Aerial platforms, particularly UAVs, have demonstrated considerable success in rapid large-scale inspections. Tu and Liang [6] developed a UAV-based bridge inspection system achieving comprehensive coverage through automated flight paths. However, these aerial systems typically sacrifice detail for coverage area.

Multi-robot systems have emerged as a promising solution to address the limitations of single-platform approaches. Cacace et al. [12] demonstrated the advantages of combining aerial and ground robots for industrial facility inspection, but their approach did not implement bidirectional learning between platforms. Yang et al. [13] explored a hierarchical inspection strategy for bridge monitoring, albeit without a comprehensive sensor fusion framework. More recent studies have advanced multi‐robot sensor fusion by emphasizing robustness and adaptability. For instance, Amorim et al. [14] introduced a modified particle filter that robustly fuses visual data from multiple robots to track targets even under severe occlusion, effectively mitigating sensor limitations. Zhou et al. [15] leveraged graph neural networks to combine multi‐view visual information, significantly enhancing individual robot perception accuracy and resilience to sensor failures. Sensor fusion techniques have become increasingly crucial in infrastructure inspection. Huang et al. [16] developed a framework for integrating visual and thermal data in structural assessments, while Nam et al. [17] implemented LiDAR-visual fusion for enhanced defect detection. However, these approaches typically focus on single-platform applications.

Adaptive path planning and learning mechanisms represent a growing focus in robotic inspection systems. Zhang et al. [18] implemented reinforcement learning for optimizing UAV inspection paths, while Zhao et al. [8] developed adaptive navigation strategies for ground robots in complex environments. The integration of market-based task allocation in multi-robot systems, as demonstrated by [19], has shown promise in optimizing resource utilization, though primarily in controlled laboratory settings.

3 Methodology

The multi-robot inspection system combines complementary aerial and ground platforms. The aerial drone uses 3D point cloud technology for large-scale mapping and identifying regions of interest. Ground robots (hexapod and tracked variants) perform detailed inspections of these areas with high-resolution sensors, enabling in-depth structural analysis.

3.1 System Architecture

As shown in Fig. 1, the system architecture is designed to facilitate seamless communication and collaboration between the aerial and ground platforms. A centralized control system coordinates the activities of both modules, ensuring an efficient and adaptive inspection workflow. Each platform is equipped with wireless communication modules to enable real-time data sharing and bidirectional learning.

The aerial module consists of a custom-designed hexacopter drone equipped with an integrated sensor suite. At its core is a primary LiDAR sensor offering 30m range with 0.5° angular resolution, complemented by a 4K RGB camera providing a 120° field of view. Thermal imaging capabilities are delivered through a FLIR (Forward Looking Infrared) camera with 640×512 resolution. An onboard computing unit handles real-time data processing, while an RTK (Real-Time Kinematic) GPS system ensures precise positioning with ±2cm

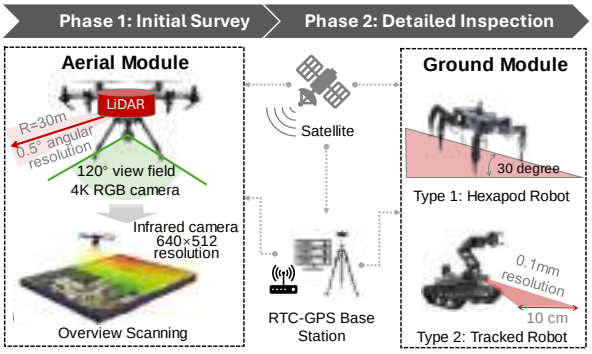

Figure 1. System with inspection phases overview

accuracy.

Two specialized ground robots complement the aerial system. The first is a hexapod robot featuring a 6-legged configuration with 18 degrees of freedom. This platform can carry a 2.5kg sensor payload and navigate terrains with up to 30° incline. Its sensor package includes high-resolution contact sensors for surface analysis and close-range LiDAR for detailed geometric mapping.

The second ground platform is a tracked robot designed for stability and precision. Operating at a maximum speed of 0.5 m/s, it incorporates an integrated stabilization system for precise measurements. The robot carries a specialized surface crack detection camera capable of 0.1mm resolution at 10cm distance for comprehensive structural analysis.

The proposed multi-robot inspection system integrates aerial and ground platforms. The system state at time t can be represented as:

$$S(t) = \{P_{a(t)}, P_{g(t)}, M(t), R(t)\} \quad (1)$$

where $P_{a(t)}$represents the aerial platform state, $P_g(t)$ the ground robot states, $M(t)$ the environmental map, and $R(t)$ the set of identified regions of interest.

The aerial platform state is defined as:

$$P_a(t) = [x_a(t), v_a(t), \omega_a(t), E_a(t)]^T \quad (2)$$

where $x_a(t) \in \mathbb{R}^3$ is position, $v_a(t) \in \mathbb{R}^3$ is velocity, $\omega_a(t) \in \mathbb{R}^3$ is angular velocity, and $E_a(t)$ is remaining energy.

For ground robots, each platform state is:

$$P_g^i(t) = \left[x_g^i(t), v_g^i(t), \theta_g^i(t), E_g^i(t)\right]^T \quad (3)$$

where i denotes the specific ground robot (hexapod or tracked).

The system employs a mesh network topology operating wireless communication. Communication reliability is ensured through redundant channels, while edge computing nodes enable distributed processing. A central server coordinates data fusion and mission control operations across all platforms.

3.2 Hierarchical Inspection Strategy

The system implements bidirectional data flow between platforms. The aerial platform provides global site mapping updates, new Region of Interest (ROI) identifications, mission priority adjustments, and environmental hazard alerts to ground units. Conversely, ground robots transmit high-resolution inspection data, updated anomaly classifications, local environment maps, and status information to the aerial platform.

Phase 1: Initial Survey

The aerial platform initiates inspection using cellular decomposition for coverage planning, operating at altitudes between 30-50m for overview scanning. The system maintains a 60% overlap ratio to ensure accurate 3D reconstruction, generating real-time point clouds with density exceeding 100 points/m².

ROI identification employs RANSAC-based segmentation for feature extraction, coupled with geometric analysis for anomaly detection. The system conducts thermal mapping to identify subsurface defects. Priority scoring incorporates geometric deviation thresholds exceeding 2cm, thermal gradient anomalies greater than 5°C, surface texture irregularities, and structural criticality indices.

The hierarchical inspection strategy prioritizes regions based on a combined score:

$$Score(ROI_i) = \beta_1 C(ROI_i) + \beta_2 A(ROI_i) + \beta_3 D(ROI_i) \quad (4)$$

where $C(ROI_i)$ is criticality, $A(ROI_i)$ is accessibility, and $D(ROI_i)$ is detection confidence for region i.

Phase 2: Detailed Inspection

The detailed inspection task allocation follows a dynamic assignment protocol based on robot capabilities. The system employs a comprehensive cost function incorporating distance to target, robot specialization, battery status, and inspection priority. Ground robot deployment utilizes the enhanced RRT* (Rapidly Exploring Random Tree) algorithm for path planning, complemented by a dynamic window approach for obstacle avoidance. The sliding window optimization approach periodically refines local trajectories based on updated environmental information and inspection requirements. This optimization considers multiple objectives including minimizing path length, maximizing sensor coverage, and maintaining stable sensor positioning for high-quality data collection. The refinement process incorporates feedback from both successful and failed inspection attempts, building a knowledge base that informs future planning decisions.

3.3 Sensor Fusion Framework

The system fuses multi-modal data streams from complementary sensors (Fig 2-a). The aerial platform uses LiDAR for structural mapping, thermal imaging for temperature analysis, and high-resolution cameras for surface inspection. Ground robots carry enhanced versions of these sensors with superior resolution for detailed close-range examination.

3.3.1 Data Collection and Synchronization

The data collection process maintains precise temporal alignment through hardware-level synchronization, achieving millisecond timing accuracy across all sensors. Each measurement receives accurate timestamps and position tags, enabling coherent data integration. The system implements rigorous calibration procedures to optimize intrinsic sensor parameters, establish inter-sensor transformation matrices, and compensate for environmental factors that could affect

measurement accuracy.

Data preprocessing begins with adaptive threshold filtering to remove noise while preserving critical structural information. The system applies statistical outlier removal techniques and motion compensation algorithms to ensure data quality. A crucial step in the pipeline involves spatial alignment of LiDAR, thermal, and visual data streams using advanced registration algorithms. This process creates a coherent multi-modal representation of the inspection site, where each data point combines structural, thermal, and visual information.

The LiDAR data provides precise 3D structural information, capturing geometric features with millimeter-level accuracy. Thermal imaging data reveals temperature variations that may indicate subsurface defects, material fatigue, or thermal stress patterns not visible to other sensors. High-resolution visual data enables detailed surface analysis, particularly for identifying cracks, corrosion, and material degradation. The fusion of these complementary data streams enables the detection of complex structural anomalies that might be missed by single-sensor approaches.

The multi-modal sensor fusion process combines data from different sensors using a weighted fusion approach:

$$F(X) = \sum_{i=1}^{n} w_i S_i(X) \tag{5}$$

where $F(X)$ is the fused data point, $S_i(X)$ represents individual sensor measurements, and w_i are confidence weights satisfying $\sum_{i=1}^{n} w_i = 1$.

3.3.2 Feature Extraction and Unified Data Integration

The feature extraction phase employs multiple specialized algorithms working in parallel. Visual feature extraction utilizes SIFT/SURF algorithms to identify surface anomalies, while geometric processing identifies structural deviations from expected patterns. Thermal pattern recognition algorithms detect temperature anomalies and track thermal gradients across structural elements.

Feature confidence scoring is calculated as:

$$C_f = \alpha_v Q_v + \alpha_t Q_t + \alpha_l Q_l \tag{6}$$

where Q_v, Q_t, and Q_l represent quality metrics for visual, thermal, and LiDAR data respectively, with $\alpha_v + \alpha_t + \alpha_l = 1$.

The final stage of sensor fusion employs an Extended Kalman Filter for state estimation, combining the extracted features into a unified structural health assessment. Point cloud registration using Iterative Closest Point (ICP) algorithms ensures precise spatial alignment of all data sources. The system implements confidence-weighted integration of features from different modalities, prioritizing the most reliable data sources for each type of structural assessment.

3.3.3 Sensor Modalities Alignment and Visualization

The alignment of different sensor modalities is achieved through a transformation matrix:

$$T = \begin{bmatrix} R & t \\ 0 & 1 \end{bmatrix} \tag{7}$$

where $R \in SO(3)$ is the rotation matrix and $t \in R^3$ is the translation vector.

The fusion framework produces comprehensive inspection outputs including detailed 3D textured meshes overlaid with thermal data. These visualizations combine geometric, thermal, and visual information into an intuitive representation of infrastructure health. The system generates detailed defect mapping and classification reports, along with confidence metrics for each detected anomaly. Quality assessment metrics provide quantitative measures of inspection coverage and data reliability, enabling informed decision-making for infrastructure maintenance planning.

By integrating diverse sensor data streams and employing advanced processing algorithms, the framework achieves superior inspection accuracy while minimizing false positives. The resulting unified representation of infrastructure health provides unprecedented insight into structural conditions, enabling more effective maintenance planning and risk assessment. The implementation of our sensor fusion framework leverages several established open-source libraries: Point Cloud Library (PCL v1.12.1) for point cloud processing and registration [20], OpenCV (v4.7.0) for image processing and feature extraction [21], and Robot Operating System (ROS Noetic) for inter-platform communication and data synchronization [22]. The RANSAC-based segmentation utilizes optimized implementations from the MRPT (Mobile Robot Programming Toolkit) [23].

3.4 Path Planning and Adaptation

The path planning and adaptation framework (Fig. 2-b) implements a hierarchical strategy that combines global coverage optimization with reactive local navigation. This multi-layered approach enables efficient site inspection while maintaining robustness to environmental changes and emerging inspection requirements.

3.4.1 Global Planning and Multi-Robot Coordination

The global path planning optimization problem is formulated as:

$$\min P \sum_{k=1}^{K} \left(\lambda_1 E(p_k) + \lambda_2 T(p_k) + \lambda_3 R(p_k)\right) \tag{8}$$

subject to:

$$|v(t)| \leq v_{max}, |\omega(t)| \leq \omega_{max}, E(t) \geq E_{min} \quad (9)$$

where $E(p_k)$ is energy cost, $T(p_k)$ is time cost, and $R(p_k)$ is risk cost for path segment p_k.

The system uses modified Boustrophedon decomposition [24] to partition inspection space efficiently, considering structural complexity, accessibility, and priorities while minimizing energy consumption. A global planner creates a task dependency graph for mission scheduling, employing dynamic programming to optimize resources based on battery constraints, sensor capabilities, and real-time requirements. A distributed coordination framework with token-based access control prevents inspection conflicts, using a market-based approach where robots bid for tasks based on position, battery life, and capabilities. Real-time communication enables continuous strategy refinement between aerial and ground platforms.

3.4.2 Local Navigation and Reactive Control

The system implements a multi-layered navigation framework where each robot platform employs specialized algorithms optimized for their mobility characteristics. At its core, ground robots utilize an enhanced RRT* algorithm for local path planning, which integrates real-time obstacle detection and dynamic avoidance capabilities. This planning framework continuously maintains optimal safety distances while ensuring comprehensive inspection coverage through trajectory adjustments based on real-time sensor feedback.

Task allocation within the system follows a sophisticated dynamic assignment protocol that evaluates robot capabilities through a comprehensive cost function. This function synthesizes multiple parameters including Euclidean distance to target, platform-specific specialization factors, current battery levels, and inspection priority weights. The cost function for task assignment can be expressed as:

$$\mathrm{C_{task}(r,t)} = \alpha_\mathrm{d} \mathrm{D(r,t)} + \alpha_\mathrm{s} \mathrm{S(r,t)} + \alpha_\mathrm{b} \mathrm{B(r)} + \alpha_\mathrm{p} \mathrm{P(t)} \quad (10)$$

where $D(r,t)$ represents the distance cost between robot r and task t, $S(r,t)$ is the specialization matching score, $B(r)$ indicates battery level, and $P(t)$ denotes task priority. The weights α_i satisfy $\sum \alpha_i = 1$.

The local navigation system incorporates a dynamic window approach for reactive obstacle avoidance, which optimizes robot velocity v and angular velocity ω within an admissible velocity space: $V_a(x) = (v,\omega)\,|v \in [0, v_{max}], \omega \in [-\omega_{max}, \omega_{max}],\ v \leq \sqrt{2 \cdot dist(x,obs) \cdot a_{max}}, |\omega| \leq \sqrt{2 \cdot \theta(x,obs) \cdot \alpha_{max}}$ where $dist(x,obs)$ is the distance to the nearest obstacle and $\theta(x,obs)$ is the angular deviation.

Trajectory optimization occurs through a sliding window approach that periodically refines local paths based on updated environmental data and inspection requirements. The optimization objective function combines multiple criteria:

$$J(\tau) = w_1 \int_t^{t+T} L(\tau(t))dt + w_2 \int_t^{t+T} C(\tau(t))dt + w_3 \int_t^{t+T} Q(\tau(t))dt \quad (11)$$

where $L(\tau)$ represents path length, $C(\tau)$ denotes coverage quality, and $Q(\tau)$ indicates sensor positioning stability. The weights w_i are dynamically adjusted based on inspection priorities.

3.4.3 Adaptive Learning and Environmental Response

The adaptation framework incorporates reinforcement learning techniques to continuously improve navigation and inspection strategies. The learning system maintains a state representation that includes current position, sensor coverage metrics, and environmental features. Action selection is guided by a policy that balances exploration of uncertain areas with exploitation of known inspection requirements. The reward function considers multiple objectives including coverage completeness, data quality, and energy efficiency.

For adaptive learning, the Q-learning update rule is:

$$Q(s_t, a_t) \leftarrow Q(s_t, a_t) + \alpha[r_t + \gamma \max_a Q(s_{t+1}, a) - Q(s_t, a_t)] \quad (12)$$

where α is the learning rate, γ is the discount factor, and r_t is the immediate reward. This optimization considers multiple objectives including minimizing path length, maximizing sensor coverage, and maintaining stable sensor positioning for high-quality data collection. The refinement process incorporates feedback from both successful and failed inspection attempts, building a knowledge base that informs future planning decisions.

This adaptive capability, combined with the continuous learning and optimization processes, ensures consistent high-quality inspection results across diverse infrastructure types and operating conditions.

4 Simulation Experiment

4.1 Experimental Setup

The evaluation of the proposed multi-robot inspection system was conducted through comprehensive simulation experiments designed to test the hierarchical inspection strategy, sensor fusion framework, and adaptive path planning capabilities. The simulation environment was developed using ROS Gazebo, incorporating physics-based modeling to ensure realistic robot-environment interactions and sensor behavior.

The test environment (Fig. 2-c) was designed as a construction site spanning 20 × 20 m with corridor widths ranging from 1.5 m to 3 m. The environment features

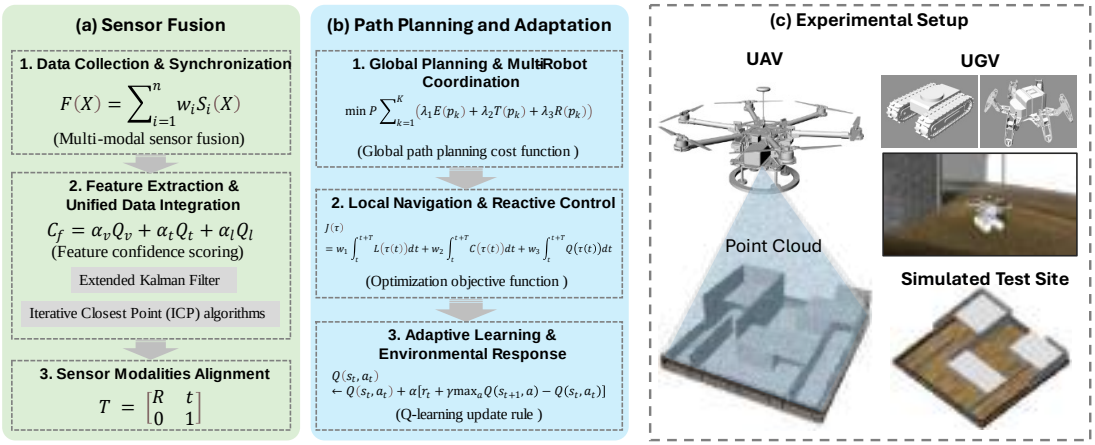

Figure 2. Methodology: (a) Mathematical framework for Sensor Fusion (b) Mathematical framework for Path Planning and Adaptation (c) Experimental Setup with UAV and UGV models

vertical structures representing construction scaffolding, with heights varying between 2 m and 6 m. The site contains both uncovered regions and areas beneath uncompleted floors, creating zones that are unflyable for UAV operation. Predefined structural anomalies were strategically placed throughout the structure, including surface cracks (0.5-2mm width), thermal variations (±5°C from baseline), and geometric deformations (2-5cm deviation from design specifications).

The simulated aerial platform matched the specifications detailed in the methodology, featuring a hexacopter configuration with 30m-range LiDAR (0.5° angular resolution), 4K RGB camera (120° FOV), and FLIR thermal camera (640×512 resolution). The RTK-GPS simulation provided ±2cm positioning accuracy. The ground robots included both the 18-DOF hexapod with 5kg payload capacity and 30° incline capability, and the tracked variant with 0.5 m/s maximum speed and 0.1mm crack detection resolution at 10cm distance.

4.2 Test Scenarios

The experimental protocol was structured to validate the three core components of the system: hierarchical inspection strategy, sensor fusion framework, and adaptive path planning. The simulation implemented the mesh network topology described in the methodology, with wireless communication between platforms and edge computing nodes for distributed processing.

The aerial platform's initial survey followed the cellular decomposition strategy outlined in the methodology, operating at 30-50m altitude with 60% overlap ratio for accurate 3D reconstruction. The point cloud density exceeded 100 points/m², enabling RANSAC-based segmentation for feature extraction. ROI identification utilized the priority scoring system defined in Equation 4, incorporating geometric deviations exceeding 2cm and thermal gradients greater than 5°C.

Ground robot deployment implemented the enhanced RRT* algorithm for path planning, with the sliding window optimization approach for trajectory refinement. The simulation tested the dynamic assignment protocol using the comprehensive cost function from Equation 9, evaluating distance, specialization, battery status, and inspection priority for task allocation.

4.3 Experimental Workflow

The simulation workflow followed the sensor fusion framework detailed in the methodology, implementing millisecond timing accuracy for data synchronization across all platforms. The data preprocessing pipeline included adaptive threshold filtering and motion compensation, followed by spatial alignment of LiDAR, thermal, and visual data streams using the transformation matrix defined in Equation 7.

Feature extraction employed SIFT/SURF algorithms for visual anomaly detection, while geometric processing identified structural deviations. The Extended Kalman Filter state estimation integrated extracted features according to the confidence scoring system defined in Equation 6. The ICP algorithm ensured precise spatial alignment of multi-modal data, with confidence-weighted integration prioritizing the most reliable data sources for each type of structural assessment.

The adaptive learning framework utilized the Q-learning update rule specified in Equation 11, with the reward function considering coverage completeness, data quality, and energy efficiency. The market-based coordination approach managed simultaneous operation of aerial and ground platforms, with the token-based access control mechanism preventing inspection conflicts.

5 Results and Discussion

The simulation experiments validated the effectiveness of our hierarchical multi-robot inspection

system through comprehensive performance evaluation of its core components. The aerial platform's global path planning optimization achieved exceptional efficiency, generating high-density point clouds (127 points/m²) that exceeded design specifications while maintaining precise positioning (±2cm accuracy). This preliminary mapping capability directly enhanced the RANSAC-based segmentation process, achieving 96.3% accuracy in feature extraction and enabling optimal task allocation for ground robots. The system generates three primary output data types from our simulation environment: structural point clouds, multi-spectral inspection maps, and classification metadata. Data is processed both onboard for real-time decisions and offloaded for comprehensive offline analysis. Outputs are formatted for BIM compatibility, enabling integration with existing infrastructure management systems. Offline processing requires approximately 45 minutes per 1000m² on standard engineering workstations.

Building upon this foundation, the sensor fusion framework demonstrated superior integration of multi-modal data streams. The transformation matrix achieved 0.7mm alignment accuracy between sensor modalities, while the weighted fusion approach dynamically adjusted confidence weights to optimize anomaly detection.. This integrated approach resulted in 95.4% accuracy for surface anomaly detection (calculated as TP/(TP+FP+FN) against 200 ground-truth annotations) and 98.2% precision in thermal pattern recognition (TP/(TP+FP)). Sensor integration errors influenced inspection performance through registration misalignment (2.8% of false detections), temporal synchronization drift (1.3% of measurements), and sensor-specific noise (±1.7% threshold variation). The system mitigated these effects through dynamic confidence weighting based on estimated reliability factors from signal-to-noise ratios and registration quality metrics.

The adaptive path planning system further enhanced these capabilities through efficient resource utilization. The enhanced RRT* algorithm, combined with the dynamic window approach, maintained path deviations within 2.8cm. This optimization extended to the Q-learning based adaptation framework, which achieved 3.2-second response times to new anomalies while maintaining 99.7% collision-free operation through the token-based access control mechanism.

The experimental results demonstrate the significant advantages of our integrated approach to infrastructure inspection, particularly in addressing the traditional trade-off between coverage and detail. The hierarchical strategy's success stems from the effective combination of aerial mapping capabilities with specialized ground robot functions, enabling comprehensive inspection while maintaining high data fidelity. This integration proves especially valuable in complex structural environments, where the system's adaptive capabilities ensure thorough coverage while optimizing resource utilization. The bidirectional learning mechanism's performance highlights the importance of real-time adaptation in infrastructure inspection. This improvement directly translates to more reliable structural health assessments, with the multi-modal approach effectively identifying both surface and subsurface defects that might be missed by conventional inspection methods.

Table 1. Performance of each system component

System Component	Metric	Performance
Mapping & Detection		
Aerial Mapping	Point Cloud Density	127 points/m²
	Feature Extraction Accuracy	96.30%
Anomaly Detection	Visual Detection Accuracy	95.40%
	Thermal Pattern Recognition	98.20%
Sensor Integration		
Multi-Modal Fusion	Registration Error	0.7mm
	Data Synchronization	<1ms
Navigation & Control		
Ground Robot Navigation	Path Deviation	2.8cm
System Adaptation	Anomaly Response Time	3.2s
Platform Coordination	Collision-Free Operation	99.70%

6 Conclusion

This paper presents a novel multi-robot inspection system that effectively addresses the fundamental challenges in infrastructure assessment through a hierarchical strategy combining aerial and ground platforms. The system's core innovation lies in its bidirectional learning mechanism and advanced sensor fusion framework, which enable dynamic adaptation to complex inspection environments while maintaining high data fidelity. Through comprehensive simulation experiments, we demonstrated that this integrated approach achieves significant improvements in both efficiency and accuracy compared to traditional inspection methods.

The experimental results validate our hierarchical inspection strategy's effectiveness, with the aerial mapping achieving 96.3% feature extraction accuracy while the ground robots maintained precise navigation within 2.8cm path deviation. The sensor fusion framework demonstrated exceptional performance through sub-millimeter registration accuracy and 3.2-second anomaly response time.

With robust performance across key metrics, the system shows significant promise for broad adoption in infrastructure maintenance. Its 99.7% collision-free operation sets a new standard for collaborative robotic inspection, confirming the feasibility of integrating multiple sensing modalities. Future work should explore deep reinforcement learning and advanced noise reduction for sensor fusion. Implementing wireless map

communication between aerial and ground platforms warrants further investigation to address bandwidth, latency, and signal degradation. Field experiments will measure communication reliability, assess data compression for point cloud transmission, and introduce fault-tolerance protocols to ensure stable operation in varied environments.

This research advances automated infrastructure inspection by presenting a scalable, efficient solution that balances comprehensive coverage with detailed examination. The demonstrated improvements in inspection efficiency and accuracy could significantly enhance infrastructure maintenance, ultimately boosting public safety and structural reliability. Despite promising results, limitations include the simulation environment's imperfect mimicry of real-world conditions, high computational demands for real-time sensor fusion, and potential performance drops in adverse settings. Future efforts will focus on field validation, algorithmic optimization for edge computing, fault detection, and integrating additional sensor modalities such as ground-penetrating radar and acoustic emissions monitoring.

Abstract –

Rebar tying is a critical yet time-consuming process in construction, often criticized by high labor intensity, repetitive motions, and low efficiency. These challenges have led to the development of rebar tying robots, which offer a promising solution to automate and enhance the process. However, existing rebar tying robots are unable to deal with varying orientations of working surface in practical environments, making it difficult for cameras to consistently maintain an ideal pose. To address these challenges, this paper proposes a vision-guided camera pose estimation method. This method includes three steps: (1) image preprosessing, (2) feature point detection and matching, and (3) transformation matrix calculation. Through these steps, the optimal camera pose can be estimated from images captured at random initial poses, allowing the camera to autonomously adjust to its ideal pose. Furthermore, an image evaluation method is introduced, forming a feedback loop with the pose estimation process to ensure high-quality image capture. The proposed method achieves a 99.5% success rate for pose estimation within three attempts, with an average computation time of 1.05 seconds. This approach helps improve the efficiency and accuracy of rebar tying operations, facilitating the automation of the rebar tying process for planar rebar cages.

Keywords –

Rebar tying, Camera pose estimation, Computer vision, Feature point matching, Rebar cage

1 Introduction

Rebar tying is a labor-intensive and repetitive process in rebar product manufacturing, often leading to physical strain [1] and reduced efficiency. To mitigate these challenges, rebar tying robots have been developed, such as Tybot [2], TOMOROBO [3], and RBBD-Bot2.0 [4], reflecting a trend toward automation in rebar tying.

Most rebar tying robots rely on vision guidance for their operations [5,6,7], mainly dealing with horizontal rebar meshes, where the camera is fixed to the robot body and does not require pose adjustments. However, in practical applications, rebar cages may be placed in various orientations, such as horizontally for composite slabs and vertically or inclined for T-beams and box girders in bridges, requiring adaptive adjustments to the camera pose. A 6-Degree-of-Freedom (DoF) robotic arm allows flexible positioning, ensuring that the camera maintains a perpendicular view of the rebar mesh, as shown in Figure 1. Additionally, efficient rebar tying requires that (1) the captured rebar mesh area remains rectangular (as shown in Figure 1); (2) rebar intersection points do not align with image edges, minimizing overlap and optimizing tying efficiency. Manual camera adjustments are time-consuming and impractical in fast-paced environments, necessitating an autonomous pose estimation method.

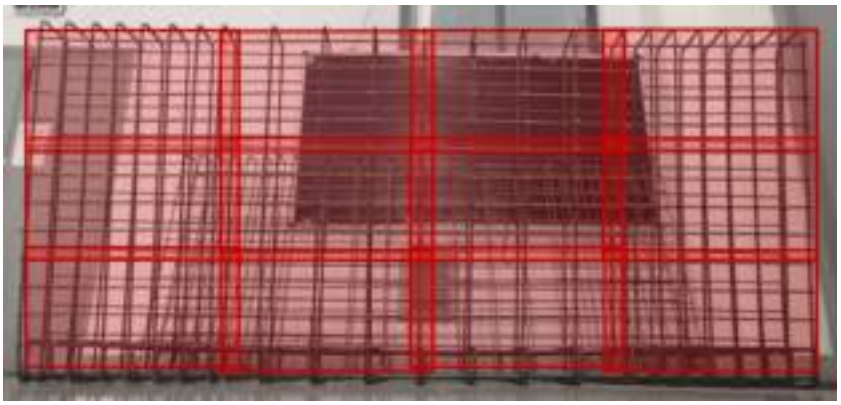

Figure 1. A rebar mesh divided into multiple rectangular work areas

Camera pose estimation involves determining the camera's position and orientation in 3D space, often using feature point matching techniques such as SIFT [8], SURF [9], and ORB [10]. However, these traditional methods struggle with rebar cages due to their uniform structure, leading to mismatches and inaccurate results.

Recent deep learning advancements, such as SuperPoint [11] and SuperGlue [12], have improved feature point detection and matching. SuperPoint provides high-quality keypoints and descriptors, while SuperGlue, based on Graph Neural Networks (GNN) [13], enhances matching accuracy. This study integrates SuperPoint, SuperGlue, and the Perspective-n-Point (PnP) algorithm to achieve accurate and reliable camera pose estimation.

To address the challenges posed by varying rebar cage orientations, this paper proposes a computer vision-based camera pose estimation method with two key innovations: (1) integrating a feature detector, a feature matcher, and PnP algorithm to determine the optimal camera pose from randomly initialized images, and (2) incorporating an image evaluation mechanism to establish a feedback loop for autonomous pose adjustment. This enables rebar tying robots to achieve optimal camera pose adjustment, improving operational efficiency and accuracy.

2 Method

The proposed method comprises three modules as illustrated in Figure 2: (1) image preprocessing; (2) the 6-DOF pose estimation of the camera; (3) image evaluation.

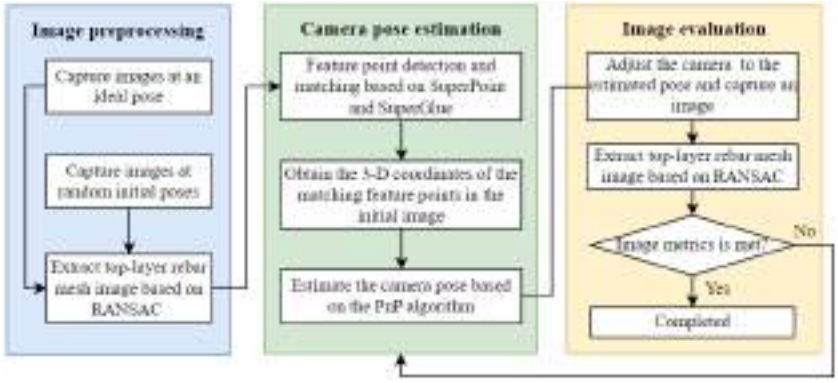

Figure 2. The workflow of the proposed method

2.1 Image Preprocessing

The proposed method requires two inputs: an RGB image and depth map, captured in an ideal pose and random initial pose, respectively. The RGB image and depth map captured in random initial poses are intended to consider the effects from the unanimous ground vehicle (UGV), which will be deviated due to its low positioning accuracy and complicated construction sites. This deviation causes the Z axis of the structured light camera, mounted at the end of the robotic arms, hard to maintain perpendicular to the top-layer rebar mesh of

the rebar cage.

The raw RGB image captured by the structured light camera contains excessive background information, making image matching and rebar crosspoints recognition difficult. To address this, it is essential to filter the background information of the raw RGB image. The process follows these steps: (1) align the captured RGB image and depth map to obtain the 3D point cloud of the rebar cage; (2) the point cloud of the top-layer rebar mesh is contained in the plane closest to the camera's optical center, which is the origin of the camera coordinate system; (3) a method based on RANdom SAmple Consensus [14] (RANSAC) is adopted to fit planes; (4) the plane closest to the camera's optical center is extracted.

After extracting the plane closest to the optical center of the camera, the point cloud belonging to this plane can be obtained. The pixel coordinates corresponding to the point cloud date can be calculated by depth values and the camera's intrinsic matrix, and an RGB image with background information removed can be obtained.

2.2 Camera Pose Estimation

This section describes a method for estimating the optimal camera pose based on RGB images and depth maps captured from a random initial pose. Initially, we perform feature point detection and matching on two filtered RGB images, which have excluded background information. Then, based on the coordinates of these matched feature points, the PnP algorithm is used to obtain the estimated camera pose.

2.2.1 Detect and Match the Feature Points

Recently, a significant number of algorithms have been substantially applied to detect the feature points between two images captured in different poses, such as FAST corner detector [15], SIFT, ORB, etc. However, these algorithms cannot cope with RGB images in complex scenarios, which exhibit poor robust during the process of detecting. Therefore, we adopt an approach based on neural network named SuperPoint, which can detect the feature points without manual annotations. After that, utilize a matching algorithm named SuperGlue to match feature points.

SuperPoint is a self-supervised network for training feature point and descriptors. In this framework, the authors trained a full convolutional network (FCN) based on synthetic dataset, which includes simple geometric shapes with no ambiguity in the feature point locations named MagicPoint. However, this pre-trained network performs poor performance in real dataset. As a result, they introduced Homographic Adaptation for boosting performance from synthetic dataset to real dataset. Finally, this framework can efficiently detect the location of feature points and provide descriptors for feature points. In this paper, we created a dataset consisting of 375 preprocessed rebar cage images as the training dataset for SuperPoint. These images were captured by the camera from different shooting distances and angles relative to the rebar cage. The image collection area is shown in Figure 3.

Figure 3. Image capture area of the SuperPoint training dataset

After detecting the positions of feature points and obtaining their descriptors, they are input into a GNN called SuperGlue. This network can match two sets of feature points using an attention-based flexible context aggregation mechanism.

2.2.2 Camera Pose Estimation

After extracting and matching feature points using the SuperPoint and SuperGlue algorithms, the pixel coordinates of the matched feature points in the initial image (filtered image obtained at a random initial pose) and the reference image (filtered image obtained at the ideal pose) can be obtained. By combining the depth map captured by the camera at the random initial pose, the 3D coordinates of the matched feature points in the initial image can be obtained. The input to the PnP algorithm includes the 3D coordinates of the matched feature points in the initial image and the pixel coordinates of the matched feature points in the reference image.

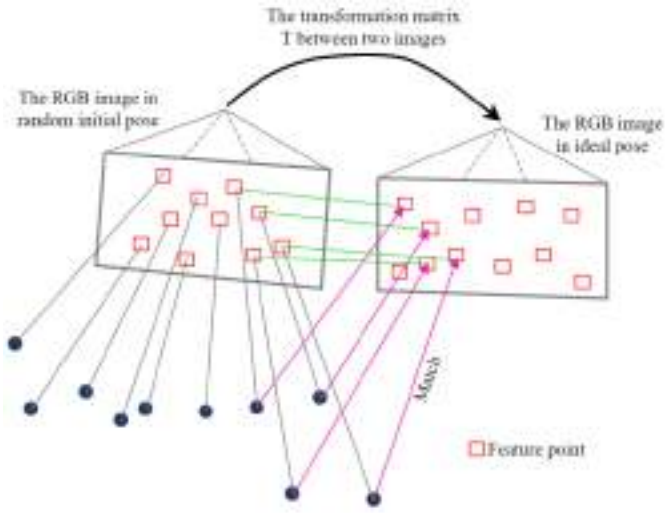

Figure 4. The core target of PnP algorithm

The core target of PnP algorithm is to get the transformation matrix from random initial pose to the ideal pose, which is illustrated in Figure 4. When getting the input of PnP algorithm, the transformation matrix T can be calculated based on Levenberg-Marquardt method [16]. As a result, the estimated pose can be determined by the equation below:

$$Pose_{estimated} = Pose_{initial} \cdot T \quad (1)$$

2.3 Image Evaluation

After obtaining the estimated pose of the camera through the PnP algorithm, move the camera to the estimated pose and collect images, and preprocess the original images to obtain the top-layer rebar mesh image. In order to ensure that the image meets the requirements, the image needs to be evaluated. The specific process is as follows: (1) the rebar crosspoints in the top-layer rebar mesh image are identified and located based on the YOLOv8-pose [17] keypoint detection algorithm; (2) find the maximum and minimum pixel coordinates along the u-axis and v-axis among all the rebar crosspoints, i.e., u_{max}, u_{min}, v_{max}, and v_{min}, as shown in Figure 5; (3) three image evaluation metrics can be calculated to assess the quality of filtered RGB images, where 'a' denotes the pixel width of the image and "b" represents the pixel height of the image.

$$delta_u = abs(1 - \frac{u_{max}}{a} - \frac{u_{min}}{a}) \quad (2)$$

$$delta_v = abs(1 - \frac{v_{max}}{b} - \frac{v_{min}}{b}) \quad (3)$$

$$sum_u = 1 - \frac{u_{max}}{a} + \frac{u_{min}}{a} \quad (4)$$

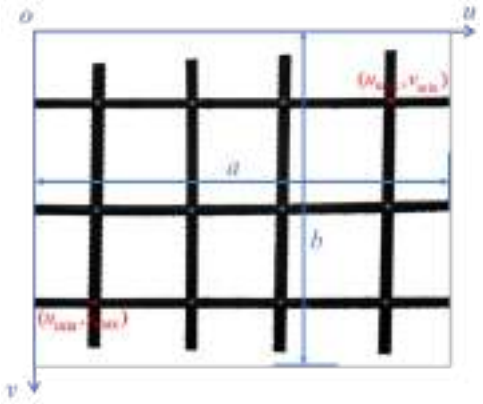

Figure 5. An ideal captured filtered RGB image

It is noticeable that all crosspoints are located on the central area of the filtered RGB image when $delta_u < 0.08, delta_v < 0.08$. Additionally, while all crosspoints are located on the center area of the RGB image, there are still a lot of places around the image that do not contain crosspoints. To make crosspoints are full of the RGB image, sum_u should be in a range from 0.1 to 0.4.

If the filtered image captured by the camera at the estimated pose meets the above metric requirements, the pose estimation is considered successful. Otherwise, if the captured filtered image does not meet the above requirements, it indicates that the camera has not yet reached its ideal pose. The filtered image captured by the camera at the current pose is used as input to the pose estimation module, and the camera pose estimation is repeated until the captured filtered image meets the above metric requirements.

3 Experiments and Results

3.1 Experiment Device

The proposed method was deployed on the rebar tying robot independently developed by our research group, as shown in Figure 6. This robot consists primarily of a mobile chassis, an industrial computer, and a 6-DOF robotic arm equipped with a structured light camera and a rebar tying actuator at the end. The structured light camera can simultaneously capture RGB images and depth maps, providing three-dimensional information of the captured objects. It is mounted at the end of the robotic arm in an "eye-in-hand" configuration, and the transformation matrix from the camera coordinate system to the robotic arm base coordinate system has been obtained through hand-eye calibration.

The industrial computer used in this study is configured as follows: Operating System: Ubuntu 20.04; CPU: 8-core ARM Cortex-A78; GPU: NVIDIA Ampere with 1,792 CUDA cores; RAM: 32GB. The development environment is primarily based on Python.

Figure 6. Rebar tying robot developed by our research group

3.2 Experiment Settings

The filtered rebar cage image shown in Figure 7 was obtained by gradually adjusting the camera pose, capturing images, and preprocessing the images. The evaluation metrics for this image is $delta_u = 0.003, delta_v = 0.026, sum_u = 0.291$, which meets the requirements of the image evaluation module. Thus, it is used as the reference image for the pose estimation module. Filtered images captured and preprocessed at all initial poses are matched with this reference image in the pose estimation module. When capturing this image, the optical center of the camera was 48 cm away from the plane of the top-layer rebar mesh. The z-axis of the camera coordinate system was perpendicular to this plane, the x-axis was parallel to the transverse rebar, and the y-axis was parallel to the longitudinal rebar.

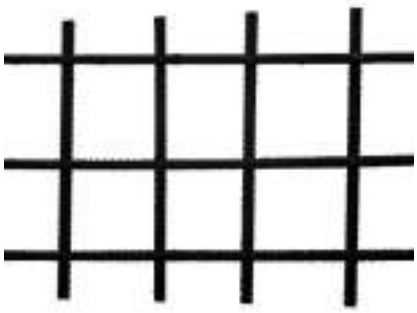

Figure 7. Reference image

To evaluate the performance of the pose estimation method when the camera is in different initial poses, the camera captured images from various shooting distances and angles as the input for the proposed pose estimation method. Additionally, to verify the robustness of the pose estimation method, the images used to test the method's performance were collected from different regions of the rebar cage, differing from the dataset used to train the SuperPoint network, as shown in Figure 3. And the design transverse rebar spacing and the design longitudinal rebar spacing of the rebar cage used in the experiment are both 10 cm.

After obtaining the initial image, the process for testing the performance of the pose estimation method is as follows: the initial image is input into the pose estimation module to calculate the estimated camera pose. The camera is adjusted to the estimated pose to capture an image, and the filtered image is input into the image evaluation module. If the image meets the required metrics, the camera pose estimation is complete, and the computation time for the pose estimation method is recorded. If the image does not meet the metrics, it is used as the initial image and input into the pose estimation module for re-estimation. This process is repeated until the captured image meets the required metrics, with the total computation time and the number of pose estimations recorded.

Considering that the recommended working distance of the structured-light camera is 30 cm to 60 cm, the camera's optical center is set at distances of 40 cm, 45 cm, and 50 cm from the plane of the top rebar mesh to ensure the depth values of rebar pixels in the filtered image fall within this range. This distance is hereafter referred to as the "shooting distance". Taking a shooting distance of 40 cm as an example, the camera pose is first adjusted so that the z-axis of the camera coordinate system is perpendicular to the plane of the top rebar mesh, the x-axis is parallel to the transverse rebar, and the y-axis is parallel to the longitudinal rebar. This pose is referred to as its "standard pose", as shown in Figure

8. Then, the camera can be rotated around its x-axis, y-axis, and z-axis respectively by the following angles: $-10°, -5°, 0°, 5°, 10°$ (counterclockwise is positive, clockwise is negative). Therefore, the camera has a total of 125 initial poses at this shooting distance, and a total of 375 initial poses at the three shooting distances.

Figure 8. Standard pose of the camera

3.3 Experiment Results

For each initial pose scenario, the following parameters are recorded: whether it can be adjusted to the ideal pose, the number of pose estimation attempts required to reach the ideal pose, and the computation time of the pose estimation method. The results are shown in Table 1. It can be seen from Table 1 that for the total of 375 initial pose scenarios at three shooting distances, the success rate of the pose estimation method within three attempts is 99.5%, and the success rate with just one attempt is 91.5%.

Table 1 Number of pose estimation attempts, corresponding scenario counts, and average computation time

Number of pose estimation attempts and the corresponding scenario counts							
Shooting distance (cm)	1	Success rate (%)	2	Success rate (%)	3	Success rate (%)	Failure
40	114	91.2	8	97.6	1	98.4	2
45	115	92.0	9	99.2	1	100.0	0
50	114	91.2	9	98.4	2	100.0	0
Total	343	91.5	26	98.4	4	99.5	2
Average computation time of pose estimation method (run once)						1.05s	

The failure of a single pose estimation attempt can be attributed to the large number of incorrect matching points in the initial image matching results, which leads to inaccurate pose estimation by the PnP algorithm. Consequently, the first estimated image fails to meet the evaluation metrics, necessitating additional pose estimation attempts. If the estimated pose renders the robotic arm unreachable or causes collisions, the pose estimation is considered a failure. The computation time in this study refers to the duration from receiving an image captured at an initial camera pose to generating the corresponding optimal camera pose that meets the predefined requirements. The proposed method achieves an average computation time of 1.05 seconds per pose estimation, meaning that the system can determine the desired camera pose within 1.05 seconds after receiving the initial image. This efficiency ensures minimal impact on production scheduling in precast plants and construction sites, making the method suitable for real-world deployment.

Figure 9 shows the test results of three initial pose scenarios, each of which includes: an image captured and preprocessed by the camera at the initial pose (referred to as "initial image"), the matching result with the reference image, and an image captured and preprocessed at the estimated pose (referred to as "estimated image"). In Figure 9(a), the initial pose of the camera for the initial image is: the shooting distance is 40 cm, and the camera rotates 10°, -10°, and -10° around its own x-axis, y-axis, and z-axis based on the standard pose. The match results show the matching between the initial image and the reference image. The image pose estimation module only requires a single run with a computation time of 1.062 seconds. The evaluation metric value for the estimated image is: $delta_u = 0.005, delta_v = 0.002, sum_u = 0.270$, which meets the requirements. It can be concluded that even when the camera's initial pose significantly deviates from its ideal pose, the proposed pose estimation method can still calculate an ideal pose, enabling the camera to capture rebar cage images that meet the evaluation metrics.

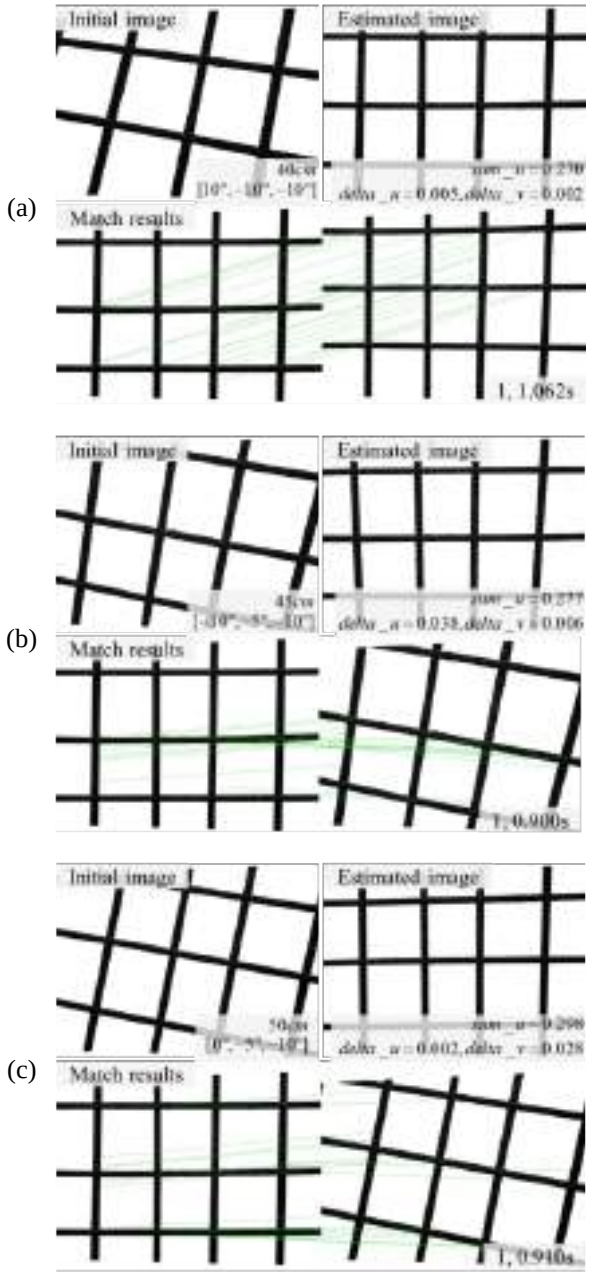

Figure 9. The initial image, matching result, and estimated image corresponding to the camera in different initial pose

4 Conclusion

This paper proposes a vision-guided camera pose estimation method for rebar tying robots, designed to calculate the ideal camera pose. This ideal pose facilitates efficient and high-quality rebar tying for rectangular planar rebar cages. The key innovations of the proposed method are as follows:

(1) A feature point-based camera pose estimation method is proposed. For the 375 initial pose scenarios tested in this study, the method achieves a 99.5% success rate for pose estimation within three attempts, with a 91.5% success rate for a single attempt. The average computation time for each estimation is 1.05 seconds, which is generally sufficient for practical applications.

(2) A method for evaluating the image quality captured by the rebar tying robot's camera is proposed. This method incorporates three evaluation metrics and forms a feedback loop with the camera pose estimation process, further ensuring the quality of the captured images. As a result, it contributes to the efficient and high-quality completion of rebar tying tasks for planar rebar cages.

However, the proposed pose estimation method requires multiple adjustments of the camera under certain initial pose scenarios and is only applicable to planar rebar cages. It is necessary to develop more efficient and robust pose estimation methods applicable to curved rebar cages and corresponding image evaluation metrics in the future.

Abstract -

Robotic manipulation is a promising technology that has the potential to further automate construction tasks such as bricklaying, concrete printing, or crane assembly of prefabricated components. With the increasing complexity of modern construction projects, more sophisticated planning algorithms are needed to optimize the efficiency of robotic manipulator operations. Reinforcement learning (RL) has emerged in recent research as a way to solve planning problems in high-dimensional state spaces or where the world model is unknown or noisy. Most RL algorithms for robotic manipulation target low-level control and is not scalable to multi-object or complex assembly tasks. This research proposes a reinforcement learning framework with integration of vision-based state estimation and inverse kinematics for generalized robotic assembly tasks. A contour detection and linear regression algorithm is used to perform initial state estimation and grasp point regression, whereas the reinforcement learning algorithm involves a discrete state space where transitions between states are handled using inverse kinematics. The proposed framework is validated through a physics simulation as well as a lab-based experimental setup with robotic assembly of wooden blocks.

Reinforcement learning; computer vision; robot assembly

1 Introduction

Automation of construction work is of great need in the building industry to allow construction tasks to be carried out more accurately and efficiently, especially in view of the increasing shortage of skilled workers. In the construction industry, roboticized work can come in the form of robotic bricklaying [1], concrete printing [2], or crane assembly of prefabricated components [3]. Still, using robotics technology for construction work remains challenging due to the unstructured and heterogeneous nature of construction environments [4].

Reinforcement learning (RL) has emerged as a promising research area for robotic control and robotic assembly of complex objects [5, 6]. Contrary to prior methods which rely on having a known physical model of an environment, reinforcement learning allows a robotic agent to learn the characteristics of an unknown environment directly through experience and taking actions in that environment.

Existing work in reinforcement learning for robotic assembly tasks [7, 6] usually define the states as end effector pose and actions as end effector displacements, both in continuous Cartesian space. However, the limitation of this approach is that the learning process involves long convergence times and low success rates due to the large state space and action space, making the task extremely difficult to learn. Additionally, robotic movement does not lend itself to discrete timesteps; robots require time to start and stop movement and so additional work is needed to ensure that an agent does not attempt to take actions when the robot is incapable of doing so. These obstacles can largely be overcome in simulation, but additional issues are faced when moving from a simulation of a robot to the real world.

To address these issues, this research proposes to leverage underlying inverse kinematics mechanisms for the robotic manipulator, allowing the reinforcement learning algorithm to act at a high level with a smaller state space, thus simplifying the learning problem. In addition, a vision module is used for state estimation, allowing the robot to adapt to equipment and materials being transported about in a dynamic construction environment.

2 Literature Review

2.1 Robotic assembly tasks

Robots are uniquely suited to handle many assembly tasks that are dull, dirty, or dangerous. As a result, robots are deployed to accomplish basic tasks in the construction industry [8], such as laying bricks [1], concrete 3D printing [2], etc. Other tasks include assembling interior structures, such as flooring installation [9], HVAC and plumbing installation [10], and assembling furniture such

as an IKEA chair using multiple collaborative robotic manipulators [11].

2.2 Planning methods in construction robotics

Planning methods find many applications in construction robots, such as for crane lift planning [12]. Work in [13] considers building information modeling in construction robotic task planning. [14] addresses the issue of long-horizon multi-robot planning in construction assembly. Sampling-based planners, such as RRT [15], have been used for crane planning and beyond. However, state-space planners and sampling-based planners mostly assume a known environment with static obstacles. To work in dynamic construction environments, multi-modal perception is key for real-time feedback and situational awareness in planning [16]. In the domain of crane lift planning, relevant work include dynamic 3D modeling in environments with low visibility and dense obstacles [17], and real-time monitoring of crane load [18].

2.3 Learning methods in construction robotics

Recently, learning methods have also been explored in construction robotics [19] to tackle problems of higher complexity and improve operation in uncertain environments. Robots empowered by reinforcement learning, for example, Deep Deterministic Policy Gradient (DDPG), have been used for the robotic assembly of timber joints [20]. Human-robot collaboration in construction [21] can also be achieved via reinforcement learning with safety and efficiency. Another learning paradigm, imitation learning, or Learning from Demonstration (LfD) [22] is also deployed in construction robots, such as performing quasi-repetitive construction tasks through human demonstration [23]. Moreover, [24] developed an imitation learning approach for robot teleoperation in construction. Nevertheless, research gaps remain in integrating these black-box learning-based methods with more established planning or kinematics frameworks, and also in integrating the manipulation system with vision-based feedback. There is also a research need for scalable reinforcement learning algorithms [25] that can work for complex, multi-agent [26] tasks in construction environments.

3 Methodology

3.1 Problem setup

In this research, tasks such as bricklaying, crane assembly etc. are represented as a generalized robotic assembly problem. The generalized robotic assembly problem involves assembling n components from initial states $\{s_1, s_2, s_3, ..., s_n\}$ to a complete structure with target states $\{t_1, t_2, t_3, ..., t_n\}$. The assembly task may involve order constraints such that some components need to be installed before other components are installed, which is specific to the assembly task. The total manipulation cost is the time taken to move each component from its initial state to the final state $\sum_n T(s_n, t_n)$. The key assumptions are that (i) the initial states are unknown, and (ii) the manipulation costs are unknown. Therefore, the optimization process involves finding the least time required for a robotic manipulator to complete the assembly task.

3.2 Vision-based initial state estimation and grasp point regression

The proposed method follows the framework described in Figure 1.The vision module starts by obtaining an image frame from a camera mounted near the end effector of the robotic arm. The robot's position remains consistent during the image acquisition process, ensuring a stable stream of extractable data. The image undergoes several preprocessing steps, including grayscale and denoising filters. Non-local means denoising is chosen due to its high retention of detail. Then, a contour detection algorithm is utilized to obtain the outline of prominent shapes within the frame. In this work, the specific target objects are rectangular wooden blocks, so our implementation uses OpenCV's contour detection algorithm to find the four corner points of any rectangular shape in the image. The preprocessing steps, including the grayscale conversion and denoising, were implemented to overcome the noise limitations induced by the camera included with the Kinova Robotic Arm. The area threshold for contour detection was set to 100 pixels, as that value effectively filtered out noise-induced false positives while maintaining accurate detection for rectangular blocks.

The position of the points in the frame are represented as $(xPixel, yPixel)$ tuples, with the top-left corner of the image serving as the origin $(0, 0)$. At this point, the tuples of the four vertices are known, but the specific object corners they represent (top/ bottom, left/ right) are not. To determine the correct assignment, we treat the 2 points with the highest $xPixel$ values as our right points, and the remaining points are treated as left points. Subsequently, the $yPixel$ values between the two right points and left points are compared. Among the right and left side points, the ones with smaller $yPixel$ values are designated as top points, and the remaining ones are assigned as bottom points. With these four points identified, we can solve for the correct rotation angle about the block's z-axis as well as the coordinates of the center of the block. These coordinates of all blocks detected are stored as the initial state of the assembly task.

Then, using the center of the block and its Z-axis rotation, we pass this data to a regression model to calculate the movement required by the robotic arm to

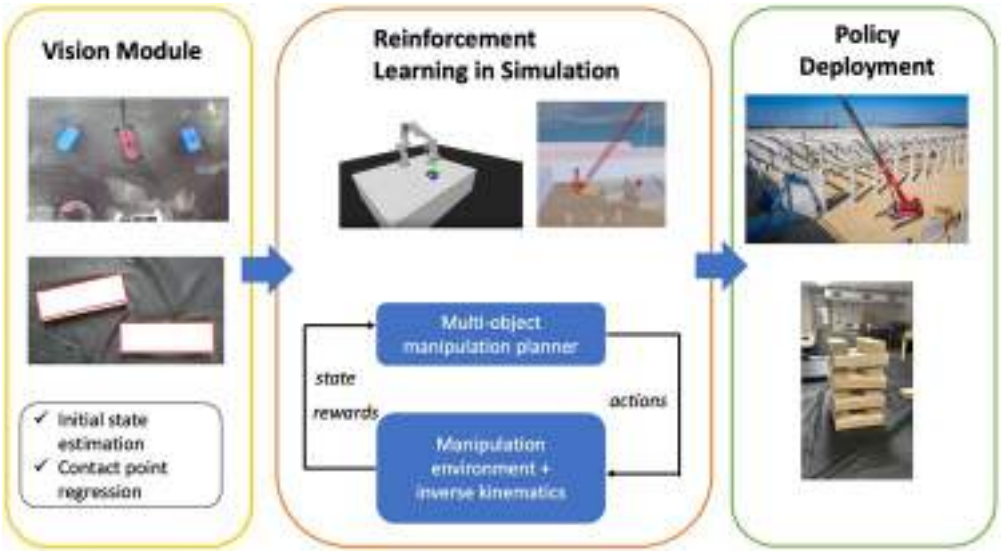

Figure 1. Proposed framework for reinforcement learning with vision-based state estimation for generalized robotic assembly (crane examples are adapted from [27])

successfully grasp the block. Our regression model is a linear model consists of 50 data points of the form $(xPixel, yPixel) \rightarrow (xMovement, yMovement)$, where $xPixel$ and $yPixel$ represent the coordinates of the center of the wooden block, and $xMovement$ and $yMovement$ represent the translational displacement required to position the robotic arm directly above the block to pick up. The training data set was manually annotated through human demonstrations by calculating the block's midpoint and recording the movements needed for the arm to transition from the initial camera position to a pick-up position above the block. The Z movement is not taken into account, as all blocks are assumed to be at the same height when placed on the surface where the arm lies. Figures 2 and 3 show visualizations of the regression model trained to predict the best robot manipulator pose given the visual position of the target object. In our study, the aforementioned linear regression model demonstrated excellent predictive performance, achieving R^2 scores of 0.9865 for the X-coordinates and 0.9985 for the Y-coordinates.

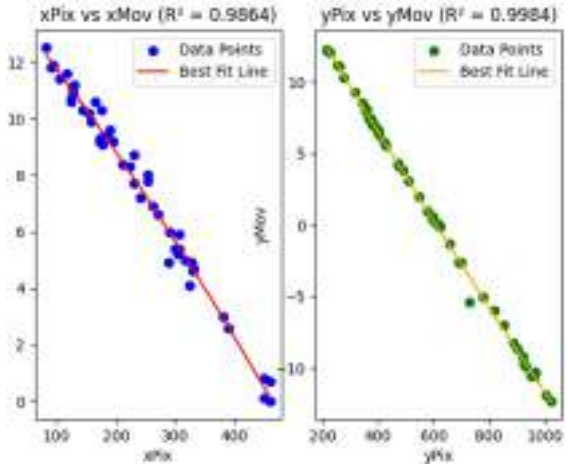

Figure 2. Plot of training data points and line of best fit for regression of desired manipulator pose

3.3 Simulation setup

The simulation consists of a modified Panda Gym environment from [7]. The Panda Gym environment was selected because it allows for simulating robotic manipulation tasks in an RL interface compatible with Stable-Baselines3 [28]. In order to utilize RL algorithms for planning, actions that normally consist of low-level movements in the arm, such as changing joint position and gripper width, are replaced by pre-planned actions. These actions are higher-level, and correspond to the underlying goal within the task; such as moving the arm to a specified location and opening and closing the gripper. In our initial work, we used the simulation of the Franka Emika Panda robot that is present in the Panda Gym environment. This robot was already present in the simulation software, and is similar to the Kinova robot that we were able to utilize it while implementing the Kinova robot. The simulation runs at 25 Hz[7], and each task is given 100 timesteps in order to complete each movement. Using the relationship that a single timestep equals 2ms, we are able to determine how long each subtask takes.

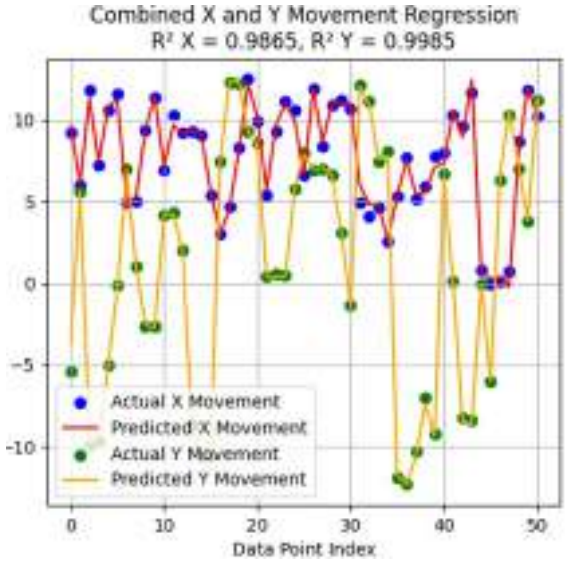

Figure 3. Graph of regression line between the desired robot manipulator pose and the visual position of the target object to be manipulated

3.4 Reinforcement learning

In typical robotic manipulator simulations, the state of the simulation is a set of continuous variables, that define the position of the components of the robot in simulated space. For example, in environments where the agent controls the end-effector's position, the coordinates of the end effector are present in the state or observation. These observations are used by the agent to select actions from a policy π, in order to maximize the returns (or sum of rewards) over the course of a training episode. These rewards are typically "sparse" in manipulator environments, meaning that the agent only receives a positive reward at the completion of the task.

Whereas, in our proposed RL framework, a discrete state space is used where transitions between discrete states are handled using inverse kinematics. The learning process thus assumes that there is an underlying inverse kinematics function which is an unknown model. The cost (i.e. manipulation time) of applying this unknown inverse kinematics model has to be learned through interactions with the environment. In this research, we also assume that this cost of manipulation can be approximated through a physics simulation. This way, the process of moving a single object can be viewed as "deterministic" since it is controlled by inverse kinematics and not varied by the RL agent. The RL agent then handles the process of optimizing the movement of multiple objects to complete an assembly task.

3.5 Implementation Details

All code and algorithms are deployed using a software stack consisting of the Kinova Gen3 API, OpenCV, Stable-Baselines3, PyBullet, and Panda-Gym's learning environment. OpenCV is used to estimate the real-world coordinates of wooden blocks positioned on a lab bench. Whereas, the Kinova API is used for manipulation planning, where our algorithm computes the desired goal state of the robot's end effector, and the underlying API will calculate the required joint angles to reach that position using inverse kinematics for the Kinova robot. The simulation environment is built upon Panda Gym, which allows for modular integration between robot simulations and reinforcement learning algorithms. The simulation environment uses PyBullet, a physics engine that models collisions, soft body dynamics, and rigid body dynamics to replicate real world environmental constraints as closely as possible. The Kinova Gen3 7DOF robot arm is loaded into simulation using the Unified Robot Description Format (URDF). The URDF contains information regarding mass, moments of inertia and force limits for each of the arm's 7 joints. Finally, the reinforcement learning algorithms used are obtained from the Stable Baselines3 library.

4 Results

4.1 Evaluation metrics in simulation

To evaluate the proposed framework, we design two assembly tasks which are the 3-layer tower structure (6 components) and the 3-layer wall structure (8 components). The wall structure is designed to simulate the brick laying task in construction. The tasks created in the simulator were designed to match, as closely as possible, the tasks performed in the lab setting. The metrics used for evaluating the performance of the agents are the assembly time and success rate, where a successful run is defined as one in which the blocks are detected, picked up, and deposited at the correct target positions accurately.

In order to evaluate our proposed "deterministic" approach compared to other RL algorithms, we evaluated three current state of the art algorithms used in robotic manipulation, Deep Deterministic Policy Gradients (DDPG)[29], Twin Delayed Deep Deterministic policy gradient (TD3)[30], and Soft Actor Critic (SAC)[31]. In addition, these algorithms make use of Hindsight Experience Replay (HER), which allows for a more sample efficient agent training process. HER was used due to the sparse nature of the rewards given in each task; with the agent only receiving a reward at end of the training loop, and even then, only when the agent has successfully completed the task. Hyperparameters used for the baseline testing match those found in HER[32].

For the RL agents, the training regime is 50M timesteps, and the hyperparameters used match those used in Panda Gym. The higher number of timesteps for training was possible due to training the agents in parallel. The reward each agent receives is -1 for each timestep taken for each subtask (moving the arm to the object, opening and closing the gripper, etc.), with a maximum number of timesteps allowed per objective task of 350 for the 3-layer tower, and 500 for the 3-layer wall and the total return and is represented as:

$$G = -\sum_{0}^{T}\sum_{0}^{\infty} t_{subtask} \quad (1)$$

Where G represents the total episodic return, T represents the total number of allowed timesteps and $t_{subtask}$ is the number of timesteps per deterministic subtask. Hyperparameters used in the deterministic approach are referenced from work by Da Costa[33].

Quantitative results for assembling the 3-layer tower and 3-layer wall are shown in Tables 1 and 2 respectively. Results show that the proposed algorithm achieves higher rewards (and therefore shorter number of steps to complete the assembly task) compared to other algorithms. The proposed algorithm also achieves a much higher success rate: since the algorithm solves the state transitions in a "deterministic" way using inverse kinematics, it is almost guaranteed to finish the assembly task. Whereas, other RL algorithms struggle to solve the task because they have to search for a policy in a very large state space and action space. Qualitative results of the completed assembly tasks in simulation are shown in Figure 4.

Table 1. Performance comparison for 3-layer tower assembly in simulation

Method	Reward	Success Rate
DDPG	-350	0.01
SAC	-349	0.02
TD3	-350	0.01
Proposed deterministic	-315*	1.00

Table 2. Performance comparison for 3-layer wall assembly in simulation

Method	Reward	Success Rate
DDPG	-498	0.015
SAC	-500	0.010
TD3	-500	0.010
Proposed deterministic	-494*	1.000

4.2 Qualitative results for lab testbed

Figure 5 shows proof-of-concept results for physically assembling a 3-layer hollow tower, and a 3-layer wall structure out of wooden blocks using a Kinova Gen3 L53 7 degree-of-freedom (DOF) robotic arm. The implementation makes use of the inverse kinematics module in the Kinova API, and the geometry of the structure to be assembled is pre-programmed in a Python script and deployed on the robot.

Table 3 shows a comparison of the total assembly time of the 3-layer tower as well as the 3-layer wall from the lab testbed. The time taken to place each component is highly dependent on the component's target position and orientation, as well as the specific implementation of the underlying inverse kinematics algorithms (the same end effector pose can be reached through many different possible joint angles). Reinforcement learning provides an opportunity to learn these interactions and arrive at an optimized policy to minimize assembly time.

Table 3. Comparison of total assembly time from the lab testbed

Structure	#Components	Assembly Time (s)
3-layer tower	6	195
3-layer wall	8	180

5 Limitations and Discussion

Currently, the vertical (Z-axis) distance between the arm's end effector and the target object to be manipulated is assumed to be fixed. Future work will look to overcome this limitation by implementing triangle similarity or using depth images, allowing for more generalized behavior that more closely resembles real-life construction environments. Moreover, the current model only accounts for rotation about the Z axis and not about the X and Y axes. Moving forward, the regression model can be adjusted to consider these additional rotation angles as parameters, and allow for more robust grasping and manipulation of objects. The current implementation only considers vision input in the initial stage for state estimation and grasp point regression. Ideally, continuous vision feedback will be important to correct state estimation errors or motion noise. Theoretically, our approach can scale to larger construction environments, as long as we can represent the scene accurately in simulation and train the agent in simulation. Our approach relies on having access to inverse kinematics and this is a key assumption. For complex construction machinery where an inverse kinematics solution is not available, probabilistic motion planning algorithms may be a viable alternative [34].

6 Conclusion

This research proposes a reinforcement learning framework with integration of vision-based state estimation and

Figure 4. Results for 3-layer tower assembly and 3-layer wall assembly in the Panda Gym simulation

inverse kinematics for generalized robotic assembly tasks. The advantage of the proposed framework is a generalized formulation of robotic assembly tasks for reinforcement learning algorithms that can also be adapted to arbitrary initial states. Future work in this area involves exploring multi-agent reinforcement learning algorithms that can allow the assembly tasks to be completed by two or more robotic manipulators that can learn to coordinate with one another. Human-robot collaboration [35] will also be explored to investigate how robotic agents can collaborate with human workers to complete assembly tasks.

Abstract -

This paper presents a robotic system developed to enhance automation in construction workflows through advanced AI and computer vision technologies. The system integrates a robotic arm with a 3D point cloud camera and state-of-the-art 2D pre-trained Deep Learning models, such as GroundingDINO and SegmentAnything, to detect and segment construction elements in 3D dynamic, unstructured environments. By processing point cloud data from the camera and aligning it with real-world coordinates, the system achieves precise object localization, enabling tasks such as element handling and assembly. Designed to address challenges like clutter, occlusion, and variability in construction sites, this system bridges the gap between controlled laboratory conditions and real-world applications. Experimental evaluations highlight its potential to improve efficiency and adaptability in construction tasks.

1 Introduction

The integration of artificial intelligence (AI) with robotics offers transformative potential for the construction industry. Construction workflows, requiring precision and efficiency, are well-suited for robotic automation, which can address critical challenges like labor shortages, high costs, and safety risks by automating repetitive tasks such as element handling, assembly, and inspection [1]. However, deploying robotics effectively in the chaotic and unpredictable environments of real construction sites remains a significant hurdle.

The transition from controlled laboratory settings to dynamic construction sites presents formidable challenges. Real-world construction environments are inherently complex, characterized by clutter, inconsistent lighting, diverse materials, and unforeseen obstacles. Unlike controlled experiments, these sites involve overlapping objects, occlusions, and constantly changing conditions that can severely limit the effectiveness of conventional robotic systems. While robotic automation has advanced, adapting these systems to the visual complexities of real-world construction remains a critical gap.

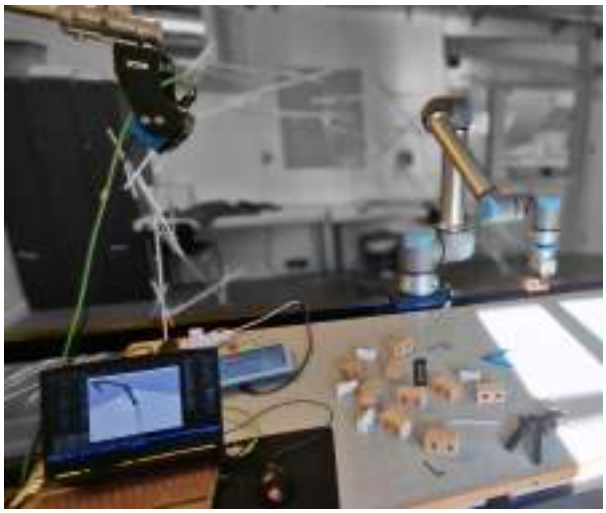

Figure 1. Robotic environment setup for object manipulation in a construction scenario. The system integrates a UR10e robotic arm and a Visionary-S point cloud scanner.

Vision is paramount for robotic automation in these environments. Although 2D image recognition models have advanced significantly [2], they often lack the spatial understanding essential for robots in complex 3D spaces. Trained primarily for 2D analysis, they struggle with depth perception and spatial relationships crucial for manipulation and assembly in cluttered scenes. In contrast, 3D vision systems, capable of capturing detailed spatial data through point clouds, offer a more comprehensive understanding of the environment, enabling robots to perceive and interact with objects more effectively, even under challenging conditions. Our work seeks to leverage the power of these advanced 2D image recognition models and apply them within a 3D context. Figure 1 illustrates our system setup.

Recent AI breakthroughs in object detection and segmentation have bolstered robotic vision. Models such as GroundingDINO and SegmentAnything leverage pre-trained deep learning techniques to detect and segment

unseen objects with high accuracy, even in cluttered, complex environments [3, 2]. These models use transformer networks to process image data, achieving high accuracy and robustness. Additionally, real-time advancements like YOLO-World [4] and EfficientSAM [5] make them suitable for dynamic environments. Extensions of such models for 3D point cloud processing [6] enable robust frameworks for detecting, segmenting, and manipulating objects under real-world constraints. However, directly applying these powerful 2D models within a comprehensive 3D robotic perception system for construction remains largely unexplored.

The integration of robotics and AI in construction has seen significant progress in object detection, manipulation, and automation of tasks. Early methods relied on feature-based approaches such as SIFT and HOG descriptors [7], which struggled with clutter and occlusions. The introduction of deep learning architectures, including transformer-based models, revolutionized object detection and segmentation [8]. Joint vision-language models like GroundingDINO and SegmentAnything demonstrated remarkable performance, enhancing applications in cluttered construction settings. Several successful applications of these techniques in construction-related tasks include ROI-based detection systems for equipment [9] and advanced point cloud segmentation using networks like PointRCNN [10]. Despite these gains, a cohesive framework effectively using 2D AI models within a 3D robotic system for construction tasks is still needed.

Robotic manipulation in construction settings also requires robust planning and control mechanisms. Recent research expanded into reinforcement learning and AI-based control strategies, as shown in [1]. Grasp planning with point clouds, advanced by tools like PointNetGPD [11], and tactile feedback integration [12] have enabled precise manipulation in real-world scenarios. Transformer-based architectures, such as RT-1 and RT-2 [13], have further shown promising results in robotic manipulation through vision-language understanding. However, realizing the potential of these manipulation advances in unstructured construction requires enhanced 3D perception, which our work addresses.

3D vision systems play a vital role in enabling robots to understand and interact with their surroundings. Point cloud data provides detailed spatial information for accurate object localization and manipulation. Enhanced registration techniques, such as Colored ICP [6], incorporate color information valuable in construction scenes. Recent depth estimation methods, such as Depth Anything V2 [14], and fusion techniques like BEVFusion [15], continue to advance 3D perception capabilities. Building on these, our system aims for a more integrated and practical approach for construction robotics by leveraging both 2D AI models and 3D point cloud data.

This paper presents a novel system designed to bridge the gap between controlled lab settings and the challenges of real construction sites. Our core novelty is the effective application of state-of-the-art 2D image recognition models within a 3D point cloud framework. This integration enhances robotic automation in construction by combining 2D AI object recognition with 3D spatial understanding. By equipping a robotic arm with a cloud scanner and advanced object detection and segmentation algorithms, the system achieves:

- Accurate detection and segmentation of unseen construction elements and tools using AI-based pretrained models, originally designed for 2D images, but adapted for 3D point cloud understanding, even in cluttered scenes.
- Precise alignment of 3D data with real-world coordinates for effective robotic manipulation.

The experimental setup, shown in Figure 1, demonstrates the system's ability to adapt to the complexities of real-world construction environments. This work is an initial step in a controlled lab setting mimicking construction scenarios. While simplified, our experiments demonstrate the feasibility and potential of our approach to tackle visual challenges in real-world construction. Future work will validate and extend these findings in more complex field conditions. By addressing challenges such as cluttered scenes, occlusions, and dynamic conditions, the proposed system aims to enhance efficiency and adaptability in construction workflows.

2 System Overview

This section provides a comprehensive overview of the hardware and software components used in the proposed robotic system, focusing on its adaptability to dynamic construction tasks. The integration of advanced AI models with a collaborative robotic arm for efficient execution of operations such as element handling, assembly, and inspection.

2.1 Hardware Setup

Our experimental setup, designed to mimic real-world construction scenarios, comprises a UR10e robotic arm, an OnRobot 2FG7 gripper, a Visionary-S point cloud scanner, and a high-performance workstation. The workspace is set on a 1000 mm x 700 mm table where construction elements are placed.

The UR10e (Universal Robots) offers a 10 kg payload capacity, 1300 mm reach, and ±0.03 mm repeatability, making it suitable for tasks like manipulating construction elements and assembling components. Its collaborative

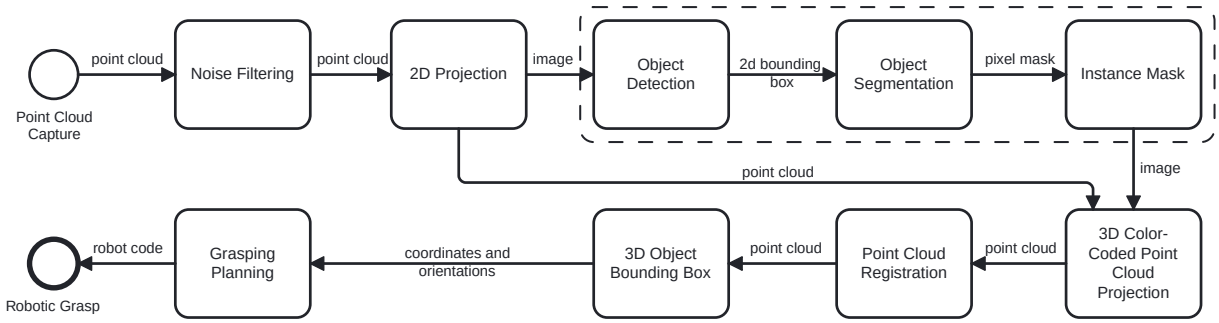

Figure 2. Flowchart of the process: integrating AI-based object detection, point cloud processing, and robotic manipulation.

design, including force sensing, enables safe human-robot interaction. Attached to the UR10e, the OnRobot 2FG7 two-finger gripper provides adjustable gripping force and width for handling various elements, such as bricks and tools.

The SICK Visionary-S point cloud scanner captures high-resolution 3D data of the environment. It boasts a pixel resolution of 640×512, depth accuracy of $\leq 0.25\,\text{mm}$, a detection angle of $60° \times 50°$, and operates within a camera distance of 0.5 to 65 meters. Long distance capture allows us to operate in large construction environments. The scanner is positioned at one end of the workspace to capture the scene from a distance of approximately 1 meter from the table. To handle the computational demands of the AI models and point cloud processing, a high-performance workstation is used. This workstation is equipped with an NVIDIA RTX 3070 GPU, an Intel i7-12700H processor, and 64 GB of RAM, providing the necessary processing power for real-time operations.

2.2 Software Architecture

The software architecture integrates advanced AI models with point cloud processing and robotic control to enable seamless operation. The Visionary-S scanner captures 3D point clouds and RGB images, which undergo preprocessing to enhance data quality. Techniques such as noise filtering using DBSCAN and voxel downsampling reduce the computational load while preserving geometric details, ensuring the accuracy and reliability of the data for subsequent stages.

AI models are employed to process the preprocessed data for object detection and segmentation. These models run within Docker containers to provide consistent and isolated environments. GroundingDINO and SegmentAnything models form the backbone of the detection and segmentation pipeline. The processed data, including the detected objects and their segmentation masks, is then used to calculate target positions and orientations for robotic manipulation. The robot executes these commands through a Python-based control system, which translates high-level instructions into precise joint movements.

2.3 AI Models

The system relies on advanced AI models, GroundingDINO and SegmentAnything, to identify and segment construction elements and components accurately. These models are optimized to handle the diverse and cluttered nature of construction environments to provide reliable performance in a wide range of tasks.

GroundingDINO is used for object detection in 2D images derived from the 3D point cloud. Using its language-guided detection capabilities, the model can identify objects based on natural language prompts, such as “brick” or “wooden block.” This adaptability allows the system to handle a wide variety of construction elements. GroundingDINO generates precise 2D bounding boxes for detected objects, even in complex and cluttered environments, as compared with YOLO-World [4] in Figure 3.

SegmentAnything complements GroundingDINO by providing detailed instance masks for the detected objects. The versatility of the model allows it to segment a diverse range of objects without requiring additional training, which makes it suitable for dynamic construction scenarios. The high-quality instance masks generated by SegmentAnything allow the robot to distinguish between overlapping objects and perform precise manipulations.

3 Methodology

The proposed system integrates advanced AI models with robotic control to achieve accurate detection, segmentation, and manipulation of objects in dynamic construction environments. This section outlines the methodological framework shown in Figure 2 for data acquisition, preprocessing, point cloud registration, AI-driven detection and segmentation, object localization, grasp planning,

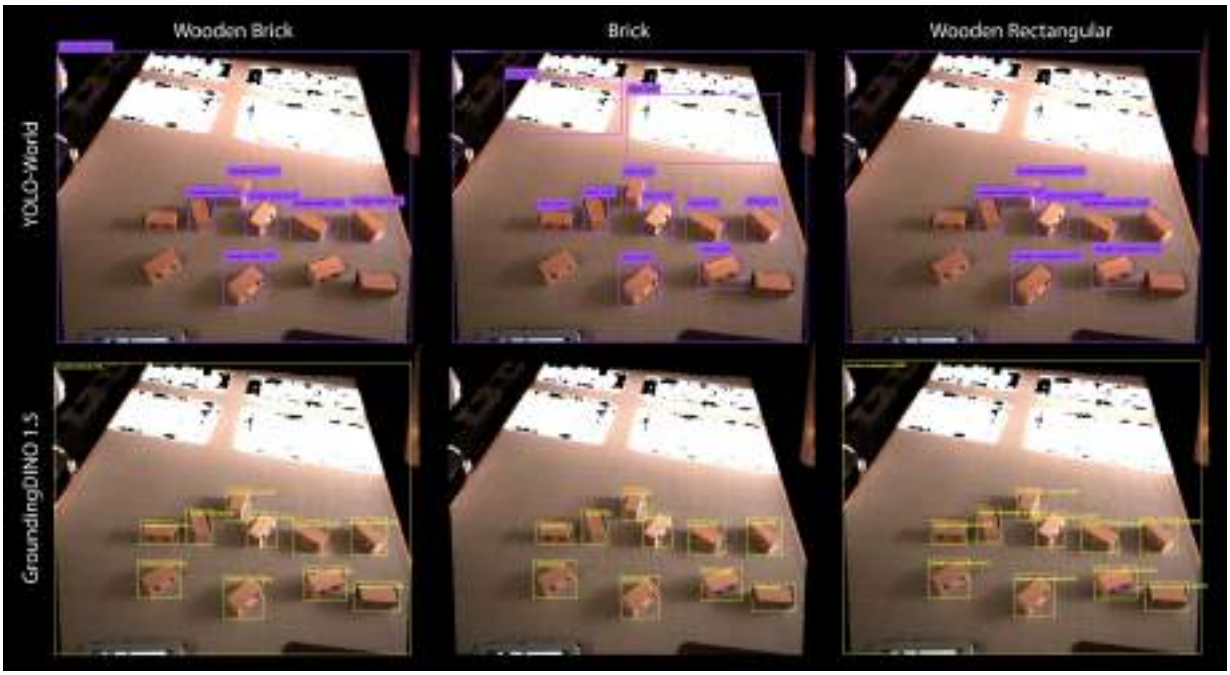

Figure 3. Comparison between GroundingDINO and YOLO-World with different prompts.

and robotic execution.

3.1 Data Acquisition and Preprocessing

The data acquisition process begins with the Visionary-S point cloud scanner capturing 3D data of the construction workspace. The scanner provides a high-resolution depth map and corresponding RGB image. Noise filtering is applied to the raw point cloud $P = \{p_1, p_2, ..., p_n\}$ using the Density-Based Spatial Clustering of Applications with Noise (DBSCAN) algorithm. DBSCAN classifies points into core, border, and noise points based on their local density. The ϵ-neighborhood of a point p is defined as:

$$N_\epsilon(p) = \{q \in P \mid \text{dist}(p, q) \leq \epsilon\} \tag{1}$$

where $\text{dist}(p, q)$ is the Euclidean distance between points p and q, and ϵ is a predefined radius. A point p is a core point if its ϵ-neighborhood contains at least minPts points:

$$|N_\epsilon(p)| \geq \text{minPts} \tag{2}$$

A point q is a border point if it is within the ϵ-neighborhood of a core point p but is not a core point itself. A point that is neither a core point nor a border point is classified as a noise point. The filtered point cloud P' consists of core and border points, excluding noise points. The filtered point cloud is then projected onto a 2D image plane using the intrinsic parameters of the Visionary-S scanner. The camera intrinsic matrix K is defined as:

$$K = \begin{matrix} f_x & 0 & c_x \\ 0 & f_y & c_y \\ 0 & 0 & 1 \end{matrix} \tag{3}$$

where f_x and f_y are the focal lengths in the x and y directions, and (c_x, c_y) is the principal point. For a point $p = (x, y, z)$ in the 3D point cloud, its projection $p' = (u, v)$ onto the 2D image plane is given by:

$$\begin{matrix} u \\ v \\ 1 \end{matrix} = K \begin{matrix} x/z \\ y/z \\ 1 \end{matrix}, \quad u = f_x \frac{x}{z} + c_x, \quad v = f_y \frac{y}{z} + c_y \tag{4}$$

This projection provides image format required for object detection. (Figure 4)

Figure 4. Projection from 3d pointcloud to 2d image.

3.2 Point Cloud Registration

Point cloud registration aligns the captured point cloud with a predefined reference frame, enabling accurate localization of objects within the workspace. The Iterative Closest Point (ICP) algorithm is used to refine the alignment between the source point cloud (captured data) and the target point cloud (reference frame). The ICP algorithm iteratively minimizes the difference between two point clouds. Let P_s be the source point cloud and P_t be the target point cloud. The algorithm aims to find the optimal transformation T that aligns P_s with P_t. The algorithm starts with an initial transformation T_0. For each point $p_i \in P_s$, the closest point $q_i \in P_t$ is found. This forms a set of corresponding pairs $C = \{(p_i, q_i)\}$. The transformation T_k that minimizes the mean squared error between the corresponding pairs is computed:

$$E(T) = \frac{1}{N} \sum_{i=1}^{N} ||q_i - T_k p_i||^2 \tag{5}$$

where N is the number of corresponding pairs. The optimal transformation can be found using Singular Value Decomposition (SVD). The source point cloud P_s is transformed using T_k:

$$P'_s = \{T_k p \mid p \in P_s\} \tag{6}$$

These steps are repeated until convergence. For improved registration accuracy the Colored ICP variant is used. Colored ICP incorporates color information in addition to spatial coordinates. The error function for Colored ICP is modified to include a color difference term:

$$E(T) = \frac{1}{N} \sum_{i=1}^{N} \left(||q_i - T_k p_i||^2 + \lambda ||c(q_i) - c(T_k p_i)||^2 \right) \tag{7}$$

where $c(p_i)$ and $c(q_i)$ are the color vectors of the corresponding points, and λ is a weighting factor that balances the geometric and color terms.

3.3 AI-Driven Detection and Segmentation

The preprocessed and registered data is fed into a pipeline comprising GroundingDINO and SegmentAnything (SAM) models. GroundingDINO processes the 2D image projection of the registered point cloud, generating bounding boxes for objects based on language prompts. The output of GroundingDINO is a set of bounding boxes $B = \{b_1, b_2, ..., b_n\}$, where each bounding box b_i is represented by its coordinates $(x_{min}, y_{min}, x_{max}, y_{max})$ and a confidence score s_i. The bounding boxes generated by GroundingDINO are refined using Non-Maximum Suppression (NMS) to eliminate overlapping and redundant detections. The Intersection over Union (IoU) between two bounding boxes b_i and b_j is computed as:

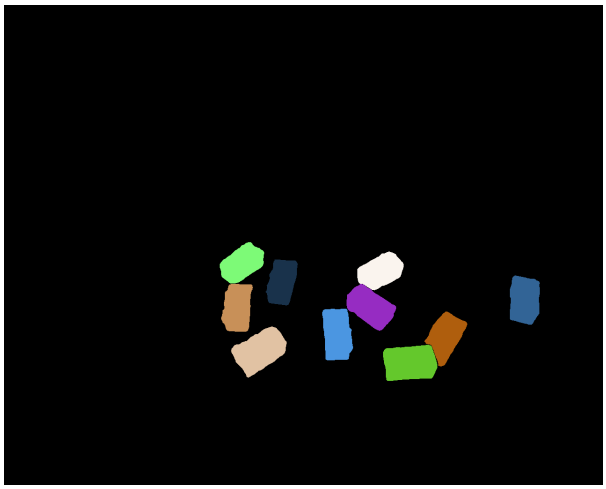

Figure 5. Segmentation mask created with SAM.

$$\text{IoU}(b_i, b_j) = \frac{\text{Area}(b_i \cap b_j)}{\text{Area}(b_i \cup b_j)} \tag{8}$$

If the IoU between two boxes exceeds a predefined threshold, the box with the lower confidence score is suppressed. The refined bounding boxes are passed to the SegmentAnything model, which generates precise instance masks for each detected object (Figure 5). The output of SAM is a set of instance masks $M = \{m_1, m_2, ..., m_n\}$, where each mask m_i corresponds to a detected object and has the same dimensions as the input image. The 2D segmentation masks are mapped back onto the 3D registered point cloud shown in Figure 6. For each point $p = (x, y, z)$ in the point cloud, its corresponding pixel (u, v) in the 2D image is determined using the projection equations derived from the camera intrinsic matrix K. The value of the segmentation mask $m_i(u, v)$ at that pixel is then assigned to the point p as shown in equation (4).

3.4 Object Localization and Grasp Planning

After detection and segmentation, localized objects are analyzed for spatial attributes using Principal Component Analysis (PCA). For a segmented point cloud P_i, the covariance matrix C is computed to determine its principal axes:

$$C = \frac{1}{n-1} \sum_{i=1}^{n} (p_i - \bar{p})(p_i - \bar{p})^T \tag{9}$$

where n is the number of points, p_i is a point, and $\bar{p}$ is the centroid. The eigenvectors of C represent the principal axes, forming the basis for the Oriented Bounding Box (OBB). The extents of the OBB are defined by projecting

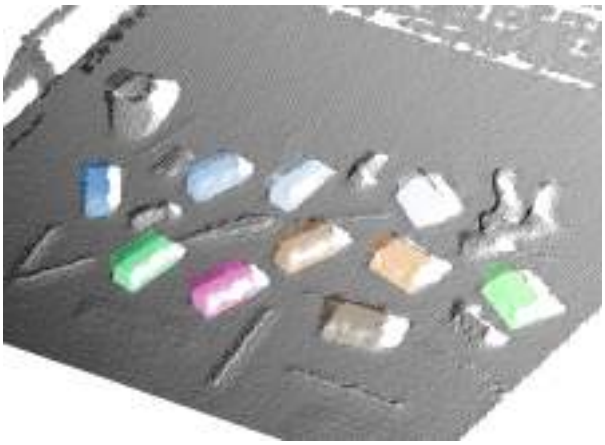

Figure 6. Mapped segmentation mask.

P_i onto the principal axes. Gripping points are selected by evaluating the longest edges of the OBB, with midpoints prioritized as candidate gripping lines:

$$m = \frac{p_j + p_k}{2} \tag{10}$$

where p_j and p_k are endpoints of the edge. Suitability of gripping points is based on gripper dimensions and workspace accessibility. Figure 7 illustrates the OBB and selected gripping locations.

Figure 7. Calculated OBB and grasping locations.

3.5 Robotic Execution

The gripping and placement actions are translated into joint commands for the UR10e robotic arm. Inverse kinematics (IK) computes the joint angles θ required to achieve the desired end-effector pose $\tilde{T}$, ensuring smooth, collision-free movements. The desired pose $\tilde{T}$ is derived from the calculated gripping points and desired placement locations. The relationship between joint angles and end-effector pose is given by:

$$FK(\theta) = \tilde{T} \tag{11}$$

where $FK(\theta)$ represents the forward kinematics function of the robot, mapping joint angles θ to the end-effector pose.

Trajectory planning generates intermediate waypoints between the initial and target poses, optimizing for speed and safety. Smooth joint-space trajectories are interpolated using cubic splines:

$$\theta(t) = a_0 + a_1 t + a_2 t^2 + a_3 t^3 \tag{12}$$

where $\theta(t)$ is the joint angle at time t, and a_0, a_1, a_2, a_3 are the spline coefficients.

The trajectory is validated in a PyBullet simulation and converted into robot-specific motion and gripper control commands. These commands are executed by the UR10e robot to perform the desired tasks, such as picking up a detected object and placing it at the target location.

4 Experimental Evaluation and Results

4.1 Experimental Setup

The experiments were carried out in the setup described in the System Overview section 2, representing typical construction scenarios. A total of 150 test scenarios were executed, with varying object arrangements of items like wooden blocks, cables and other common construction items, and environmental conditions to evaluate the robustness and adaptability of the system.

4.2 Evaluation Metrics

The performance of the system was evaluated using the following metrics:

- **Detection Accuracy:** The percentage of correctly detected objects compared to the ground truth, measured for both bounding boxes and segmentation masks.
- **Segmentation Precision:** The Intersection over Union (IoU) between predicted and ground-truth masks, averaged across all detected objects.
- **Manipulation Success Rate:** The percentage of successful grasp-and-place operations out of the total attempts.
- **Processing Time:** The average time required for data acquisition, detection, segmentation, and command generation.

4.3 Results

The system achieved high performance across all evaluated metrics, demonstrating its robustness and adaptability

Table 1. Performance Metrics of the Robotic System

Metric	Average Value
Detection Accuracy	95.8%
Segmentation Precision (IoU)	89.6%
Manipulation Success Rate	93.2%
Average Processing Time	6.3 s

to diverse scenarios. The results, averaged over the 150 test scenarios, are summarized in Table 1.

The integrated use of GroundingDINO and SegmentAnything resulted in an average detection accuracy of 95.8% and an average segmentation precision (IoU) of 89.6%. These results demonstrate the system's ability to accurately detect and segment objects even in cluttered environments with varying object arrangements. Figure 8 illustrates the detection and segmentation outputs for a sample scene, highlighting the precision of bounding boxes and instance masks generated by the AI models.

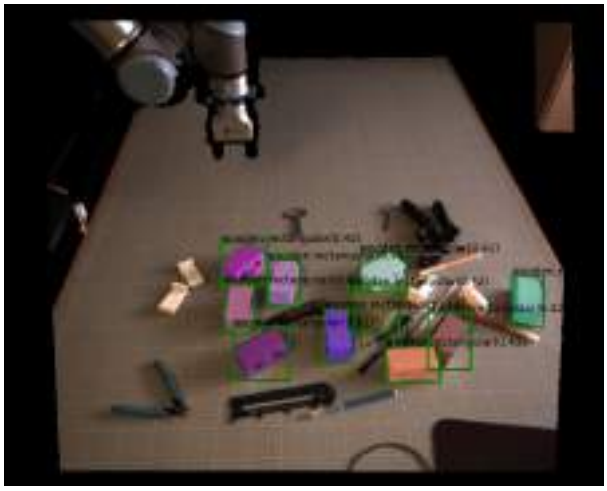

Figure 8. Sample outputs showing object detection and segmentation results.

The robotic arm successfully completed 93.2% of the grasp-and-place tasks across the 150 test scenarios. This high success rate demonstrates the system's capability to handle objects with varying shapes, sizes, and orientations. The few instances of failure were primarily attributed to limitations in the accuracy of the point cloud data for objects located further away from the scanner or those with highly reflective surfaces. These inaccuracies occasionally led to slight errors in the generated bounding boxes, making grasping more challenging.

The average processing time from data acquisition to command execution was 6.3 seconds. This includes 2.1 seconds for point cloud preprocessing and registration, 1.5 seconds for detection and segmentation using GroundingDINO 1.0 and SAM, and 2.7 seconds for object localization, grasp planning, trajectory generation, and command execution. Experiments were also conducted with GroundingDINO 1.5, which resulted in a slightly higher processing time of 9.5 seconds. The increased time is attributed to its API-based object detection approach, which added latency. However, GroundingDINO 1.5 provided a marginal improvement in detection precision (+2.5%).

4.4 Discussion

The lab evaluation demonstrates the system's potential for construction robotics, achieving high accuracy in detection and segmentation using 2D AI models in a 3D context. However, the controlled lab environment differs significantly from complex real-world construction sites, which involve dynamic lighting, dust, and larger scales. Sensor limitations were observed with reflective surfaces and distant objects, suggesting lab performance may not directly translate to real-world scenarios. Processing time, while acceptable for lab demonstrations, could limit real-time applications in dynamic environments. Validation metrics are encouraging for lab experiments, but failure analysis highlights areas for improvement. Manipulation failures were mainly due to perception inaccuracies from degraded point clouds, leading to grasping errors. Even with accurate detection, subtle 3D localization errors impacted grasping, emphasizing manipulation's dependence on robust perception in challenging conditions. Qualitatively, compared to methods like PointNetGPD, [11], RT-2 [13], PointRCNN [10] our 2D AI-in-3D approach, using pre-trained GroundingDINO and SAM, offers a balance of generalization and performance. It leverages 2D vision advancements but involves a pipeline that may introduce latency. Quantitative comparisons are needed to validate our approach against state-of-the-art methods. The successful manipulation rate in the lab confirms perception-to-action feasibility in a controlled setting.

5 Conclusion and Future Works

This work demonstrates a robotic system for object detection, segmentation, and manipulation in a controlled lab, showing promise for construction automation. Leveraging 2D AI models like GroundingDINO [3] and SegmentAnything [2] for 3D vision was effective in simulations, and manipulation success validated grasp planning strategies under these conditions. Future efforts will prioritize robustness, versatility, and real-time performance for real-world deployment. Rigorous virtual testing using game engines and datasets is crucial to assess robustness and bridge the gap to real-world validation. Future research should generalize AI models to diverse construction elements and tools, exploring adaptation strategies.

Improving robustness requires better sensing solutions, including sensor fusion and advanced point cloud processing, to address challenges like reflective surfaces and distance. Future directions include integrating advanced depth estimation models like Depth Anything V2 [14], exploring tactile sensing [16] for dexterous manipulation, and optimizing efficiency for real-time performance. Expanding to multi-robot collaboration using multi-RGBD camera setups [6], addressing occlusion, and investigating intuitive human-robot interaction via AR [17], NLP, and voice commands using reasoning LLMs like OpenAI's o1 [18] are also key. Furthermore, continual learning will be explored for autonomous adaptation. Building upon the findings of this research, our next step involves implementing the system on a larger KUKA robot and deploying it in a real construction site environment to further evaluate its performance and address real-world challenges. Pursuing these paths aims to create a highly adaptable and efficient robotic solution to enhance construction productivity, safety, and flexibility, enabling broader robotic automation and transforming building practices.

Abstract

Ensuring the proper use of personal protective equipment (PPE), particularly helmets, is crucial for enhancing safety on construction sites. This study proposes a novel approach for detecting helmet usage and worker states using ultra-wideband (UWB) localization sensors combined with machine learning algorithms. Unlike traditional sensor-based or image-based systems, the proposed method integrates helmet detection into existing proximity warning systems, offering a cost-effective solution without the need for additional hardware. Data was collected from 12 participants in a controlled environment using UWB sensors, and a machine learning model was developed to classify four worker states: standing with a helmet, standing while holding a helmet, walking with a helmet, and walking while holding a helmet. The Gradient Boosting Decision Trees (GBDT) algorithm was selected for model development due to its superior performance. The model achieved an overall accuracy of 74.46% and performed well in detecting unsafe conditions. However, variability was observed in identifying safe states. Additionally, the study explored the impact of worker height on Z-axis localization error, revealing a correlation that suggests the need for height-adjusted safety monitoring systems. This research demonstrates that UWB-based systems can enhance PPE monitoring, reduce computational costs, and address privacy concerns, while also highlighting areas for future improvement, such as expanding the model to detect other PPE and refining its ability to differentiate between worker postures.

Keywords

Personal Protective Equipment (PPE); Construction Safety; Ultra-wideband Technology (UWB); Machine Learning.

1 Introduction

Construction sites are among the most hazardous environments for workers, with many sustaining injuries or losing their lives in workplace accidents every year. Numerous solutions have been proposed to enhance safety on construction sites, one of which is the use of personal protective equipment (PPE). The use of PPE can significantly reduce workplace risks and fatal accident [1, 2]. Previous studies have demonstrated that safety behaviors, including the consistent use of PPE, are strongly associated with a reduction in work-related injuries. Conversely, unsafe behaviors, such as the failure to wear PPE, are key risk factors in workplace accidents [3].

One of the challenges related to construction worker safety is the ineffective use of PPE. Factors such as discomfort, inadequate training, and poor communication between safety managers and workers can hinder the effective use of PPE. As a result, one of the main responsibilities of safety managers is to ensure that workers are wearing PPE on site. However, due to the dynamic and expansive nature of construction sites, manual supervision of PPE usage by safety managers is often inefficient. Consequently, efforts have been made to develop automated solutions for monitoring PPE usage by workers. Solutions include wearable devices, computer vision, and deep learning models [4-6].

These technologies enable real-time monitoring of PPE usage and can proactively warn workers of potential safety hazards, ensuring that they are properly wearing their safety gear, thereby reducing the likelihood of accidents. However, the adoption of these technologies is not without challenges [7-9]. For instance, the use of cameras on construction sites, in addition to the high costs associated with purchasing and processing equipment, raises concerns about worker privacy.

One technology used to improve worker safety is real-time localization through Ultra-wideband (UWB) sensors. This technology is typically employed in proximity warning systems to locate workers on construction sites and provide alerts when they approach hazardous areas. While these systems generally offer accurate two-dimensional localization of workers, three-dimensional localization, which involves the z-axis, often results in significant errors [10]. Consequently, using the z-axis for tasks that require high precision may not yield

satisfactory results. However, if machine learning can be used to detect helmet usage based on the relatively imprecise z-axis data from these systems, it would be possible to extend their functionality without additional equipment.

Therefore, the objective of this research is to develop a model for detecting helmet usage by workers on construction sites using machine learning and UWB technology. By developing this model, it will be possible to monitor both the location of workers and their PPE status using current proximity warning systems without the need for additional equipment. This method not only preserves worker privacy but also reduces the financial and computational costs associated with system development.

2 Literature Review

Given the importance of safety in construction sites, numerous previous studies have proposed various solutions to ensure the appropriate use of PPE by workers. These solutions typically follow two main approaches: sensor-based methods and image processing techniques. Sensor-based studies often use proximity sensors, such as Bluetooth and RFID, to monitor the use of PPE [8, 11-13]. However, due to the limited applicability of these solutions, using such equipment solely to track PPE usage can increase initial costs. Another limitation of these methods is their inability to detect individuals outside of the predefined system. Moreover, the need for separate hardware to address different safety-related applications ultimately reduces the feasibility of implementing these solutions in construction sites.

On the other hand, image processing and deep learning models have gained significant attention in recent years. In this line of research, scholars typically collect images from construction site environments and process them using deep learning models. These models first detect target equipment, such as helmets and vests, and then assess whether workers are wearing the equipment by analyzing the relationship between the worker and the detected gear [4, 6, 9, 14-16]. Researchers have worked to incorporate equipment of various colors into their models and evaluate the performance of different models, such as YOLO and YOLACT-based approaches. However, this method also presents challenges.

One such challenge is the dependence of cameras on direct line of sight. Additionally, using cameras to monitor workers on construction sites raises concerns about worker privacy. Furthermore, many studies that employ this approach often integrate several deep learning models to achieve their goals, which significantly increases computational load. As a result, to achieve near-real-time performance, costly hardware is required to run the models. Considering the advantages and disadvantages of these approaches, there is a need to develop a model that retains the strengths of both methods while addressing their associated challenges.

3 Methodology

This research followed a three-step process to achieve its objective of developing a model for detecting helmet usage in construction sites using UWB sensors. These steps included data collection, machine learning model training, and performance evaluation. In the following sections, the scope of the research will first be outlined, followed by a detailed description of each step in the methodology.

3.1 Research Scope

Construction workers engage in various tasks on site, during which wearing a helmet is mandatory. Since this study aims to explore the use of UWB sensors and machine learning models for helmet usage detection, four possible worker states were considered: (1) standing while wearing a helmet (CL1), (2) standing while holding a helmet (CL2), (3) walking while wearing a helmet (CL3), and (4) walking while holding a helmet (CL4). These states represent typical conditions encountered in construction sites. Accordingly, the necessary data for developing a machine learning model to differentiate between these states were collected, followed by the model's development.

3.2 Data Collection

Data collection was conducted in a controlled laboratory environment. UWB Real-Time Location Systems (RTLS) generally consist of anchors and tags, where the anchors serve as reference points and the tags represent moving objects. In this study, the DWM1001C 6.5 GHz transceiver was used, which can function as both tags and anchors. Four anchors were placed at a height of 1.9 meters, covering a square area of 7 by 7 meters. Additionally, a tag was attached to a helmet, which was used for data collection in this study (Figure 1c).

To gather the data, participants were asked to perform each of the states outlined in the research scope for a duration of two minutes, during which their localization data, including x, y, and z coordinates, were recorded. The UWB modules were set to a frequency of 10 Hz, ensuring that data points were collected at 10 readings per second. Prior to data collection, participants' demographic information, such as height and gender, was recorded. A total of 12 participants took part in the experiment, resulting in the collection of 66,446 data records. Their collective demographic information is presented in Table 1.

Figure 1. (a) Laboratory setup with UWB anchors. (b) UWB anchor at 1.9 m. (c) Helmet with UWB tag.

Table 1. Participant demographics: gender, count, height stats.

Gender	Count	Avg. Height (m)	Min. Height (m)	Max. Height (m)	Std. of Height
F	3	1.64	1.62	1.69	0.03
M	9	1.80	1.68	1.93	0.07
Total	12	1.76	1.62	1.93	0.09

3.3 Data Preprocessing

3.3.1 Data Cleaning

As previously mentioned, the aim of using machine learning algorithms in this study to detect helmet usage by workers is addressing the significant error in the z-axis measurements provided by UWB sensors. Therefore, outlier removal must be handled with extra care, as removing a substantial portion of the data could limit the model's generalizability. Additionally, given the wide range of data values due to variations in participant heights, removing outliers based on aggregated user data could introduce bias into the model. To avoid this, the Isolation Forest [17] algorithm was applied individually to each participant's data, with a contamination rate of 2% used to identify and remove outliers. The data preprocessing was implemented using Python 3.8.9 with Scikit-learn 1.3.2 and Pandas 2.0.3. After performing outlier detection and cleaning, the total number of data records decreased from 66,446 to 64,380.

3.3.2 Feature Engineering

Feature selection and extraction are critical steps in developing a machine learning model when working with location data collected in a laboratory environment. Since the laboratory space is limited, the data range in all three dimensions is also constrained, which can lead to overfitting. In such cases, the model may associate different states with the participants' specific locations in the lab, rather than identifying meaningful relationships between the data points. For instance, if participants remain in one specific area of the lab while performing a particular state, the model might incorrectly link that state to those specific coordinates. However, this would not hold true in real-world construction sites.

To mitigate overfitting, instead of using the raw x and y coordinates, the changes in these coordinates relative to previous steps were used as features for model training. The specific time intervals (10, 50, 100, and 150 steps) were selected based on temporal considerations. Since the UWB modules were set to a frequency of 10 Hz, each 10 steps correspond to approximately 1 second of data collection. The selected intervals therefore represent time windows of approximately 1, 5, 10, and 15 seconds, respectively. This range was chosen to balance the trade-off between model accuracy and real-time performance capabilities. Shorter intervals (e.g., 10 steps) capture immediate movements but may miss longer patterns, while longer intervals (e.g., 150 steps) capture more comprehensive movement patterns but increase the latency of detection in real-time applications. Table 2 lists the features selected for developing the machine learning model. It should be noted that, in addition to the rationale mentioned above, these features were also chosen based on their significance as determined through feature importance analysis.

3.4 Machine Learning Model Development

3.4.1 Algorithm Selection

The model training process involved training multiple models based on different machine learning algorithms, evaluating the performance of each, selecting the best-performing algorithm, and subsequently optimizing the chosen model and reporting its performance. In the initial selection of algorithms, a range of options was considered, from less complex algorithms such as SVM to more complex ones like deep learning algorithms. The rationale behind this approach was to identify an algorithm with lower computational cost and greater transparency. All models were implemented using Scikit-learn 1.3.2, with the Gradient Boosting Decision Trees (GBDT) implementation utilizing XGBoost 2.1.1. Additional libraries used in the analysis include NumPy 1.24.4 and Seaborn 0.13.2 for data manipulation and visualization. After evaluating the models developed in the first step, the GBDT algorithm was selected for further development and optimization due to its superior performance compared to other algorithms. A list of the evaluated algorithms and their performance is presented in Table 3.

Table 2. Selected features for ML model to mitigate overfitting

Feature	Description
z	Z coordinate values
z_norm	Z coordinate values normalized by the participant's height
dz_10	Change in Z coordinate compared to the value 10 steps earlier
dist_10	Distance change compared to the position 10 steps earlier (using X, Y, and Z)
dz_norm_10	Normalized Z changes compared to 10 steps earlier
dz_50	Change in Z coordinate compared to the value 50 steps earlier
dz_norm_50	Normalized Z change compared to 50 steps earlier
dist_50	Distance change compared to the position 50 steps earlier (using X, Y, and Z)
dz_100	Change in Z coordinate compared to the value 100 steps earlier
dz_norm_100	Normalized Z changes compared to 100 steps earlier
dist_100	Distance change compared to the position 100 steps earlier (using X, Y, and Z)
dz_150	Change in Z coordinate compared to the value 150 steps earlier
dz_norm_150	Normalized Z changes compared to 150 steps earlier
dist_150	Distance change compared to the position 150 steps earlier (using X, Y, and Z)

Table 3. Performance metrics of ML algorithms.

Model	AUC	F1	Prec.	Recall
Random Forest	0.945	0.712	0.721	0.724
SVM	0.763	0.398	0.415	0.395
Decision Tree	0.803	0.671	0.674	0.682
AdaBoost	0.773	0.626	0.629	0.635
Logistic Regression	0.928	0.585	0.674	0.615
kNN	0.843	0.489	0.49	0.491
Gradient Boosting	0.946	0.717	0.731	0.728
Naive Bayes	0.891	0.571	0.596	0.596

3.4.2 Model Training and Evaluation

The XGBoost library was used to implement the GBDT algorithm. One critical aspect to consider was the division of the available data for training, validation, and testing of the model's performance. In this study, instead of merging the data from all participants and splitting it based on a percentage of the total data, the data were divided based on the number of participants, without merging. Specifically, data from 6 out of the 12 participants were used for training the model, 3 participants' data were used for testing, and 3 participants' data were reserved for validation during training.

The model training process involved optimizing the model's parameters to achieve the best possible results. This was done using a Grid Search approach with 5-fold cross-validation to find the optimal hyperparameters. The parameter grid explored ranges for learning rate (0.05-1), max depth (3-9), number of estimators (50-150), subsample ratio (0.5-0.9), column sample by tree (0.5-1), and gamma (0-0.1). The XGBoost model was configured to utilize GPU acceleration via CUDA, and hyperparameter tuning was performed by selecting the parameter combination that achieved the highest accuracy. The training and optimization process was performed on an Nvidia RTX 4070 Ti GPU. Once the optimal parameters were obtained, the model was trained and tested 100 times to assess its performance. In each iteration, the participants were randomly assigned to training, testing, and validation sets. The results of the model evaluation will be discussed in the next section.

4 RESULTS

After repeating the training and evaluation process 100 times, the model's performance for each class was recorded in every iteration. The average performance metrics from these evaluations can be seen in Table 4 and Figure 2. The overall accuracy of the model, considering all classes, was 0.744. The developed model demonstrated satisfactory capability in distinguishing between safe and unsafe conditions. In Classes 2 and 4, where workers are not wearing helmets and are thus considered in an unsafe state, the model performed well. The average accuracy for Class 2 was 69%, with a precision of 74.2%, while for Class 4, the accuracy was 83%, and the precision was 86.7%. These results indicate that the model effectively identifies unsafe conditions.
However, the model's performance was more variable for Classes 1 and 3, where workers are wearing helmets and are considered to be in a safe state. Class 1 achieved an average accuracy of 66.6% and a precision of 66.4%, while Class 3 had a higher accuracy of 79.1%. Overall, the model was able to adequately differentiate between safe and unsafe conditions, but improvements in accurately detecting safe workers could help reduce false negatives and enhance the system's overall accuracy.

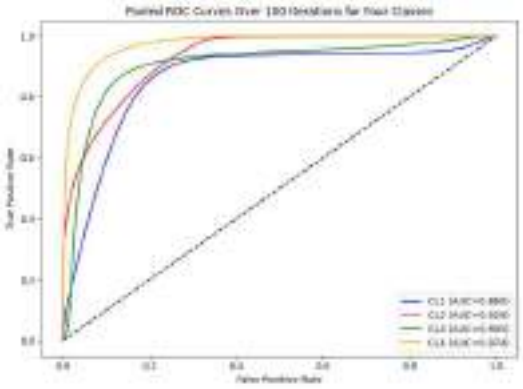

Figure 2. One-vs-Rest ROC curve showing AUC values across four classes.

Table 4. Performance metrics for each class.

Class	Acc.	Precision	Recall	F1	AUC
CL1	0.666	0.664	0.666	0.652	0.860
CL2	0.690	0.742	0.690	0.696	0.929
CL3	0.791	0.750	0.791	0.766	0.905
CL4	0.830	0.867	0.830	0.845	0.974

As the model demonstrated, it not only performed well in distinguishing safe conditions—where workers are wearing helmets—from unsafe ones, but it also showed the ability to differentiate between various worker states, such as standing or walking. Based on this capability, it was decided to assess the model's performance with the addition of another class. A new class was introduced, which involved the worker sitting on a chair while wearing a helmet. The entire training and testing process was repeated to evaluate the model's performance with this additional class. The results of this extended evaluation can be found in Table 5 and Figure 3.

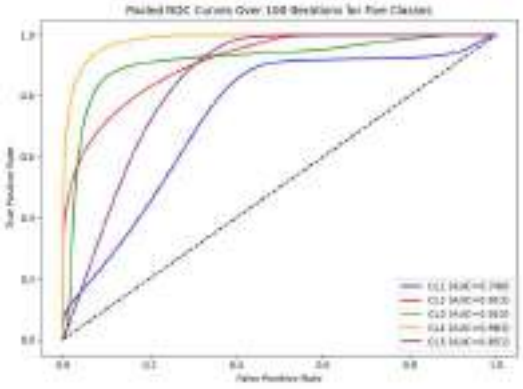

Figure 3. One-vs-Rest ROC curve showing AUC values across five classes.

Table 5. Performance metrics for five classes.

Class	Acc.	Precision	Recall	F1	AUC
CL1	0.318	0.415	0.318	0.341	0.740
CL2	0.673	0.733	0.673	0.684	0.913

5 DISCUSSION

5.1 Advantages and Limitations of the Proposed UWB and Machine Learning Approach

This study aimed to develop a model that not only detects whether workers are wearing helmets but also identifies various worker states using UWB RTLS, which are commonly used for tracking workers and issuing warnings when they approach hazardous areas or to prevent collisions. Machine learning algorithms were employed to achieve this goal.

The solution presented in this study offers both advantages and limitations compared to previous research. One of the key advantages of this approach over other sensor-based methods is that the UWB RTLS are not limited solely to PPE detection. Because this method can be integrated as an additional layer of safety monitoring within proximity warning systems, due to its software-based nature, it addresses the challenge of high initial costs typically associated with sensor-based methods. Moreover, the proposed model demonstrated that this approach can also be used to recognize different worker gestures, which could provide additional information to safety systems, facilitating their further development.

Additionally, the proposed model, being independent of cameras, avoids the disadvantages of image processing-based methods, such as privacy concerns, reliance on direct line of sight, and heavy computational loads. This independence allows for near-real-time performance in the dynamic environments of construction sites. However, it is important to note that this study focused solely on detecting helmet usage. In contrast, image processing methods can potentially detect the use of various other safety equipment, such as vests.

Moreover, the proposed model was tested in a controlled laboratory environment. However, previous studies have demonstrated that the accuracy of UWB RTLS can be impacted by various factors present in real construction sites, such as metal structures, equipment, and environmental conditions. Therefore, it is important

to validate the developed model in construction environments in future studies. Future work should also extend this model to include the detection of additional PPE to further enhance its applicability.

5.2 Impact of Participant Height on Z-Axis Localization Error

As demonstrated in the results section, while the models presented in this study are capable of distinguishing between safe conditions—indicated by helmet usage—and unsafe conditions, this capability fulfills the primary research objective of providing a model for differentiating these states using UWB. However, to improve the model's ability to differentiate between similar states, it is essential to identify the root cause of the existing error. One potential factor contributing to the increase in sensor error in the 3D space is the placement of the tags and anchors on the same plane (at the same height), which can reduce localization accuracy along the Z-axis.

To investigate this issue further, localization errors were evaluated based on the participants' heights. As shown in Figure 4, as the participants' height increases, the absolute localization error along the Z-axis also increases. The correlation between participant height and absolute error is 0.75, and the statistical significance of this relationship, with a p-value of 0.0052, suggests that as participants' height approaches the height at which the anchors are placed (1.9 meters), the error significantly increases. This finding is important because individuals with varying heights experience differing levels of error, and using the same system for individuals of different heights would result in varying safety levels. Therefore, it is necessary to adopt more flexible approaches, such as machine learning models, that can account for these variations.

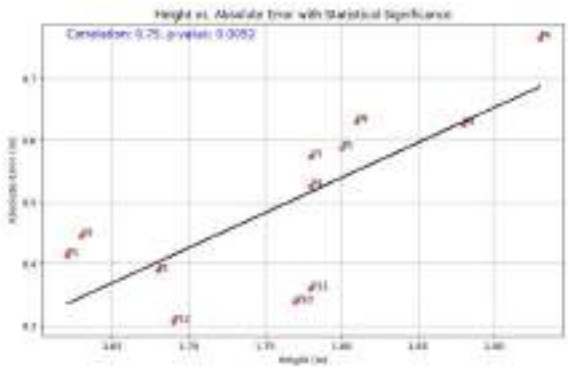

Figure 4. Correlation between participant height and Z-axis error.

6 Conclusion

This study successfully demonstrated the feasibility of using UWB sensors and machine learning algorithms to detect helmet usage and differentiate between various worker states on construction sites. The proposed approach offers significant advantages over existing sensor- and image-based methods by integrating PPE detection into existing proximity warning systems, thereby reducing costs and addressing privacy concerns. The model proved capable of accurately identifying unsafe conditions, though further improvements are necessary to enhance the detection of safe worker states, particularly in distinguishing between specific postures. Additionally, this study highlighted the impact of worker height on localization errors, suggesting that future systems should account for this factor to improve overall performance.

Future research should focus on several directions. First, expanding the model to detect other types of PPE, such as safety vests, would enhance its applicability in construction safety monitoring. Second, field validation in real construction site environments is needed to test the solution's reliability and performance under authentic conditions. Finally, as this study built its solution on top of existing proximity warning systems to decrease adoption costs, future studies can explore this approach to expand current safety systems and increase the practicality of proposed solutions for different applications in construction.

Abstract –

Rebar tying is a time-consuming and labor-intensive process that involves repetitive bending and hand motions to secure rebar with wire, often leading to muscular and skeletal injuries. To address these challenges, rebar tying robots have been developed to automate the process. However, existing studies primarily focus on tying point localization for horizontal rebar mesh, neglecting the 6 Degrees of Freedom (DoF) pose estimation necessary for tying complex reinforcement skeletons where rebar may be arranged in various spatial orientations. Therefore, this study proposes a 6-DoF rebar pose estimation method based on keypoint detection and point cloud registration. A deep learning-based keypoint detection algorithm is employed to extract point cloud data from each rebar intersection. Additionally, to tackle challenges posed by texture-less and self-occluding features of rebar point clouds, a coarse registration method utilizing geometric features and a fine registration method based on adaptive displacement correction is introduced to ensure accuracy and stability in rebar pose estimation. The proposed method enables the robot to autonomously understand the relative spatial relationship between itself and the tying objects, facilitating precise tying across a broader range of reinforcement skeletons, thereby significantly reducing the demand for manual labor.

Keywords –
Rebar tying; Rebar pose estimation; Keypoint detection; Point cloud registration; Reinforcement skeleton.

1 Introduction

Rebar tying is a crucial process in reinforced concrete construction. Its primary purpose is to secure the position of rebar, ensuring that it remains correctly positioned according to the design drawings during concrete pouring. However, manual rebar tying is a labor-intensive task that requires workers to bend repeatedly and tie each rebar crosspoint by hand [1].

To overcome this problem, vision-guided robotic systems have been applied to automate rebar tying tasks in recent years. For example, Tybot [2], a gantry-mounted tying robot shown in Figure 1 (a), navigates along the screed or porta-rail and uses a dual-camera system to extract tying information for bridge deck operations. Similarly, the rebar tying robot developed by the Beijing Institute of Technology [3], as shown in Figure 1 (b), moves steadily in four directions across the rebar mesh and employs a vision system to detect crosspoints and guide the tying process. A similar robot, T-iROBO [4], is shown in Figure 1 (c). In both types of robots, the vision system plays a critical role in tying operations by extracting spatial information about tying points through visual perception technology, thereby guiding the robot to complete tying tasks efficiently.

(a) (b) (c)

Figure 1. Rebar tying robots: (a) Tybot [2], (b) the rebar tying robot developed by the Beijing Institute of Technology [3], (c) T-iROBO [4].

For tying information extraction in the vision systems of rebar tying robots, Jin et al. [3] proposed using a deep learning-based keypoint detection algorithm to identify pixel coordinates of the rebar crosspoint and then calculate the rebar crosspoint's spatial coordinates by integrating the depth value of the point. Similarly, Cheng and Deng [5] introduced a rebar crosspoint recognition

method based on MobileNetV3 and the SSD algorithm. Previous research on rebar tying robots has primarily focused on detecting rebar crosspoints, enabling the robotic arm to perform three linear motions to position the end effector at the tie point. However, estimating the tying orientation has been less explored, despite its importance in guiding the end effector to rotate to the appropriate angle. This ensures that the tying wire correctly wraps around the rebar and facilitates subsequent tying operations. In construction practice, rebar planes are often positioned in various orientations on construction sites, such as the reinforcement skeletons of beams and walls, which can be vertical or inclined as well as horizontal. In these scenarios, a robotic arm with at least 6 Degrees of Freedom (DoF) is typically required to perform 6-DoF tying operations, enabling flexible positioning and orientation to meet complex rebar tying requirements. Consequently, merely detecting tying position information in previous research is insufficient for addressing rebar tying tasks in reinforcement skeletons, and it is desired to develop advanced vision perception methods to enable rebar tying robots to adapt to various spatial configurations and perform 6-DoF tying operations effectively.

Object pose estimation plays a crucial role in 6-DoF robotic manipulation, enabling robots to determine the spatial position and orientation of objects for accurate task execution [6]. Traditional methods determine the object pose by aligning the template point cloud with the scene point cloud using point cloud registration techniques [7]. The Iterative Closest Point (ICP) algorithm is one of the most commonly used point cloud registration methods for object pose estimation. It is typically employed to refine the pose after an initial rough estimate, as ICP is prone to get trapped in local optimal without a good starting pose [7]. Coherent Point Drift (CPD) is another widely used registration method capable of handling rigid, non-rigid, and affine transformations, making it suitable for pose estimation of deformable objects like cables and ropes [8,9]. Additionally, feature-based registration techniques, including point feature histograms (PFH) and fast point feature histograms (FPFH) have also been adapted for object pose estimation [10]. However, despite their widespread use, traditional methods exhibit limitations when applied to texture-less objects, as similar surface features can lead to incorrect matches between corresponding and non-corresponding points during the registration process [11]. Rebar point cloud models often exhibit texture-less surfaces, and occlusions caused by outer rebar obscuring inner rebar further complicate point cloud registration. These challenges increase the risk of inaccurate rebar pose estimation, potentially leading to collisions between the robot and the rebar. Therefore, there is a pressing need for a novel rebar pose estimation method capable of addressing the challenges posed by texture-less and self-occluding features to enhance the accuracy of robotic tying operations.

To enhance the robot's capability to perform tying operations on complex reinforcement skeletons, where rebar may be arranged in various spatial orientations, this paper proposes a rebar pose estimation method that using deep learning-based keypoint detection and point cloud registration. The proposed method includes several key innovations: (1) Introducing a tying point localization method based on keypoint detection, generating input data with prior displacement information. (2) Proposing a coarse-to-fine registration approach to handle texture-less and self-occluding rebar point clouds for rebar pose estimation. This innovative method enables the robot to adapt to diverse spatial configurations of the reinforcement skeleton and perform tying operations from various orientations and positions.

2 Method

To apply robotic rebar tying technology to diverse reinforcement skeletons in three-dimensional (3D) space, this paper develops a rebar pose estimation method to guide a 6-DoF robot in performing flexible tying operations from various orientations and positions. As shown in Figure 2, the proposed method comprises three modules: data generation, coarse registration, and fine registration. The data generation module functions as a preprocessing component, generating input data and prior displacement information for rebar pose estimation. The coarse registration and fine registration modules implement a coarse-to-fine point cloud registration method to address the challenges of texture-less and self-occluding, enabling accurate alignment of the template point cloud from the template frame to the camera frame for precise rebar position estimation. A detailed explanation is provided below.

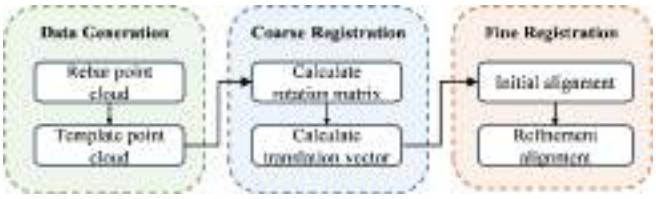

Figure 2. Flowchart of proposed formwork

2.1 Data Generation

2.1.1 Rebar Point Cloud

Keypoint detection is a critical task in computer vision, aimed at identifying essential features such as edges, corners, and textured areas within images or videos. In this study, the recently proposed deep learning-based keypoint detection model YOLOv8 [12] is employed to generate rebar point cloud data and extract the coordinate information of tying points for rebar pose estimation. This is achieved by detecting the bounding boxes and rebar crosspoints, followed by extracting the point cloud from the depth map of the tying area.

Reinforcement skeletons often contain multiple rebar layers at varying depths, presenting a visual challenge for keypoint detection algorithms in accurately identifying the top-layer crosspoints. To mitigate visual interference from rebars at different depths, this study uses a preprocessing technique [13] that applies a point cloud plane fitting algorithm to segment the point cloud at various depths and extract data corresponding to the nearest plane. The resulting point cloud data is transformed into a 2D color image containing only the pixels from the top-layer rebar. By focusing exclusively on the relevant layer, the preprocessing step facilitates accurate localization of tying points on the top layer, ensuring precise coordinate and point cloud data in the crosspoint area. Throughout this paper, the rebar point cloud in the area of the rebar crosspoint is referred to as the "rebar point cloud".

2.1.2 Template Point Cloud

Traditional object pose estimation method determines the pose of an object by aligning a template point cloud, which represents the object's shape and geometric features, with the object point cloud using point cloud techniques. In this study, the template point cloud used for rebar pose estimation is designed based on the typical layout of two intersecting cylindrical rebars in the tying area. The rebar length in the template point cloud is set to *3d*, where *d* is the diameter of the largest rebar in the intersection. Furthermore, to ensure a clear interpretation of registration results, the template's coordinate frame is aligned with the camera's coordinate frame with the Z-axis normal to the rebar plane and the X- and Y-axes aligned with the horizontal and vertical rebars, respectively.

2.2 Coarse Registration

The goal of the coarse registration module is to achieve a rough alignment between the template point cloud and the rebar point cloud. As shown in Figure 3, this is accomplished by determining the appropriate rotation matrix R and translation vector t based on the geometric feature of the rebar point cloud.

The rotation matrix R is computed by aligning the template point cloud parallel to the rebar point cloud using the normal vectors of the planes associated with both point clouds. Let n_t and n_r represent the normal vectors of the planes corresponding to the template point cloud and the rebar point cloud, respectively. In this study, we assume that n_t=(0,0,1). The normal vector n_r can have two possible orientations, which can result in different rotation axes and angles. To ensure consistent alignment, we control the orientation of n_r by ensuring its Z-component is positive, thereby aligning it with n_t. The rotation angle and axis can then be uniformly determined using the following equations:

$$n_r^{'} = \begin{cases} n_r, if\ (n_r)_z > 0 \\ -n_r, if\ (n_r)_z < 0 \end{cases} \tag{1}$$

$$\theta = \arccos\left(\frac{|\, n_r^{'} n_t \,|}{\| n_r^{'} \| \| n_t \|}\right) \tag{2}$$

$$k = \frac{n_t \times n_r^{'}}{\| n_t \times n_r^{'} \|} \tag{3}$$

where $(n_r)_z$ represents the Z-component of the vector n_r, θ refers to the rotation angle from n_t to $n_r^{'}$, and k represents the rotation axis vector. To determine the desired rotation matrix, an extended Rodrigues vector rotation formula is employed, which is widely utilized to describe rotations involving known rotation axes and specified angles [14].

$$R = E\cos\theta + (1-\cos\theta)\begin{pmatrix} k_x \\ k_y \\ k_z \end{pmatrix}(k_x, k_y, k_z) + \sin\theta \begin{pmatrix} 0 & -k_z & k_y \\ k_z & 0 & -k_x \\ -k_y & k_x & 0 \end{pmatrix} \tag{4}$$

where k_x, k_y and k_z denote the three components of the rotation axis k.

Furthermore, the translation vector t is determined by the difference in spatial coordinates between the tying point in the rebar point cloud, calculated from the pixel coordinates $p_r(u,v)$ predicted by YOLOv8, and the corresponding predefined point P_t.in the template point cloud. To obtain the spatial coordinate of the tying point in the rebar point cloud, pixel coordinates $p_r(u,v)$ are converted into spatial coordinates $P_r(X,Y,Z)$ using the following formula:

$$\begin{pmatrix} X \\ Y \\ Z \end{pmatrix} = d \cdot K^{-1} \cdot \begin{pmatrix} u \\ v \\ 1 \end{pmatrix} \quad (5)$$

where d is the depth value of tying point, and K represents the camera intrinsic matrix. The translation vector t can be calculated as:

$$t = P_r - R \cdot P_t \quad (6)$$

2.3 Fine Registration

To further enhance the registration accuracy, the point-to-plane ICP method [15] is employed to minimize the alignment errors between the template point cloud and the rebar point cloud during fine registration. Upon completion of the registration process, the ICP algorithm yields the transformation matrix that aligns the roughly registered template point cloud with the rebar point cloud, ensuring precise alignment for subsequent processing tasks. However, the rebar point cloud often exhibits uneven density between the inner and outer rebar due to self-occlusion, which can cause the registration algorithm to prematurely converge to a local optimum. This typically occurs when the outer rebar is aligned, leaving the sparser inner rebar unaccounted for. To address this issue, an adaptive displacement correction strategy is designed to help the algorithm escape from local optima, as shown in Figure 3. Specifically, after the initial fine registration using point-to-plane ICP, the registration quality is evaluated based on the root mean square error (RMSE) threshold ε. If the RMSE between the aligned template and rebar point clouds exceeds ε, it indicates insufficient alignment and necessitates corrective action. The correction involves introducing displacement value s along both the positive and negative directions of the outer rebar axis in the template frame, followed by recalculating the RMSE for both cases. The displacement correction is then applied in the direction that minimizes the error. Point-to-plane ICP is subsequently reapplied until either the accuracy requirement is satisfied or the maximum number of iterations is reached. In this paper, the RMSE threshold ε was set to 0.9, and the displacement value s was set to $2d$, where d represents the diameter of the inner rebar. This displacement correction strategy enhances alignment robustness and improves overall registration accuracy, leading to more accurate pose estimations for the rebar tying task.

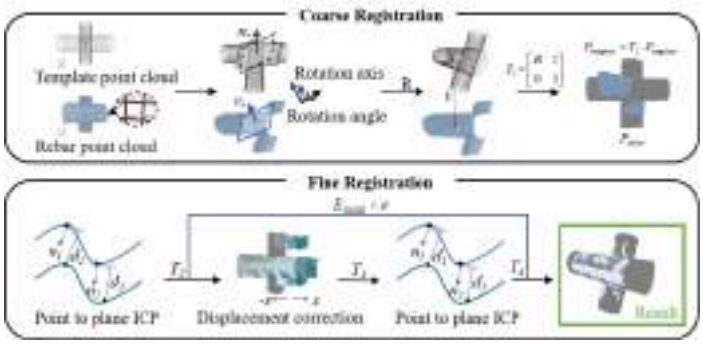

Figure 3. Coarse registration module and fine registration module.

3 Experiment Design

3.1 Experiment Device

The proposed rebar pose estimation method has been integrated into a rebar tying robot developed by our research team, as shown in Figure 4. This system comprises several key components: a 4WD mobile base with a load capacity of 150 kg for enhanced mobility; a 6-DoF robotic arm with a working radius of 1,300 mm for versatile manipulation; and a rebar tying gun as the end effector. Additionally, a 3D camera is configured in an "eye-in-hand" setup, providing a resolution of 1280×1024 and achieving a repeatability of 0.1 mm at a distance of 0.5 m. The industrial PC, operating on Ubuntu 20.04, is equipped with an NVIDIA Ampere GPU and an 8-core ARM Cortex-A78AE CPU, ensuring robust computing capabilities for efficient processing.

Figure 4. Rebar tying robot developed by our research team.

3.2 Experiment Settings

Two experiments were conducted to validate the proposed method. Experiment 1 aimed to test the effectiveness of the proposed coarse-to-fine point cloud registration algorithms for rebar pose estimation, comparing it with other mainstream registration algorithms, such as ICP [15], RANSAC [16], and FGR [17]. All algorithms were implemented using Open3D. To assess the performance of each algorithm in complex scenes, a dataset comprising 3,000 point clouds was created, with 600 point clouds captured at each of the following angles: 0°, 10°, 20°, 30°, and 40°. As shown in Figure 5, the production process involved the following steps: (1) Color maps and depth maps were captured at various angles, with 0° being the ideal camera orientation (Z-axis perpendicular to the rebar plane, X- and Y-axes are aligned parallel to the rebar). Other angles were achieved by rotating around the X-, Y-, and Z-axes. (2) The collected color images underwent preprocessing before being input into the YOLOv8 model for tying point localization. (3) Based on the predicted bounding boxes from the YOLOv8 model and the corresponding depth maps, point cloud models of crosspoint regions were extracted.

Experiment 2 aimed to explore the significance of the proposed visual perception technique by deploying it on a rebar tying robot developed by our team (as shown in Figure 4) and comparing it with other rebar tying methods, including manual tying, handheld tying machine, and other rebar tying robots. To verify the robustness of the proposed method across different scenarios, tying accuracy and efficiency are analyzed through tests involving rebars positioned horizontally, vertically, and inclined, as illustrated in Figure 6.

Figure 6. Different test scenarios: (a) horizontal tying work surface, (b) vertical tying work surface, and (c) inclined tying work surface.

4 Results

4.1 Result of Experiment 1

In Experiment 1, the average RMSE and processing time were utilized to evaluate the performance of four point cloud registration methods. To ensure a fair and reliable comparison of different registration algorithms, an initial translation vector based on the spatial coordinate difference between the tying points in the rebar and template point clouds was provided to each algorithm. This improved both the convergence speed and stability of the registration methods. The experimental results are presented in Table 1. The proposed point cloud registration method significantly reduced the average RMSE error compared to unaligned raw data, effectively addressing texture-less and self-occluding issues during template alignment for rebar pose estimation. Furthermore, the proposed method outperformed other algorithms in registration accuracy across all camera angles and is less affected by camera

angle variations. The superior performance of this method suggests its suitability for the rebar pose estimation task. According to Table 2, the proposed method was slightly slower than ICP, but higher than the other point cloud registration algorithms and still maintained high real-time performance.

Table 1. Average RMSE of different point cloud registration methods (unit: millimeter)

Method	0°	10°	20°	30°	40°
"Raw"	1.039	1.817	3.340	4.913	5.354
ICP	0.522	0.597	0.613	0.812	1.287
RANSAC	1.527	1.751	1.965	2.221	2.532
FGR	2.860	2.893	3.495	4.394	4.637
AnyDirectTying	0.480	0.551	0.526	0.602	0.650

Table 2. Average time consumption of different point cloud registration methods (unit: seconds)

Method	0°	10°	20°	30°	40°
ICP	0.009	0.009	0.010	0.013	0.014
RANSAC	0.098	0.103	0.112	0.119	0.112
FGR	0.032	0.033	0.037	0.039	0.038
AnyDirectTying	0.019	0.024	0.027	0.033	0.034

Given that the ICP algorithm generally outperforms other mainstream methods in terms of accuracy, Figure 7 presents a comparison of the point cloud registration results from the proposed method and the ICP algorithm at various shooting angles. As shown in Figure 7, when the camera angle was at 0°, the performance of ICP algorithm was excellent due to the unaligned raw data being closely aligned, providing an ideal initial state that allowed the ICP algorithm to converge quickly to the correct registration result. However, as the camera angle increased, the accuracy of the algorithm declined. At angle of 10° and 20°, the ICP algorithm tended to fall into local optima rather than achieving the global optimum. This issue was primarily due to self-occlusion, where fewer points were captured from the inner rebar, causing the algorithm to align more readily with the outer rebar while overlooking the misalignment of the inner rebar. This problem became more pronounced when the camera angle reached 30° and 40°, resulting in a rapid decrease in ICP registration accuracy. The proposed method effectively reduces interference by applying an adaptive displacement correction strategy.

In summary, current mainstream point cloud registration methods generally exhibited higher RMSE errors, with some even exceeding those of the unaligned raw data. This discrepancy suggested that existing methods were unsuitable for the task of rebar pose estimation. In contrast, the proposed coarse-to-fine point cloud registration method significantly reduced the RMSE error across different scenarios. This indicated that the proposed method effectively addresses issues related to texture-less surfaces and self-occlusion during template alignment for rebar pose estimation, enabling the robot to accurately perceive the spatial relationship between itself and the tying object, thereby facilitating tying tasks across a broader range of scenarios.

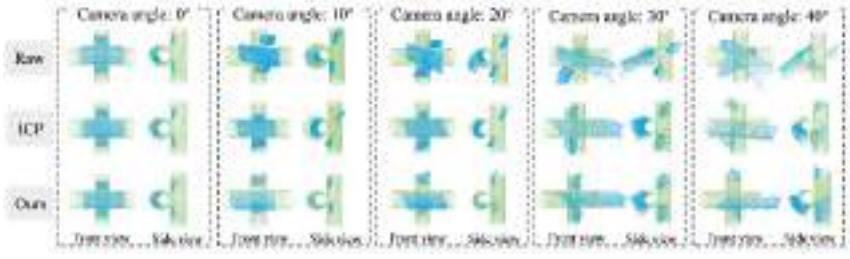

Figure 7. The registration effects of the ICP and the proposed method at different photo angles.

4.2 Result of Experiment 2

To evaluate tying accuracy, 100 rebar crosspoints were tied point by point using the rebar tying robot developed by our research team under different working conditions. As shown in Table 3, the robot achieved a high tying success rate across various working conditions.

In contrast to the visual perception methods of existing robots, which are mainly designed for horizontal rebar mesh and predict only the spatial position of tying points, the proposed method enabled robot to determine the 6-DoF rebar pose in crosspoint region. This capability allows the robot to autonomously perceive the spatial relationship between itself and the tying object, making it capable of performing tying tasks across a broader range of scenarios and demonstrating greater adaptability than existing robotic systems.

Moreover, tying efficiency was analyzed by comparing the average tying time of various tying methods. As shown in Table 4, the average tying time of the rebar tying robot developed in this study was reduced by approximately 39.71% in safe mode and 57.84% in extreme mode compared to manual tying. When compared to handheld tying machine, the robot shortened operation time by approximately 14.58% in safe mode and 40.28% in extreme mode. These results demonstrate that the robot significantly outperforms manual labor by completing more tasks within the same period, thereby boosting construction efficiency. Additionally, the average tying time of our robot was faster than that of other tying robots in extreme mode, although it was slightly slower in safe mode. Nonetheless, the robot maintained a notable overall efficiency advantage.

A further analysis of the tying time components in safe mode revealed that visual perception method accounted for only 0.05 seconds per tying point, just 2.03% of the total tying time. Most of the time was consumed by the execution of the tying action and the movement of the robot arm. This indicates that the slightly lower efficiency in safe mode is primarily due to the mechanical speed of the equipment rather than the performance of the algorithm. Future improvements could focus on deploying the proposed algorithms onto faster, more robust tying robots to enhance their adaptability to multi-directional tying and further improve operational efficiency.

Through the above experiments, it was found that the proposed 6-DoF rebar pose estimation method enabled the robot to perform tying operating across a broader range of scenarios accurately. Additionally, the rebar tying robot deployed with the proposed method demonstrated significant efficiency advantages compared to manual tying and other automatic tying techniques, highlighting the potential of the proposed method to improve construction productivity by guiding the robot towards more efficient and accurate robotic operations.

Table 3. Success rates of our rebar tying robot under different working conditions

Scenario	horizontal	vertical	inclined

Ours (safe mode)	2.46

5 CONCLUSIONS

Traditional visual perception algorithms for rebar tying robots are often limited to tying objects on horizontal rebar meshes. This study proposes a 6-DoF rebar pose estimation method to guide robotic arms in executing tying operations at arbitrary positions and orientations in 3D space, thereby broadening the application of automated tying technology to various rebar configurations. The key innovations include using a deep learning-based keypoint detection algorithm to extract rebar point data, along with a coarse registration method based on geometric features and a fine registration method utilizing adaptive displacement correction strategy. These innovations effectively address the challenges of rebar pose estimation caused by weak texture and self-occlusion.

Two experiments validated the effectiveness of the proposed algorithm. Experiment 1 demonstrated that the proposed coarse-to-fine point cloud registration method outperformed other mainstream algorithms (ICP, RANSAC, and FGR) in accuracy across different camera angles, achieving an average RMSE of 0.650 mm in complex environments and 0.480 mm in ideal conditions. The algorithm maintains real-time performance, with processing time ranging from 0.019 to 0.034 seconds, demonstrating its capability to handle the challenges posed by the weak texture and self-occlusion in rebar point clouds.

Experiment 2 revealed that the tying robot equipped with the proposed algorithm achieved success rates of 99%, 98%, and 98% for horizontal, vertical, and inclined rebar, respectively, demonstrating improved flexibility and adaptability. The robot also exhibited notable efficiency advantages, completing ties in 1.72 seconds (extreme mode) to 2.46 seconds (safe mode), compared to manual methods and other robots.

In summary, this study enhances the tying capabilities of vision-guided rebar tying robots by developing a 6-DoF rebar pose estimation method, thereby extending their applicability to diverse rebar configurations. This research fills a research gap in 6-DoF rebar pose estimation for robotic rebar tying,

offering an advanced visual perception method that reduces reliance on manual labor. Future work will focus on improving the accuracy and stability of the algorithm, particularly regarding variations in rebar diameter or spacing.

Abstract –

Robotic systems for inspection have advanced significantly in construction. Hexapod robots offer unique advantages for navigating complex construction terrains, yet their performance on sloped and irregular surfaces is hindered by limitations in existing control strategies. . In this work, we present an integrated control framework that combines a dynamically tuned fuzzy PD controller with a Bézier curve-based trajectory generator. This unified approach addresses the critical research gap by simultaneously ensuring precise posture regulation and smooth gait execution, thus enhancing hexapod stability and efficiency. Simulations in the Gazebo environment validated the system's performance on various roof pitches (2/12, 4/12, 6/12) and structural transitions (ridges, valleys, flashings). Results showed a 21% improvement in stability margin on 2/12 slopes, precise body orientation control within ±5° roll, ±10° pitch, and ±1.3 m/s² vertical acceleration variations. Also, this system achieved 80-100% success rates in three different types of surface transitions. This research provides a robust framework for deploying hexapod robots in challenging architectural contexts, advancing autonomous inspection capabilities in construction environments.

1 Introduction

The construction industry is undergoing a transformative shift, propelled by the integration of robotic systems that streamline workflows and boost operational efficiency [1]. Among these applications, robotic systems developed for inspection tasks have advanced significantly, with researchers focusing on innovative locomotion methods that enable robots to navigate complex architectural structures [2,3]. Robots equipped with AI and computer vision are increasingly outperforming human capabilities in detecting and analysing maintenance needs, providing more accurate and timely assessments [4,5].

Despite these technological advancements, deploying robots for high-precision inspection tasks on construction sites remains challenging, often limiting their practical application [6]. Roof inspections, for instance, are particularly demanding due to diverse types of visible damage—curling, cracking, flaking, granule loss, and missing shingles—as well as less apparent issues, such as water infiltration, loosening, and blistering, which further complicate assessment [7]. To address these specialized inspection challenges, researchers have explored various robotic platforms with different locomotion mechanisms. Aerial robots, including Unmanned Aerial Vehicles (UAVs), offer potential solutions [8] but are constrained by payload capacity, battery life, and regulatory restrictions in urban settings, along with limited close-up inspection capabilities. Unmanned Ground Vehicles (UGVs) offer a viable alternative, as they support heavier payloads and can sustain longer operational times, making them more suitable for close-range inspections. However, standard UGVs often lack the adaptive locomotion needed to navigate the complex, sloped, and discontinuous surfaces commonly found on roofs, emphasizing the need for UGVs specifically designed for safe, slope-adaptive movement [9].

Among the various UGV configurations available for construction inspection tasks, multi-legged designs offer distinct advantages for complex terrain navigation. UGVs encompass various configurations, including wheeled, tracked, multi-legged, and hybrid forms, each with distinct advantages. Multi-legged UGVs excel on rough and uneven terrain [10]. Their ability to step over or around obstacles allows them to maneuver effectively in unstructured environments, making them well-suited for complex terrains. Multi-legged robots also offer greater agility, enabling movement in multiple directions, such as sideways and diagonally, which is particularly beneficial on sloped surfaces. Additionally, these designs

ensure stability on downhill slopes by distributing load more effectively and provide resilience, allowing continued operation even with a compromised leg. Among multi-legged designs, hexapod robots stand out for their optimal balance between stability and complexity [11]. With six legs, they maintain static stability by keeping the Center of Gravity (CoG) within a support triangle formed by three legs, enabling a tripod gait that is both stable and efficient. This configuration provides redundancy, allowing the robot to function even if one or more legs malfunction, while avoiding the added complexity and energy demands of designs with more legs. Compared to quadrupeds, hexapods offer superior stability without requiring sophisticated dynamic balancing, as well as enhanced ground clearance and obstacle traversal. Furthermore, the hexapod design distributes load effectively, enabling the robot to carry heavier payloads while maintaining stability on uneven or inclined surfaces.

Despite these inherent advantages, hexapod robots still face challenges when navigating sloped and irregular terrains, as they often lack specialized kinematic and dynamic control mechanisms needed for such environments [12]. In applications like roof inspection, where safe and adaptive movement is critical, these gaps can lead to risks, including fall hazards [13], increased maintenance costs, and elevated energy consumption. This paper addresses this gap by proposing a novel integrated control framework that enhances both the kinematic and dynamic performance of hexapod robots. Our primary contributions include:

1. Providing an integrated control framework that synergistically combines an adaptive fuzzy PD controller and a Bézier curve-based trajectory generator. This unified approach dynamically adjusts leg motor angles based on center-of-gravity errors while generating smooth, energy-efficient swing-phase trajectories, resulting in superior posture regulation and enhanced stability on variable roof slopes and irregular terrains.
2. Validating the approach through extensive simulations, demonstrating a 21% improvement in stability margin on standard roof slopes and robust performance during complex structural transitions.

2 Methodology

This section presents a comprehensive description of the module-enhanced hexapod robot platform developed for automated roof inspection tasks.. This method adapt the traditional fuzzy PD controller with dynamic gain adjustments tailored for real-time leg motor control. Our study also extends the conventional use of Bézier curves by tuning the parameters for swing-phase trajectory generation. This results in smoother, energy-efficient leg movements that significantly improve gait stability over traditional semicircular trajectories. Furthermore, the novel aspect of our work is the integration of these two modified components into a unified control framework. This synergy not only leverages the strengths of both techniques but also produces superior performance,

2.1 Hexapod Kinematic Model

The hexapod robot platform utilized in this study is based on the model Muto [14], an 18 degrees-of-freedom (DoF) six-legged walking robot. The robot is equipped with a Jetson NANO board [15] for on-board processing. Locomotion is achieved through 18 high-torque servo motors. For precise posture measurement and adjustment, the robot incorporates an inertial measurement unit (IMU), capable of measuring acceleration, gyroscope data, magnetometer readings, and temperature. In default standing position, the hexapod robot measures 465 mm in length (forward direction) and 514 mm in width (lateral direction). Each of the six legs is composed of three segments: coxa (50 mm), femur (75 mm), and tibia (140 mm). The robot's coordinate frame is defined as shown in Fig.1(a): **{c}** is the mass center coordinate frame of hexapod robot determined by right-hand rule, with X_c along the body transverse direction, Y_c along the forward direction, and Z_c perpendicular to the ground. As shown in Fig.2(b), $\mathbf{\{O_{ij}\}}$ is the coordinate frame of the j_{th} joint of the i_{th} leg of the robot, $i \in \{1,2,3,4,5,6\}$, $j \in \{1,2,3,4\}$. Note when j=4, $\mathbf{\{O_{i4}\}}$ presents the coordinate frame of the foot end. Axis $\mathbf{Z_{i,j}}$ is the rotation axis of the joint, the $\mathbf{X_{i,j}}$ is chosen along the common normal from axes $\mathbf{Z_{i,j}}$ and $\mathbf{Z_{i,(j-1)}}$, and the $\mathbf{Y_{i,j}}$ is determined by righthand rule. Respectively, L1, L2, L3 represent the length of coxa (C_i), femur (F_i), and tibia (T_i), $i \in \{1,2,3,4,5,6\}$.

2.1.1 Forward Kinematics

The forward kinematics of the 18-DOF hexapod robot is based on the Denavit–Hartenberg (DH) convention. This approach allows for a systematic representation of the spatial relationships between adjacent link coordinate frames, facilitating the calculation of the end-effector position (in this case, the foot position) given the joint angles. The transformation matrix between two adjacent leg coordinate systems is

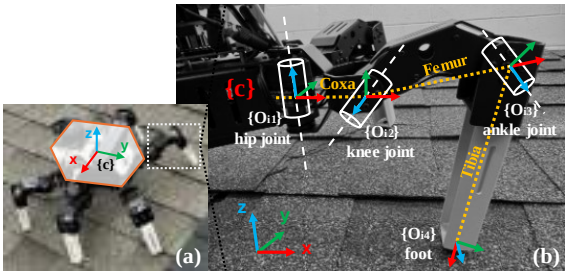

Figure 1. Kinematic Model of a Hexapod Robot Leg: Joints, Links, and Coordinate Frames

expressed in the DH convention:

$$\mathbf{M}_{\mathrm{j}}^{\mathrm{j-1}} = \begin{bmatrix} c_{\theta_j} & -s_{\theta_j}c_{\alpha_j} & s_{\theta_j}c_{\alpha_j} & \alpha_j c_{\theta_j} \\ s_{\theta_j} & c_{\theta_j}s_{\alpha_j} & -c_{\theta_j}s_{\alpha_j} & \alpha_j s_{\theta_j} \\ 0 & s_{\alpha_j} & c_{\alpha_j} & d_i \\ 0 & 0 & 0 & 1 \end{bmatrix} \quad (1)$$

where c_{θ_j}, s_{θ_j} denotes cos (θ_j) and sin (θ_j), respectively, and α, a, θ, d is the DH parameters with the values listed in Table 1.

Table 1. Denavit–Hartenberg Parameters Between **{c}** and the Hexapod's foot $\mathbf{p_i}$

Transformation	α_i	a_i	θ_i	d_i
{c}→{O$_{i1}$}	0	l_1	θ_{i1}	0
{O$_{i1}$}→{O$_{i2}$}	$\pi/2$	l_2	θ_{i2}	0
{O$_{i2}$}→{O$_{i3}$}	0	l_3	θ_{i3}	0
{O$_{i3}$}→{O$_{i4}$}	0	l_4	θ_{i4}	0

In Table 1, $\boldsymbol{\alpha}$ is the angle about common normal, from old z axis to new z axis; $\boldsymbol{a}$ is the length of the common normal; $\boldsymbol{\theta}$ is the angle about previous z from old x to new x; $\boldsymbol{d}$ is the offset along previous z to the common normal. Let $\mathbf{p^c}$ be the foot-tip position of the leg in the coordinate system relative to the mass center and $\mathbf{p^4}$ be the foot-tip position in the foot-tip coordinate system. Then the mapping between the body coordinate system and the foot-tip coordinate system is given by the following kinematic chain:

$$\mathbf{p}_{\mathrm{i}}^{\mathrm{c}} = \mathbf{T}_i^c \mathbf{M}_2^1 \mathbf{M}_3^2 \mathbf{M}_4^3 \mathbf{p}_{\mathrm{i}}^4 \quad (2)$$

where $\mathbf{T}^{\mathrm{i}}$ is the transformation matrix between the body center frame **{c}** and the coxa coordinate frame of the $\mathrm{i_{th}}$ leg, given as a rigid body transformation:

$$\mathbf{T}^i = \begin{bmatrix} c_{\beta^i} & -s_{\beta^i} & 0 & p_x^i \\ s_{\beta^i} & -c_{\beta^i} & 0 & p_y^i \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \quad (3)$$

where β^i, $\mathrm{p_x^i}$, and $\mathrm{p_y^i}$, are the body parameters of the $\mathrm{i_{th}}$ link which are known by default setting.

2.1.2 Inverse Kinematics

The inverse kinematics for the hexapod robot is simplified by its joint configuration, allowing for an analytical solution. Given the desired foot-tip coordinates in the global frame, the inverse kinematics calculates the required joint angles for each leg. For a given foot-tip position $\mathbf{p^c} = [\mathrm{p_1^c}, \mathrm{p_2^c}, \mathrm{p_3^c}]$ in the global coordinates, the hip joint angle θ_1^i of the $\mathrm{i_{th}}$ is obtained as:

$$\theta_1^i = \begin{cases} 0, i = 1 \\ arctan\left(\frac{l_a}{l_b}\right), i \in \{2,3,5,6\} \\ \pi, i = 4 \end{cases} \quad (4)$$

where $\mathrm{l_a}$ and $\mathrm{l_b}$ are illustrated in Figure 2(a).

The angle θ_2^i is calculated with respect to the fixed reference frame {**h**} located at the **hip** joint (Fig. 1b):

$$\theta_2^i = \tan^{-1}\left(\frac{x_p^h}{y_p^h}\right) \quad (5)$$

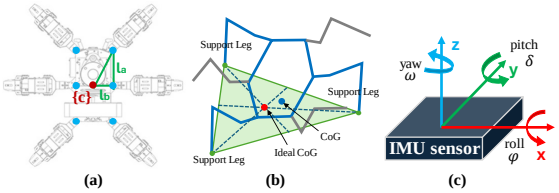

Figure 2. (a) Hip Joint Relative to the Center Frame, (b) Diagram Explaining CoG and CSP, (c) Rotation Angles Measured by the IMU Sensor

where $\mathbf{p}_{\mathrm{i}}^{\mathrm{h}} = \{x_p^h, y_p^h, z_p^h\}^T$ is the position of $\mathbf{p}_{\mathrm{i}}$ relative to {**h**}, obtained by:

$$\mathbf{p}_{\mathrm{i}}^{\mathrm{h}} = (\mathbf{T}_1^0)^{-1}\mathbf{p}_{\mathrm{i}}^{\mathrm{c}} \quad (6)$$

in which $\mathbf{T}_1^0$ is the transformation matrix between the center frame {**c**} and the reference frame {**h**}. To calculate the remaining angles, we need the position of reference frame {**k**} at the knee joint, defined by the Denavit-Hartenberg convention as:

$$\mathbf{k}_{\mathrm{i}}^{\mathrm{h}} = (\mathbf{T}_1^0)^{-1}\mathbf{T}_2^0 \quad (7)$$

Considering the vector $\mathbf{s}_{\mathrm{p}}$ between the knee frame {**k**} and the foot, the angle θ_3^i and the θ_4^i are calculated as:

$$\theta_3^i = \cos^{-1}\left(\frac{{l_3}^2 + \|\boldsymbol{s_p}\|^2 - {l_4}^2}{2l_3\|s_p\|}\right) - \sin^{-1}\left(\frac{z^k - z^p}{\|\boldsymbol{s_p}\|}\right) \quad (8)$$

$$\theta_4^i = \pi + \cos^{-1}\left(\frac{{l_3}^2 + {l_4}^2 - \|\boldsymbol{s_p}\|^2}{2l_3l_4}\right) \quad (9)$$

z^k and z^p represent the vertical positions of the knee frame {k} and the foot, respectively. These equations form the foundation for the robot's motion control and gait design in subsequent sections.

2.2 Integrated Control System for Slope and Terrain Stability

2.2.1 Adaptive Control System for Slope Navigation

The stability of a hexapod robot during locomotion on both inclined and uneven surfaces is crucial for effective roof inspection tasks. This section presents an integrated approach that combines slope-adaptive posture control with enhanced gait stability mechanisms to ensure reliable operation across diverse terrain conditions. The foundation of the system's stability is based on the principle that the hexapod robot maintains static stability when the vertical projection of its Center of Gravity (CoG) falls within the Conservative Support Polygon (CSP) formed by its supporting legs (Fig. 2b). While this principle is straightforward on flat surfaces where the D-H convention and forward kinematics can directly calculate support points and CoG projection, inclined surfaces present additional complexity as the robot's reference frame **{c}** becomes misaligned with the global reference frame **{s}.** To address this misalignment,

a rotation matrix is introduced to transform positions from the robot's reference frame **{c}** to the space reference frame **{s}:**

$$\mathbf{R_{sc}} = \begin{bmatrix} c_\omega c_\delta & c_\omega s_\delta s_\varphi - s_\omega c_\varphi & c_\omega s_\delta c_\varphi + s_\omega s_\varphi & 0 \\ s_\omega c_\delta & s_\omega s_\delta s_\varphi + c_\omega c_\varphi & s_\omega s_\delta c_\varphi - c_\omega s_\varphi & 0 \\ -s_\delta & c_\delta s_\varphi & c_\delta c_\varphi & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \quad (10)$$

where the rotation angles φ around X-axis, δ around Y-axis, and ω around Z-axis are measured by the IMU sensor (Fig. 2c) positioned at the robot's center of mass.

Stability on inclined surfaces is further improved using a fuzzy Proportional-Derivative (PD) controller, which dynamically adjusts the supporting leg motors' angles. This study chooses the fuzzy PD controller for three main reasons: (1) it handles the nonlinearities and uncertainties of slope navigation without requiring a precise dynamic model, (2) it dynamically adjusts control parameters based on error magnitude and rate of change, ensuring better adaptation to varying slopes, and (3) it strikes an optimal balance between performance and computational efficiency, essential for real-time embedded systems in field robotics. The controller maintains the real CoG's projection close to the ideal CoG within the CSP by calculating errors e_x and e_y, representing differences between the actual and ideal CoG positions. The compensation angles $\Delta\mu_x$ and $\Delta\mu_y$ are calculated as:

$$\Delta\mu_x = K_{p,x}e_x + K_{d,x}\dot{e}_x \quad (11)$$

$$\Delta\mu_y = K_{p,y}e_y + K_{d,y}\dot{e}_y \quad (12)$$

where $K_{p,x}$ and $K_{p,y}$ are the proportional gains, $K_{d,x}$ and $K_{d,y}$ are the derivative gains, all of which are dynamically adjusted by the fuzzy PD controller based on the magnitude of errors and their derivatives [16]. This approach allows the system to respond appropriately to varying conditions. For instance, when errors are large, smaller gains are applied to prevent the robot from overturning. Conversely, when errors are small, larger gains are used for fine-tuning motor adjustments, enhancing stability (Table 2,3., Figure 3).

Table 2. Consequent membership Functions

Parameter \ Value	↑	↑↑	↑↑↑	↑↑↑↑
$K_{p,x}$	0.05	0.1	0.15	0.2
$K_{p,y}$	0.2	0.3	0.4	0.5
$K_{d,x}$	0.05	0.07	0.09	0.15
$K_{d,y}$	0.05	0.07	0.09	0.15

Table 3. Fuzzy rule table for the proportional and derivative gains

$K_{p,x}$ $K_{d,y}$	$K_{p,y}$ $K_{d,x}$	e_y				
		− −	−	0	+	+ +
$\dot{e}_y$	− −	↑	↑↑	↑↑↑	↑↑	↑
	−	↑↑	↑↑↑	↑↑↑↑	↑↑↑	↑↑
	0	↑↑↑	↑↑↑↑	↑↑↑↑	↑↑↑↑	↑↑↑
	+	↑↑	↑↑↑	↑↑↑↑	↑↑↑	↑↑
	+ +	↑	↑↑	↑↑↑	↑↑	↑

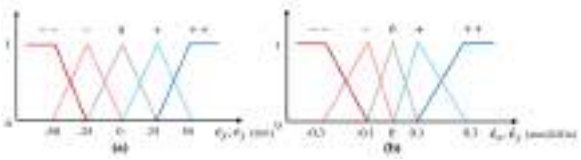

Figure 3. Fuzzy rule plots for e_x, e_y and $\dot{e}_x, \dot{e}_y$

In practice, the global reference frame rotates with the robot's reference frame around the Z-axis to ensure that compensation angles remain effective regardless of the robot's orientation. The fuzzy PD controller's ability to adapt dynamically outperforms traditional linear PD controllers, particularly on inclined surfaces, by maintaining stability without detailed dynamic modelling. This adaptive control strategy was validated through experiments on roof pitches of varying slopes, detailed in the *Experimental Validation* section.

2.2.2 Stability Enhancement for Uneven Terrain

The robot employs a tripod gait as its primary locomotion strategy, where three legs remain in the stance phase while the other three are in the swing phase. The legs are divided into two sets: Set A (legs R1, L2, and R3) and Set B (remaining legs). This configuration enables a four-step sequence: initial six-foot contact (Fig. 4a), Set A forward movement (Fig.4b), Set B forward movement with Set A thrust (Fig.4c), and Set A lift returning to initial position (Fig.4d). The swing leg trajectory is the curve connecting the lifting point and the landing point of the swing leg's tip.

Traditionally, a semicircular trajectory algorithm is used for the swing phase, generating uniform foot arcs. While computationally efficient, this method produces abrupt transitions between the stance and swing phases, increasing energy consumption and destabilizing the robot's posture. To mitigate these issues, this study introduces a Bézier curve-based trajectory for the swing phase. This method, modelled as a third-degree curve, ensures more consistent height control during the swing phase. This study chose Bézier curves over polynomial, spline, and semicircular trajectories for three main reasons: (1) control points enable smoother stance-to-swing transitions, (2) Bézier curves avoid the oscillations typical of high-order polynomials and maintain stability under varying terrain conditions, and (3) they strike an optimal balance between trajectory quality and computational efficiency.

During the swing phase, the feet follow a 3rd-degree

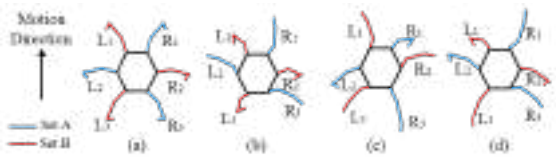

Figure 4. Diagram of four-step tripod gait

Bézier trajectory described by:

$$\mathbf{p}_{i,j}^{c}(t) = \sum_{j=0}^{3} \binom{3}{j} t^{j} (1-\mathrm{t})^{3-j} \mathbf{p}_{i,j}^{c},$$

$$t \in [0, t_{int}], i \in [1,6], j = 0,1,2,3 \quad (13)$$

$$\binom{3}{j} = \frac{3!}{j!\,(3-j)!} \quad (14)$$

where 3 denotes the curve degree, j denotes the number of joint, t_{int} is the trajectory's time interval, and $\mathbf{p}_{i,j}^{c} = \{x_p^c, y_p^c, z_p^c\}^T$ denote the control points of the trajectory.

This approach provides superior stability compared to traditional methods, particularly in terms of roll and pitch velocity variation and height stability. The control points for the Bézier curve are strategically positioned to ensure smooth transitions between phases while maintaining stability. The first control point corresponds to the foot's initial position $\mathbf{p}_{i,0}^{c}$ is defined by Eq. (2), which can also be derived as:

$$\mathbf{p}_{\mathrm{i,0}}^{\mathrm{c}} = \begin{Bmatrix} c_{(\theta_0+\theta_1)}(L_3 c_{(\theta_2+\theta_3)} + L_2 c_{\theta_2} + L_1) + L_0 c_{\theta_0} \\ s_{(\theta_0+\theta_1)}(L_3 c_{(\theta_2+\theta_3)} + L_2 c_{\theta_2} + L_1) + L_0 s_{\theta_0} \\ L_3 s_{(\theta_2+\theta_3)} + L_2 s_{\theta_2} \end{Bmatrix} \quad (15)$$

The remaining control points are determined as:

$$\mathbf{p}_{\mathrm{i,1}}^{\mathrm{c}} = \left\{0, \frac{s}{4}, \frac{h}{3}\right\}^{\mathrm{T}} + \mathbf{p}_{\mathrm{i,0}}^{\mathrm{c}} \quad (16)$$

$$\mathbf{p}_{\mathrm{i,2}}^{\mathrm{c}} = \left\{0, \frac{3s}{4}, \frac{h}{3}\right\}^{\mathrm{T}} + \mathbf{p}_{\mathrm{i,0}}^{\mathrm{c}} \quad (17)$$

$$\mathbf{p}_{\mathrm{i,3}}^{\mathrm{c}} = \{0, s, 0\}^{\mathrm{T}} + \mathbf{p}_{\mathrm{i,0}}^{\mathrm{c}} \quad (18)$$

where h is the maximum height, and s denotes the stride length. During the stance phase, where the feet maintain ground contact while propelling the torso forward, the foot trajectory is defined as:

$$\mathbf{p}_{\mathrm{i}}^{\mathrm{c}}(\mathrm{t}) = \left\{0, -\frac{s}{t_{int}} t, 0\right\}^{\mathrm{T}} + \mathbf{p}_{\mathrm{i,0}}^{\mathrm{c}}, t \in [0, t_{int}] \quad (19)$$

By integrating slope-adaptive posture control with a stability-enhanced gait system, this approach addresses the dual challenges of inclined and uneven terrain navigation. The adaptive slope system ensures that the CoG remains properly aligned within the CSP, while the Bézier curve trajectory smooths leg movements, enhancing stability and energy efficiency.

3 Experimental Validation

The experimental validation of the proposed control system was conducted through two comprehensive simulation tests implemented in the Gazebo environment, each designed to evaluate different aspects of the hexapod robot's performance. The simulation environment was configured using Robot Operating System (ROS) and Gazebo, providing a physics-accurate testing platform. The same hexapod robot URDF (Unified Robot Description Format) model was employed across both test setups, ensuring consistency in the robot's physical parameters and joint configurations throughout the experimentation process. Gazebo and ROS together provide a comprehensive and flexible setup for simulating and measuring with the appropriate sensors, plugins, and ROS nodes.

3.1 Test 1: Diverse Slopes

Test 1 evaluated the control system's stability across various roof inclines using the tripod gait, which balances stability and speed at 0.1 m/s. Three standard residential roof pitches were tested: 2/12 (9.5°), 4/12 (18.4°), and 6/12 (26.6°). The simulation used a 3.0m × 2.0m platform with high-friction coefficient (μ = 0.8) to simulate roofing material. For each slope, the hexapod performed five ascending trials covering 3.0m distance.

The robot model incorporated an IMU sensor at its center of mass, providing orientation data through ROS "sensor_msgs" for accurate CoG projection calculations. Performance metrics included stability margin, body orientation angles, foot placement accuracy, and power consumption. The simulation featured realistic physics parameters to ensure accurate representation of the robot's behavior on inclined surfaces. For all experiments, we implemented a comparative analysis between our integrated control system and a traditional control approach. The baseline system utilized a standard PD controller with fixed gains (Kp = 0.5, Kd = 0.15) for posture regulation and conventional semicircular trajectory generation for leg movements.

3.2 Test 2: Surface Transitions

Test 2 evaluated the control system's ability to navigate common roof structural transitions using the same hexapod model from Test 1. The simulation focused on three critical elements: ridge lines (30° angular transition), valleys (135° angles), and flashings (10mm elevation change).

For each transition type, ten trials were conducted at 0.1 m/s from identical start positions to ensure statistical reliability. Data was collected using the robot's integrated sensors, including IMU readings for stability assessment and foot pressure sensors for contact force analysis.

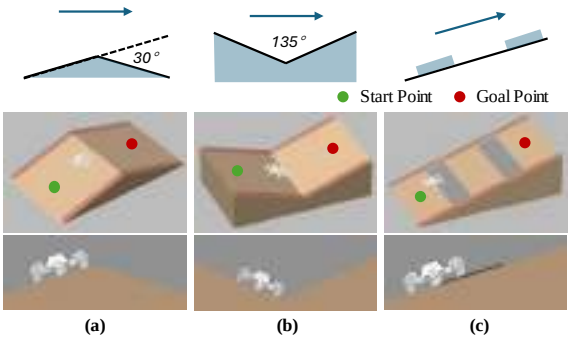

Figure 6. Three different surface transition trials in Test 2: (a) Ridge (30 degree), (b) Valley (135 degree), (c) Flashing (10mm elevation).

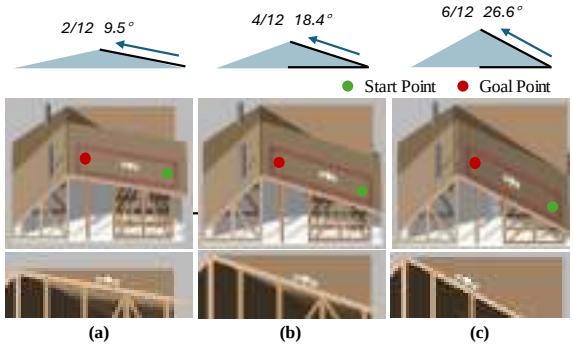

Figure 5. Three different slope angle trials in Test 1: (a) Pitch 2/12 (~9.5 degree), (b) Pitch 4/12 (~18.4 degree), (c) Pitch 6/12 (~26.6 degree).

Performance evaluation concentrated on two key metrics: transition success rate and crossing time.

3.3 Performance Metrics

To comprehensively evaluate the hexapod robot's performance across both slope navigation and structural transition tests, a multi-metric evaluation framework was implemented. The primary stability indicator was the stability margin (SM), defined as the shortest distance from the horizontally projected Center of Gravity (CoG) to the edge of the support polygon (McGhee and Frank 1968):

$$S_m \equiv \min(D_1, D_2, D_3)$$

where D_i represents the perpendicular distance from the projected CoG to each edge of the support triangle formed by the supporting legs. This metric has been extensively validated in previous studies for analysing hexapod stability [17] and designing fault-tolerant gaits [16]. Body orientation control was monitored through roll (φ) and pitch (θ) angles, measured in degrees from the horizontal plane. The maximum allowable deviations were established at 15° for roll angle, 20° for pitch angle on slopes, and 12° for pitch angle during structural transitions. These measurements were crucial for assessing the robot's ability to maintain proper posture throughout locomotion.

For Test 1 (Diverse Slopes), specific performance metrics included: (1) Average stability margin maintained during continuous slope walking; (2) Maximum and minimum body orientation angles during slope traversal; (3) Vertical Acceleration variations. For Test 2 (Surface Transitions), additional metrics were implemented: (1) Transition success rate, defined as the percentage of crossings completed without stability failures such as turnover or keep stepping in place; (2) Crossing time, measured from the initiation of transition approach to completion of crossing from fixed start and end positions. All metrics were recorded through the ROS framework using custom message types, with data synchronized through the ROS time stamp system. The results are analysed in the following section.

4 Results and Discussion

4.1 Results Analysis

4.1.1 Test 1: Diverse Slopes Performance

The experimental results revealed significant stability gains with our control system for all tested slope angles (Figure 7), namely 2/12 (9.5°), 4/12 (18.4°), and 6/12 (26.6°). On the gentlest slope, the system maintained an average SM of 115 mm, 21% higher than the default. Although this margin dropped to 84 mm at 4/12 pitch, it still surpassed the default by 15%. On the steep 6/12 pitch, our system recorded 44 mm—over double the 20 mm minimum for stable locomotion—while the default system repeatedly overturned or stepped in place. These results highlight the inherent challenges of steep inclines, which our adaptive control strategy successfully mitigated. Overall, we achieved a 100% success rate, with only brief interruptions during initial slope engagement.

Body orientation control also showed strong performance (Figure 8). Our system maintained body height between 255 and 272 mm, while the uncontrolled approach varied from 228 to 289 mm, especially on steeper slopes. Roll angles stayed within ±2°, ±3°, and ±5° at 9.5°, 18.4°, and 26.6°, respectively—well below the ±15° limit. By contrast, the default approach reached ±15° on the 6/12 pitch. Pitch angles similarly stayed within ±10° under our system, far beneath the 20° cutoff, while the default reached ±25°. The fuzzy controller's adaptive nature minimized sudden orientation changes, containing vertical acceleration within ±1.3 m/s², whereas the uncontrolled approach hit ±2.5 m/s². These findings confirm the robust stabilization capabilities of our system on inclined surfaces.

Such improvements in stability and orientation are critical for preventing slip or rollover events. By minimizing abrupt shifts, our system reduces mechanical stress and power consumption, enabling safer, more efficient navigation and real-world roof inspections. Hence, it effectively supports steep-roof applications requiring reliable locomotion.

4.1.2 Test 2: Surface Transition Performance

As shown in Table 4, the system demonstrated high success rates across all structural surface transitions, with 80% successful completions for ridge line crossings (30° angle) among 10 trials, compared to 50% success rate without our control system. Under another 10 trails on valley transitions (135° angle), trails under our control system gained 100% success, while only 6 of another 10 trails succeeded without our control system. For flashing interface navigation (10mm elevation change), both trails

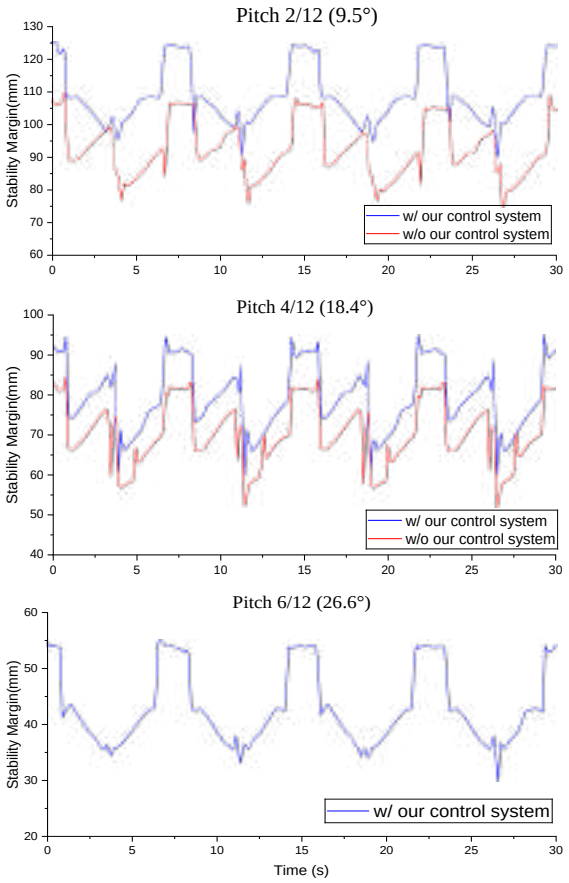

Figure 7. Stability Margin Comparison w/ and w/o Our Control System on Pitch 2/12, 4/12, and 6/12.

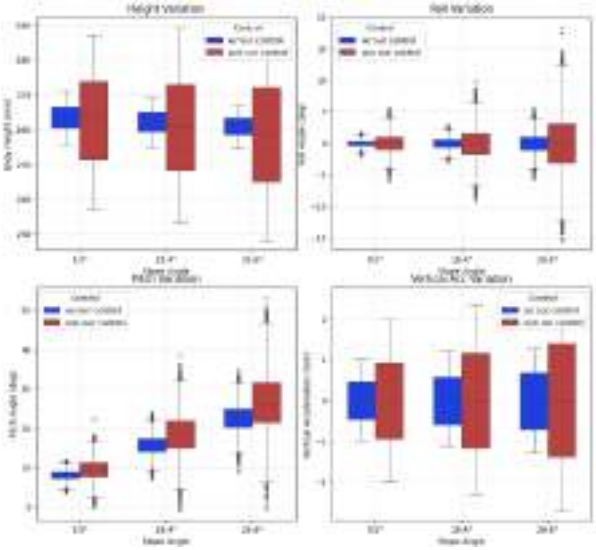

Figure 8. Orientation (Height, Roll, and Pitch) Variation and Acceleration Variation on Pitch 2/12, 4/12, and 6/12

w/ and w/o our control system achieved 100% success rate, but the trails without our control system had trouble with stepping in place for a while before going through the transition area, which lead to longer task complete time. The average crossing times shown in Table 1 varied significantly by transition type: 8.6 seconds (w/ our control system) and 11.5 seconds (w/o our control system) for ridge lines; 5.7 seconds (w/ our control system) and 6.8 seconds (w/o our control system) for valleys; 7.7 seconds (w/ our control system) and 8.9 seconds (w/o our control system) for flashing interfaces.

Table 4. Result Metrics of Test 2

Subtest	Transition Type	Success Rate (%)		Average Crossing Time (s)	
		w/ ours	w/o ours	**w/ ours**	w/o ours
#1	ridge	**80%**	50%	**8.6**	11.5
#2	valley	**100%**	60%	**5.7**	6.8
#3	flashing	**100%**	100%	**7.7**	8.9

4.2 Discussion

The results of Test 1 and Test 2 demonstrate that our integrated control system significantly enhances hexapod robot performance in both slope navigation and structural transition scenarios.

In Test 1, the system demonstrated enhanced stability across different roof slopes, with notable improvements in stability margin and body orientation control compared to the default control system. The use of a fuzzy PD controller was instrumental in maintaining consistent body orientation, particularly in challenging inclines. The improvement becomes more crucial at steeper angles, as demonstrated by the system's ability to maintain stable locomotion on 6/12 pitch slopes where default controls failed. The ability to maintain roll and pitch angles within acceptable limits highlights the system's robustness, allowing for effective traversal of various roof pitches without compromising stability. The Bézier curve-based gait trajectory further contributed to a smoother and more energy-efficient movement, reducing abrupt transitions that could destabilize the robot.

Test 2 focused on the hexapod robot's ability to navigate structural transitions commonly encountered during roof inspections, such as ridges, valleys, and flashings. The high success rates achieved across different transition types (80% for ridge lines, 100% for valleys) represent a marked improvement over conventional control methods. The reduced crossing times for all transition types indicate that our system not only improves success rates but also enhances efficiency. This is particularly evident in flashing interface navigation, where both control systems achieved 100% success rates, but our system demonstrated superior efficiency in transition completion times. The fuzzy PD controller's dynamic adjustments ensured that the robot could adapt its posture in real-time, thereby mitigating risks associated with sudden changes in terrain. The Bézier curve-based trajectory also played a crucial role in ensuring smooth foot placement during these transitions, reducing the likelihood of slips or missteps.

However, certain limitations were observed during testing. The slight decrease in stability margin with increasing slope angle suggests that additional optimization may be needed for extremely steep slopes. Furthermore, the 80% success rate in ridge line crossings, while superior to conventional methods, indicates room for improvement in handling sharp angular transitions.

5 Conclusion

This research presents an adaptive control system for hexapod robots that improves stability in complex construction environments. By integrating a fuzzy PD controller with a Bézier curve-based trajectory generator, our system maintains stability across varied terrain. This work advances construction robotics in three significant ways: (1) it demonstrates how intelligent control strategies can overcome traditional limitations of ground robots on variable construction surfaces, (2) it provides a validated framework for autonomous inspection in previously challenging environments, reducing human exposure to hazardous conditions, and (3) it establishes quantifiable performance benchmarks for robotic systems in construction inspection tasks, creating a foundation for future developments in this domain. The findings highlight the potential for deploying hexapod robots in challenging construction environments, extending beyond roof inspections to other applications that require adaptive locomotion on irregular or inclined surfaces, such as structural health monitoring of bridges, post-disaster building assessment, and maintenance of complex industrial facilities.

Future work will focus on further refining the control algorithms, including exploring machine learning-based adaptations to enhance real-time decision-making and developing a more robust physical prototype for field testing. Additionally, we plan to investigate energy efficiency improvements to extend operational time, thereby enhancing the practicality of hexapod robots for prolonged inspection and maintenance tasks. Although our evaluations were performed in the Gazebo simulation environment, these results offer a robust preliminary assessment of our method while minimizing associated risks and costs. Future work will involve validating our approach through controlled real-world experiments to further substantiate its practical applicability and performance.

Abstract

In the construction industry, achieving high standards in surface finishing is essential for structural integrity and aesthetic quality, yet traditional inspection methods can be slow and miss subtle defects. This paper introduces a drone-based system that utilizes advanced sensor processing for automated surface quality assessment in construction finishing tasks. The system integrates Light Detection and Ranging (LiDAR) and high-resolution RGB cameras to collect detailed surface data. The LiDAR module applies Gaussian filtering for noise reduction, followed by bicubic interpolation to generate a smooth and continuous elevation map, allowing for precise flatness estimation across the scanned surface. For visual defect detection, a Convolutional Neural Network based de-blurring algorithm is first applied to captured images to remove motion blur caused by drone movement. This process enhances image sharpness by passing the blurred image through multiple convolutional layers, where each layer reconstructs finer details, resulting in a deblurred image. Subsequently, a zero-shot transformer-based segmentation model uses multi-head self-attention to analyze spatial relationships within the deblurred image, allowing for effective identification and segmentation of defect regions without requiring extensive training data. Testing was conducted in both a ROS-based simulation and on real-life surface work. The LiDAR-based flatness estimation achieved a Root Mean Square Error (RMSE) of 0.2 mm in simulation and 0.8 mm in real-life tests, with Mean Absolute Error (MAE) values of 0.4 mm and 1.1 mm, respectively. The camera-based defect detection showed substantial improvement with the de-blurring module, increasing Intersection over Union (IoU) for defect segmentation to over 95% with de-blurring.

1 Introduction

Ensuring consistent surface quality is an essential aspect of construction that significantly impacts the functionality of buildings [1]. Surface finishing operations—such as plastering, painting, floor leveling, and coating—are not merely cosmetic but serve as critical elements for achieving structural performance and regulatory compliance. These processes contribute to the durability, safety, and appearance of finished structures, underscoring their importance across various construction projects, from residential homes to industrial facilities. However, maintaining high standards in surface quality remains a complex task [2], particularly as project scales and technical requirements continue to grow. The ability to accurately monitor surface conditions and promptly identify defects is crucial, not only for achieving desired design outcomes but also for reducing potential maintenance issues and ensuring the longevity of the finished surface [3].

Despite the fundamental role of surface finishing, current methods for tracking progress and assessing quality still rely heavily on manual inspections. Traditional approaches are predominantly labor-intensive, involving visual assessments and basic measurement tools like spirit levels, tape measures, and straight edges [4]. These methods, while useful for identifying major defects, are limited in their capacity to detect subtle surface imperfections, such as minor texture inconsistencies, fine cracks, or small deviations in flatness. As a result, errors can be missed, leading to compromised surface quality that may only be detected during later stages of construction or post-completion inspections. Additionally, manual inspection processes are time-consuming and often contribute to delays, especially in large-scale projects where extensive surface areas must be monitored [5]. The variability in human assessment further complicates achieving consistent quality, making it difficult to maintain uniform standards across diverse site conditions.

Given these limitations, the adoption of automation in construction has gained momentum, with drones emerging as a promising tool for progress monitoring and quality assessment in surface finishing [6]. Drones offer advantages that extend beyond traditional methods, including rapid data collection, broad area coverage, and

the ability to access elevated or hard-to-reach locations without scaffolding or other support structures [7]. Equipped with high-resolution cameras and LiDAR sensors, drones can capture detailed surface data, enabling comprehensive analysis and monitoring in real-time [8]. This capability allows for faster and more systematic inspections, improving both accuracy and consistency in quality control. By integrating drone technology into surface finishing workflows, construction teams can reduce reliance on manual processes, increase inspection speed, and enhance defect detection.

However, despite the growing use of drones for surface monitoring, existing systems still face significant challenges that limit their effectiveness. Current drone-based systems often depend on basic imaging techniques that lack the sensitivity needed to identify fine surface defects. Issues such as slight texture variations, minor cracks, and subtle flatness deviations may go undetected due to inadequate image resolution and algorithm limitations. Additionally, many drone systems are not designed to handle real-time data analysis, making them less effective in dynamic conditions where factors like changing light levels, reflective surfaces, or varying environmental conditions can influence inspection accuracy. As a result, these systems may fail to provide the precision required for complex surface assessments, prompting the need for more advanced solutions that can adapt to diverse monitoring conditions.

To overcome the limitations of traditional inspection methods in surface finishing, this paper proposes an advanced drone-assisted system for real-time progress tracking and quality assessment. The system integrates high-resolution cameras and LiDAR sensors to capture comprehensive data on surface characteristics, including smoothness, evenness, and potential defects such as cracks and texture inconsistencies. To enhance measurement accuracy, the raw sensor data undergoes pre-processing with Gaussian filtering to reduce noise, followed by calibration for reliable results.

For defect detection, a Convolutional Neural Network (CNN)-based de-blurring module first restores clarity in motion-blurred images captured by the drone, ensuring sharper details. This deblurred data is then processed by a zero-shot transformer-based segmentation model, which uses multi-head self-attention to examine spatial relationships, accurately segmenting defect areas without the need for extensive labeled training data.

In parallel, the system employs bicubic interpolation on the LiDAR data to generate a smooth elevation map, facilitating precise flatness estimation. The system's combination of enhanced sensor processing and adaptive algorithms offers a robust and efficient solution for monitoring surface quality in complex construction settings. This method minimizes the risk of rework, improves accuracy, and supports consistent adherence to quality standards, contributing to more reliable and efficient surface finishing in construction environments. Additionally, the system employs a vision transformer-based segmentation model, which reduces the need for extensive training across different test environments, enhancing adaptability in diverse construction scenarios while maintaining high defect detection accuracy.

2 Current Developments in Surface Finishing and Drone-Based Quality Tracking in Construction

2.1 Limitations of Traditional Surface Quality Monitoring Methods

Traditional methods for monitoring surface quality in construction primarily rely on manual inspections [9]. These techniques often involve visual evaluations and the use of handheld tools to measure attributes such as smoothness, flatness, and texture consistency [10]. While these approaches can be effective in identifying major defects, they are inherently limited by their reliance on human observation. Subtle surface imperfections, such as minor texture variations, small cracks, or slight deviations in flatness, are frequently overlooked during manual inspections [11], compromising the overall quality of the finished surface. Additionally, these methods are time-consuming and labor-intensive [12], making it challenging to achieve consistent results across large or complex surfaces. Irregularly shaped areas and confined spaces pose further difficulties, as inspectors may struggle to access or measure these regions accurately. This often results in uneven quality, the need for rework, and delays in project timelines [13]. As construction projects grow in scale and complexity, the demand for more accurate, efficient, and real-time quality assessment tools has become increasingly evident, necessitating a shift toward automated solutions.

2.2 Emergence of Drone Technology in Construction

Drones have increasingly been adopted in construction for a variety of applications, owing to their versatility and capability to access areas that are otherwise difficult to reach [14]. Drones have proven to be valuable tools for tasks such as site inspections, surveying, and progress tracking [15], providing real-time aerial data that can be used to monitor various aspects of a project. Equipped with high-resolution cameras, LiDAR sensors, and GPS, drones can rapidly collect comprehensive visual and spatial information [16], covering large areas more quickly than manual methods [17]. Drones offer non-invasive data collection

capabilities, allowing for detailed topographical mapping, structural inspections, and general site monitoring without the need for direct contact [18].

Despite these advantages, the use of drones for surface-specific quality monitoring in finishing operations remains relatively underdeveloped. While some research has explored drone manipulation of tools or objects for surface tasks, achieving the precision and stability needed for delicate surface analysis and adjustments has proven challenging.

2.3 This Paper's Contribution to Drone-Based Surface Monitoring and Quality Tracking

This paper addresses a critical need in construction quality control by introducing a drone-based system that integrates high-resolution LiDAR and RGB camera sensors with advanced machine learning algorithms to monitor surface quality. The proposed system improves upon existing methods by combining multiple innovations to enhance accuracy, adaptability, and efficiency in surface assessment tasks.

To improve flatness estimation, the system incorporates a LiDAR-based mapping module enhanced with Gaussian filtering to reduce noise and bicubic interpolation to generate a smooth and continuous elevation map. This approach enhances measurement precision, improving surface elevation mapping accuracy and ensuring consistent results across diverse conditions.

For defect detection, our system integrates a CNN-based de-blurring module that effectively restores motion-blurred images captured during drone operation. This enhancement improves image clarity, ensuring sharper details that are crucial for identifying subtle surface defects such as cracks and texture inconsistencies.

Additionally, the system employs a vision transformer-based segmentation model, which requires significantly less training across diverse test environments compared to conventional CNN-based models. This reduced training requirement improves the system's adaptability and scalability, minimizing the need for extensive data collection and retraining when applied to different construction scenarios. Together, these advancements improve the precision of flatness mapping, enhance defect detection through improved visual data clarity, and increase the system's adaptability with reduced training demands. The resulting framework offers a robust, efficient, and scalable solution for real-time surface quality assessment in construction environments.[19].

3 Drone-Based Real-Time Surface Quality Assessment and Defect Detection

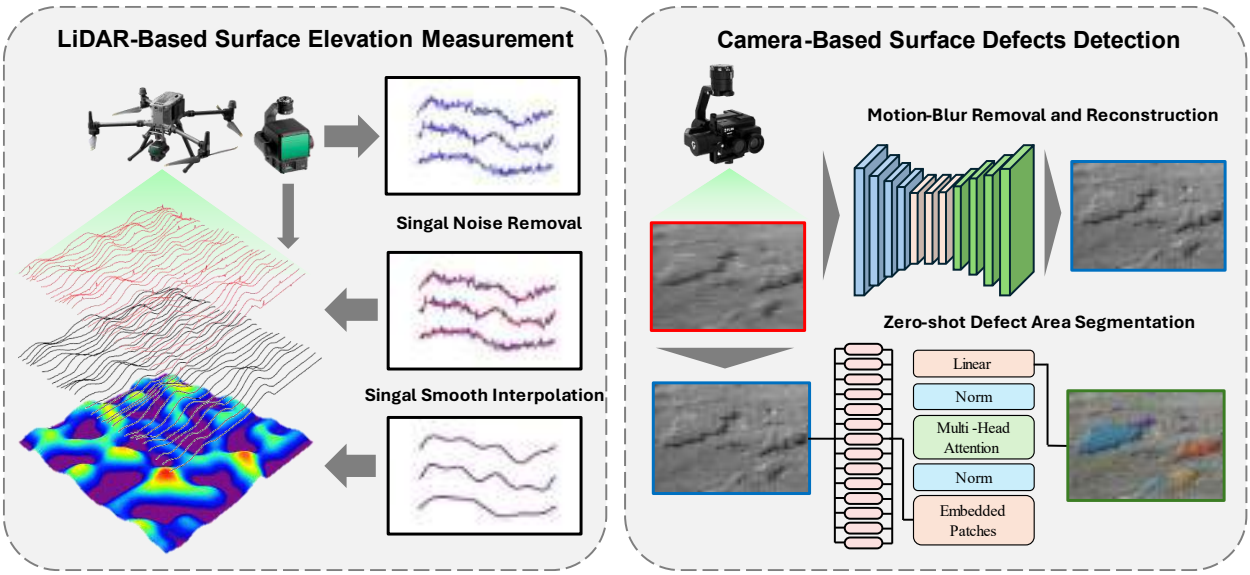

Figure 1. Drone-Based Real-Time Surface Quality Assessment and Defect Detection System Overview

The proposed UAV-based system for surface quality assessment and defect detection in construction applications is divided into two main components: LiDAR-Based Surface Elevation Measurement and Camera-Based Surface Defect Detection as shown in Figure 1. Each component is designed to address different aspects of surface monitoring, enabling the

system to capture both topographical and visual defects with high accuracy.

3.1 LiDAR-Based Surface Elevation Measurement

The LiDAR module scans the target surface to obtain detailed elevation data. This initial scan captures the surface topography, producing a series of elevation profiles that can identify height variations indicative of surface irregularities. The LiDAR data is represented as a 3D point cloud, with each point denoted by coordinates (x_i, y_i, z_i), where:

$$L = \{(x_1, y_1, z_1), (x_2, y_2, z_2), \ldots, (x_n, y_n, z_n)\} \quad (1)$$

(x_i, y_i, z_i) represents the spatial position and height of each LiDAR data point on the surface.

3.1.1 Noise Removal Module

The raw LiDAR data often contains noise due to environmental factors or sensor inaccuracies, which can lead to errors in surface mapping. To enhance accuracy, a Gaussian filtering approach is applied to the LiDAR data, effectively smoothing out noise while preserving the underlying topography. The Gaussian filter calculates a weighted average of neighboring points, giving higher importance to points closer to the target point and gradually reducing the influence of more distant points. The filtered height value $z_{\text{filtered}}(x, y)$ at each position (x, y) is computed as:

$$z_{\text{filtered}}(x, y) = \frac{1}{2\pi\sigma^2} \sum_{i=-k}^{k} \sum_{j=-k}^{k} z(x-i, y-j) \exp\left(-\frac{i^2 + j^2}{2\sigma^2}\right) \quad (2)$$

where σ is the standard deviation of the Gaussian kernel, controlling the extent of smoothing, and k is the filter size determining the neighborhood around each point (x, y). This Gaussian filtering process reduces noise effectively while preserving the surface's structural features, ensuring a more accurate representation of the surface elevation for subsequent analysis.

3.1.2 Smooth Interpolation for Elevation Estimation

After noise removal, a bicubic interpolation method is applied to fill gaps between scanned points, creating a continuous and smooth elevation map of the surface. Bicubic interpolation estimates the elevation between data points by fitting a smooth surface through the existing points, calculated as:

$$z(x, y) = \sum_{i=0}^{3} \sum_{j=0}^{3} c_{ij} x^i y^j \quad (3)$$

where c_{ij} are coefficients derived from the neighboring data points. This interpolation process generates a smooth elevation profile, allowing the system to visualize height changes continuously across the surface and detect any deviations from expected flatness, such as undulations or depressions.

3.2 Camera-Based Surface Defect Detection

The Camera Module captures high-resolution RGB images of the surface, allowing the system to detect visual defects such as cracks, texture inconsistencies, or other surface imperfections. This component involves two main steps: motion-blur removal and defect area segmentation.

3.2.1 Motion-Blur Removal Using Convolutional Neural Networks (CNN)

During UAV operations, motion blur can be introduced due to drone movement, compromising the clarity and accuracy of captured images. A Convolutional Neural Network (CNN) is applied to each image to remove any motion blur, reconstructing the image with sharp details. The blurred image $I_{\text{blurred}}(x, y)$is processed through several convolutional layers, where the output deblurred image $I_{\text{deblurred}}(x, y)$ is generated as:

$$F_l(I) = \sigma(W_l * I + b_l) \quad (4)$$

where $F_l(I)$ denotes the feature map at layer l, W_l and b_l represent the weights and biases of the filters, $***$ denotes the convolution operation, and σ is the activation function (commonly ReLU). We adopted a Multi-Scale Convolutional Neural Network architecture [20]. This architecture was chosen due to its improved stability during training, reduced computational overhead, and lower risk of generating artifacts in low-texture regions, which are common in construction environments.

The CNN model employs three parallel convolutional branches operating at different scales to effectively capture both fine textures and large structural patterns. The network integrates residual connections to improve gradient flow and enhance detail preservation, particularly in texture-rich environments such as concrete and brick surfaces. The multi-scale outputs are fused through a concatenation layer, followed by additional convolutional layers for image reconstruction. The final output layer adopts a ReLU activation function to enhance image contrast and preserve sharp details.

3.2.2 Zero-Shot Defect Area Segmentation Using Transformer Networks

After deblurring, a zero-shot transformer-based

network is used to segment defect areas without requiring extensive labeled data for training. This network utilizes a multi-head self-attention mechanism to highlight areas likely to contain defects, based on spatial features in the image. The segmented defect map $M_{\text{def}}(x, y)$ is generated by passing the deblurred image through the transformer network, resulting in a probability map that indicates the likelihood of defects at each pixel:

$$M_{\text{def}}(x, y) = \text{softmax}\left(\sum_{h=1}^{H} \text{Attention}(Q_h, K_h, V_h)\right) \quad (5)$$

where H is the number of attention heads, and Q_h, K_h, V_h represent the query, key, and value matrices for each head. This multi-head attention mechanism allows the transformer to capture nuanced spatial relationships within the image, enabling it to effectively identify defects such as cracks, discolorations, or texture inconsistencies on the surface.

4 Implementations

This section describes the implementation and testing of the two primary components of the proposed system: LiDAR-Based Surface Elevation Detection and Camera-Based Surface Defect Detection. Testing is conducted in both a ROS (Robot Operating System) simulation environment to provide controlled, reproducible conditions and on a compact real-life setup with an uneven concrete surface for real-world evaluation. These tests aim to assess the system's performance in de-blurring and segmenting surface defects, as well as accurately estimating surface flatness.

4.1 Training and Testing for Surface Defect Detection Methods

The CNN-based deblurring model was initially trained using the GoPro Blur Dataset [20] and further fine-tuned using 500 images collected from construction sites. This fine-tuning dataset captured materials such as concrete, brick, and plastered walls under varying lighting and motion conditions to better simulate realistic UAV inspection scenarios. The zero-shot transformer segmentation model was adapted from a pre-trained Vision Transformer model [21]. During evaluation, the model was tested on images collected from three construction sites featuring varied building materials (e.g., concrete, brick, and plastered walls) to assess adaptability. The vision transformer model enhances the system's adaptability by reducing the need for scenario-specific retraining. By leveraging pre-trained weights and multi-head attention mechanisms, the model efficiently identifies surface defects in environments it has not been explicitly trained on. During tests, the system successfully identified defects without additional fine-tuning.

4.2 ROS-Based Simulation for Surface Defect Detection and Flatness Estimation

The ROS environment serves as an initial testing ground for the proposed UAV system, simulating real-world construction surfaces under controlled conditions. This simulation is designed to evaluate both the LiDAR-based surface elevation detection and the camera-based defect detection modules, allowing for precise performance assessment before moving to real-world testing.

In the ROS environment, a simulated construction site surface is created with a variety of textures, irregularities, and defects. The simulated surface includes flat regions, textured areas, and sections with artificial cracks and bumps to mimic typical construction site conditions. This environment allows for thorough testing of both the LiDAR and camera modules under a variety of scenarios.

The virtual UAV in the ROS simulation is equipped with simulated RGB camera and LiDAR sensors, both of which are configured to replicate real-world data acquisition processes. The RGB camera captures high-resolution images of the surface from a consistent altitude of 2 meters. To evaluate the de-blurring module, synthetic motion blur is introduced to the images to simulate the drone's movement during flight. The LiDAR sensor, positioned alongside the camera, continuously scans the surface to create a 3D point cloud that represents surface elevation data, including controlled noise to test the noise removal and interpolation modules.

In the first phase of testing, the UAV captures both RGB images and LiDAR data as it hovers over the surface at a designated altitude.

4.3 Real-Life Test for Motion Blur Removal and Defect Segmentation

Following the ROS simulation, a real-life test is conducted to validate the de-blurring and segmentation capabilities on an actual uneven concrete surface. This real-life setup is designed to closely replicate the types of surfaces commonly encountered on construction sites, including intentional irregularities such as cracks, bumps, and texture inconsistencies. This research also used open-access dataset to validate the effectiveness and accuracy of the defect detection methodology [22]. This experiment provides insights into the system's performance under realistic lighting, material, and environmental conditions.

The experimental setup employed a quadcopter drone,

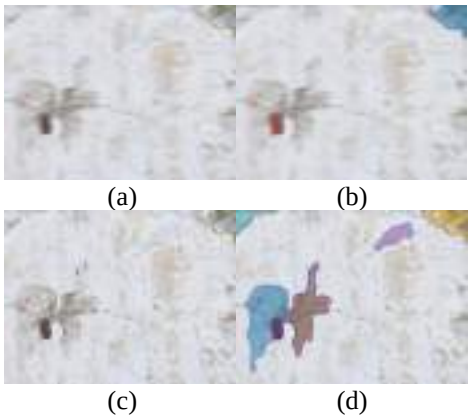
equipped with a compact Runcam Phoenix 2 camera (1000 TVL resolution, 2.1mm lens) and an Ouster OS1-32 LiDAR sensor with ±0.01° angular sampling accuracy for both vertical and horizontal directions. The UAV maintained a flight speed of 0.5 – 1.0 m/s and followed a predefined grid pattern at a height of 1.5 meters to ensure comprehensive data coverage with a 75% forward overlap and 60% lateral overlap. Data collection occurred in both indoor and outdoor construction environments under varied lighting conditions to evaluate system adaptability and robustness. Due to unavoidable minor movements during hover, moderate motion blur is naturally introduced into the images. The captured images are processed in real-time by the de-blurring module, which uses a CNN architecture to remove the motion blur and enhance clarity. This de-blurred image is then fed into the zero-shot transformer-based segmentation model to detect and isolate defect areas. The segmentation output is visualized as a colored mask, with highlighted regions indicating the presence of cracks, texture inconsistencies, or other defects. This test not only verifies the effectiveness of the de-blurring and segmentation process but also provides a realistic evaluation of how well the system performs in identifying defects on rough, uneven surfaces like concrete.

The ROS simulation is conducted in 20 different environment and the real-life test collects 200 images to gather performance metrics. Key metrics include defect detection accuracy, de-blurring effectiveness, and the system's ability to accurately estimate flatness. In each test, the accuracy of defect detection is measured by comparing the binary defect maps with known defect locations on the test surfaces. The success of flatness estimation is assessed by measuring the deviation between the estimated surface heights from the LiDAR data and the actual surface profile, with an emphasis on identifying areas with elevation deviations exceeding acceptable tolerance levels.

Through these tests, the proposed UAV-based system demonstrates its capability to accurately detect defects, segment surface irregularities, and estimate surface flatness.

5 Results

The results of the implementation are presented in this section, focusing on the performance of the LiDAR-based surface elevation measurement and camera-based surface defect detection modules.



5.1 LiDAR-Based Surface Elevation Detection

To evaluate the accuracy and consistency of the LiDAR-based surface elevation detection, several metrics were calculated to compare the estimated surface elevation data with the actual physical surface measurements obtained from the test environment. The main metrics used were Root Mean Square Error (RMSE) and Mean Absolute Error (MAE), both of which quantify the deviation between the LiDAR-generated elevation map and the actual surface profile.

Root Mean Square Error (RMSE): The RMSE was calculated to quantify the average magnitude of errors in the LiDAR-derived elevation data. This metric reflects how well the LiDAR data matches the actual surface heights across all tested points. The RMSE for the LiDAR-based flatness estimation was observed to be approximately 0.2 mm in the ROS simulation and 0.8 mm in the real-life test, indicating a high degree of accuracy for both controlled and real-world environments.

Mean Absolute Error (MAE): The MAE provides an alternative error measurement, representing the average of absolute differences between estimated and actual surface heights. The MAE for the flatness estimation was 0.4 mm in the ROS environment and 1.1 mm in the real-life setup, further demonstrating the LiDAR system's consistency in representing surface elevation.

Consistency Across Multiple Runs: To assess consistency, the LiDAR module's flatness measurements were repeated across multiple runs in both the simulated and real-life environments. The Standard Deviation of the RMSE across five independent runs was 0.1 mm in the ROS simulation and 0.4 mm in the real-life test, demonstrating consistent performance with minimal variation, even in the presence of environmental noise.

5.2 Camera-Based Surface Defect Detection

The effectiveness of the de-blurring module can be observed in Figure 2. The first image (a) represents the

raw data captured by the camera, where significant motion blur obscures surface details, making it challenging to identify surface defects accurately. Texture and fine structural elements, crucial for detecting cracks or bumps, are blurred, which would likely hinder the segmentation module's ability to accurately isolate defect areas. The third image (c), after processing through the CNN-based de-blurring module, shows a marked improvement in clarity and sharpness. Fine textures and subtle surface irregularities that were previously obscured are now distinctly visible. The improved clarity allows for enhanced contrast in texture features, essential for precise defect detection. This qualitative improvement demonstrates the critical role of the de-blurring module in enhancing the fidelity of image data, ultimately supporting higher segmentation accuracy and ensuring robust defect detection.

The effectiveness of the camera-based surface defect detection module was evaluated by measuring the Precision, Recall and Intersection over Union (IoU), for the segmentation results. The experiments compared segmentation performance with and without the de-blurring module, revealing a significant improvement in defect detection accuracy when the de-blurring process was applied.

Precision was calculated to assess the proportion of correctly identified defect pixels out of all pixels classified as defects. Without de-blurring, precision was observed to be around **78%**, indicating a high rate of false positives due to motion blur. After de-blurring, precision improved to **96%**, showing that the de-blurring module reduced false positives significantly, enabling the system to accurately classify defect regions. **Recall** was also used to measure the proportion of actual defect pixels that were correctly identified. The recall score without de-blurring was around **15%**, highlighting that many true defect areas were missed due to image blurriness. With the de-blurring module, recall improved to **94%**, indicating that the system could accurately capture almost all defect areas present on the surface.

Intersection over Union (IoU) was used as the primary metric to evaluate segmentation accuracy, measuring the overlap between the predicted defect regions and the ground truth defect areas. Without applying the de-blurring module, the IoU for defect segmentation was approximately **28%**, indicating a high degree of misalignment between the segmented defects and actual defect locations due to motion blur in the images. However, with the de-blurring module applied, the IoU increased dramatically to over **95%**, showing that the de-blurred images allowed for accurate identification of defect areas, with high consistency between predicted and actual defects.

6 Conclusions

This paper presents a novel UAV-based system designed for real-time surface quality assessment in construction, integrating LiDAR for flatness estimation and a camera module for defect detection. The implementation of a CNN-based de-blurring module significantly enhanced defect segmentation accuracy, achieving an IoU improvement from 28% to over 95%, by restoring image clarity affected by motion blur. The LiDAR module demonstrated high consistency with actual surface elevations, with low RMSE and MAE values, validating its effectiveness in accurately representing surface topography. Field tests in both simulated and real-world environments confirmed the system’s robustness, achieving reliable performance in detecting surface defects and estimating flatness.

Future research directions include conducting more comprehensive real-life field tests in diverse construction environments to evaluate the system's adaptability to varying lighting, weather, and material conditions. Additionally, exploring the integration of advanced machine learning techniques, such as self-supervised learning or transformer-based models, could further improve defect detection and flatness estimation across a broader range of surface types.

Abstract -

This study presents the development and evaluation of a hydraulic excavator equipped with a built-in angular velocity controller to improve the precision of excavation operations. By integrating a velocity control system that takes into account the characteristics of the hydraulic system, the proposed approach enhances the path-tracking accuracy of the bucket edge during digging tasks. Experimental results demonstrate that the angular velocity controller significantly reduces path errors compared to conventional lever-based control systems, achieving improvement in path accuracy. This advancement facilitates the automation of hydraulic excavators, and provides a reliable foundation for further developments in construction robotics.

Motion Control; Hydraulic System Dynamics; Excavation Path Tracking;

1 Introduction

In recent years, there has been a growing demand for the automation of construction machinery, driven by labor shortages in construction and industrial plants, particularly the declining availability of skilled workers. To address this issue, technologies enabling the autonomous operation of construction machinery, such as hydraulic excavators performing excavation tasks automatically, have been developed [1].

Previous automation technologies were typically built upon conventional machines designed for manual operation. These systems relied on human-optimized interfaces—lever manipulation, pedal operation, and steering inputs—and replaced human inputs with a controller mounted externally on the machine. Moreover, feedback elements, such as rotary angle sensors, optical cameras, LiDAR, and GNSS, were often added to the machinery to determine control inputs, which required additional hardware installations. However, this approach presents several challenges:

- Nonlinear elements optimized for human operation (e.g., play, sensitivity adjustments) make it difficult to enhance servo system responsiveness[2].
- The cost of modifying the hardware of the machinery is significant for users.
- Modeling and parameter identification necessary for controlling the hydraulic excavator system are technically complex for users[3].

To overcome these issues, it is desirable for hydraulic excavator manufacturers to incorporate controllers into the machinery itself, taking into account the system's characteristics and enabling users to provide input directly through interfaces. This integration facilitates automation by treating the excavator's components as a four-degree-of-freedom manipulator and developing a control framework similar to that of industrial robotic arms. This facilitates the ease of automation for hydraulic excavator. This approach is expected to enable highly precise control of the bucket's edge path. If such technology is realized, it could automate hydraulic excavator operations that require strict conformance to design specifications, such as shaping embankment slopes. Additionally, it would facilitate autonomous operations in environments with surrounding obstacles, allowing the excavator to avoid contact with them effectively.

Hitachi Construction Machinery has previously provided machine control functions, such as the automatic control of boom movements to ensure the bucket of a hydraulic excavator follows a target surface [4]. Additionally, the company developed the ZCORE® system platform, which allows for easy function expansion and customization based on automation needs [5]. By enabling hydraulic excavators to operate using common control

messages proposed by the Public Works Research Institute [6], it is anticipated that construction operators will be able to command multiple hydraulic excavators from different manufacturers using a unified system, thereby promoting the widespread adoption of automation. In September 2022, Hitachi Construction Machinery (Hitachi CM) and the Public Works Research Institute (PWRI) launched a joint research project aimed at improving the productivity of mechanized earthwork using the OPERA autonomous construction technology open platform [6]. In this project, Hitachi Construction Machinery developed a hydraulic excavator equipped with a built-in angular velocity controller, taking into account the characteristics of the hydraulic system (Figure 1). This paper confirms the effectiveness of the developed system in advancing the automation of hydraulic excavators and is organized as follows.

In Chapter 2, the system architecture for controlling the path of the edge of the bucket is described. We present an example of a conventional approach where a servo system outputs lever operations from an external motion controller of the excavator. In contrast, an example of the proposed approach using the developed velocity controller, which outputs target joint angular velocity from an external motion controller, is also explained.

Chapter 3 provides a detailed explanation of the developed velocity controller. Chapter 4 reports on the experimental validation by performing excavation tasks using both the conventional and proposed methods, comparing the behavior of each actuator in the excavator. Finally, Chapter 5 concludes the findings of this study.

Figure 1. Developed excavator built-in velocity controller.

2 System configuration for bucket edge path control

This chapter describes the system configuration required to automate the bucket edge path control of a hydraulic excavator. The excavator used in this study is equipped with an electronically controlled hardware system capable of receiving pilot pressure commands corresponding to lever operations. Figure 2 illustrates the hardware system configuration.

2.1 Conventional method: Lever operation-based commands

In the conventional approach, the hydraulic excavator is controlled using lever operation commands as the operational input. The system architecture is shown in Figure 3-(a). A motion planner sequentially calculates the target joint angles required to achieve the desired bucket edge pose. These angles are then controlled by a Joint Position Controller, which outputs lever operation commands to the Joint Control Unit (JCU). The JCU sends the vehicle control data to the Motion Control Unit (MCU) as feedback data and generates target pilot pressure for the actuators.

2.2 Proposed method: Angular velocity-based commands

The proposed method replaces lever operation commands with angular velocity commands as the operational input. Figure 3-(b) illustrates this system configuration. The motion planner calculates the sequential target joint angles for achieving the desired bucket edge pose. These angles are converted into target angular velocities by the joint position controller and transmitted to the JCU. Within the JCU, a dedicated velocity control algorithm calculates the necessary target pilot pressure and sends commands to the solenoid valve controller, thereby driving the hydraulic system. The output of the Hydraulic Pressure Sensors in Figure 2 is used to measure the load applied to the actuator and improve the accuracy of angular velocity control. Details are described in Chapter 3.

The proposed method offers significant advantages over the conventional approach. By directly controlling the angular velocity of each joint, the system improves path tracking accuracy and responsiveness. Moreover, this method simplifies the control architecture by reducing dependency on external hardware, enabling easier integration into automated systems.

3 Joint velocity controller considering hydraulic system characteristics

This chapter details the joint velocity controller that considers the characteristics of the hydraulic system built

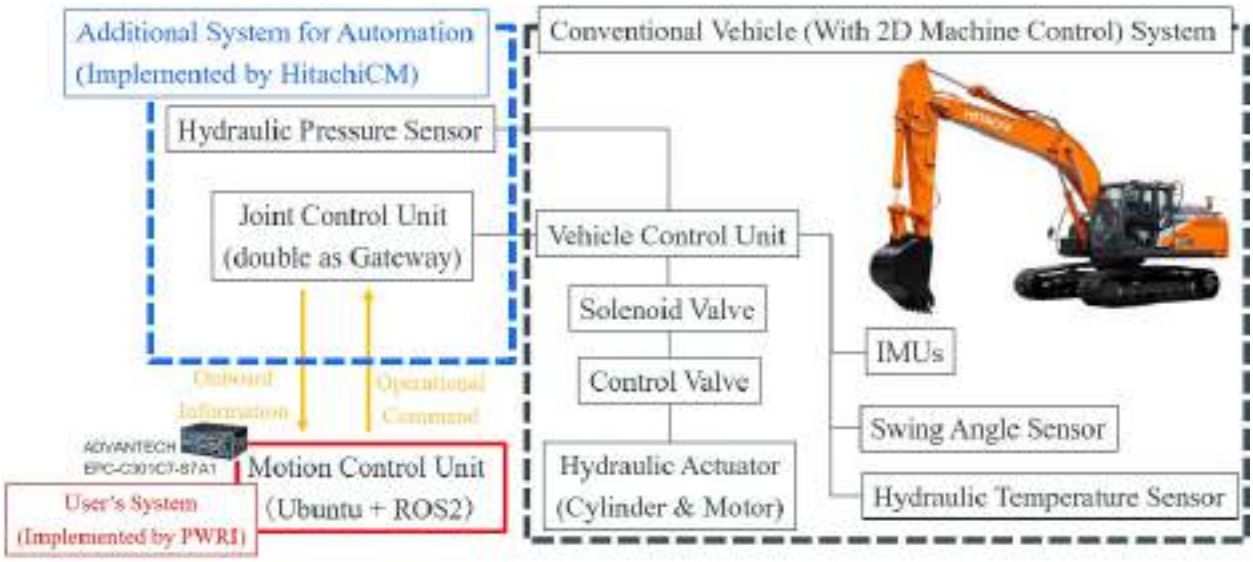

Figure 2. Hardware system configuration of the hydraulic excavator.

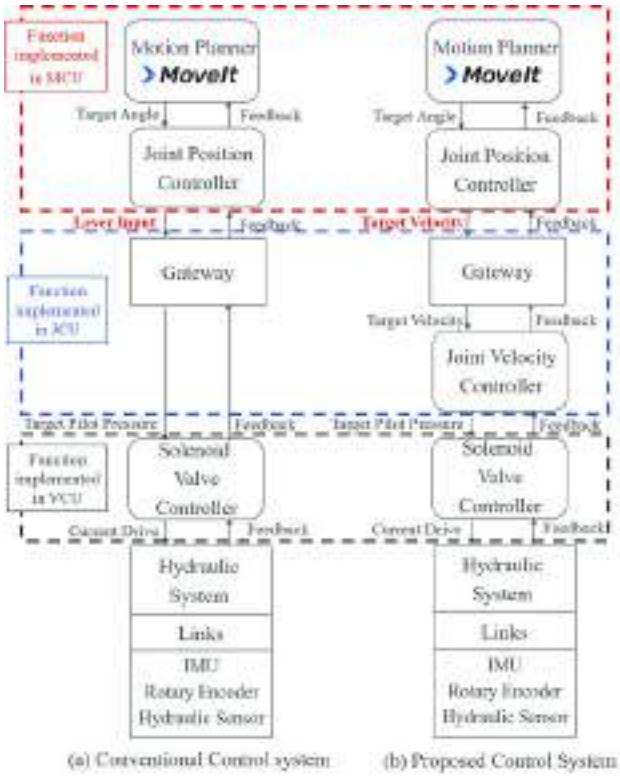

Figure 3. Schematic diagram of automated system for excavator.

into the excavator. As shown in Figure 4, this controller consists of three computational processes: (a) Link calculation, (b) Pump flow rate calculation, and (c) Valve opening calculation. Each of these processes is described in the following subsections.

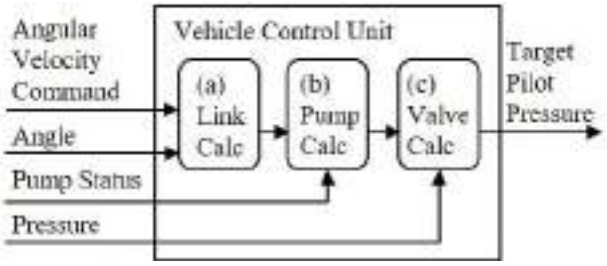

Figure 4. Schematic diagram of the Joint Velocity Controller.

3.1 Link calculation

As an example, the relationship between the boom angle and the boom cylinder length is explained. The kinematic relationship between the boom and the boom cylinder is shown in Figure 5. The relative angle $\angle BAC$ of the boom to the chassis and the boom cylinder length BC can be expressed by Equation (1).

$$\overline{BC}^2 = \overline{AB}^2 + \overline{AC}^2 - 2\overline{AB} \cdot \overline{AC} \cos \angle BAC \qquad (1)$$

The relationship between the angular velocity ω of the boom and the boom cylinder speed can be derived by differentiating Equation (1) with respect to time, resulting in Equation (2).

$$\frac{d\overline{BC}}{dt} = \frac{\overline{AB} \cdot \overline{AC} \sin \angle BAC}{\overline{BC}} \omega \tag{2}$$

Assuming the hydraulic fluid is incompressible and the cylinder has a circular cross-section, the boom cylinder speed obtained in Equation (2) can be converted to the flow rate Q of the hydraulic fluid using the cylinder cross-sectional area A_{cyl}, as expressed in Equation (3).

$$Q = A_{\text{cyl}} \frac{d\overline{BC}}{dt} \tag{3}$$

In this manner, the angular velocity command can be converted to the flow rate Q of hydraulic fluid supplied to the actuator from the pump.

When an angular velocity command is input to the JCU, a process is implemented to calculate the optimal target pilot pressure required for operation at the target angular velocity, taking into account the pump output and the load on the actuator. Figure 6 shows a schematic diagram of the power transmission to the actuator. The changes in joint angles of each link can be converted into the volume of incompressible hydraulic fluid supplied from the pump to the actuator, which is a cylinder. Based on this, the flow rate of the actuator corresponding to the commanded angular velocity can be calculated.

$$Q = CA \sqrt{\frac{2\Delta P}{\rho}} \tag{4}$$

The flow rate Q_{in} from the pump to the actuator is generally expressed by the orifice equation (4), which relates the opening area A of the spool on the path to the pressure difference before and after it. Therefore, the spool opening area A required to achieve the target angular velocity can be calculated. In equation (4), C is the flow coefficient, ρ is the fluid density, and ΔP is the differential pressure across the spool opening ($P_P - P_{\text{in}}$). The relationship between the spool opening area A and the pilot pressure is determined by the opening characteristics of each spool.

3.2 Pump flow rate calculation

Hydraulic excavators are generally designed with hydraulic circuits that allow a single pump to operate multiple actuators. Therefore, when simultaneous operation commands are input to multiple joints, calculating the target pilot pressure for each command as if operating a single joint may result in the total flow exceeding the output capacity of a single pump. In such cases, differences in the load on each actuator may lead to an uneven distribution of flow, causing one side to receive more flow and making it impossible to achieve the target angular velocity. Particularly, if the ratio of the current value to the target value differs among joints, the bucket tip may deviate from the path planned by the Motion Controller. This issue can be critical in use cases where avoiding contact with obstacles around the hydraulic excavator is required.

On the other hand, even if there is a deviation between the current value and the target value for each joint, as long as the ratio of the current value to the target value remains consistent across all joints, the planned path can be maintained. This is considered desirable in use cases that involve avoiding surrounding obstacles. To address this, when angular velocity commands are simultaneously given to multiple joints, a control algorithm is implemented in the Joint Velocity Controller to determine the target pilot pressure. This algorithm ensures that the ratio of angular velocities is maintained such that the total flow does not exceed the pump's discharge capacity.

Figure 7 shows an example of a circuit where flow is distributed to multiple actuators from a single pump. When the pressure in the hydraulic line does not reach the bleed-off pressure, the bleed-off flow Q_T flowing into the tank in the figure can be considered as $Q_T = 0$. In this case, as shown in Equation (5), the pump flow Q_P is equal to the sum of the actuator flows Q_{in1} and Q_{in2}.

$$Q_p = Q_{\text{in1}} + Q_{\text{in2}} \tag{5}$$

On the other hand, based on the linkage mechanism calculations described in Section 3.1, the required flows $Q_{\text{Req in1}}$ and $Q_{\text{Req in2}}$ for each actuator at the commanded angular velocity can be determined.

$$\begin{aligned} \text{If } Q_p &< Q_{\text{Req in1}} + Q_{\text{Req in2}}, \\ Q_{\text{in1}} &= \frac{Q_{\text{Req in1}}}{Q_{\text{Req in1}} + Q_{\text{Req in2}}} Q_p, \qquad (6) \\ Q_{\text{in2}} &= \frac{Q_{\text{Req in2}}}{Q_{\text{Req in1}} + Q_{\text{Req in2}}} Q_p, \qquad (7) \end{aligned}$$

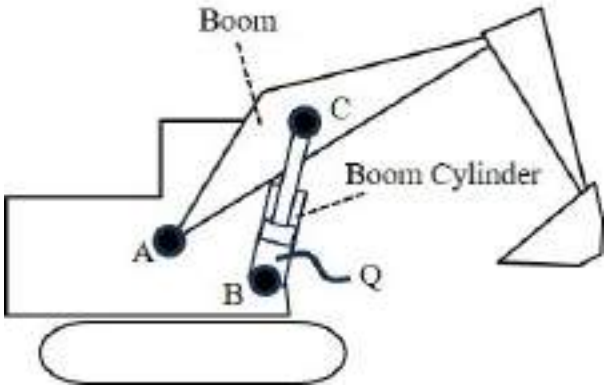

Figure 5. Kinematic relationship between the boom and the boom cylinder.

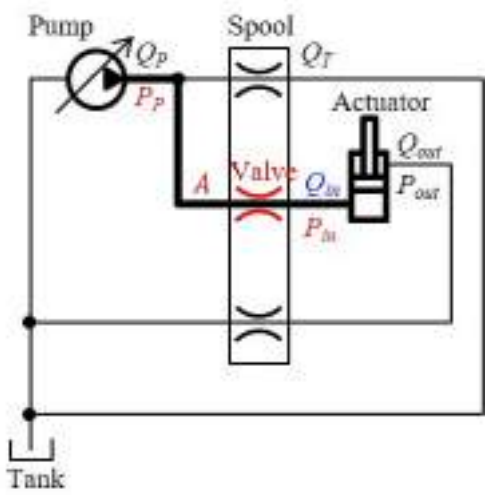

Figure 6. Hydraulic circuit diagram of power transmission from pump to actuator(Single pump to single cylinder).

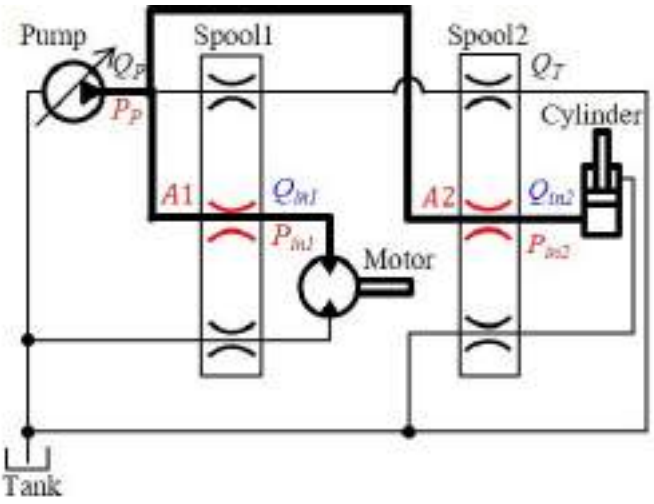

Figure 7. Hydraulic circuit diagram of power transmission from pump to actuator(Single pump to double cylinder).

As shown in Equation (6) and (7), if the sum of the required flows $Q_{\text{Req in1}}$ and $Q_{\text{Req in2}}$ exceeds the pump's discharge capacity Q_P, the target actuator flows Q_{in1} and Q_{in2} are adjusted by multiplying them by the ratio of the pump's discharge capacity to the required flow. By doing so, deviations of the bucket tip from the target path can be suppressed within the pump's discharge capacity.

$$Q_{\text{in1}} : Q_{\text{in2}} = Q_{\text{Req in1}} : Q_{\text{Req in2}}, \tag{8}$$

$$\omega_1 : \omega_2 = \omega_{\text{Req1}} : \omega_{\text{Req2}}, \tag{9}$$

$$Q_{\text{in1}} = CA1 \sqrt{\frac{2(P_p - P_{\text{in1}})}{\rho}}, \tag{10}$$

$$Q_{\text{in2}} = CA2 \sqrt{\frac{2(P_p - P_{\text{in2}})}{\rho}}, \tag{11}$$

$$A1 = \frac{1}{C} \frac{Q_{\text{Req in1}} Q_p}{Q_{\text{Req in1}} + Q_{\text{Req in2}}} \sqrt{\frac{\rho}{2(P_p - P_{\text{in1}})}}, \tag{12}$$

$$A2 = \frac{1}{C} \frac{Q_{\text{Req in2}} Q_p}{Q_{\text{Req in1}} + Q_{\text{Req in2}}} \sqrt{\frac{\rho}{2(P_p - P_{\text{in2}})}}. \tag{13}$$

3.3 Valve opening calculation

The flow rate Q_{in} flowing into the actuator from the pump is generally expressed by the orifice equation (Equation (4)) using the valve opening area A of the spool and the pressure difference ΔP before and after the valve. Therefore, the valve opening area A required to achieve the target angular velocity can be calculated. The relationship between the valve opening area A and the pilot pressure is uniquely determined by the valve characteristics.

4 Experimental verification of conventional and proposed methods

4.1 Experimental purpose

The objective of this experiment was to confirm the effectiveness of the velocity controller, which takes into account the characteristics of the hydraulic system of the excavator's working mechanism. The comparison was made with the conventional method outlined in Section 2.1, which uses simple proportional controllers (P controllers) on the external *Joint Position Controller* of the excavator. The conventional method does not consider hydraulic system characteristics and relies on lever inputs as commands.

4.2 Experimental procedure

The experiment involved excavating a flat surface using the hydraulic excavator. During this process, errors in the cutting-edge path and joint angle control (the difference between the commanded and actual values) were measured. The excavator was placed on a nearly level ground surface. To standardize the hardness of the ground, the excavation area was manually dug beforehand to loosen the soil, and the terrain was leveled to ensure that the plane of the excavation surface matched the ground plane of the excavator.

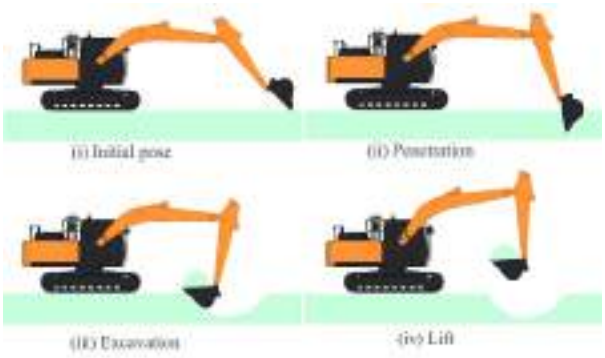

Figure 8. Display of test movements: (i) Initial pose, (ii) Penetration, (iii) Excavation, (iv) Lift.

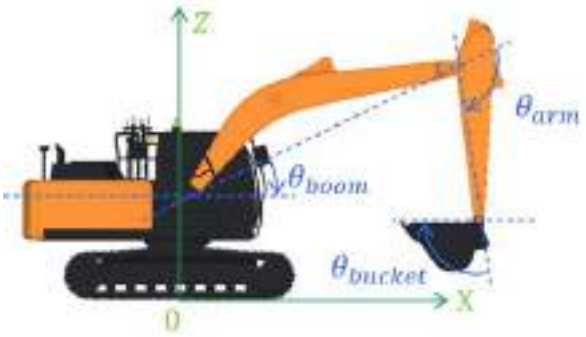

Figure 9. The definition of each coordinate.

The experimental motions were carried out sequentially as shown in Figure 8 from states (i) to (iv). The target joint angles for each state are summarized in Table 1. The definition of each joint angle and cartesian coordinates system are shown in Figure 9 .

During the transitions between these states, the commanded and actual joint angles (calculated using sensors such as IMUs) were recorded. The recorded joint angles were then used to calculate the cutting-edge path using forward kinematics. This allowed the path traversed during the experiment to be determined. Deformations caused by external forces acting on the excavator's links during motion were not considered.

Table 1. Target joint angles for each state (i)-(iv)

State	Boom	Arm	Bucket
(i) Initial Pose	-0.24 rad	1.19 rad	-0.07 rad
(ii) Penetration	-0.24 rad	1.57 rad	-0.07 rad
(iii) Excavation	-0.24 rad	1.92 rad	1.36 rad
(iv) Lift	-0.44 rad	1.92 rad	1.55 rad

4.3 Experimental conditions

Two experimental conditions were evaluated to compare the path followed by the cutting-edge:

1. **Condition 1: Conventional method (Without velocity control)**
   The method described in Section 2.1 was employed, where lever inputs were commanded to the excavator. The target angles for the cutting-edge were calculated sequentially using *MoveIt2*[7], and these values were input to the P controllers outside the excavator.

2. **Condition 2: Proposed method (With velocity control)**
   The method described in Section 2.2 was employed, where target joint angular velocities were directly commanded to the excavator. The target angular velocities required to achieve the desired cutting-edge pose were calculated and directly input to the excavator.

The various parameters related to the motion controller, MoveIt2, used in the experiment are summarized in Table 2. In this table, θ_{limit}^{upper} and θ_{limit}^{lower} represents upper or lower limit angles of the range of motion, $\dot{\theta}_{limit}$ represents angular velocity limit, and $\ddot{\theta}_{limit}$ represents angular acceleration limit, for each joint respectively. Additionally, variables K_P, K_I and K_D with the superscript "lev" and "vel" represent the P, I, and D gains of the joint position controller in conventional method or proposed method respectively. Essentially, in this experiment, the joint position controller is a pure proportional controller in both conditions. This is a measure to simplify the comparison between the conventional method and the proposed method.

The tolerance value for the control error of joint angles was set to 0.03 rad for all axes and tests. This means that the target poses from (i) to (iv) are switched only when the control errors of all joint axes fall within this allowable range. The control timeout was set to 30 seconds. This means that if 30 seconds have elapsed since the control target value stabilized, the bucket edge target position will be forcibly switched to the next target position, even if a control error exceeding the tolerance remains.

Table 2. Parameters related to the motion controller

Parameter	Boom	Arm	Bucket
θ_{limit}^{upper}	0.349 rad	2.687 rad	2.372 rad
θ_{limit}^{lower}	-1.137 rad	0.594 rad	-0.622 rad
$\dot{\theta}_{limit}$	0.3 rad/s	0.7 rad/s	1.0 rad/s
$\ddot{\theta}_{limit}$	0.2 rad/s^2	0.7 rad/s^2	1.0 rad/s^2
K_P^{lev}	1.7	1.4	0.6
K_I^{lev}	0.0	0.0	0.0
K_D^{lev}	0.0	0.0	0.0
K_P^{vel}	1.4	1.5	1.0
K_I^{vel}	0.0	0.0	0.0
K_D^{vel}	0.0	0.0	0.0

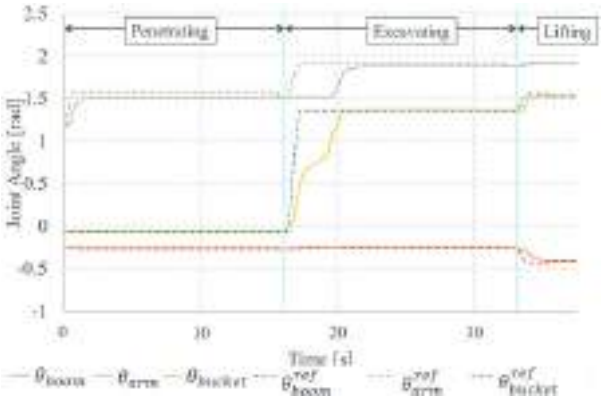

Figure 10. Angle profile in conventional control system.

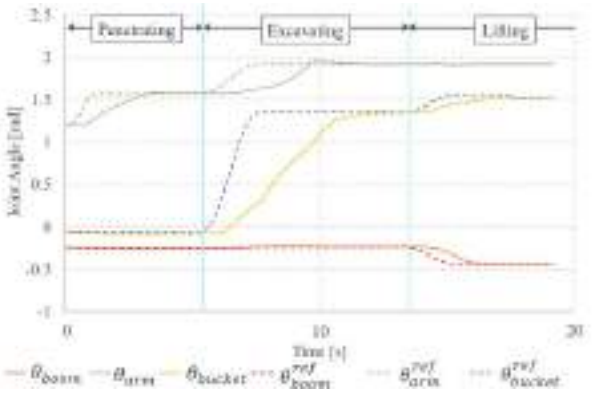

Figure 11. Angle profile in proposed control system.

4.4 Experimental results

Figure 10 and 11 present the angle profiles (commanded and actual) for the conventional and proposed methods, respectively. Figure 12 shows the path of the cutting-edge for both methods compared to the target path.

The horizontal axis (X) represents the forward direction from the excavator's crawler as projected onto the ground, while the vertical axis (Z) represents the upward direction. The line $Z = 0$ corresponds to the ground plane. The operational modes are labeled as *Penetration*, *Excavation*, and *Lift*, as indicated in Figure 8.

From Figure 12, it is evident that during *Penetration* and *Excavation*, the proposed method achieved trajectories closer to the target than the conventional method. During the *Lift* phase, both methods performed comparably, indicating that the proposed method maintained path accuracy even under reduced load conditions.

Next, Figure 13 shows the results of comparing the control errors of the bucket edge path between the conventional and the proposed method. The vertical axis represents the control error, which is the Root Mean Square (RMS) value of the bucket edge position. The calculation was performed across the entire bucket edge path. It can be observed that the proposed method reduces the error to 41% compared to the conventional method.

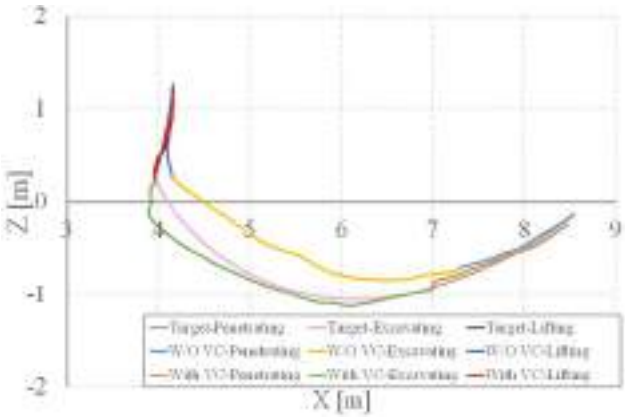

Figure 12. Cutting-edge path comparison: conventional vs. proposed methods.

4.5 Discussion

As shown in Figure 12, the proposed method effectively maintained cutting-edge path closer to the target than the conventional method, particularly during the *Penetrating* and *Excavating* phase. Analysis of the control profiles in Figs. 10 and 11 indicates that the conventional method experienced delays, particularly for the arm joint, where *Excavating* phase started, for approximately 3 seconds after receiving the command. This discrepancy can be attributed to unbalanced oil flow in the conventional method, as lever inputs cannot ensure balanced motion across multiple joints. Furthermore, at the end of both the *Penetrating* and *Excavating* phases, the arm joint exhibited a steady-state deviation exceeding the tolerance range of 0.03 rad relative to the target value, which persisted for more than 10 seconds, resulting in a prolonged operating time.

Conversely, the proposed method mitigated this issue by utilizing angular velocity control via joint velocity controller, allowing the system to compensate for variations in resistance and disturbances encountered during excavation. This feature ensured adherence to the target path, which was unattainable with the conventional proportional control approach. In the conventional method, the lever operation amount is determined by proportional (P) control based on the angle. Consequently, when external loads act on each joint during excavation, the operation halts when the load balances with the force generated by the lever operation amount output by the P controller. For

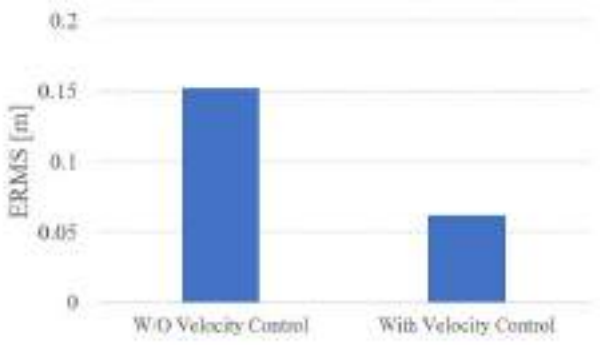

Figure 13. Error comparison: RMS cutting-edge error for conventional and proposed methods.

this reason, it is considered that the conventional method required about 30 seconds (equals to the control timeout) to reach the final target position in each operation mode.

5 Conclusion

To advance the automation of construction, we prototyped automated system for a hydraulic excavator with a velocity controller considering the characteristics of the hydraulic system. This velocity controller allows users to issue rotational velocity commands for each axis of the excavator's working device. Using this controller, the excavator performed ground excavation tasks, and the path control accuracy of the bucket cutting edge was compared between cases with and without the proposed controller.

The results confirmed that the path deviation of the cutting-edge was reduced to less than half when using the proposed velocity controller. This finding demonstrates that for automating hydraulic excavators, embedding controllers capable of realizing actuator angular velocities within the excavator and using angular velocity commands from the upper motion control system instead of lever-based commands is a a preferable approach. The proposed velocity control method is effective in achieving this goal.

Skilled human operators adeptly perform various tasks through lever operation. For example, during excavation, they adapt their operations based on the load conditions, distinguishing between hard and soft ground. This suggests that, even if control commands are given only as lever operation inputs, it may be possible to develop an autonomous system capable of executing tasks at a level comparable to humans, provided the upper-level control system is sufficiently sophisticated. However, implementing such an advanced upper-level system poses significant technical challenges for users. By contrast, if the angular velocity control utilizing hydraulic pressure information proposed in this study is pre-installed within the hydraulic excavator, the upper-level system can be simplified. In future work, we will not only aim to further enhance the robustness of angular velocity control but also explore optimal system configuration to improve user-friendliness in automation. This includes integrating a high-level controller within the excavator, allowing users to specify the desired path of the bucket's cutting edge.

Abstract -

Advancing the adaptivity of autonomous mobile robots (AMRs), particularly empowering them to align with human expertise and learn from past experiences to infer optimal decisions in response to changing task demands and dynamic environment, is critical for their application in modular construction automation and reducing operational carbon footprints. Although a few learning paradigms based on human demonstrations have been introduced, robots remain rigid in structured tasks and lack internal adaptivity and authentic learning capabilities. This research explores a fundamental approach to equipping robots with an internal drive for self-reflection and conscious learning within a shared control setting, where human supervisors provide occasional corrective inputs and interventions. This approach is centered on the concept of interoception, which we factorize as "cognitive dissonance" within the robotic cognitive architecture. When significant decision divergence with human counterparts occurs, the robotic agent will actively seek decision rationale from semantic inputs, extracts knowledge from human scaffolding, encodes it into a memory system, and retrieves this "cached" knowledge for future decision-making in similar scenarios. This paper explores this new perspective to help build adaptive motion planning in AMRs. First, we propose integrating the legacy of heuristic costs from grid/graph-based path planning algorithms with a hypergraph model that caches declarative and procedural knowledge extracted from human semantic inputs. Second, we design a velocity-replay module that uses few-shot contrastive learning with a encoder-decoder architecture and compare its performance against reinforcement learning with human feedback and imitation learning. Two simulation demonstrations were conducted using the Issac Sim platform to showcase multi-robot synchronization and stacking collaboration. In addition, the proposed shared control paradigm was tested in a Gazebo environment in ROS, where human inputs were provided via relatively noisy brainwave-based control, compared to conventional peripheral devices. The results demonstrate how this approach better mitigates human input errors while facilitating autonomy for task completion compared to existing dominant shared control methods. The insights from this study resonate with recent advances in neuroscience and reinforcement learning, and pave the way toward artificial general intelligence in AMRs, fostering their progression from complexity to competence in construction automation.

1 Introduction

Automation in construction can significantly contribute to achieving sustainability goals [1]. In particular, modular construction using offsite prefabrication and onsite assembly have the potential to address climate action by reducing operational carbon footprints compared to traditional onsite methods such as concrete mixing and curing [2]. In additional to potential environmental benefits, automation can improve worker safety by mitigating exposure to hazardous conditions. For example, automated robotic machinery used for onsite tasks, such as assembly, reduces risks like falls from scaffolding, inhalation of welding fumes, and electrocution [3]. Mobile robots, including forklifts, cranes, and dozers, have been increasingly used to streamline offsite and onsite construction processes [4]. However, the integration of mobile robotics in construction introduces new challenges. Without effective coordination of multi-robot path planning that manages sequential task dependencies and precise velocity control to adapt to dynamic nature of construction workflows, risks such as struck-by hazards increase [5].

In addition, autonomous mobile robots (AMRs) reshape the power dynamics between humans and machines. These robots can operate with programmed autonomy, performing tasks such as delivering materials across a precast factory or a site to support fabrication or assembly processes [3]. Although they remain under the supervision of human workers, their autonomy shifts the relationship from subservience—where robots follow human instructions without intrinsic understanding—to augmentation, where robots act more like symbiotic co-workers with spe-

cialized capabilities. This shift, however, can provoke apprehension among industry practitioners, often fueled by fear of the unknown [6]. Concerns about the emergence of superintelligent systems, often referred to as singularity, suggest a future where robots could become uncontrollable and irreversible in their autonomy. Such fears are compounded by the opaque reasoning processes of robots and the asymmetry in knowledge between humans and machines, leading to uncertainty about whether these systems are truly beneficial and trustworthy.

To address these challenges, this research advocates for advancing the cognitive capabilities of AMRs to align with human intelligence. A critical focus is to learn from humans and learn the way how humans learn. In fact, many principles of robotics have been inspired by how humans perceive, reason, and act. For instance, robotic sensing mimics human sensory organs: cameras (RGB, depth, or infrared) parallel human vision, force sensors replicate touch, microphones simulate hearing, and joint encoders mirror proprioception. State-of-the-art robots have developed highly dexterous manipulation skills comparable to those of humans. However, a key distinction between humans and robots lies in adaptability, self-reflection, and learning. Human workers can consciously think, learn from past experiences, and modify their behaviors to adapt to changes. In contrast, robots are mechanical and purpose-built, lacking genuine situational awareness and the ability to abstract knowledge, let alone reuse it. More fundamentally, robotics research has primarily focused on replicating exteroception (sensing the external environment), while overlooking interoception (perceiving internal states). Interoception, however, plays a criticla role in human cognition, facilitating individuals to maintain homistasis, extrapolate mental schemas from observations, and make decisions based on hierarchical prioritization [7]. Inspired by this, a logical next step in robotics reseach should explore equipping mobile robots with interoceptive-like capabilities.

Interoception in mobile robots is a novel concept, and its conceptualization and implementation require a formal definition of the phenotypic characteristics—particularly the internal states—of mobile robots. Unlike human interoception, we are not suggesting that robots experience genuine emotions, pain, or self-consciousness. Instead, we define ”cognitive dissonance” as an abstract internal cognitive state variable robotic agents possess and factorize it based on the intensity of human inputs to refine robotic autonomy in shared control paradigms. This is proposed along with a new shared control architecture as illustrated in Figure 1: Rather than allowing human interventions to override robotic decisions, our proposed shared control integrates human inputs as a tributary that converges with autonomous decisions to produce a collaborative decision-making output forwarded to the robot's actuators. Simultaneously, this architecture inherently introduces a potential state of conflict between the robot's internal beliefs and its executed actions. Such conflicts create an internal drive for the robotic agent to reflect on its decisions, seeking insights from human feedback to identify potential biases or missed factors causing misalignment with human expectations. Through this reflective process, the robot engages in conscious-like learning and can gradually evolve into a meta-level understanding that reconciles discrepancies with its human counterparts.

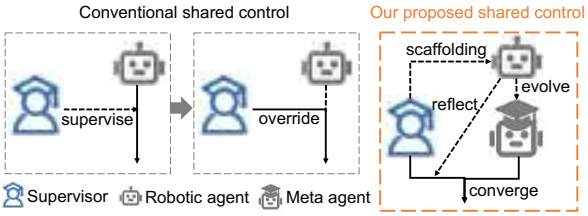

Figure 1. Shared control architectures

This framework is particularly designed for spatio-temporal-sensitive motion planning situations in multi-robot systems that navigate shared spaces and must dynamically adapt to evolving task sequences. For example, robots delivering panels must complete their task before façade installation can proceed. Precise velocity control is requrid thoughtout the process to avoid collisions and minimize downtime. To achieve this, the knowledge required by the robotic agents to make efficient motion planning decisions can be categorized into declarative knowledge and procedural knowledge. Declarative knowledge includes those facts (e.g., terrain features that were previously unavailable from the spatial grid map, traffic regulations with safety margins around obstacles, and path preferences provided by human supervisors) that inform future path-planning decisions. In our approach, this knowledge is acquired through human feedback that is prompted by an intuitive Graphical User Interface (GUI). The GUI facilitates the formalization of human knowledge while providing contextual dependency. This feedback is then encoded using natural language processing (NLP) techniques, including tokenization, tagging, and logical reasoning, and finally constructed as a knowledge graph (scaffolding). This design aligns with Lev Vygotsky's theory of the Zone of Proximal Development, which highlights bridging the gap gradually between what the learner (robotic agent) can do independently and what it can do with guidance from a more knowledgeable other [8].

Procedural knowledge pertains to how the mobile robot accurately replicates velocity profiles. Unlike dominant methods such as reinforcement learning (RL) and imitation learning—which start from a “blank slate”, rely on

random exploration in large state spaces, or require explicitly designed rewards (a challenging task)—our approach formalizes learning as a structured process of schema representation and modification. This process is regulated by goal-oriented behavior, avoiding the habituation tendencies of RL that often fail to adapt quickly to reward contingencies and thus sacrifice flexibility [9]. Our approach conceptualizes learning as a sequential production of components comprising a human-corrected velocity repertoire, implemented using an encoder-decoder architecture based on few-shot contrastive learning and Gated Recurrent Unit (GRU) to capture temporal dependencies. These designs lay the groundwork for factorizing the ontology of mobile robot motion planning and appeal to diverse optimization principles for routing decisions. An illustration of the robotic interoception concept, along with its relationship to modern topics in RL, is shown in Figure 2.

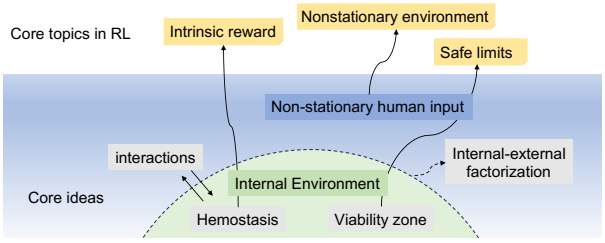

Figure 2. Overview of the interocepltive framework

In practice, the workflow of the proposed approach is illustrated in Figure 3. While acknowledging the multifaceted nature of interoceptive robotics, this paper narrows its focus to a detailed methodology for motion planning in Section 2, followed by three illustrative examples in Section 3.

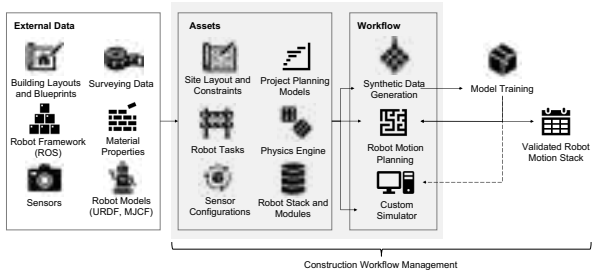

Figure 3. Simulation-enabled workflow for on-site robot motion planning

2 Methodology and Experimentation

The overarching pipeline of the designed methodology is shown in Figure 4. The motion planning consists of two components: path planning and velocity planning.

2.1 Path Planning

The path planning is defined to find a continuous path from a start location to a goal location throughout the subset of spatial configuration space consisting of traversable space. The space is created as a discretized approximation of connectivity using an occupancy grid, which can also be seen as a graph in which vertices are individual configurations and edges represent the transitions between pairs of configurations. Paths are found by searching the space using A* [10] (see Figure 5 for an abstracted formulation of the physical spatial environment and paths).

Given the designated paths, the tracking of the AMRs' positions is available (see Figure 5) with a hypothesized constant velocity. In practice, however, the human supervisors occasionally adjust the velocity to accommodate ground or floor conditions, task hierarchies, and interaction dynamics with other entities. This research proposes a shared control paradigm based on a Bayesian updating framework, leverageing robotic autonomy (scaled in absolute terms) as the prior and velocities from human agency (scaled as increments) as the likelihood. Using the integral of velocity curves (often approximated with sample-based approaches, e.g., Monte Carlo) at a pre-defined sampling rate along the designated path, the distances of the AMRs can be tracked in real time, with proximity thresholds set to trigger automated alerts.

In the proposed shared control paradigm, the factorized cognitive dissonance of AMRs' reasoning and action—as parameterized by the intensity of human inputs—is demonstrated using a contour plot (see Figure 6). This provides an intuitive representation for retrospective documentation of rationale behind human interventions. The texts inputs from human supervisors are processed with NLP open information extraction (OpenIE) focusing particularly on two attributes—terrain features and task sequences—as declarative knowledge mapped to the space vertices. Additional attributes are preserved as episodic knowledge, which is however beyond the scope of this article. The source code for this simulation is available at `https://github.com/XiaoshanZhou624/A-star-with-GUI-for-human-inputs`.

Task sequence attributes partially overlap with positional information from the spatial space but require an additional task space to define the availability state of the objects at the target workspace where robots offload or load and the occupancy state of critical pathways shared by robots approaching the workspace. We propose to use hypergraphs to model this new configuration space that requires additional complexity. A hypergraph is an extension of a graph where hyperedges (or hyperarcs) are not restricted to connecting only two vertices [11], thus allowing us to accommodate more dependence conditions. A graph-based model also facilitates to modify the heuristic

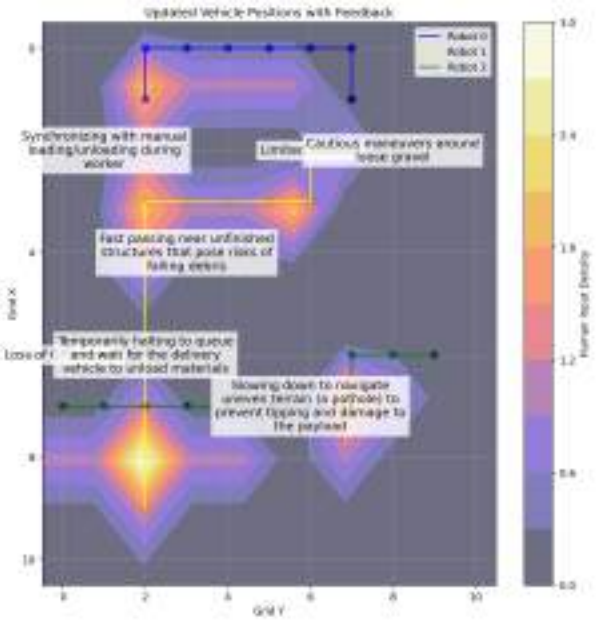

Figure 6. Contour plot of human intervention intensity and GUI for human semantic inputs in rationale

costs in A*, thus automatically influencing path planning in the algorithmic logic that determines which nodes are first expanded as leaf nodes and added to the closed set. The task space states define the preconditions for admissible moves to the explored nodes. A visual depiction of the hypergraph is shown in Figure 7, and the pseudocode for the modified A* algorithm is provided in Figure 8.

2.2 Velocity Planning

As the spatial configuration expands in the hypergraph model, terrain attributes can be coded to trigger the replay of human-refined velocity profiles. We propose an encoder-decoder network architecture, as shown in Figure 9. Given only one trial of data, we designed a sliding time window to segment the velocity profiles into smaller segments. Leveraging the similarity contrast principles of few-shot learning, we construct positive pairs from consecutive windows and negative pairs from random windows. A Gaussian filter is applied to smooth the data within each window. Subsequently, these pairs are processed through

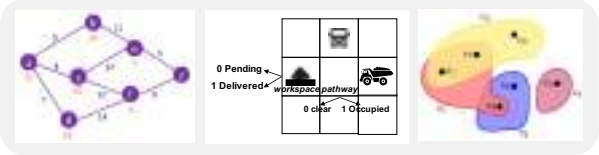

Figure 7. Hypergraph attribute visualization

Algorithm 1 Hypergraph A* with State-Dependent Costs

Input:

$H = (V, E)$: A hypergraph where:
- V: Set of nodes $v = (p, s)$, with p as position and s as binary state.
- E: Set of hyperedges $e \subseteq V$, where the cost of each node $v \in e$ depends on the s of other nodes in e, represented by $c(v, e, \text{states})$.

start: Starting node.
goal: Goal node.
Output: The optimal path from *start* to *goal*.
Procedure:

Initialize $open_set \leftarrow$ PriorityQueue() ▷ Stores nodes to be explored, ordered by f_score
$g_score[v], f_score[v] \leftarrow \infty$ for all $v \in V$ ▷ Initialize cost scores
$g_score[start] \leftarrow 0$ ▷ Cost to reach the start node is zero
$f_score[start] \leftarrow$ `heuristic_cost`$(start, goal, H)$ ▷ Estimate total cost from start to goal
$open_set.push(start, f_score[start])$ ▷ Add start node to the open set
while $open_set \neq \emptyset$ **do** ▷ Main loop: Process nodes until the open set is empty
  $current \leftarrow open_set.pop()$ ▷ Retrieve node with lowest f_score
  if $current == goal$ **then**
    return `reconstruct_path`$(current)$ ▷ Return the reconstructed optimal path
    Break ▷ Terminate the loop as the goal is reached
  end if
  for $neighbor \in neighbors(current)$ **do** ▷ Explore each neighbor of the current node
    if $neighbor \notin e$ for all $e \in E$ **then** ▷ Check if neighbor is part of any hyperedge
      $h_cost \leftarrow$ `heuristic_cost`$(neighbor, goal, \emptyset)$ ▷ No hyperedge states to consider
    else
      $connected_states \leftarrow \{n.s \mid n \in e.connected_nodes\}$ ▷ Retrieve nodes' states in hyperedge
      $h_cost \leftarrow$ `heuristic_cost`$(neighbor, goal, connected_states, e)$ ▷ Update heuristic
    end if
    $tentative_g \leftarrow g_score[current] +$ `edge_cost`$(current, neighbor)$
    $tentative_f \leftarrow tentative_g + h_cost$ ▷ Compute total estimated cost
    if $tentative_g < g_score[neighbor]$ **then** ▷ Update path if better cost is found
      $g_score[neighbor] \leftarrow tentative_g$
      $f_score[neighbor] \leftarrow tentative_f$
      $open_set.push(neighbor, f_score[neighbor])$ ▷ Re-add neighbor to the open set
    end if
  end for
end while

Figure 8. Pseudocode for hypergraph A* with state-dependent costs

a Siamese Network [12] with GRU modules to extract embeddings for each window, using the Euclidean distance as the contrastive loss for network training.

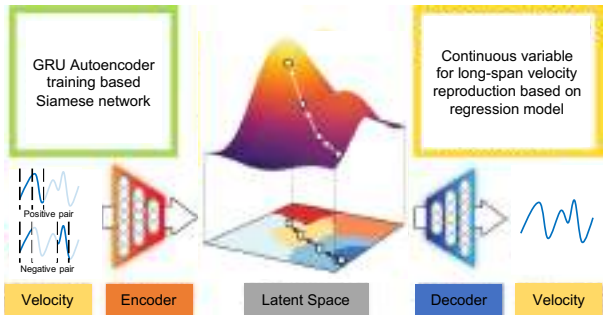

Figure 9. Technical overview of the encoder-decoder architecture for velocity replay

During retrieval, a regression model is designed and trained using Mean Squared Error as the loss function to map the embeddings back to velocity values (see Figure 13 for a demonstration). These values can then be directly broadcasted and subscribed to by robotic servo motor nodes in the Robot Operating System (ROS) environment. Detailed algorithm designs are available in the open-source code repository at `https://github.com/XiaoshanZhou624/velocity-replay`.

3 Demonstration in Simulation

3.1 Multi-Robot Coordination for Pick-and-Place

This section provides two examples of multi-robot coordination in motion planning and adaption to workpiece properties. The scenes and simulations were set up in Nvidia Omniverse Issac Sim (version 4.1.0).

As shown in Figure 10, two Jetbots navigate the workspace using a differential drive controller with physically accurate articulated joints. The task sequence dependencies are: after the first Jetbot delivers material to the workspace, it must reverse to clear the pathway. Simultaneously, the second Jetbot must wait and avoid entering the workspace prematurely to prevent blocking the pathway. A cube was added to the scene as an abstracted form of the material. To ensure realistic interactions, physical properties such as force and rigidity were applied to enable the first Jetbot to push the material toward the Franka Panda manipulator for handover. A Franka Panda manipulator was positioned in the workspace to pick up the object and rotate to hand it over to the second Jetbot. The hypergraph vertices' preconditions were incorporated into the program logic by parameterizing tasks or programming states to transition between subtasks, such as the Franka's handover or allowing the Jetbot to resume movement instead of being blocked by non-steppable areas influenced by A* heuristic costs. A video of this simulation is available at `https://youtu.be/RwKJ0zggWfE`. In real-world applications, precise localization is often achieved using land-marked AprilTags for accurate positioning of robots and manipulators. As demostrated in the video, when the goal location of the transport robot overlaps with the handover location of the manipulator's end-effector, collisions can occur. This highlights the need for research on precise spatial alignment, timing calculations, and accurate velocity control to synchronize robotic motion. These considerations are particularly crucial in large automated machinery, such as forklifts, or when dropping large-scale material panels that require significant space for maneuvering, reorientation, or flipping before placement.

Although block stacking tasks have been widely studied in robotic manipulation and have demonstrate high dexterity, real-world placement present greater complexity. Unlike uniform blocks with consistent shapes, sizes, and weights that can be easily aligned in horizontal or vertical stacks, construction materials exhibit considerable variability. For instance, pieces of lumber often differ in di-

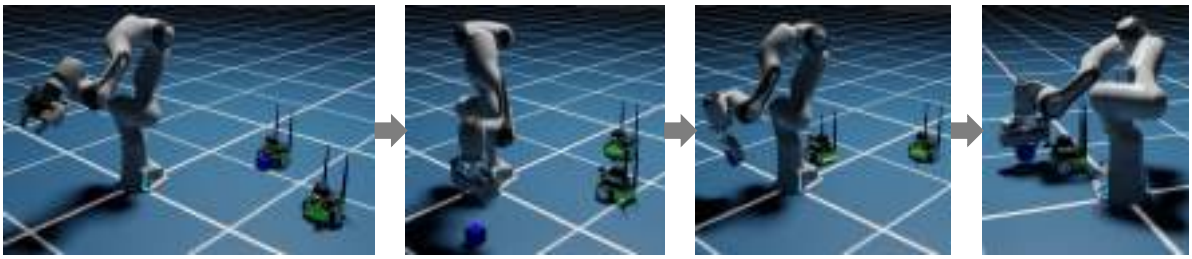

Figure 10. Robot motion planning for material delivery and handover coordination

mensions, while palletized materials may contain different items, such as tiles and shingles, each varying in weight. Moreover, some materials may need repositioning during unloading to facilitate subsequent tasks. For example, glass panels may require flipping to expose the correct side for façade installation. Proper planning must account for balanced weight distribution during transport to mitigate the risk of tipping caused by uneven loads affecting inertia and centrifugal forces, particularly for wheeled robots. An example is provided in Figure 11. This demonstration was adapted from a UR 10 Bin Stacking application containing a conveyor belt, a pallet where the bins should be stacked, and a UR 10 robot with a suction gripper. Bins arriving right-side up were flipped at a designated station to ensure proper stacking upside down. The placement alternated between sides of the pallet to balance weights. A supplementary video demonstrating the robot's motion planning is available at `https://youtu.be/yHbuoG7d05A`. Future work will integrate sensors for weight tracking and incorporate this data into the the manipulator's motion planning to maintain load balance while minimizing travel distance. In addition, sim-to-real discrepancies will be analyzed by examining how stiffness and damping parameters in the simulation setup correlate with the accuracy of joint properties in URDF robotic models and real-world variations in loads and terrain friction.

Figure 11. UR10 bin stacking and motion planning with weight-balanced placement

3.2 Velocity Replay

The velocity embeddings obtained after training are visualized in Figure 12, with dimensionality reduced using t-Distributed Stochastic Neighbor Embedding (t-SNE). These embeddings are stored as compressed vectors of the original velocity profiles. During retrieval, they are mapped back to velocity, as shown in Figure 13, where regression models reconstruct multiple possible original profiles.

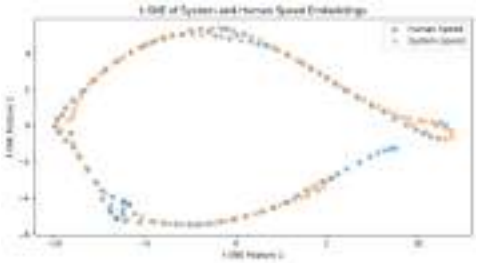

Figure 12. t-SNE visualization of velocity embeddings after contrastive Siamese Network learning

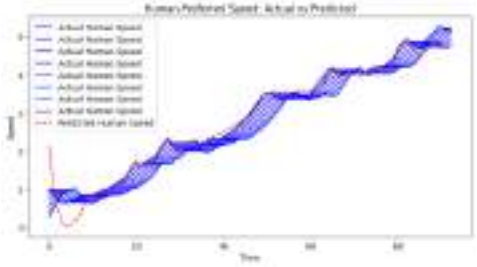

Figure 13. Illustration of mapping embeddings back to velocity using the regression model

The core objective here is to contrast our proposed method with currently dominant approaches—Reinforcement Learning with Human Feedback (RLHF) and Imitation Learning (IL). The learning mechanisms of the three methods and their performance comparisons are shown in Figure 14. Mostly importantly, IL functions similarly to behavioral cloning, allowing for a near-perfect replay of velocity profiles with high learning efficiency. However, as a supervised learning method, IL does not involve reasoning or prediction beyond what it has seen during

end-to-end training. Once the environment changes (e.g., unexpected obstacles, disruptions, or external forces), IL cannot adapt. RLHF uses human input to shape the reward function, guiding the robotic agent's actions. With extensive training episodes, the agent is likely to develop a well-represented internal world model that informs its decisions. However, the training process can be highly time-consuming. Given the semi-structured nature of construction sites, robots are expected to follow designated paths while remaining aware of unexpected proximity intrusions. In our approach, a dedicated module for velocity embeddings enables compact storage and efficient replay. This approach offers greater flexibility and better aligns with the ontology of human learning.

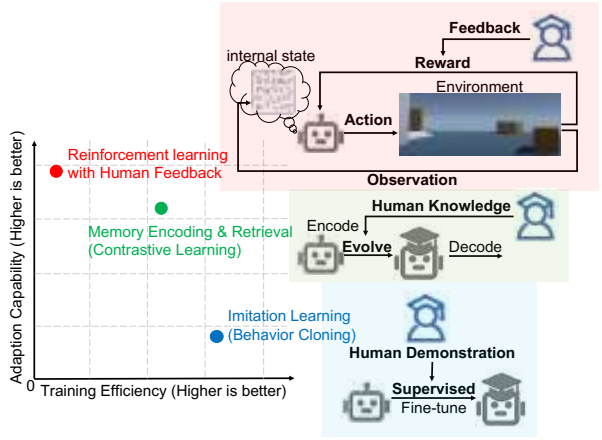

Figure 14. Comparison of RLHF, IL, and our contrastive learning approach using an encoder-decoder model

3.3 Shared Control Comparisons with EEG-Based Brainwave Input

We present a case study that simulates the possibility of incorrect human inputs in shared control. These inaccuracies can arise from two factors: (1) humans making incorrect decisions and (2) errors in detecting their intentions, such as missed detections or false alarms. In this simulation, we introduce potential detection errors by interpreting human inputs from brain signals measured via scalp electroencephalography (EEG). We trained a Bayesian inference framework to interpret EEG signals related to velocity adjustment intentions (acceleration or deceleration). Details on the EEG signal methodology can be found in the authors' other publications. Although the methodological framework accounts for uncertainty by using probabilistic reasoning, inherent noise in the signal spectrum and human inability to maintain consistent control can lead to fluctuations and inaccuracies in detected inputs.

Figure 15. Simulation platforms: (left) Gazebo in third-person perspective; (right) Unity in first-person perspective

To evaluate our approach, we tested in two scenarios (as shown in Figure 15). First, we set up a TurtleBot in Gazebo to follow another TurtleBot moving at a predefined velocity profile. Human users can intervene the following Turtlebot through three shared control paradigms: overriding, weighted pooling, and the proposed Bayesian updating method. EEG signal was streamed via WebSocket from Emotiv, processed into velocity commands in real time, and broadcast using the `cmd_vel` topic in ROS, which was subscribed to by the following TurtleBot. We measured how shared control can reconcile fluctuations in human inputs while achieving a balanced integration with robotic autonomy. As evidenced in Figure 16, our Bayesian updating method can smooth fluctuation in human inputs, always preserve the dual-agent decision-making rationale, and allows the robotic agent to follow preferred velocity patterns without requiring continuous human intervention.

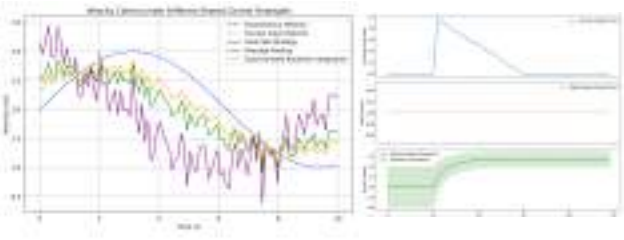

Figure 16. Shared control performance comparisons

Second, we tested how well a robot in Unity resumes motion after stopping due to autonomous obstacle avoidance detected by LiDAR monitoring. Although collisions were prevented, the key question was whether and how the robot could navigate past a narrow passage threshold and continue moving without getting stuck. In Unity, autonomous driving was enabled using the NavMeshAgent component, and the EEG data stream was subscribed to via the TCP protocol. Task completion times were measured across multiple trials for the three shared control modes and are presented in Table 1. In overriding mode, the human required significantly more time to complete the maneuver. In weighted (average) pooling mode, the hu-

man had to exert strong mental effort to insert control and influence the robot's motion. However, in our proposed Bayesian updating approach, a small human input acted as a minor disturbance but could help the robot escape a local deadlock. After a brief intervention, the human can hand over control to the robot to resume autonomous mode and complete the task efficiently.

Table 1. Task Completion Time

Shared Control Mode	Task Completion Time (s)
Overriding	> 30
Weighted Pooling	10–25
Bayesian Updating	< 10

4 Conclusion

Mobile robots are envisioned as learning agents within a shared control paradigm, where we define an interoceptive cognitive architecture that enables them to develop an internal drive for self-reflection based on feedback from collaborative decision-making human counterparts. The knowledge acquired through this shared control process is abstracted, structured, and encoded, allowing for more flexible retrieval and faster adaptation in future similar situations compared to conventional RLHF and IL frameworks. The proposed shared control framework also helps counterbalance potential errors in human inputs by leveraging dual-agent intelligence and empowers robotic autonomy to automatically follow human-preferred velocity patterns compared to coventional overriding and weighted pooling shared control. This proposed approach is expected to advance robotized construction automation by shfiting from rigid, pre-programmed behaviors to greater autonomy and adaptive intelligence, enabling robots to coordinate better with human coworkers and multi-robot systems. Furthermore, this research creates opportunities to handle more heterogeneous and complex tasks within the modular construction vision, thus contributing to safer and more sustainable, decarbonized construction practices.

Abstract

This paper evaluates the applicability of an autonomous driving dumper for a construction project. Conducted as part of a joint lecture between Stanford University and the Technical University of Munich in 2024, this study provides students with hands-on experience in field assessments of construction robotics. The dumper, developed in partnership between the Technical University of Munich and the industry partner Wacker Neuson, is analyzed using the Robotics Evaluation Framework. Autonomous dumpers present a promising solution in the construction industry, offering improved safety, productivity, and the ability to address labor shortages, particularly on small and confined sites. The Robotics Evaluation Framework used is a systematic methodology for assessing feasibility and performance across safety, quality, schedule, and cost metrics. The results demonstrate that the autonomous dumper improves safety through better ergonomics, enables operators to focus on higher-value tasks, and enhances overall efficiency. While quality remains comparable to conventional dumpers, the autonomous system experiences 20% longer cycle times, presenting a scheduling challenge. Despite this, cost analysis reveals amortization after 1.43 years or 75 projects, highlighting its economic viability and potential for fleet scalability.

Keywords – Construction robotics; Autonomy; Mobile Robotics; Robotics Evaluation Framework (REF)

1 Introduction

The construction industry faces a transformative era of unprecedented demand and significant challenges [1, 2]. With global infrastructure needs surging and urbanization accelerating, the demand for construction work continues to grow. However, a critical labor shortage, driven by a shrinking pool of skilled workers, directly impacts productivity, making it increasingly difficult for the industry to keep pace with rising workloads [3, 4]. This shortage contributes to inefficiencies, as fewer trained professionals can complete projects on time and within budget. As a result, the construction sector continues to lag behind other industries in productivity, highlighting the urgent need for innovative solutions to bridge this gap. Construction projects overrun average cost and time relative to the original budget and schedule at 70 percent and 61 percent, respectively [4]. These delays due to labor shortages and inefficient workflows underscore the need for automation to bridge productivity gaps.

In this context, the market for autonomous construction equipment is emerging as a pivotal force. This market is projected to expand from USD 4.40 billion in 2024 to USD 9.77 billion by 2030 at a compound annual growth rate of 14.2% [5]. Despite its potential, the adoption of automation in construction faces significant hurdles. In Germany, challenges include a rigid labor training structure that mandates three years for operator qualification. A shortage of skilled operators further exacerbates the issue. Procurement practices prioritizing the cheapest bid over innovation pose further challenges. [6]. There is also limited familiarity with robotics or advanced automation, alongside resistance to autonomously driven equipment during operator training. A lack of widespread experience with autonomous systems in construction workflows compounds these issues.

This paper employs the Robotics Evaluation Framework (REF) from Brosque and Fischer [7] to systematically evaluate an autonomous driving dumper, developed by Zöls et al. [8] from the Chair of Materials Handling, Material Flow, Logistics at the Technical University of Munich (TUM) and the dumper manufacturer Wacker Neuson. The REF is a structured methodology designed to evaluate construction robots based on product, organization, process, safety, quality, schedule, and cost metrics.

This paper is structured as follows. Section 2 provides insights into the current development of automated construction equipment. The REF is introduced in section 3, and section 4 applies the REF to the autonomous dumper compared to conventional dumpers to evaluate similar processes and sizes to accurately assess their capabilities. This use case relies on direct testing under lab conditions on the outdoor facilities at TUM. Section 5 presents challenges and opportunities. Finally, section 6 is dedicated to the conclusion and outlook.

2 Literature review

This section explores the landscape of construction robotics, outlining the field's advantages, challenges, and current state of development. Construction robots offer significant potential to revolutionize the construction industry by enhancing efficiency, precision, and safety. These robotic systems, equipped with advanced sensors, actuators, and cognitive algorithms, outperform traditional methods by executing tasks with greater accuracy, yielding higher-quality results with fewer errors [9]. Their ability to undertake repetitive, dangerous, or physically demanding jobs significantly reduces site accidents [10]. By assuming such tasks, robots enable human workers to focus on higher-value activities, fostering safety and efficiency.

While construction robotics presents numerous benefits, the field is still evolving and tackling considerable challenges. Current research primarily emphasizes technological advancements to boost productivity and automate specific construction processes. However, a comprehensive evaluation framework for comparing these technologies, especially against traditional practices, remains absent, highlighting a critical research gap.

Despite the promising advantages, deploying robotics in the construction industry faces challenges due to the dynamic and unstructured nature of construction sites [9–11]. These challenges can be broadly categorized:

- **Safety Challenges:** Ensuring safe robotic operations on crowded construction sites is a critical concern [9]. Multiple activities – often involving workers, materials, and equipment – occur simultaneously, making task execution more complex [10].
- **Process Adaptability Challenges:** Construction processes lack standardization and frequent, unpredictable changes [9, 11]. This dynamic environment demands robotic systems capable of adapting to diverse circumstances and adjusting their actions based on real-time conditions [9, 11].
- **Environmental Challenges:** Uncontrollable weather conditions, such as rain, strong winds, and dust, significantly impact the consistent performance and reliability of robots on construction sites [10].

These factors can degrade sensor accuracy, limit mobility, and impact the overall effectiveness. Achieving full autonomy for construction robots is particularly challenging due to the obstacles posed by unstructured environments and the need for real-time multi-system coordination [11]. Nonetheless, several robots have been successfully deployed to perform specific repetitive tasks that are well-suited for automation.

Construction projects are typically divided into three main tasks: superstructure, substructure, and site preparation [11]. The subsequent sections will explore robotic applications within these categories and related areas.

Table 1 offers an overview of current robotic applications to provide context for the subsequent discussion. These are listed according to their relevance to an autonomous driving dumper. Relevance is judged by process, specific tasks, their on-/off-site usage and whether they are mobile or stationary. The overview also indicates the robot's automation level, based on degrees of freedom and operating conditions. In addition, it shows whether safety, quality, schedule, and cost aspects have been evaluated – aspects detailed further in Section 3.

Table 1. Evaluating relevant construction robotics

Drawing from the successful implementation of industrial robot arms in manufacturing, off-site construction presents a viable area for robotics adoption. To address the challenge of non-standardized building components in construction, multi-functional robotic cells are being developed to automate labor-intensive and

time-consuming prefabrication processes [12]. Automated Guided Vehicles (AGVs), another mature technology widely utilized in logistics, are also highly relevant. AGVs offer high levels of automation, flexible mobility, and efficient space utilization. This makes them valuable for material handling in stationary prefabrication and module production systems [13].

Transitioning to on-site applications, cable-driven robots have emerged as a versatile solution. Their lightweight design facilitates easy transport and deployment on construction sites [14, 15]. Operated using elevated pulleys, these systems can support full-scale architectural projects. They also adapt to irregular site geometries. For instance, cable-driven robots have been validated for accurately placing granular materials in complex architectural-scale enclosures [14]. Moreover, a cable-driven parallel robot with a concrete extruder demonstrates precise 3D printing capabilities for complex concrete structures. This approach reduces material waste and labor costs while accommodating diverse construction environments [15].

Beyond cable-driven systems, specific robots are designed for repetitive tasks and productivity enhancement on-site. Robotic beam assembly systems automate bolting processes, allowing operators to control robotic transport mechanisms and bolting devices [16, 24]. Ceiling construction robots automate the positioning and installation of ceiling boards [17]. This minimizes the need for human work at elevated positions, improving safety.

In substructure processes, autonomous robots are designed for tasks such as transporting and driving interlocking sheet piles into the soil. This robot ensures precise positioning and interlocking by utilizing a vibratory hammer and its weight, coupled with alignment mechanisms. This enables the construction of continuous stabilization walls [18].

Robotics is also being applied to broader site management tasks. For example, a robotic system equipped with computer vision can autonomously patrol construction sites. It identifies and sorts waste materials and employs optimized gripping strategies for handling diverse waste types and forms [19].

Furthermore, mobile robots are increasingly being developed for earthmoving tasks in site preparation. The hydraulic excavator for an autonomous purpose (HEAP), a walking excavator, demonstrates precise localization, movement tracking, and accurate end-effector control. Its unique wheeled-legged design allows adaptability to uneven terrains, validated in applications like dry stone wall assembly and forestry work [20]. A retrofitted dump truck also showcases autonomous capabilities. It manages steering, acceleration, and braking. Path tracking performance has been evaluated, and an emergency stop feature is integrated to ensure safety [21].

In line with advancements in Artificial Intelligence (AI), autonomous navigation for wheel loaders in short-loading cycles is being explored using reinforcement learning. By decomposing loading tasks, AI agents manage to reverse, reach reversal points, navigate to dump trucks, and control steering, velocity, and bucket positioning [23]. Automated shovel trajectories have been developed and evaluated against manual operation for shoveling. Metrics include full bucket rate, operation time, and fuel consumption [22].

Finally, the autonomous driving dumper, as presented by Zöls et al. [8] with obstacle detection capabilities, exemplifies the potential of collaborative robots in construction environments.

While current robotic applications focus primarily on enhancing productivity, their evaluation often overlooks critical factors such as safety and cost-effectiveness. The REF offers a structured, uniform approach to assess the implementation of construction robots, addressing both practical performance and broader structural considerations [25, 26].

3 Methodology

This analysis focuses on utilizing the REF, a methodical tool used for uniform evaluations of the integration of robotics and autonomous systems into construction sites [7]. The REF was selected for this study due to its structured approach to assessing the integration of robotics into construction projects. The REF balances feasibility, performance, and risk considerations, offering a comprehensive evaluation addressing technical and operational factors critical to successful deployment. The REF consists of two key stages. The first stage evaluates the feasibility of deploying a robot on a project [7, 27]. This is done by analyzing three independent variables – product, organization, and process – referred to as the POP analysis:

1. **Product:** Evaluates robot features for the work environment.
2. **Organization:** Assesses worker and organizational requirements.
3. **Process:** Covers operational changes, quality assurance, and documentation.

After determining feasibility through the POP analysis, the REF then evaluates the overall performance and impact of robotic implementation compared to manual construction through the SQSC analysis, which focuses on safety, quality, schedule, and cost. This offers a comparison between robotic implementation and manual deployment [7, 27]:

4. **Safety**: Focuses on quantifying the impact accidents, ergonomic strain, and hazards.

5. **Quality**: Evaluates the accuracy of robotic construction work.
6. **Schedule**: Assesses task completion time with robots vs. traditional construction.
7. **Cost**: Compares initial investment to long-term returns.

4 Use Case

4.1 Overview

The REF methodology is being implemented on the autonomous driving dumper, developed by the Chair of Materials Handling, Material Flow, Logistics at the Technical University of Munich (TUM) together with the industry partner Wacker Neuson (see Figure 1). It is compared with its conventional counterpart, Wacker Neuson DT10e Dumper and is evaluated in terms of feasibility and advantages for the use on-site.

Figure 1. Autonomous dumper project, developed by TUM and Wacker Neuson

4.2 POP analysis

The first step is to perform an initial feasibility check for the robot, in this case, the autonomous dumper, using the POP analysis.

4.2.1 Product analysis

To perform product analysis, thorough information was gathered through dispatched observations based on pictures, videos, and interviews with researchers, industry partners, and instructors. The objective of the autonomous dumper is to transport bulk materials on construction sites. The dumper has a high degree of mobility, making it capable of remote control operation or even following autonomously. In the future, this equipment might interact with other dumpers or equipment at the site. The dumper has a steering interface, a remote control via WLAN, and sensors such as IMUs for the position of the bucket, the loading unit, and the main vehicle, GNSS for the global position, cameras for object detection, and ultrasonic sensors for safety reasons. Sensor data is processed locally by the autonomous dumper. Weighing 680 kg and featuring a ground clearance of 80 mm, the autonomous dumper can operate in harsh conditions. However, challenges may arise during heavy rain when certain sensors struggle to detect objects. The dumper is not commercially available, as it is part of a research project at the Chair of Materials Handling, Material Flow, Logistics at the TUM. Its potential applications extend to any construction site requiring the transportation of bulk materials in confined spaces.

4.2.2 Organization analysis

Introducing the autonomous dumper into the construction process offers some organizational advantages. In Germany, operators must undergo three years of training before operating heavy equipment, making the existing manual labor shortage more noticeable. Using the autonomous dumper requires less training, and the operator can simultaneously work on multiple pieces of equipment, allowing for a more efficient work outcome. Instead of a conventional dumper, one can use one or multiple autonomous dumpers and improve flexibility on the construction site. However, there is no experience with robots or higher levels of automation, and there is little acceptance of electric or automated equipment at the training grounds.

4.2.3 Process analysis

The processes were analyzed using the videos provided for the autonomous dumper, the results of Zöls et al. [8], and expert interviews at the Bayerische Bauakademie. There are some process changes when switching from the conventional to the autonomous dumper. The communication shifts from verbal to digital. While transporting bulk materials is not typically considered a value-adding task, basic quality control measures — such as ensuring load stability and minimizing spillage — are still relevant. In this use case, manual and autonomous dumpers maintain similar standards in these areas, leading to no significant difference in quality outcomes. There are also no progress reports on a process level, except for a construction load, which documents whether an area is cleared. The detailed workflows of manual and robotic construction are depicted in Figure 2.

The process for the conventional dumper begins with the operator starting the vehicle and getting on the equipment. The operator starts with the loading process, which takes 51s. Then, the operator maneuvers the load to its destination for 51s and unloads it within 11s. To end the process, the operator drives to the starting point for

23s while being empty.

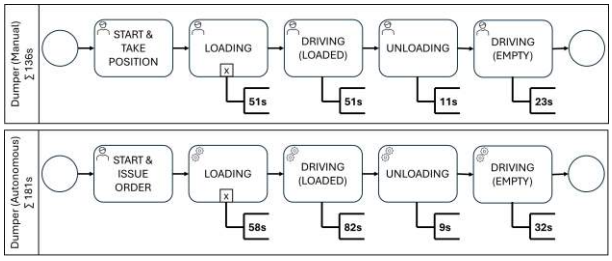

Figure 2. Comparison of the conventional and autonomous dumper

The workflow of robotic construction is slightly different. The process begins with the operator providing the autonomous dumper with its task. After this, no interaction with the operator is required, and the operator can focus on value-adding tasks. The process for the autonomous dumper follows the process of the conventional dumper. The loading takes about 58s, the driving with the load 82s, the unloading 9s, and the driving with no load 32s.

Since the conventional and autonomous dumper can perform similar tasks, the initial feasibility check for the process is positive. All three independent variables check positive for the initial feasibility. This allows for further investigation of this project according to the dependent variables to assess the impacts of deploying the robot.

4.3 SQSC analysis

The dependent variables are now evaluated following the SQSC analysis and the initial feasibility check. The Technique for Order Preference by Similarity to Ideal Solution (TOPSIS) method was selected for this evaluation because it ranks alternatives based on multiple criteria. It effectively balances safety, quality, schedule, and cost factors. This allows for weighted prioritization — such as emphasizing safety over minor schedule delays. This approach ensures a comprehensive assessment of the autonomous dumper's performance relative to manual operations [28]. Safety, given its paramount importance, has a TOPSIS weight of 0.5. Quality, with a TOPSIS weight of 0.1 is less critical since the transportation of bulk materials does not have strict quality standards that either equipment could compromise. The schedule is assigned a weight of 0.2, reflecting the importance of clearing areas within a reasonable timeframe. Costs are also weighted at 0.2, highlighting the need to offer the robot solution competitively.

4.3.1 Safety Analysis

In manual operations, safety depends on several factors. The operator's level of experience plays a crucial role. Additionally, safety is influenced by how well workers adhere to safety rules, such as avoiding movement in blind spots. Manual operation exposes the operator to constant vibrations, impacting health and performance over time. The age of the dumper also impacts safety, as does the type of dumper, particularly in terms of its ergonomics connected to comfort variables. In robotic operations, safety is determined by different criteria. The effectiveness of sensors and software is paramount. The type of human interaction required also affects safety, as does the level of collaboration between humans and robots. The autonomous dumper demonstrated better safety outcomes in terms of ergonomics compared to manual operation, reducing repetitive tasks for operators by 10%. This lowers the risk of strain-related injuries due to vibrations since the operator does not have to stand on the dumper.

4.3.2 Quality Analysis

In manual operations, the quality depends on the operator's experience for accuracy and repeatability, and it is comparable to that of robots. The operator's experience influences the rework needed, but it tends to be slightly better than that of robots. Material waste is excluded since the use case involves transporting bulk material. In robotic operations, the quality depends on the effectiveness of sensors and software for accuracy and repeatability, and it is comparable to that of a conventional dumper. The sensors and software influence the needed rework. Material waste is also excluded from consideration since the use case involves transporting bulk material.

4.3.3 Schedule Analysis

The schedule was evaluated according to Figure 2. The cycle times for the conventional and the autonomous dumper of bulk material are calculated as the sum of the different subprocess times of loading, driving (loaded), unloading, and driving (empty). The overall cycle time of the conventional dumper accumulates to 136s. The cycle time of the autonomous amounts to 181s which is about 20% higher.

4.3.4 Cost Analysis

An autonomous dumper's purchase price is higher than a conventional dumper's, increasing initial capital expenditure (+52.42k euros). However, conventional dumpers lack sensors, limiting automation, while autonomous dumpers are equipped with advanced sensors that enhance efficiency and safety (+5k euros). Conventional dumpers demand more human labor (+22 hours or +1k euros using 44,50 euros/hour), often requiring both an operator and a helper. In contrast, one operator can oversee multiple autonomous dumpers, optimizing labor costs. In total, the costs for the

autonomous dumpers are only 2 % higher (+4k euros p.a.). Autonomous dumpers are cost-competitive for smaller projects with high labor needs, as they handle smaller bulk loads with minimal operator support, making them ideal for confined sites. By enabling operators to focus on value-adding tasks, these dumpers boost productivity. They could also function in collaborative fleets, improving efficiency and reducing project duration and costs [29]. According to the REF framework, autonomous dumpers are viable and cost-effective for small to medium-scale projects, with a payback period of approximately 1.43 years or 75 projects for a full 4-year utilization.

4.3.5 Sensitivity Analysis

In the assessed case, the autonomous dumper outperforms the conventional dumper in the REF. A sensitivity analysis was conducted to further evaluate the performance of the conventional and autonomous dumper. The sensitivity analysis explored variations in cost and cycle time, with deviations of ±25%, ±50%, and ±75%. Results showed that while increased cycle times negatively impacted schedule performance, the autonomous dumper consistently outperformed manual operations in safety and cost metrics. The dumper maintained economic viability even under conservative cost assumptions, with amortization still achievable within 1.6 years. These findings confirm the robustness of the autonomous solution across varying operational scenarios.

5 Challenges and Opportunities

Adopting autonomous construction equipment like the Wacker Neuson DT10e Dumper offers opportunities and challenges. Safety is paramount, requiring reliable systems and technologies like SLAM-based dynamic mapping to ensure seamless integration with workers and equipment, which must be tested across varied conditions to build trust. Limited acceptance of autonomy, particularly in training environments, and the need for effective collaboration with traditional equipment are notable hurdles. The initial dumper tests have demonstrated key safety enhancements in autonomous operation. Unlike conventional dumpers, the autonomous DT10e eliminates operator exposure to vibrations, significantly improving ergonomics. Additionally, the dumper has advanced human-recognition capabilities, allowing it to detect nearby workers and either follow or stop accordingly. These safety features enhance on-site interaction between autonomous and manual operations, reducing the risk of accidents and improving overall workflow efficiency. Scalability also demands advanced systems to manage interconnected fleets. Advanced systems might involve a combination of centralized fleet management software, real-time data-sharing platforms, and robust communication networks.

Despite these challenges, the potential benefits are substantial. The autonomous dumper's compact size and ability to handle lighter loads make it ideal for smaller projects, automating transport tasks so workers can focus on value-adding activities and boosting productivity. Scalable fleets of dumpers could reduce costs and downtime, even competing with wheel loaders. Dynamic mapping enhances collaboration, enabling integration with connected fleets or complementary products like vibratory plates. Contractors can improve efficiency by outsourcing non-value-adding tasks, while manufacturers like Wacker Neuson have the opportunity to expand their market by offering interconnected fleet solutions. The REF evaluation underscores the dumper's potential to address labor shortages, improve efficiency, and drive construction industry innovation.

6 Conclusion and Outlook

The REF evaluation of the autonomous Wacker Neuson DT10e Dumper demonstrates its potential to enhance construction workflows. While quality remains comparable to conventional dumpers, the autonomous system experiences 20% longer cycle times, presenting a scheduling challenge. Despite this, cost analysis reveals amortization after 1.43 years or 75 projects, highlighting its economic viability and potential for fleet scalability. Currently, the dumper's autonomy is limited to driving. Extending its capabilities to include automated loading and unloading would enable fully autonomous bulk material transport, reducing the need for human intervention and increasing operational efficiency. In doing so, it can complement larger equipment, allowing operators to focus on value-adding tasks. In the future, fleets of dumpers could improve efficiency, generate dynamic site maps, and adapt to smaller projects or confined spaces [29]. Future advancements in autonomous dumpers could be driven by integrating AI for task coordination, path planning, enhanced sensor systems for improved real-time obstacle detection, and robust communication networks to facilitate seamless data exchange between machines in a fleet. These technologies enable more complex, coordinated operations, improving overall site efficiency and safety. Future REF studies could explore the scalability of autonomous dumpers and their performance in complex earthmoving tasks, particularly by comparing autonomous fleets to larger traditional equipment.

This paper underscores the value of the REF as a systematic framework for evaluating construction robotics, supporting informed decision-making, and promoting the integration of innovative technologies. While challenges such as acceptance and scalability

remain, the findings underscore the promise of autonomous dumpers to boost productivity and drive innovation. Autonomous construction robotics, such as the Wacker Neuson DT10e Dumper, hold significant potential to address key industry challenges, including labor shortages, low productivity, and the growing demand for innovation and automation in construction workflows. Advancements in technology and broader adoption of REF will be crucial for realizing the full potential of construction robotics.

zhaofeng.hu@stonybrook.edu, ci-jyun.liang@stonybrook.edu

Abstract -

This study introduces a novel prioritized coverage path planning method that combines the efficiency of Large Language Models (LLMs) with traditional optimization techniques to enhance the identification and traversal of key points of interest (POIs) on semantic maps of complex environments. By leveraging LLMs, the proposed approach dynamically identifies POIs, addressing inaccuracies and inefficiencies associated with manual selection. The LLM-A* algorithm is then utilized to compute the shortest paths between POIs, significantly reducing operational and storage parameters and thereby minimizing computational overhead. Finally, the traversal problem is formulated as a Traveling Salesman Problem for optimal route planning. This method demonstrates substantial improvements in computational efficiency, particularly benefiting resource-constrained robotic systems, and offers a scalable solution for efficient path planning in complex environments.

Keywords -

Prioritized Coverage Path Planning ; Large Language Model; A* Algorithm;

1 Introduction

The use of autonomous robots and drones [1] in task-specific environments has gained significant attention due to their ability to optimize operations, reduce human error, and improve safety [2]. In outdoor construction sites, indoor warehouses, and other complex environments, efficient path planning for robotic systems is essential to achieve task goals effectively. In robot navigation, coverage path planning (CPP) focuses on ensuring complete area coverage [3]. However, these uniform approaches fail to account for the heterogeneous complexity of real-world environments, leading to redundant scans in simple regions and insufficient focus on critical areas.

To address these challenges, prioritized CPP has emerged as a promising solution for selectively covering critical points of interest (POIs) while minimizing resource consumption [3]. However, identifying these POIs is a challenging and error-prone process, often reliant on manual input or predefined heuristics, which limits scalability and introduces inaccuracies. Moreover, computational constraints in resource-limited devices, such as drones or small mobile robots, require more efficient algorithms for coverage path planning.

This study introduces a novel prioritized CPP method that leverages Large Language Models (LLMs) for identifying POIs on semantic maps, combined with the LLM-A* [4] algorithm for optimizing paths between these points. By utilizing the rich contextual information embedded in semantic maps [5], our approach enables more accurate and dynamic identification of key regions of interest, addressing inefficiencies and errors associated with manual selection. LLMs analyze the semantic structure of the environment, allowing the system to prioritize areas based on task-specific relevance. The LLM-A* algorithm further enhances efficiency by reducing operational and storage requirements, making it particularly suitable for resource-constrained robots. After connecting the identified POIs through LLM-A*, the problem is modeled as a Traveling Salesman Problem (TSP) [6] to determine the optimal path.

2 Related Work

2.1 Coverage Path Planning

Coverage Path Planning (CPP) is a fundamental problem in robotics, with applications ranging from environmental monitoring to robotic cleaning and agricultural surveying. Traditional CPP methods aim to ensure complete area coverage [3]. Although these approaches are straightforward and widely used, they often fail to account for semantic information about the environment, leading to inefficiencies in resource allocation and redundant coverage in simple regions. To address these limitations, non-uniform CPP strategies have been proposed. For instance, Kazemdehbashi [7] introduced an adaptive grid-based decomposition algorithm that optimizes UAV coverage paths by dynamically adjusting grid size based on environmental complexity, reducing computation and coverage time. In addition, Girdhar et al. [8] proposed a curiosity-driven path planning approach, leveraging information-theoretic metrics to prioritize regions with higher informational value. Similarly, Sadat et al. [9] introduced a coverage strategy

utilizing space-filling curves to achieve efficient exploration of regions with varying levels of interest, making it suitable for tasks requiring adaptive focus on high-priority areas. Manjanna et al. [10] proposed a reward-driven selective coverage path planning algorithm using a finite-horizon Markov Decision Process (MDP), which prioritizes high-value regions and generates time- and energy-efficient trajectories for multi-robot path planning.

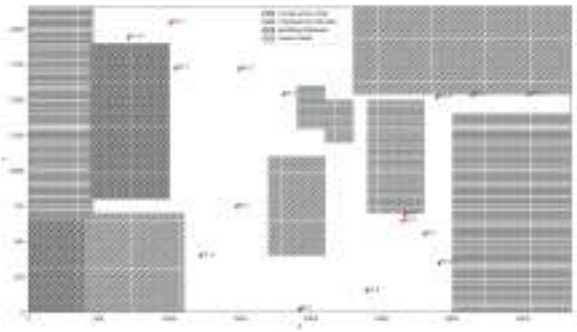
While non-uniform CPP strategies demonstrate adaptability and regional prioritization, their reliance on predefined heuristics and manual metrics often limits their applicability in complex environments. Our approach addresses these limitations by utilizing LLMs for automated and dynamic identification of POIs from semantic maps. Additionally, the integration of the LLM-A* algorithm ensures computational efficiency and scalability, making it well-suited for diverse real-world scenarios.

2.2 Large Language Models in Path Planning

Large Language Models (LLMs), such as GPT [11], have been employed to generate task-specific goals, interpret natural language instructions, and provide context-aware decision-making for navigation tasks [12]. The integration of LLMs into robots has opened new avenues for enhancing path planning through their ability to process and interpret high-level semantic information. Latif [13] proposed a probabilistic path planning approach using GPT-3.5-turbo, showcasing its ability to optimize robot navigation in complex environments. The method outperformed traditional algorithms like A* and RRT in processing time, demonstrating the potential of LLM in terms of efficiency and cost savings. Meng et al. [4] introduced LLM-A*, a hybrid algorithm combining the global reasoning capabilities of large language models with the precise pathfinding of A*. The approach significantly reduces computational operations and memory usage while maintaining path validity, making it well-suited for large-scale path planning scenarios.

Furthermore, LLMs have been utilized in coverage path planning tasks. Kong et al. [14] developed a multi-layer framework that integrates LLMs into coverage path planning for mobile robots. Their approach enhances the spatial inference capabilities of LLMs and achieves efficient, reliable path planning by combining high-level reasoning with low-level control, demonstrating the potential for LLMs in embodied AI tasks. These studies demonstrate the potential of LLMs to go beyond traditional numerical optimization methods by incorporating contextual and semantic understanding into the path planning process. Despite these advancements, those methods are limited to path planning tasks between two points or simply covering path planning tasks without obstacles. Our study builds on these foundations by leveraging LLMs to identify POIs and integrating them into a prioritized coverage path planning framework. This framework can handle complex environments and effectively bridge the gap between semantic understanding and efficient navigation.

3 Methodology



Our proposed methodology integrates semantic information extraction, point of interest (POI) identification, and optimized path planning. First, the environment is represented as a 2D semantic grid map, combining spatial and contextual information. Points of Interest (POIs) are then identified using a Large Language Model (LLM), which leverages semantic reasoning to prioritize task-relevant regions. The LLM-A* algorithm computes efficient paths between POIs while maintaining scalability and computational efficiency. Finally, the problem is formulated as a Traveling Salesman Problem (TSP), with the optimal route derived through heuristic and constraint-based optimization.

3.1 Semantic Information Grid Map Construction

To enable computational processing and algorithmic path planning, the first step is to convert the real-world environment into a 2D semantic information grid map. This discretization captures the spatial features of the environment while simplifying the problem for efficient computation. Data representing the real-world environment is collected through various sources, such as satellite imagery, LiDAR scans, or high-resolution drone footage (Figure 1a). This data provides essential spatial and structural details, including boundaries, obstacles, and open areas. Subsequently, data processing is performed to construct the grid map, ensuring that the number and size of the grids align with the resolution of the original image to maintain high-fidelity modeling, as shown in Figure 1b. Each cell in the grid represents a discrete area in the real-world environment. The processed data is converted into a grid-based matrix representation. Each cell in the matrix is assigned a binary value indicating its navigability. For example, cells representing obstacles are marked as non-navigable, while open spaces are marked as traversable. We convert the obstacles to rectangular shapes for computational efficiency, but they can be represented as complex geometries. This grid map forms the basis for subsequent steps, enabling spatial computations and path planning algorithms. In addition, this grid map is accompanied by semantic information, i.e., natural language descriptions indicating the location and type of obstacles, which will be provided to the LLM for reasoning.

(a) A real environment captured by a drone.

(b) Semantic grid map.

Figure 1. Real Environment and Semantic Grid Map.

3.2 Point of Interest (POI) Identification

The process begins with identifying Points of Interest (POIs) within the grid map. These POIs represent critical locations that must be prioritized during path planning and are determined using the semantic and contextual capabilities of a Large Language Model (LLM). By employing prompt engineering [15] to provide the LLM with a detailed description of the grid map and task-specific objectives, such as locating operational zones, high-risk areas, or strategic points, the model processes the input and leverages its contextual understanding to identify areas of significance based on task requirements.

The LLM then generates a list of potential POIs, which are subsequently validated against predefined criteria to ensure their relevance and alignment with the overall objectives. For example, POIs may include equipment storage areas, hazard zones, or task-specific targets. Once validated, the identified POIs are annotated on the 2D grid map, as illustrated in Figure 1b. This annotated visualization serves as a tool to verify the accuracy of the LLM's output and provides a clear depiction of the prioritized areas, laying the foundation for the subsequent path planning processes.

3.3 Distance Calculation Using LLM-A*

The next step is to compute the shortest paths between all pairs of POIs using the LLM-A* algorithm. This hybrid approach improves computational efficiency and reduces memory usage while maintaining path validity. The LLM-A* algorithm works by integrating LLM-generated waypoints as intermediate targets to guide the A* search process.

The POIs and the obstacles in the grid map are first defined as input states. The LLM-A* algorithm generates a sequence of waypoints using global insights from the LLM, providing a coarse roadmap through the environment. Waypoints divide the entire environment into distinct regions for partitioned processing, followed by path computation using the standard A* algorithm. This method of regional division significantly optimizes the computational cost of heuristic path planning algorithms [16]. Additionally, with the introduction of LLM for waypoint identification, the waypoints gain functional coverage capabilities. While the robot's path length may slightly increase, it enables the robot to cover more points on the map that are rich in semantic information.

The algorithm builds a distance matrix by calculating the shortest paths between all pairs of POIs. Each pairwise calculation leverages the LLM-A*'s ability to avoid unnecessary node expansions, significantly reducing the number of operations and storage requirements compared to traditional A*. By incorporating LLM-generated global insights with the deterministic precision of A*, LLM-A* enables the efficient and accurate computation of the distance matrix, laying the groundwork for the subsequent Traveling Salesman Problem (TSP) optimization. This hybrid approach addresses the limitations of standalone A* and LLM-based methods, ensuring both scalability and robustness in large-scale path planning scenarios.

3.4 Traveling Salesman Problem (TSP) Solution

To determine the optimal path visiting all identified POIs exactly once and returning to the starting point, the Traveling Salesman Problem (TSP) is formulated using the distance matrix from 3.3. Google OR-Tools is employed to solve the TSP, utilizing a hybrid approach that balances computational efficiency with solution quality. The initial solution is generated using the *PATH_CHEAPEST_ARC* heuristic, which iteratively selects the minimum-cost edges to construct a feasible route. This strategy provides a fast approximation to the TSP. Further optimization is achieved through constraint-based refinement, ensuring the path adheres to task-specific requirements, such as visiting all POIs exactly once and returning to the starting point. This approach leverages heuristic initialization and constraint optimization to

achieve near-optimal solutions while maintaining computational efficiency.

4 Expirement

4.1 Experimental Setup

To evaluate the effectiveness and efficiency of the proposed approach, we conducted experiments in simulated environments with varying levels of complexity, including one virtual indoor scene and two real outdoor construction site scenes. The experiments were designed to evaluate the performance of the LLM-A* algorithm and its integration into the overall system for solving the TSP.

Real outdoor construction site scenarios were represented using 2D grid maps generated with different resolutions and varying distributions of obstacles. The maps ranged from simple layouts with minimal obstacles to highly complex configurations with dense barriers. POIs were placed strategically across the maps to simulate real-world task requirements.

The simulation environment was configured to reflect realistic constraints, including image resolution, number of POIs (5 to 15 per map), and obstacle density (low 10%, medium 30%, and high 50%).

The experiments were implemented in Python, with the LLM-A* algorithm and TSP solver integrated into the workflow. The LLM used for global reasoning was GPT-3.5, accessed via API. For TSP optimization, a genetic algorithm was employed. The intermediate targets for LLM A* were determined in LLM and fed to A* Python code independently.

4.2 Evaluation Metrics

The proposed approach is evaluated using three key metrics: path length, operations, and storage.

Path Length: This metric measures the total distance of the computed path. While shorter paths are typically desirable in many scenarios, for prioritized coverage path planning (PCPP) tasks, a slightly longer path may be beneficial as it allows for the exploration of more semantically rich areas, aligning with the task's objectives.

Operations: The number of computational steps required to compute the path is recorded. This metric reflects the algorithm's efficiency in terms of processing effort and computational complexity.

Storage: The memory usage during the pathfinding process is measured to evaluate the algorithm's scalability and suitability for resource-constrained systems. Lower storage requirements indicate better optimization of the search process.

4.3 Experimental Details

4.3.1 Experiment 1: Complex Outdoor Construction Site Scenario

The first experiment evaluates the performance of the proposed approach in a complex outdoor construction site scenario derived from drone footage. The scene was converted into a high-resolution semantic grid map to simulate realistic navigation challenges. This real-world scenario and related grid map are shown in Figure 1. The resolution of the grid map is 3840×2160 with a high obstacle density, representing 50% of the grid cells. ChatGPT-4o served as the agent for generating semantically meaningful POIs and providing heuristic guidance for the LLM-A* algorithm. Table 1 summarizes the key parameters of this experimental setup.

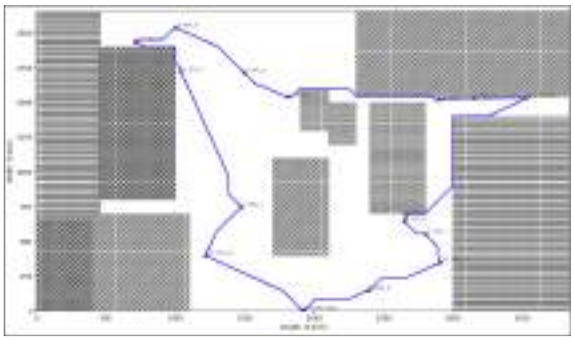


Table 1. Details of Experiment 1: Complex Outdoor Scenario

Parameter	Value
Grid Map Resolution	3840 × 2160
Obstacle Density	High (50%+)
Obstacle Types	Green Fields, Construction Sites, Equipment, Building Materials
Task Guidance	Avoid the obstacles, ensure coverage of most areas
LLM Agent for POIs	ChatGPT-4o
LLM Agent for LLM-A*	ChatGPT-4o
Number of POIs	14

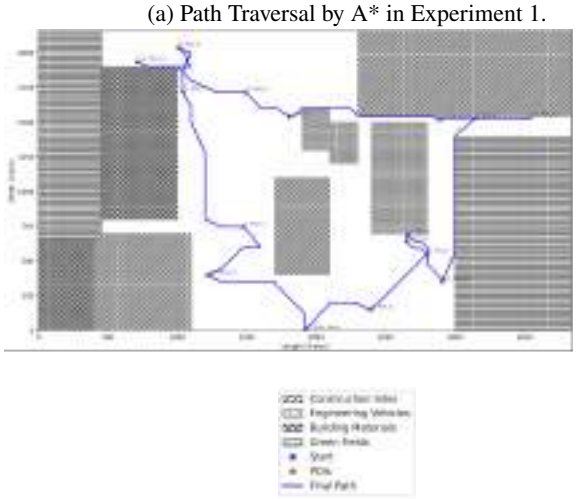

Figure 2 and Table 2 illustrate the comparative performance of A* and LLM-A* in Experiment 1. Figure 2 presents the specific paths taken by each algorithm. The paths highlight LLM-A*'s focus on semantically rich exploration over strict distance minimization. Table 2 provides quantitative insights into the results, demonstrating that while the total path length for LLM-A* increased by 13.6%, it significantly reduced operations by 41.1% and storage requirements by 36.9%. Therefore, Figure 2 and Table 2 highlight LLM-A*'s effective balance between computational efficiency and semantic exploration, making it an appropriate choice for prioritized coverage path planning tasks in complex environments.

Table 2. Comparison of A* and LLM-A* in Experiment 1

Metric	A*	LLM-A*
Total Path Length (TSP)	9270.45	10530.60 ↑ 13.6%
Total Operations	72343616	42636892 ↓ 41.1%
Total Storage	44987486	28383237 ↓ 36.9%

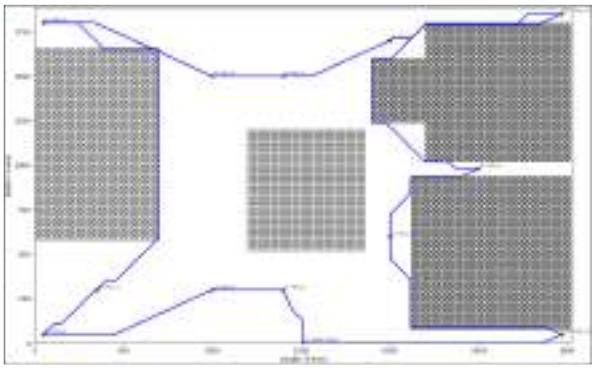
(b) Semantic grid map with POIs in Experiment 2.

Figure 3. Real Environment and Semantic Grid Map in Experiment 2.

4.3.2 Experiment 2: Simple Outdoor Construction Site Scenario

The second experiment evaluates the performance of the proposed approach in a simple outdoor construction site scenario derived from drone footage. The scene was transformed into a semantic grid map with a lower resolution compared to Experiment 1, representing a simpler environment for navigation. Points of Interest (POIs) were generated using ChatGPT-o1, while the LLM-A* algorithm employed ChatGPT-4o for heuristic guidance. The scenario of experiment 2 and the related grid map with POIs are in Figure 3.



This experiment involved a grid map with a resolution of 3024×1890 and a medium obstacle density, representing 30% of the grid cells. The goal was to evaluate the algorithm's performance in less complex scenarios, focusing on efficiency and scalability. Table 3 summarizes the key parameters of this experimental setup.

Figure 4 and Table 4 illustrate the specific paths and performance metrics for A* and LLM-A* in Experiment 2. Figure 4 highlights the distinct paths taken by each algorithm, showing LLM-A*'s preference for semantically rich exploration, which resulted in a 23.9% increase in total path length as detailed in Table 4. At the same time, LLM-A* demonstrated superior computational efficiency with a 34.2% reduction in operations and a 34.0% reduction

Table 3. Details of Experiment 2: Simple Outdoor Scenario

Parameter	Value
Grid Map Resolution	3024 × 1890
Obstacle Density	Medium (30%)
Obstacle Types	Green Fields, Construction Sites, Equipment, Building Materials
Task Guidance	Avoid obstacles, ensure coverage of most areas
LLM Agent for POIs	ChatGPT-o1
LLM Agent for LLM-A*	ChatGPT-4o
Number of POIs	11

in storage requirements. These findings demonstrate that LLM-A* continues to balance computational efficiency and semantic exploration even in simpler environments.

(a) Path Traversal by A* in Experiment 2.

(b) Path Traversal by LLM-A* in Experiment 2.

Figure 4. Path Planning Comparison in Experiment 2: A* vs LLM-A*.

Table 4. Comparison of A* and LLM-A* in Experiment 2

Metric	A*	LLM-A*
Total Path Length	13562.50	16300.53 ↑ 23.9%
Total Operations	60556220	39873931 ↓ 34.2%
Total Storage	39494015	26063827 ↓ 34.0%

4.3.3 Experiment 3: Virtual Indoor Warehouse Scenario

The third experiment evaluates the performance of the proposed approach in a virtual indoor warehouse scenario. The scene was designed with a resolution of 3024×1890 and included medium obstacle density (30%). The environment featured four types of obstacles: shelves, automated sorting stations, cold storage areas, and hazardous areas. To evaluate the comprehension capabilities of LLMs and expand potential application scenarios, we conducted task guidance tests in this environment focusing not only on obstacle avoidance and maximizing map coverage but also on executing specific task instructions tailored to the setting, such as ensuring detailed exploration around the cold storage area for proper monitoring. LLMs were prompted to understand the task and generate additional Points of Interest (POIs) near the cold storage area. The virtual scenario of experiment 3 only has a designed grid map with POIs, which is in Figure 5.

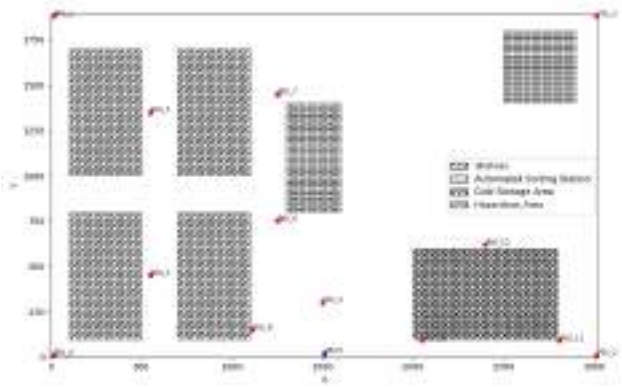


Figure 5. Semantic grid map with POIs in Experiment 3.

ChatGPT-o1 was used to generate semantically relevant POIs, and ChatGPT-4o provided heuristic guidance for LLM-A*. Table 5 summarizes the key parameters of this experimental setup.

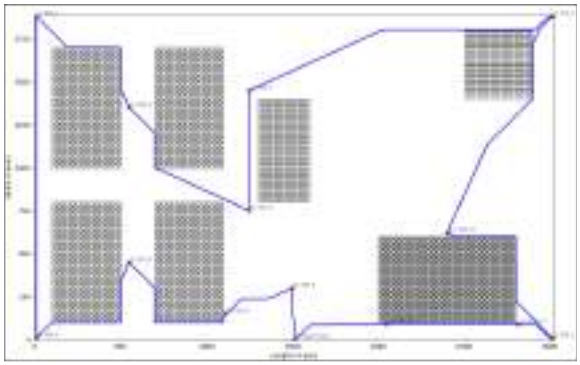

Table 5. Details of Experiment 3: Virtual Indoor Warehouse Scenario

Parameter	Value
Grid Map Resolution	3024 × 1890
Obstacle Density	Medium (30%)
Obstacle Types	Shelves, Sorting Stations, Cold Storage, Hazardous Areas
Task Guidance	Emphasis on cold storage
LLM Agent for POIs	ChatGPT-o1
LLM Agent for LLM-A*	ChatGPT-4o
Number of POIs	78

Figure 6 and Table 6 present the comparative performance of A* and LLM-A* in Experiment 3, conducted

within a virtual environment with specific task guidance. Figure 6 illustrates the distinct paths traversed by each algorithm, showcasing LLM-A*'s approach to semantically rich exploration, which aligns with the task's guided objectives. As shown in Table 6, LLM-A* increased the total path length (TSP) by 18.7% (from 13208.39 to 15682.17), reflecting its prioritization of meaningful interaction over strict path minimization.

At the same time, LLM-A* significantly reduced computational demands, with a 41.8% reduction in total operations and a 30.6% reduction in storage requirements. These improvements demonstrate the algorithm's ability to optimize resources while fulfilling specific guidance task requirements in a controlled virtual setting. Overall, Experiment 3 also highlights LLM-A*'s strength in balancing computational efficiency with task-specific semantic exploration.

(a) Path Traversal by A* in Experiment 2.

(b) Path Traversal by LLM-A* in Experiment 3.

Figure 6. Path Planning Comparison in Experiment 3: A* vs LLM-A*.

Table 6. Comparison of A* and LLM-A* in Experiment 3

Metric	A*	LLM-A*
Total Path Length	13208.39	15682.17 ↑ 18.7%
Total Operations	61625226	35904779 ↓ 41.8%
Total Storage	35970025	24992699 ↓ 30.6%

4.3.4 Comparative Analysis

The results provide a comprehensive evaluation of LLM-A*'s performance in varying environments and task setups. While LLM-A* consistently yields longer overall paths (ranging from 13.6% to 23.9% increases), it significantly reduces computational operations (by 34.2% to 41.8%) and lowers storage requirements (by 30.6% to 36.9%) compared to standard A*. These results underscore the advantage of incorporating semantic guidance into path planning: the algorithm selectively emphasizes task-relevant regions (e.g., general guidance for avoiding obstacles in outdoor settings and specific guidance for monitoring cold storage in warehouses), effectively accessing large segments of the search space.

Furthermore, the slight increase in total path length should not be considered a negative outcome. This increase is akin to an exploration phase, effectively expanding the overall coverage area of the map and fulfilling the requirements of PCPP tasks for semantically rich regions. Therefore, this additional path length enhances the algorithm's capability to cover complex environments. In terms of efficiency, LLM-A* consistently demonstrated significant reductions in both computational operations and storage requirements. These results highlight its strong adaptability and scalability, particularly in resource-constrained systems.

Moreover, the performance of LLM-A* remains consistent across all experiments, demonstrating robustness in various levels of environmental complexity. Notably, the performance slightly improved in Experiment 1, which involved complex environments, and in Experiment 3, which featured medium-density environments with specific task guidance. This suggests that the algorithm is not only adaptable to different environments but also excels when faced with customized task requirements.

5 Conclusion

This paper presented a novel Prioritized Coverage Path Planning (PCPP) approach—referred to as LLM-PCPP—that integrates large language models with conventional path planning techniques. By leveraging LLMs to identify context-rich Points of Interest (POIs) and employing LLM-A* to compute efficient paths between these points, the proposed method significantly reduces com-

putational overhead and memory usage. The experimental results across three distinct scenarios (complex outdoor, simple outdoor, and virtual indoor) demonstrated that, while path lengths increased moderately (13.6% to 23.9%), LLM-PCPP consistently reduced the number of operations (34.2% to 41.8%) and memory requirements (30.6% to 36.9%) compared to standard approaches. These findings underscore the advantage of incorporating semantic cues into coverage path planning by LLM.

Future work will focus on exploring collaborative multi-robot systems and developing complex task-specific guidance, such as determining the farthest points for advanced robots to explore in unknown environments. These efforts will further validate the robustness and scalability of LLM-PCPP, positioning it as a promising solution for advanced coverage applications in resource-constrained and semantically diverse settings. In addition, the POIs found by LLM will be validated in the future. This can be done by consulting with field experts. Finally, benchmarking with the state-of-the-art CPP methods will be conducted to evaluate our PCPP method.

Abstract

The construction industry heavily uses many different categories of heavy equipment on a daily basis. Generally, such equipment is used extensively and lasts a long time with limited to no possibility of updating or enhancing. Especially, with the current advancements of technology, there is a need to modernize such mechanical equipment. With regard to equipment control, most equipment requires users to stay close to or directly control the equipment. In this paper, the authors propose an upgrading system that allows the remote operation of heavy equipment through push and pull mechanism. By utilizing a single-board computer such as Raspberry Pi with linear actuators, the system can allow the users to control the heavy equipment remotely. The proposed system is successfully demonstrated by upgrading an indoor tower crane in the D. Dorsey Moss Construction Lab at Purdue University. This type of upgrade could support other heavy equipment in the construction field through integrating various sensors and actuators for digital enhancement.

Keywords –

Heavy Equipment Upgrading; IoTs; Construction 4.0; Actuators; Construction Automation

1 Introduction

Construction 4.0 concepts lead to more adoption of various advanced digital technologies into the construction industry, including Building Information Modelling (BIM), Internet of Things (IoTs), Robotics, Automation, etc. [1]. Such integration spurs the need for more digitalization and automation, which results in increased productivity, safety and efficiency in the construction sector. With a focus on IoTs and Robotic Automation, the heavy equipment systems in construction need to be upgraded from traditional control (hands-on) to remote control, and eventually to fully autonomous systems.

While new construction equipment is built with certain smart capacities, there are still many problems with traditional heavy equipment in the sector. This equipment needs upgrades to fit the IoTs and Robotic application contexts of the future. In the work of Khan et al., a lot of emerging technologies have been equipped with heavy construction equipment such as Radio Frequency Identification (RFID), Geographic Information System (GIS), Onboard Instrumentation System (OBIS), Artificial Intelligence (AI), Digital Twin (DT), Internets of Things (IoTs), Cyber Physical Systems (CPSs), Computer Vision (CV), Telematics, and so on [2]. Their study showed how those add-on technologies improved the performance of construction equipment. For example, Hera et al. successfully experimented with fully autonomous forestry machine by equipping the AORO platform with GNSS, UEISIM RTW target and I/O computer, Jetson Xavier and Router, Stereo camera, and so on [3]. Zhang et al., with the purpose of guiding and improving the quality of dynamic compaction for geotechnical improvement process, developed a control system with mounting various supported devices such as AT311 antenna, Hydraulic sensors, Code the sensor, CB71108 car tablets and MC100 Beidou smart host on a mobile crane [4].

While many studies focus on the use of those technologies and their integrated benefit, there are not many that address the upgrade of existing physical systems. In case of an attached innovative physical system, Chen et al. developed a Proportional-Integral-Derivative (PID) based Rotation-control device which

was used to attach at the end of a construction crane's hoist and effectively control suspended item with precise rotation through wireless remote control [5]. Yusof et al. developed a new tele-operated electro-hydraulic actuator which was attached with mini excavator to achieve a full tele-operation of the machinery [6].

While equipment has control buttons for hands-on operations, the ability to control these buttons from a distance is one of the key features for upgrading the system to an IoT with remote control access. Therefore, this paper focuses on developing a plug and play system with a push and pull mechanism, which can be used to allow the remote and/or algorithmic operation of heavy equipment in the construction industry. The proposed system aims to illustrate the potential integration with remote control of a construction crane as a case study.

2 Literature Review

Seeing the significance of automation and robotics in construction, especially the need to upgrade machinery to align with the construction 4.0 concepts, enabling the remote operation of construction tools and equipment is the first step to get them connected. The development of tele-operated electro-hydraulic actuators by Yusof et al. [6] could be seen as a key example of the mechanical attachment to the existing machinery for remote operations. In their work, electro-hydraulic actuators are developed specifically to attach to the mini excavator's various driving shifts through a push-pull mechanism. While the design showcased the possible use of the electro-hydraulic actuator with mechanical levers, the system was overly powerful and too complicated for smaller control hardware such as button press or reduced force lever. For smart control actuators, they were seen the most in IoT applications for smart home control and monitoring [7,8]. In the home IoT applications development, control and monitoring devices' "IoT brains", connectivity protocol, user interface, sensors, actuators, and others are the key components to successfully develop an IoT system [9]. With the purpose of developing a low-cost smart automation system, Eleyan and Fallon [8] developed a system that used Phidget Module to control a Servo with actuator that was used for locking the door. The system was designed to communicate with android phone's application through Message Queuing Telemetry Transport (MQTT) communication protocol [8]. In the development of smart home security system by Islam [10], the microcontroller, Yun Arduino, was used while the MQTT was selected due to its light weight connecting protocol to connect with Android application (from phone) and Arduino board. Rubies et al., while emphasizing the non-contact and non-intrusive device which enable users to control elevator button remotely (from phone), proposed an IoT system using servo motor (actuators) for pushing the button, Esp32 microcontroller, web-based interface, and Wi-Fi as communication protocol [11]. Laluma et al. implemented the IoT in the water treatment plant with the purpose of creating a control automation process through Adafruit.io server. Laluma et al. proposed a control system which uses Raspberry Pi, MQTT protocol, and servo motor (actuator) to control the waterflow [12].

Through the literature review, MQTT protocol is identified as a lightweight message protocol commonly used for IoT applications. And for the brain of the IoT, there are many boards available with different capabilities. Raspberry Pi was seen as a capable Single Board Computer (SBC) which can be used with MQTT protocol and can be configured for various control systems.

3 Methodology

In many IoTs projects that include the remote-control operation, single board computer/micro control is becoming more and more affordable and has sufficient capability in supporting system control development. While the system was purposefully developed for controlling any push-pull mechanism such as button- or lever-based control remotely, our proposed plug and play system in this paper makes use of single board computer, electrically motorized actuators, and control algorithm with MQTT communication protocol. The smart control module/components can be easily customized and attached to the existing control components/buttons of an existing machinery. The potential of the proposed system is demonstrated through lab testing of a tower crane control system.

Figure 1 illustrates the proposed system architecture, which contains two main sub-systems: (1) the user interface which can be run on any computer, and (2) the control system.

3.1 User Interface (UI)

The User Interface (UI) is implemented as a runnable .exe file which is customized to fit the requirement of the control system. Figure 2 shows the interface which is used in the crane control case study in Section 4.

The UI algorithm is developed with TKinter python library with MQTT communication protocol. MQTT is a publish-subscribe and machine to machine (M2M) communication protocol which is widely used for IoTs connectivity [13]. The UI used MQTT as the communication backbone and acted as a client which connected to the MQTT Broker running on the SBC. The MQTT Publisher in the UI allows the user to publish the message from those control actions to the control system (Section 3.2) which will further act accordingly.

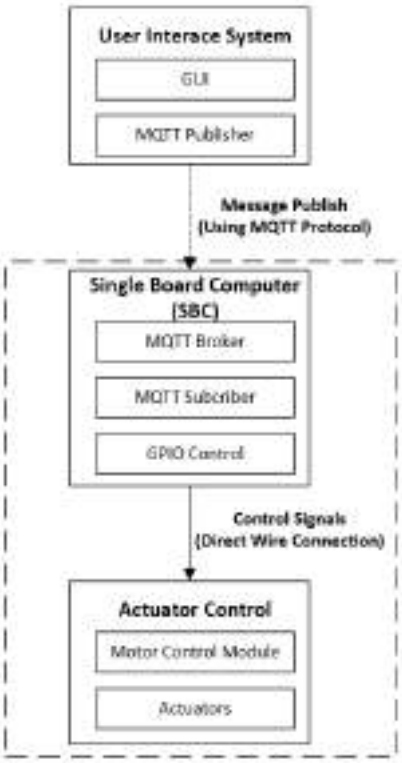

Figure 1. System architecture.

Figure 2. Custom user interface for crane control.

3.2 Control System

The control system (Figure 3) is a key hardware circuit which contains three main components: SBC, motor control driver, and actuator. The SBC, while running the developed control algorithm (Figure 1), triggered the MQTT broker (a central hub for all message exchange between the clients) with a specific IP address. At the same time, the SBC also acted as clients. From the UI, when IP address was provided, the system was connected. It means that through MQTT, the clients (UI) were connected to server. When the message was published from UI, the client on the SBC (MQTT subscriber through server) received the published message. The message through direct General-Purpose Input/Out (GPIO) pins were connected to the actuator control system. In the control algorithm, there is also an error handling part that triggers the emergency stop condition or reset the control when the SBC loses communication with the server.

The actuator control unit is the circuit which makes use of the motor control driver to run the motorized actuators. The selection of the motor control driver allows the control of different states of the motor in the actuator.

The circuit of the control system which uses Raspberry Pi 4B as SBC, L298N as motor driver controller, and Actuonix pq-12-30-12-P as actuator is shown in Figure 3.

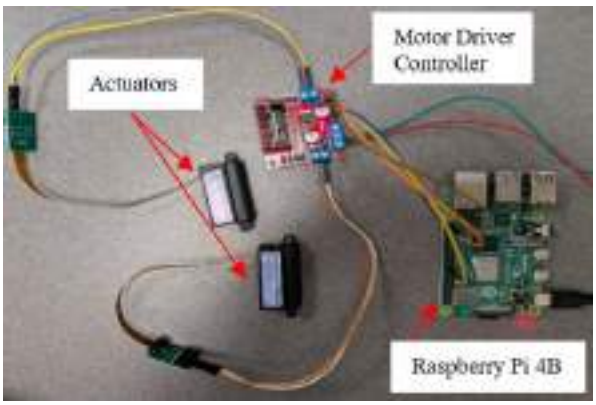

Figure 3. Control system circuit.

4 Application and Discussion

4.1 Hardware Setup

The system was customized as a plug and play instrument to control a crane controller for an indoor tower crane located in the D. Dorsey Moss Construction Lab in the KNOY building at Purdue University. The crane is operated by direct wire controller as shown in Figure 4.

Figure 4. Default crane control.

The default controller has 8 buttons with 8 different operational functions including START, STOP, UP, DOWN, LEFT (IN), RIGHT (OUT), FORWARD (clockwise), and REVERSE (counterclockwise). While the START and STOP are latching buttons, the others are momentary buttons. They are only activated when being pressed.

To attach the control system to the controller, a mount for the actuator was designed and 3D printed, as shown in Figure 5. The mount contains two parts: the upper part supports the actuator, and the lower part secures the entire structure on the crane's controller. The shape and size can be customized and modularized based on various types of crane controllers. This method can replace manual operation while achieving high speed and accuracy for remote button control.

Figure 5. 3-D printed customized mount for the actuator.

As shown in Figure 3, two actuators can be connected to a motor driver controller and connected to Raspberry Pi. To control the 8 buttons of the crane's controller, 8 actuators are connected to 4 motor driver controllers and connected to Raspberry Pi through 16 GPIO pins. For this case, GPIO in and out for STOP, START, UP, DOWN, IN, OUT, FORWARD, and REVERSE are (23;24), (25;8), (26;16), (20;21), (2;3), (17;27), (5;6), and (22;13) respectively. The configuration of the mount with actuators on to the crane's controller is shown in Figure 6. Figure 7 shows the complete set up and testing of the system on the lab's crane.

Figure 6. Crane remote control with mounts and actuators.

Figure 7. System setup for remote access crane.

The system setup for this crane controller needs two sources of power: (1) 12V power was needed for all the motor driver controllers which supplied to the actuators, (2) the Raspberry Pi ran on 3.3V power supply.

4.2 Crane Control User Interface

The development of the crane control UI (shown in Figure 2) resembles the crane controller. The interface required input from: (1) the IP address of the control system (Raspberry Pi as sever), and (2) status information whether the system is connected to the control system or not. As shown in Figure 8, the UI has 8 buttons as the controller which are divided into two different groups. Group 1 controls latching buttons for which a button is pushed to lock in place and the actuator can be used to push the button again to release it back. Figure 9 shows the algorithm which, when applied, allows the actuator to travel 0.3 seconds and push the latching button, then retreat to the original location.

Figure 8. Crane remote control GUI.

```
def extend_and_retract(pin_in, pin_out):
    GPIO.output(pin_in, GPIO.HIGH)
    GPIO.output(pin_out, GPIO.LOW)
    time.sleep(0.3)
    GPIO.output(pin_in, GPIO.LOW)
    GPIO.output(pin_out, GPIO.HIGH)
    time.sleep(0.3)
    GPIO.output(pin_in, GPIO.LOW)
    GPIO.output(pin_out, GPIO.LOW)
```

Figure 9. Control function algorithm for latching button.

The group 2 buttons are of the momentary type, for which continuous pressing is required to activate the

corresponding function. For the interface and activation, when pressing, the state of the button of group 2 (as shown in Figure 10) changes its state in the interface when informing the user that the button is being pressed. When the user clicks on the button one more time, the button state will change to normal, and the actuator retreats to its initial state. The governing function of extending the actuator while being pressed and retreating it when being re-clicked are shown in Figure 11.

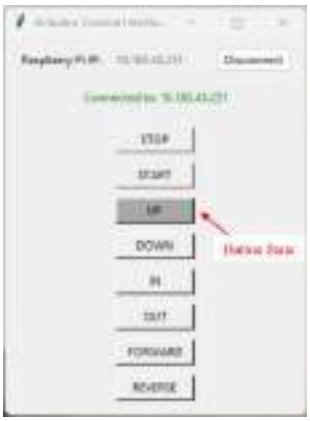

Figure 10. Button state change.

```
def extending(pin_in, pin_out):
    GPIO.output(pin_in, GPIO.HIGH)
    GPIO.output(pin_out, GPIO.LOW)
    time.sleep(0.3)
    GPIO.output(pin_in, GPIO.LOW)
    GPIO.output(pin_out, GPIO.LOW)

def retracting(pin_in, pin_out):
    GPIO.output(pin_in, GPIO.LOW)
    GPIO.output(pin_out, GPIO.HIGH)
    time.sleep(0.3)
    GPIO.output(pin_in, GPIO.LOW)
    GPIO.output(pin_out, GPIO.LOW)
```

Figure 11. Control function algorithm for extending or retracting the button.

As shown in Figures 9 and 11, the *time.sleep* function of the algorithm allows the actuator to travel (extend or retreat) for 0.3 seconds. It is a trial-and-error value which can make sure the length of travel distance is long enough to press the core of the button firmly. The duration can be varied based on the design of the mount.

4.3 Crane Control

After setting up the system as shown in Figure 7 and powering on the raspberry pi, the autorun of the system triggers the algorithm and allows the MQTT broker to operate. On a laptop computer, after launching the crane remote control application (Figure 2), with knowledge of IP address of the Raspberry Pi, the App was successfully connected to the PI. While remotely running the system, the proposed mounted platform allowed the user to remotely control all the functions of the crane's controller successfully. This demonstrates that the proposed system with push and pull mechanism can be integrated with various human-hand-friendly control mechanisms by simply altering the 3D printed mount design or mounting mechanism. For example, the system can be integrated to push or release buttons in a tower crane's cab or to shift operating levers and sticks inside an excavator or a forklift.

5 Conclusion

The construction industry relies heavily on the use of heavy equipment which needs an upgrade to align with the digitalization trend of the construction 4.0 concept. Remote control of those equipment such as excavator, crane, and other mechanical machinery which usually requires hand-on operation are the first steps toward a fully autonomous machine operation. However, to retrofit those components requires significant time and budgets. To address that, this paper illustrates a plug and play system with simple and effective solutions for upgrading existing equipment with button- or lever-based control. This is achieved through a push and pull mechanism to connect to the existing controller. With the MQTT communication protocol, the remote control of the system can be achieved. The completed remote-control system was tested with a construction tower crane in the lab environment. The result showed that it allows the user to successfully control the crane wirelessly. It is a proof of concept that can be used for all different devices with button- or lever-based control mechanism.

Despite the successful demonstration of the system, the following limitations of the system are acknowledged: (1) the 3D printed mounting mechanism is required to be modelled and designed based on the retrofitting purpose and existing control hardware, (2) the control system is mainly based on one type of single board computer (Raspberry Pi 4) and communication protocol (MQTT), and (3) only one selected type of actuator was used. Despite those limitations, the case study demonstrates promising capability and good potential of the system. Future research is recommended to investigate the full tele operation of the crane, linking the physical system with the digital system for digital twin applications, and the development of autonomous operations.

Abstract -

Workers often spend significant time locating tools on construction sites, resulting in productivity losses. With the continuous advancement of robotic technologies, robot-to-human handover offers a potential solution to address this issue. However, existing robot handover methods face challenges in handling the irregular shapes and dangerous nature of tools, as well as the dynamic and complex environments of construction sites. To tackle these challenges, this research proposes a method that enables robots to effectively predict and grasp construction tools while ensuring safety. A grasp dataset consisting of four commonly used construction tools—pliers, screwdrivers, wrenches, and safety glasses—was generated in a simulation environment. During the annotation process, grasping areas for robots and humans are distinguished to reduce potential risks in handover processes. The dataset includes multi-angle RGB-D images and detailed annotated grasp poses specifically designed for robotic grasps. This proposed dataset provides a foundation for training and validating grasp prediction models, enabling robots to handle tools with irregular shapes in various scenarios. The proposed approach integrates data annotation, scene generation, grasp pose prediction, and motion planning to achieve safe and efficient handovers. Validation experiments conducted in a simulation environment using a UR5 robotic arm equipped with a parallel gripper demonstrate a 92.5% success rate. This research provides a foundation for the application of robot-to-human handovers on construction sites and highlights the potential of using virtual datasets to address real-world challenges.

Robot-to-human Handover; 6-DOF Grasp Dataset; Robotic arm; Grasp pose prediction

1 Introduction

The construction industry is facing labor shortage [1], and workers on construction sites often spend significant time searching for tools, further reducing productivity [2]. With the continuous advancement of robotic technologies, more construction sites are adopting automation and robotic systems to improve efficiency [3]. For example, an increasing number of construction robots have been deployed on construction sites [4]. In this context, robot-to-human handover has become a critical approach to addressing this issue.

Robot-to-human handover consists of three main steps: object searching, localization, grasping, and delivering tools. The entire process must ensure both efficiency and safety [5]. However, construction sites are highly dynamic and complex environments. Most current construction robots perform pre-programmed tasks, making them less adaptable to the variability of construction sites [6]. Compared to the operational environments of existing robot-to-human handover methods, construction sites present greater challenges in terms of environmental complexity, requiring robots to adapt to diverse scenarios and respond flexibly [7]. In addition, construction tools vary widely in size and shape, often exhibiting irregular geometries and potential hazards. Ensuring safety during the handover process is therefore critical.

To address the issues mentioned above, this paper proposes a grasp prediction method for hazardous construction tools. We develop a 6-DOF grasp pose dataset and introduce a method to distinguish between robotic and human grasping regions. The proposed method integrates a grasp dataset from GraspNet [8], grasp pose prediction, and motion planning, enabling robots to effectively grasp handheld tools while ensuring safety. The rest of this paper is organized as follows. Section 2 reviews related work on grasp pose prediction and robot-to-human object handover, identifying research gaps. Section 3 describes the proposed model architecture. Section 4 outlines the experimental setup. Section 5 presents the results. Section 6 concludes the paper and discusses future work.

2 Related Work

This study addresses the challenges of safe and efficient grasping and handover in human-robot interaction, particularly on construction tools, which involve higher safety risks. Consequently, two main research areas are reviewed: (1) Grasp Pose Prediction and (2) Robot-to-Human Han-

dover. We focus on these domains because the quality of a robot's initial grasp directly influences the risk of subsequent handovers—an issue of critical importance in high-risk environments such as construction sites. By examining previous methods, we establish a foundation for our proposed approach to ensure efficient tool handovers through accurate and context-aware grasp prediction.

2.1 Grasp pose prediction

Grasp pose prediction is a critical component of robotic manipulation, especially in tasks that require safe and stable object handovers. Several methods have been proposed to tackle this problem in recent years. Traditional methods often rely on geometric heuristics or predefined rules [9]. However, these methods are limited in their ability to generalize to objects with complex geometries. To address these limitations, some researchers have leveraged CNNs and deep learning techniques, enabling the model to adapt to various shapes [10][11][12]. While deep learning has shown promising results, these methods typically lack context-awareness. Recent research such as Co-Grasp [13] incorporates human preferences in the grasping process, enhancing collaboration between robots and humans.

2.2 Robot-to-Human Handover

Robot-to-human handover refers to a collaborative interaction where one party, the giver, transfers an object to another, the receiver. This process requires precise coordination of both cognitive and physical actions to ensure a smooth exchange [5]. Therefore, researchers have developed a range of approaches to address the difficulties involved in robot-to-human handovers.

Some studies rely on heuristic rules, such as positioning the robotic arm's grasping point on the opposite side of the object from the human hand pose [14]. However, such approaches are not suitable for all types of objects. Other methods remove potential collision-prone grasp points from the human affordance map [15]. While these methods are effective for objects with regular shapes, the inherent risks associated with construction tools place a greater emphasis on safety considerations during the handover process. Additionally, some researchers have proposed using tactile and auditory cues to ensure safety during handovers [16]. However, their work does not address the prediction and selection of optimal grasping points.

In this paper, we propose a method for robotic arms to predict grasping positions specifically for construction tools. Our approach prioritizes safety and provides a foundation for secure and efficient handovers after the grasping phase.

3 Methodology

While traditional grasping methods often rely on simple geometric heuristics or rectangular grasp annotations, they tend to fall short in handling objects with irregular geometries and in providing the necessary context-awareness for dynamic environments. In contrast, GraspNet leverages 6-DOF grasp pose annotations, which allow for more precise and adaptable grasp predictions. This capability is particularly crucial for our application on construction tools, which frequently exhibit complex shapes and potential safety hazards. Therefore, despite the existence of simpler strategies, we chose GraspNet as our baseline due to its demonstrated robustness and superior performance in generating accurate grasp poses for irregular objects.

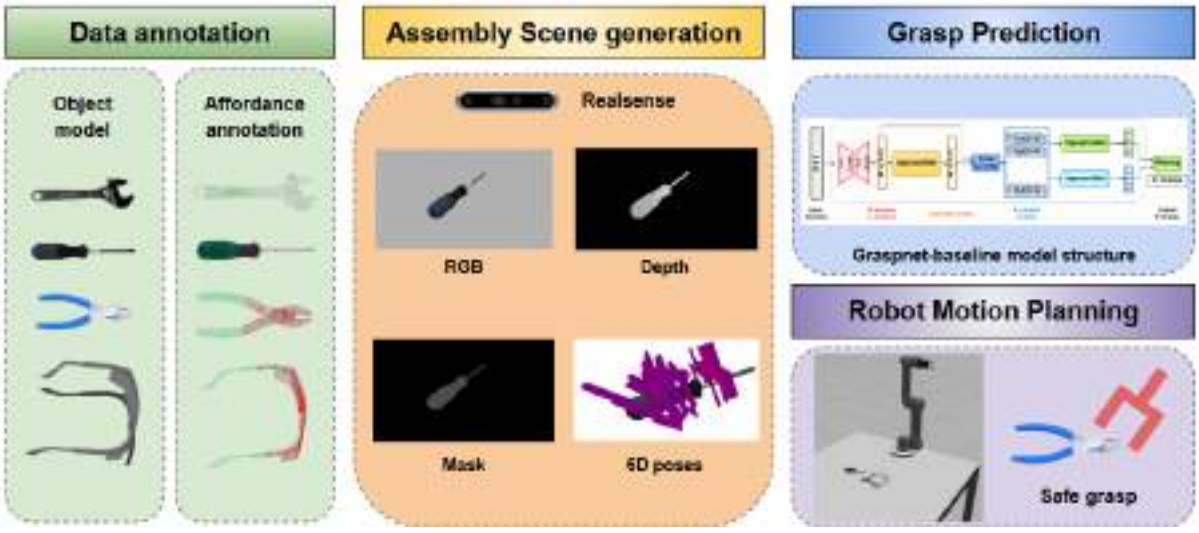
Based on the limitations in existing studies, we developed a comprehensive workflow to achieve safe construction tool handovers. The proposed methodology is composed of four main components: data annotation, assembly scene generation, grasp prediction, and robot motion planning. These components are designed to work in synergy, enabling safe robot-to-human tool handovers. The proposed framework is shown in Figure 1.

For tool selection, we chose tools commonly found on construction sites. Additionally, the shape of the tools was an important consideration; the selected tools exhibit significant diversity and irregularity in their shapes. In the annotation process, we differentiated between human and robotic grasping regions. This distinction ensures that the predicted grasp poses are focused on designated locations. After annotating the data, we generated the scenes using a Realsense D435 camera to capture images in a simulation environment. Each scene includes RGB-D images, object 6D poses, and masks. For grasp prediction, we employed the GraspNet-baseline [8] model as our prediction framework. We fine-tuned it using the generated dataset and conducted experiments in a simulation environment to verify the reliability of the predicted grasp poses. This approach ensures that the workflow effectively addresses safety in robot-to-human handover.

3.1 Data Annotation

We selected four tools from the Occupational Safety and Health Administration (OSHA) Hand and Power Tools Manual classified as hazardous during operation: adjustable wrench, screwdriver, pliers, and safety glasses. This highlights the importance of ensuring safety during the handover process. The selected tools are illustrated in Figure 2. The screwdriver and adjustable wrench are sourced from the YCB dataset [17], while the pliers and safety glasses are newly introduced objects in this dataset.

Among the selected tools, wrenches, pliers, and screwdrivers are widely used handheld tools on construction



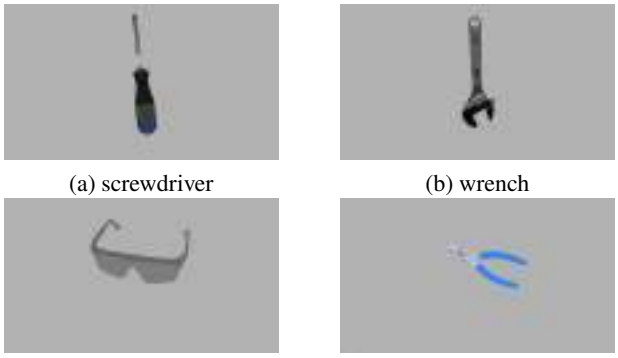


Figure 1. The overview architecture of the proposed handover strategy

(a) screwdriver (b) wrench

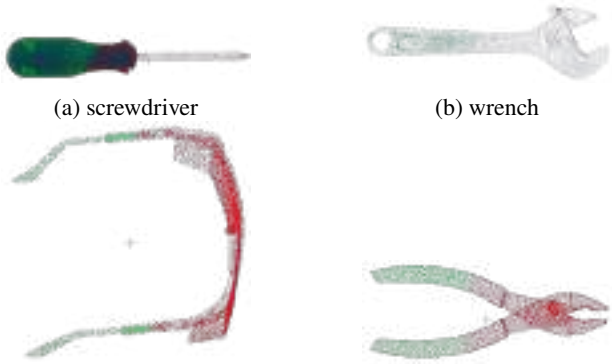
(c) safety glasses (d) plier

Figure 2. Commonly used construction tools on construction sites

sites. These tools were specifically chosen for their diverse shapes and sizes, providing a comprehensive evaluation of the versatility of the proposed handover method. Additionally, safety glasses, as an essential protective tool on construction sites, are included to assess their grasping and handover performance in the construction site scenario.

The annotation process consists of two steps. First, based on the tool's usage scenario, we manually annotate the grasping areas for both human and robot interactions. The annotated data is then saved for grasp label generation. For example, in the case of a wrench, humans typically hold the handle for operation, while the other end may pose safety risks due to its sharpness. Therefore, the robot grasping area is annotated on the sharp end of the wrench, while the human grasping area is annotated on the handle.

The second step involves annotating the grasp labels. Various grasp datasets employ different annotation methods based on their intended usage. Examples of well-known datasets, such as Jacquard [18] and Cornell grasping dataset [19], are shown in Table 1. These datasets use rectangle annotations for grasp labels, which are less flexible compared to GraspNet. GraspNet employs annotations in the form of 6-DOF poses, which are particularly advantageous in complex construction environments. The additional precision provided by 6-DOF annotations enhances the robotic arm's ability to execute accurate and reliable movements in such challenging settings. As a result, we chose GraspNet as the annotation format for our grasp labels.



The annotated data are stored as point clouds, with green areas representing human grasping regions and red areas representing robot grasping regions. This separation not only ensures that the robot and human grasping positions are distinguished during the grasp prediction process but also facilitates safe handling by enabling humans, as receivers, to take the object securely from the handle. This dual focus enhances safety in robot-to-human handover scenarios. The annotation for each tool is shown in Figure 3.

3.2 Assembly Scene Generation

In order to construct a dataset for model training, we placed the tools flat on a table and selected the Realsense D435 camera for data collection. Camera calibration was performed prior to data collection to ensure accurate camera poses. The camera captured RGB-D images from 33 different poses, allowing us to gather more information about the tools from various angles. Corresponding masks were manually annotated, and both the camera and object

Table 1. Properties of public grasp datasets

Dataset	Grasp label	6D pose	Total images	Modality	Data source
Cornell [19]	Rect.	No	1035	RGB-D	1 Camera
Jacquard [18]	Rect.	No	54K	RGB-D	Sim
GraspNet [8]	6-DOF	Yes	97K	RGB-D	1 Camera
Ours	6-DOF	Yes	132	RGB-D	Sim

(a) screwdriver (b) wrench

(c) safety glasses (d) plier

Figure 3. Visualization of annotated 3D models of every tool

6D poses were recorded. The dataset included a total of 132 images, along with their corresponding camera and object 6D poses.

3.3 Grasp Prediction

After preparing the training data, we used GraspNet-baseline as the model to predict grasp poses. The structure of the model is shown in Figure 4. During training, the initial learning rate was set to 0.01, and the batch size was 4. The learning rate was reduced to half its value every 5 epochs.

Once the training was completed, we first visualized the predicted grasp poses to verify their validity. Next, the RGB-D images from the simulation environment were used as input to the model, which generated the predicted grasp poses. In the following step, motion planning was employed to test the accuracy of these predicted grasp poses.

3.4 Robot Motion Planning

Once the dataset and scene setup were complete, we employed a fine-tuned model that takes RGB-D images as input and predicts multiple candidate grasp poses in 6-DOF, each accompanied by a confidence score. Among these predicted grasp poses, we select the one with the highest score as the optimal grasping position. The UR5 robotic arm then executes the grasp at this selected pose. This ensures stable and precise grasping by leveraging the model's scoring mechanism to identify the most reliable pose for each tool.

4 Experiment

To evaluate our approach, we compare its performance against the original GraspNet model, which serves as a benchmark. Specifically, the benchmark uses the official GraspNet implementation with the original pretrained weights, without being fine-tuned on our newly collected dataset. In contrast, our model starts from the same pretrained weights but is then fine-tuned on a custom construction-tool dataset containing domain-specific annotations. By juxtaposing the benchmark and our fine-tuned model, we can measure the impact on grasp prediction performance.

We first conduct robotic experiments to demonstrate that our predicted grasp poses can align well with simulation-world grasping. The success rate is calculated as the ratio of successful grasps to total attempts. A grasp is considered successful if the robot securely holds the tool without slippage, avoids collisions during both grasping and returning to the home position, and remains in stable contact with the tool throughout the entire motion. Failures are categorized into three primary types: (1) slippage during the grasping process, (2) collisions with the tool or environment, and (3) the tool dropping while the robot returns to the start pose.

4.1 Experimental Setup

The experiments were conducted in the Gazebo simulation environment using a UR5 robotic arm equipped with a parallel gripper. A RealSense D435 camera was employed for visual input, providing RGB-D data. The detailed experimental setup is depicted in Figure 5. All tools were placed flat on a table to simulate realistic conditions.

4.2 Evaluation Procedure

We tested both the benchmark and our fine-tuned model by predicting the top ten grasp poses (based on each model's grasp scores) for each tool, then executing each

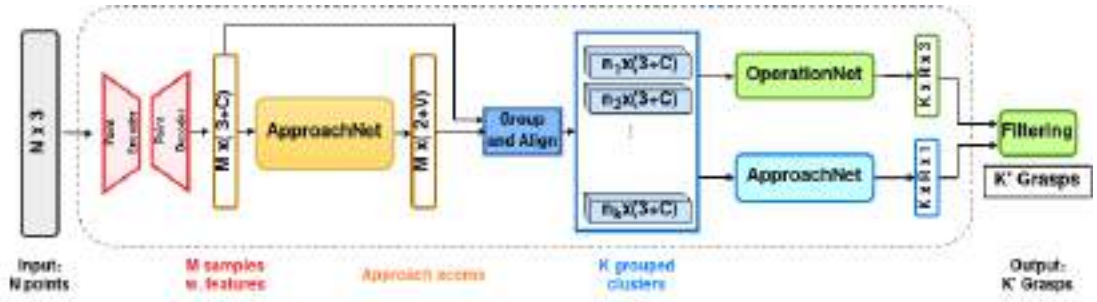


Figure 4. The overview of Graspnet-baseline [8] network

pose in simulation. To determine whether a grasp was successful, we checked:

1. Whether the predicted grasp pose lay within the designated "robot grasp region" of the annotated tool model.
2. Whether the grasp was maintained without slippage throughout the approach and retraction phases.
3. Whether no collision occurred between the robot and the tool (or the environment) at any point.

Any violation of these conditions such as grasping outside the annotated region, colliding with the tool, or dropping the tool during motion was recorded as a failure. In addition to evaluating the top 10 highest-scoring grasp poses, we also tested the highest-scoring pose specifically to check if the model's top-ranked grasp was valid. This procedure provides insight into each model's robustness and flexibility for a range of grasp candidates.

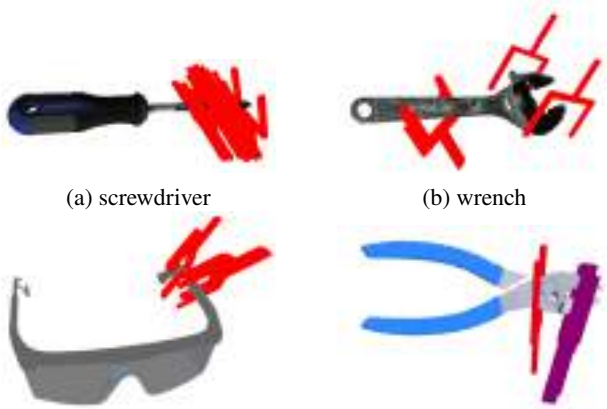
Figure 5. The experiment scene in Gazebo

5 Results

5.1 Benchmarking with GraspNet-baseline

Tables 2 summarizes the results of the benchmark model. The benchmark model achieve a success rate of 30% . For certain objects such as the screwdriver and plier, it exhibits a high collision failure rate. Specifically, with the screwdriver, half of the top 10 grasps failed due to collisions. In particular, when using the original GraspNet model, many predicted grasps lie outside the designated robot-grasp region and often result in collisions with the object, which reduces the overall success rate.

Table 2. Benchmark results: Success rates for the original GraspNet-baseline (top 10 grasp scores)



Object	Success rate
Screwdriver	20%
Adjustable wrench	40%
Plier	20%
Safety glasses	40%

5.2 Performance of Our Fine-Tuned Model

The predicted grasp poses were visualized and are shown in Figure 6, demonstrating the fine-tuned model's ability to generate feasible and collision-free grasp predictions. The model consistently produced grasp poses within the annotated regions for all tools, ensuring that the predictions were both accurate and aligned with safety requirements. The next section presents the results of the experiments, evaluating the predicted grasp poses in successfully grasping the objects.

The predicted grasp scores for each tool are summarized in Table 3. The success rates of the two experiments are detailed in Tables 4 and 5. For the highest-scoring grasp poses, all tools achieved a success rate of 100%, indicating that the proposed dataset and the trained model can generate highly reliable grasp poses. For the top 10 scoring grasp poses, the success rates were 100%, 80%, 90%, and 100% for the screwdriver, adjustable wrench, pliers, and safety glasses, respectively, with an overall average success rate of 92.5%. These results demonstrate the effectiveness of the proposed dataset in training the model to predict accurate grasp poses.

Despite the overall high success rates, some failure cases

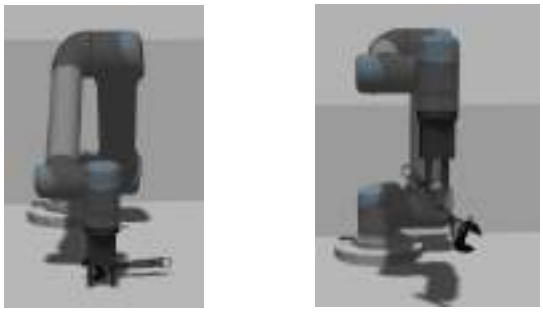
(c) safety glasses (d) plier

Figure 6. Qualitative results of the predicted grasp poses (top 10 highest-scoring grasps)

Table 3. Predicted grasp scores from fine-tuned model

Object	Highest	Top 10 average
Screwdriver	0.446	0.241
Adjustable wrench	0.680	0.467
Plier	0.385	0.376
Safety glasses	0.665	0.550

Table 4. Success rate of grasps with the highest grasp scores (fine-tuned model)



Object	Success rate
Screwdriver	100%
Adjustable wrench	100%
Plier	100%
Safety glasses	100%

Table 5. Success rate of grasps with top 10 grasp scores (fine-tuned model)

Object	Success rate
Screwdriver	100%
Adjustable wrench	80%
Plier	90%
Safety glasses	100%

were observed, particularly with the adjustable wrench, which achieved a success rate of 80% in the top 10 grasp experiments. Two failure cases occurred: one involved a collision between the robotic arm and the wrench during the grasping process, while the other involved slippage from the gripper. Figure 7 illustrates these two failure cases, with the left image showing a collision and the right image showing slippage.

The primary cause of these failures is the wrench's low height (1.4 cm) and flat geometry, which makes accurate grasp planning challenging. When the robotic arm executes the motion planning for grasping, the reduced thickness of the wrench can lead to misalignment, resulting in slippage or collisions. Similarly, the pliers slipped when lower-scoring grasp poses were tested. To further mitigate collisions and slippage, we plan to adopt a more rigorous collision detection strategy that discards grasp poses likely to cause interference. During the handover process, we will integrate reinforcement learning to optimize grasp stability and minimize the human operator's joint torque and displacement. By enhancing the robot's ability to adaptively maintain a secure grip while simultaneously reducing strain on the human arm, we aim to improve both safety and convenience in the tool handover process.

(a) collision (b) slippage

Figure 7. Failure cases of robotic arm grasping wrench

The computational efficiency of the approach is a critical factor for practical applications. The inference process requires an average of 1.6 seconds, while the motion planning process, including moving to the object, executing a stable grasp, and returning the arm to its home position takes 10.4 seconds. Although the current motion planning process takes longer to test the grasp stability. Integrating a reinforcement learning strategy during the handover phase will help reduce the overall planning time and enhance the system's for real-world deployments.

Overall, the experimental results confirm that the proposed dataset enables the GraspNet-Baseline model to predict reliable grasp poses. Despite occasional failures

with specific tools like the adjustable wrench, the dataset demonstrated its ability to adapt to diverse tool shapes and sizes. These results validate the applicability of the dataset and model for safe and accurate robotic grasping in construction tool handover scenarios.

6 Conclusion and Future Work

In this paper, we proposed a method for robot-to-human hand tool handover grasp prediction and developed a dataset that includes four types of handheld tools commonly used in the construction industry. The dataset consists of multi-angle RGB-D images and detailed annotations. During the annotation process, we introduced a method to distinguish between human and robotic grasping regions, ensuring that the robotic arm predicts grasp poses concentrated on the potentially dangerous end of the tool. This approach minimizes safety risks during human handling by keeping the safer end of the tool accessible. Furthermore, we trained the dataset using the GraspNet-baseline model and validated the predicted grasp poses in a simulation environment. The experimental results demonstrated that our dataset aligns well with grasping requirements.

Despite the promising results, there are several limitations. First, the study is based on simulation experiments with a relatively limited dataset. The dataset doesn't capture the diversity of tools in real-world construction sites (e.g., variations in covers, handles, and materials), which may affect the model's generalizability. We plan to expand the dataset by incorporating a wider range of tool types and shapes, and to conduct real-world experiments to validate the transferability.

Finally, while the study focuses solely on grasp prediction, we acknowledge that human-robot interaction factors such as grip force control and handover timing are critical for ensuring safe tool handover in dynamic construction environments. In our future work, we plan to integrate sensor-based feedback (e.g., tactile sensors for grip force and vision-based human motion tracking) and adaptive control algorithms to dynamically adjust the handover process. This approach will not only enhance the grasp prediction module but will also optimize the overall handover process, providing a more robust and practical solution for real-world applications.

Overall, by addressing these limitations, our work aims to advance the state-of-the-art in robotic tool handover and bring the approach closer to practical deployment in real-world human-robot collaborative tasks.

Abstract – Maintenance, repair, and replacement (MRR) strategies for bridges are critical requirements for infrastructure management, demanding effective decision-making to balance cost and performance objectives. This research presents an automated decision-making tool designed to optimize long-term scheduling of MRR strategies, addressing the complexities of multi-objective problems in bridge management. The tool integrates performance modeling with a modified genetic algorithm to generate optimal MRR plans, ensuring efficient resource allocation while maintaining structural integrity. A case study demonstrates the tool's application, predicting bridge deterioration and proposing cost-effective MRR actions under performance-based contracting frameworks. Results highlight significant cost savings and enhanced bridge serviceability through timely interventions. While the tool currently focuses on bridge decks, it establishes a foundation for future enhancements to include additional bridge components and broader infrastructure networks. This study advances automated MRR scheduling by offering a robust solution for sustainable bridge management.

Keywords – Automation; Decision-Making; Maintenance, Repair, and Replacement (MRR); Optimal MRR Strategies; Long-Term Scheduling; Modified Genetic Algorithm (GA); Sustainable Bridge Asset Management; Infrastructure Management

1 Introduction

The optimization of bridge maintenance, repair, and replacement (MRR) strategies has gained substantial attention in infrastructure management, especially with the introduction of automated decision-making tools that enhance scheduling efficiency. These approaches utilize various mathematical models, algorithms, and data-driven techniques to assess the optimal timing and scope of MRR interventions for bridges. Predictive algorithms further enhance decision-making by identifying optimal MRR strategies based on projected deterioration. The study by Bolukbasi et al. [1] presents an optimization model that employs deterioration curves to forecast the degradation of bridge components, allowing for more timely and effective scheduling of rehabilitation activities. In a similar vein, Alsharqawi et al. [2] introduced an integrated condition rating and forecasting methodology to provide accurate condition assessments for bridge decks. This dual-method approach allows for a refined understanding of bridge deck health, contributing to effective long-term scheduling and resource allocation for MRR strategies. Furthermore, Neves et al. [3] proposed a probabilistic optimization model that combines preventive and essential maintenance actions, underscoring the value of a hybrid approach in optimizing bridge maintenance costs while maintaining safety standards.

Implementing performance-based contracting (PBC) has emerged as a valuable approach to bridge maintenance, focusing on setting specific performance metrics and outcomes rather than prescribing maintenance actions. This approach incentivizes contractors to meet defined service levels, often resulting in more efficient use of resources and improved bridge performance over time. Alsharqawi et al. [4] highlight the advantages of PBC in maintaining transportation assets, particularly bridges, by setting outcome-focused targets that contractors must meet to fulfill their obligations. Similarly, performance-based approaches in bridge maintenance have been shown to support innovative solutions, including the use of advanced materials and real-time monitoring systems, which help contractors maintain the infrastructure within specified parameters [5]. The use of PBC aligns with the goals of long-term scheduling in bridge maintenance as it provides structured, measurable goals that guide the maintenance schedule, allowing for optimized resource allocation and enhanced reliability of bridge infrastructure over its lifecycle [6].

2 Literature Review

Automated decision-making tools and frameworks play a crucial role in optimizing the long-term scheduling of MRR for infrastructure, especially for bridge networks. These tools address complex, multi-objective problems involving cost, reliability, traffic flow disruption, and network performance, among others. Multi-objective models in bridge maintenance scheduling often aim to minimize both maintenance costs and traffic delays. For instance, Mao et al. proposed a bi-level programming model that minimizes traffic delays while maximizing the number of bridges maintained within budget constraints. By using a simulated annealing algorithm, the model has shown effectiveness in reducing maintenance costs and traffic disruptions [7]. Another approach, developed by Bocchini and Frangopol, introduces a probabilistic framework utilizing multi-objective genetic algorithms for preventive maintenance scheduling across a highway bridge network. Their model optimizes between cost and network performance, offering bridge managers a Pareto front of solutions to balance engineering and economic considerations [8]. Montazeri and Touran propose a reliability-based decision-making framework, emphasizing the importance of life-cycle performance and maintenance costs. Their model aids bridge managers in evaluating the best repair and replacement strategies across a bridge's lifespan, considering structural specifications and budget limitations [9]. Computational models help optimize bridge maintenance schedules under uncertainty. Liu and Frangopol developed a probabilistic maintenance planning model using Monte Carlo simulations to address uncertainties in bridge deterioration, which improves prediction accuracy and provides confidence-based maintenance solutions [10]. For network-level optimization, Orcesi and Cremona introduced a genetic algorithm-based model that considers the bridge's position within a transportation network, which ensures optimal resource distribution and maintains the level of service across the network [11].

An important aspect of automated MRR tools involves balancing cost and reliability. Frangopol et al. demonstrated how integrating reliability-oriented models with cost analysis could enhance bridge maintenance planning by identifying economically viable MRR schedules that ensure safety over the structure's lifetime [12]. This approach aligns with the work of Liang et al., who developed decision criteria based on cost-benefit theory to maintain bridge deck pavement, underscoring the importance of a balanced approach in prioritizing both safety and budget considerations [13]. Lee et al. developed a preference-based maintenance scheduling method tailored for bridges in Korea, balancing life-cycle costs with bridge performance. Their multi-objective optimization model allows for stakeholder preferences, helping decision-makers choose cost-effective maintenance strategies [14]. The integration of innovative decision support model under performance-based contract settings has advanced MRR scheduling significantly. Alsharqawi et al. developed a model capable for budget optimizing of MRR decisions under PBC settings. Implementing the model enables contractors to execute various MRR plans under different budget and performance requirements, where each resulting plan is optimal along the contract period [15], [16].

In recent years, the complexity of bridge MRR scheduling has underscored the need for advanced automated tools that leverage algorithmic optimization to streamline decision-making. Traditional approaches to MRR scheduling are often constrained by manual assessments and simplistic cost-benefit analyses, which may fall short in capturing the dynamic and multi-faceted nature of bridge deterioration and maintenance requirements. An automated, algorithm-based tool can enhance this process by rapidly processing large datasets, predicting deterioration with high accuracy, and generating optimized schedules that minimize maintenance costs while maximizing bridge reliability and performance. This data-driven approach to MRR scheduling is essential for infrastructure managers seeking to allocate resources effectively, reduce traffic disruptions, and ensure the long-term safety and functionality of bridge networks.

3 Development of Automated Tool

The automated decision-making support tool inputs, tools, techniques, and outputs are illustrated in Figure 1 and discussed in the following sections. The proposed tool in this paper considers bridge deck in particular because it deteriorates faster than other components due to its direct exposure to traffic in addition to the external environmental factors (e.g., freeze-thaw cycling) [17], [18].

The development of the automated tool involves two key components: first, modeling the performance of the bridge deck, and second, optimizing the selection of MRR strategies.

3.1 Performance Modeling

3.1.1 Performance Evaluation

To evaluate current performance, assessing the condition of the bridge deck is essential. This assessment provides insights into the physical state of the infrastructure and an estimate of its remaining useful life

or maximum lifespan. Regular detailed inspections are conducted to identify significant defects and evaluate the extent of bridge deterioration. In North America, visual inspection and close observation of bridge elements are commonly used due to their low cost and minimal expertise requirements. If severe damage is identified during visual inspection, a more comprehensive condition survey is conducted using both destructive and non-destructive testing methods [2].

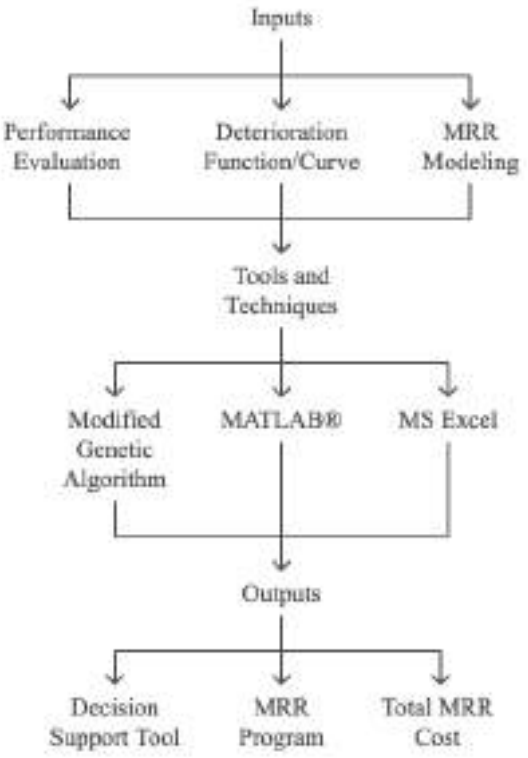

Figure 1. Development of the decision-making support tool inputs, tools, techniques, and outputs

3.1.2 Deterioration Function

To estimate element degradation over time, probabilistic or stochastic models are used, given that bridge deterioration follows a stochastic, rather than deterministic, process. Among these models, the Weibull distribution function (WDF) is frequently employed due to its advantages including: (i) it has been proven its effectiveness in representing concrete deterioration, and (ii) its parameters are straightforward to calculate [2]. Future performance rates are predicted based on the most recent inspection or condition assessment, providing a realistic representation of deterioration over time using Equation 1:

$$P(t) = 1 \times e^{ln(P_i)(t/t_i)^3} \quad (1)$$

where: P = component performance at time t; P_i = performance at time t_i; and t_i = inspection time.

3.1.3 MRR Modeling

MRR modeling involves identifying appropriate MRR strategies, estimating the resulting performance improvements, and calculating the associated costs. These MRR strategies are categorized into three types based on the bridge deck's performance (Table 1). For bridge decks in good condition, routine maintenance can be performed. Bridge decks with poor performance may require repair actions, such as increasing deck thickness through localized concrete repairs. For decks with critical performance levels, full deck replacement is recommended.

Modeling performance improvement and predicting the deterioration behavior of an asset after a MRR action is essential. The improvement values associated with each type of MRR relied on a study that was performed by Seo [19], as shown in Table 1. According to the literature review, performance is estimated to improve by 20% when repair actions are implemented to the bridge deck. In the case of bridge deck replacement, performance increases to approximately 90%. For maintenance actions, no performance improvement occurs, but this action slows the deterioration rate of the bridge deck, resulting in a gradual decline over time.

Calculating MRR costs is typically performed either as a fixed percentage of the initial construction or replacement cost, or as a unit cost. For instance, Seo [19] proposed predefined percentage-based estimates for different types of MRR, while Abu Dabous and Alkass [20] developed unit cost models for each MRR type. Each MRR action's unit cost includes direct costs, indirect costs, and a markup to cover contractor profit and contingency. Table 1 summarizes MRR action costs as a percentage of initial construction costs [19] and as fixed unit costs [20] , with unit costs adjusted to 2024 Canadian dollars for inflation.

Table 1. MRR strategies, improvements, and costs per strategy

MRR Strategy	Improvement	MRR Cost	
		% of initial construction	unit cost ($/m²)
Maintenance	0%	28.5%	$58.39
Repair	20%	65.0%	$1,098.89
Replacement	90%	100.0%	$1,438.72

3.2 Optimizing MRR Strategies

3.2.1 Long-Term Scheduling

As discussed earlier, integrating innovative PBC frameworks within a decision-making support methodology has significantly advanced MRR scheduling. There is a strong shift towards PBCs over traditional contracts for infrastructure management, including bridges, primarily due to cost savings. Additional advantages noted in the literature [21] include but not limited to more integrated services, improved asset management, and economies of scale. This approach incentivizes contractors to achieve specified service levels, often leading to more efficient resource use and enhanced bridge performance over time. Furthermore, the use of PBCs aligns with long-term bridge maintenance goals by providing structured, measurable objectives that guide the maintenance schedule, optimize resource allocation, and improve bridge reliability over its lifecycle [6]. Consequently, the proposed automated tool incorporates PBC settings.

3.2.2 Modified Genetic Algorithm

Since genetic algorithms (GAs) can provide a comparable level of accuracy in the area of global optimization while being more time efficient than conventional optimization techniques [22], they have been extensively used by many researchers in maintenance optimization problems for bridge management. Recently, Ghodoosi et al. [23], Xie et al. [24], Allah Bukhsh et al. [25], and Alsharqawi et al. [15] proposed models to find optimal maintenance and rehabilitation strategies using genetic algorithms. As a modification to the well-known GAs, several works started to design customized variants of the GA. These customized variants use multiple chromosomes with real numbers that represent the different parts of the solution for each individual rather than one chromosome. In addition, the GA operators are specially designed to fit the problem context. The modified GA starts with feasible individuals satisfying all constraints, which makes it easier to search for the optimal solution compared to the case of the original GA, where the feasibility of individuals might not be satisfied. It is worth noting that in this type of modified GA, a certain number of operators is defined and applied in all iterations; thus, the probabilistic nature of changing the individuals is removed, which reduces the number of parameters needed to be tuned. In this research, a modified GA is used due to its quick convergence and excellent performance, as in this modified GA, for each individual, a chromosome defines the potential MRR actions over the planning years. The chromosomes are generated in a way to satisfy the predefined performance thresholds. The population is replaced with a new random one in case of no improvement over several generations. The modified GA code is developed using MATLAB® software language and optimization toolbox.

In order to solve the MRR optimization problem, this algorithm starts by generating V individuals, each individual ($v \in V$) contains a random MRR strategy for each n year ($n \in N$). It sets the global total MRR cost to $+\infty$ and the global average performance to $-\infty$. In each iteration δ ($\delta \in \varphi$), the algorithm performs the following steps:

1. It calculates the yearly performance for each individual (p_v^n).
2. Then, it checks in each year if the yearly performance is within the limits and modifies the selected MRR strategy randomly as an attempt to fix any performance violation.
3. It calculates the average performance for each individual (P_v).
4. It calculates for each individual v the total MRR cost.
5. It identifies the local minimum total MRR cost and the local maximum average performance and uses them to update the global total MRR cost to $+\infty$ and the global average performance.

It is worth noting that the modified GA differs than the original GA in the following aspects: i) the generated population is feasible prior applying any operator; ii) the entire population is discarded if the optimal solution did not improve for iteration and a new population is generated randomly to allow for more diversity in the searching domain; and iii) the probability of crossover and mutation are eliminated. Crossover and mutation operators are applied in a different manner. In each iteration, the population is divided into subsets. Each subset has five individuals. The five individuals in the subset are ranked based on their fitness value. The best individual in the subset is selected and the five operators are applied on it. It should be noted that the first operator is do nothing which keeps the individual unchanged. Therefore, each subset of five individuals is replaced with a new subset containing the best individual in the subset and four new individuals.

3.2.3 Optimized MRR Program

As previously mentioned, bridge MRR actions are typically categorized into maintenance {2}, repair {3}, replacement {4} and no action {1} which is a do-nothing strategy. Specific MRR actions can be found under each category. With these four major categories, several combinations of actions can be generated over the analysis period producing large number of strategies or possible solutions. The longer the analysis period, the larger the search space is because the number of possible solutions equals to the number of MRR actions raised to

the power of number of years (i.e., analysis or contract period). For example, if the analysis period is ten years and there are four different MRR actions, the search space will be 1,048,576 (4^{10}). Accordingly, the modified GA-based optimization technique, as a non-linear mathematical modeling, is used to obtain an optimal or near-optimal solution from this large list of solution while meeting the needs and constraints related to the PBC settings. This approach can consider all possibilities and produce enhanced and robust solutions compared to the existing tools and simplified matrices typically used in practice.

The output from the automated tool is an optimized MRR program in which the MRR actions should be executed are determined, the performance prediction in each year is forecasted, and the calculations of the net present value (NPV) during the specified years of MRR plan is estimated. Furthermore, the deterioration curve forecasts the performance for the same duration. The performance of the bridge deck before and after MRR is computed, and performance values are determined based on the Weibull distribution function discussed earlier. The performance improvement is defined based on the type of the applied MRR action.

4 Application of the Tool

4.1.1 Description and Assumptions

A case study is discussed here as a proof of concept and illustration of the presented decision-making support model. The model is applied to a bridge located in Québec, Canada. Names and exact locations of the bridge are not given for confidentiality purposes as per agreements with data providers. An optimization scenario was carried out over the initial remaining life-cycle time of the bridge (till year 2040). The implementation of PBCs over periods of 10 years or more has proven to be an effective strategy for the sustained preservation of transportation networks. Additionally, the Australian experience with the 10-year contract in New South Wales (NSW) demonstrates that realistic PBC criteria and targets are both achievable and effective on a network-wide scale. For the MRR plan, a budget equals to $225,000 is set allowing for a possibility to cover the cost of replacing the bridge deck.

To run the tool, users must input the condition rating, construction year, year of the last inspection from the latest inspection report, and current year. The tool automatically calculates the current performance, utilizing its embedded deterioration function. Additional input variables are required to execute the decision-making optimization process. These variables include the duration of the MRR plan, budget constraints, interest rate (i=4% is used in this study), and performance thresholds. Moreover, MRR costs are incorporated based on the MRR modeling formulation, as showed in Table 1. Table 2 summarizes the case study data attributes. The subsequent section will present a set of trade-off list detailing MRR actions applied.

Table 2. Case study data attributes

Bridge Attribute	Input
Construction Year	1965
Age	58
Construction Cost	N/A
Area (square meter)	152
Inspection Year	2021
Performance at Inspection Year	63.99%

4.1.2 Results and Discussion

The 2021 inspection assessed the bridge deck's physical condition at 63.99%, indicating poor performance during that year. Using performance modeling, deterioration curves were mapped, starting with the ideal deterioration curve (representing ideal performance), knowing that the bridge was constructed back in 1965. To create the deterioration curve (performance without intervention), data from the 2021 inspection survey was used, and the curve was plotted using Eq. 1, with t_i corresponding to 2021. Implementing the automated tool on the case study allowed for the reconstruction of the updated deterioration curve (performance with MRR intervention).

The implementation of the modified GA-based optimization technique presented earlier provides a variation of MRR strategies applied at various years throughout the time horizon of the described scenario. Figure 2 shows the bridge deck performance without and with MRR interventions after applying the developed tool. The present worth of the optimized scenario for the case study is also calculated. The total MRR actions costs equal to $1,686,557.11. Table 3 presents the optimal MRR program developed from applying this tool where the MRR action and its corresponding cost are shown. In this case, it is suggested that the contracting agency tendering the contract can allocate a budget of no more than the total MRR actions costs. The budget assignment is based on the developed decision-making support tool which minimizing the total cost while maximizing the performance.

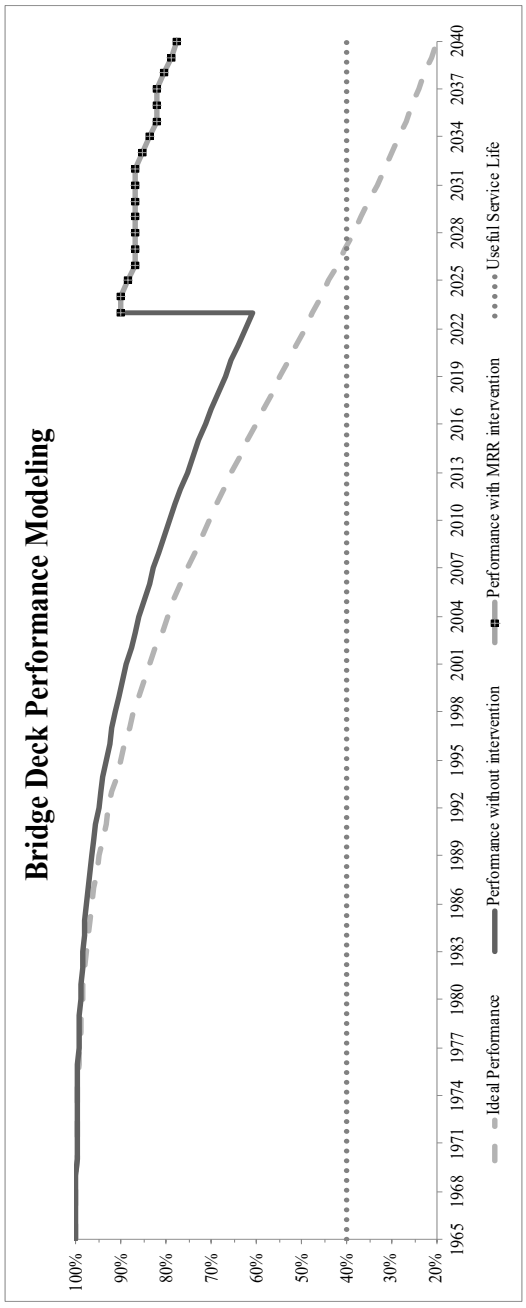

Figure 2. Case study performance modeling, including curves without and with MRR interventions

Based on the performance monitoring data, actual performance may vary compared to the predicted from the deterioration curve. Using real time data after performing inspections, the MRR program may be updated by running the tool again. The significance of this is that re-optimization of the MRR program using real time data and continuous validation of deterioration curve may result in cost saving and higher profit to the contractor in case of overestimating the deterioration rate and consequently scheduling the MRR action earlier than needed.

Table 3. Case study optimal MRR program

Year	MRR Action	MRR Cost	Total MRR Cost
0			$ 1,686,557.11
1	{4}	$ 210,274.46	
2	{2}	$ 4,591.20

5 Conclusion

The majority of existing decision-making methodologies for bridge management aim to balance the dual objectives of maintaining or extending bridge serviceability while minimizing total costs. These inherently conflicting goals significantly complicate the decision-making process. To address this bi-objective optimization challenge, this research has developed an automated decision-making tool for the long-term scheduling of MRR strategies. The convergence of probabilistic models and multi-objective optimization approaches in this study underscores the advancements in MRR planning, enhancing both efficiency and effectiveness. Further, research findings concluded that integrating the PBC approach into the MRR decision-making process offers better results in long-term plans. The developed tool not only achieves substantial cost savings but also prolongs the functional lifespan of bridges through timely and strategic maintenance interventions. By enabling bridge managers to tailor MRR strategies to various conditions and constraints, this tool promotes sustainable and efficient resource utilization while ensuring the serviceability and structural integrity of bridge infrastructure over time.

However, the research does have certain limitations: (1) the study primarily focused on bridge decks, without extending the tool's application to other bridge components or related assets; (2) the effects of MRR actions on bridge performance were restricted to maintenance, repair, and replacement strategies; (3) user and external costs (e.g., user delays) associated with MRR actions were excluded from the calculation of MRR unit costs, though these costs could be incorporated in future studies; and (4) the 10-year planning horizon was chosen to align with common performance-based contracting practices, yet it limits the direct comparison of predicted MRR plans against the actual long-term degradation of bridge decks.

To address uncertainties inherent in long-term forecasts, the tool supports periodic re-optimization with updated inspection data, and future work will incorporate extended monitoring and sensitivity analyses to further validate model predictions. Moreover, future research could expand the scope of the tool to encompass additional bridge elements and broader infrastructure networks, further enhancing its applicability and impact. Additionally, future work could integrate real-time sensor data from structural health monitoring systems to dynamically update the predefined deterioration models.

Abstract -

Prefabrication of building components holds the potential to revolutionize the construction industry. Prefabrication consists of manufacturing building components, modules, and other elements in a factory to be shipped and installed on a construction site. Prefabricated components have been produced for various applications including precast concrete panels for new construction and exterior wall retrofits. The manufacturing process has seen much innovation in recent years; however, the installation process has seen minimal advancements. A real-time evaluator (RTE) was developed to reduce the installation cost of prefabricated components by reducing installation time, decreasing rework, and improving accuracy. The RTE uses off-the-shelf hardware and novel algorithms to assist erectors with component installation by measuring the real-time positions of connections and prefabricated components, providing installation guidance through a graphical user interface, and monitoring the accumulated installation errors. An overview of the RTE and the proposed workflow is presented. Previous on-site demonstrations provided valuable feedback from users on the potential areas for improvement of the system. One common request was real-time measurement of component orientation during lifting, a process that previously required that the component remain stationary while the laser tracker cycled through target prisms. This paper will present the incorporation and testing of a real-time orientation measurement system as it was implemented into the RTE, allowing for measurement of component orientation during movement.

Keywords -

prefabrication, installation, real-time, automation, accuracy, time

1 Introduction

Prefabrication of building components holds the potential to revolutionize the construction industry [1]. Prefabrication consists of manufacturing building components, modules, and other elements in a factory to be shipped and installed on a construction site [2]. Manufacturers can maximize production efficiency and better control quality by constructing elements within a controlled environment [3].

Modern surveying instruments, such as robotic total stations, expedite, automate, and improve the accuracy of building and land surveying. Modern instruments also include reality capture devices such as 3D laser scanners that can accurately measure the surrounding area. However, these devices are more commonly used to survey the as-built conditions after construction is completed. Recent research has developed algorithms to automatically generate as-built 3D models using laser scanning [4, 5, 6]. Methods like these are often utilized immediately after the components are placed and construction is completed. A more proactive use of the technology would be the active monitoring of the quality of construction compared to the design as it is assembled. By addressing errors as they occur in the construction process, the total construction time and cost can be reduced.

An installation tool that provides corrective guidance in real-time to reduce installation time, decrease rework, and reduce cost would revolutionize the construction industry. In other industries such as manufacturing, laser trackers are used to precisely assess and guide the assembly process. For example, in the aviation industry, three laser trackers measuring targets attached to a plane wing have been used to generate real-time guidance during attachment of the wing to the aircraft body [7]. Other machine vision techniques are used during the robotic assembly of cars [8]. Adaptation of these methods in construction applications could enable real-time evaluation of components during placement, providing guidance for users such that errors are addressed in a timely fashion.

To innovate the installation process with modern technologies in the construction industry, a real-time evaluator (RTE) was developed to reduce the installation cost of prefabricated components by reducing installation time, decreasing rework, and improving accuracy [9]. The function of the RTE is illustrated in Figure 1. The RTE uses developed software solutions with off-the-shelf hardware

to assist erectors in completing a prefabricated component installation by measuring the real-time positions of connections and prefabricated components, providing installation guidance through a graphical user interface, and monitoring the accumulated installation errors. Previous on-site demonstrations provided valuable feedback from users on the potential areas for improvement of the system. One common request was real-time measurement of component orientation during lifting, a process that previously required that the component remain stationary while the laser tracker cycled through target prisms [10].

This paper will present the incorporation and testing of a real-time orientation measurement system as it was implemented into the RTE, allowing for measurement of component orientation during movement. The paper makes the following primary contributions to the body of knowledge:

- Laboratory experiments show that some off-the-shelf inertial measurement units (IMU) have a high-enough degree of orientation measurement accuracy to provide real-time orientation estimates to guide the crane-positioning of large-scale building components while still meeting typical tolerances. A laser tracker system is still required to meet positional accuracy requirements.
- Comparisons of measured changes in orientation of some off-the-shelf IMUs with advanced laser 6-degree-of-freedom measurement systems show good agreement even during highly dynamic movements.
- Laboratory experiments proved that a system integrating a laser tracker measuring a retroreflector prism position and an IMU measuring orientation can successfully track the position and pose of a rigid-body during typical construction crane-installation processes with an accuracy meeting the typical requirements for tolerances.

1.1 Related Work

This work aims to supplement the prior research work that only utilized a single laser tracker to (1) track a single target during movement with all motion assumed to be rigid body translation and (2) measure three retroreflector targets while stationary within a total time of 10 seconds to determine pose [10]. This paper presents an integrated system that uses (1) a laser tracker to measure the real-time position of a component based on the measured location of a retroreflector prism and (2) an inertial measurement unit (IMU) to measure real-time orientation of the component. The addition of the IMU enables real-time estimation of the pose of the measured component without having to stop motion and wait for approximately 10 seconds.

Prior literature review of work on crane lifting operations has determined that little research is conducted to track the position and orientation of the lifted object specifically for high-precision installation purposes [11]. Prior work has utilized Radio Frequency Identification (RFID), Global Positioning System (GPS), laser scanning, sensors, photogrammetry, and more to estimate the location and orientation of a crane payload. Most applications were for the purposes of path planning, blind lifting, and safety.

For example, previous work utilized GPS and RFID to monitor the position of the crane for safety purposes [12]. However, these systems were not accurate enough for the typical tolerances required for precise installation. Other work consisted of using vision-based systems to determine the 3D position and pose of a component from images [13]. However, the accuracy of the vision-based system depends on the distance per pixel which is affected by camera specifications and distance to target. For large construction applications, sight distances will likely be large (more than 10 meters), and therefore, the accuracy of the vision-based system to determine precise position and pose of the component during lifting may not be adequate without significant investment of multiple camera systems.

For RTE, the system uses an off-the-shelf robotic laser tracker, which many construction companies performing large-scale crane installation of components already have access to. The use of a laser tracker also ensures that positional accuracy of the component location can be measured within 3 mm which is the smallest typical tolerance for the installed position of a component. The addition of the IMU enables real-time estimates of component orientation during movement; however, it is not intended to completely replace the highly-accurate method of measuring component orientation through measurement of three retroreflector targets attached to the component determining pose of the rigid body.

2 Methodology

2.1 System Overview

The existing RTE system utilizes a robotic multi-station controlled by novel software including communication protocols to measure the locations of three reflectors attached at known distances from the corners of the object to be measured. To measure the orientation of the object, the laser tracker sequentially cycles between the three prisms, measuring their positions in 3D space. The time to cycle between all prisms takes roughly 10 seconds. This positional data is then used to establish a frame of reference, allowing for the calculation of the panel's position and orientation [10]. The measured orientation is compared to the target rotation matrix, which is derived from the digital twin model of the expected construction configuration. This difference determines the necessary translations and rotations required for the panel to align with its goal pose.

Figure 1. A real-time evaluator to expedite prefabricated component installation. It provides real-time guidance on installing prefabricated components. [9]

In the current setup for initialization, it is assumed that the panel remains stationary during the orientation measurement cycle, which takes approximately 10 seconds to complete because the total station must turn to, search for, and measure each of the three prisms. This first cycle provides the real-time position and orientation at that time frame. Once the first cycle is completed, the tracker locks on to one of the isolated prisms and updates the real-time translation values from the centroid of the panel assuming all movement is rigid body translation. While this system is highly accurate, it has a significant limitation: it can only update the panel's translation in real time when the panel is moving in 3D space. To calculate the rotation, the panel must be held stationary, and the laser tracker must complete a full cycle through the three prisms again, causing latency. This results in a slower update rate for rotation data and presents a bottleneck in dynamic scenarios where faster orientation updates are necessary. Because of this limitation in measurement speed, all motion is assumed to be rigid body translation while the panel is moving. Additionally, the assumption that the panel remains stationary during cycling through prisms is critical. In reality, if any movement occurs during measurement of the three targets, the calculated component orientation will not be accurate. To address these limitations, there is a need to integrate an Inertial Measurement Unit (IMU) into the system, which can provide approximate orientation estimates in real-time during the panel movement, improving the overall responsiveness of the system.

2.2 Proposed System

2.2.1 IMU Integration

In the proposed system, the IMU is integrated as a complementary sensor to address the limitation of the existing methodology, which requires the object to remain stationary for orientation calculation. The IMU provides approximate orientation updates while the object is in motion, significantly enhancing the system's responsiveness. Our system has two separate coordinate frames (described as RTE and IMU). In order to integrate the IMU's rotation matrix which is determined about its local body frame to the RTE, it is first aligned with the panel to establish the necessary transformation tree (identity matrix in our case). This alignment allows both systems to compute the rotation of the panel with respect to the system RTE frame. The goal pose for the panel is derived from the digital twin model. Once the complete transformation tree is established, the IMU is initialized in the RTE frame using orientation data obtained from the laser tracker and prisms. The algorithm calculates the panel's orientation and reports the difference between its current pose and the goal pose (from the digital twin). This initialization step ensures the IMU's measurements are accurately calibrated

and aligned with the reference frame of the system.

The IMU's orientation estimates are fused with the laser tracker's translation data to create a hybrid system. While the panel is in motion, the laser tracker system provides real-time translation measurements but cannot update rotation data due to its reliance on target cycling while the component is stationary. The IMU addresses this gap by providing real-time approximate orientation updates, which are less precise but sufficiently accurate to ensure continuous monitoring of the panel's orientation. The laser tracker, on the other hand, provides precise but intermittent orientation updates when the panel is static. By synchronizing and fusing data from these two sensors, the system benefits from the high accuracy of the laser tracker for precise orientation correction and the IMU's ability to offer continuous updates during motion. This hybrid approach ensures both precision and responsiveness, enabling dynamic tracking and adjustment of the panel's pose in real-time scenarios. In order to fuse the readings from both devices, it has to be calculated on the same reference frame. IMU and RTE's measurements are synchronized using the following transformation tree:

R_{imu} = rotation_imu
$R_{\text{imu_panel}} = I$
$R_{\text{RTE_m}} = R_{\text{mat_RTE}}$
$R_{\text{goal_m}} = I$
$R_{\text{final_imu_m}} = R_{\text{imu}} @ R_{\text{imu_panel}} @ R_{\text{RTE_m}} @ R_{\text{goal_m}}$

2.2.2 Communication System Enhancements

In the previous system, RTE used Bluetooth to communicate between a laptop computer running the software and the MultiStation. However, due to range limitations and constraints of concurrent active connections with Bluetooth, it was decided to switch to a Wireless Local Area Network (WLAN). The switch to WLAN enables seamless, fast, long range communication. Attempts to fuse data collected from the Multistation and IMU simultaneously via Bluetooth encountered communication issues. The switch to WLAN connection facilitates the synchronization and fusion of time-stamped sensor data from both systems thereby enhancing the overall performance of the system for field trials at actual construction sites where the range of Bluetooth could have been a limiting factor.

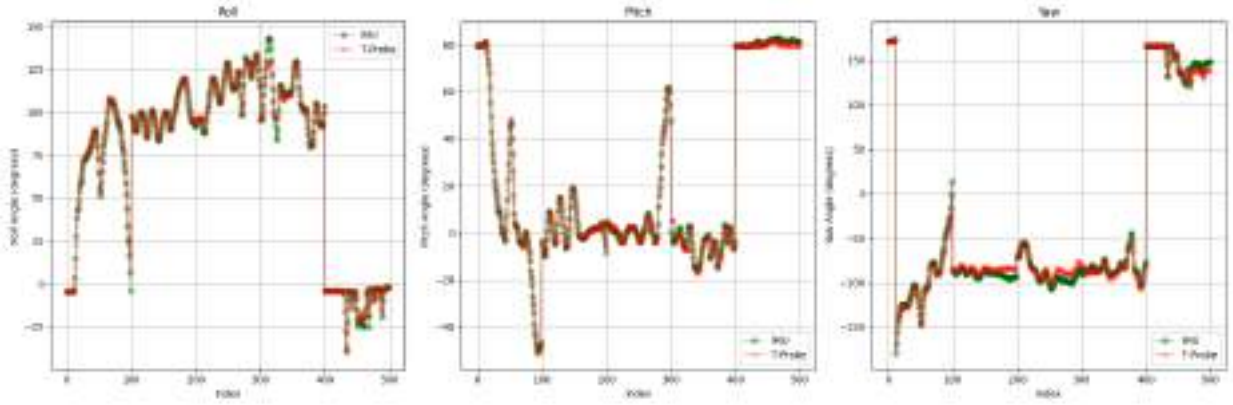
2.3 Lab Scale Experiments

For sensor selection, tests were conducted to compare the performance of multiple IMUs against the output of a Leica Absolute Tracker AT960 paired with T-probe. However, only the performance of the selected IMU is reported in this paper. The AT960 paired with a T-probe gives highly precise measurements of change in orientation (±15 microns) and translation of any object to which the T-probe is rigidly attached. For a final integration test, the performance of the IMU was evaluated using the Leica Nova MS60 Multi-Station in a lab-scale mockup panel installation setup. The algorithms were written in Python and interfaced with IMU and the robotic total station through WLAN connection automated using Leica GeoCOM commands. The following sections describe the scenarios in which the IMU was tested.

2.3.1 Experimental Setup - Sensor selection

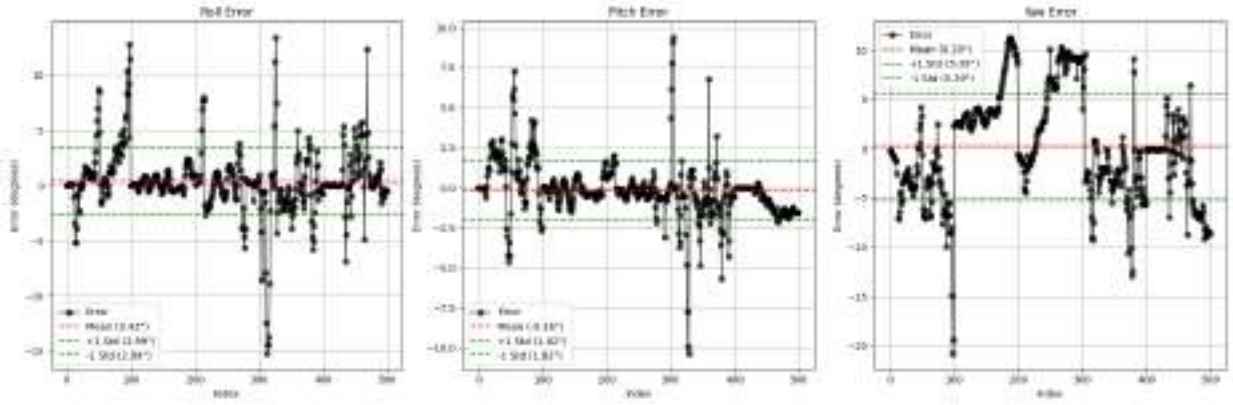
The experimental system consists of a laser tracker and an IMU sensor (x-IMU3) integrated to achieve faster orientation estimation within the semi-loop cycle. The laser tracker is used for precise 3D position and orientation measurements by cycling between three trackable targets. While this method ensures high accuracy, it suffers from an average latency of 10 seconds per update, necessitating the integration of the IMU for quicker approximate orientation estimates.

Table 1. Static accuracy RMS error for a 360° rotation around each axis from the datasheet



Characteristic	Static Accuracy
Inclination	0.5° RMS
Heading	1° RMS

Table 2. Dynamic error metrics for Roll, Pitch, and Yaw from our lab scale test



Metric	Roll (°)	Pitch (°)	Yaw (°)
Mean Error	0.43	-0.16	0.20
Standard Deviation	2.99	1.82	5.39

The IMU sensor was chosen based on the following criteria:

- **Accuracy and drift testing:** The IMU demonstrated high static accuracy as seen in Table 1, ensuring reliable orientation measurements during stationary or near-stationary conditions. To evaluate the dynamic accuracy, the IMU was mounted on T-probe and tracked using Leica's Absolute Tracker AT960, a 6DoF laser tracker technology. Data from AT960 and IMU were timestamped and synchronized. A comparison lab scale test between the AT960 and IMU was conducted over a duration of 5 minutes and repeated 3 times. From the results of this test, we concluded that the IMU is reliable enough to provide approximate orientation in highly dynamic scenarios. As shown in Figure 2b the maximum error was observed on the yaw axis, with a standard deviation of

(a) Ground truth vs IMU Data

(b) Error, mean and Standard Deviation

Figure 2. Dynamic accuracy tested using AT960 Laser Tracker as ground truth

5.39. Given that the IMU can provide data at a frequency of 10 Hz or better, it is not expected that the high standard deviation will be an issue since the result will simply be averaged over time. Additionally, the dynamic movements during the test were executed at a significantly higher severity than expected during crane lifting of prefabricated construction elements.

- **Dynamic testing (translation only):** In a translation only dynamic test, the IMU was mounted on a gantry robot system and translated in a square path with zero rotation. The highest average drift was observed in the yaw axis, with an average drift of 2.3 degrees over a period of 10 minutes. For crane-lifted installation of prefabricated components, a drift in yaw axis rotation of over 2.3 degrees in 10 minutes is not insignificant. However, the IMU can be recalibrated to eliminate drift each time the orientation is measured using the object-stationary target-cycling method.

- **Low latent wireless communication and software support:** The x-IMU3 sensor's customizable wireless data stream and its compatibility with Python API simplified its integration into the existing system, allowing seamless data acquisition and processing in rotation matrices, and other formats. Initial tests revealed magnetic drift near ferrous metals, which affected the accuracy of the IMU's rotation values. This issue was subsequently resolved by disabling the magnetometer readings.

2.3.2 IMU integration with RTE:

From the validation tests, we finalized x-imu3 as our choice of sensor for semi-loop integrated real-time orientation approximation. These tests were conducted using a lab-scale setup constructed for previous testing of the RTE system [9]. Figure 3 shows a representation of the lab-scale setup that depicts a 1/3rd scale overclad panel retrofit. Six panels can be assembled on a metal frame that supports a layer of oriented strand board, which serves as a working surface. Twelve connections can be attached to the working surface to serve as hanging points for the six panels. A simulated crane is located on top of the metal frame and can be operated behind the frame to move panels up

and down and left and right. While panels are moved with the crane, a set of three retroreflector prisms is attached to the panel. A multi-station is set up at least 5 meters away from the test frame to measure prisms. For the purpose of these experiments, the IMU is rigidly attached directly to the panel to be measured.

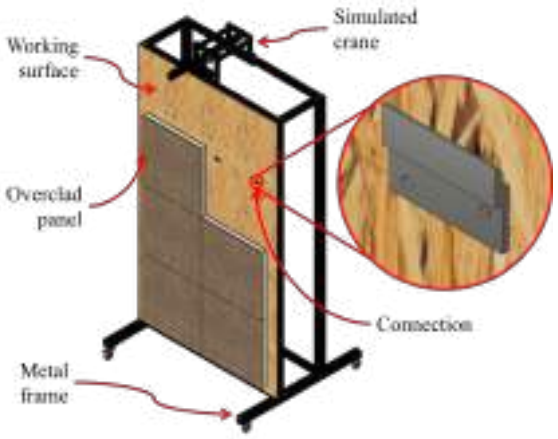


Figure 3. Representation of the lab experiment setup [9]

For the final integration of the IMU into the semi-loop system, a total of five tests were conducted following this procedure:

1. To simplify the test procedure, the panel is attached to a mock crane setup and the experiment begins with the panel located in the goal pose (i.e. the location where the panel should be installed).
2. The coordinates of the three prisms are measured using the multi-station. These measurements provide the position and orientation of the panel required to reach the goal pose based on the digital twin. This initial cycle takes 10 seconds on average.
3. The IMU, which reports orientation in the global frame, is initialized using the previous measurements from the RTE. A coordinate transformation tree is established to align the IMU and RTE's data with the digital twin's reference frame.
4. After initialization, the panel is moved away from its initial pose and RTE tracks a single prism, providing real-time translation updates, while the IMU delivers approximate orientation updates needed to achieve the goal pose.
5. After movement, the panel is brought to a stationary state, and the RTE algorithm commands the multi-station to cycle and measure the coordinates of the three prisms.
6. Upon completing the cycle, the RTE calculates and reports the precise rotation and translation needed to reach the goal pose. Simultaneously, the IMU's readings are timestamped and recorded and the offset value is observed.

The accuracy of the algorithm was evaluated by the difference between the rotation angles calculated from the IMU and those calculated from the RTE algorithm. The measured error in rotation angle was determined by subtracting the angle measured by the RTE in Step 2 from the angle measured by IMU in Step 6. Table 3 below summarizes the resulting Euler Angles observed from our tests, comparing the IMU's performance against precise measurements from the RTE system.

2.4 Results

The results of the experiments highlight the differences between the systems with and without IMU integration. The IMU integration significantly enhances the system's capability by eliminating the need for precise measurements from the RTE mid-cycle while the panel was in motion. Previously, the system did not provide orientation updates when the panel was in dynamic movement, as it required the panel to remain stationary to provide orientation updates. With the IMU integrated, real-time orientation updates became possible even when the panel was in motion, providing a significant improvement in responsiveness.

While the IMU does not reduce the cycle time for precise measurements conducted by the RTE, it complements the system by enabling approximate dynamic orientation updates during motion. This capability ensures that orientation data is continuously available, improving the system's utility in dynamic scenarios. The trade-off between accuracy and speed is analyzed, showing that the IMU effectively supports the laser tracker by maintaining acceptable accuracy levels for dynamic orientation tracking. The integration approach shows promise for scaling the system to larger applications. Future implementations could involve integrating multiple sensors to handle more complex scenarios and adapting the system for deployment in real-world environments.

However, the integration of the IMU introduces challenges such as drift, calibration, and maintaining accuracy under varying conditions. The lab-scale tests were conducted for durations of less than 10 minutes, suggesting that extended testing may help mitigate drift over longer periods. Nonetheless, the accuracy of the IMU is not sufficient enough to replace precise measurements from the RTE system, reinforcing its role as a complementary tool rather than a standalone solution.

Table 3. RTE vs IMU lab scale test results

Test	Angles (°)								
	RTE			IMU			Error		
	Roll	Pitch	Yaw	Roll	Pitch	Yaw	Roll	Pitch	Yaw
Initialization	0.00	0.00	0.00	0.00	0.01	0.01	0.00	-0.01	-0.01
Test 1	-26.05	-0.60	-0.30	-26.77	-1.08	-0.03	0.72	0.48	-0.27
Test 2	-0.09	-15.19	-0.11	0.19	-15.24	-0.56	-0.28	0.05	0.45
Test 3	0.01	25.16	0.06	-0.43	24.98	0.81	0.44	0.18	-0.75
Test 4	1.20	1.03	-21.93	-2.19	2.67	-21.61	3.39	-1.64	-0.32

3 Conclusions

An Inertial Measurement Unit (IMU) was successfully integrated into a Real-Time Evaluator (RTE) system to measure the approximate orientation of crane-lifted components during movement. Previous versions of the RTE required that the component be held stationary to measure the location of three targets attached to the component. After IMU integration, approximate orientation can be measured in real-time without stopping the movement of the component. However, at the current levels of tested accuracy, we do not expect the IMU to completely replace the practice of precisely measuring stationary pose of the component by measuring three targets attached to it's rigid body to determine orientation. Lab experiments were conducted to evaluate IMU performance compared to a highly-accurate six-degree-of-freedom measurement system. Both static and dynamic laboratory experiments showed errors in roll- pitch, and yaw less than 0.5 deg compared to highly-accurate 6DoF laser tracking devices. The IMU was then integrated with the RTE, and an experiment was conducted to verify the integration of the IMU within the workflow of measuring a crane-lifted component as it is installed, providing real-time guidance to installers.

The results of the research prove that IMUs can be used as supplementary devices to measure an approximation of the roll, pitch, and yaw of crane-lifted components. However, for accurate assessments of plumbness and levelness, the IMU measurements alone are not accurate enough to replace conventional methods. Based on these results, the authors see a clear use case for the IMU to approximate orientation while the component is being moved. However, near the final installation point, more accurate methods of orientation measurement such as the previous method of cycled measurements of targets attached to the stationary component are required.

3.1 Future Research

Full-scale demonstrations, both in the laboratory and real-world environments, will be performed to assess the RTE's potential for improving installation efficiency. Future work will include testing the system at an actual construction site to quantify time savings and accuracy improvements on a full scale. Efforts will also focus on refining IMU accuracy over extended period of time, and exploring additional sensor integration to enhance the overall system capability. Additionally, advanced methods using artificial intelligence or machine learning may be explored to improve the accuracy and reliability of the IMU output, which may enable users to install only a single retroreflector on the lifted components and rely entirely on the IMU for orientation measurements, thereby reducing costs.

Abstract –

This study introduces an innovative robot-assisted 3D scene reconstruction approach featuring a fixed field-of-view (FOV) LiDAR-based depth camera. The approach integrates a quadruped robot with LiDAR-camera for depth measurement and for capturing RGB colour and texture. The RGB-D information is then used in SLAM to enable detailed 3D scene reconstruction and representation of as-built conditions. This hybrid system reduces the costs and operational limitations of traditional terrestrial laser scanning (TLS) while maintaining decent accuracy for downstream tasks such as condition monitoring and scan-to-BIM. By enhancing scanning productivity, this approach can be further integrated with automated point cloud semantic instance segmentation techniques for a streamlined workflow in high-fidelity geometric modelling, advancing robotic 3D BIM reconstruction and contributing to efficient and accurate digital construction applications.

Ground Robot; LiDAR; Image-based Sensing; 3D Scene Reconstruction; Scanning

1 Introduction

There is a growing momentum to harness automated, intelligent technologies to capture and reconstruct 3D digital representations of the built environment, translating the information into virtual platforms. The digital representations (such as Building Information Models) are useful in the architecture, engineering and construction (AEC) industry due to their capability to enhance communication and information exchange between project stakeholders, facilitating lifecycle management of built assets [2]. Traditionally, this process relies on accurate scanning to capture 3D point cloud data reflecting the as-built condition of the structure. This is followed by extensive manual processing of the scan point cloud data to generate the 3D scene or geometric model [3]. This workflow is not only labour-intensive and time-consuming, but also prone to human errors [4].

Several studies have explored the use of Light Detection and Ranging (LiDAR) integrated with robotic platforms, such as ground quadruped robots and wheeled robots, for 3D scene reconstruction of built environments [5-9]. For example, ground robots equipped with 3D LiDAR sensors can autonomously plan routes, navigate to specific targets, and collect point cloud data. The integration of BIM and IndoorGML were presented to optimise quadruped robot navigation for 3D scanning, achieving 70–90% coverage with high accuracy (0.006–0.021 mm), reducing human effort, and outperforming heuristic algorithms in efficiency, coverage, and scan planning [10, 11]. Likewise, an automatic 3D scaffold reconstruction using robot-dog-acquired point clouds was also investigated, achieving 90.84% F1 in semantic segmentation and generating 3D CAD models through deep learning for improved safety management [12]. For building façades [13], ground robot was also used for automated 3D scene reconstruction and visual inspection, demonstrating its growing potential in addressing unique challenges in complex environments. Researchers are actively exploring Simultaneous Localisation and Mapping (SLAM) as a viable option to 3D scene reconstruction. SLAM enables real-time mapping and localisation by allowing a robot or sensor system to build a spatial map of its environment while simultaneously determining its position within that map [1]. In one of the studies, an autonomous mobile robot using 2D SLAM and real-time 3D point cloud mapping was introduced [14] to navigate construction sites, optimise scan positions, and capture RGB-mapped point clouds, addressing occlusions and reducing time for geometric reconstruction.

Nowadays, unmanned aerial vehicles (UAVs) have been utilised for tasks such as surveying outdoor areas,

which collect data more efficiently than ground robots. Collaborations between UAVs and ground robots have shown potential to overcome some limitations. Kandath et al. [15] proposed a system where UAVs enhance ground robot navigation by providing real-time obstacle location data in indoor environments. Furthermore, Kim et al. [16] introduced UAV-based 3D terrain mapping and generation. Peterson et al. [17] also developed an integrated robotic system with ground robots with drones, significantly enhancing the navigation and exploration for outdoor settings.

An example of multi-agent robotic system (MARS) in previous research is shown in Figure 1. The UAV agent is a lightweight drone equipped with an onboard camera, Wi-Fi module, and open-source controller. The UAV can capture 5MP images or 720p live video streams, transmitting data to a processing unit for tasks like path planning. It has a flight time of 8 minutes and 30 seconds, making it ideal for short inspection missions. The ground robot features a wheeled chassis with an intelligent controller and modules for human detection and avoidance. Designed for heavy payloads, the ground robot supports advanced sensing devices and extended operation times.

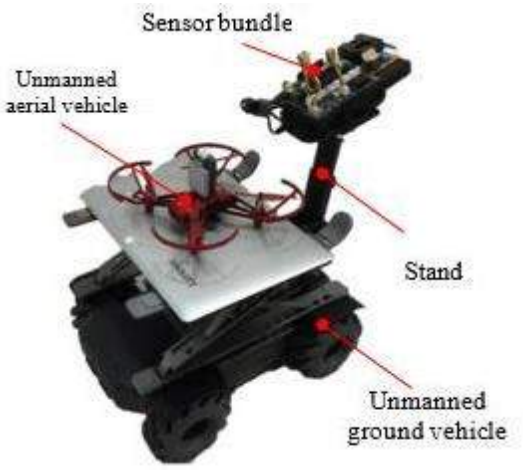

Figure 1. Ground robot equipped with UAV (configuration adapted from Reference [1])

In collaborative operation, the ground robot inspects surroundings and streams video data. As Figure 2 shows, the ground robot carries the UAV and follows a predefined path, capturing facility data and transmitting it to the mediating agent. The mediating agent directs the UAV when obstacles block the ground robot. The mediating agent calculates the optimal UAV trajectories for inaccessible areas and controls the UAV in navigating and scanning the areas that are inaccessible for the ground robot. Results validate the system's feasibility for indoor inspections in cluttered environments. With potential semantic navigation capabilities, ground robots and UAVs can further enhance their ability to interpret the built environment and navigate indoors. This advancement enables efficient and robust 3D scanning by intelligently interpreting and adapting to complex surroundings, ensuring comprehensive spatial data acquisition in challenging environment [18]. Previous research has highlighted the evolving role of ground robots and UAVs in advancing automated data capture in AEC projects.

Nevertheless, research in this field remains in progress with challenges persisting in achieving high-quality scanning outcomes [19]. In particular, significant challenges exist in achieving optimal scanning quality and cost efficiency. Traditional methods such as terrestrial laser scanning (TLS), while highly accurate, are often expensive and cumbersome, especially for large scenes where complex feature mapping requires manual intervention. Current robot-assisted systems, integrated with SLAM algorithms, show good potential for navigating complex environments while effectively capturing data. However, they often struggle to produce dense, high-quality 3D measurements. Furthermore, the use of cost-effective sensors to capture both depth and RGB information in a dense format remains underexplored, particularly without compromising depth accuracy.

This paper investigates a robot-assisted 3D scene reconstruction approach featuring a fixed field-of-view (FOV) LiDAR-based depth camera. By integrating a quadruped robot with this sensor, the approach leverages LiDAR for depth measurement and an integrated camera for capturing RGB, delivering detailed 3D representations of as-built conditions. This approach addresses the cost barriers of traditional TLS by employing an affordable sensor while preserving measurement accuracy. The quadruped robot's manoeuvrability enables it to efficiently scan diverse and complex structural areas, even in cluttered environments. By combining cost-efficient sensors with robotic mobility, this approach not only advances the field of robot-assisted 3D reconstruction but also opens new possibilities for applications such as smart city modelling, continuous monitoring, surveillance, and facilities management, providing a scalable and practical solution for the built environment.

Figure 2. Ground robot equipped with UAV for automated robotic inspection (configuration adapted from Reference [1])

2 Methodology

To achieve complete and accurate point cloud reconstruction that reflects as-built conditions, this study emphasises the integration of a ground quadruped robot with a fixed FOV LiDAR-based depth camera. This integration ensures robust spatial data acquisition while addressing scanning complex environments. To validate the proposed approach, an experiment is conducted on the NUS campus. The scan data are further analysed using two metrics: the completeness and accuracy of the point clouds.

The results provide insights into the feasibility and effectiveness of using quadruped robot-based scanning for detailed 3D scene reconstruction. The methodology and experimental setup are detailed in the subsequent sections.

2.1 Quadruped Robot-assisted Scanning

Figure 3 illustrates the setup of the quadruped robot, featuring an Intel RealSense L515 LiDAR-based depth camera mounted on top. The quadruped robot incorporates high-torque-density electric motors at each leg's knee, thigh, and hip joints, enabling precise control over its movements. This advanced actuation mechanism allows the robot to perform various dynamic actions,

such as walking, jumping, and executing pitch, roll, and yaw motions. These capabilities make it well-suited for operating efficiently in confined and cluttered environments for 3D scanning.

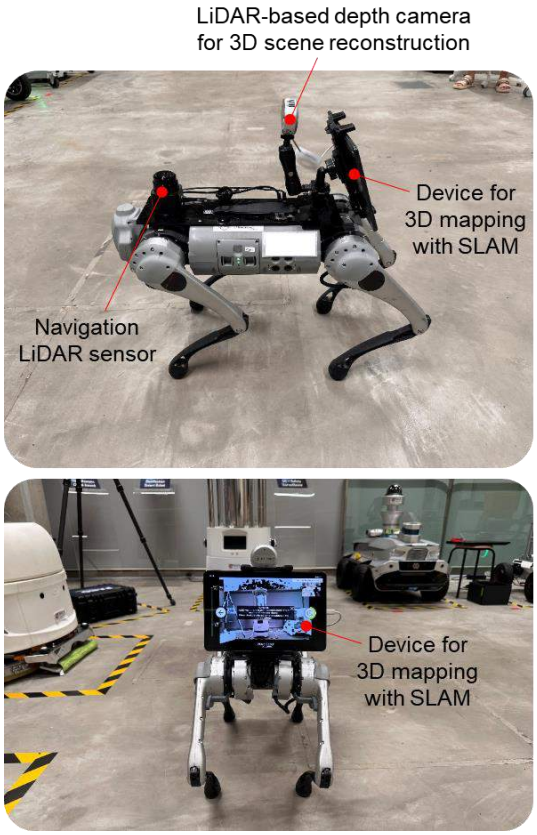

Figure 3. Ground quadruped robot equipped with fixed FOV LiDAR-based depth camera

Inspired by Reference [9], the LiDAR-based depth camera is directly connected to a device mounted on the quadruped robot for real-time SLAM-based 3D mapping. The sensor captures detailed depth maps and RGB colour and texture data, which are processed by the device for 3D scene reconstruction.

By integrating the LiDAR-based depth camera with the quadruped robot, the system utilises the robot's exceptional manoeuvrability to compensate for the fixed FOV of the LiDAR-based depth camera. As the robot moves in confined and cluttered spaces, this configuration enables efficient scanning of structural components while addressing obstacles and occlusions commonly encountered in such environments. The resulting data acquisition ensures decent 3D representations of as-built conditions, with depth measurements and rich spatial data supporting comprehensive mapping and scanning.

2.2 3D Scene Reconstruction

In this study, SLAM algorithm is utilised to map the constructed environment. SLAM operates by generating point clouds from individual scans and matching them within a global coordinate system. To overcome challenges such as obstacles and occlusions, the viewpoints for the robots are strategically identified, ensuring comprehensive scan completeness of the 3D scene. The ground robot then moves along the optimised path while scanning and capturing the RGB-D information for SLAM algorithm to generate the point clouds. This process results in the as-built 3D scenes with further refinement through loop detection.

The Intel RealSense L515 LiDAR-based depth camera is employed. This portable device is mounted on the ground robot's microprocessor and operated using Dot3D Scan software. The placement height is carefully adjusted to maximise the effective scanning range. Key specifications of the sensor include:

- **Dimensions**: 61 mm (diameter) x 26 mm (thickness)
- **Depth Range**: 0.25 to 9 meters
- **Accuracy**: ±14 mm
- **Horizontal Field of View (FOV)**: ~70°
- **Vertical Field of View (FOV)**: ~43°

LiDAR captures depth maps, while the image sensor captures RGB colour, and both are fused into SLAM for 3D scene reconstruction. This setup enables ground robot-mounted scanning to efficiently generate as-built 3D point clouds of the environment.

3 Experiment Results and Discussion

3.1 Testing Site

The effectiveness of quadruped robot-based scanning is demonstrated through experiments conducted on the NUS campus, focusing on 3D scanning and mapping within a selected laboratory in an educational building. Figure 4 illustrates the process of 3D scene reconstruction. In Figure 4(a), the robot moves to the first predefined scanning waypoints. In Figure 4(b), the robot adjusts its motion dynamically (e.g., tilting its head/sensor upward and downward) to scan both upper and lower parts of the structures. The captured RGB-D data are processed in real time for point cloud generation and 3D scene reconstruction (Figure 4(c)). In Figure 4(c), the depth sensor's FOV has a pyramid shape with a square projection at its bottom. This is a result of the sensor's line of sight on structural elements such as walls, meaning that when scanning a planar surface, the projected area should appear square-shaped rather than spherical.

L515 LiDAR sensor is fixed on the quadruped robot, meaning that as the robot moves and tilts its head upward or downward, or reorients in different directions, the sensor's viewpoint shifts accordingly. This movement allows the sensor to capture different regions of the indoor environment to enhance the completeness of 3D scene reconstruction. Using SLAM, the robot achieves dense, accurate scene mapping while travelling to subsequent viewpoints, including confined areas (Figure 4 (d, e)). The final output, shown in Figure 4(f), is a detailed, integrated 3D map of the scanned environment, seamlessly combining data from multiple scanned frames.

3.2 Visual Inspection of 3D Scenes

Figure 5 (a, b) showcases the reconstructed 3D scenes of the testing site, highlighting various structural elements. The reconstruction combines depth and RGB data captured by the LiDAR-based depth camera and processes it in real time using SLAM. The results are dense, visually enriched point clouds that represent the spatial and visual characteristics of the structure and the environment, including the orientation, shape, and

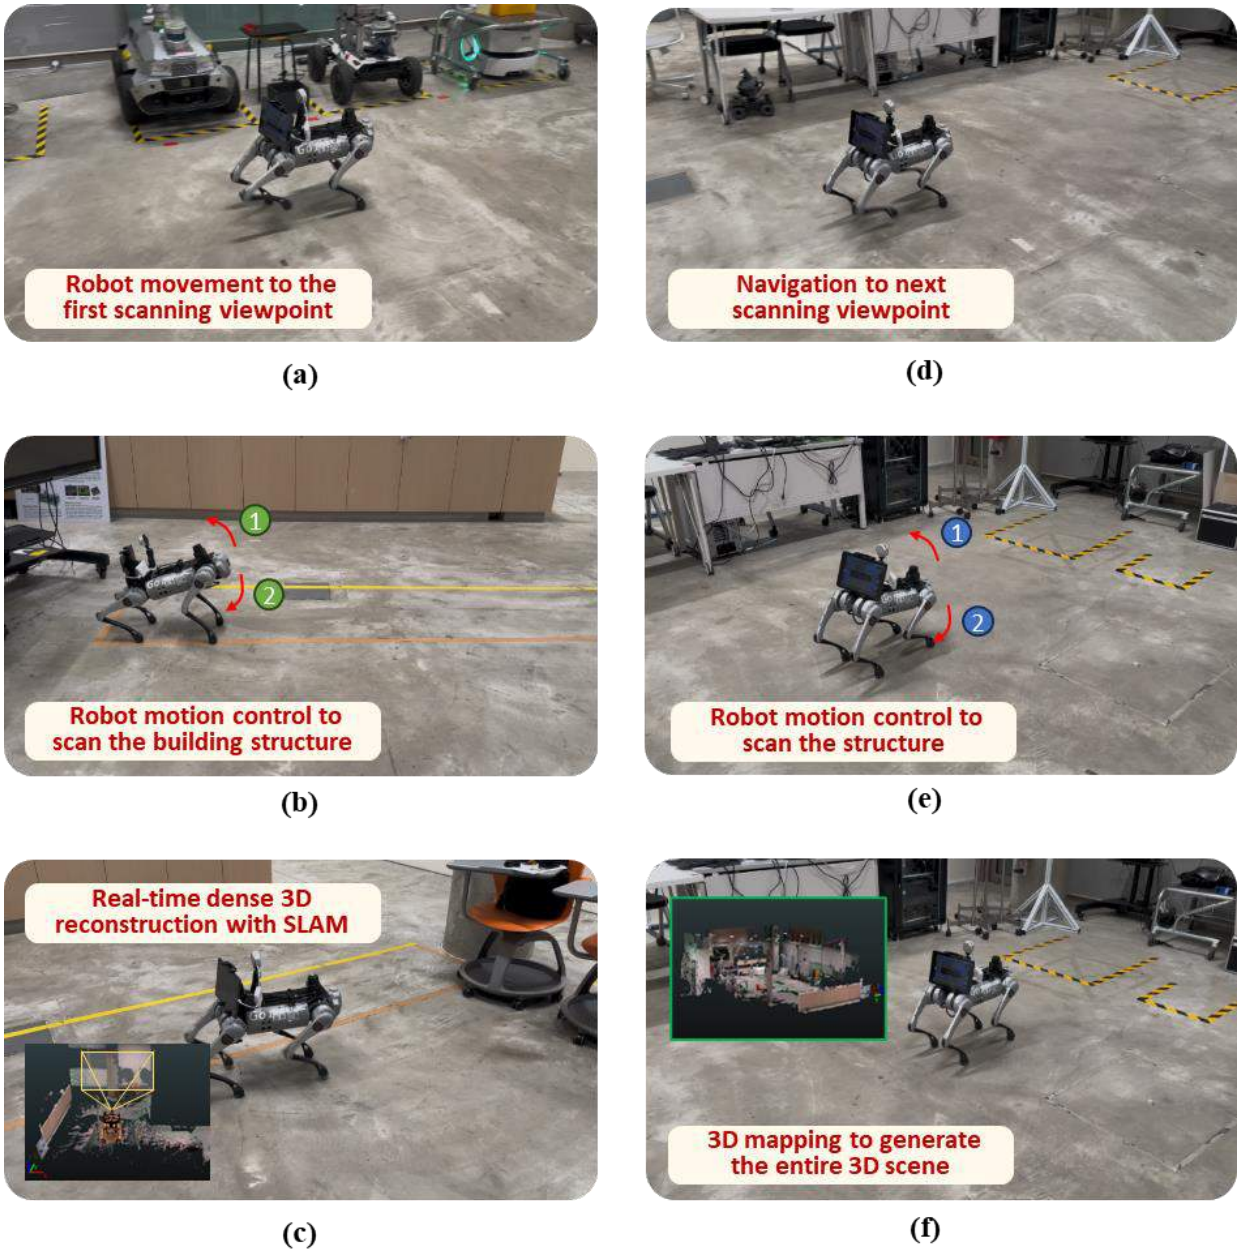

Figure 4. Automated 3D scanning using quadruped robot and fixed FOV LiDAR-based depth camera

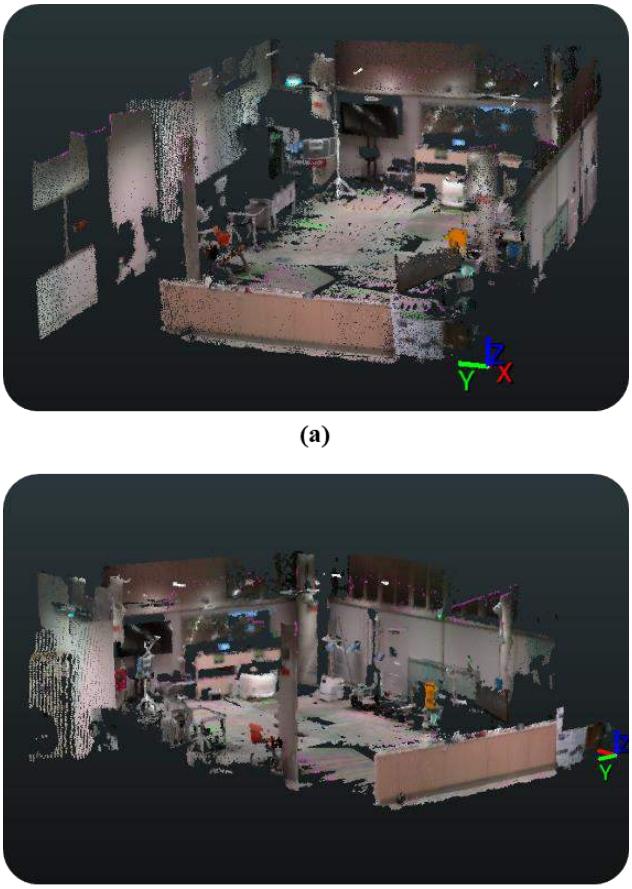

Figure 5. Reconstructed 3D scenes for the testing site

dimensions of walls, floors, furniture, and other architectural components. The addition of colour data further enhances the 3D scenes by reflecting surface textures and material properties. This rich geometric and texture information is invaluable for applications like training AI models for semantic segmentation, enabling effective differentiation and classification of structural and non-structural elements.

The limitation of robot-assisted scanning with a fixed FOV LiDAR-based depth camera is also apparent. Due to its limited FOV, the dimensions of the theoretical measurement area are constrained. The length and width of the measurement area can be calculated using Equations (1) and (2), as follows:

$$L = 2 \cdot \tan\left(\frac{\text{FOV}_{\text{horizontal}}}{2}\right) \cdot \text{Distance} \quad (1)$$

$$W = 2 \cdot \tan\left(\frac{\text{FOV}_{\text{vertical}}}{2}\right) \cdot \text{Distance} \quad (2)$$

wherein L refers to the length of the measurement area, W represents the width of the measurement area, $\text{FOV}_{\text{horizontal}}$ and $\text{FOV}_{\text{vertical}}$ stand for the horizontal and vertical FOV respectively (in degrees), and Distance is the distance from the sensor to the measurement area. Even with the quadruped robot's ability to adjust its sensor orientation for scanning ceilings and floor slabs, the ceiling and upper sections of the structure, including mechanical and electrical (M&E) systems, remain difficult to capture comprehensively due to the sensor's limited measurement distance and area. Such limitations may prevent the reconstructed 3D scenes from meeting the requirements of various applications, such as digital twin creation for M&E systems.

3.3 Quantitative Analysis of Data Quality

The completeness and accuracy of the scan data are analysed using 2D projections of the XZ and YZ planes from the 3D scenes, as shown in Figures 6 and 7. Unscanned areas, highlighted in purple in Figure 6, indicate that approximately 65% of the selected planes were successfully covered. Key structural elements, including walls, windows, and equipment, are clearly identifiable, though corner areas remain partially unscanned due to occlusions and the limited FOV of the LiDAR-based depth camera. A notable fraction of the

purple areas corresponds to windows, and the absence of depth data in these regions should not be considered an error but rather a natural limitation of the LiDAR sensor, as L515 struggles with reflective or transparent surfaces, making it unable to capture reliable depth data. However, this missing data can be leveraged to approximate or identify window boundaries from wall point clouds. The missing data in the upper regions of the wall is not solely due to transparent glass surfaces but may also result from sensor occlusion or range limitation. Future research could further analyse the correlation between these factors on 3D scene reconstruction.

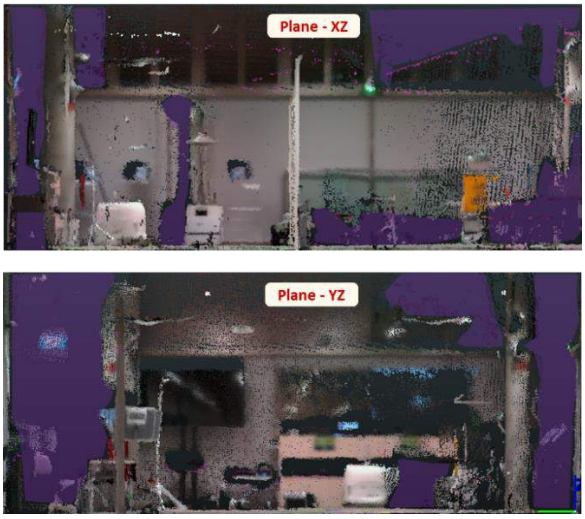

Figure 6. Completeness of scan data

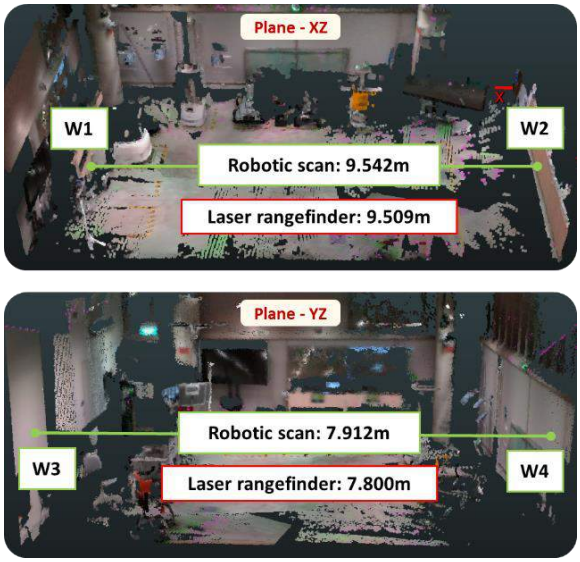

Figure 7. Accuracy of scan data

Figure 7 compares the distance measurement from robotic scanning against conventional laser rangefinders. For the XZ plane, the robotic scan records 9.542m from W1 to W2, while the laser rangefinder measures 9.509m. Similarly, for the YZ plane, the robotic scan reports 7.912m from W3 to W4, compared to the laser rangefinder of 7.800m. Figure 8 illustrates the discrepancies between the measurements obtained from robotic scan and laser rangefinder. The differences are minimal, with a deviation of only 1.4% in the XZ plane and 0.3% in the YZ plane. These differences may result from vibration during the robotic dog's movement, affecting SLAM-based 3D mapping, and the lower accuracy of L515 LiDAR-based depth camera used in the robotic scan.

Despite these constraints, the results demonstrate that robot-assisted scanning using a fixed FOV LiDAR camera is a viable approach for producing decent as-built 3D measurements. This highlights the potential of integrating robotics with LiDAR to facilitate spatial data collection, enabling downstream applications such as scan-to-BIM and facility inspection.

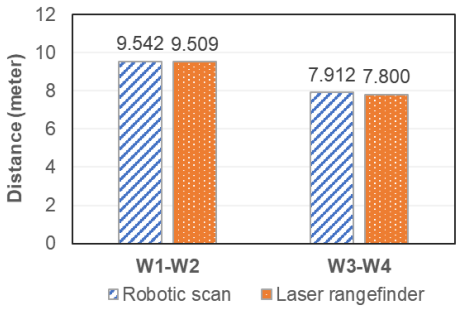

Figure 8. Comparison of distance measurement by robotic scan and laser rangefinder

4 Conclusions

This study demonstrates the potential of integrating a quadruped ground robot with a fixed FOV LiDAR-based depth camera for 3D point cloud reconstruction. The proposed system addresses challenges in capturing spatial data by leveraging the advanced manoeuvrability of a quadruped robot and the precision of a LiDAR-based depth camera. This combination enhances the robot's ability to efficiently move in confined spaces and cluttered environments, while enabling detailed 3D scanning and mapping. The research involves the validation through experimental studies conducted on NUS campus. The field tests focus on scanning an educational building to assess the system's capabilities in capturing as-built conditions. The quadruped robot, equipped with the Intel RealSense L515 LiDAR camera, demonstrates its ability to perform detailed 3D measurements. The results underscore the feasibility and effectiveness of the proposed quadruped robot-based scanning for detailed environmental mapping.

Integrating a fixed FOV LiDAR camera into robotic

systems marks a significant advancement, but several areas require improvement. Firstly, the sensor's limitations in depth measurement, RGB colour, and texture highlight the need for adopting 3D LiDAR-camera. Additionally, given that the L515 sensor provides RGB and depth maps in addition to point clouds, future work of this research could consider integrating these depth maps with RGB data during the 3D mapping process using novel SLAM algorithms, such as Gaussian Splatting-based SLAM, to improve 3D scene reconstruction accuracy. Lastly, advanced data acquisition planning optimisation is essential to guide the robot effectively through complex structural environments. These algorithms should also ensure adaptability to confined spaces, broadening the system's applicability across various use cases.

Abstract -

In future automated construction sites, multiple autonomous agents must navigate safely and efficiently. While velocity obstacle-based algorithms like Optimal Reciprocal Collision Avoidance(ORCA) handle microlevel control, achieving efficiency also requires the management of macrolevel dynamics, similar to human social behavior. The existing C-Nav algorithm, which incorporates the concept of "consideration for others" to promote yielding behavior, shows promise, but its evaluation method can lead to inefficient or nonconsiderate actions. This study found out that insufficient space for yielding causes these issues, and proposes a new evaluation method to encourage social behaviors. The results indicate reduced stacking in narrow areas, although some inefficiencies persist. As a result, the "waiting behind" action functions as an auxiliary mechanism that reinforces the mutual yielding behavior intended by C-Nav, thereby enhancing overall operational efficiency. These insights suggest that further refining the algorithm, guided by a deeper understanding of human social interactions, can lead to more robust and efficient navigation strategies.

Multiagent navigation; Coordination; Robotics

1 Introduction

Owing to the growing shortage of skilled workers in the construction sector, the automation of construction machinery is advancing to improve productivity and safety. A noteworthy example is Taisei Corporation's T-iCraft®, which tests coordinated operations using four types of autonomous machines, namely backhoes, crawlers, dump trucks, and bulldozers.

Path planning for autonomous robots relies heavily on their ability to "pass each other." For instance, in environments in which robots cannot pass each other, all pathways must be one-way or single-track, which leads to inefficient movements.

Figure 1 illustrates a situation in a construction site where passageways are blocked by construction materials, making it difficult for robots to pass each other. Such situations are expected to frequently occur in construction sites, and developing methods to address them is crucial for advancing automation.

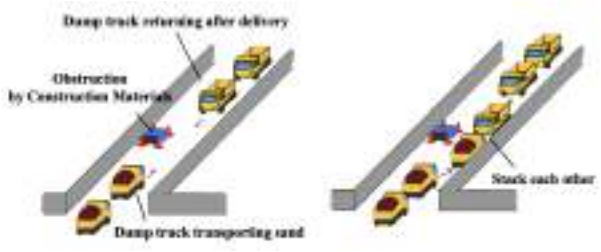

Figure 1. Illustration of the Situation in Which Robots Cannot Pass Each Other

Planning the movements of multiple autonomous construction machines (referred to as "agents") in continuous space to avoid collisions is not easy. Although humans can easily manage passing movements, autonomous machines require advanced algorithms. Velocity obstacle-based algorithms like Optimal Reciprocal Collision Avoidance (ORCA) [1], Reciprocal Velocity Obstacle (RVO) [2], Hybrid Reciprocal Velocity Obstacle (HRVO) [3], and Extended Velocity Obstacle (EVO) [4] treat other agents as dynamic obstacles and calculate safe velocities to prevent collisions.

Velocity obstacle-based algorithms use distributed systems in which each agent independently calculates its movement based on predefined rules. . This ability is aligned well with construction sites, where obstacles frequently appear, as illustrated in Figure 1. In addition, construction machines are typically large and lack maneuverability, making detours less feasible compared to waiting for clearance. This constraint is unique to construction sites, and under this premise, the avoidance-focused algorithm proposed in this study is expected to be highly effective.

However, the algorithms often leads to overall efficiency reductions such as traffic jams (referred to as "stacks"). By drawing inspiration from human interactions, such as crowd dynamics and mutual respect, and incorporating a social modeling framework into these algorithms, these types of problems may be mitigated. The literature on

game theory and other related disciplines in the social sciences has a crucial role in developing these enhanced algorithms.

C-Nav [5] is a collision avoidance algorithm that incorporates the concept of "empathy," voluntarily balancing agents' progression toward their goals in consideration of the freedom of others. While C-Nav improves movement efficiency in narrow passages, challenges remain in diverse site conditions and parameter dependencies. Strengthening the generalizability and robustness of such algorithms is essential for their practical deployment.

The purpose of this study is to analyze the effects of enhancing sociality, by introducing more social parameters within the existing C-Nav algorithm, on resulting group performances. It aims to apply analogies with human social behaviors to agent interactions and examine whether they improve the algorithm's performance. Methodologically, we conduct herein computer simulations based on existing ORCA and C-Nav codes, visualize agent behaviors, propose improvements, and compare results to evaluate enhancements. The novelty of this study is its emphasis of algorithmic robustness and strengthening of this robustness through the incorporation of new social behavior concepts.

2 Related Work

2.1 Overview of Collision Avoidance Algorithms

Various approaches exist for collision avoidance algorithms in a continuous space. The mainstream approach is that associated with the use of velocity obstacle-based algorithms. In these algorithms, agents calculate the velocity (to be adopted next) at each time step based on information about their surrounding environment. One of the advantages of this approach is its distributed nature. Instead of relying on a central decision-maker overseeing the entire environment, individual players plan their paths based on their judgments. This improves the computational efficiency and allows flexible responses to dynamic environments.

2.2 Overview of ORCA

Various formulations have been proposed to determine "safe" velocities, aiming to ensure safety while maintaining the maximum possible freedom for velocity selection. Among these, ORCA is currently one of the most extensively used methods. ORCA calculates the "collision velocity range" based on the velocities and positions of the surrounding agents. By "sharing" velocity vector adjustments to escape from this range with other agents, ORCA can estimate a "safe velocity range" with reasonable accuracy. Within this "safe velocity range," agents are free to select velocities (e.g., by choosing the direction and speed that brings them closest to their goal).

This method has been demonstrated to enable collision avoidance among thousands of agents, with the computation time scaling linearly with the number of agents. However, as ORCA focuses on guaranteeing safe velocities at each time step, there is room for improvement in motion planning from a macroscopic perspective. For example, in narrow passages, simply directing groups of agents toward their goals can lead to stacking when the two groups intersect.

Since the introduction of ORCA, research on velocity-based collision-avoidance algorithms in environments that guarantee accurate and complete communication has primarily focused on addressing these types of inefficiencies. Examples include the VGVO [6], proxemics [7], and GrpAvoid [8]. The mainstream approach proposes improvements in velocity decisions at a slightly higher macrolevel than ORCA. The same approach was adopted in this study.

2.3 Limitations of the ORCA Algorithm and the C-Nav Algorithm

When proposing algorithms to address the aforementioned limitations of ORCA, many researchers have drawn inspiration from human social behaviors and game-theoretic considerations. Among these, the C-Nav algorithm yields particularly interesting results. C-Nav is an algorithm that incorporates the advanced social behavior concept of "yielding." Explicitly integrating the concept of "empathy" from the related disciplines in social sciences, it predicts actions several steps ahead and rewards movements that reduce constraints on the actions of others. Consequently, it enables construction machines to pass each other in narrow passages, where only one machine can pass at a time.

3 Problem Formulation

3.1 Definition of the Velocity Obstacle Problem

According to Van Den Berg et al. [1], the velocity obstacle (VO) problem is formulated as described below. We consider an environment shared by n agents. Each agent was modeled as a disk moving in a two-dimensional plane. The following information is provided for agent A:

- Current position ($\mathbf{p}_A$): The agent's current location in the 2D plane
- Current velocity ($\mathbf{v}_A$): The agent's current speed and direction
- Radius ($\mathbf{r}_A$): The radius of the agent assumed to be a two-dimensional circle
- Maximum velocity ($v_A^{\max}$): The upper limit of the agent's speed

- Preferred velocity ($\mathbf{v}_A^{\text{pref}}$): The desired velocity in the absence of obstacles, typically directed toward the goal with magnitude $\mathbf{v}_A^{\max}$

The symbols $\mathbf{p}_A$, $\mathbf{v}_A$, and $\mathbf{r}_A$ are considered as external states that are observable through environmental sensing. By contrast, $\mathbf{v}_A^{\max}$ and $\mathbf{v}_A^{\text{pref}}$ are internal states that are not directly observable by the other agents. With a time-step interval τ, each agent selects a new velocity based on the parameters at each time step.

3.2 ORCA Algorithm Details

The primary objective of ORCA is for each agent to select a velocity that ensures that there are no collisions with other agents or obstacles in the subsequent time step. In addition, as a secondary objective, the agent may choose a velocity that is as close as possible to the preferred velocity v_{pref}^A. ORCA was designed to satisfy these requirements.

The collision velocity range refers to the range of velocities based on two agents that may collide within a specific timeframe. Selecting a velocity within this range introduces a risk of collision. The collision avoidance set is the set of velocities that avoids this range in the subsequent time step. By selecting the velocity from this set, we guaranteed that no collisions would occur. Based on this idea, each agent calculates the minimum necessary velocity adjustments to avoid collisions with all surrounding agents. From the convex set of safe velocities obtained through this process, Agent A selects the velocity closest to v_{pref}^A.

3.3 C-Nav Algorithm Details

In this section, we describe the setting of v_{pref}^A, which is a unique feature of C-Nav, according to the explanation of Godoy et al. [5].

At each time step, the agent first simulates hypothetical actions over several future steps for various possible actions it can take in the subsequent time step based on observations of the positions and velocities of the surrounding agents. Examples of possible actions include movements in eight directions based on the direction directly toward the goal.

Each action is then scored according to its degree of goal achievement and those of the surrounding agents. Herein, the agent's degree of goal achievement is defined as the distance moved closer to the goal. The degree of goal achievement for the surrounding agent j (more precisely, the extent to which the agent's action affects the agent's goal achievement) is given by the value $P_{a,j}$

$$P_{a,j} = v^{\max} - \|\mathbf{v}_j^{\text{intent}} - \mathbf{v}_j^{\text{new}}\| \tag{1}$$

where v_j^{intent} is assumed to be communicated by an agent j via a signal.

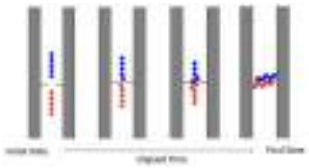

Figure 2. Behavior in the Case of Optimal Reciprocal Collision Avoidance

Consequently, the reward for each action is calculated using the following equations:

$$R_a = (1-\gamma)\cdot R_a^g + \gamma \cdot R_a^c \tag{2}$$

$$R_a^g = \frac{\sum_{t=0}^{T-1}\left(\frac{\mathbf{v}_i^{\text{new}}\cdot(\mathbf{g}_i-\mathbf{p}_i)}{\|\mathbf{g}_i-\mathbf{p}_i\|}\right)}{(T\cdot v^{\max})} \tag{3}$$

$$R_a^c = \frac{\sum_{t=1}^{T-1}\sum_{j\in C_{\text{rank}}} P_{a,j}}{(T-1)\cdot k\cdot v^{\max}} \tag{4}$$

where γ is a parameter that balances the agent's goal achievement and the consideration of other agents. A value of γ closer to zero places more emphasis on the agent's goal achievement, whereas a value closer to one places more emphasis on the consideration of other agents. This γ is known as the coordination factor.

Finally, the action with the highest R_a value is selected and passed to ORCA as v_{pref}^A to determine the final velocity.

4 Observation and Analysis

In this section, we determine what needs to be improved regarding the behavior of agent groups resulting from the existing C-Nav algorithm based on observations of our simulations.

4.1 C-Nav's Superiority over ORCA in Narrow Passages

In this section, we explain how C-Nav overcomes the challenges presented by ORCA and what concrete improvements it achieves in practice. In section 4.2, we present examples of undesirable behaviors in which C-Nav deviates from its intended principles, thereby clarifying directions for further refinement.

First, in the case of a simple ORCA, the two agents are set to move straight toward their respective goals; thus, they both enter a narrow passage. Because they collide, the leading agents of each line try to avoid each other by moving to the left and right, as calculated by the ORCA algorithm. However, because the narrow passage is adequately broad for only one agent, they cannot pass each other and become stuck in the passage (Figure 2).

We now explain the ideal avoidance behavior intended to be used in the original paper [5] in the case of C-Nav. In

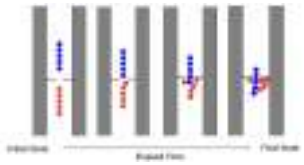

Figure 3. Behavior in the Case of C-Nav

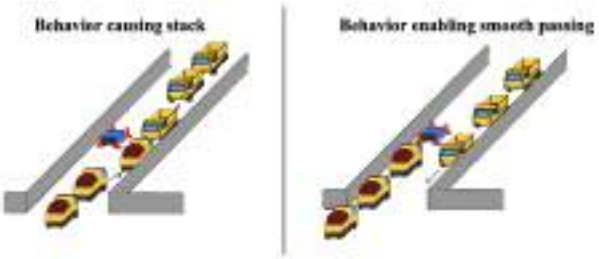

Figure 4. Illustration of the Real-world Narrow Passage Scenarios

Figure 3, the red agent determines that proceeding straight ahead would obstruct the blue agent, and will thus avoid moving to the right. Meanwhile, the blue agent notices that the red agent has moved to the right and proceeds straight ahead, resulting in "passing each other" behavior.

These simulated behaviors correspond to real-world movements observed at construction sites, as shown in Figure 4, specifically as these pertain to the passing of dump trucks heading to transport soil and those returning from transportation.

4.2 Unintended Stacking Caused by C-Nav in Narrow Passages

We also observed the behavior after modifying the width of the narrow passage to allow the two agents to pass through each other side-by-side. The ideal behavior in this field is for the agents to shift to the left and right directions and pass each other while maintaining their formation, as shown in Figure 5. However, when we conducted repeated trials under the same conditions, the following behavior often occurred (Figure 6). In their efforts to predict several

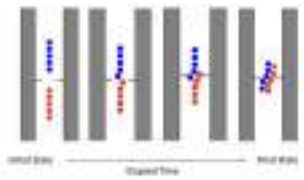

Figure 5. Smooth Behavior Attained in the Case of C-Nav

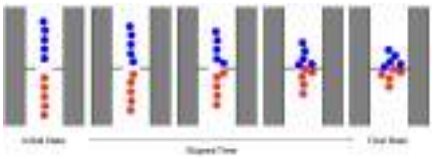

Figure 6. Stacking in the Case of C-Nav

steps ahead of their current positions in cases of straight motion trajectories, both the leading agents of the red and blue groups obstruct each other and fail to achieve their own goals; accordingly, they try to change their courses by moving to the right or left. However, the directions they chose to avoid were the same, resulting in a situation where they blocked each other's paths. In this case, the two leading agents that are "hesitating" restrict the width of the narrow passage, and the agents which follow can only pass through one at a time, reducing the efficiency of the crossing.

The fact that this inefficient behavior occurs often, presents a challenge when considering applications to actual construction sites and indicates a lack of robustness in the current algorithm. Therefore, modifications are required to the algorithm to avoid these types of inefficiencies.

4.3 Analysis of the Cause of Stacking

4.3.1 Changes in Behavior When Switching to Sequential Turns

First, let us consider an analogy to human behavior. In the narrow passage situation presented in Section 4.2.3, it is common to experience congestion in reality because the avoidance directions of oncoming individuals overlap. The essential cause in this example is that "the choice of avoidance direction is made simultaneously." If you knew (from your perspective) that another person would avoid it, you would not avoid it. Believing that this phenomenon also occurs in C-Nav, we modified the algorithm. We changed the evaluation of the actions in each direction, which was previously performed simultaneously based on the desired velocities of each agent at the start of the for-loop—to be performed sequentially. With this change, each agent performs evaluations while recognizing the preferred velocities of surrounding agents.

However, even when this algorithm was used, avoidance actions in the same direction occurred (Figure 7).

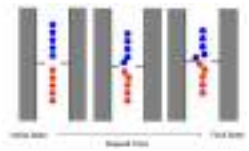

Figure 7. Same-direction Avoidance in the Case of Sequential Turns

Therefore, we concluded that this behavior was not due to the order of turns.

4.3.2 Changes in Behavior When the Number of Agents was Altered

We verified this by changing the number of agents and their intervals.

First, in the one-on-one case, the results were as follows: out of 1000 trials, the shortest and longest completion times were 98 and 112. In other words, severe stacks, such as those described in Section 4.2.3, did not occur.

In another case, the following trajectories were observed: The red and blue lines represent the agents moving upward and downward, respectively. If we focus on the points where each agent first changes its direction of movement, we can observe that both avoid the right side of the screen. However, after several adjustments in direction, these two agents eventually passed through (Figure 8).

Figure 8. Elimination of "Hesitation" Observed in the 1 on 1 Case

Based on the results presented earlier, we can infer that when there is sufficient space around oneself and the target agent that needs to be avoided, repeated directional adjustments are made; as a result, stacking due to mutual avoidance does not occur.

4.3.3 Specific Mechanism of Stacking in C-Nav and Opportunities for Algorithm Improvement

Based on the results of Sections 4.3.1, and 4.3.2, it can be inferred that the presence of the following agents influences the occurrence of stacks owing to mutual avoidance. Reinterpreting the behavior based on this, the sequence is as follows:

1. In Figure 6, both the red and blue agents first move to the right side of the screen to avoid obstacles.
2. The following agents proceeded straight into the space that had opened up.
3. The leading red and blue agents, who had initially avoided each other by moving to the right, lose the freedom to readjust their direction of movement as in the one-on-one case owing to the entry of the agents that followed; these two agents are continually pushed further to the right by these incoming agents.

It is considered that the stacks occurred because of the aforementioned mechanism.

Considering the meaning of this behavior, it implies that "even though the leading agents are trying to yield the way to the opposing agents, the following agents attempt to overtake and proceed." This contradicts one of the major themes of the C-Nav algorithm, which is "consideration for others."

Furthermore, this behavior was observed in cases where the

1. coordination factor was increased
2. reward target was limited to only the nearest agent
3. agents were allowed to select low-speed actions or stop at desired velocities

These observations indicate that with the current reward function, it is difficult to restrict "overtaking."

4.4 Proposed Improvements

As pointed out by Godoy et al. [5], an attempt to vary the way rewards are given, depending on whether the agents are moving in the same or opposite directions, is considered useful for constructing a more efficient algorithm. Based on this, we will revisit the current method of assigning rewards by focusing on the "direction of movement of the agent being considered."

The current method for assigning consideration rewards is as follows:

$$P_{a,j} = v^{\max} - \|v_j^{\text{intent}} - v_j^{\text{new}}\| \tag{5}$$

In other words, this method values "not hindering the movement of others."

Based on our observations thus far (e.g., passing through narrow passages in one-on-one situations), it has been confirmed that this is effective for agents moving in opposite directions. However, for agents moving in the same direction—especially the agent immediately ahead who is stalled—the possibility that one's actions will directly block the agent's desired path is low. Consequently, differences in the rewards for each of one's actions were less likely to occur. Moreover, as we have observed, blocking the space necessary for avoidance actions between that agent and agents facing it becomes a "hindrance" when viewed over a longer number of time steps. Therefore, a

more appropriate method for assigning rewards is required to avoid this.

We can draw an analogy with human social behavior. Suppose that at a place where only one person can pass—such as an automatic door at a building entrance—a few people from inside and another group from outside arrive and stumble across each other. In this situation, the leader of the group (coming from inside or outside) will step aside by the door and yield the way to the other group. At this time, the highest priority for the other members of the group that is yielding (assuming everyone in this group is considerate) is "not to step ahead of the person who is yielding."

Based on the above, a more desirable way of consideration is to "ensure freedom of action for agents moving in the opposite direction as in the existing method, but for agents moving in the same direction, if that agent yields the way or its movement stalls, to line up behind and wait."

In the existing method case, the reward calculation is performed for a specified number of agents in order from those with the largest speed change, regardless of the distances from each other. However, this method of assigning rewards depends on how the neighborhood is defined (e.g., the setting of the neighborhood radius); correspondingly, robustness against the problem situation is not guaranteed. In Godoy et al. [5], there is limited discussion on the order of consideration. When introducing the movement of "lining up behind a stalled agent ahead," it is more intuitive to consider agents as targets for this reward concept in order of increasing proximity to oneself.

Based on this, we propose changing the method for assigning consideration rewards as follows.

Existing reward assignment methods

Without distinguishing the agents, we calculate $P_{a,j}$ for each agent using Eq. 5, and estimate the average of a specified number of agents in order from the ones with the largest $P_{a,j}$ as a consideration reward.

Proposed method for reward assignment

We define whether the "flow directions are the same or opposite" based on whether the inner product of one's desired velocity vector and that of the other agent is positive or negative. In addition, we define an agent's movement as "slow" if its current speed is less than half its maximum speed. In this case,

- For agents j moving in the opposite direction, calculate $P_{a,j}$ using Eq. 5.
- For agents j moving in the same direction, calculate $P_{a,j}$ using the following equation:

$$P_{a,j} = \alpha \times \frac{(p_j - 4.0 \times r_j \times v_j^{\text{intent}}) - p_i}{\|(p_j - 4.0 \times r_j \times v_j^{\text{intent}}) - p_i\|} \cdot v_a \tag{6}$$

In this study, we refer to this method of providing rewards as "Q-Virtue," inspired by the Japanese queuing culture (the virtue of standing in line).

5 Experiments

We conducted experiments to verify whether the proposed changes in the reward rules led to a reduction in stacking in narrow passages.

5.1 Evaluation Method

Using C-Nav as a comparison point, we evaluated the C-Nav algorithm using the proposed reward allocation method.

In this study, we focused on actions to determine whether it is possible to avoid the phenomenon according to which the movement completion time becomes considerably longer than when ideal crossing occurs, owing to stacks resulting from the existing C-Nav. Therefore, we evaluated the method by performing 100 trials and comparing the frequency distribution of the movement completion time (the average time required for 10 agents to reach their goals).

Regarding the parameters of C-Nav, we fixed them at the following values, which showed the best performance in the existing algorithm as a result of the experiments; coordination factor (γ) = 0.9, and number of agents considered in reward = 1.

5.2 Results

For each scenario, we present the following for both the existing C-Nav and the proposed assignment method:

1. A distribution plot with the average completion time (in s) on the horizontal axis and the frequency on the vertical axis
2. A sequence of representative snapshots of observed behavior (the left image shows the initial state and the right image shows the state after some time has elapsed)

5.2.1 Narrow Passage Scenario

First, we consider a situation in which agents can pass through two narrow passages simultaneously.

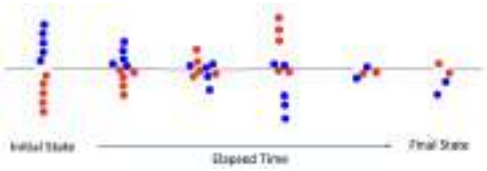

Figure 9. Behavior in the Case of C-Nav

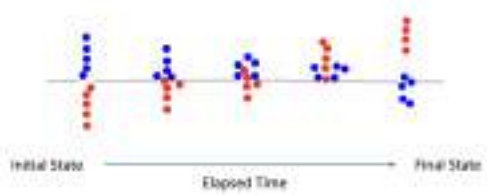

Figure 10. Behavior in the Case of Q-Virtue

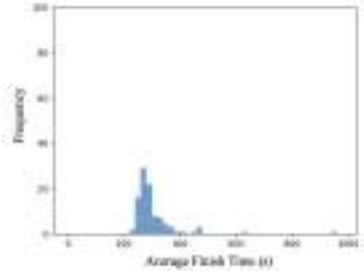

Figure 11. Completion Times in the Case of C-Nav

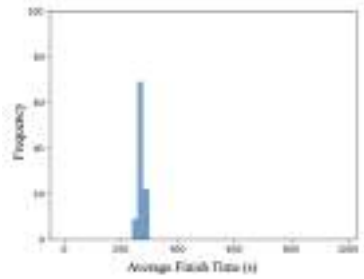

Figure 12. Completion Times in the Case of Q-Virtue

In contrast to the existing C-Nav method, where Figure 9 illustrates numerous instances of agents blocking each other's paths in narrow sections, the Q-Virtue demonstrates movements where groups on the avoiding side align in orderly rows, as shown in Figure 10. Additionally, virtually no time was spent obstructing each other's paths. Consequently, compared with the existing C-Nav (Figure 11), the distribution of movement completion times for the Q-Virtue (Figure 12) is skewed to the left. This shift led to a decreased number of trials in which crossing completion required a long time.

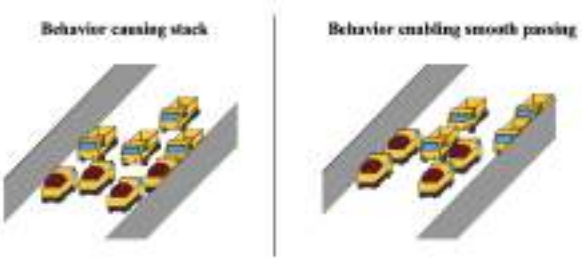

Figure 13. Illustration of the Real-world Situations Associated With the Group Crossing Scenario

5.2.2 Group Crossing Scenario

We focus next on the crossing of two groups consisting of multiple agents in a crowded situation and compare the behaviors resulting from each method handled so far. We verified whether Q-Virtue, which focuses on improving behavior in narrow passages, is also efficient in other situations. These simulated behaviors correspond to the real-world movements observed at construction sites, as shown in Figure 13.

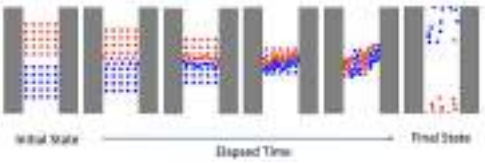

Figure 14. Behavior in the Case of C-Nav

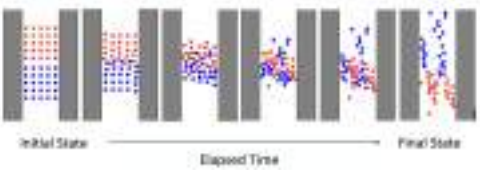

Figure 15. Behavior in the Case of Q-Virtue

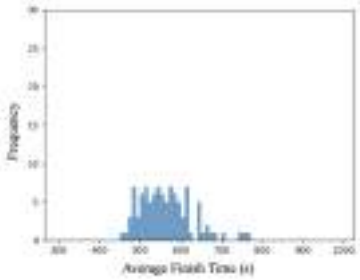

Figure 16. Completion Times in the Case of C-Nav

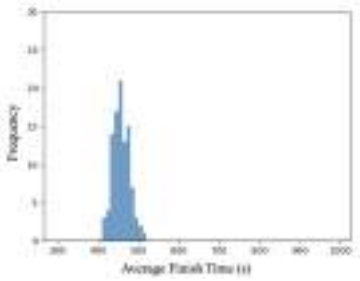

Figure 17. Completion Times in the Case of Q-Virtue

When comparing the existing C-Nav method (Figure 14) with the Q-Virtue (Figure 15), the latter exhibits formations at an earlier stage, which consequently alleviates crowding during crossings. Consequently, the distribution of movement completion times for the Q-Virtue (Figure 17) is skewed to the left compared with the existing C-Nav method (Figure 16). This shift leads to a decreased number of trials in which crossing completion requires a long time.

5.3 Summary

In all situations, the distribution of the average movement completion time shifted to a side with a smaller length because of the Q-Virtue.

6 Conclusion and future work

The existing C-Nav yielded interesting results by designing the algorithm to incorporate information related to the "consideration for others," generating yielding behaviors. However, it was found to be parameter-dependent, especially concerning behaviors during crossings in narrow passages, revealing robustness issues as areas for improvement in practical applications. To elicit the unique performance intended by C-Nav, which is "mutual yielding," we proposed the addition of auxiliary processes and consequently achieved an improvement in robustness. These findings provide new insights into refining velocity obstacle-based collision avoidance algorithms and can help alleviate congestion and facilitate more efficient passage among agents in future automated construction sites.

In this study, we demonstrated that for C-Nav (and for many other collision avoidance algorithms proposed as improvements of ORCA), the action of "waiting behind" is an important factor in achieving efficient movement. However, discussions on methodologies to induce the behavior of "waiting behind" and the conditions under which it becomes effective are still insufficient, and more detailed analyses and improvements are required.

Due to limitations in research duration and equipment, this study did not conduct experiments in actual construction sites. Future work will focus on testing the algorithm in real environments to assess the impact of construction-specific physical and social factors.

Abstract –

Over the past decade, Industrialized Construction (IC) has experienced increasing attention, with numerous studies examining the integration of various technologies to boost productivity and efficiency through manufacturing-oriented strategies. Among these, robotic arms have emerged as a dominant solution. However, further research is required, as the interactions between robotic arms and the surrounding environment often remain suboptimal or even hazardous. This challenge is primarily attributed to the absence of a practical benchmarking tool for selecting appropriate path-planning pipelines under different scenarios. Moreover, existing benchmarking frameworks often disregard the complexity inherent in IC robotic stations, producing path-planning rankings that are not feasible for the required assembly strategies. To address these gaps, this study proposes a novel framework for generating a benchmarking tool that accounts for both the specific robotic arm task and user-defined criteria, enabling a ranking system for evaluating multiple path-planning pipelines. The proposed framework was validated in a simulated robotic station designed for manufacturing structural wooden assemblies. Findings highlight the framework's robustness by demonstrating how a criteria-driven evaluation metric can effectively compare diverse path-planning pipelines during a wooden stud pick-and-place task featuring complex geometric dimensions.

Industrialized Construction; Prefabrication; Robotics; Automation; Modular Construction

1 Introduction

Industrialized construction (IC) and prefabrication have gained significant traction over the past few decades primarily involving the off-site assembly of structural components, which are subsequently transported and installed at the construction site [1]. However, several persistent challenges continue to hinder the widespread adoption of IC, including issues related to design and quality, as well as limitations in technology adoption and the readiness of current practices [2]. In response, numerous studies have attempted to integrate advanced technologies into this sector. Among these advancements, the introduction of robotics into the IC is particularly promising, as it can substantially reduce both construction costs and time, in addition to enhancing labor productivity by alleviating or even eliminating labor-intensive tasks [3].

In this context, laying the groundwork for the incorporation of robotics into industrialized construction, thereby advancing it toward industrialized methods, has been acknowledged as a feasible outcome. Several robotic stations have been developed and assessed to facilitate the sector's transition toward industrialization and manufacturing [4]. Additionally, research has explored the use of robotic arms as components within mass production (or manufacturing line) stations [5]. Despite the recognized enhancements in productivity achieved through the integration of robotic arms within these sectors, substantial barriers continue to impede the broader implementation of robotic stations in IC practice.

These impediments are rooted in the unique attributes of raw construction materials (e.g., wooden studs), which display characteristics—particularly dimensional asymmetries in their geometries—that diverge significantly from the standardized components commonly utilized in robotic manufacturing lines [6]. Such discrepancies frequently often lead to unpredictable, and potentially hazardous, robotic movements within the manufacturing environment when performing collision-free path planning while carrying construction elements.

In response to these challenges, various studies have introduced new and innovative path-planning algorithms [7] or have developed robotic stations adapted from commercial solutions [5], [8]. Such planning pipelines, commonly referred to as inverse kinematic path planning pipelines, are designed to compute and generate collision-free trajectories for a robotic arm, transitioning from its initial configuration to a specified goal state while avoiding contact with environmental obstacles.

However, these newly proposed algorithms generally

lack robust evaluation metrics, often relying solely on binary success-failure criteria, which stand in contrast to the algorithms widely tested using the existing simulation packages and software like MoveIt [9] and Isaac Sim [10]. These simulation platforms are designed to visualize the collision-free trajectories of robotic arms using diverse path-planning algorithms, thereby ensuring that the real robotic arm can replicate these validated movements efficiently once deployed. Moreover, the commercial path planning solutions—such as the ABB path planner integrated into RobotStudio®—have not demonstrated sufficient practicality when handling construction components. This shortcoming arises because these proprietary solutions typically do not support online predictive planning or widely tested adaptation.

To overcome these limitations, this research aims to establish a standardized validation framework capable of evaluating a variety of robotic arm path planning algorithms within IC strategies. By selecting validation metrics that align with key performance criteria (e.g., safety, efficiency, and real-time responsiveness), this framework can systematically prioritize each metric in relation to specific testing scenarios (e.g., performing pick-and-place operations on construction components) by comparing nominated path planning algorithms. As a result, these ranked metrics serve as a reliable benchmarking tool, enabling informed selection of appropriate path planning algorithms for each IC task—an essential step in effectively integrating robotic technologies into the IC sector.

2 Literature Review

Previous investigations into path planning algorithms for robotic applications have typically utilized a range of benchmark scenarios, varying in complexity and evaluation metrics. In some of the earliest works, for instance, Zhao et al. [11] presented a straightforward scenario in which a robot moves from a start to a goal configuration without incorporating either environmental complexity or object manipulation tasks. Subsequent other studies introduced simple geometric obstacles (e.g., spheres and cubes) to evaluate path planning performance [12], [13], while others extended this approach by incorporating more complex obstacles, such as shelves [14], or by progressively increasing scene complexity from cuboidal obstacles to shelves [15]. Despite these advancements, two significant limitations are apparent in the existing literature. First, although dimensional asymmetry and shape complexity are critical factors when considering objects to be manipulated, most studies have not fully integrated picking and placing tasks into their test scenarios. As a result, the reported evaluation metrics—often limited to basic measures—may not reliably represent conditions encountered in robotic IC environments. Second, although some research has examined more intricate obstacle arrangements, these scenarios still fail to approximate the full complexity of manufacturing lines associated with IC strategies [5]. Accurately reflecting the intricacies of such environments is essential for ensuring that path planning algorithms are not only collision-free but also contextually suitable for real-world assembly tasks.

Several studies have begun to acknowledge these issues by introducing pick-and-place tasks into their experimental setups, although the objects remained relatively simple and symmetrical [6], [16]. To bridge this gap, [7] proposed a series of case studies involving pick-and-place operations with progressively more complex scenes, approaching the richness found in IC environments. Nonetheless, their evaluation remained restricted to fundamental metrics such as planning time and success rate, leaving room for more comprehensive assessments. Another noteworthy contribution is found in Metvaei et al.'s work [5], which presented a robotic station capable of automatically performing component pick-and-place tasks for manufacturing structural wall panels. However, this framework relied on RobotStudio® and an offline conversion of paths into RAPID code, limiting adaptability and responsiveness. In IC workflows, the ability to dynamically adjust paths is crucial due to component tolerances and variations that arise on the production floor. Offline programming and proprietary software constrain real-time adaptability, potentially leading to misalignments and decreased product quality. These findings underscore the necessity of employing open-source path planning algorithms that offer greater flexibility and integrative evaluation. By doing so, researchers can more thoroughly assess a range of metrics—beyond mere planning time and collision avoidance—ensuring that the proposed solutions are well-suited to the demanding conditions of robotic IC tasks.

3 Objectives

This study aims to address the existing limitations in evaluating path planning algorithms within robotic IC tasks by developing a standardized evaluation framework. By integrating this framework, researchers can systematically assess the robustness and effectiveness of various path planning algorithms across construction tasks with differing complexity levels. To achieve this, the proposed framework will be applied to a simulated robotic station equipped with an ABB IRB6620 robotic arm featuring a custom multifunctional end effector. A representative pick-and-place operation involving wooden studs is employed as a case study to illustrate the framework's utility, enabling the comparative analysis of path planning algorithms by informing the refinement of

validation criteria.

4 Methodology

4.1 Overview

The proposed framework is structured into three consecutive phases, each designed to collectively yield a robust benchmarking tool for assessing path planning algorithms in IC tasks. As illustrated in Figure 1.A, the first step focuses on deriving a comprehensive set of evaluation metrics. These metrics are obtained by synthesizing those previously employed across various studies, each of which has assessed one or multiple path planning algorithms. The selection of metrics is guided by predetermined qualitative criteria, prioritizing those that best align with the requirements and constraints of the designated robotic testing environment. The second step (Figure 1.B) entails the systematic identification and selection of experimental procedures to serve as evaluation case studies. This involves deconstructing the overall strategy for producing construction assemblies into a series of discrete tasks that highlight critical points of interaction between robotic systems and construction components. Among these identified tasks, those that expose the limitations of previously studied scenarios are chosen to evaluate the candidate path planning algorithms. Finally, in the third step (Figure 1.C), each selected path planning algorithm is assessed through direct observation of its generated motions. By comparing these observed trajectories against the established qualitative criteria from the first step, it becomes possible to assign appropriate weights to the extracted metrics. These weighted metrics thus enable a nuanced evaluation of path planning algorithms, ensuring that their performance can be rigorously compared and optimized for diverse qualitative requirements across a range of IC tasks.

4.2 Evaluation Metrics Selection

Although no standardized benchmarking tool currently exists for evaluating the efficiency of various path planning algorithms, numerous studies have employed diverse metrics to compare newly proposed algorithms with existing methods or to benchmark different planning pipelines against each other. To establish a more consistent framework, this section not only introduces a metric selection pipeline to be used as the evaluation metrics in testing scenarios, but also compiles a reference of metrics commonly found in the literature (Table 1). By providing researchers with a streamlined approach for selecting appropriate evaluation measures, this work facilitates more meaningful comparisons of path planning pipelines within various case studies involving the implementation of robotics in the IC sector.

The fundamental evaluation metric employed in many path planning studies is the binary assessment of whether a given pipeline succeeds or fails in solving a case study scenario. For instance, You et al. [17] introduced a GPT-based robotic task solver that uses ChatGPT4.0 to interpret provided 2D and 3D data—such as the initial state of a Hanoi Tower Puzzle—and

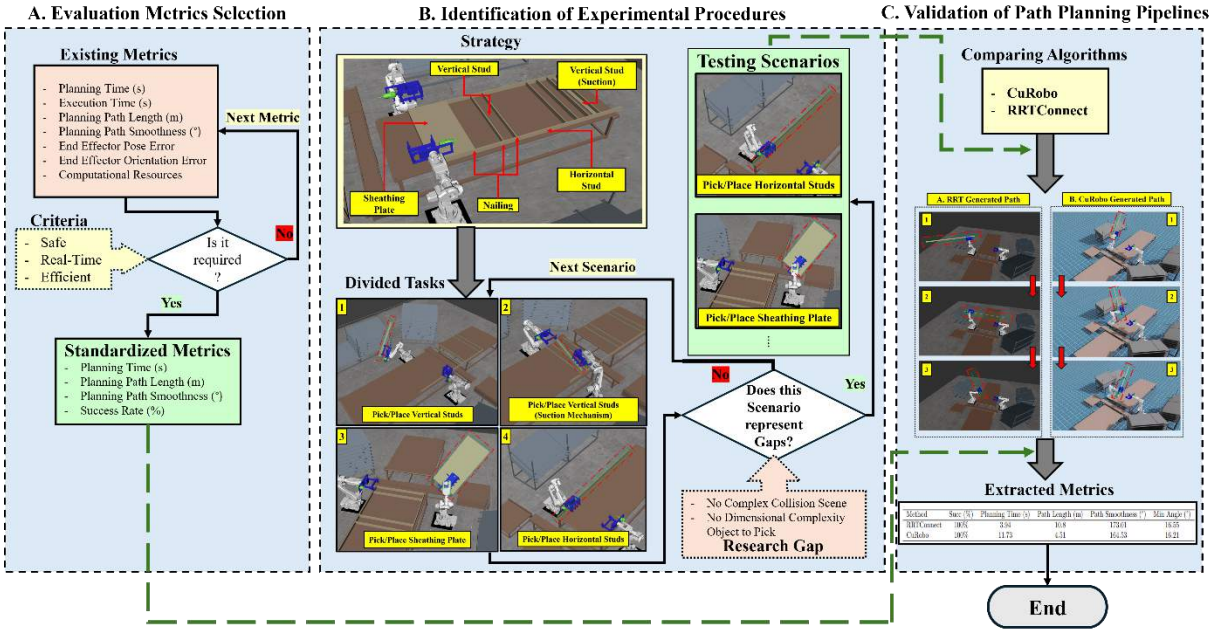

Figure 1. Methodology Overview.

generate a sequence of movements. These movements are then integrated into a ROS-based path planning framework to execute the robot's tasks. Although their work offers an initial exploration of employing Large Language Models (LLMs) for identifying task sequences in IC robotic assembly, it does not validate the path planning algorithm itself. Beyond the fundamental success/failure metric, other measures—including the accuracy of pick-and-place operations—would be valuable for such construction-oriented applications. In a more comprehensive comparative study, Ying et al. [6] developed a deep learning–based path planner optimizer and evaluated its impact on several path-planning pipelines using two principal metrics of planning time and the travel distance of the robotic tool. Similarly, Yi et al. [13] examined these metrics—planning time and path length—when proposing an enhanced P_RRT* [18] path planner. They utilized the average number of sampling nodes as a metric, reflecting computational resource demands [12]. However, within robotic IC tasks, where computational resources are less constrained, this measure is less relevant. Other studies have also considered cost function optimality, particularly in reinforcement learning–based planners [16], [19]. While cost optimality is crucial for path-planning algorithmic evaluations, it does not substantially impact IC tasks, where metrics affecting path characteristics are more informative.

In addition to these established metrics, Liu and Zuo [14] introduced path smoothness as another critical evaluation criterion. This concept involves assessing the continuity of directional changes along the generated trajectory. While they did not formally quantify smoothness for direct algorithmic comparison, their visualization underscored its importance, indicating that smoother directional changes can enhance both safety and efficiency. Building upon this notion, Zhou et al. [16] proposed a quantifiable smoothness metric derived from three consecutive path points and the angle formed between them; values approaching zero indicate trajectories closer to a straight line, thus denoting a smoother path. Furthermore, they introduced "path clearance" as an additional metric, defined as the average distance between each path point and the nearest obstacle or invalid state. Larger clearance values correlate with safer and more reliable paths.

Moreover, some studies have considered additional metrics, such as evaluating the end effector position and orientation error relative to the desired coordinates [11] or measuring the energy consumption of the robotic arm under different planning algorithms [20]. While these metrics offer insights into precision and efficiency in certain contexts, they are less directly applicable to the nuanced demands of IC tasks.

In conclusion, while certain metrics employed in previous studies may have been limited to specific robotic tasks within IC strategies, the key metrics for effectively selecting an appropriate path planning pipeline include success rate, planning time, path length (which can also reflect execution time), path smoothness, path clearance, and end effector coordination error (applicable only to real-world contexts). Accordingly, when utilizing the proposed framework to identify a suitable path planning pipeline for robotic IC applications, it is essential to select relevant metrics from the compiled reference set (Table 1)—encompassing those drawn from prior evaluation studies—based on the predetermined criteria established for comparing planning pipelines.

Table 1. Existing Metrics.

Metric	Parameter	Source
Success Rate	(%)	[6], [13], [16], [17], [19]
Planning Time	(s)	[6], [13]
Path Length	(m)	[6], [13]
Path Smoothness	(°)	[14], [16]
Path Clearance	(m)	[16]
End Effector Error	(mm)/(°)	[11]

4.3 Identification of Experimental Procedures

The overarching objective of this framework is to develop a benchmarking tool that prioritizes relevant metrics for assessing diverse path planning pipelines within different IC tasks. To achieve this, it is necessary to identify and incorporate those scenarios where the limitations of existing metrics become evident, thereby revealing gaps in current benchmarking approaches. This entails deconstructing and categorizing assembly strategies into more elementary operational tasks performed by the robotic arm. By focusing on tasks that address these identified research gaps, the testing scenarios can be enriched to more accurately reflect real-world demands. As a result, the framework can generate a metric prioritization scheme that evaluates the performance of path planning pipelines within the corresponding tasks.

4.4 Validation of Path Planning Pipelines

In the final step, the standardized metrics selected should be used to evaluate the chosen path planning pipelines. These pipelines, identified for validation, must showcase the defining characteristics of either optimal or nonoptimal solutions according to the criteria outlined by the standardized metrics. To facilitate this assessment, the trajectories generated by each selected algorithm should be visualized within a simulated environment,

allowing a comparison of the outcomes against the established criteria and the subsequent designation of each pipeline as either optimal or nonoptimal.

Moving forward, the standardized metrics identified in the literature should be calculated for each nominated path planning pipeline after generating the corresponding robotic arm trajectory in the chosen experimental scenario. By comparing the resulting metrics and ordering them according to the specified satisfaction criteria, a comprehensive benchmarking system can be established. This system will enable researchers to systematically compare any path planning pipeline within the defined testing context.

4.5 Case Study

Among the various approaches to robotic IC, the production of wooden structural assemblies has gained traction due to the relative ease of manufacturing and assembly compared to systems relying on steel or concrete components. In this study, the selected manufacturing strategy focuses on the fabrication of wooden structural panels, encompassing tasks such as the precise picking and placement of wooden studs with varying dimensions and functions, the positioning of wooden sheathing plates, and the nailing of these components. The simulated robotic workstation employs a multifunctional end effector—incorporating a gripper, suction system, and nail gun—in conjunction with conveyor belts that enhance the reachability of materials. This integrated setup enables the efficient production of wooden structural assemblies that may differ in length, include openings, and exhibit other variable design features. Figure 2.A illustrates the overall configuration of the robotic workstation, which comprises two ABB IRB6620 robots, two conveyor belts, and multiple material tables, thereby allowing the robots to access wooden studs of various lengths and thicknesses as required.

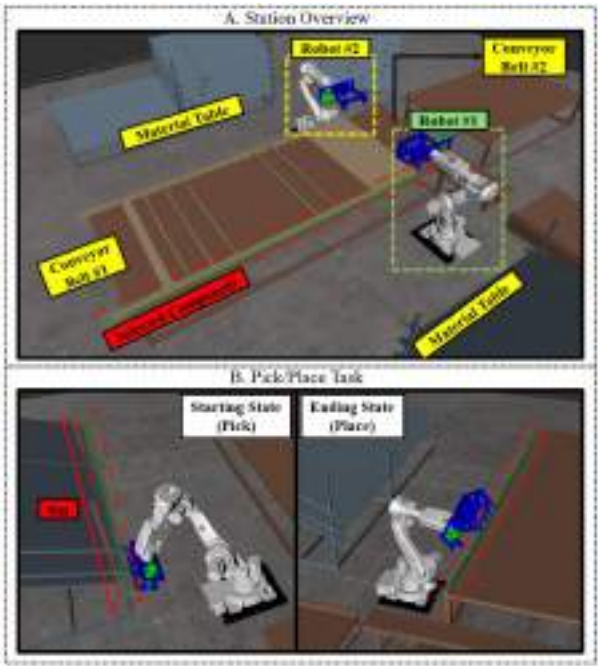

Figure 2. A) Robotic station overview. B) Selected pick/place task

4.5.1 Metrics Selection

In this study, the primary objective is to ensure the safe and reliable handling of components by simultaneously achieving the desired final configuration and minimizing potential hazards associated with both motion trajectories and tool–component interactions. To achieve this end, the most critical metrics for evaluating the effectiveness of path planning are considered success/failure, planning time, path length, and path smoothness. These metrics reflect the practical priorities of safety and efficiency more accurately than alternatives such as end effector positioning error, energy consumption, or computational optimality, which are more relevant in other domains or under different operational constraints. Furthermore, while path clearance is a common metric in standard pick-and-place tasks, it becomes less informative in scenarios involving dimensionally asymmetric construction components—such as wooden studs or sheathing plates—since the tool center point often fails to align symmetrically with the component's volume.

4.5.2 Identification of Experimental Procedures

The manufacturing of a wooden structural panel can be divided into three primary tasks, each informing the selection of path planning algorithms. The first task involves picking and placing wooden studs—both vertical and horizontal—using a robotic gripper. These studs vary in length, resulting in pronounced dimensional asymmetries that must be accommodated by the path planning strategy. The second task entails the handling of both wooden studs and sheathing plates through suction mechanisms. Although these components also exhibit dimensional asymmetries, their centers of volume are comparatively closer due to the more uniform distribution of their length and width, thereby posing a simplified set of path planning challenges compared to picking and placing wooden studs utilizing gripper. The third task centers on nailing the wooden components and involves two robots working in parallel: while one robot stabilizes the studs, the other applies the nails. Notably, this task does not include pick-and-place operations and thus does not address the dimensional asymmetry issues present in the first two tasks.

To specifically address the limitations identified in previous studies the chosen testing scenario focuses on

placing the top plate stud. The top plate represents the component with the greatest length, thereby maximizing the offset between its center of volume and the robot's tool center point. By incorporating the top plate placement task into the experimental setup, this scenario directly confronts the challenges associated with handling asymmetrical components (Figure 2.B). Furthermore, the simulated environment depicted in Figure 2.A introduces more complex spatial constraints, thereby rectifying the shortcomings of earlier studies that relied on overly simplistic obstacle configurations.

4.5.3 Validation of Path Planning Pipelines

While initially deploying open-source path planning algorithms from the MoveIt framework (OMPL library [21]), we confirmed their ability to generate collision-free trajectories. However, despite demonstrating acceptable validation metrics in previous studies, these algorithms did not consistently produce movement plans that could be characterized as safe and efficient (Evaluation Metrics Criteria). As shown in Figure 3.A, the RRTConnect-based [22] solution yielded abrupt rotational motions of the wooden stud, potentially increasing the risk of collisions in a dynamically changing environment. In contrast, the CuRobo [23] path planning algorithm—recently introduced and benchmarked favorably against other approaches—produced more stable, contextually appropriate trajectories (Figure 3.B). Based on this comparative assessment, we selected CuRobo to represent an effectively functioning path planning algorithm and RRTConnect as a pipeline for suboptimal performance within our robotic IC station. Although these two algorithms operate on different computational platforms (RRTConnect using the CPU and CuRobo leveraging GPU capabilities), planning time remains an essential performance metric. The implications of these differences in computational resources and their influence on algorithmic efficiency and suitability will be analyzed further in the Results and Discussion section.

5 Results and Discussion

In this study, 4 performance metrics were extracted to determine an appropriate path for robotic arms engaged in a pick-and-place scenario involving a 6-meter wooden stud. These metrics—Success Rate (%), Planning Time (s), Path Length (m), Path Smoothness (°), and the Minimum Angle (°) as derived from the average path smoothness—were assessed for two distinct path planning algorithms: RRTConnect (integrated with MoveIt and Rviz), serving as a motion generator misaligned with the desired criteria, and CuRobo (utilizing Isaac Sim), serving as a motion generator aligned with the desired criteria. As indicated by multiple studies evaluating path planner pipelines [15], RRTConnect is widely regarded as one of the most efficient planners in complex environments. Because offsite modular construction work zones often exhibit such complexity—particularly due to the presence of materials, components, and human workers—we selected RRTConnect as the representative graph-based planner and then compared it to a state-of-the-art planner announced by NVIDIA in 2024 to demonstrate our proposed benchmarking framework. Notably, the STOMP [24] planner was also tested but failed to compute a solution within the 60-second timeout period and was therefore excluded from our results.

Therefore, Each scenario was repeated ten times for both planners, and the results—summarized in Table 2—show that while both algorithms achieved a 100% success rate, CuRobo required, on average, more than 7.5 seconds longer to plan than RRTConnect.. Nonetheless, this additional time does not substantially impact the suitability of the generated paths for real-world pick-and-place operations, particularly given the possibility of reducing planning time by employing more powerful computational resources (e.g., GPU-based training seeds). Meanwhile, CuRobo generated significantly shorter paths, with a length of approximately 4.51 meters, less than half that achieved by RRTConnect, thus meeting the initial criteria favoring reduced path length. However, path length alone is insufficient for full

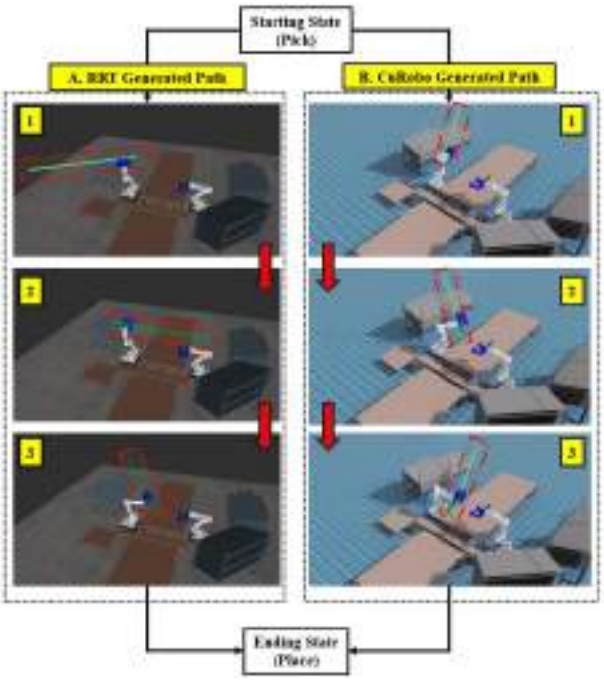

Figure 3. Representing the generated path utilizing RRT (A) and CuRobo (B) algorithms.

evaluation, and consideration must also be given to path

smoothness to avoid unsafe abrupt directional changes. Although both algorithms demonstrated negligible differences in path smoothness (less than 10° variation) and produced minimum angles of around 16°, the CuRobo algorithm ultimately proved more effective in this scenario. Accordingly, the metrics can be ranked in descending order of importance—beginning with Success Rate, followed by Path Length, then Path Smoothness, and subsequently Minimum Angle—while Planning Time emerges as comparatively less critical for the tested scenario.

Table 2. Experiment Results

Methods	Success Rate (%)	Planning Time (s)	Path Length (m)	Path Smoothness (°)	Min Angle (°)
RRTConnect [22]	100	3.94	10.8	173.01	16.55
CuRobo [23]	100	11.73	4.51	164.54	16.21

6 Conclusion

In conclusion, this study successfully identified, defined, and applied a set of weighted validation metrics to compare distinct path planning algorithms under conditions of dimensional asymmetry, which, although demonstrated here with a single robotic workstation, could be extended to various workstations and manufacturing strategies within the IC sector. Future efforts could involve categorizing these manufacturing strategies to form a comprehensive dataset of tasks for robotic stations, ultimately enabling the creation of a standardized, rule-based methodology for robotic operations in industrialized construction sector.

Abstract –

3D printing has gained significant popularity in construction in recent years, along with a growing focus on earth-based materials. These materials must adhere to certain principles to ensure printability and extrudability, allowing for good consistency during the printing process. This would need extra water, resulting in a wet mixture that could decrease the production printing rate per day and limit overhang structures due to the wet materials.

One challenge facing these materials is their slow drying process, especially in low temperatures and humid climates. However, the strength and stiffness of these materials are gained by time when water evaporates. Given the limited studies on the drying process during 3D printing, this research aims to explore the structural stability of maximum support-free overhangs using a custom-designed heating system based on Active Hot Air Drying System (HADS) that mimics sun drying. This system accelerates and aids the drying process of the layers, ensuring greater structural stability without deformation.

According to the results, the contentious heating system increased layer stability by reaching more layers at once. The maximum overhang reached was an angle of 50 degrees before failure at 60 degrees. In conclusion, the research highlighted and promoted the use of earth-based materials and offered some solutions to ensure that printed buildings could be dried fast. This is a solution to establish earth as a reliable material in structures in a contemporary way with the use of 3D printing.

1 Introduction

3D printing (3DP) has been gaining more popularity in the construction sector for its ability to reach complex customized geometries without any formwork or support structure [1]. When it comes to using 3DP techniques in construction, the effect of the environment on the materials is a crucial topic to consider regardless of the drying process, in which both humidity and temperature play the main role. Most earthen-based materials used in 3DP require more water than conventional construction techniques such as rammed earth, adobe, and cob, which allows good printability and extrusion. Thus, this could be a problem for cold climates where extra time will be needed until the materials dry and the water vapour. In addition, the wet material would limit the amount of printed layers per day, which might decrease the production rate. Complex geometries are another limitation while the materials are wet. For instance, overhanging geometry, as a self-supported structure, is one of the main challenges in 3DP, as certain overhanging parts can compromise structural stability, especially when using slow-drying materials like earth. This typically limits design flexibility, reduces printing speed, and consequently lowers the daily production rate of printed layers.

Many researchers have investigated the maximum self-supporting overhanging geometry of earthen-based materials for 3DP, finding that the angle typically ranges between 17 and 20 degrees before failure [2, 3, 4]. The importance of studying the material's rheology allows controlling the climatic conditions that affect their internal bonding, which is responsible for the mechanical strength [5]. In 3DP with concrete, the material dries quickly, generating more layers per day and increasing the production rate. This occurs when concrete is exposed to air and reacts with chemical agents, such as admixtures and plasticizers. These additives alter the chemical formulation, resulting in a stiffer bonding material [5]. However, the concrete faces high drying shrinkage due to the high exposure, especially when the aggregates are not carefully selected [6]. When earth-based materials are exposed to air, they become stiffer over time as water evaporates, while the chemical composition remains unchanged [5]. Although cementation materials have been explored for their durability and the effects of additives added, yet, limited

research covered the drying process of earthen materials during printing. Research done by [5] focused on the ”Forced Layer Drying” (FLD) technique to increase the mechanical properties of the wet mortar they used during printing. The results concluded that airflow, temperature, and geometry are factors affecting the evaporation rate, mechanical properties, and structure stability of the whole printed layers.

This research explores the feasibility of a custom-designed Active Hot Air Drying System (HADS) that aids in drying the layers during printing. The goal is to achieve the maximum stable overhanging angle with earthen materials, ensuring structural stability. The research method is tested on eight different inclination angles (Figure 2) of a modular overhanging arch using 3DP with clay as shown in Figure 1.

Figure 1: Overhanging example reaching 33° visualization inside 10mm grid. The object is 150 mm high and varies in length and depth depending on the overhanging angle

The printing and structural stability of the prototypes are tested both with and without an HADS. All the printing speed and flow rates remained constant. The results show that the heating system installed on both sides of the nozzle allows for achieving more overhanging arches at wider angles.

2 Related Work - 3DP drying process of earthen materials

Earthen materials typically require additional drying time to allow water to evaporate, unlike concrete. In 3DP, this challenge can impact daily productivity as layers rely on sunlight for drying. Unlike filament-based 3D printing, which requires cooling, the travel time between layers can affect bonding, leading to weaker connections and a drop in temperature [7].

Earthen material mechanical performance can be enhanced through several aspects; 1) adding admixture, alcohol, or alginate [5], 2) reducing the water content, which then could affect the extrudability of the layer. Yet both factors are affected by the climate, for example, a hot-arid climate allows water to evaporate faster than in a cold climate. Thus, the buildability will limit the printed layers from holding the upper layer until it dries and gets strength. It is important to mention the conflict between both printability and buildability for 3DP where pumping efficiency requires more wet materials which results in a lower strength, while buildability requires a material with a higher strength [5].

Architects are seeking designs that are innovative and cost-effective for their material optimization and stability without the need for any formwork. A research done by [8] produced a double-curvature façade panel by printing clay on a developed non-planar surface using a multi-forming machine with a movable actuator. This gives the flexibility to adapt the surface based on the customized geometry for each different tile without any waste formwork.

Research done by Motamedi et al. [5] implemented conductive heating through a heat gun with an 1800-watt and two heat guns with 3300 watts on two 30cm 3D printed clay blocks. The results show that the first experiment had a collapse at the 25th layer, while the second case reached higher layers with the 30th layer [5]. These results were done on a block with no overhanging consideration. A different drying process is done using infrared radiation to the deposited printed layer to allow increasing the past’s yield stress which the geometry keeps its shape [9]. Another study was conducted by [10] from IAAC, where a wooden formwork was used to support 3D-oriented clay overhanging at angles of 45°, 60°, and 75°, resulting in significant timber waste. Gomaa et al. [11] demonstrated in their research that cob, a mixture of earth and fibers, can be printed with overhangs up to 40 degrees. This finding indicates that fibers enhance the mechanical properties of the material, thereby improving structural stability. In our research, however, we will not incorporate fibers into the earth mixture.

2.1 State of the art

Building on previous studies, the effect of heat and self-supported overhanging angles on the stability of earthen materials remains unexplored. This will be the focus of our research. Accordingly, the heating process will be controlled after a specific number of layers to ensure the stability of overhanging geometries without causing cracking.

3 Method

To achieve the aim of this paper—creating structurally stable overhanging geometries with the maximum angle using earthen materials—an experimental method was developed. This method is based on a digital design-to-fabrication workflow and is divided into three main phases: geometry consideration, fabrication and assessment.

3.1 Geometry consideration and design parameters

The geometry was designed to achieve maximum overhanging through a balanced shape with a small area base of 27 x 64 mm, as shown in Figure 1 and 2. The total height is constant at 150 mm with a layer height of 1.7 mm and a total of 88 layers.

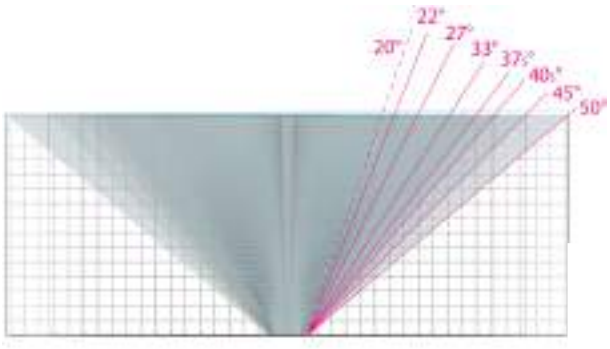

Figure 2. Inclination steps with a dotted line indicating the previously achieved maximum inclination of 20°

3.2 Fabrication

Nine prototypes were 3D printed using cla angles of 22°, 27°, 33°, 37.5°, 40.5°, 45°, 50°, and 60 assess which angle achieves the goal before failure, with and without HADS. A similar approach was ado based on the method outlined by [5]. They used tunnel experiment which act as a heating effec calculate the evaporation and drying rate of the mat while printing based on airflow speed and temperat with and without forced layer drying.

Accordingly, a HADS was added to both side the nozzle, with the assumption that it would impr structural stability by accelerating the drying of layers.

The first two angles, ranging from 17° to have been validated in previous research as the maxi achievable in clay printing [2, 3, 4]. This study, theref aims to explore new angles with the objective exceeding these limits to achieve stable geometries.

3.3 Setup

This robotic system is controlled by a computer running Rhino 3D, Grasshopper (GH), and the Machina plugin, which directly transmits URScript paths to the Universal Robot UR10. The robot is equipped with an end effector featuring a 3 mm nozzle and HADS on both sides. The clay is extruded from a cylinder cartridge by a motor, which is regulated by a controller (see Figure 4). This controller is directly connected to the UR's control unit. The parametric 3D model is sliced in Grasshopper, and the generated paths are merged and transferred via the Machina Bridge software.

3.4 Assessment

The structural stability of each prototype is measured within a setup (Figure 3 and 4) that hosts several tools. This begins with counting the maximum number of layers each prototype achieved before failure, using a grid installed behind the robot. A fixed camera was positioned in front of the model during printing. Additionally, a thermal camera was used to measure humidity, temperature, and water content in the layers to analyze the differences between each prototype.

3.5 Materials and Tools

The clay used is beige with Chamotte 20% 0 - 0,2 mm and JK Drop Spike [12] test of 3.5. A universal robotic arm (UR10) is used for 3D printing with a payload of 10kg and a nozzle size of 3mm. Flow rate was not calculated and is very depended on the nozzle size. The feed rate or the printing speed is 20mm/sec.

Two heater fans were installed on both sides of the nozzle to ensure consistent drying while printing. The heating system mimics the sun and air ventilation which increases the drying process of the layer. The heaters have not yet been designed to synchronize with the robotic arm, as each operates independently. Currently, the heater is manually activated. However, future adjustments could enable synchronization with both the robotic arm and the thermal camera, allowing for further experimentation.

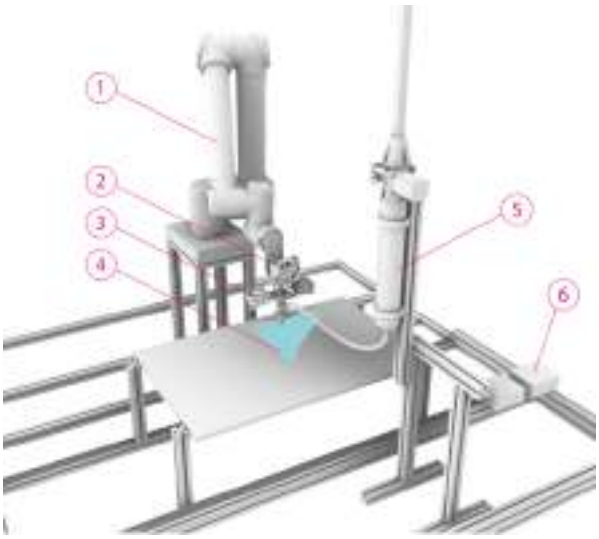

Figure 4. Experimental Setup: 1)robotic arm (UR10); 2)Screw-Extruder (custom-build); 3)PTC Fan Heater; 4)Test Object with inclined Overhangs; 5) Ram Extruder (custom-build); 6) Extruder controllers

4 Results & Discussion

4.1 The structure stability

Based on previous references, where the maximum stable inclination angle was documented as 20 degrees, it is acknowledged that this value can vary depending on the clay type and water ratio. The results showed that failure occurred at the maximum inclination angle tested. Our observations revealed that an angle of 22° remained stable without heating, while failure occurred at 27°. Table 1 compares the results for different inclinations with and without HADS, highlighting that all prints utilizing HADS were successfully completed, achieving angles up to 50°. Figure 5 illustrates the outcomes of the nine trials and the extreme overhangs achieved. Regarding stability, prototypes printed without HADS were observed to be overly wet, leading to loss of stability and self-deformation when moved from the bed post-printing. In contrast, prototypes exposed to HADS dried quickly, with layers bonding firmly to one another, resulting in greater stiffness. These prototypes retained their geometry and were easy to move, exhibiting behavior comparable to materials like PLA or ABS.

Although the research could have employed spiral continuous path planning, we deliberately decided to create a seam in the middle of the left overhang of the testing part. This decision was made to study the behavior of the printed object in the seam area, as shown in Figure 6. The 3DP process successfully achieved maximum overhang angles of 50°.

Table 1 Printing iterations

Angle	Drying System	Stable
22°	No	Yes
27°	No	No
27°	Yes	Yes
33°	Yes	Yes
37.5°	Yes	Yes
40.5°	Yes	Yes
45°	Yes	Yes
50°	Yes	Partially
60°	Yes	geometry fail

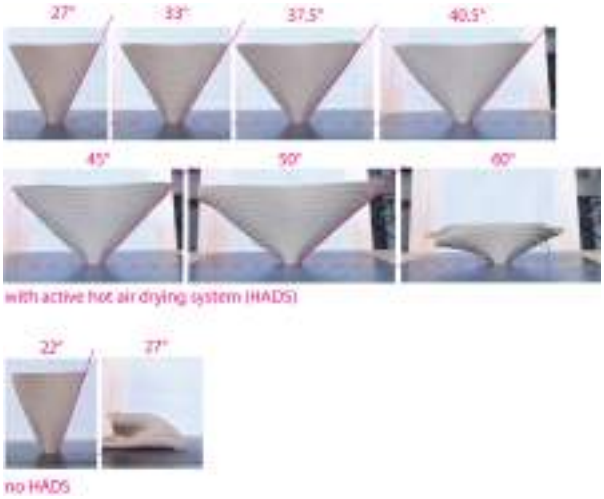

Figure 5. The different inclination angles printed with and without HADS

We assume that overhangs between 50° and 60° can be achieved which can be subject of further research. Both angles experienced failure on the seam side. This failure was attributed to the seam formed by the reverse extrusion after each layer, as illustrated in Figure 5.

Figure 6. The seam concept

This suggests that the HADS limit is 50° before failure occurs. While the 60° inclination did not result in failure, the layers did not align properly, which could be attributed to geometric limitations. At 45°, the layers overlap by 50%, indicating that further increases in inclination angles would likely lead to failure. This is due to the volumetric overlapping of the material, which shifts the geometry's center of gravity outside the footprint of its support. A similar issue could arise when validating the scalability of the prototypes on-site.

In the referenced paper by Motamedi, the overhang angle was achieved after 30 layers, heated with two heat guns, without collapsing. In contrast, our approach reached 88 layers. However, due to differences in the size of the printed material, these methods are not directly comparable. Scaling the nozzle increases both the material volume and the encapsulated humidity, requiring proportional adjustments in ventilation for effective heating. This should be further tested in future experiments.

Compared to the findings in [10], our prototypes underperformed, as their approach utilized formwork with angles ranging between 50 and 75 degrees.

4.2 Thermal Camera Temperature analysis

The monitoring of the prototypes during printing revealed a correlation between failures and the moisture levels of the layers. It was observed that the layers at the base were excessively wet, compromising their ability to support the weight of the layers above, leading to deformation. However, with the application of the HADS system, the temperature of the lower layers decreased, allowing them to solidify and better resist the loads from above. The HADS distributed heat evenly, ensuring that the entire printed body, rather than just the printed stripe, was surrounded by heated air, as shown in Figure 7. The thermal images show that the printing bed reflects heat, which supports the overall distribution of warm air. Although the surrounding area warms up to 36°C compared to the undried state at around 20°C, the object itself does not heat up and may even become cooler due to the heat-exchange effect. This assumption could be a subject for further research.

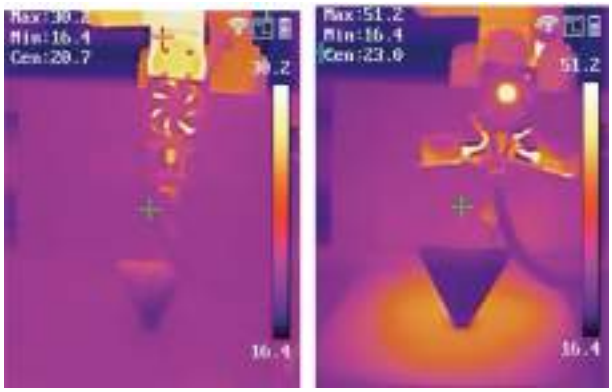

Figure 7. Thermal images. Left: 3DP without HADS. Right: 3DP with HADS

4.3 Limitation and further research

Although the printing speed was constant, it significantly impacted the structural stability especially when dealing with wet materials. Increasing the speed can lead to insufficient layer bonding, as the lower layers may remain too wet and unable to support subsequent layers. This can result in structural weaknesses and increased bucking and failure. Conversely, slower printing speeds allow for better moisture control and layer adhesion, enhancing the stability of the printed structure. Balancing print speed is, therefore, crucial for achieving optimal stability in 3DP clay components.

The room temperature was maintained at a constant 15°C; however, the same settings may exhibit different behavior when dealing with fluctuations in varying climates and humidity levels. Additionally, scaling up could impact the stability of the geometry, even if it is stable at a smaller scale. This is due to the increased volume in larger scales, which can affect the bonding between layers. Moreover, larger geometries may necessitate adjustments in printing parameters, such as speed and layer height, to ensure consistent quality and performance.

Furthermore, different clays can vary in their drying process which might cause cracks and uneven shirking problems by fast or unequal drying. Each clay should be tested and their percentage of water checked to observe the drying time and predict any cracks.

Concerning the technical issue, some failures occurred due to the seam observed on the one side of the object. Consequently, the design of the toolpath can influence the structural stability of the geometry, whether it follows a spiral path or a continuous path without reversal, as in our case.

Overall, scaling up necessitates careful consideration of these factors to ensure successful outcomes. HADS on a small scale could be durable, while on a large construction scale, we can rather find another way to absorb the humidity of the wall or ensure equal sun heat distribution across the whole building surface. The HADS process should be observed to prevent any cracking that might occur in the material.

Another recommendation for further research in large scale 3DP on-site is to add a larger heating system that can absorb the humidity from the large printed walls in the case of not controlling the sun distribution across the building surface especially when having the side of the building in the North direction where no sun is exposed on that side.

For further research, additional sensors could be integrated above the extruder to automate the HADS based on air humidity and the deformation of the printed output. Furthermore, a differentiated implementation of HADS could be explored, such as turning it off, or adjusting the temperature by reducing or increasing it on specific parts of the layer or object.

5 Conclusion

This research explored the maximum support-free overhanging angles that 3D-printed clay can achieve without additional support. Building on previous studies that reached a maximum of 20 degrees, our results surpassed this limit, achieving angles of up to 50 degrees with the implementation of the HADS. This new system ensured even heat distribution across the entire geometry, addressing challenges found in real-world applications where building surfaces, such as northern sides, are not naturally exposed to sunlight.

Our active hot air drying system, mounted on the printing head on a robot arm, ensures consistent heat distribution across the entire layer surface. This approach differs from previous studies that used handheld heat guns, which led to issues like cracking and shrinkage.

Looking ahead, this study raises further research questions, such as how the heating system would perform in humid or dry climates. Additional tests may be needed to adjust the water content in the clay and calibrate the heater temperature for optimal performance in different environmental conditions.

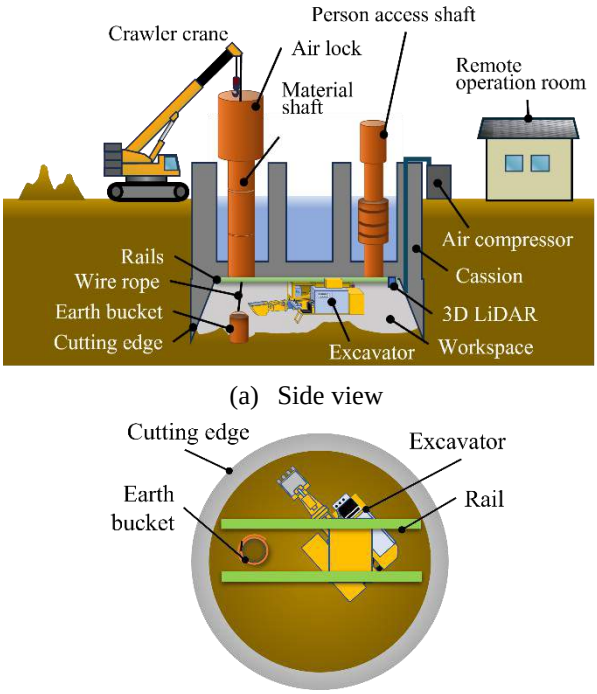
Abstract –

The pneumatic caisson method, which is used in the construction of bridge piers and other structures, is used in a variety of different sites. Currently, many processes in the pneumatic caisson method in Japan are carried out remotely. However, In Japan, the declining birthrate and aging population have created a shortage of experienced field workers. Therefore, research into the automation of the pneumatic caisson method is being actively conducted in Japan.



In this paper, we describe the results of experiments using an actual machine to test a method using the greedy algorithm with the purpose of automating the pneumatic caisson method. Our research group has previously proposed a method using the greedy algorithm for optimizing the excavation process. In this paper, we have reviewed the cost calculation equation and conducted experiments in a test field using an actual excavator. As a result of these experiments, we were able to achieve a construction speed equivalent to actual construction.

Keywords –

Automatic construction; The pneumatic caisson method; Actual machine test; Job scheduling; Process optimization; Greedy algorithm

1 Introduction

The pneumatic caisson method, which is a construction method for burying structures such as bridge piers and underground pumping plants, is used in a variety of different sites. In the pneumatic caisson method, as shown in Figure 1, a workspace is provided at the bottom of the concrete caisson. Rails are installed in the ceiling of the workspace, and an excavator is suspended from the rails. The excavator moves by traveling on and turning around these rails. By removing the soil at the bottom of the caisson using this excavator, the caisson sinks underground by its own weight and is buried. The excavated soil is loaded into an earth bucket and carried out aboveground through a material shaft. In the pneumatic caisson method, compressed air is blown into the workspace at the same pressure as the water pressure to prevent groundwater from entering the workspace. As a result, the pressure in the workspace increases as the caisson sinks. Construction work under high pressure increases the physical burden on field workers.

(b) Diagram of workspace from above

Figure 1. Pneumatic caisson method overview

For this reason, many of the processes involved in the pneumatic caisson method in Japan are carried out

remotely. However, In Japan, the declining birthrate and aging population have created a shortage of experienced field workers. For this reason, research into the automation of the pneumatic caisson method is being actively carried out in Japan.

In our previous research, we defined the excavation field and temporary soil storage area and developed a system that loads soil into an automatically recognized earth bucket or disposes of soil at the temporary soil storage area by excavating the soil at the excavation positions within the field. We have confirmed the effectiveness of this system through experiments at construction sites [1, 2, 3, 4]. Also, with the purpose of achieving automatic excavation of the entire workspace, excluding excavation under the cutting edge, we proposed a method of optimizing the excavation position and soil disposal position given to the Automatic Excavation System using the linear programming method, and compared the results with actual construction in a simulation experiment. The results showed that the proposed method achieved good results, with a volume of soil of 28.5 m^3 taking 74 minutes, compared to 98 minutes in actual construction [5].

In this paper, we describe the results of experiments in a test field using a method for optimizing excavation positions and soil disposal positions for an Automatic Excavation System, which was developed for automatic excavation of the entire workspace, excluding excavation under the cutting edge.

2 Relational Works

In Japan, there has been a lot of research into construction automation due to the shortage of manpower in the construction and civil engineering industries caused by the declining birthrate and aging population. Much of this research has focused on automating general construction machinery used in outdoor environments such as dam construction [6, 7, 8, 9, 10]. Research related to excavation planning includes the work of TERENZI et al. [11, 12, 13]. TERENZI et al. propose a method for automating back shovel excavators that divides the wide-area excavation plan into a global plan and a local plan. The global plan is treated as a Coverage Problem, and the order of the cells is determined using graph navigation algorithms. There is also research on autonomous mobile robot behavior planning, such as the research of LI et al. [14, 15].

There has also been a lot of research into the automation of the pneumatic caisson method [16, 17, 18]. In particular, in the research by TAKADA et al. [18], a job scheduling algorithm for multiple excavators is proposed using the Munkres algorithm based on the positional relationship between the soil mountain and the excavator bucket. This method achieves cooperative work by multiple excavators using a 1/10 scale model and has achieved some results. However, the experiments using the model were conducted under optimal conditions, such as the shape of the soil mountain, and the excavation conditions did not match the actual conditions of the pneumatic caisson method. In addition, this method is one in which the location of the temporary soil storage and soil disposal is specified in advance, and the excavators are assigned to work at each location, and the definition of the temporary soil storage and soil disposal locations is done manually.

In this method, we propose a method for automatically selecting the optimal excavation positions or temporarily placing positions within the excavation field. In addition, we used an excavator that is actually used in construction for the experiment, so the experiment is in line with actual construction conditions.

3 System Configuration

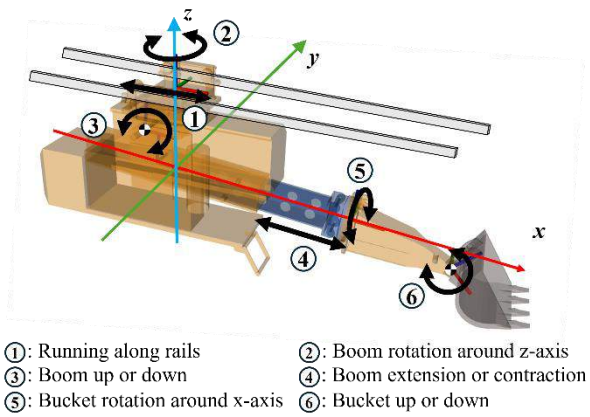

Figure 2. Diagram of excavator model

First, we will explain the excavator used in the pneumatic caisson method. Figure 2 shows a model diagram of the excavator. This excavator has six degrees of freedom: (1) running along rails, (2) boom rotation around the z-axis, (3) boom up or down, (4) boom extension or contraction, (5) bucket rotation around the x-axis and (6) bucket up or down. Basically, excavation is carried out using the (3) boom up or down, (4) boom extension or contraction and (6) bucket up or down axes, and movement is carried out using the (1) running along rails and (2) boom rotation around z-axis, and soil disposal is carried out using the (5) bucket rotation around x-axis. This excavator is operated by remote control in actual construction, so rotary encoders or potentiometers are attached to all axes. The physical quantities obtained from these are sent to the remote operation room by a wireless connection. In addition, this excavator is powered by hydraulics, as are other

construction machines. The amount of stick operation on the remote-control panel in the remote operation room is sent to the excavator by wireless connection, and the hydraulic actuator is operated by opening and closing the solenoid valve. These remote-control functions are used to automate the excavator. In addition, the excavation method of the excavator is different from that of the back shovel excavator, and it excavates by scooping up the soil from below.

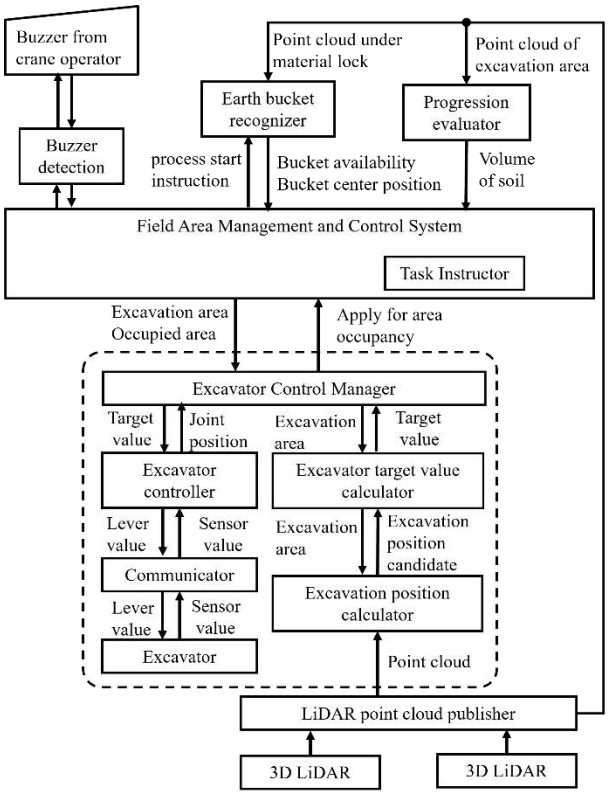

Figure 3. Diagram of the automatic excavation system configuration

Figure 3 shows an overview of the system. This system is based on the Automatic Excavation System [1] that we have been developing. It is composed of a group of software that mainly consists of the Field Area Management and Control System that manages the entire field, and a group of software that mainly consists of the Excavator Control Manager that manages the excavator. This system is a new addition to the former Field Area Management and Control System, adding a Task Instructor to instruct excavators on their tasks and where to move to. The Task Instructor instructs excavators on their tasks and where to move to, based on the volume of soil in the excavation area, the condition of the excavator and the earth bucket.

The process is as follows: First, the Excavator Control Manager requests the Task Instructor to perform a task. The Task instructor, having received the request, instructs the excavator on the work to be done, the excavation positions or the destination of the soil disposal, according to the volume of soil in the excavation area and the state of the earth bucket. Next, the Excavator Control Manager requests the Field Area Management and Control System to provide a route to the destination received from the Task Instructor. The Field Area Management and Control System then returns to the Excavator Control Manager the shortest route to the destination without coming into contact with any obstacles.

4 Methodology

In the normal excavation process of the pneumatic caisson method, excavation begins in the center of the workspace, leaving the soil near the inner wall, called the cutting edge, in place. After that, the sinking of the caisson begins by removing the soil under the cutting edge. The purpose of this research is to achieve automatic excavation of the entire central area of the workspace, excluding excavation under the cutting edge. Our research group proposed a method of optimization by replacing the excavation process of the pneumatic caisson method with a transport problem of soil [5]. The following constraints are set in this replacement:

1. Constraints on the excavator
   - The excavator can move only on rails.
   - The excavator moves by traveling and turning on the rails, at which time the speed of movement is assumed to be constant.
   - The time required for one excavation and disposal of the soil is assumed to be constant.
   - Not to excavate under the caisson cutting edge or to fill up the soil around the cutting edge.
   - The volume of soil that can be moved in one excavation depends on the size of the excavator bucket, and the excavator that our research group is targeting is 0.25 m^3.
   - When there are multiple excavators on the same rail, each one has a limited range of movement.
2. Constraints on the Earth Bucket
   - While there is no earth bucket in the workspace, soil cannot be carried out of the caisson.
   - The capacity of the earth bucket is constant at 1 m^3.
   - Only one excavator can load soil into one earth bucket at a time.
   - The time required for a full earth bucket to rise and be returned to the workspace again is

assumed to be constant. The time required depends on the length of the material shaft. Furthermore, the length depends on the amount of sinking of the caisson, but the amount of sinking is only a few tens of centimeters per day. Therefore, note that the time required does not change over one day.

- The number of earth buckets that can be loaded at one time is limited to the number of material shafts.
- The location of the earth bucket is limited to directly below the material shaft.

3. Constraints on the excavation field
   - Excavation cells are cells that divide the excavation field into grid-like sections, and the size of each cell is 0.5 x 0.5 m. Here, the cell size is set to 0.5 m to ensure that there is no excavation left when excavating adjacent cells, as the excavator bucket width is 880 mm.
   - The goal of excavation is to excavate all cells to the target depth.

We defined an objective function like Equation 1 for the above constraints. Here, N is the number of times the earth bucket is raised during construction, T_B is the time when the earth bucket is not in the workspace, T_{Ei} is the time taken for excavation and disposal of soil, T_{movei} is the time taken to move to the excavation and disposal location, and the subscript i indicates one operation.

$$\text{Minimize } T = \sum_{i=1}^{I} \left(T_{E_i} + T_{move_i}\right) + T_B N \qquad (1)$$

The objective function was solved using the greedy algorithm. The greedy algorithm is one of the methods used to solve optimization problems. The greedy algorithm obtains the optimal solution by dividing the elements of the problem into subproblems, evaluating each of them independently, and incorporating them in order of their evaluation values. For example, the greedy algorithm is used in the scheduling problem of trucks and yard cranes at quay [19, 20]. The reason we chose the greedy algorithm in this method is that it is easier to implement than other algorithms and has a fast computational time.

In previous research, we have proposed a method of dividing the excavation field into a grid, calculating the movement cost of each cell with coordinates (i, j) using Equation 2, and selecting the cell with the lowest cost, and have evaluated this method through simulation [5].

$$cost_{(i,j)} = L_{(i,j)} - (G_{(i,j)}/R) \qquad (2)$$

Here, $L_{(i,\ j)}$ is the distance from the excavation cell with coordinates (i, j) to the earth bucket, $G_{(i,\ j)}$ is the volume of soil in the excavation cell with coordinates (i, j), and R is the available capacity of the earth bucket.

However, when the cost calculation formula in Equation 2 was implemented in an actual machine and experiments were conducted, when the available capacity of the earth bucket became low, the excavator would select an excavation cell that was far away from the earth bucket and had a large volume of soil, and it did not operate efficiently.

In this paper, we will revise this movement cost calculation formula and propose a method that uses Equation 3 for excavation and Equation 4 for soil disposal. Here, $L_{\mathrm{mt}(i,\ j)}$ is the Euclidean distance from the excavation cell at coordinates (i, j) to the material shaft, $V_{(i,\ j)}$ is the volume of soil in the excavation cell at coordinates (i, j), and $D_{(i,\ j)}$ is the minimum Euclidean distance from coordinates (i, j) is the minimum value of the Euclidean distance from the coordinate (i, j) to the cell where the soil is temporarily placed, and $L_{\mathrm{rovo}(i,\ j)}$ is the Euclidean distance from the excavation cell at coordinates (i, j) to the excavator's cutting edge, and α, β, γ and δ are weighting coefficients. In addition, $L_{\mathrm{mt}(i,\ j)}$, $V_{(i,\ j)}$, $D_{(i,\ j)}$, and $L_{\mathrm{rovo}(i,\ j)}$ are normalized by their respective maximum values. Also, u is a coefficient that changes depending on whether or not an earth bucket is present and is when there is one and when there is not. The earth bucket shape is recognized from the point cloud data measured by the 3D LiDAR attached to the ceiling. When recognized, the position of the opening at the top of the earth bucket and the volume of soil loaded are obtained. The recognition program is not described in detail in this paper, but it is a high-speed version of the automatic recognition program developed by OSAKI et al. [2].

The following actions are selected based on whether or not an earth bucket is present, as determined by the recognition program:

1. When an earth bucket is placed under the material shaft.

   When excavating, the cell with the lowest cost is selected using the calculation in Equation 3. When disposing of soil, the position of the recognized earth bucket is returned.

2. When the earth bucket is not placed under the material shaft.

   When excavating, the cell with the lowest cost calculated using Equation 3 is selected. When disposing of soil, the cell with the lowest cost calculated using Equation 4 is selected. If the soil mountain is allowed to continue being temporarily placed in the same cell, it will become too high and interfere with the movement of the excavator. Therefore, if the distance from the highest point of the soil mountain to the ceiling becomes 1.9 m or

less, the soil is disposed of in the excavation cell with the lower movement cost. This value was determined with a margin of safety, as the bottom of the excavator is 1.6 m from the ceiling.

$$cost_{e_{(i,j)}} = \alpha_e {L_{mt}}_{(i,j)}^{\ u} + \beta_e {V_{(i,j)}}^{-1} + \gamma_e {D_{(i,j)}}^{u} + \delta_e {L_{rovo}}_{(i,j)} \quad (3)$$

$$cost_{d_{(i,j)}} = \alpha_d {L_{mt}}_{(i,j)} + \beta_d V_{(i,j)} + \gamma_d D_{(i,j)} + \delta_d {L_{rovo}}_{(i,j)}^{\ -1} \quad (4)$$

5 Evaluation Experiment

5.1 Experiment Overview

To evaluate this method, we conducted an evaluation test using an actual machine in a test field. Figure 4 shows the excavation field and the location of the material shaft. The excavation field is a 3 x 3 m square centered on (x, y) = (0.0 m, –1.0 m), and the target excavation depth is 0.5 m from the ground surface. The size of the excavation field was determined based on the maximum size of our test field. The size is small, but in actual construction sites where we have conducted experiments, the size has been the same or smaller than this. In this experiment, we measured the time required to excavate all the cells in the excavation field to the target depth.

The material shaft is a circle with a radius of 1.5 m centered on (x, y) = (0.0 m, 3.0 m), and the soil disposal bucket is placed within this circle. The earth bucket is placed and carried out directly below the material shaft by crane. The time from when a full earth bucket is carried out of the workspace to when it is placed in the workspace again is about 4 minutes. This is the same as in actual construction. The earth bucket can load 1 m^3 of soil at a time. In this experiment, the total volume of soil excavated is calculated based on the number of full earth buckets.

In addition, the weighting coefficients for Equation 3 are α = 0.2, β = 0.3, γ = 0.3, δ = 0.2, and the weighting coefficients for Equation 4 are α = 0.2, β = 0.0, γ = 0.5, δ = 0.3. These weighting coefficients were determined by repeated experiments.

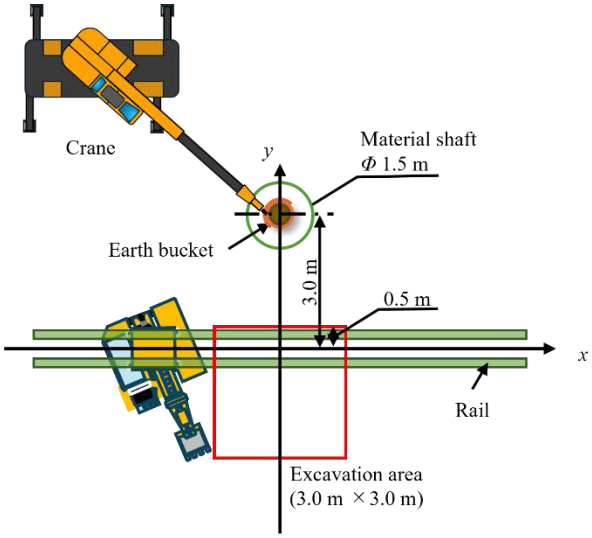

Figure 4. Diagram of Evaluation Experiment

5.2 Results and Discussion

The experiment is shown in Figures 5 and 6. The right side of both figures shows the test field. The left side of both figures shows the display screen of the Automatic Excavation System. The red frame shows the excavation field, and the green frame shows the excavation cells selected by the method. The Automatic Excavation System controls the excavator so that the blade tip is at the center of the green frame, and then performs excavation or soil disposal at that point. The heat map in both figures shows the height of the ground, with red indicating low areas and purple indicating high areas.

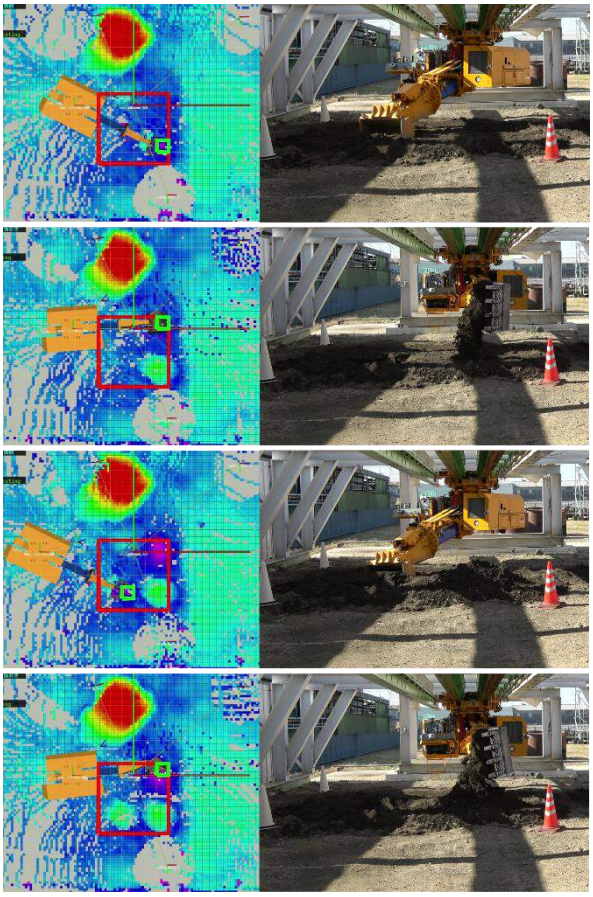

Figure 5. Experimental result when the earth bucket is not placed under the material shaft

Figure 5 shows the situation when the earth bucket is not placed under the material shaft. In the top row, the excavator is digging the cell with the lowest cost calculated using Equation 3. In the second row from the top, the excavator is temporarily placing the earth in the cell with the lowest cost calculated using Equation 4. The two bottom rows are the same as the top row, but the cell that was excavated the first time is no longer selected due to a decrease in the volume of soil. This process is repeated until the earth bucket is placed under the material shaft. Looking at the entire process, the earth in the excavation field is moved towards the material shaft. When disposing of soil in temporary soil storage, cells with high soil mountains were passed over in the calculations, and cells with low costs were selected next. As a result, the distance from the highest point of the soil mountain to the ceiling was never less than 1.6 m, and there were no problems with the movement of the excavator.

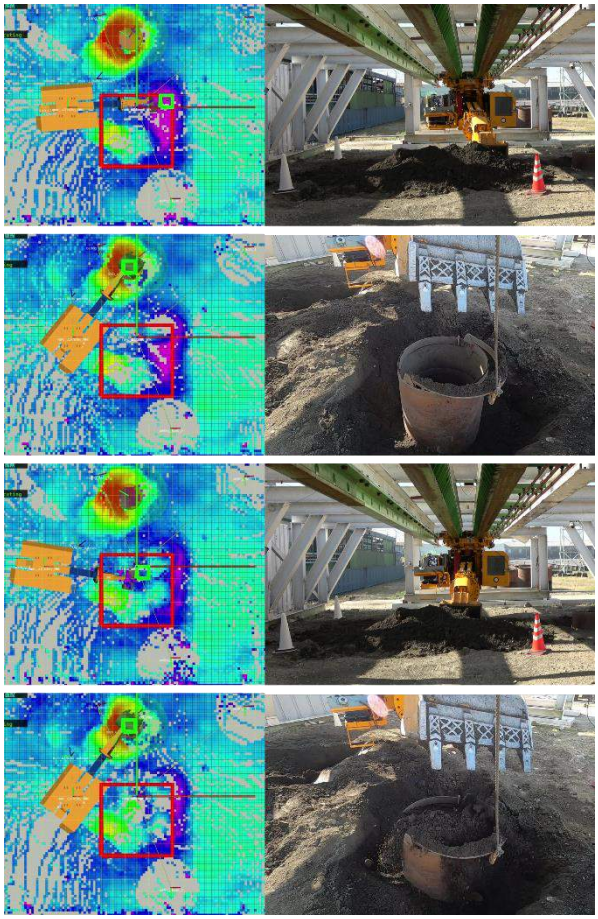

Figure 6. Experimental result when the earth bucket is placed under the material shaft

Figure 6 shows the situation when the earth bucket is placed under the material shaft. The earth is loaded until the Automatic Excavation System judges that the bucket is full. The top row in Figure 6 shows the state after the earth bucket is placed under the material shaft. The excavation cell with the lowest cost, as calculated by Equation 3, is excavated. The second row from the top shows the situation where the earth is loaded into the earth bucket. The location where the earth is directly thrown is the location of the recognized earth bucket, which also matches the actual location where it is placed. In addition, the recognition rate for the earth bucket was 100% out of the 30 times it was loaded during the evaluation experiment. The accuracy of the recognition posture was an error of 0.07 m in position and 5.73 degrees in orientation.

Table 1. Required time for each state of the excavator

Step	Case	Time [h:min:s]	Excavated soil volume [m^3]
1~6	Temporary	0:06:22	—
7~11	Disposal	0:06:27	1.00
12~16	Temporary	0:05:20	—
17~22	Disposal	0:09:42	1.00
23~27	Temporary	0:04:42	—
28~35	Disposal	0:08:49	1.00
36~40	Temporary	0:05:22	—
41~45	Disposal	0:08:19	1.00
46~49	Temporary	0:04:47	—
50~56	Disposal	0:10:20	1.00
Total		1:10:00	5.00
Actual construction process time		1:07:06	5.00

Table 1 shows the results of measuring the time required for each operation of the excavator. In this table, the process from when the excavator excavates the soil and moves it to when it is temporarily placed or directly thrown is considered to be one step. As a result, it took 56 steps and 1 hour and 10 minutes. During actual construction, the same conditions were completed in 1 hour, 7 minutes, and 6 seconds, so it can be said that effective results were obtained.

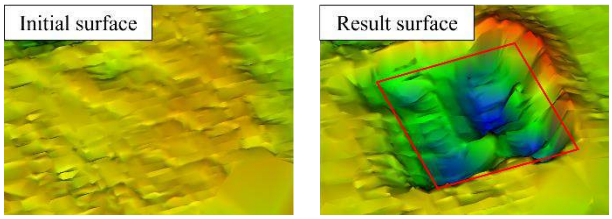

Figure 7. Ground surface before and after the experiment

Figure 7 shows the changes in the ground before and after excavation, with the left side showing the state before the experiment began and the right side showing the state at the end of the experiment. The excavator is located on the left side of both figures, and the material shaft is located on the upper side. The colors of the ground in the figures indicate the height of the ground, with blue indicating low ground and red indicating high ground. The red frame in the figure on the right shows the excavation field. Looking at the excavation field in the ground in the figure on the right, you can see that the left side of the excavation field is higher than the right side. Also, looking at the area outside the excavation field in the figure, you can see that the left side has been excavated and the right side has been piled up with soil. The standard deviation of the depth to the ground surface after excavation is 0.27 m with respect to the target depth.

Because the excavation operation of this system measures the ground height using 3D LiDAR, the bucket cutting edge is placed at that point, and excavation is carried out to the target depth from there. However, the excavation positions are not the center of the excavation cells, but the starting points of excavation in front of the excavation cells as seen from the excavator. Therefore, when the excavator excavates a cell that is further away from the excavator than the cell that has already been excavated, it is thought that the excavator will excavate deeper than the excavation cell. From this, there is still room for improvement in the excavation method of this system.

6 Conclusion and Future Works

In this paper, we propose a method using the greedy algorithm for the purpose of automating the pneumatic caisson method, and we confirmed that we achieved a construction speed equivalent to actual construction in experiments using an actual machine.

In the future, we plan to review weighting coefficients and cost calculation equations, and consider other optimization algorithms, with the purpose of minimizing the required time. In addition, in the large-scale pneumatic caisson method, multiple excavators are used. Our research group has achieved the automatic excavation and soil disposal of multiple excavators without causing them to collide with each other. Therefore, we plan to propose a method for multiple excavators.

Abstract –

Construction robots must perform complex construction tasks robustly under extreme and unpredictable conditions. Although current reinforcement learning methods, including imitation learning, show promise for this goal, they face inherent challenges, such as time-consuming reward function design or substantial data requirements that limit their generalizability to unstructured environments. These limitations are exacerbated by energy constraints of deep neural network-based algorithms, making them less viable for lunar surface construction, where data collection and power supply are significantly constrained. This study integrates inverse reinforcement learning with neuroscientific theories of human decision-making to equip construction robots with robust autonomy. The proposed approach modularizes a given task into simpler subtasks governed by learned parameters and explicitly models state features such as spatial and temporal distances, enabling the agent to anticipate and adapt to diverse scenarios while reducing computational overhead. Experimental results indicate that the agent modeled by the proposed approach achieved a 73% success rate in a lunar-like simulation environment, exceeding the 30 % success rate of an agent modeled by a conventional method. The findings demonstrate that the proposed approach can enhance adaptability for autonomous infrastructure construction, especially in lunar surface construction missions constrained by minimal human oversight and limited resources. This study contributes to the advancement of autonomous construction robotics, offering a novel and scalable solution for extreme construction settings.

1 Introduction

Driven by prospects such as abundant resource acquisition and advances in cutting-edge technologies, the global space exploration ecosystem is shifting its paradigm toward human habitation and resource extraction on the Moon [1]. This ambitious shift hinges on developing infrastructure and capabilities to support sustainable operations beyond Earth. However, the lunar environment is harsh, dynamic, and fraught with unpredictable events [2,3], thereby necessitating the deployment of construction robots capable of minimizing human intervention while reliably performing complex construction tasks on the lunar surface.

Nevertheless, it remains challenging to imagine current commercial construction robots operating stably under such dynamic and adverse conditions. These robots have been primarily designed to perform repetitive tasks in factories or other relatively controlled and static environments, thereby depending substantially on human oversight. Indeed, human operators are often required to intervene in unexpected situations directly or engage in indirect collaborative forms, such as sequential task execution. In light of these considerations, the development of fully autonomous construction robots that can function robustly in demanding and unpredictable lunar environmental settings becomes imperative.

Reinforcement learning (RL) approaches, including imitation learning (IL), present a potential avenue to surmount these challenges, as they allow robotic agents to be trained through interactions with their environment to accomplish assigned tasks, either by exploring and exploiting independently or by utilizing cues provided by experts. By leveraging such approaches, robots can potentially deliver robust and adaptive performance, facilitating stable execution of complex construction tasks in dynamic and harsh environments [4]. However, conventional RL methods have inherent limitations, such as the time-consuming process of reward function design and an excessive dependence on training data [5,6].

Prevailing IL methods still require extensive datasets of high-quality demonstrations, even though they circumvent these limitations [7]. These constraints may prevent construction robots from overcoming scenarios that deviate from their training set or from performing reliably in environments characterized by limited resources and accessibility [8]. Moreover, many state-of-the-art algorithms, which inherently rely on deep neural networks (DNN), demand substantial energy consumption. These challenges pose significant obstacles to lunar surface construction where accessibility is highly constrained.

To mitigate these challenges, this study draws inspiration from the remarkable adaptability and responsiveness that humans exhibit across diverse conditions [9]. To embed these capabilities into construction robots, this study proposes an approach grounded in robust biological evidence, integrating a human-like decision-making architecture with inverse reinforcement learning (IRL) framework. Through this integration, the resulting construction robots will be endowed with the capacity to operate robustly under lunar environments, ultimately contributing to the realization of autonomous infrastructure construction in outer space.

2 State of the Art

RL approaches have recently gained traction in construction robotics because of their ability to learn robust and adaptive behaviors through continuous interaction with the environment ([5,10–12]). By updating policies or value functions based on trial-and-error, agents can theoretically handle dynamic and uncertain scenarios, making them appealing candidates for tasks conducted in extreme environmental settings, such as those on the lunar surface. Generally, they employ DNN to approximate policies, and in many instances, they leverage expert trajectories to enhance learning efficiency [13].

However, these predominantly policy-based RL approaches suffer from several drawbacks that can be especially pronounced in extraterrestrial construction contexts. First, they often rely on extensive, high-quality datasets—an issue exacerbated by the inaccessibility of the lunar surface, where data collection is highly constrained [5]. Second, their dependence on DNN results in high energy consumption, necessitating substantial computational capabilities in hardware [4]. Lastly, in conventional RL methods, the need for sophisticated reward function design and the challenge of sparse rewards can make it difficult for agents to obtain the necessary signals to guide their learning in a timely manner [6], particularly when tackling complex, long-duration tasks under extreme conditions. As a result, these challenges can impede the scalability and reliability of construction robots, preventing them from swiftly attaining the necessary performance for diverse and uncertain tasks, such as those encountered in the lunar environment.

In contrast, IRL has not yet been widely explored within construction robotics despite its promising potential to provide computational models of human and animal behavior [14]. Unlike policy-based RL approaches, IRL aims to uncover the underlying reward structure from expert demonstrations, thereby distilling implicit cues that can guide learning toward higher-level objectives [15,16]. This characteristic of IRL makes it especially attractive for complex tasks where reward design is difficult and for scenarios where sample efficiency is paramount due to data collection constraints. In lunar construction, these strengths of IRL could enable robust adaptation to diverse or novel circumstances, alleviating the burdens of large-scale data gathering and intricate reward engineering.

A particularly relevant extension is modular IRL, which draws from neuroscientific findings indicating that humans decompose tasks into simpler subtasks that can be evaluated separately [17]. By framing a complex construction activity as multiple subtasks, the approach can assign simplified Q-values to each subgoal. These modular Q-values can then be estimated using Bayesian IRL [18]. For instance, Zhang et al. [19] demonstrated the potential of such an approach for reproducing human sensorimotor decisions by incorporating a discounting factor that regulates impulsive behavior in virtual reality settings. Compared to policy-based RL approaches, this value-based technique shows greater sample efficiency and a reduced computational footprint [4], making them particularly well suited for physically and energetically constrained environments like the Moon. Nevertheless, while modular IRL has proven its capabilities primarily in spatial navigation tasks, its broader application to industrial contexts, including automation in construction, has yet to be fully explored.

In summary, contemporary research into RL-based robotic control indicates great potential for autonomous operation in construction tasks. Still, multiple hurdles, ranging from data scarcity to energy constraints, must be addressed to realize robust performance in lunar environments. In this regard, an IRL-based approach integrating human-like decision-making processes can be a promising way to overcome the hurdles. Building on these insights, the next section proposes a novel approach that integrates modular IRL to endow construction robots with robust, adaptive capabilities suited to the rigors of lunar surface construction.

3 Methods

Lunar construction imposes unique constraints due to limited on-site supervision, power restrictions, and complex terrain. To demonstrate the proposed IRL-based approach under these demanding conditions, this study focuses on an excavator swing operation, a frequent maneuver for material transport and debris clearance. Continuous horizontal swinging has been identified as a primary source of struck-by hazards on Earth-based sites, and this risk is magnified in off-Earth contexts where immediate human intervention is challenging [20]. As such, the excavator swing task represents an ideal testbed for validating an autonomous decision-making scheme that effectively balances safety and task efficiency.

3.1 Problem Formulation

Initially, the excavator's swing is modeled using a Markov Decision Process (MDP):

- States (S): Each state describes the excavator's relevant kinematic features (joint angles and velocities of boom, stick, cab) and key environmental cues (e.g., nearby obstacles, target locations).
- Actions (A): Discrete maneuvers include moving the boom up/down, the stick in/out, rotating the cab left/right, or performing no movement. Actions that exceed joint limits or risk an immediate collision are excluded from consideration.
- Reward (R): A single reward function penalizes collisions and rewards movement toward a defined dump area, implicitly treating all safety and positioning objectives as one.
- Discount Factor (γ): A scalar in (0,1) that weighs future returns; γ near 1 values cautious, long-term strategies, whereas smaller γ emphasizes immediate outcomes.

A SoftMax policy, as shown in Equation (1), governs action selection:

$$\pi(s,a) = \frac{\exp\left(Q(s,a)/\eta\right)}{\sum_{a' \in A} \exp\left(Q(s,a')/\eta\right)} \quad (1)$$

where $Q(s,a)$ is the action-value function, and $\eta \in (0,1]$ manages exploration versus exploitation. Although this single-task MDP is straightforward, it does not fully capture human-like strategies that partition tasks into sub-goals and consider spatial and temporal dimensions when avoiding collisions.

3.2 Task Modularization with Explicit State Features

Drawing on empirical findings in human motor control and decision-making [17,19], a main task is replaced with multiple subtasks. For instance, the swing operation might split into:

- Obstacle Avoidance (Subtask 1): Minimizing collisions.
- Targeted Material Placement (Subtask 2): Reaching or depositing material in the designated area.

Each subtask n is assigned:

- A subtask weight $r^{(n)} \in, with\ \sum_n r^{(n)} = 1$.
- A unit reward $u^{(n)}$, reflecting baseline significance for that objective.
- A sub-discount factor $\gamma^{(n)} \in (0,1)$, enabling each subtask to handle near- vs. long-term gains differently.

Hence, the total action-value $Q(s,a)$ is shown in Equation (2).

$$Q(s,a) = \sum_{n=1}^{N} Q^{(n)}(s^{(n)}, a) \quad (2)$$

where $Q^{(n)}$ focuses on a particular sub-goal. This modularization can make the overall decision process more transparent and potentially more adaptable, as each subtask can be updated independently.

Beyond subdividing tasks, psychological distance [21] is introduced to emulate how skilled operators anticipate future collisions or time-critical steps:

- Spatial Distance: The Euclidean distance between the excavator's bucket and key objects (e.g., a rock, the dump area).
- Temporal Distance: The estimated time until a collision (or successful arrival) if a chosen action is executed.

These distances are computed at each timestep, using a brief forward simulation. By incorporating distance-based features explicitly, one can reduce reliance on DNN, thus lowering computational demand—a crucial advantage in energy-constrained lunar construction missions. This approach also strengthens safety, as the agent "looks ahead" before finalizing an action.

3.3 Parameter Estimation

The following steps outline the process of estimating subtask weights $r^{(n)}$ and discount factors $\gamma^{(n)}$ from expert demonstrations:

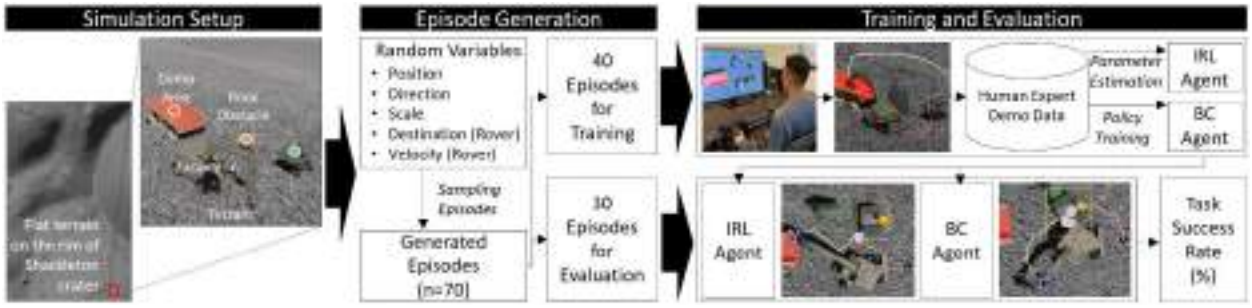

Figure 1. Overall experimental steps for training and evaluating IRL and BC agents in a simulation environment

1. Data Collection: Human experts run the excavator in a simulation, completing the swing operation multiple times under simulation environments. This yields state–action pairs $\{(s_1, a_1), \dots, (s_T, a_T)\}$, where T is the end of an episode.
2. Likelihood Computation: For a trial parameter set $\Theta = \{r_1, \dots, r_N, \gamma_1, \dots, \gamma_N\}$, the likelihood $\mathcal{L}$ of human expert demonstration data is calculated by Equation (3), where Q sums up each subtask's value function $Q^{(n)}$, weighted by $r^{(n)}$ and discounted by $\gamma^{(n)}$.

$$\mathcal{L} = \prod_{t=1}^{T} \frac{exp^{Q(s_t, a_t)\eta}}{\sum_{a \in A} exp^{Q(s_t, a)/\eta}} \quad (3)$$

3. Parameter Set Sampling: Each subtask's reward and discount factor are estimated by a sampling method. This study uses a Hamiltonian Monte Carlo (HMC) technique to explore the parameter set spaces. Key constraints, $\sum_n r^{(n)} = 1$ and $0 < r^{(n)}, \gamma^{(n)} < 1$, are enforced to ensure valid solutions.
4. Convergence to Final Parameter Set: Parameter sets aligning closely with expert actions are accepted, leading to a convergent estimate $\widehat{\Theta}$. This final parameter set grants the excavator robot agent.

4 Experimentation

4.1 Experimental Goal and Setup

The primary goal of this experiment is to determine whether the IRL agent modeled by the proposed IRL-based approach can robustly execute a construction task compared to an agent modeled by behavior cloning (BC), a conventional IL method. To do so, as shown in Figure 1, A total of 70 episodes were devised in a simulated lunar environment constructed based on real lunar terrain data [22] in the Unity game engine [23], with 40 episodes for training and 30 episodes for evaluation. Each episode included five key objects—an excavator, a dump truck, a rock obstacle, a moving rover, and the surrounding terrain, which are randomly arranged to generate varied spatial layouts and dynamics using the Latin Hypercube Sampling method [24]. To ensure dynamic interaction throughout each episode, constraints were applied during the generation process. These constraints included maintaining a minimum distance between the moving rover and other objects, as well as selecting episodes where the rover's linear path did not result in collisions with other objects, thus preserving the intended episode dynamics. Episodes are terminated upon the excavator bucket reaching the designated dump area or upon reaching the time limit of 150 timesteps, which is approximately three times longer than an expert requires. The workstation on which the experiments were conducted has the following specifications: Intel Xeon W-2123 CPU, 64 GB RAM, NVIDIA GeForce RTX 2080 GPU.

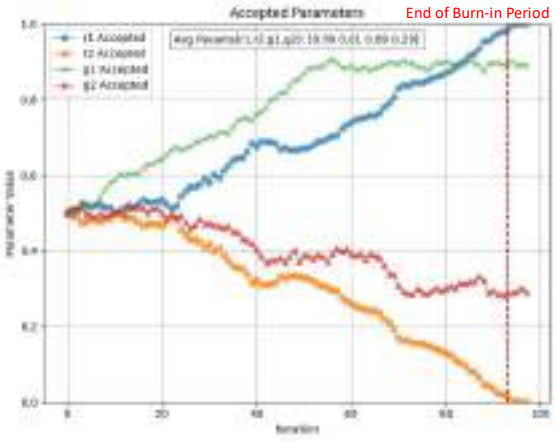

Figure 2. Accepted parameter trajectories during HMC sampling

4.2 Experimental Procedure

Human expert demonstrations were recorded in a simulation equipped with joystick controls and a first-person view. Each demonstration began with five seconds of situational awareness from an overhead perspective, allowing participants to plan their route

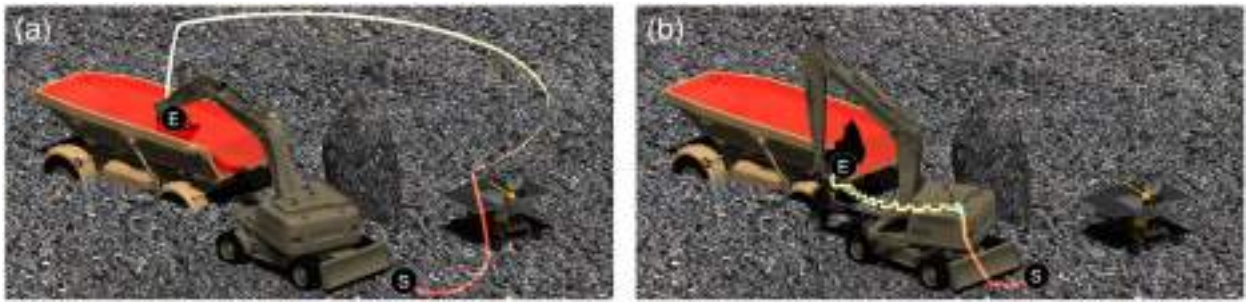

Figure 3. Trajectory comparison of a successful episode between (a) a human expert and (b) the corresponding IRL agent employing different detour strategies

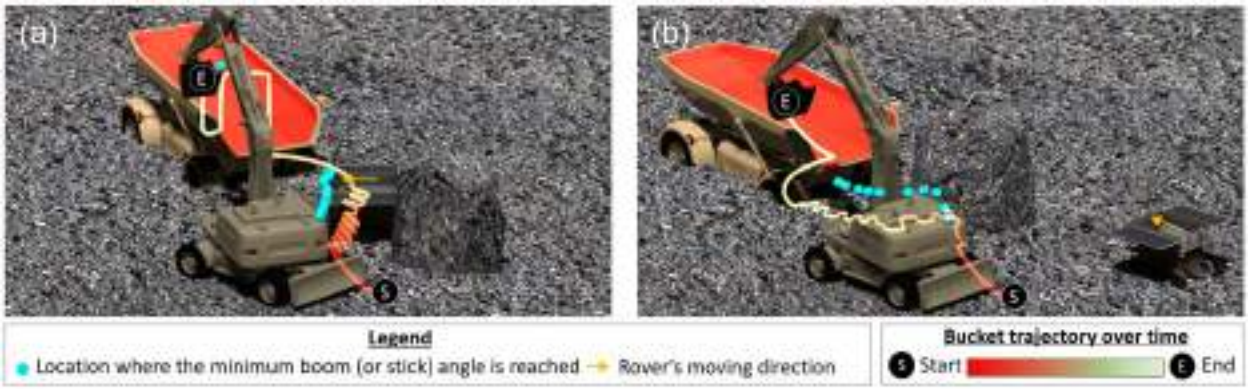

Figure 4. Failure cases of IRL agents: (a) and (b) illustrate inefficient movement leading to episode termination

[25,26]. Participants then navigated the excavator bucket to the dump area using what they perceived as the safest, most efficient path. The collected state–action pairs formed the training data for parameter estimation in the IRL agent and supervised training in the BC agent.

Afterward, the IRL agent's parameters, $\Theta = \{r^{(1)}, r^{(2)}, \gamma^{(1)}, \gamma^{(2)}\}$, were inferred from the recorded demonstration data via HMC. After discarding an initial burn-in, the final accepted samples were aggregated to define a robust parameter set. Figure 2 illustrates the evolution of these parameters over iterations, highlighting their convergence after the burn-in phase. On the other hand, the BC agent was trained using a neural network architecture with optimal hyperparameters determined through a grid search: dropout probability of 0.1, learning rate of 1e-4, neural network dimension of 256, and depth of 3.

Both agents were subsequently evaluated in the 30 remaining episodes, and the task success rate was measured as the proportion of runs where the bucket reached its target without a collision.

5 Results and Discussion

5.1 Robustness Compared to BC Agent

The IRL agent demonstrated a success rate of 73%, significantly outperforming the BC agent, which achieved only 30%. This notable difference underscores the limitations of relying solely on policy imitation, as seen in the BC agent's performance in dynamic environments. In contrast, the IRL agent exhibited superior adaptability to diverse layouts, including a moving rover. Additionally, the IRL agent achieved a traveled distance of 15.71 meters on average (S.D.=3.91), compared to the BC agent's average traveled distance of 17.98 meters (S.D.=4.61). These findings highlight that the proposed IRL-based approach enables construction robots to robustly perform construction tasks more efficiently than the existing RL methods. This finding aligns with prior literature emphasizing that conventional policy-based IL methods can struggle in unseen or high-variability contexts [8]. On the other hand, the IRL agent exhibited robust performance and more efficient path selection.

Interestingly, as shown in Figure 3, the IRL agent often exhibited detour strategies that differed from human experts. Both tended to detour around obstacles; however, the strategy employed diverged. While the human expert consistently chose the safest and farthest routes to avoid collisions, as depicted in Figure 3(a), the IRL agent opted to detour in the opposite direction, as shown in Figure 3(b). This strategic variation resulted in the IRL agent adopting a more efficient trajectory, reducing the required timesteps and minimizing redundant movements. Consequently, the IRL agent not only maintained a higher success rate but also enhanced overall task efficiency compared to the BC agent.

Figure 4 illustrates two distinct failure cases of the

IRL agent. In Figures 4(a) and 4(b), the IRL agent repeatedly reaches the minimum boom angle without progressing toward the target, leading to the termination of the episode at the maximum timestep limit. These failures occur not due to collisions but because the agent's movements become inefficient, highlighting a lack of comprehensive exteroceptive perception of the excavator's body. This inefficiency suggests that the IRL agent's decision-making process does not fully account for the excavator's physical constraints, leading to suboptimal movement strategies.

These observations underscore the critical role of parameter diversity within the IRL framework. Unlike traditional IL approaches that merely replicate observed behaviors, the proposed IRL approach models human-like decision-making strategies through modular subtask decomposition and explicit distance-based state features. This enables the agent to develop its strategic approaches to overcome harsh and complex environments and tasks. This capability to generate unique strategies, rather than simply imitating human actions, highlights the advantage of the proposed modular IRL approach in fostering more resilient and effective autonomous agents.

5.2 Summary and Implications

This study illustrates how the proposed IRL-based approach that models human-like decision-making can outperform a traditional IL approach in a demanding robotic construction task, echoing the importance of deeper reward representations and highlighting that direct behavior imitation can lead to failures when the environment is dynamic or partially observable.

In practical terms, the proposed approach could be adopted in extraterrestrial construction scenarios or similarly constrained environments where robotic autonomy must manage unpredictable conditions. By leveraging task modularization and employing explicitly modeled state features, the IRL agent demonstrated adaptability and robustness that could reduce mission risks and resource waste. In this regard, autonomous construction robots modeled by the proposed approach could perform construction tasks (i.e., excavation or debris clearance) with minimal human oversight, saving time and costs.

Several assumptions and abstractions were made to manage complexity and computational overhead. The excavation task was described with a limited number of subtasks, which may not capture all subtasks of the human decision-making process. Additional constraints, including simplified collision models and a uniform gravitational field, might not reflect every aspect of lunar physics. These simplifications allowed the method to converge more quickly and highlight possible limitations when extending to higher-fidelity simulations or more intricate tasks. Future work might consider expanding the subtask framework or incorporating fine-grained terrain and machine dynamics.

These experimental findings indicate that the proposed IRL-based approach can significantly improve construction robots' robustness. By recognizing both the strengths and constraints of the proposed approach, researchers and practitioners can refine this approach for even more robotic applications in extreme construction settings.

6 Conclusion

This study was motivated by the escalating complexity and risk inherent in construction robotics, particularly in extreme environments like the Moon. The current body of research emphasizes the need for construction robot modeling methods that can adapt to uncertain conditions with minimal human oversight. However, traditional RL approaches often replicate narrow expert behaviors and can fail when the environment diverges from the training set.

In response to these challenges, this study proposes an IRL-based approach integrated with neuroscientific theories of human decision-making. By identifying underlying reward structures rather than imitating actions outright, the IRL agent demonstrated a capacity for more adaptive and reliable decision-making, even in scenarios characterized by moving objects and variable layouts. The proposed approach’s novelty is that it leads to an agent that can synthesize multiple expert strategies and yield robust performance. The experimentations showed that the agent modeled by the proposed IRL-based approach outperformed an agent modeled by BC, a conventional IL approach regarding task success rates under a simulated lunar environment setting.

Several assumptions were made in this study. The limited number of subtasks used in this study simplifies the complexity of real-world construction tasks, which often involve numerous interdependent and dynamic processes. Moreover, the high-level representations of state features may not fully translate to highly unstructured or rapidly changing environments without further customization. Future studies should consider extending the subtask framework, refining state features, or integrating more detailed physics to bridge the gap between simulated experiments and real deployment.

This study demonstrates the effectiveness of an IRL-based approach in automating construction tasks, particularly in scenarios like extraterrestrial excavator operations, where supervision is limited. The integration of human-inspired decision-making with IRL establishes the foundation for the development of robust and adaptable robotic systems capable of thriving in extreme environments. This work contributes to the broader vision of achieving fully autonomous infrastructure

development in space by addressing the unique demands of extraterrestrial construction environments.

Abstract -

This paper presents a safety-focused, closed-loop grasping approach for object manipulation in dynamic environments, leveraging simulation data to ensure adaptive and safety-aware operations. We extend the OpenAI Safety Gym library by integrating a robotic arm model and propose 'Grasp Mechanics,' a novel method for adaptive gripping. Using a constrained variant of Proximal Policy Optimization (cPPO), we emphasize secure object manipulation in human-robot interaction scenarios. Preliminary experiments show that cPPO, while requiring longer training, achieves policy performance comparable to baseline PPO and significantly outperforms it in safety compliance. Our work highlights the potential of integrating advanced RL techniques with robust safety mechanisms, advancing the capabilities of robotic systems for real-world applications. These findings lay the groundwork for future advancements in safe autonomous robotics, emphasizing the importance of integrating safety considerations from the ground up.

Keywords -

Safe reinforcement learning, Robotic grasping, Autonomous learning, safety-critical coordination.

1 Introduction

performance using task success, constraint adherence, and safety violation costs. We adopt these metrics to balance task efficiency and safety compliance.

Building on Safety Gym, we integrate the Panda robotic arm, creating a novel safety-aware environment for object manipulation. Unlike prior work relying on predefined policies [5], our approach combines obstacle avoidance, movement planning, and grasping through learning-based policies. By adapting Safety Gym's constraint mechanisms, we develop customized reward and cost functions that balance task completion with safety.

In this study, we introduce a novel approach for robotic grasping in dynamic environments. Our method employs 3D translation control with a strategically fixed orientation, optimized for grasping common household objects such as a Lipton tea box or a teacup on various surfaces. While full 6D grasping (with dynamic orientation control) presents significant challenges in motion planning and feedback integration, our simplified approach achieves remarkable effectiveness while reducing computational complexity. Unlike typical bin-picking implementations where top-down approaches suffice, our method addresses more complex scenarios through adaptive motion planning and real-time feedback. Previous work has largely focused on grasp pose generation rather than complete motion trajectories, limiting effectiveness in dynamic environments [6, 7]. In contrast, we propose a novel closed-loop grasping and motion planning policy that integrates proprioceptive and tactile feedback, enabling the robot to adapt to real-time object interactions without relying on high-dimensional real-world data (such as images). Our key innovation lies in the hierarchical RL framework [1], which decomposes complex grasping tasks into manageable sub-goals, significantly reducing learning complexity while maintaining robust performance across diverse objects and tasks.

uisite for successful robotic manipulation. This aligns with recent approaches such as the teacher-student training framework [8], where a teacher policy first trained with privileged information then guides a student policy relying on image-based inputs.

A video demonstration of the simulation experiments can be found at: `https://www.youtube.com/watch?v=9oEhdw1F3aI&t=28s`.

2 Related Works

Recognizing the challenges of ensuring safe interactions, we draw upon the consensus that safe behavior in robots equates to avoiding hazardous states, a perspective supported by [9] and further elaborated through various safety and learning strategies in the literature. Significant contributions to safety in RL include the development of constraints to prevent unsafe actions, as suggested by [10], and the incorporation of concepts like reachability and stability in algorithm design. Advanced techniques emphasize aligning robot actions with human preferences for enhanced safety [4], explored through ergodicity criteria and the mitigation of adverse "side effects" in agent behaviors. In addressing the intricacies of robotic grasping and task achievement, our study is inspired by and aims, in the future, to rely on Learning from Demonstration (LfD) and RL, with a specific focus on blending these methodologies for optimized task performance. Influential works by [11] demonstrate the potential of merging human demonstrations with RL for nuanced strategy development. This hybrid approach, along with advancements in deep learning, offers new pathways for robotic control and manipulation, particularly in the realm of object grasping where recognizing and handling objects of various geometries remains a complex challenge. Recent advancements in DRL, including PPO and its constrained variant, highlight improved efficiency and safety in robotic tasks. Leveraging these innovations, our research focuses on enabling robots to safely grasp and manipulate objects in dynamic, unstructured environments, mitigating risks in human-robot interaction and advancing autonomy in safety-critical scenarios.

2.1 Our Contributions

- **Safety Gym Extension:** Integrated a robotic arm into OpenAI's Safety Gym, creating a novel environment for safe object manipulation.
- **cPPO Advantages:** Through a rigorous comparison with standard PPO, demonstrated cPPO's capability to maintain safety constraints during robotic manipulation, while achieving comparable task performance.
- **Zero-Shot Generalization:** Achieved effective policy transfer to unseen objects after training on a simple cube.
- **Efficient Learning:** Demonstrated rapid convergence within 200,000 steps while maintaining safety constraints.

Our approach addresses a critical gap in robotic manipulation by maintaining strict collision avoidance with obstacle while preserving task performance, a balance often overlooked in existing systems that prioritize task success metrics while overlooking operational safety considerations.

2.2 Finding Technical Solutions

The availability of Python resources and simulators based on various physics engines offers significant advantages but also introduces integration challenges. Our goal was to demonstrate constrained RL algorithms using a robotic arm in human-robot interaction scenarios. However, the Safety Gym library [4] lacks robotic arm agents, posing integration challenges. Initially, we attempted to integrate a robotic arm from a Gym environment into Safety Gym, assuming compatibility due to their shared MuJoCo foundation [12]. However, this revealed dependency conflicts and required older versions of Python and TensorFlow. We also explored integration with CoppeliaSim via PyRep but faced similar compatibility issues. Ultimately, we adopted a PyBullet-based Gym environment [13], which supports robotic arms and provided comprehensive documentation and examples, simplifying the configuration process.

3 Problem Formulation

The state is an 8-dimensional vector encoding the end-effector's position, the object's position, and the gripper's status, enhanced by Grasp Mechanics for adaptive and precise manipulation.

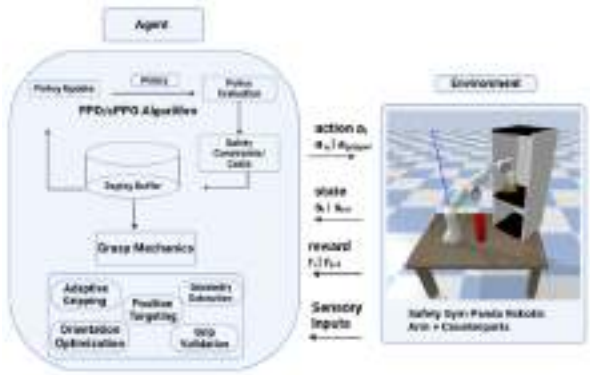

Figure 1. Agent Equipped with Grasp Mechanics

4 METHODOLOGY

4.1 Safe Reinforcement Learning Through Constraints

RL[4] is an advanced methodology focused on training RL agents to operate within predefined safety constraints, ensuring safe behavior both during training and deployment. An optimal policy in safe RL is defined as:

$$\pi^* = \arg\max_{\pi \in \Pi_C} J_r(\pi) \quad \text{where} \quad \Pi_C = \left\{\pi : J_{c_i}(\pi) \leq d_i,\ i = 1, \ldots, k\right\} \tag{1}$$

Where $J_r(\pi)$ represents an objective function driven by rewards and each J_{c_i} signifies a cost-oriented constraint function, with thresholds d_i chosen as hyper-parameters by humans. This Constraint mechanisms define a valid set of permissible policies Π_C that meet the constraints, within the framework of CMDPs. The Lagrangian technique employs a composite loss function, integrating both reward-driven and cost-driven elements. In the equation below, cost-related aspect is incorporated within the set of allowable policies Π_C. This optimization task is formulated as follows:

$$\max_{\theta} \min_{\lambda \geq 0} L(\phi, \theta) = f(\theta) - \lambda g(\theta) \tag{2}$$

Within the loss function, the two components pertain to the reward and cost, incorporating the policy model parameters θ and the Lagrangian hyper-parameter λ.

4.1.1 Pre-Learning Phase

to define requirements, establishing boundaries for task performance and safety.

Expert Knowledge: Expert input encodes operational context aligned with real-world applications, embedding task requirements via reward functions and safety constraints [16], defining action spaces leveraging existing robot skills [17], establishing state spaces with necessary perception capabilities, and incorporating demonstrations to accelerate learning [18].

We partially automate the encoding process using hierarchical RL, where sub-goals guide the agent toward specific sub-tasks. The environment uses standard robot description models (URDF), and the RL agent is trained to identify hazardous states while maintaining performance.

4.1.2 State Space

Our framework integrates simulation data with proprioceptive state information, including robot states (forces on the end-effector), fingertip states, object states, force sensor data, object geometry extraction, and distance measurements. These elements provide tactile feedback for adaptive gripping, ensuring a continuous state space essential for effective manipulation task learning. In continuous state spaces, deep neural networks (DNNs) excel at learning low-dimensional representations that map states to optimal control actions.

4.1.3 Action Space

In Human-Robot Collaboration (HRC) scenarios, the action space is defined by complex interactions in a six-dimensional space (the robot's end-effector pose). This continuous action space poses significant challenges for RL agents, often requiring millions of time steps for training, even with robust exploration and exploitation algorithms [19]. To address this, recent approaches constrain the action space by leveraging Inverse Kinematics (IK) solvers instead of directly learning joint angles [20].

This method reduces the action space dimensionality from seven (corresponding to the robot arm's seven degrees of freedom) to three, focusing only on positional changes in Cartesian space $(\Delta x, \Delta y, \Delta z)$ with fixed orientations. This reduction accelerates learning, enhances task efficiency and safety, and promotes robust output behaviors by minimizing unintended actions. Furthermore, it facilitates the transferability of learned behaviors across different robots, improving generalization and adaptability in diverse HRC applications.

4.1.4 Reward Function

60% of development effort, directly influencing learning efficiency and task performance.

4.2 Hierarchical RL Framework

In recent years, Hierarchical RL (HRL) has emerged as a powerful framework for solving complex decision-making tasks by decomposing them into a hierarchy of simpler subtasks [1]. This approach is particularly beneficial for robotic manipulation tasks, where a robot must perform a sequence of actions with long-term dependencies and complex goals. In this work, we apply HRL to a robotic arm tasked with manipulating objects in an environment. The task is divided into phases approaching, grasping, and lifting each governed by a low-level policy, while the high-level policy coordinates the transitions between these phases, with each phase having its corresponding reward function to guide learning. This hierarchical structure enhances both learning efficiency and execution performance by allowing the robot (agent) to focus on simpler sub-problems sequentially.

5 IMPLEMENTATION SETTINGS

We employ the PPO algorithm with the PPO-Clip variant [21] to enhance policy gradient stability and efficiency.

To address safety concerns within the RL framework, our work integrates the PPO algorithm with the Lagrangian method for constrained optimization. This integration allows us to define a feasible set of policies (πc) that satisfy predefined safety constraints $J_{ci}(\pi) \leq d_i$, CMDPs incorporate a set of cost functions $c_1, ...c_k$, which are distinct from the reward function, as outlined in the framework of CMDPs [4] (see subsection 4.1 in Methodology). In our scenario, if the agent makes contact with an obstacle at time step t, it incurs a cost of $c(s_t) = 1$; otherwise, the cost is 0. This is represented by $d_i = 1$ if the robotic arm violates the safety constraint, and $d_i = 0$ otherwise. This is essential to constrain hazardous behavior within the Safety Gym environment. Our integration of PPO and its Lagrangian extension advances both policy optimization and safety-aware human-robot interactions, ensuring robotic agents operate within safety margins in simulated environments, a foundation for constrained RL solutions applicable to real-world scenarios.

5.1 Multi-step Dense Reward System

This section describes a multi-step dense reward system for training agents in object manipulation tasks, providing continuous feedback to guide the arm through approaching, grasping, and lifting phases.

The core of the reward system is a distance-based reward, incentivizing the agent to minimize the Euclidean distance between the end-effector and the target object. This reward shaping [22], ensures incremental improvement in positioning. Additionally, a contact stability reward encourages stable grasping: $r_{\text{contact}} = 2$ for first contact with both fingers, 3 for maintaining stable contact, -2 for persistent single-finger slip, and -1 for losing established contact.

Once the object is lifted above a threshold, a significant positive reward reinforces the desired behavior: $r_{\text{grasp_lift}} = 5$. Safety is ensured through collision detection: $c_{\text{collision}} = \mathbb{1}(\text{contact between robot and obstacle})$, with info = $\{\text{cost} : c_{\text{collision}}\}$, aligning with CMDPs [23] to evaluate both task performance and safety.

5.2 Model Structure and Training

Our method employs two RL algorithms: PPO [21] and its Lagrangian variant. The agent explores the environment through on-policy learning, collecting data via controlled policy rollouts rather than random exploration. While we use actor-critic algorithms, our approach is generalizable to any deep Q-learning algorithm, whether online or offline.

PPO: An on-policy actor-critic algorithm that optimizes cumulative rewards using a clipped surrogate objective, known for its simplicity and stability in continuous control tasks.

PPO Lagrangian Variant: Extends PPO by incorporating a Lagrangian multiplier to enforce safety constraints during training, making it ideal for safety-critical tasks. Both algorithms utilize low-dimensional state information and tactile feedback, enhanced by Grasp Mechanics for adaptive manipulation.

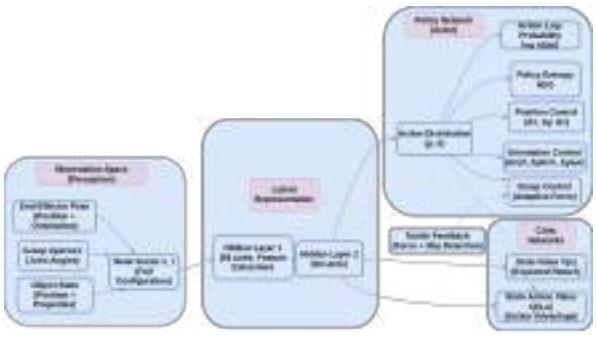

Figure 2. Actor-Critic Architecture for Robotic Manipulation with Tactile Feedback.

`cost_gamma` (0.99), `lam` (0.97), `cost_lam` (0.97), `ent_reg` (0.01), `cost_lim` (25), `penalty_init` (1.0), `target_kl` (0.01), and `vf_iters` (80). Optimization techniques include 80 gradient descent iterations per update cycle, a clipping ratio to prevent drastic policy changes, and backtracking steps for efficient optimization.

  Log performance and stats;
end
Main Function: Parse args, initialize logger and agent. Execute `run_polopt_agent(parameters)`.

5.3 Grasping Policy via Grasp Mechanics

5.4 Task Success and Evaluation Metrics

Task success is evaluated using three metrics from the Safety Gym protocol [4]: (1) **Task Performance**, measured as the percentage of successfully completed tasks (approaching, grasping, and lifting) out of total attempts (Figure 3), Success Rate $= \frac{\text{Successful Tasks}}{\text{Total Tasks}}$; (2) **Constraint Satisfaction**, tracking safety violations (e.g., collisions), with fewer violations indicating better safety; and (3) **Average Regret**, reflecting cumulative safety costs during training, Average Regret $= \frac{1}{N}\sum_{i=1}^{N} C_i$, where C_i is the safety cost at step i, and N is the total number of steps. These metrics balance task efficiency and safety compliance.

5.5 Zero-shot Policy Transfer Across Objects

We trained our robotic manipulation system through 500,000 iterations using a cube as the reference object. The system's MLP actor-critic architecture processed state vectors containing object pose, gripper state, and spatial relationships. To evaluate generalization capabilities, we tested the trained policy on unseen objects: a Lipton tea box, teacup, soap bar, and remote control. The system successfully grasped all test objects, with highest success rates for the Lipton tea box 95% and soap bar 90%. While performance remained robust on objects with regular geometries, success rates decreased slightly for the teacup 87% and remote control 85% due to their complex or asymmetrical shapes challenging gripper alignment. The system demonstrated effective zero-shot transfer of manipulation policies without object-specific training.

5.5.1 Performance Metrics

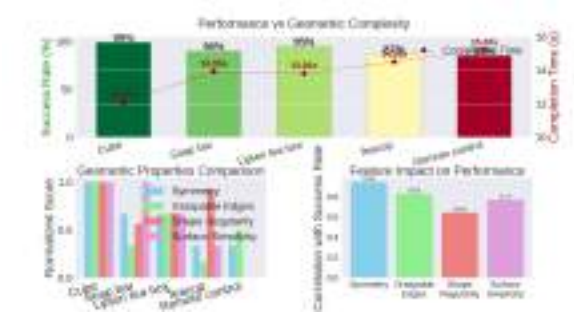

Figure 3. Performance evaluation of zero-shot policy transfer across objects with varying geometries, demonstrating the system's ability to generalize and highlighting the impact of features like symmetry, graspable edges, shape regularity, and surface simplicity on success and completion time. Note: Results averaged over 40 attempts per object.

5.5.2 Comparative Analysis

We compared our closed-loop grasping approach to object manipulation, which fundamentally differs from traditional fixed-policy methods [7]. Unlike these fixed-sequence approaches [6],[7], our system utilizes a purely learning-based framework that dynamically adapts within a sequential decision-making architecture. The key innovation lies in its ability to monitor and adjust behavior based on the current state. For example, in failure scenarios, such as when a grasp attempt fails and the object is not secured, the system reassesses and retries, rather than continuing with the predefined sequence. As shown in Figure 3 and Table 1, our approach achieves higher success rates and adapts more effectively to varying object shapes and positions.

Comparison with Existing Approaches

We empirically compared our approach with baselines across several key features as shown in Table 1.

Table 1. Comparison of Object Grasping and Manipulation Approaches

Feature	Our Approach	Baselines [7, 6]
Learning Paradigm	Goal-Directed Reinforcement Learning	Imitation Learning (predefined behavior + learning from data)
Decision Making	Sequential, state-dependent with learned policy	Fixed action sequences with predefined policy
Failure Handling	Dynamic reassessment with real-time adaptation	Continue with predefined sequence, static behavior
State Awareness	Continuous monitoring of gripper state	Limited state feedback
Task Execution	Safety-aware operation while maintaining performance	Performance optimization without safety considerations

6 EXPERIMENT DESIGN AND REALIZATION

Our analysis of robotic arm control in 3D Cartesian space reveals that increasing the state vector's dimensionality does not significantly improve learning efficiency for adaptive grasping. However, integrating 'Grasp Mechanics' as a feedback mechanism enhances both learning efficiency and overall effectiveness. A comparative study of PPO and its constrained variant, cPPO, shows that cPPO incorporating Lagrangian safety methods achieves lower average costs, indicating safer training despite slightly longer training periods. Figure 4 illustrates this trade-off, comparing reward values and costs across training cycles. The graph differentiates between average cumulative rewards and episode-wise costs for PPO and cPPO, demonstrating the impact of constrained optimization on safety and effectiveness in robotic control.

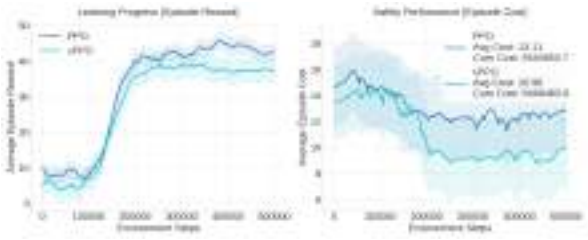

Figure 4. PPO vs. cPPO Rewards and Costs Comparison in Object Manipulation.

The visual comparison highlights cPPO's gradual learning curve and consistently lower cost metrics, reflecting its prioritization of safety. This systematic minimization of costs ensures safer operational dynamics for the robotic arm.

The Table 2. compares the average costs per run for the standard PPO algorithm and its constrained variant (cPPO). While PPO incurs an average cost of 13.11, cPPO achieves a lower cost of 10.96, reflecting its enhanced safety performance. This evaluation is based on a task involving the manipulation of various geometries and securing them at target locations under strict safety constraints, using a 3D action representation in Cartesian space.

Table 2. Average comparison costs per run for PPO and cPPO.

Algorithms	Average Cost Incurred
PPO	13.11
cPPO	10.96

6.1 Discussion and Conclusion

robots must interact with diverse objects while adhering to safety constraints. Our approach leverages cPPO to develop policies that balance task performance with safety. We introduce Grasp Mechanics, a novel closed-loop grasping policy that combines compact state information acquisition with precise positional control. By relying primarily on proprioceptive, low-dimensional kinematic data, our system achieves effective manipulation without requiring detailed object shape information, a key advantage in real-world environments where high-dimensional data, such as images, may be unavailable.

Our experimental results validate two key contributions. First, the cPPO implementation demonstrates consistent improvement in safety performance, reducing the average episode cost from approximately 14 to 10.96 while maintaining task effectiveness. This reduction in safety cost, combined with the stable learning progress shown in the reward curve, indicates that our approach successfully balances safe navigation with task completion. Second, the system demonstrates an 89% success rate in grasping previously unseen objects using a purely learning-based policy, highlighting that safe manipulation can be achieved without compromising task effectiveness. In contrast, previous work relied on predefined policies [5], which may have limited flexibility and adaptability.

The learning curves from our experiments reveal both strengths and limitations of the current approach. While cPPO demonstrates consistent convergence to safe policies within 200k training steps, we observed that the initial exploration phase requires careful tuning of safety boundaries to prevent constraint violations. This highlights a trade-off between learning efficiency and safety guarantees that warrants further investigation.

6.1.1 Limitations and Future Work

menting a teacher-student framework [8], where our safe manipulation policies serve as teachers for training vision-based students. This approach could reduce the computational cost of learning from visual inputs while maintaining safety, with significant implications for real-world applications. Our research contributes to the field of autonomous robotics by demonstrating that effective object manipulation can be achieved while strictly adhering to safety requirements. The combination of constrained RL and proprioceptive feedback provides a particularly promising foundation for future sim-to-real transfer. Unlike vision-dependent approaches that often struggle with the reality gap due to visual discrepancies, our proprioceptive-focused policy relies on physical interactions and low-dimensional state representations that theoretically transfer more reliably across domains. This design choice deliberately addresses a critical challenge in robotics: policies that perform well in simulation often degrade significantly when deployed on physical hardware. By prioritizing contact dynamics, force-based feedback, and physics-grounded policy constraints, our approach is inherently more resilient to the domain transfer challenges that typically hinder real-world deployment. Future work will focus on systematically bridging the simulation-reality gap through domain randomization and progressive transfer techniques, with particular emphasis on preserving safety guarantees while improving sample efficiency across the full spectrum of manipulation tasks from controlled laboratory environments to dynamic human-centered settings.

Abstract -

With the number of people with disabilities (PWD) increasing worldwide each year, the demand for mobility support to enable independent living and social integration is also growing. Wheelchairs commonly support the mobility of PWD in both indoor and outdoor environments. However, current powered wheelchairs (PWC) often fail to meet the needs of PWD, who may find it difficult to operate them. Moreover, existing research on robotic wheelchairs typically focuses either on full autonomy or enhanced manual control, which can lead to reduced efficiency and user trust. To address these issues, this paper proposes a Robot Operating System (ROS)-based smart wheelchair (CoNav Chair) that incorporates a shared control navigation algorithm and obstacle avoidance to support PWD while fostering efficiency and trust between the robot and the user. Our design is divided into hardware and software components. Experimental results conducted in a typical indoor social environment demonstrate the performance and effectiveness of our smart wheelchair's hardware and software design. This integrated design fosters trust and autonomy, crucial for the acceptance of assistive mobility technologies in the built environment.

Keywords -

Smart Wheelchair; Navigation; Shared Control

1 Introduction

With the number of people with disabilities (PWD) increasing annually, more and more people will have to rely on wheelchairs to facilitate their mobility to live their lives independently. In the United States, nearly 2.7 million people experience mobility challenges leading them to rely on wheelchairs in their daily lives [1]. That is expected to increase by 7% annually [2] leading to a growing demand for mobility support systems that enable independent living and social integration. Wheelchairs, especially powered wheelchairs (PWC), are the most common means of assisting PWD in both indoor and outdoor environments where these devices provide crucial mobility assistance, allowing users to navigate their surroundings more easily [3]. In addition, smart wheelchairs created to introduce autonomy in PWC operation have demonstrated significant potential in improving the quality of life for PWD [4].

Current smart wheelchairs face a notable limitation: they often focus exclusively on either full autonomy or enhanced manual control [4]. This imbalance can result in inefficiencies during navigation and a lack of trust in the technology—critical factors that influence the successful adoption of these devices [5]. Shared control enables users to partially override the autonomous navigation system, allowing them to contribute to decision-making during navigation. This approach not only enhances the mobility of PWD but also fosters user trust by offering a balanced partnership between autonomy and manual control.

Building on insights from previous smart wheelchair designs [6, 7, 8, 9, 10, 11] and shared control-based navigation structures [12], we developed both the hardware and software for such a shared control-based smart wheelchair that we call the CoNav Chair.

For hardware design, We based our hardware design on a widely used commercial PWC. The key elements include the integration of LiDAR, a camera, an inertial measurement unit (IMU), and two encoders. These sensors collectively provide comprehensive input data for the system. To accommodate all the sensors and the controller board, we designed a dedicated sensor mounting board located under the wheelchair. This sophisticated hardware integration lays the foundation for the implementation of the advanced shared control-based navigation algorithm, ultimately contributing to a more intuitive, reliable, and efficient mobility solution for people with disabilities. Additionally, we implemented a closed-loop proportional–integral–derivative (PID) [13] motor control module to manage the wheelchair's motors effectively.

The software design centers around a ROS-based Simultaneous Localization and Mapping (SLAM) and navigation framework, which facilitates navigation and interactive motor control. For the SLAM module, we employ Faster-LIO [14] to estimate the wheelchair's states and positions and RTAB-Map [15] to construct

Figure 1. Development Timeline of Smart Wheelchairs

a detailed map of the indoor environment. This 2D map is then used in our shared control-based navigation system. By integrating the user's control input signals with the autonomous navigation system, the wheelchair can navigate effectively through the mapped area.

In general, our proposed system has the following contributions:

- We developed the CoNav Chair, a shared control-based smart wheelchair platform that bridges the gap between full autonomy and manual control by leveraging our proposed shared control algorithm, setting a new benchmark for assistive mobility solutions.
- At the hardware level, we developed a ROS-based smart wheelchair hardware platform built from a widely used commercial PWC with essential control electronics and sensors to enable advanced perception, mapping, autonomous navigation, and precise motor control.
- At the software level, we proposed a novel shared control-based navigation framework for assistive mobile robots integrating a user's desire for path preference and control during navigation to improve the efficiency and human-robot trust.
- We have tested our wheelchair system in a built environment and demonstrated that our robot system outperforms other autonomous wheelchair navigation systems both in effectiveness and user comfort.

2 Related Work

The development of smart wheelchairs has been a focal point in the literature aimed at improving the mobility and independence of PWD. A lot of research on wheelchair hardware instrumentation and software integration has been conducted and implemented to address the limitations of the traditional PWC.

The research on smart wheelchairs started in the 1990s, and a lot of work related to smart wheelchairs has been developed such as VAHM [6], Vulcan1.0 [7], Wheelsley [8] and NavChair [9], Vulcan2.0 [10] and Cyberwork Wheelchair [11]. The development timeline of the smart wheelchair system is shown in Figure 1. VAHM is equipped with a contact sensor, ultrasonic and infrared sensors to detect collisions, and wall-following algorithms to allow the wheelchair to navigate by following the wall. Wheelsley allows wheelchair users to give navigation commands by using an eye-tracking system. Vulcan1.0 uses 2D LiDAR and RGB camera input to build a visual 2D map for the wheelchair user to visualize their current location and their surroundings to let them better operate the wheelchair. The NavChair is an assistive wheelchair navigation system that integrates autonomous navigation, obstacle avoidance, door passage, and wall-following which allow the wheelchair to navigate autonomously. Vulcan2.0 is the improved version of Vulcan1.0 which integrates autonomous navigation algorithms and reduces the cost by using 2D LiDAR only. The Cyberwork Wheelchair is a commercially available smart wheelchair which is equipped with multiple RGB-D cameras to get the surrounding information and use it to navigate autonomously while avoiding obstacles. The performance comparison is shown in Table 1.

While these wheelchair platforms offer significant navigational assistance to individuals who struggle with traditional powered wheelchairs, they rely heavily either on sensor data or human input, which can have limitations and sensitivity to environmental changes [16]. For user controlled wheelchair systems, such as those using

Figure 2. Hardware Design of the CoNav Chair

eye-tracking control [8], they require substantial cognitive effort or fine motor skills, which can be fatiguing or unreliable over extended periods. Fully autonomous systems, on the other hand, can fall short in dynamic and unpredictable environments due to sensor limitations or algorithmic shortcomings [17]. Our proposed system is equipped with multiple sensors and a shared control-based navigation system that allow users to partially control the wheelchair which increases the reliability of the intelligent wheelchair system, addressing the limitations of fully autonomous systems in dynamic and unpredictable environments.

3 Hardware Design

For this project, we have equipped a commercially available PWC, Quantum Q6 Edge 2.0, with control electronics, optical encoders, and multiple sensors such as VLP-16 LiDAR, ZED stereo camera, and Witmotion IMU. Although LiDAR and cameras are fundamental for these robotic functions, most commercial PWCs (e.g., Quantum Q6 Edge 2.0, Pride Mobility) are not manufactured with such sensing systems by default, and many current "smart" wheelchairs on the market remain prohibitively expensive or do not implement shared control. Inspired by the widely used Turtlebot3 platform [18], our goal is to develop a universal, research-oriented standard for shared-control smart wheelchairs. While our prototype employs a 3D LiDAR and an RGB-D camera to demonstrate robust performance, the architecture is modular—it can readily accommodate alternative sensors such as a 2D LiDAR or a single RGB-D camera. This flexible design allows researchers and manufacturers to balance cost and functionality as needed, thereby fostering accessible, shared-control mobility solutions for a broader range of users. The hardware architecture is shown in Figure 2.

As shown in Figure 3, Our hardware structure follows the Sensing - Reasoning - Acting structure. For the Sensing part, all of the sensors, such as the LiDAR and the camera will provide the robot with environmental information about the surroundings and publish the sensor data to a laptop PC for further processing. For the Reasoning module, the laptop PC is connected to the sensors and motors, which run a Linux operating system and ROS. Our shared control-based navigation program will run on this PC and send actuator control commands to motors. For the Acting module, a motor control system based on R-Net is designed, and a closed PID control system is integrated to ensure the stability of the lower-level control system.

3.1 Motion Control Module

For the motor control module, we are using the alternative control interface embedded in the wheelchair. The alternative control interface is on the enhanced display, which has a 9-way pin-out. We design our motor controller board, which can output two ways of voltage ranging from 4.8V - 7.2V to both control the forward and rotation velocity. The board is programmed to have a *rosserial* module to take command velocity signals sent from our laptop by publishing and subscribing nodes and topic protocol. Inside the board, two digital Potentiometers are used to convert the control message to the voltage signal and send it to the alternative control interface. After the alternative control interface gets the voltage output from the controller board, the interface will convert the voltage signals to CAN messages and send

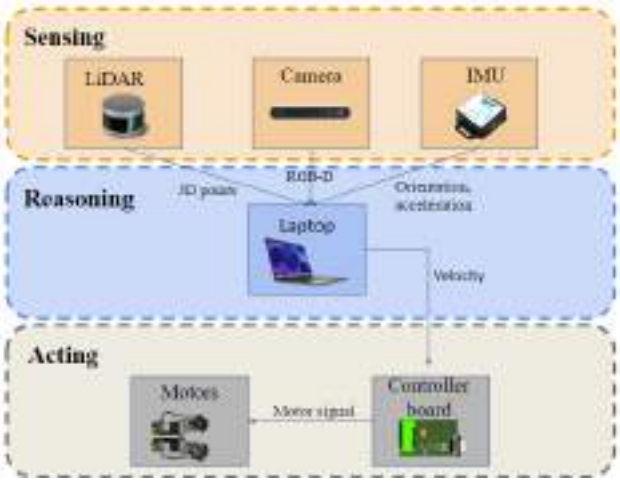

Figure 3. Hardware Dataflow of CoNav Chair

Figure 4. Motor Control Module

them to the wheelchair base. The way we connect the motor controller module is shown in Figure 4.

3.2 Sensor Module

The LiDAR and camera were mounted on the wheelchair using T-slotted aluminum extrusions to avoid obstructing leg movement. Both extrusions were attached to the wheelchair's armrest and seat rail using L brackets and square nuts, as shown in Figure 5. Cables were routed along the extrusions and secured with zip ties for a clean installation. The LiDAR and camera were mounted at the front of the wheelchair to prioritize forward-facing perception, since most powered wheelchair navigation involves moving and avoiding obstacles in the forward direction. Given that our wheelchair is a differential-drive system, it can rotate in place and thus rarely needs to travel backward; this reduces the necessity for rear coverage.

The wheelchair's motors were modified to retrofit new encoders while retaining the functionality of the integrated electromagnetic brakes. This involved preparing the motor shafts by drilling and threading them to accommodate an encoder mount. The encoders were securely installed

Figure 5. Sensor Module

using existing mounting points, following standard guidelines, to ensure precise and reliable operation.

4 Software Design

Our proposed SLAM and shared control-based navigation system of the smart wheelchair is based on ROS [19]. ROS provides a robust and flexible framework for writing robot software, allowing developers to leverage a vast ecosystem of tools, libraries, and conventions designed for robot applications. The general structure of the software arrangement is shown in Figure 6. The structure consists of three parts: a 3D mapping module, a Localization module, a Shared control-based navigation module, and a Motor control module.

4.1 Mapper and Localizer

For the mapping module, the system employs RTAB-Map [15], which is a graph-based SLAM algorithm capable of generating both 3D maps and their 2D projections of the surrounding environment. The RGB-D sensor serves as the primary input to RTAB-Map, enabling the construction of detailed 3D maps through real-time point cloud data processing. This map data is stored in a database, which is also used for managing obstacle point clouds for effective collision avoidance. The RTAB-Map framework integrates with a map server to publish the map information, accessible under the `/map` topic, which is crucial for high-level path planning and navigation tasks.

Simultaneously, the system utilizes Faster-LIO [14], a LiDAR-inertial odometry framework, for accurate localization. Faster-LIO processes data from the 3D LiDAR and IMU inputs. Initially, the raw LiDAR

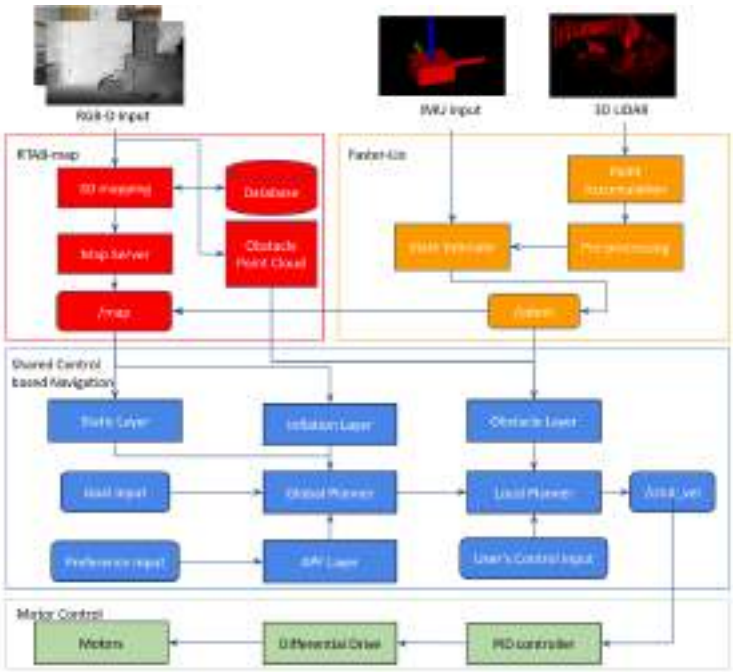

Figure 6. Software Structure of CoNav Chair

data undergoes pre-processing to filter out noise and structure the point cloud for efficient processing. These pre-processed point clouds are then accumulated to provide consistent spatial information. The state estimation module combines the IMU data with the processed LiDAR information, ensuring robust and precise localization even in dynamic environments. The resulting odometry data is published under the `/odom` topic, providing real-time position and orientation feedback to the wheelchair system.

4.2 Shared Control-based Navigation

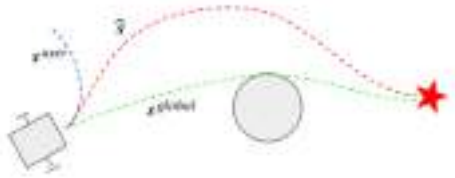

Figure 7. Shared Control-based MPC

Considering a wheelchair's role as an intimately user-integrated robotic system, it becomes essential to incorporate considerations of the user's control. Therefore, within our current framework, we have incorporated methods and concepts of shared control. In order to combine both user's control and autonomous navigation, we proposed a Shared Control-based Model Predictive Control local planner [12] to allow users to adaptively combine their control signals into the whole navigation process.

Here we utilized a non-linear model predictive control (MPC) [20] formulation for indoor environments navigation. The optimization problem is formulated below:

$$\begin{aligned} \boldsymbol{u}^* &= \arg\min_{\boldsymbol{u}\ \mathcal{U}} \mathcal{J}\ \boldsymbol{s}, \hat{\boldsymbol{s}}, \boldsymbol{u} \\ s.t. s_{t\ 1} &= f\ s_t, u_t \\ \boldsymbol{s} &\quad \mathcal{S}_{free} \\ \boldsymbol{u} &\quad \mathcal{U} \end{aligned} \tag{1}$$

where $s = s_0, ..., s_T$ is the state sequence of the robot drawn from the feasible set S_{free} by passing a control sequence $u = u_0, ..., u_{T\in 1}$ drawn from a control space U through the robot dynamic f. $\hat{s} = \hat{s}_0, ..., \hat{s}_T$ is the combined reference states of robot by considering both the user's control signal sequence and the global path plan generated by the user-preference field. $\mathcal{J}$ is the cost function that expresses the considerations of efficiency, safety, and user control.

To enable the user to take control of the navigation process, we incorporate the predicted state generated by the user's control sequence into the cost function $\mathcal{J}$, as shown below.

$$\begin{aligned} \mathcal{J}\ \boldsymbol{s},\hat{\boldsymbol{s}},\boldsymbol{u}\ &= \mathcal{J}_s\ \boldsymbol{s},\hat{\boldsymbol{s}}\quad \mathcal{J}_u\ \boldsymbol{u} \\ \mathcal{J}_s\ \boldsymbol{s},\hat{\boldsymbol{s}}\ &= \ \boldsymbol{s}\in\hat{\boldsymbol{s}}\ ^T\boldsymbol{Q}_s\ \boldsymbol{s}\in\hat{\boldsymbol{s}} \\ \hat{\boldsymbol{s}} = \eta\ k\ \boldsymbol{s}^{user}\quad & 1\in\eta\ k\ \ \boldsymbol{s}^{global} \\ \mathcal{J}^u &= \boldsymbol{u}^T\boldsymbol{Q}_u\boldsymbol{u} \end{aligned} \tag{2}$$

where $\mathcal{J}_s$ represents the state cost and $\mathcal{J}_u$ represents the input cost. The combined cost, denoted as $\hat{s}$, takes into account both the global planning state sequence $\boldsymbol{s}_{global}$ and the user's control sequence $\boldsymbol{s}_{user}$. The parameter $\theta\ k\quad 0,1$ acts as a weight for the user's control sequence, determining the degree of control the user exerts. The variable k indicates the number of control signals the user provides within a given time frame. To adjust the levels of user control in our system, we devised a weight function based on the frequency of user control, reflecting their intent to steer the wheelchair. Specifically, each press of the user control interface (e.g., joystick or button) increases the weight of user input, indicating a stronger desire to steer the wheelchair. Conversely, if pressing frequency decreases, the system gradually shifts to rely more on autonomy. We capture this behavior with an exponential weighting function, as shown below, ensuring that urgent user interventions result in greater manual influence while non-urgent scenarios default to a higher degree of autonomous control. An exponential function is used to model the user's intent, as shown below:

$$\theta\ k\ = 1\in e^k \tag{3}$$

As shown in Figure 7, the reference path combined the user's control signal and the global path plan. The MPC local planner will then allow the robot to follow the combined path while avoiding obstacles.

5 Experiment Setup and Result

In this part, we set up a real-world experiment and tested our wheelchair within an indoor-built environment. The experiment setup and the result are shown below.

5.1 Experiment Setup

The CoNav Chair runs on Ubuntu 20.04 with ROS Noetic on board. The navigation task is set up in the corridor on the first floor of an academic building on our campus, shown in Figure 8. We created four corridor scenes, each within a 1.2m-wide hallway, where obstacles were distributed to test maneuverability. The CoNav Chair measures approximately 0.8m in width, leaving only 0.4 m of total clearance. The four scenes—Scene 1, Scene 2, Scene 3, and Scene 4—differ by the number of obstacles (3, 4, 5, and 6, respectively), introducing progressively tighter navigation constraints. One of these scenes is shown in Figure 8. This setup was used to evaluate the performance of our shared-control algorithm against both fully autonomous and fully manual control methods. We assessed the planner based on time, success rate, collision rate, user satisfaction, trajectory length, and angle difference summary representing smoothness [21] against fully manual and autonomous controls.

Figure 8. Experiment Environment and Navigation Route

5.2 Experiment Result

The quantitative results in Figure 9 show that the proposed shared control-based framework significantly outperforms fully manual and autonomous navigation [22] modes in both efficiency and reliability. The shared control planner achieves shorter completion times and trajectory lengths, reflecting faster and more direct navigation. Its smoother trajectories, indicated by lower cumulative absolute angle differences, ensure fewer abrupt turns and more natural directional changes—critical for applications like assistive robots where comfort and predictability are key. Additionally, the shared control planner demonstrates superior reliability, with higher success rates and fewer collisions across all scenarios.

From the qualitative results in Figure 10, we see that shared control yields fewer collisions compared to either autonomous or manual control. Under manual control, the trajectory is more curved, and users can lose control due to unfamiliarity with the system. In contrast, autonomous control tends to choose the most efficient path, sometimes compromising safety and resulting in collisions. With shared control, users can assume partial control as needed, allowing the system to safely avoid obstacles without risking a complete loss of control.

Manual control, while allowing users to choose direct routes, often suffers from increased collisions and lower success rates due to users' unfamiliarity with the robot's dynamics and excessive adjustments near obstacles. Autonomous navigation, on the other hand, excels at obstacle avoidance and path optimization but struggles in complex scenarios like sharp turns or centrally positioned obstacles, often leading to inefficiencies or 'freezing

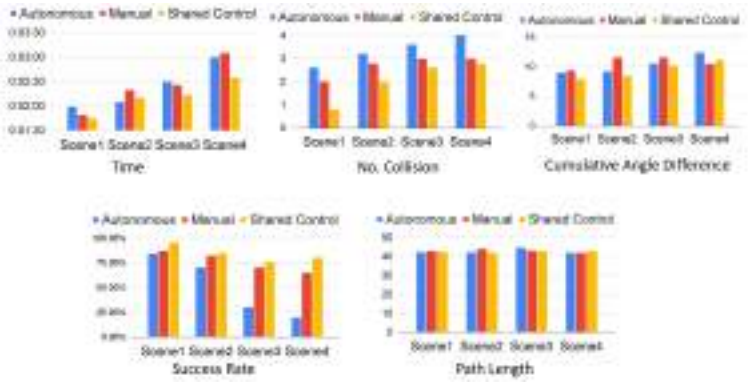

Figure 9. Quantitative Results of the CoNav Chair Evaluation Experiments

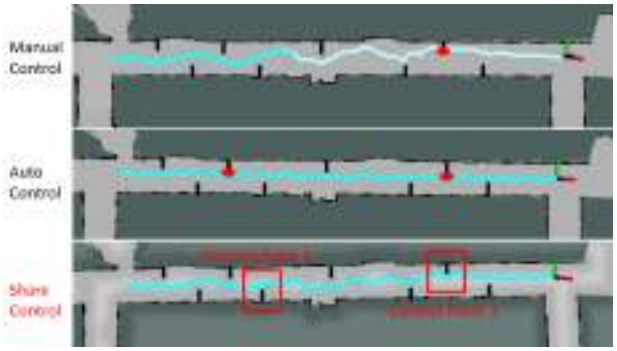

Figure 10. Qualitative Results of the CoNav Chair Evaluation Experiments. (Red explosion shape represents collision)

robot' issues [23]. The shared control framework combines the strengths of both approaches. It leverages autonomous navigation in simpler environments while enabling user intervention in complex scenarios, allowing for effective handling of challenging conditions. This hybrid strategy provides a balanced solution, enhancing efficiency, smoothness, and overall reliability.

6 Conclusion

In this work, we propose the CoNav Chair, a ROS-based smart wheelchair with shared control-based navigation and obstacle avoidance that addresses critical gaps in current PWC designs, by overcoming the limitations of fully autonomous or manual systems. Combining a multi-sensor hardware platform with LiDAR, a camera, an IMU, and encoders for real-time situational awareness and a ROS-based shared control software framework, our system integrates user inputs with autonomous navigation for smoother and more efficient mobility. Tested in real-world built environments, the CoNav Chair demonstrates superior performance in navigation effectiveness and user comfort, offering a reliable and intuitive solution to enhance independence for PWD.

Advancing Automated Building Inspection: A BIM and GSD Integrated Framework for UAV Applications

Emadaldeen Benshaaban[1], Po-Han Chen[2], Shahinuzzaman[3]

Gina Cody School of Engineering and Computer Science, Concordia University, Canada
Emadaldeen.Benshaaban@Concordia.ca, pohan.chen@concordia.ca, s_sujon@live.concordia.ca

Abstract –

Unmanned Aerial Vehicles (UAVs) have become indispensable for building inspections, offering safer, more efficient, and automated alternatives to traditional manual methods. However, current approaches often rely on predetermined inspection parameters, such as fixed distances, without adequately aligning with specific inspection goals or ensuring consistent data quality. This paper presents a novel methodology that addresses these challenges by integrating Building Information Modeling (BIM) and Ground Sampling Distance (GSD) into the inspection planning process. BIM is leveraged to automate the generation of Field of Views (FoVs) and viewpoints, significantly reducing human intervention and ensuring precise coverage of inspection areas. GSD is utilized to determine the optimal distance between the UAV and the surface, guaranteeing that collected data meets predefined objectives, such as detecting fine defects. To further enhance efficiency, a Genetic Algorithm (GA) is employed to optimize the flight path, minimizing travel distance while maintaining comprehensive coverage of all required areas. While the methodology is developed primarily for building inspections, it is scalable and adaptable to other infrastructure types, demonstrating its versatility in diverse scenarios. By combining BIM-based automation, GSD-driven planning, and advanced optimization techniques, this work provides a robust solution for automated, efficient, and high-quality UAV-enabled inspections for future innovations in automated inspection systems.

Keywords –

Building Inspection; Unmanned Aerial Vehicles (UAVs); Ground Sampling Distance (GSD); Field of View (FoV)

1 Introduction

Infrastructure inspections, particularly for high-rise buildings, are essential for ensuring public safety and maintaining structural integrity. Traditional visual inspection methods have been the primary approach for identifying surface defects such as cracks, spalling, and corrosion due to their simplicity and accessibility [1]. However, these methods are often subjective, time-intensive, and risky for inspectors, especially when accessing high-rise structures or geometrically complex components [2]. Moreover, manual inspections frequently rely on an inspector's expertise and judgment, leading to inconsistencies and potential inaccuracies [3]. These challenges highlight the urgent need for more reliable and efficient solutions. Unmanned Aerial Vehicles (UAVs) have emerged as a transformative tool in building inspections, offering advantages such as enhanced safety, efficiency, and accessibility. By utilizing UAVs, inspectors can reduce physical risks, streamline data collection, and minimize disruptions to building operations. Despite their potential, current UAV-enabled inspection methodologies face notable challenges, including reliance on fixed inspection parameters and limited integration of specific data quality goals [4]. Most existing approaches employ arbitrary distances for data collection without scientific justification, which can compromise the accuracy and resolution of inspection data. Furthermore, these approaches often lack automation in critical stages, such as generating inspection viewpoints and planning efficient flight paths [5]. To address these challenges, this study proposes an autonomous UAV-based framework specifically designed for façade defect inspection, focusing on the detection of surface cracks and

corrosion. Unlike general UAV-based reality capture for progress monitoring or 3D reconstruction, our approach ensures precise defect visibility by optimizing data collection based on Ground Sampling Distance (GSD). The framework integrates GSD calculations with UAV flight planning to guarantee that surface details are captured at the required resolution for defect identification. Automation and optimization techniques, including advanced algorithms for flight path planning, are integrated to streamline the process and reduce human intervention.

The remainder of this paper is organized as follows: Section 2 provides a comprehensive review of the existing literature on UAV-based inspections, emphasizing current advancements and challenges. Section 3 details the proposed methodology, outlining its key components and implementation. Lastly, the conclusion discusses the findings of this study and highlights directions for future work.

2 Literature Review

2.1 UAV-Based Building Inspections

The advent of UAVs has revolutionized the field of building inspections by offering a safer, faster, and more cost-effective alternative to traditional methods. UAVs are particularly advantageous in inspecting high-rise structures, complex geometries, and hazardous environments, where manual inspections pose significant risks. Equipped with advanced sensors and cameras, UAVs can capture high-resolution data for defect detection and structural analysis. Studies such as Rakha and Gorodetsky [6] emphasize the potential of UAVs in automating building inspections, particularly in capturing data for damage detection. They outline the benefits of UAVs in reducing human error and operational costs while enhancing the accuracy of data collection processes. Kerle et al. [7] highlight the integration of AI and machine learning algorithms with UAVs to process large datasets and automate the identification of structural damage. Their work underscores the transformative potential of UAVs when combined with intelligent systems to achieve fully autonomous inspection workflows. Recent studies have introduced optimization techniques to improve UAV-based reality capture plans. Ibrahim et al. [8] proposed a set of metrics to evaluate the effectiveness of UAV-based image capture for construction monitoring, focusing on visual coverage, resolution, and viewpoint orientation. Their later work [9] presented a multi-objective optimization model for improving reality capture plans, integrating flight path adjustments based on redundant observations and 3D reconstruction stability. While these studies introduced systematic UAV capture planning methods, they primarily optimize for construction progress monitoring, focusing on improving overall visual data collection efficiency.

2.2 Challenges in Current UAV-Based Inspection Methods

Despite the numerous advantages, UAV-based inspections face several challenges that limit their widespread adoption. A critical issue is the dependence on operator skills for flight path planning and data collection, which often leads to inconsistent coverage. Additionally, environmental factors such as wind, lighting, and weather conditions can significantly affect data quality. Feroz and Abu Dabous[10] identify key limitations in UAV-based inspections, such as the inefficiency of flight paths and the need for manual intervention in data collection. They argue that the lack of standardized protocols for UAV inspections contributes to inconsistencies across projects. Similarly, Mader and Westfeld [11] discuss the challenges of using UAVs in varying lighting and weather conditions, emphasizing the importance of robust data processing algorithms to mitigate these effects. Another significant challenge is the integration of UAV data into existing inspection workflows. The large volume of data collected by UAVs often requires extensive post-processing, which can delay decision-making. Addressing these challenges necessitates advancements in automation, optimization, and data integration.

2.3 Role of BIM in UAV-Driven Inspections

Building Information Modeling (BIM) has emerged as a powerful tool to enhance UAV inspections by providing a digital representation of structures. BIM facilitates automated planning of inspection paths and the overlay of inspection data onto structural models, enabling more efficient defect identification. Tan and Zhou [12]

demonstrate how BIM can optimize UAV flight paths to ensure complete coverage of building surfaces. By integrating UAV data into BIM, they propose a system that reduces human intervention and improves data accuracy. This integration is particularly valuable in large-scale projects, where manual inspection planning is impractical. Feroz and Abu Dabous [13] highlight the potential of BIM to streamline data analysis by integrating inspection results with structural models. They argue that BIM not only improves data visualization but also aids in predictive maintenance by identifying areas prone to future damage. Despite these advantages, the seamless integration of UAVs and BIM remains challenging, requiring advanced data fusion techniques.

2.4 Ground Sampling Distance (GSD) in Data Collection

Ground Sampling Distance (GSD) can play a critical role in UAV-based inspections by determining the spatial resolution of captured images. High-resolution data is essential for accurate defect detection, but achieving optimal GSD often requires balancing flight altitude, speed, and camera settings. Mader and Westfeld [14] explore the impact of GSD on the accuracy of structural analyses. Their study shows that lower GSD values result in higher-resolution images, which are critical for identifying small defects. However, achieving low GSD often necessitates slower flight speeds and lower altitudes, which can increase inspection time and costs. The study by Kerle et al [15] highlights the need for adaptive GSD settings to optimize data collection across varying structural features. They propose dynamic adjustments to UAV flight parameters based on the complexity of the structure being inspected, ensuring both efficiency and data quality.

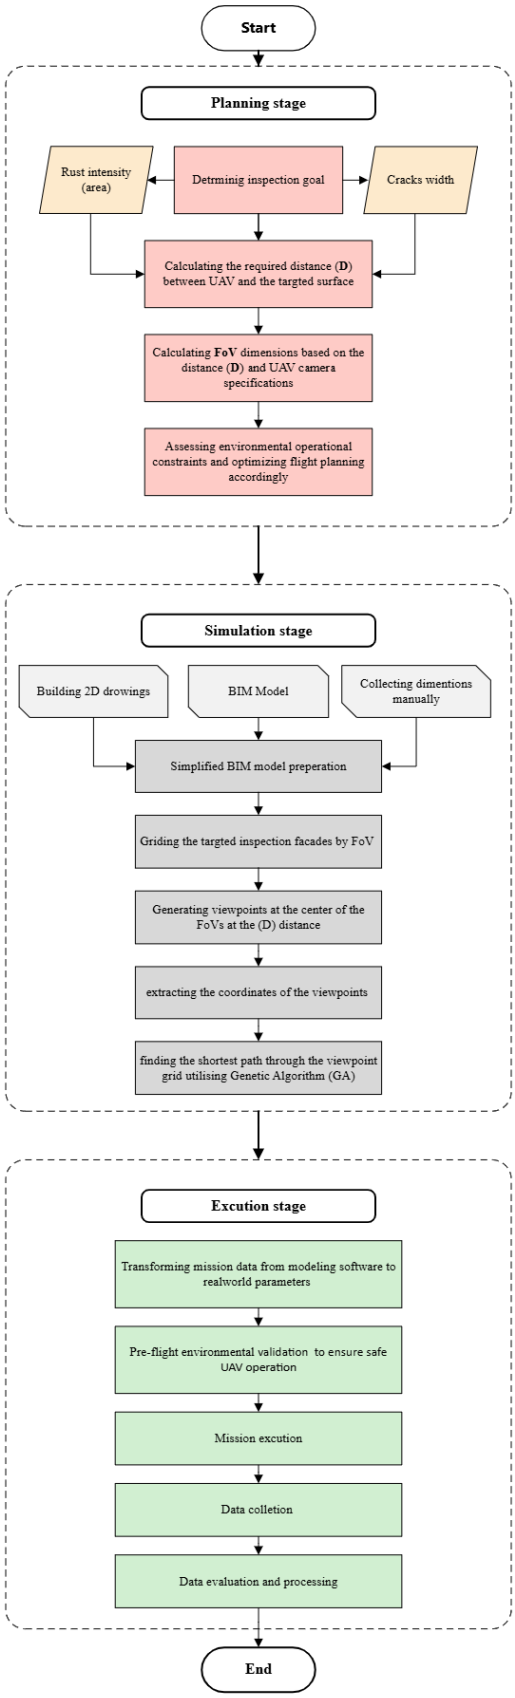
2.5 Optimization Algorithms in UAV Inspections

Optimization algorithms are critical for enhancing the efficiency and effectiveness of UAV inspections. Techniques such as Genetic Algorithms (GAs), Particle Swarm Optimization (PSO), and neural networks have been widely applied to optimize flight paths and reduce redundant data collection. Liu et al [16] present a framework for automated UAV-based inspections using optimization algorithms. Their work demonstrates how GAs can minimize flight time while ensuring comprehensive coverage of building façades. The framework also incorporates collision avoidance mechanisms, enhancing operational safety. Tan and Zou [17] explore the integration of edge computing with optimization techniques to enhance data processing efficiency. By processing data in real-time during inspections, their approach reduces the need for extensive post-processing and accelerates decision-making. The reviewed literature underscores the growing reliance on UAVs for building inspections, driven by their ability to enhance safety, efficiency, and precision. Despite notable advancements in integrating UAVs with BIM and optimization techniques, challenges such as inconsistent data quality, limited automation, and better adaptability to structural complexities remain. Research into optimizing Ground Sampling Distance (GSD) and leveraging advanced algorithms, such as Genetic Algorithms and real-time edge computing, provides promising pathways to overcome these issues. This study seeks to address these gaps by developing a robust, automated framework that integrates UAVs, BIM, GSD, and optimization strategies, thereby advancing the state of the art in building inspection methodologies.

3 Methodology

This study proposes a framework for UAV-based building inspections. It is designed to automate and optimize the inspection process while considering external environmental constraints that may impact UAV operations. The framework integrates Building Information Modeling (BIM), Ground Sampling Distance (GSD) calculations, environmental condition assessment, and optimization techniques to ensure efficient, adaptable, and high-quality inspection coverage.

3.1 Framework for Automated UAV-Based Building Inspection



The framework is structured into three key stages: Planning, Simulation, and Execution, as shown in Figure 1. Each stage incorporates systematic processes to enhance accuracy and efficiency while adapting to real-world environmental conditions.

3.1.1 Planning Stage: The planning stage is crucial for defining inspection objectives and determining UAV flight parameters. The key components include:

a) *Defining Inspection Goals*: The UAV inspection is designed to detect surface defects such as cracks and corrosion while ensuring optimal data quality. *b) Calculating Required Distance (D):* to derive a generic equation for calculating the required distance between a UAV and a targeted surface based on inspection goals, we need to know all the parameters involved, understand how they affect the distance (D), and learn how to obtain them. The parameters influencing UAV distance can be classified into three categories, as detailed in Table 1. Deriving the final equation for D can be summarised in two simple steps. Step 1: *Relationship between GSD and sensor parameters:* Ground Sampling Distance (GSD) can be defined as the real-world size of one pixel in an image captured by a camera. It represents the spatial resolution of the image and determines the level of detail that can be captured from the ground [18].

Table 1. Parameters influence the distance between a UAV and the targeted surface

1- Inspection Requirements
GSD_r: Desired Ground Sampling Distance (mm/pixel). Figure 2
R_c: Crack width resolution requirement (mm).
FoV_w: Field of view width (mm). Figure 2
FoV_h: Field of view height (mm). Figure 2
2- Lens Parameters
f: Focal length of the camera (mm).
3- Sensor Parameters
S_w: Sensor width (mm).
S_h: Sensor height (mm).
P_x: Sensor resolution width (pixels).
P_y: Sensor resolution height (pixels).

As (GSD) is a function of the sensor size, resolution, and flight distance, it can be expressed mathematically:

$$\text{GSD} = \frac{Sw * D}{Px * f} \quad (1)$$

rearranging the equation (1) for D

$$\text{D} = \frac{GSD * Px * f}{Sw} \quad (2)$$

Step 2: *Incorporating Desired GSD and Crack Resolution:*

The desired GSD (GSD_r) is defined based on the inspection requirement for crack detection (R_c). To detect cracks of width (R_c), the resolution per pixel must satisfy:

$$GSD_r = R_c$$

Substituting GSD_r into the equation (2):

$$\boxed{\text{D} = \frac{Rc * Px * f}{Sw}} \quad (3)$$

c) Calculating FoV Dimensions: The Field of View (FoV) is calculated based on the camera's specifications and the desired distance (D). This ensures that the UAV captures an adequate area of the surface in each frame, balancing coverage with image resolution.

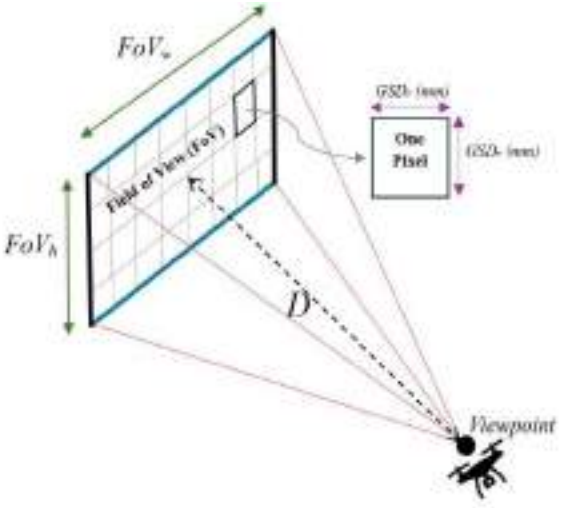


Figure 2. Field of view details, and GSD_r

d) Assessing Environmental Constraints: Environmental factors such as wind speed, temperature, lighting conditions, and GPS accuracy can significantly impact UAV stability and data quality; therefore, these variables are carefully considered during the planning phase. Wind speed constraints are analyzed to ensure stable flight, while lighting conditions are assessed to optimize visibility and defect detection. Temperature variations are considered, as extreme conditions can affect battery performance. Additionally, GPS accuracy is evaluated to minimize navigational errors.

*3.1.2 Simulation Stage***:** This stage involves virtually preparing the inspection environment and optimizing the UAV's flight path. It begins with creating a simplified BIM model of the targeted building by removing unnecessary architectural details from the facades included in the original BIM. In cases where a BIM model is unavailable for the building, the simplified model can be constructed using 2D building drawings or by manually collecting the required measurements. *Next Step:* Gridding the Inspection Facades: The targeted facades for inspection are segmented into a grid based on the calculated Field of View (FoV) dimensions. This segmentation ensures systematic coverage of the entire surface area, as illustrated in Figure 3. The FoVs can be distributed on the facades with or without overlapping, depending on dimensions and inspection requirements. Once the grid is established, viewpoints are generated at the center of each FoV, positioned at the calculated distance (D). These viewpoints act as reference points for precise UAV positioning during the inspection. It is important to note that both the grid creation for FoVs and the generation of viewpoints have been automated using Autodesk Dynamo software. The last step in the simulation stage is the flight path optimization. There are several methods and techniques for path planning; however, in this study, a Genetic Algorithm (GA) is employed to determine the shortest and most energy-efficient path through the grid of viewpoints. This optimization minimizes UAV flight time and energy consumption while ensuring full coverage of the

building façades. Figure 4 illustrates the optimal path obtained using GA.

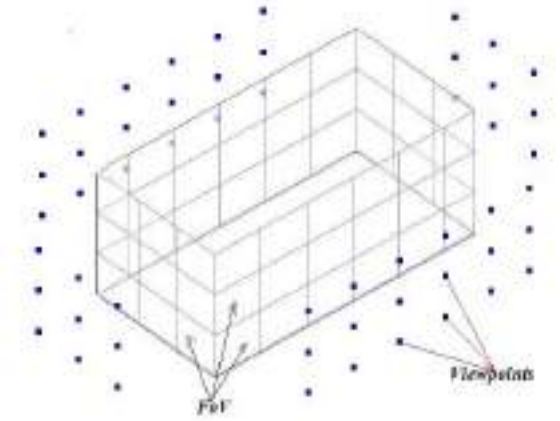

Figure 3. Griding the targeted facades and generating viewpoints at the desired distance

While the proposed framework ensures complete coverage in simulation, real-world conditions introduce uncontrollable variables such as UAV stability, environmental disturbances, and GPS accuracy, which may impact actual coverage. Therefore, a field experiment is planned to validate the methodology in real-world conditions and assess its effectiveness in achieving comprehensive façade inspection coverage.

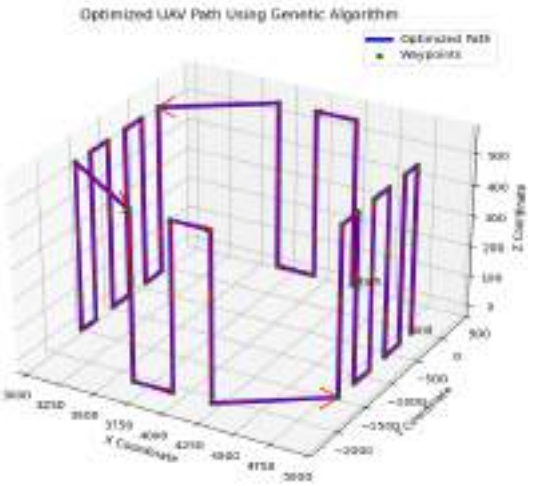

Figure 4. Optimized path planning using GA

3.1.3 Execution Stage: The execution stage translates the simulated flight plan into real-world UAV operations, ensuring reliable and environmentally adaptive data collection. This phase incorporates real-time validation and adjustments to maintain data accuracy and operational efficiency. The main steps are: (a) Mission Data Transformation: Data from the simulation stage, including waypoint (as same as viewpoints) coordinates and optimized flight paths, is transformed into real-world mission parameters compatible with UAV navigation systems. (b) Pre-Flight Environmental Validation and Adaptation: Before takeoff, real-time environmental conditions such as wind speed, lighting, and GPS stability are assessed. If any parameter exceeds operational thresholds, indicating a potential disruption, the operation is cancelled to ensure safety and data integrity. While such cancellations are rare, they are necessary to prevent compromised results and ensure mission reliability. (c) Mission Execution and Data Collection: The UAV executes the inspection mission based on the predefined flight path, capturing images and other required data for each FoV. (d) Data Evaluation and Processing: The collected data should be processed to extract actionable insights. This includes assessing rust intensity, crack width, and other structural defects.

4. Conclusion and Future Work

This study presents an automated framework for UAV-based building inspections, integrating Building Information Modeling (BIM), Ground Sampling Distance (GSD)-driven planning, and optimization algorithms. While the framework has yet to be experimentally validated, its design demonstrates significant potential to enhance inspection accuracy, operational efficiency, and scalability. The key contribution of this work is the development of a GSD-based equation to calculate the required distance (D) between the UAV and the targeted surfaces. This ensures high-resolution data collection tailored to specific defect detection needs, such as crack width and rust intensity. Additionally, the framework incorporates: (1) Automation of inspection parameters, including

Fields of View (FoVs) and viewpoints, to reduce human intervention and enable systematic and precise surface coverage. (2) The use of Genetic Algorithms (GA) to optimize UAV operations by minimizing travel time and energy consumption, enhancing inspection efficiency as part of the overall framework design. By combining these elements, the proposed framework provides a robust and adaptable solution for automated UAV-enabled building inspections, laying the groundwork for future innovations in infrastructure monitoring. While simulation results demonstrate full coverage of the inspection area, a future case study will be conducted to validate these findings in real-world conditions, accounting for potential operational constraints.

Future experiments will focus on validating these capabilities in real-world settings. Additionally, further research will explore the integration of real-time adaptive algorithms and AI-driven defect detection systems to enhance the framework's robustness and usability under varying environmental conditions.

[†]These authors contributed equally to this work

Abstract

This work explores the integration of Large Language Model (LLM)-powered agents into robotic construction workflows. An LLM-based agent framework by leveraging standardized IFC format is proposed to guide robotic tasks, such as bricklaying and 3D concrete printing. Through a combination of tailored tools, prompt templates, and a *CustomMemory* module, the framework enables efficient extraction of building information and execution of robotic tasks. Finally, experimental validation in a simulated environment demonstrates the framework's potential to streamline robotic construction workflows from textual or voice commands to physical construction activities, while reducing redundant operations and enhancing reliability through thoughtful design.

Keywords – LLM Agents, Robotic Construction, IFC, BIM, 3D Concrete Printing

1 Introduction

The construction industry is witnessing rapid advancements in automation, driven by the need to address challenges such as large-scale tasks, stringent precision requirements, and dynamic environments. Robotics has emerged as a promising solution, enabling efficient and precise execution of tasks like bricklaying and 3D concrete printing. Despite significant progress in robotic construction, the integration of large language models (LLMs) into these workflows remains limited, particularly for tasks requiring seamless communication between building information modeling (BIM) data and robotic operations. While LLMs have shown great potential in robotics operations through their emergent and reasoning capabilities, their applications have mainly focused on the design stage, where generative tools powered by LLMs are widely adopted. However, their use in robotic construction processes remains largely unexplored.

This work addresses this gap by proposing an IFC-enhanced LLM agent framework for robotic construction. The framework leverages the standardized Industry Foundation Classes (IFC) format to extract building information efficiently and accurately. Furthermore, by incorporating tailored tools, structured prompt templates, and a designed *CustomMemory* module, the framework effectively guides robots in performing tasks such as bricklaying and 3D concrete printing. Experimental validation in a simulated environment demonstrates the framework's effectiveness in streamlining workflows, avoiding redundant operations, and enhancing reliability.

2 Related Works

2.1 Robotic Construction and LLM

LLMs have shown significant potential in robotics operations, enabling tasks such as natural language and code generation, numerical prediction, motion planning, and fault detection [1]. Works like RoboCodeX [2] and Reasoning Tuning [3] integrate visual and physical data in multimodal models to generate executable numeric predictions, achieving cross-platform and cross-scenario generalization by decomposing high-level semantics into traceable low-level actions. Methods like ReKep [4] enhance skill planning by identifying critical points, allowing robots to handle complex environments effectively, while Code-as-Monitor [5] combines Vision Language Models (VLMs) with real-time monitoring to predict risks and detect errors proactively.

Robots are advancing automation in construction, particularly in bricklaying and 3D concrete printing. For instance, mobile robots are used for automated bricklaying, integrated within BIM [6]. 3D concrete printing allows robotic arms to fabricate components efficiently, reducing material waste [7]. However, challenges in efficiency and structural stability persist, especially in large-scale projects. While robotic construction progresses, integration with LLMs remains limited. In contrast, LLM-driven tools like text2BIM [8] and AIstructure-Copilot [9] are making strides in generating layouts and BIM models from textual

descriptions during the design phase.

2.2 IFC Standardization

The IFC was introduced by buildingSMART International, to address interoperability challenges within the Architecture, Engineering, and Construction (AEC) and facility management (FM) industries [10]. IFC provides a standardized, neutral, and non-proprietary data format that spans the entire lifecycle of construction projects [11], including design, construction, and maintenance. By promoting seamless communication and reducing reliance on proprietary formats, IFC has become a universal standard in domains such as buildings, bridges, airports, and railways [12]. Leading AEC software platforms, including Autodesk and Bentley Systems, have adopted IFC to facilitate interoperability and enable efficient data exchange across stakeholders.

IFC's structured representation of building elements and attributes, accessible via tools like IfcOpenShell [13], supports automated construction workflows. By extracting dimensions, material properties, and placement information from IFC elements such as IfcWall and IfcBeam [14], the format facilitates integration with downstream processes like robotic assembly. Technologies like ifcJSON [15] further enhance this integration by converting IFC data into structured formats compatible with modern workflows. Leveraging IFC data in robotic construction, combined with LLM, has significant potential to address key industry challenges like large-scale task automation and precision requirements. For instance, LLM agents can potentially guide robots to efficiently and accurately perform complex tasks based on IFC files, including wall masonry and rebar tying.

3 Methodology

This work builds on prior research in the Text2BIM framework [8], [16], which utilizes LLM-based multi-agent systems to convert natural language commands into editable 3D building models. Extending this concept to robotic construction, our approach transforms engineers' natural language instructions into actionable robotic tasks based on BIM. A cornerstone of the approach is the use of IFC, offering a standardized and structured format for building design data to enable accurate extraction and utilization.

Directly processing IFC data with LLMs poses challenges due to its complexity and domain specificity, often resulting in parsing inaccuracies. Moreover, token limitations further restrict handling large files. To address these issues, IfcOpenShell [13] is employed for precise data extraction, effectively avoiding token limitations associated with processing large IFC files and ensuring efficient and structured retrieval of BIM data.

Hence, a suite of tools based on IfcOpenShell is developed for LLM-based agents to handle necessary calculations and generate operational code in robotic construction. The workflow, as shown in Figure 1, demonstrates seamless integration of tool usage, memory modules, and task performance to transform BIM models into robotic construction operation.

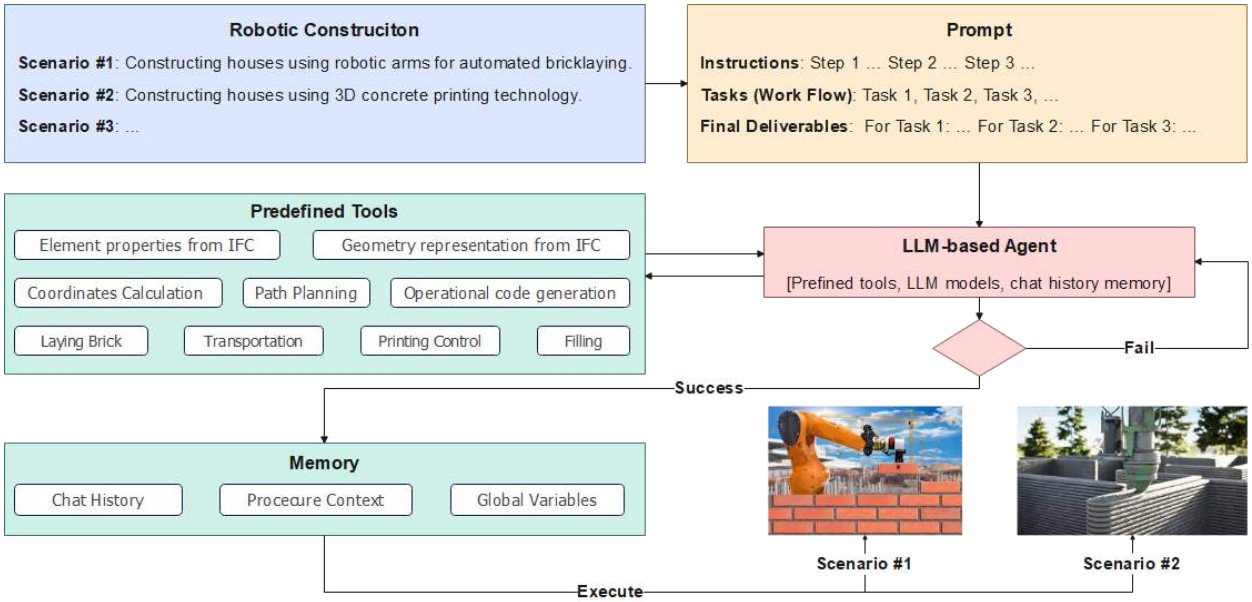

Figure 1. Proposed LLM agent-based Robotic Construction Framework

3.1 Toolset Design

Tools are designed from three key perspectives: (a) information extraction from IFC files, including both entity objects and geometric representations. Entity objects include building components such as walls, doors, windows, beams, columns, and roofs, while geometric representations cover attributes like shapes, placement, profiles, dimensions, extrusions, orientations, and spatial relationships. (b) essential calculations, such as brick coordinate calculation and printing path planning. (c) robotic operations, like bricklaying, printing control, material transportation, and filling.

Table 1 Examples of predefined tools

Name	Description	Outcome
LoadIFC File	Load an IFC file and return the ifcopenshell.file object.	The IFC file has been successfully loaded.
Extract Wall	Extract wall properties from an IFC file using ifcopenshell.	Wall properties are stored as variable *all_wall_props_global*
Calculate Bricks	Calculate brick coordinates based on wall dimensions and brick size. Input is a JSON format with keys: wall_properties, door_properties, window_properties, and brick_size.	Filtered brick coordinates are stored as variable filtered_brick_coordinates_global with {len(filtered_brick_coordinates_global)} records.
LayBricks	Lay bricks at the specified coordinates. Input is JSON format containing keys: filtered_brick_coordinates.	The system has successfully laid bricks at the specified coordinates.

The context of each tool is structured as three key components: 1) Name, to identify the tool during operation, 2) Description, to guide invocation and input format, and 3) Outcome, detailing the output variables and their storage locations, which are explicitly incorporated into memory module for LLM's contextual awareness. Table 1 presents examples of predefined tools and their descriptions. Prompt Template

The prompt template used in this work consists of three key components: Instructions, Tasks, and Final deliverables.

Instructions include directives to ensure: a) check for required data before each task; b) reuse available data from memory; c) use the provided tools and update results; d) transit between tasks with clear statements; 5) provide reasoning and results for each task before proceeding.

Task prompts are designed in two styles: a) open-ended prompt: providing a high-level instruction that allows the LLM to determine the appropriate tools and workflow based on its emergent and reasoning capabilities; b) tool-specific prompt: combining tool descriptions with input variables to guide precise tool invocation and task execution.

Final deliverables specify the expected output, which is stored in the memory module's chat history to ensure consistent progress tracking and provide context for subsequent tasks. Additionally, tools can be re-invoked at this stage to perform supplementary functions, such as saving output in a specific file format.

The tailored prompt template is shown in Figure 2.

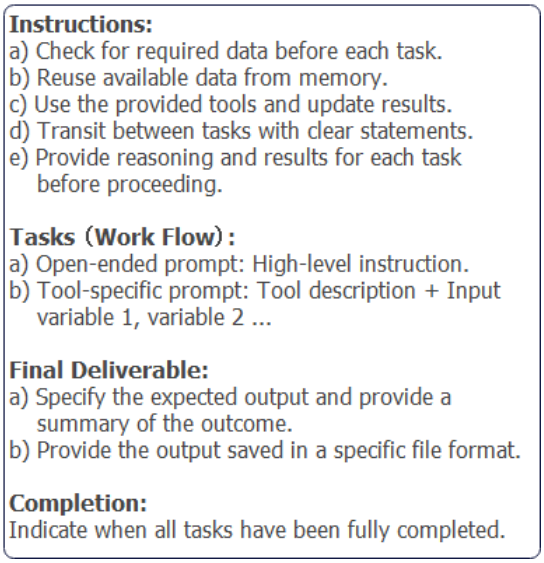

Figure 2. Structured prompt template

3.2 Memory Module

The memory module in this work consists of three components: 1) chat history, 2) output variables, and 3) procedure context. Using *ConversationBufferMemory* in LangChain [17], each prompt and the corresponding answers from the final deliverables section are recorded in the chat history. Meanwhile, the output variables during tool invocation are explicitly stored (e.g., as

global variables) and returned in an outcome summary, informing the agent to reuse these variables within the same session. However, once a session is completed, the outcomes generated during the process are discarded, leading to recalculations of previously generated variables in subsequent prompts.

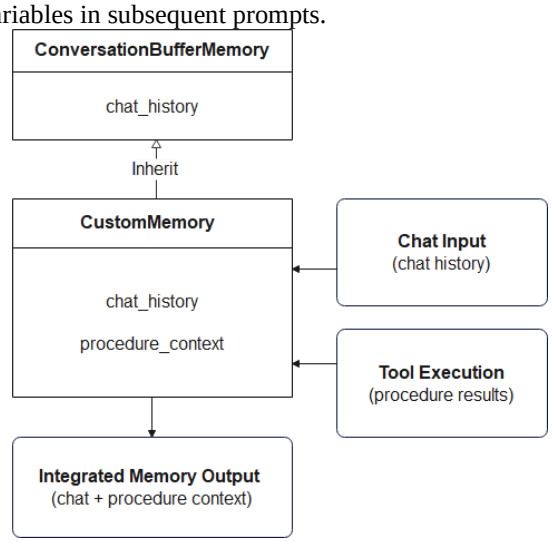

Figure 3. *CustomMemory* class and data flow

To address this issue, a *CustomMemory* class is designed, as shown in Figure 3, extending from *ConversationBufferMemory*, to retain chat history and store tool execution outcomes (i.e., procedure context). This integration enables the agent to review procedure results in any session, ensuring informed decisions and avoiding redundancy.

However, it is worth noting that memory content may continuously accumulate over multiple sessions, potentially leading to the scalability challenge. To mitigate this, efficient context management strategies, such as hierarchical summarization, may be required in future development to optimize memory usage while preserving relevant procedural data.

4 Proof of Concept

4.1 Preparation

To validate the effectiveness of the proposed LLM-based autonomous agent framework in robotic construction, experiments were conducted for two different scenarios: robotic bricklaying and 3D concrete printing. The experimental setup featured a simple structure comprising four walls, a door, and two windows, as shown in Figure 4. For simplicity, the bricks used in wall construction were cubic, with dimensions matching the wall thickness. Likewise, the layer height for 3D concrete printing was set equal to the wall thickness.

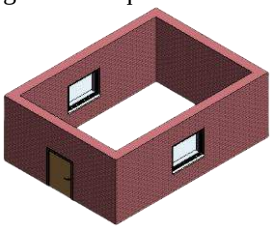

Figure 4. Experimental Structure

LangChain is adopted as the development foundation and a series of tools are developed for the experiment. The GPT-4 is utilized as the LLM engine, with the prompts shown in Figure 5.

Instructions:
0. Complete all tasks sequentially in the given order. Do not stop until all tasks are fully completed.
1. Before performing each task, explicitly use the QueryMemory tool to determine if the required information is already available, even if it is the first task.
2. If any part of the required information is already available in memory, reuse it instead of recalculating or re-extracting it.
3. Use the provided tools to complete the remaining parts of the tasks, storing results in the indicated global variables. Confirm that the variables are updated for subsequent use.
4. After completing each task, explicitly transition to the next task by stating, "Task [N] completed. Moving to Task [N+1]."
5. Provide clear reasoning and results for each task before transitioning to the next.

Tasks:
1. Load the project3.ifc file.
2. Extract all the elements from the loaded ifc object.
3. Calculate brick coordinates for the walls based on wall dimensions and brick size (300 mm cubic bricks), then filter out coordinates conflict with other structural elements or openings.
4. Generate 3D concrete printing paths for walls based on wall dimensions and layer height (300 mm), avoiding areas occupied by other structural elements or openings.
5. Lay bricks at the specified coordinates provided in the `filtered_brick_coordinates` input. Ensure all coordinates are processed, and return the result, including the number of bricks laid.
6. Print concrete along the 3D paths provided in the `layers_print_paths` input. Ensure all paths are processed, and return the result, including the number of layers printed.

Final Deliverable:
For Task 3: Save the filtered brick coordinates into a JSON file named 'filtered_brick_coordinates.josn'.
For Task 4: Save the 3D concrete printing paths into a JSON file named 'printing_paths.json'.
For Task 5: Summarize the brick-laying task, including the total number of bricks laid.
For Task 6: Summarize the 3D concrete printing task, including the total number of layers printed.

Completion:
Indicate when all tasks have been fully completed.

Figure 5. Prompts in the experiment

```
The first task is to read the project3.ifc file and initialize processing. However, before I do that, I need to check if the file has
already been loaded into memory.
Action: QueryMemory
Action Input: {}
Observation: Memory is empty. No prior actions or outputs are available.
Thought:Since the memory is empty, the project3.ifc file has not been loaded yet. I will now load the file using the LoadIFCFile tool.
Action: LoadIFCFile
Action Input: {"file_path": "project3.ifc"}{'file_path': 'project3.ifc'}
project3.ifc
<ifcopenshell.file.file object at 0x000001E5235BC610>

Observation: project3.ifc loaded successfully and stored as variable ifc_object.
Thought:The project3.ifc file has been successfully loaded and stored in the variable ifc_object. Task 1 is now completed. Moving to
Task 2, which is to identify and extract architectural elements from the IFC file.
Action: ExtractWallProperties
Action Input: {"ifc_object": "ifc_object"}
Observation: Wall properties stored as variable all_wall_props_global with 4 records.
Thought:The wall properties have been successfully extracted from the IFC file and stored in the variable all_wall_props_global. Now, I
will extract the door properties.
Action: ExtractDoorProperties
Action Input: {"ifc_object": "ifc_object"}
Observation: Door properties are stored as variable all_door_props_global with 1 records.
Thought:The door properties have been successfully extracted from the IFC file and stored in the variable all_door_props_global. Now, I
will extract the window properties.
Action: ExtractWindowProperties
Action Input: {"ifc_object": "ifc_object"}
Observation: Window properties are stored as variable all_window_props_global with 2 records.
Thought:The window properties have been successfully extracted from the IFC file and stored in the variable all_window_props_global.
Task 2 is now completed. Moving to Task 3, which is to calculate and filter bricks for potential 3D printing.
Action: CalculateAndFilterBricks
Action Input: {"wall_properties": "all_wall_props_global", "door_properties": "all_door_props_global", "window_properties":
"all_window_props_global", "brick_size": 300}
Observation: Filtered brick coordinates stored as variable filtered_brick_coordinates_global with 394 records.
Thought:The brick arrangement has been computed successfully, taking into account the size of the bricks and eliminating any conflicts
with doors and windows. The filtered brick coordinates are now ready for 3D printing path generation.
Action: Generate3DBrickPrintPath
Action Input: {"filtered_brick_coordinates": "filtered_brick_coordinates_global", "layer_height": 300}
Observation: 3D printing paths stored as the global variable layers_print_paths_global for 7 layers.
Thought:The 3D printing paths have been successfully generated and stored in the variable layers_print_paths_global. The paths are
structured into 7 layers, each with a height of 300 mm.
Action: QueryMemory
Action Input: {}
Observation:
### Procedure Context (Tools) ###
Tool: load_ifc_tool - Result: project3.ifc loaded successfully and stored as variable ifc_object.
Tool: extract_wall_tool - Result: Wall properties stored as variable all_wall_props_global with 4 records.
Tool: extract_doors_tool - Result: Door properties are stored as variable all_door_props_global with 1 records.
Tool: extract_windows_tool - Result: Window properties are stored as variable all_window_props_global with 2 records.
Tool: calculate_and_filter_brick_tool - Result: Filtered brick coordinates stored as variable filtered_brick_coordinates_global with
394 records.
Tool: calculate_and_filter_brick_tool - Result: 3D printing paths stored as the global variable layers_print_paths_global for 7 layers.

Action: ExecuteBrickPlacement
Action Input: {"brick_coordinates": filtered_brick_coordinates_global}
Action: {"StartBrickSupply", "RobotArmStart", "ArmMove from [supply_point] to [0.24,-0.36,0.15]",
 …,
"ArmMove from [supply_point] to [0.21,0,1.95]", "StopBrickSupply", "RobotArmStop"}
Thought:The brick laying task was completed, and a total of 394 bricks were laid.
Action: Execute3DPrinting
Action Input: {"print_paths": layers_print_paths_global}
Action: {"RobotArmStart", "MoveArm to layer_1_start", "StartExtrudeConcrete", "FollowPath layer_1_path", "FollowPath layer_2_path",
"FollowPath layer_3_path", "FollowPath layer_4_path", "FollowPath layer_5_path", "FollowPath layer_6_path", "FollowPath layer_7_path",
"StopExtrudeConcrete", "RobotArmStop"}
Thought:The 3D printing task is completed, with a total of 7 layers printed.
Final Answer: All tasks have been fully completed.
```

Figure 6. Tasks execution instructed by LLM agent

4.2 Experiment and Results

In the prompts, a robotic construction workflow is manually decomposed into a series of tasks. The experimental results demonstrate that the designed LLM-based agent can sequentially complete these tasks as specified, ultimately achieving robotic bricklaying and 3D concrete printing in a simulated environment.

The tasks execution instructed by the developed LLM agent is shown in Figure 6.

The tasks 5 and 6 execution instructed by the developed LLM agent is shown in Figure 7.

The experiments demonstrate that the proposed LLM-based framework can accurately invoke predefined tools according to the prompts. Moreover, the agent can consistently achieve reliable variable transmission through well-structured tool descriptions. For example, the building element properties are organized into *Action Input:{"wall_properties":all_wall_props_global,"door_properties":all_door_props_global,"window_properties":all_window_props_global,"brick_size":300}* based on the *CalculateBricks* tool description — "Input is a JSON format

with keys: wall_properties, door_properties, window_properties, and brick_size". Additionally, the agent can establish logical connections between tasks through well-designed outcome summaries in the results.

4.3 Efficiency and Reliability

The efficiency of *CustomMemory* is also validated in the experiment. For instance, when wall properties have already been extracted previously, and a task to extract properties of all elements is required, the agent can correctly identify that only the remained properties need to be extracted — *"The wall properties have already been extracted and stored in the variable all_wall_props_global. Now, I need to extract the properties of the doors and windows"*, demonstrating the ability to prevent the agent from redundant operations.

Similarly, both brick coordinates calculation and 3D printing path generation require extracting properties of all building elements. To quantify the efficiency improvement, we conducted controlled experiments to compare execution time with and without *CustomMemory* for the above tasks in a scenario where these properties had already been extracted in previous sessions.

As shown in Table 2 and Figure 8, the results indicate that *CustomMemory* reduces the execution time by over 60%. This is because, through the tailored procedure memory, the agent can recognize that the necessary data had already been extracted and stored, thereby avoiding unnecessary operations. In practice, the efficiency improvement is directly proportional to the number of previously generated and stored variables.

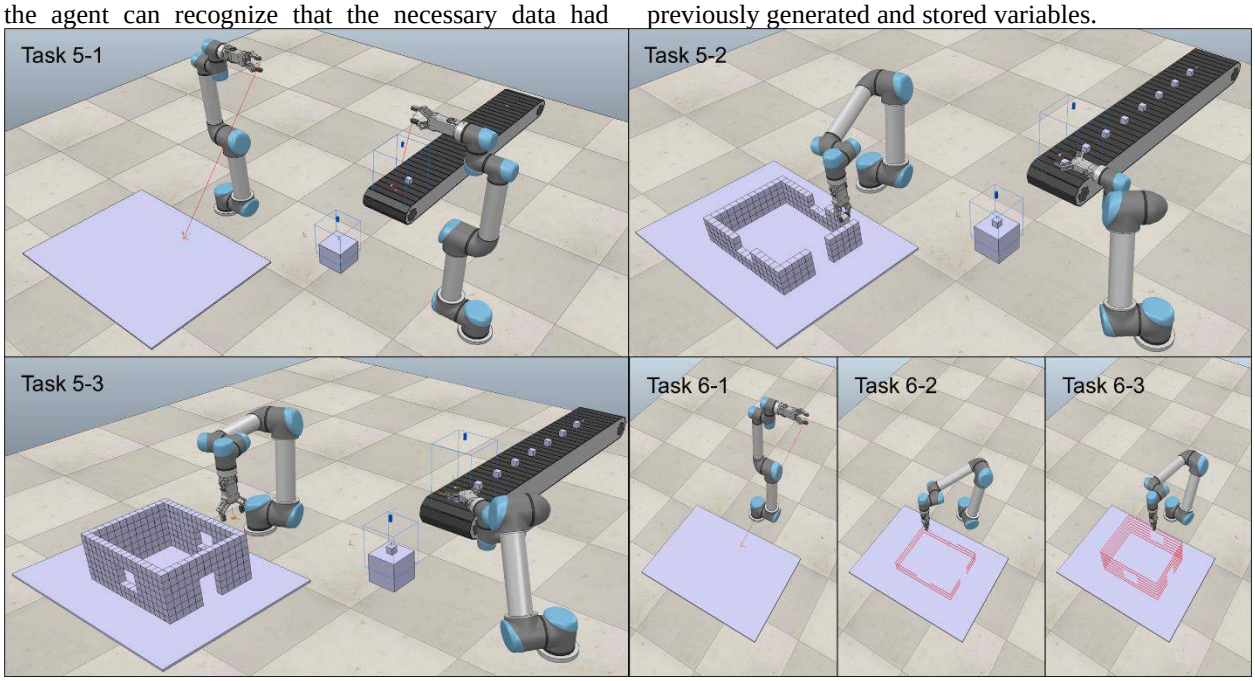

Figure 7. Tasks 5 and 6 executions instructed by LLM agent

Table 2 *CustomMemory* efficiency comparison

Tasks	Without CustomMemory	With CustomMemory
Brick Calculation	37.14s	13.67s
3D Path Generation	44.35s	15.87s

To assess the reliability of the proposed agentic framework, 10 similar prompts are generated using ChatGPT-4o to evaluate the execution success rate. Since the Instructions section is pre-designed as a fixed template, only the Tasks section is replaced in each prompt variation. Successful execution is measured based on how many tasks are correctly carried out.

The result shows that when the required parameters are explicitly specified (such as project3.ifc, 300-mm cubic brick, and 300-mm layer height), all 10 variations of the modified prompts successfully complete their respective tasks, demonstrating the excellent reliability of the proposed agentic framework and its robust adaptability to variations in input language.

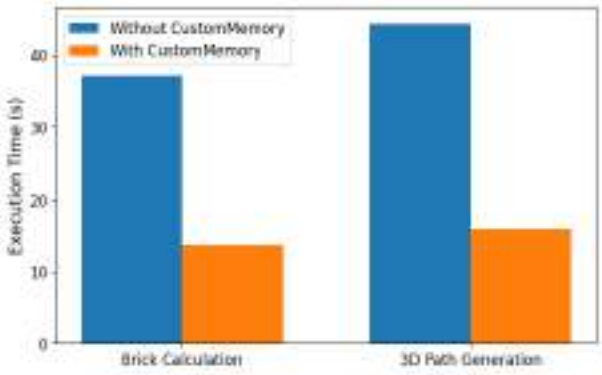

Figure 8. Execution time with vs without *CustomMemory*

However, it is worth noting that if these parameters are not explicitly provided (excluding variables generated dynamically by the agent during execution), the LLM tends to infer missing values, potentially leading to hallucinations. For example, it may assume a commonly used brick size, which could introduce unintended variations in execution.

5 Conclusion

This work presents an IFC-enhanced LLM agent framework for robotic construction, leveraging the standardized IFC format to enable efficient and accurate data extraction while avoiding computationally expensive approaches such as LLM fine-tuning or Retrieval-Augmented Generation (RAG). The tailored agent accurately invokes predefined tools through structured prompts, ensuring robust and reliable performance. Additionally, a *CustomMemory* module is developed to retain procedural context across sessions, significantly reducing execution time by eliminating redundant operations. The framework is validated in a simulation environment for robotic bricklaying and 3D concrete printing, demonstrating its effectiveness in automating construction workflows.

Furthermore, this work adopts an agentic workflow similar to Text2BIM, making it a natural extension of its approach. While Text2BIM primarily focuses on design-phase automation, this framework advances the concept by integrating LLM-driven robotic task execution, bridging the gap between BIM-based design generation and physical construction automation. Future research can explore the development of a full-process agentic pipeline, seamlessly connecting design-phase reasoning with robotic construction execution. This would enable an end-to-end intelligent workflow where LLMs autonomously generate, refine, and execute construction tasks based on BIM models, further enhancing efficiency, adaptability, customization, and automation in smart construction.

6 Discussion

Although the proposed framework demonstrates efficiency and reliability in simulation, transitioning to real-world robotic construction presents additional challenges. Integrating sensor feedback is crucial for real-time perception, as construction environments require adaptive decision-making based on LiDAR, cameras, and IMUs to handle unexpected obstacles. Error handling is essential for correcting deviations in robotic construction movements, such as bricklaying and 3D concrete printing, to ensure precise execution. Additionally, safety measures, including collision avoidance, emergency stop mechanisms, and regulation compliance, are required to ensure secure deployment in dynamic environments.

A promising solution to these challenges is the use of multiple agents to enhance coordination and execution. For example, instead of relying on a single agent, a multi-agent system could include: 1) a task planning agent, responsible for autonomous task decomposition and organization based on high-level construction goals; 2) an execution agent, handling low-level robotic control, ensuring precise movement, material placement, and process execution; 3) a supervisory agent, monitoring real-time sensor feedback, detecting errors, and triggering corrective actions when needed. By distributing responsibilities across specialized agents, this approach could improve reliability and scalability in real-world robotic construction.

Additionally, further investigation is needed to assess how the system handles ambiguous or conflicting instructions, particularly when multiple interpretations could lead to different robotic execution strategies. The risks of LLM hallucinations, such as generating incorrect or assumed parameters, require quantitative analysis to evaluate error rates and system robustness. Moreover, a deeper exploration of failure cases and error recovery mechanisms will be essential to ensuring the framework’s adaptability and robustness in real-world robotic construction.

Furthermore, while the framework has already demonstrated some chain-of-thought (CoT) reasoning in its current stage. For example, executing Tasks 1, 5, and 6 in Figure 5 (skipping Tasks 2, 3, and 4), the agent can still extract building elements and their properties, as well as perform necessary calculations based on its reasoning and tool descriptions. In future work, we will continue to explore leveraging LLM's CoT capabilities to further enhance autonomous task decomposition and organization, improving the framework’s adaptability in complex construction workflows.

Abstract –

Beyond increasing productivity, improving quality, performing hazardous tasks and reducing costs, robotics also offers sustainable solutions by optimizing the use of materials and improving energy efficiency. In addition, modern robots are highly adaptable platforms that result in more intelligent systems capable of performing complex tasks. The following article presents the advances in the development of an end effector that promises to be a more economical and efficient option, which is used together with a single robotic arm to allow for the gripping, positioning and fixing of construction panels. The focus of this research effort has been the programming of a digital twin in the Robot Operating System (ROS) framework which allows to analyze the kinematics of the robot and the end effector working together; in addition, the redesign of the physical connectors between the robot and the end effector is also discussed. It is known that nowadays digitization, simulation and the use of digital twins in robotic systems are essential to maximize efficiency and accuracy in the modern construction industry; besides, they have become competitive factors that give added value to construction processes.

Keywords –

End Effector; Robotic Arm; Digital Twin; Construction Robotics; Automation in Construction

1 Introduction

Population growth and urbanization have increased the demand for housing and buildings. However, construction faces a shortage of qualified personnel due to the risks and efforts involved, discouraging young people as the current workforce emigrate, age, or can no longer continue their work due to accidents or other complications. The construction industry is a sector of the global economy exposed to significant risks of workers' health and safety. In general terms, this is a sector with high ergonomic risks in its execution due to lifting heavy weights, handling tools that can be dangerous in their use, and in general, because most of the activities are carried out in environments where there are constantly changing and dangerous situations. Consequently, falls and injuries related to the use of tools and construction materials are relatively frequent.

The high physical demands of construction work, coupled with the prevalence of injuries, underscore the urgent need for innovative solutions to improve safety and efficiency. For instance, the repetitive task of handling plywood sheets, often weighing fifty pounds or more, exemplifies the ergonomic and safety challenges faced by workers. Manual handling exposes workers to risks of back injuries and fatigue, which could also contribute to workflow inefficiencies. Additionally, according to the International Labor Organization (ILO), construction workers experience some of the highest rates of occupational accidents and injuries, the leading causes being falls, being struck by objects, and repetitive strain injuries [1]. Furthermore, just in 2022, the United States Occupational Safety and Health Administration (OSHA) reported over 5,000 fatalities in the construction industry, accounting for nearly 20% of all workplace deaths [2]. Furthermore, non-fatal injuries, which include musculoskeletal disorders and cuts, contribute to billions of dollars in compensation claims, lost productivity, and medical expenses annually, according to the Workplace Safety Index, in 2024, $58.07 billion dollars were invested in compensation for worker injuries, the main cause being excessive physical effort involving external sources, which represents 21.5% of the total [3].

The use of robots and automation technologies in construction is increasingly heard, such is the example of the work conducted by T. Hachijo. and S. Igarashi [4] where they describe the development of an autonomous mobile system of two robots for construction called “Robo-BC”. In addition, incredible advances are seen in the way these types of robotic systems are trained, such as in the case of the work of L. Ci-Jyun and collaborators [5] where they teach a robotic arm to place panels on the

ceiling through videos, along with which they call "Learning from Demonstration".

The creation of digital twins continues to revolutionize all industries, A. Ali created a digital twin that identifies dangerous areas and tracks worker movements to ensure safety [6]. Another interesting way to take advantage of the digitalization of cyber-physical systems is the remote control and monitoring of applications where robotic elements are employed [7]. In this context, robotics has proven to be a fundamental ally in addressing the challenges of a society that demands more and more infrastructure solutions that are faster to build, affordable, and with fewer risks for those who build them.

To address these challenges, this research effort focuses on the improvement and continuation of an end effector conceived from the patent of Zhang J. et al [8], which gave rise to the work by Borgo et al. [9], where details of the design and construction of the end effector are provided. This first approach was designed for a commercial robotic arm available on the market, capable of grasping and placing plywood sheets, as shown in Figure 1, as well as manipulating them and nailing them in the context of residential construction projects. By leveraging robotics, the system aims to improve safety, precision and efficiency, thereby transforming conventional construction methods. The overall goal of this work is to create more economically accessible automation tools that improve the safety and efficiency of building construction.

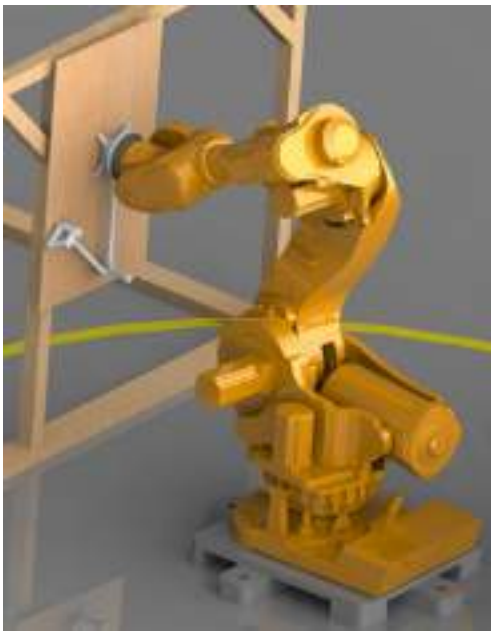

Figure 1. Render in SolidWorks of a robotic arm and end-effector placing a plywood panel on a wooden frame.

2 Methodology

Two significant advances were made in this work, the first advance was to analyze and make updates to the original design of the end effector to improve the robustness of the physical connection to the robot flange. [9]; the second was to use the ROS framework to simulate the motion of the end effector together with a robotic arm to test algorithms safely and inexpensively.

2.1 Observation

A comprehensive review of the lineage project documentation was undertaken to gain a thorough understanding of the target end effector's functionality and goals [9]. In addition, a detailed inventory of the materials, components, and resources available for the project was compiled. With this knowledge, a comprehensive literature review was conducted using SCOPUS as the primary database.

2.2 Proposal

Based on the gathered information regarding the project's current state and available resources, some proposals were formulated to enhance the development of the end effector, culminating in the objectives outlined at the beginning of this article. Besides, a workflow diagram was designed as shown in Figure 2, for the period of August to December 2024 as the proposed allocated timeframe.

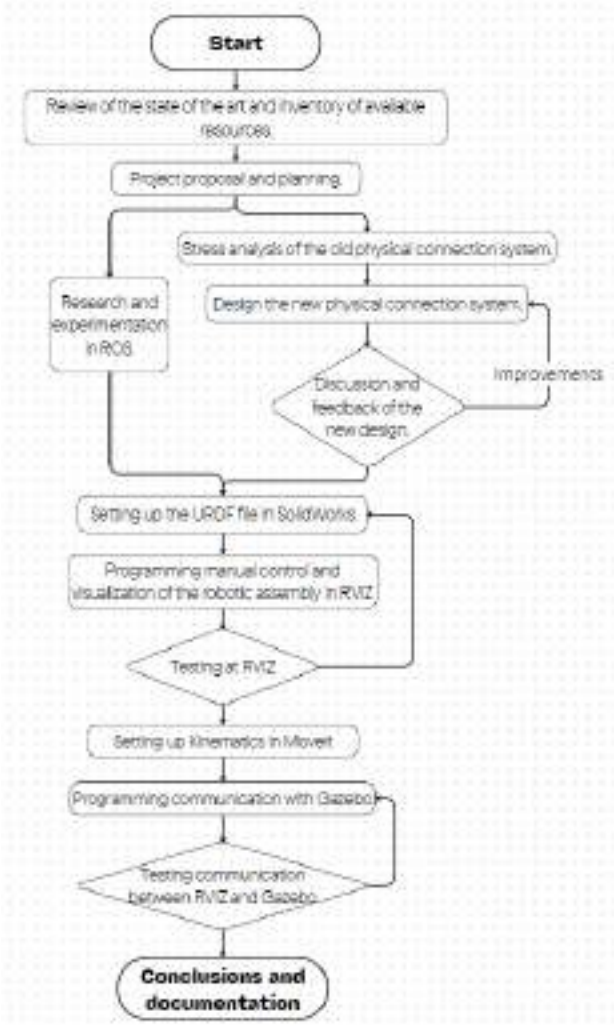

Figure 2. Workflow diagram showing the flow of work performed.

2.3 Experimentation and Results

Research was conducted to learn about the use and functionality of ROS, Gazebo and RVIZ for implementing project digitalization. Also, adjustments were made to the original design to attach the end effector to a new IRB7600 robotic arm, with heavier load capacity and simulating the real-world application better than the previous arm used, as well as certain improvements to strengthen the new component that connects these two elements. Furthermore, several programs were developed within the ROS framework to simulate the joint movement of an IRB7600 robot and the end effector, and some opportunity areas were found to carry out updates on the original design of the end effector. The modifications are aimed at improving performance, expanding the operation and improving the robustness of the end effector.

3 End effector Design

This robotic tool, as shown in Figure 3, possesses two degrees of freedom. The primary degree of freedom involves a rotary vacuum system equipped with suction valves to rotate a cross-shaped piece. The secondary degree of freedom allows the elbow of the end effector arm to rotate, enabling the nail gun to move in two dimensions within a circular area of approximately 4.15 square meters.

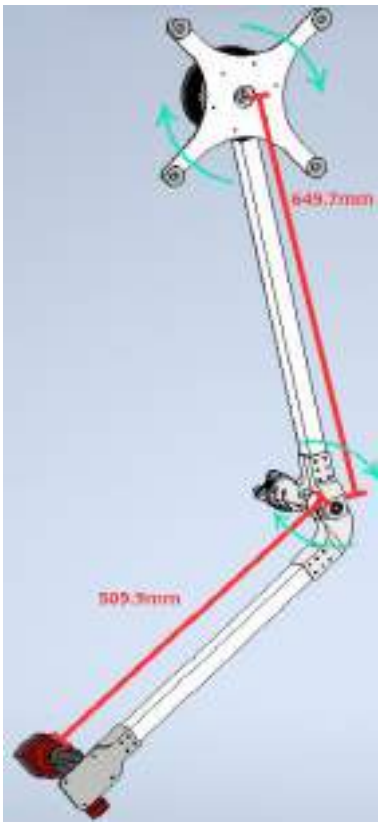

Figure 3. End effector assembly in Inventor.

3.1 Connector Design

The two components that physically connect the robot and the end effector have been redesigned [9]. The initial designs were intended for a KUKA KR16 L6, as shown in Figure 4. This component is attached to the robot's end and features small teeth that engage with the end effector. This initial design highlighted the importance of a simple coupling system that allows for easy separation and attachment of the end effector to the robot. In addition, it offers a cost-effective solution for attachment to other robots, as only this component needs to be redesigned and manufactured to suit the specific dimensions of the robot flange. However, a stress analysis, as shown in Figure 5, where a distributed load of 14 kg was applied, approximately equivalent to the weight of the end

effector and an attached wooden panel, shows a critical concentration of stresses in regions susceptible to shear failure. Furthermore, this component is made of an ABS plastic material, which is not flexible, and the two protruding teeth are too thin.

For practical and prototyping purposes, all components were analyzed using ABS plastic, as it is suitable for 3D printing and, unlike conventional PLA, offers greater strength and better temperature resistance. Additionally, ABS is more accessible, and less abrasive compared to materials like carbon fiber. With this approach, the aim is to create a low-cost prototype to validate the design and functionality before manufacturing it in a more robust and expensive material like aluminium.

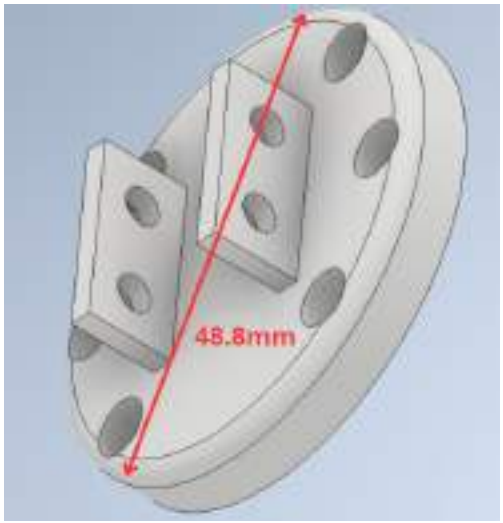

Figure 4. Old connector for the flange of a KUKA KR16 robot.

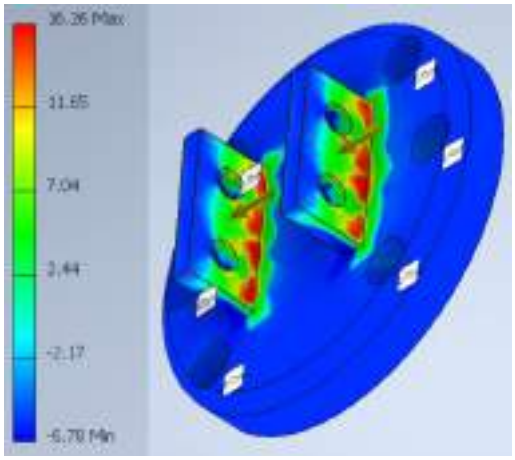

Figure 5. Stress analysis of the old connector. A total distributed load of 14 kg was applied. The color bar indicates the stress levels in MPa.

Due to the above, a new connection system, as shown in Figure 6, was designed to attach the end effector to an IRB7600 robot and incorporate physical features that improve its structural integrity by better distributing the stress caused by the loads, thus reducing the risk of shear failure in this component.

Figure 6. The assembly of the new connection system between the robot and the end effector. The white piece corresponds to the connection with the robot's flange, while the black piece is the base of the end effector.

In this new design, as shown in Figure 7, two additional teeth were added, and the design was smoothed with chamfers and fillets, resulting in a larger contact area and fewer stress concentrators. The original design had stress concentrations of up to 16.26 MPa in critical areas, as shown in Figure 5, while the new connector has only small stress concentrations in non-critical points, reaching a maximum of only 0.705 MPa, as shown in Figure 8. The new design also improves stress redirection during rotation thanks to the circular symmetry of the four teeth. Another notable aspect is that assembly only requires four screws.

Additionally, in this same stress analysis, it was found that the old connector exhibited a displacement of 0.2318 mm in the two connector teeth, compared to the new design, which showed a maximum displacement of only 0.0089 mm. This provides a clearer indication of the improved resistance to deformation and stress accumulation in the new connector. By reducing these factors, the new design enhances durability, especially considering that ABS material has very low flexibility, and the layer-by-layer nature of 3D printing makes it more susceptible to breaking even under slight deformations.

Figure 7. The new connector for the flange of an IRB7600 robot.

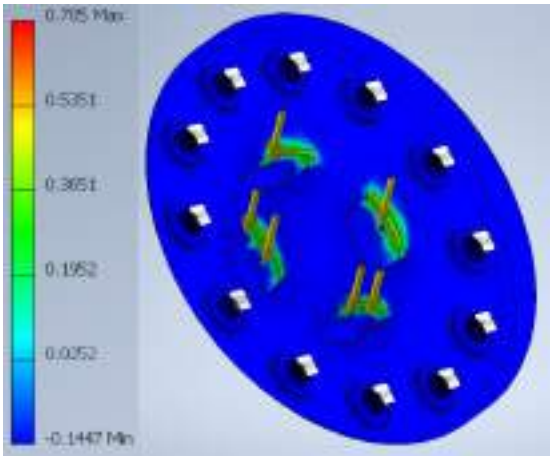

Figure 8. Stress analysis of the new connector for the flange of an IRB7600 robot. A total distributed load of 14 kg was applied. The color bar indicates the stress levels in MPa.

Due to the new robot connector, the end effector connector had to be adjusted, as shown in Figure 9. As with the previous parts, a stress analysis was performed, which shows that there are no stress concentrations at cut points, as shown in Figure 10.

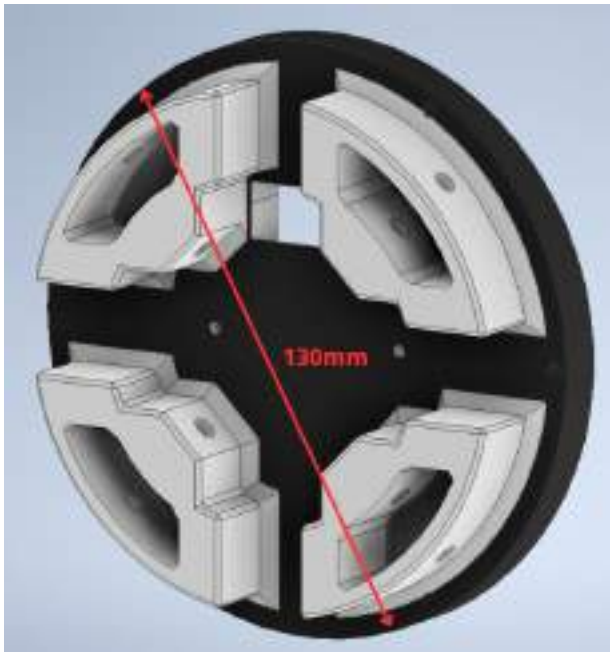

Figure 9. The new connector for the end effector.

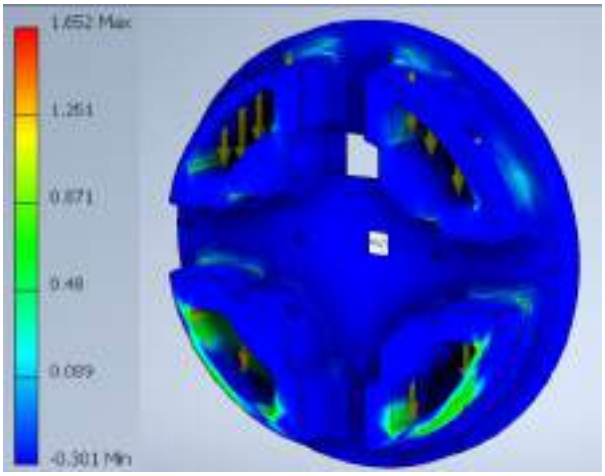

Figure 10. Stress analysis of the new connector for the end effector. A total distributed load of 14 kg was applied. The color bar indicates the stress levels in MPa.

4 ROS Simulation

The ROS structure allows decomposing a robotic system into nodes that communicate with each other through messages. This facilitates the creation of complex simulations and the integration of different sensors and actuators. With this approach, more functions and components are added to the representation towards improving the capabilities of the herein end-effector, all integrated into a single robust and efficient operating system.

After several tests to program and configure the simulation of a robotic arm and the end effector in ROS,

three significant advances were reached for this digitization. The first breakthrough was to visualize the robotic assembly in RVIZ, the second was to generate the inverse and direct kinematics of the robot with Moveit, finally, communication to a digital twin in Gazebo was achieved.

4.1 Configuration of the URDF file in SolidWorks 2021

Specialized Software for computer aided design was employed to model and assemble an IRB7600 robot and the proposed end effector. SolidWorks has an extension that allows the use of URDF (Unified Robot Description Format) file where the details of the robot are described, such as 3D models, joints, hierarchies, type of movements, masses of components, inertial properties, collision meshes, among other factors. The IRB7600 robotic arm, as shown in Figure 11, has six degrees of freedom and with the end effector they total eight degrees of freedom.

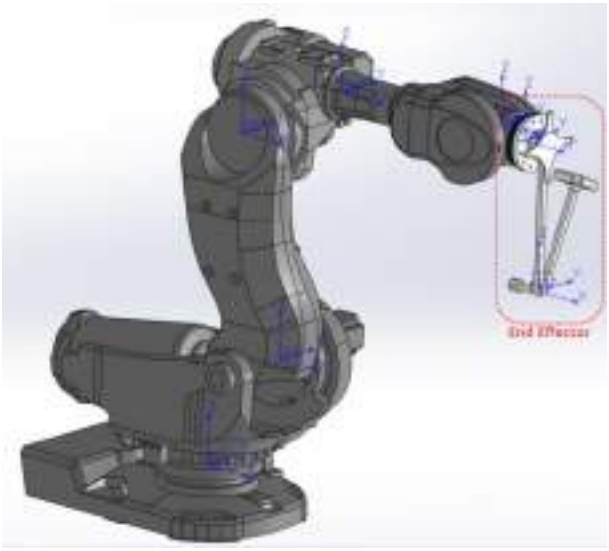

Figure 11. SolidWorks assembly of the IRB7600 robot with the end effector and in blue the coordinates of the joints of both systems.

4.2 Visualization of the URDF file in RVIZ

RVIZ is a tool that allows 3D visualization, as shown in Figure 12, within the ROS ecosystem. Thanks to this, a program, as shown in Figure 13, was designed and coded. In his algorithm, the IRB7600 robot and the end effector are displayed together in the RVIZ environment. In this program it is possible to manually control each of the degrees of freedom of the system independently. To obtain this result it was necessary to generate the URDF file.

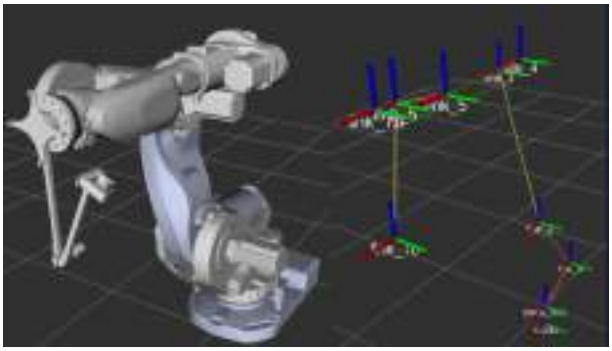

Figure 12. Visualization of the robotic assembly and its kinematic chain in RVIZ.

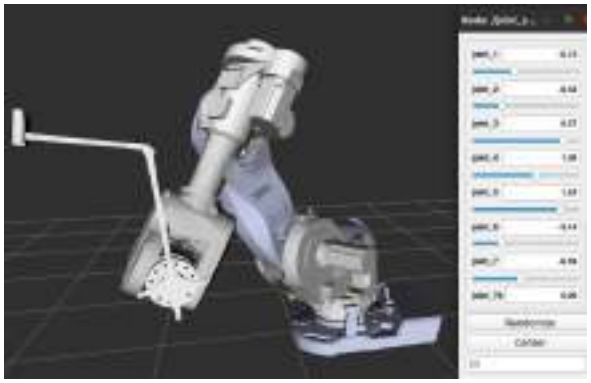

Figure 13. Program visualized in RVIZ that allows to manipulate each degree of freedom of the robotic system.

4.3 Robot Kinematics with Moveit software

The “Moveit” application was used as a framework to create the kinematics and control of the robot and to define some poses to test the movements of the assembly. As can be seen in Figure 14, with this tool the movements and groups of the robotic assembly are planned. In addition, it allows generating YAML (YAML Ain't Markup Language) files that were used to configure the controllers and startup parameters for the nodes.

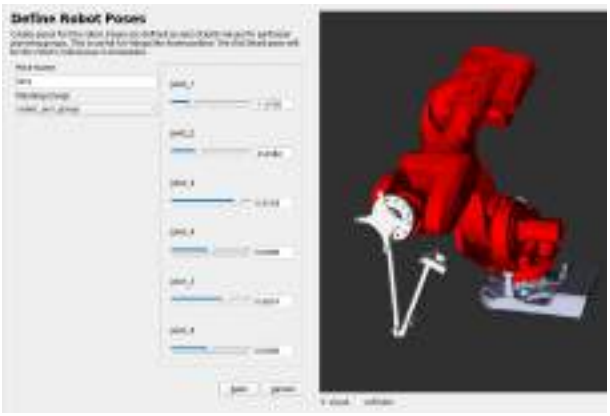

Figure 14. Moveit assistant to define positions.

4.4 Twin communication in Gazebo

This program displays two windows, the first one shown in Figure 15, depicts the robotic system in RVIZ with the displacement and rotation axes of the robot flank. The program calculates the inverse kinematics of the robot, performs several iterations from the original point to the target point, generating a linear displacement between both points.

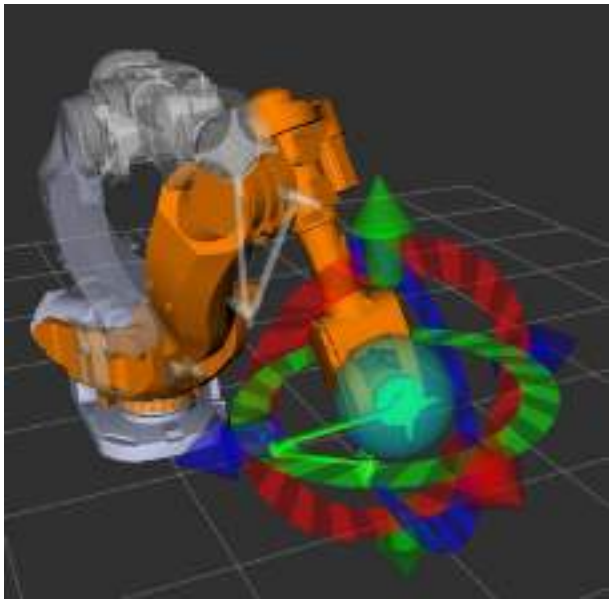

Figure 15. Inverse kinematics of the robotic system in RVIZ.

After the program calculates the robot's displacement path, it performs the movement and communicates it to the twin in Gazebo. This is included in the second window, as shown in Figure 16, and replicates the previous movements.

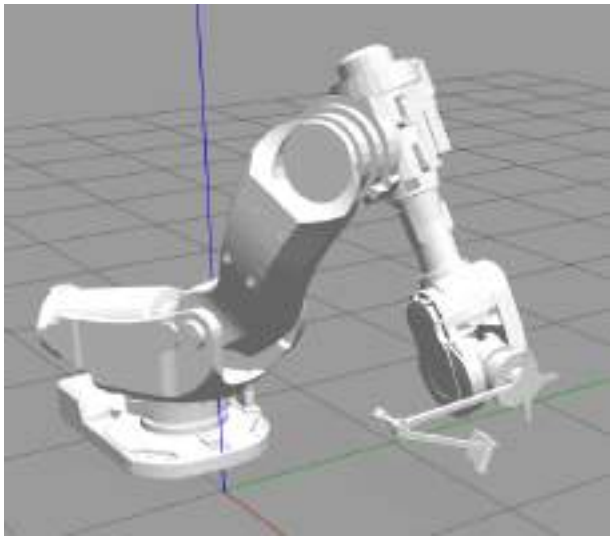

Figure 16. Visualization of the twin robotic system in Gazebo.

Unlike traditional ROS-based simulations, the herein work develops and implements the fundaments of a new frame that integrates ROS for Digital Twin. This integration provides enhanced real-time simulation and visualization capabilities that are not typically available in standard ROS-based digital twin frameworks. In another hand, the proposed approach aims to provide technical capabilities to the ARM and End Effector System for prediction. By leveraging ROS simulation environment, the ability to model and anticipate robotic interactions is improved by enhancing decision-making processes and reducing errors in real-world deployment. Furthermore, although digital twins are broadly used, this work intends to apply this technology to the construction engineering field. To create a training environment for construction workers, allowing them to interact with robotic systems learning process before real-world implementation. This addresses a critical gap in robotics education and deployment in construction.

5 Results and Conclusions

Progress in the design of an end-effector for a robotic arm, oriented to automated construction tasks has been presented. This manuscript introduces the development, analysis, and refinement of a patented robotic end effector for timber construction. Improvements in the design of the connection between the robot and the end effector provide greater robustness due to a larger contact area and better distribution of stress. Furthermore, the connector's teeth allow for easier coupling and decoupling and offer the advantage of physical

compatibility with other robots, as it is easier to design a single piece that does not modify the function or structure of the end effector.

During the programming of the end effector and robotic arm in ROS, an inconvenience was found with the current design of the end effector, which prevented it from acting independently of the robotic arm. This represents a problem as it complicates the algorithm necessary to synchronize the robotic arm and the end effector and prevents the same programming from working for a different robot, meaning that the robot's kinematics would have to be recalculated and reprogrammed each time it is attempted to use on a different robotic arm. The implementation in ROS of the proposed solution digitalization brings a new perspective on the project's scope, as it allows for a faster development pace by eliminating the need for a physical robot. This enables safe testing of algorithms, making changes, and adding more features to the simulation.

The time required to recalculate the robot's kinematics may vary depending on its design and degrees of freedom. However, this can be avoided by implementing a design in which the robotic arm's end-effector can be isolated to function independently of the robot. This would also provide the advantage of using the end-effector for testing or other tasks without the need for a physical connection to the robot.

This improved end-effector design will increase the lifespan of the robotic system. Stress concentrations in the critical areas where the end-effector connector and the robotic arm met, were reduced, as well as the deformations caused by the load from the actuator and the plywood. This enhancement will improve task safety and the precision with which the plywood is placed. Furthermore, the automated system will reduce construction times for handling, placing, and securing the plywood, thereby reducing construction costs.

6 Future Work

Thanks to the use of cutting-edge, the kinematic behavior of the robotic assembly has been understood in greater detail, allowing the identification of areas for improvement in the end effector design. As a result, it is planned to make improvements to the original design, leading to a more robust and functional version. It is also planned to continue programming and simulation in ROS, aiming to create a digital twin that integrates other functions such as fault anticipation, maintenance support, and other aspects and characteristics of a digital twin.

As part of the future work, an effort to mitigate the effects of latency and noise in the proposed system could be implemented. Techniques such as Extended Kalman filtering (EKF) and fusion sensor techniques could be applied to eliminate or minimize these issues and enhance system accuracy. Additionally, it is planned to implement robust communication protocols, including I2C, UART, and Serial, to minimize latency and noise in data transmission between the robotic arm and the end effector. These improvements will contribute to a more realistic and reliable digital twin representation.

Abstract –

The emergence of concrete 3D printing presents a transformative opportunity for decarbonizing the construction industry by enabling innovative design solutions that prioritize material efficiency and sustainability. While 3D-printed lattice beams have demonstrated significant material reductions using conventional, repetitive patterns, nature-inspired shapes have not been explored. This study investigates the potential of nature-inspired Voronoi patterns for material-efficient concrete beams. Their performance is compared with traditional Truss patterns for symmetrical and unsymmetrical loading conditions. A parametric design system integrated with a genetic algorithm is used to generate various infill patterns for 3D-printable beams. Beam dimensions, orientations, and configurations are optimized while ensuring adequate structural performance. The findings confirm the feasibility of using nature-inspired Voronoi patterns in concrete 3D printing and demonstrate substantial material savings. This approach not only reduces embodied carbon in construction but also enables innovative architectural designs.

Concrete 3D Printing; Voronoi; Shape Optimization; Nature-inspired patterns

1 Introduction

The construction industry is one of the major contributors to carbon emissions, with CO_2 from cement production reaching a staggering 2.9 billion tons in 2021 [1], [2]. Traditional construction methods, which have long dominated the sector, are increasingly unable to meet the growing economies' demands and satisfy sustainability goals at the same time. As a result, optimizing construction processes and materials is crucial for advancing sustainable practices and meeting modern-day demands within the industry.

Additive manufacturing, particularly concrete 3D printing, is emerging as a transformative technology with the potential to address these challenges. By eliminating the need for formwork and enabling direct use of CAD files for construction [3], concrete 3D printing offers significant cost savings, particularly in formwork materials, which typically account for 25-30% of total structural construction costs [4]. Beyond economic benefits, this technology also provides architects and engineers with unprecedented design flexibility, enabling the creation of complex and unconventional geometries that would be difficult or impossible to achieve using traditional methods.

The technology is rapidly advancing, fueled by ongoing research aimed at improving efficiency and broadening adoption. Early studies in concrete 3D printing focused on developing printing technologies [5], [6], optimizing printable mix designs with specific rheological properties [7], [8], integrating supplementary cementitious materials (SCMs) for sustainability [9], and investigating the impact of print parameters on material properties. However, most research has centered on vertical structural elements, such as columns and wall panels, with little attention given to horizontal members [10]. These horizontal elements, such as beams, represent around 43% of the material used in reinforced concrete construction [11]. To further advance concrete 3D printing, research must shift towards optimizing these horizontal, flexural members for improved material efficiency.

Some studies have explored innovative approaches to 3D printing beams. For instance, one method involved assembling smaller units with rebars to print beams, like the process for printing columns [12]. However, this modular approach doesn't fully capitalize on the advantages of 3D printing. Other research focused on optimizing beam structures by printing hollow boundaries and filling them with concrete conventionally [13], but this also fails to maximize the benefits of 3D

concrete printing. Recent studies have tested the bending performance of 3D-printed lattice beams with various patterns, showing that triangular lattice beams offer superior performance [14]. Yet, these studies typically use fixed lattice configurations and do not incorporate shape-optimized geometry, which would have further enhanced material efficiency and load-bearing performance.

One promising approach to optimizing 3D-printed beams involves using shape optimization techniques to minimize material usage while maximizing flexural strength. Prior studies have demonstrated the potential of shape-optimized 3D-printed reinforced concrete beams [15], but scalability remains a challenge, particularly as load complexity increases. To make concrete 3D printing a viable solution for large-scale construction, further research is needed to develop optimized, scalable beam designs with a high strength-to-weight ratio.

Structural optimization plays a key role in improving material efficiency, but the complexity of optimized geometries can pose challenges for traditional construction methods, especially when it comes to fabricating formwork. Concrete 3D printing, with its ability to produce complex geometry, aligns well with structural optimization, enabling more sustainable and efficient architectural designs. Nature, with its inherent resource efficiency, has long been a source of inspiration for optimization strategies in materials and structures [16]. However, applying nature-inspired designs in conventional construction has been limited by practical challenges. Concrete 3D printing, on the other hand, is uniquely suited to implement nature-inspired principles, offering the potential to enhance structural efficiency, reduce material usage, and expand the variety of possible constructions [17].

One example of a nature-inspired pattern suitable for 3D-printed lattice beams is the Voronoi pattern, a tessellation often found in nature (e.g., giraffe skin, dragonfly wings, soap bubbles). Previous research has explored the use of Voronoi patterns to optimize the tensile strength of porous structures through genetic algorithms, suggesting potential applications in structural materials [18]. Some parametric studies on 2D rectangular beams with Voronoi tessellations have examined the effects of cell sizes, uniformity, and support conditions on load-carrying capacity [19].

However, the application of Voronoi patterns in concrete 3D printing has not yet been explored. While fabricating Voronoi lattice beams using traditional construction methods would present challenges, concrete 3D printing offers a more feasible and promising approach. Traditionally, Truss patterns have been favoured for their efficiency in load distribution and ease of mass production due to their modularity, whereas the potential of Voronoi patterns remains untapped, mainly in this context.

2 Objectives

The primary objective of this study is to explore the material savings potential of shape-optimized lattice beams featuring Voronoi cell patterns and compare them against the conventional Truss pattern and a regular solid beam for both symmetrical and unsymmetrical loading scenarios.

3 Methodology

The potential for material savings is assessed by comparing various geometric configurations of lattice beams, each individually optimized for shape. 3D-printable lattice beams with different infill patterns are created using a parametric design system and optimized via a genetic algorithm. The system adjusts the geometric parameters within defined limits, and each design is analyzed using finite element software. The sizes of the beam members are determined based on the forces from the analysis, ensuring that all relevant constraints are met. Subsequent sections provide further details on the methodology adopted.

3.1 Geometric Modelling

The study compares beams with two distinct lattice patterns—Truss and Voronoi—against a conventional rectangular beam for both symmetrical and unsymmetrical loading scenarios to assess material efficiency under similar constraints. The beams are modelled as assemblies of line elements representing the edges of the lattice structures. Each lattice type includes multiple variants generated through a combination of parameters. Adopting a parametric modelling approach eliminates the need for manual creation of each variant, enabling efficient exploration of a large design space. The parametric model is implemented using Rhinoceros3D, Grasshopper3D, and Python.

A 6 m span beam is used as a case study to perform the comparative evaluation, with the length-to-depth (l/d) ratio varied between 2 and 20. In addition to the self-weight of the beam, for the symmetrical loading condition, a uniformly distributed load (UDL) of 5 kN/m is applied on the beam's top surface (Figure 1), while for the unsymmetrical loading condition, a point load of 10 kN at 1.5 m from the left support along with a UDL of 5 kN/m running across the full span is applied (Figure 2). The support conditions taken for the study are fixity at both ends. The beam's bottom profile can take either a convex or concave shape, depending on "arc – midpoint offset" parameter. The beam bottom is modelled as a three-point arc with the arc-midpoint offset defining the

offset of the midpoint on the arc. The minimum offset is restricted to 10 cm from the midpoint of the beam to facilitate printability. The first and last points of the three-point arc are dependent on the l/d ratio adopted. The depth of the beam at the center changes depending on the offset position of the arc's midpoint, which can range from 0 to 7 meters in steps of 0.1 meters. The thickness and width of all elements are kept constant for a given configuration, where an element represents the connectivity between two nodes. The element dimensions are calculated within specified ranges of the respective parameters, provided in Table 1 and Table 2 for the two lattice beam configurations, ensuring the internal forces remain within specified stress limits. To facilitate thorough design exploration, the starting and ending values of each parameter are deliberately set far apart. These ranges are later verified to confirm that they do not constrain the optimization process.

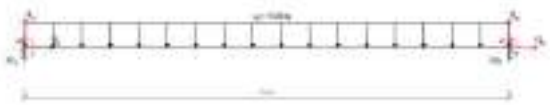

Figure 1. Symmetrical Loading Scenario

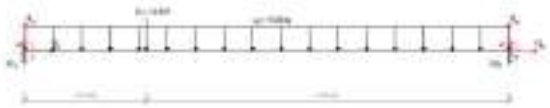

Figure 2. Unsymmetrical Loading Scenario

Table 1. Truss Beam

Sl no	Input parameters	Start Value	End Value	Total Possible Values
1	l/d (ratio)	2	20	19
2	Arc - midpoint offset (m)	-7.0	0.0	71
3	Truss Divisions	5	50	46
4	Thickness (cm)	1	20	20
5	Width (cm)	10	100	91

Table 2.Voronoi Beam

Sl no	Input parameters	Start Value	End Value	Total Possible Values
1	l/d (ratio)	2	20	19
2	Arc - midpoint offset (m)	-7.0	0.0	71
3	Voronoi Count	12	100	89
4	Voronoi Seed	0	1000	1001
5	Thickness (cm)	1	20	20
6	Width (cm)	10	100	91

3.2 Numerical Study

3.2.1 Optimization

Due to the impracticality of manually exploring all possible parameter combinations, a genetic algorithm was employed to optimize the beam configurations for each case, enabling a more efficient identification of the optimal design. Wallacei software, an evolutionary engine for Grasshopper3D, was used for this purpose [20]. Wallacei utilizes the NSGA-2 algorithm [21] as its primary evolutionary algorithm and applies the K-means clustering method. To determine suitable values for population size and the number of generations, multiple trials were conducted with varying parameters, and combinations leading to convergence were identified.

Practical constraints, such as the minimum and maximum lengths of Voronoi edges and cell sizes, were accounted for by defining a range for Voronoi numbers. These constraints were enforced using a penalty function that combines step and ramp components (Figure 3). Penalty functions assign penalty values to solutions that violate constraints, with the penalty magnitude proportional to the degree of violation. The ramp function helps steer the optimization process by gradually reducing constraint violations, while the step function sharply differentiates the feasible design space by assigning high fitness values to feasible regions and penalizing boundary regions with violations. This approach discourages solutions with significant constraint violations, ultimately guiding the optimization toward feasible solutions. Over time, this ensures convergence to designs that fully satisfy all constraints.

To prevent premature convergence to local optima, the genetic algorithm maintains variation within the population. This diversity is introduced using random seed points, with the Voronoi beam utilizing up to 1000 seed points. A higher number of seed points broadens the range of potential configurations, enhancing spatial adaptation under the applied loading conditions. However, increasing the seed points also significantly raises computational power requirements.

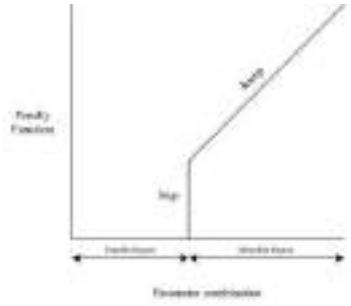

Figure 3. Step and Ramp Function

3.2.2 Implementation Details

The Voronoi pattern was generated using the Voronoi module in Grasshopper3D, based on specified values for the parameters Voronoi seed and Voronoi count. The generated Voronoi was trimmed to fit within the beam's defined boundaries. All parametrically generated line elements were converted into 2D beam elements for structural analysis. This analysis was carried out using Karamba3D [22], a structural analysis plugin for Grasshopper that integrates seamlessly with the parametric modelling approach adopted in the study.

The fixity conditions at the beam's supports were enforced by applying constraints to the nodal points at both ends. A custom Python script was developed to identify the node numbers at these locations and impose the necessary boundary conditions whenever the parametric model was updated during the genetic algorithm's execution.

The beam elements were assigned Material C30/37, compliant with the EN 206-1:2000 standard [23], as its compressive strength closely matched the concrete print mix used in the study. Strength-based constraints were applied, with a maximum allowable tensile stress of 2 MPa and compressive stress of 20 MPa. These constraints guided the optimization process, as no reinforcement is incorporated in this study.

The genetic algorithm varied the cross-sectional dimensions and orientations of the beam elements to ensure compliance with the stress limits. The primary objective was to determine the most efficient configuration for each lattice type by minimizing weight while satisfying criteria for allowable tensile stress, compressive stress, and displacement.

The large design space, resulting from numerous parameters and their wide range of values, facilitated an extensive and systematic search for optimal solutions.

3.2.3 Optimization Results

The masses of beam configurations for the same span were compared to assess potential material savings. Table 3 and Table 4 present the overall mass and percentage material savings relative to the conventional rectangular beam for each configuration for the symmetrical and unsymmetrical loading scenarios respectively.

Table 3. Overall mass and material savings (%) for symmetrical loading

Sl no	Beam Geometry	Mass (kg)	Material Savings (%)
1	Regular Beam	1350	-
2	Truss Beam	875	35.19
3	Voronoi Beam	761	43.64

Table 4. Overall mass and material savings (%) for unsymmetrical loading

Sl. no	Beam Geometry	Mass (kg)	Material Savings (%)
1	Regular Beam	1892	-
2	Truss Beam	1182	37.53
3	Voronoi Beam	833	55.95

The optimized variants of the Truss and Voronoi configurations are detailed in Table 5 and Table 6, respectively. Figure 4 and Figure 5 illustrate the Voronoi and Truss configurations for symmetrical loading case respectively and Figure 6 and Figure 7 represent the same for unsymmetrical loading respectively.

Figure 4. Optimized Voronoi Configuration for Symmetrical Loading

Figure 5. Optimized Truss Configuration for Symmetrical Loading

Figure 6. Optimized Voronoi Configuration for Unsymmetrical Loading

Figure 7. Optimized Truss Configuration for Unsymmetrical Loading

Table 5. Selected variants of Truss beam configuration

Sl no	Input parameters	Symmetrical Loading	Unsymmetrical Loading
1	l/d (ratio)	5	4
2	Arc - midpoint offset (m)	0	0
3	Truss Divisions	13	16
4	Thickness (cm)	12	7
5	Width (cm)	10	19
6	Mass (kg)	875	1182
7	Displacement (cm)	0.0468	0.0470
8	Maximum Tensile Stress (MPa)	0.192	0.198
9	Maximum Compressive Stress (MPa)	0.319	0.392

Table 6. Selected variants of Voronoi beam configuration

Sl no	Input parameters	Symmetrical Loading	Unsymmetrical Loading
1	l/d (ratio)	4	6
2	Arc - midpoint offset	0	0
3	Voronoi Count	25	18
4	Voronoi Seed	227	885
4	Thickness (cm)	13	19
5	Width (cm)	11	10
6	Mass (kg)	761	833
7	Displacement (cm)	0.0407	0.0498
8	Maximum Tensile Stress (MPa)	0.199	0.190
9	Maximum Compressive Stress (MPa)	0.267	0.495

After optimization, the total mass for the Truss and Voronoi configurations in the symmetrical load case was 875 kg and 761 kg, respectively. This resulted in material savings of 35.19% and 43.64% compared to the regular solid beam. As for the unsymmetrical load case, the total mass for the Truss and Voronoi configurations was 1182 kg and 833 kg, respectively. These values correspond to material savings of 37.53% and 55.95% compared to the regular solid beam.

3.3 3D Concrete Printing

To illustrate the printability of Voronoi patterned lattices, a small-scale Voronoi patterned beam is printed. The mix design used for printing the Voronoi beam incorporates a 45 % partial replacement of cement with a blend of limestone and calcined clay [9], and the corresponding mix design is as detailed in Table 7. Superplasticizers and viscosity-modifying admixtures were added at dosages of 0.6% and 0.1% of the binder, respectively, to achieve a printable consistency. This mix had a flow value of 180 mm, measured using the mortar flow table test with 25 drops, and retained 90% of its workability for 60–90 minutes (open time). The mix achieved a density of 2184 kg/m³ and a compressive strength of 30 MPa. The Voronoi lattice pattern generated was converted to G-code and fed to the 3D printer. The mix was fluid enough to bond well at the joints. Figure 8 shows the small-scale printed Voronoi beam.

Table 7. Mix Design

Material	Quantity (kg/m^3)
Quartz Sand – Grade B, 30-80 Mesh	1139
Ordinary Portland Cement (OPC) – 53 Grade	418
LC2 (Limestone + Calcined Clay in 1:2 ratio)	342
Water	304

Figure 8. 3D printed Voronoi Lattice Beam

4 Discussion

The optimization results reveal that the lattice patterns adopted an arch-shaped bottom soffit for both load cases, which helps improve load redistribution and reduce tensile stress in the concrete. Among the patterns analyzed, the Voronoi configuration shows a higher potential for material savings in both load cases, with much more saving potential for the unsymmetrical loading case. This superior performance can be attributed to the unstructured nature of Voronoi patterns. This illustrates the pattern's flexibility in efficiently distributing material where it is most needed and adapting its geometry to the specific characteristics of the design problem.

Of the six optimization variables in the Voronoi beam, the Voronoi seed variable is inherently random. This randomness introduces a degree of disorder along that axis, which limits the genetic algorithm's ability to optimize the seed value globally. However, the algorithm effectively determines the optimal combination of the remaining variables for a fixed seed value. Thus, in the case of Voronoi beams, increasing the number of iterations can help the algorithm uncover even better solutions, although this improvement comes at the cost of additional computational time.

This study thus adopted a parametric-driven approach to shape and topology optimization to develop efficient beam geometries based on load and support conditions. The approach presented is scalable and can be readily applied to larger spans and more complex loading conditions.

5 Conclusion

This study explored the potential of nature-inspired Voronoi patterns for shape optimization in 3D-printed concrete beams. It compares two modular configurations—Truss and Voronoi patterns—against a standard solid beam for both symmetrical and unsymmetrical loading conditions. The key findings include:

- For the symmetrical loading case of the 6m span beam, the percentage savings in the material by the Truss and Voronoi configurations were 35.19% and 43.64% respectively.
- As for the unsymmetrical loading case, the material savings for the Truss and Voronoi configurations were 37.53% and 55.95% respectively.
- The superior performance of the Voronoi configuration for the unsymmetrical loading case is attributed to its non-uniform, unstructured nature-inspired design, which enables optimal material distribution and geometric orientation tailored to specific design requirements.
- This research provides proof of concept that Concrete 3D Printing can successfully fabricate complex Voronoi patterns—challenging to achieve with traditional formwork—while significantly minimizing material usage.

This study highlights how nature-inspired patterns, made feasible through additive manufacturing methods like Concrete 3D Printing, can advance sustainability goals and address the evolving demands of modern architecture. Due to the limitation of testing, we have conducted only numerical study which will be a limitation; however, it is assumed that the theoretical model will be applicable for structures of any scale. Future research will focus primarily on strategies for optimal reinforcement to further enhance load-bearing performance and incorporate ductile failure mechanisms.

Abstract -

This paper presents the design and development of an open-source browser-based interface for coordinating a multi-robot system for on-site construction inspections. The developed system enables remote human operators to effectively oversee and direct automated inspection tasks using both aerial and ground-based robotic platforms. The interface incorporates gaze-tracking technology for intuitive target selection and implements a containerized microservice architecture to ensure reliable deployment across different operating environments. The complete system architecture, implementation methodology, and a real-world inspection scenario are presented. The application has been released as open-source software to encourage adoption and further development by the construction automation community.

Keywords -

Human-machine interface; Construction inspection; Teleoperation; Human-robot interaction

1 Introduction

Recent trends in infrastructure construction show a rising usage of off-site construction of components [1]. While off-site manufacturing facilities maintain rigorous quality control, the components can still suffer damage during transportation and on-site storage, requiring additional on-site inspection to ensure structural integrity before final assembly. On-site inspections, however, can be time-consuming, labor-intensive, and may not be as accurate as desired due to human error and limitations in inspection equipment [2].

Automated inspection systems have the potential to address these challenges by providing consistent, accurate, and efficient inspection capabilities. Robotic systems can be used to conduct the inspections in an efficient and automated manner [3]. Moreover, Artificial Intelligence (AI) enabled systems can leverage machine learning algorithms to better identify defects and anomalies [4], as well as navigate the challenging environments of construction sites [5].

In this paper, we present a human-machine interface for remote multi-robot on-site component inspection which capitalizes on the ongoing advancements in robotics and AI. Our application allows for the integration of rapidly acquired contextual data by one robot (e.g., drone) into an inspection mission for another robot (e.g., ground robot), all while allowing a human operator to monitor and direct the inspection process and provide additional context as needed.

We have also designed the application to allow for gaze-enabled inputs, providing an intuitive method for an operator to communicate intention and interest in a particular object.

In the following sections, we will provide further context on the use of robots in construction and infrastructure inspection, the need for human operators in automated systems, the use of gaze tracking for human input, and how the developed application fits into this context. We will then describe the design and development of the application, as well as an example use case. Performance evaluations and real-world case studies are planned for later work.

The interface's software has been released as open-source software under the MIT license on GitHub: `https://github.com/AIConLab/gaze_based_remote_user_interface`.

Our contributions to this paper are as follows:

- Development of a novel containerized architecture specifically designed for multi-robot construction inspection that ensures flexibility and portability.

- Integration of gaze-tracking as an intuitive human input method for remote inspections, which addresses challenges in traditional input methods on construction sites.
- Creation of a platform-agnostic interface human interface for coordinating aerial and ground robot inspection.
- Release of a complete open-source implementation that can serve as a foundation for further research and development in construction automation.

2 Background

GPS-based navigation systems have been a staple in outdoor robotic applications, allowing for precise navigation based upon a common coordinate system. Importantly, the common coordinate system allows the absolute positioning of a robot or multiple robots [6].

As reported in [7], ground robots have been more popular in the past for general civil infrastructure tasks, being able to do both contact and non-contact tasks, while aerial robots have been more popular for contactless tasks, such as visual inspection tasks of bridges, buildings, and other structures. Aerial robots, however, face fundamental challenges when it comes to extended usage and large payloads, limiting the amount of sensing and inspection equipment that can be carried and the time that the drone can be in the air [8].

Ground-based mobile robots, in contrast, can carry larger sensor payloads and operate for extended periods of time [9], but lack the mobility of aerial robots.

Combined approaches using both aerial and ground robots provide a more promising solution for infrastructure inspection tasks as these approaches can take advantage of the strengths of both systems as shown in [10].

In both fully autonomous and human-in-the-loop systems, human decision-making is still required at some stage of the system process, such as for providing the robots with an initial plan or additional context at the time of inspection.

Even in AI-enabled systems there exist limitations in their ability to generalize to new and unseen scenarios. In such cases, providing large amounts of training data could improve the performance of a model for a specific scenario, but this is not always possible in real-world applications as high-quality data can be difficult to collect [11]. Thus, human operators are often needed to provide additional context and guidance to the system to ensure that the inspection is conducted correctly and efficiently.

To provide human input into the system, gaze tracking has been shown to be one promising solution [12]. The incorporation of gaze tracking has the benefit of allowing the operator to provide input without the need for physical interaction, which can be important in situations where the operator is wearing gloves or is in a hazardous environment.

A user interface or visualization tool then allows the human user to manage how their input is processed and how the robot(s) respond to the input. One such visualization tool is Rviz [13], an open-source software package that allows the user to see navigation plans, robot transform frames, and more. Mission planning plugins for Rviz such as [14], create more sophisticated planning interfaces within Rviz allowing the human operator to view and plan for multi-robot systems.

Notably, these tools are designed to be used within the Robot Operating System (ROS) ecosystem, which is a popular framework for developing robotic applications. Our application differs in that it is designed to provide a standalone, browser-based interface that has the ability to communicate with ROS-based systems - but importantly does not require them to run.

An ongoing challenge in modern robotics research has been software replicability [15]. Our application provides a working example of one approach to providing software replicability through the use of Docker containers.

Docker is a platform for creating containerized applications. Containers contain everything needed to run a specific application, are lightweight, and are loosely isolated from the host machine allowing a developer to access host files, hardware, and resources when needed. A container will run an image instance, which is a snapshot of a certain environment, for example a specific version of Ubuntu with a specific version of Python. Docker Compose provides a tool for orchestrating multiple containers. A Docker Compose file and Docker image are extremely portable text-based files that allow an application to be built and run on almost any host machine.

3 Methodology

This section provides a high-level overview of the application's architecture, data handling, and software module descriptions. In the Implementation section, we will provide an example implementation of the application based on trials done with real-world robots. The application, however, is designed to be platform agnostic and can be used with any robot platform that provides the required input data and can receive the output data. These inputs and outputs are further described in the following section.

3.1 System Overview

The developed application allows for the input of GPS-based waypoint coordinates of structural inspection targets, along with the reference images of those targets. Video streams from a variety of sources can be passed

to the application for viewing by the user. Gaze and fixation data is also streamed to the application to allow for the gaze-based segmentation mask generation output when remotely inspecting a structure. The application outputs are directed at the ground robot which will be performing the remote inspection. The outputs include formatted Robot Operating System (ROS) 1 messages including mission commands, target reference images, the GPS waypoints, and the structure segmentation mask. Handling and formatting of the input and output data will be further discussed in the following sections. Figure 1 provides a visualization of the system's inputs and outputs, where the inputs are the incoming arrows and the outputs are the outgoing ones.

Figure 1. System inputs and outputs.

To allow for wide compatibility and guarantee software functionality across different systems, we containerized the application with Docker and separate module concerns to different Docker compose services. By separating services and images used, we have the flexibility to configure the software environment as needed to run specific packages. Figure 2 visualizes the described architecture, where the *App* contains the services defined in our Docker Compose file - namely *Mission Manager*, *Web Host*, *Segmentation*, *Module Processor*, and *Pupil Dev* services. Each service then contains modules that run certain functionality, for example, the *Frontend* and *Backend* modules within the *Web Host* service provide the live updating and rendering of the browser-based user interface. Arrows between each service represent data that is transferred asynchronously between containers. The modules within the application are further explained in the following sections.

3.2 Data Handling

Our architecture for the asynchronous messaging is inspired by that of ROS 1 [16]. Inter-container and inter-module message passing is achieved through an asynchronous ZeroMQ (ZMQ) publish-subscribe system using the ZMQ proxy pattern, wherein a central message broker facilitates the distribution of published messages to subscribers. The message broker acts as an intermediary that decouples publishers from subscribers, allowing for flexible and scalable communication between modules regardless of whether they are in the same container or not. For serialization and deserialization of messages, we use the MessagePack protocol.

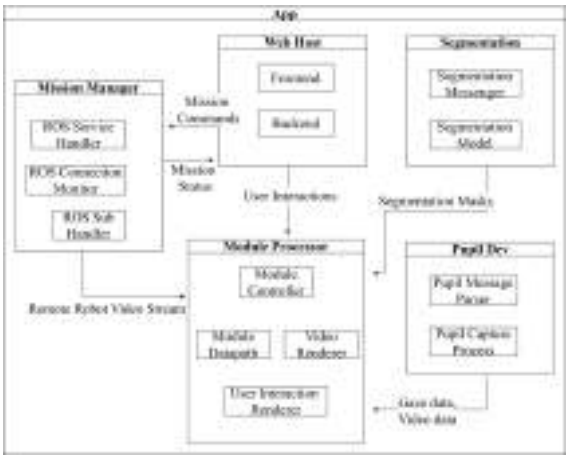

Figure 2. Docker compose services and module data flow within the application. The containers represent the services, and the modules are represented by the contained rectangles.

3.3 Module Descriptions

3.3.1 Mission Manager

The GPS locations of targets to be inspected, along with their respective reference images, are inputted into the application through its local file system. Once loaded, the files are processed within the Mission Manager service which provides modules for interacting with the remote ROS robot. The Mission Manager service also contains modules for connection to a remote ROS Master URI, subscribing to published ROS data from the robot, and publishing data to the robot. The receiving robot and Mission Manager service require ROS service files for structuring the mission command formatting, remote file transfer, and mission state updates. These are included within the applications repository.

3.3.2 Module Processor

Most other data is routed through the Module Processor service which centralizes multi-container data flow. In particular, the Module Datapath serves as the central subscriber for video stream inputs and gaze data. Once data is received, it publishes the data to any subscribed modules.

Video topics from a remote robot or from a local camera would be published to the Video Render module for frame-by-frame processing depending on the application's processing state and the current video topic selection. The application processing state is managed by the Module Controller module, which receives commands generated by user interactions (button clicks, video topic selection,

etc.) from the Frontend. Based on the application's processing state, the Frontend will either render a live stream of a selected video topic via the Video Render module or provide a still image of the latest frame and rendered fixation point via the User Interaction Render module.

3.3.3 Web Host

The Web Host service uses quart – a python based asynchronous web microservice based on Flask. The Frontend module handles the User Interface (UI) layout and user input capture from the web app, while the Backend module handles the data publishing and subscribing between different services.

3.3.4 Pupil Dev

Gaze data refers to normal gaze detection from eye activity, while fixations refer to gaze in a localized region for a certain period of time. We use the fixation data as a point trigger for identifying an operator's point of interest from a screen. Gaze data and gaze-related video stream are handled in the Pupil Development service, in this case, the service is named specifically for the hardware used to capture the gaze data. This is discussed further in the Implementation section.

3.3.5 Segmentation

The Segmentation services host the segmentation model and messaging modules. It is used to generate segmentation masks over images when a fixation point prompt is passed. The generated mask can then be used by the ground robot for target localization and specific area structural inspections.

3.4 User Interface

The User Interface (UI) is the primary means of interaction with the application. Figure 3 provides a skeleton of the interface design and the terms used to describe the regions in the UI. These regions include the *Mission Controls*, *Workspace*, and *Banner*.

The Workspace comprises the majority of the application display space, as it handles visualization of rendered video streams and display of fixation and segmentation outputs.

The Mission Controls section allows for the display of any mission state information, remote robot network status, and mission related utility functions.

The Banner offers state-driven button rendering based on the application's state as well as a persistent video topic selection drop down and a persistent button to toggle the gaze related functionality. The three states considered in this design are shown in Figure 4, where *Normal* is the normal operating state, *Fixation Captured* is the state when the Pupil Capture application detects a fixation on the screen, and the *Segmentation Results* state which activates once the segmentation masks have been generated, allowing a user to select which mask to send to robot during inspection time.

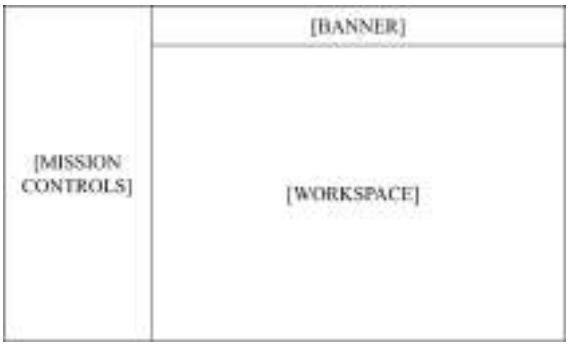

Figure 3. Skeleton of the UI layout.

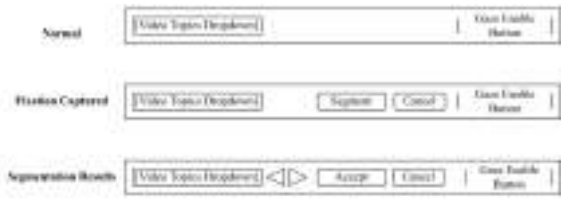

Figure 4. UI components display.

4 Implementation

As of the writing of this paper, the latest release of the application is V1.0.1. In the release, we have designed the application's implementation to function for the system shown in Figure 5. The arrows in Figure 5 describe the data flow between hardware as mentioned in Figure 1. The Ground Robot, Drone, and Gaze tracking hardware used in this test are as follows:

- Drone: DJI Matrice 30T
- Ground Robot: Clearpath Husky A200
- Gaze Tracking Hardware: Pupil Labs Core eye-tracking glasses

The User Computer block in Figure 5 defines the computer hardware used by the Remote Operator during testing. In this test, a Lenovo ThinkPad T490s with an Intel Core i7-8565U quad-core processor and 8 GiB of RAM is used. The laptop is running Ubuntu 24.04.2 LTS as the Operating System.

Further details of the implementation scenario and module implementation are described in the following sections.

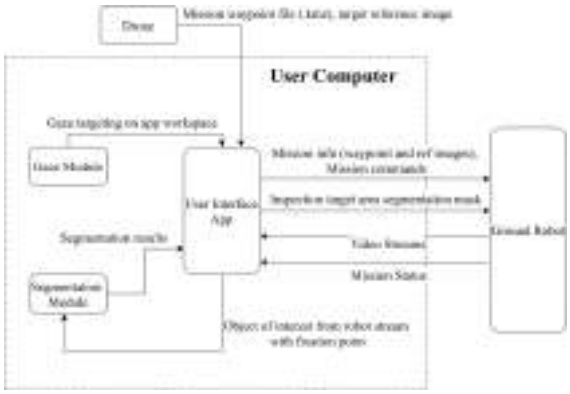

Figure 5. Overview of the system used in the implementation.

4.1 Task Scenario

In this inspection scenario, a remote operator is tasked with inspecting a mock bridge structure using a drone and a ground robot. We set up the inspection environment at the University of Texas at San Antonio's (UTSA) drone enclosure area, a 15000 square-foot and 60-foot-tall netted facility for drone testing. The wooden mock bridge was placed inside of the drone cage to act as our inspection object along with construction cones to add noise to the environment.

The remote operator is stationed outside of the cage with a laptop and the Pupil Labs Core eye-tracking glasses. An EAP225-Outdoor access point was set up to create a local wireless network between the ground robot and the operator's laptop. Images of this setup are shown in Figure 6. The entire inspection sequence is described in the following section.

Figure 6. (a) Outdoor testing environment showing the bridge structure and cones used for the scenario. (b) An image captured by the drone during the inspection mission. (c) The UGV and drone's starting position within the caged testing area.

4.2 Application Setup

Prior to starting the mission, the user must calibrate the Pupil Labs Core eye-tracking glasses and create a Surface in the Pupil Capture software [17]. The Surface is used to define the boundary of the gaze input area restricting it to a certain area which allows us to then extract exact pixel coordinates corresponding to that area. A Surface is defined by four Apriltags [18] which are rendered in the application's Workspace area and captured by the Pupil Core glasses' front-facing camera. These Apriltags are visualized in Figure 7(a)

Figure 7. (a) Apriltag rendered in the corner of the Workspace area of the application. (b) Teleoperation interface for manual UGV operation. (c) Mission control buttons and file viewer. (d) Mission and connection state.

In addition, the user must place a .env file in the .docker directory of the application. This .env file is used to define the IP address and hostname of the remote robot to connect to the ROS Master URI.

4.3 Mission Inspection Sequence

The operator must create a GPS-based waypoint of the bridge structure and capture a reference image using the drone. In our implementation, we use the DJI pilot app in order to save the waypoints as a KMZ file. The KMZ file contains a KML file from which we extract waypoint IDs and their respective latitude and longitude.

The reference images are stored under a directory named for their respective waypoint ID. The gathered drone data can then be placed in a directory within the application for formatting and processing.

When the operator selects "Process Mission Files" in the application, the Mission Manager service processes the GPS coordinates and reference images to prepare them for transmission to the UGV. The files are then wirelessly transferred over the local network when the "Mission Start" button is pressed. These buttons are shown in Figure 7 (c).

Upon receiving the files, the UGV converts the GPS coordinates into a local map point and creates a global and local navigation plan to autonomously navigate to the area. The operator can monitor the UGV's state (Figure 7 (d)) and video feed for any issues or anomalies while the robot navigates to the target location. If manual control of the robot is required at any point, the remote operator can teleoperate the ground robot's navigation base through the interface. The controls for this are shown in Figure 7 (b).

When the inspection target is reached, the operator directs the UGV to locate the inspection object of interest using the gaze-interface in the workspace. The UGV will wait until an inspection target area is specified by the remote operator.

The inspection target area is generated by the gaze-enabled input feature of the application. When the gaze is enabled, Apriltags are rendered in the workspace area of the application and overlaid on the video stream. The Apriltags create a bounded area to filter gaze/fixation points so that they correspond directly to pixel coordinates in the video stream frame. An example is shown in Figure 7 (a).

When a fixation is detected, the application stops rendering new video frames and displays the latest frame and respective fixation. The user can then accept the fixation as an input to the segmentation module or attempt the fixation process again.

An image and fixation point sent to the segmentation module are passed to the Segment Anything 2 model (SAM2) [19] which outputs three segmentation mask predictions. These are then displayed to the user in the application's Workspace area, where they can select a mask or reattempt the fixation process. An example of a segmentation mask is displayed in Figure 8. Here the mask is shown as an orange overlay over a pillar of the mock bridge the remote operator wishes to inspect. Within the mask, a red dot shows the specific point the user's fixation was captured at.

Figure 8. An example of a segmentation mask generated after fixation. The orange area depicts the target area, while the red dot depicts the fixation point.

With a target surface area mask received, the UGV could begin the required inspection and data-capturing process. When the inspection of the previous mask is complete the operator could provide another inspection target area or terminate the inspection and move on to the next waypoint. If no more waypoints were available, then the mission would be completed.

The entire mission sequence is visualized in Figure 9, showing a sequence chart with the Drone, Operator, and the UGV as actors. In the chart, the 3 phases of the implemented inspection process are the *Data Gathering Phase*, *Mission Execution Phase*, and *Inspection Phase*. The arrows show actions each actor takes from start to finish. Loops are shown as dashed rectangles that continue until an exit condition.

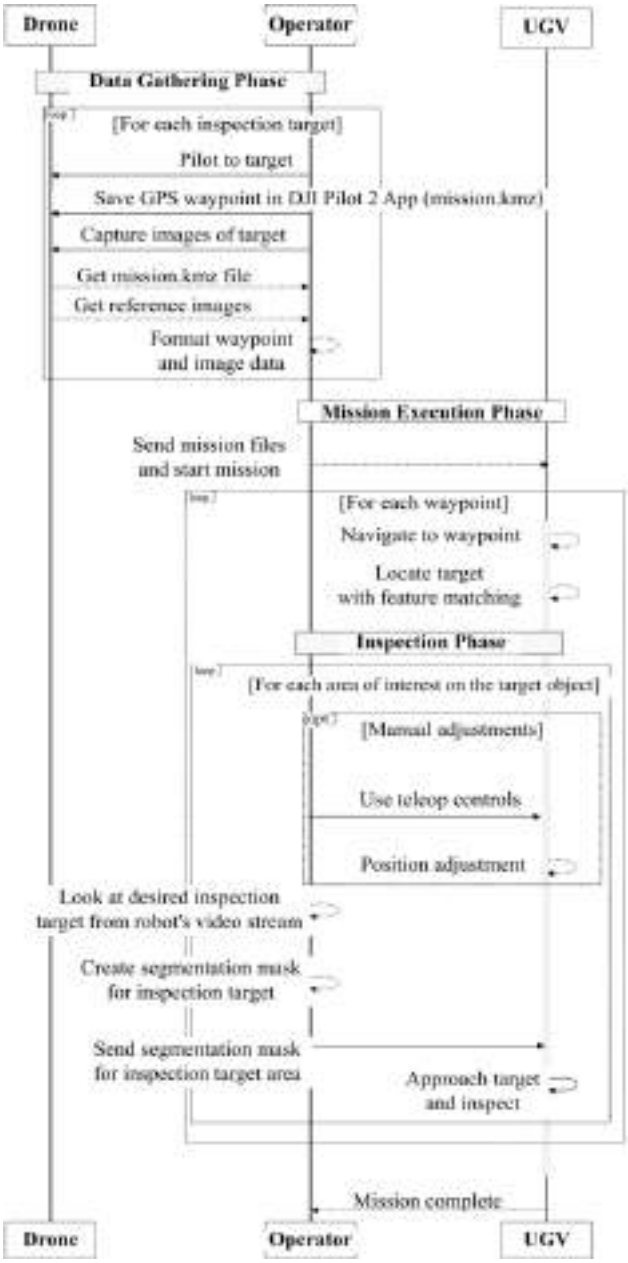

Figure 9. Mission Sequence

5 Limitations

The current approach assumes the drone can safely gather images and a GPS coordinate for the inspection

targets and that the ground robot can navigate to those targets. A mission may still be possible if image data can be captured of the objects, and the GPS coordinate for waypoints can be formatted to a KMZ file, but this approach requires additional effort by the operator and is not the intended approach for our implementation.

Image data captured by the first robot (the drone in our example) may lose relevancy over time if, for example, the images were captured at a different time of day or there was a significant scene change from when the initial images were captured.

6 Conclusions

On-site construction inspection is critical to ensure the quality and durability of infrastructure structures. On-site inspections, however, can be time-consuming, labor-intensive, and may not be as accurate as desired due to human error and limitations in inspection equipment. Automated inspection systems have the potential to address these challenges by providing consistent, accurate, and efficient inspection capabilities. Robotic systems can be used to conduct the inspections in an efficient and automated manner. However, due to the complexity of construction sites, human operators are often needed to provide additional context and guidance to the system to ensure that the inspection is conducted correctly and efficiently.

In this work, we provided an architecture overview and dataflow description of the developed human-machine interface application for multi-robot on-site component inspection. Our application allows for the integration of rapidly acquired contextual data by one robot (e.g., drone) into an inspection mission for another robot (e.g., ground robot), all while allowing a human operator to monitor and direct the inspection process and provide additional context as needed. An implementation of the application was demonstrated in a real-world scenario, showing the application's functionality and user interface design.

In future studies, we plan to run more inspection case studies to evaluate the application's usability and impact on productivity in more realistic inspection scenarios.

The current implementation serves as a functional base for use in novel inspection applications where the software can be easily modified to extend functionality and hardware compatibility. We encourage any interested parties to incorporate the applications into their projects.

Abstract

In concrete troweling for building construction, robots can significantly reduce workload and improve automation level. However, as a primary task of coverage path planning (CPP) for troweling, delimitating area of interest (AOI) in complex scenes is still challenging, especially for swing-arm robots with more complex working modes. Thus, this research proposes an algorithm to delimitate AOI for swing-arm troweling robot (SatAOI algorithm). By analyzing characteristics of the robot and obstacle maps, mathematical models and collision principles are established. On this basis, SatAOI algorithm achieves AOI delimitation by global search and collision detection. Experiments on different obstacle maps indicate that AOI can be effectively delimitated in scenes under different complexity, and the algorithm can fully consider the connectivity of obstacle maps. This research serves as a foundation for CPP algorithm and full process simulation of swing-arm troweling robots.

Keywords –

Construction robotics; troweling robot; swing-arm robot; area of interest; path planning

1 Introduction

With the development of automation technology, the application of robots in the construction industry is becoming increasingly widespread [1]. On the one hand, construction robots can replace workers to complete detrimental or monotonic tasks. And on the other hand, robots equipped with high-precision sensors can improve productivity and quality [2], which makes construction robots an important part of achieving intelligent construction. Currently, common on-site construction robots are qualified to perform tasks such as bricklaying, wall painting, building components assembly, and concrete construction [6]. Take concrete floor troweling as an example, to ensure sufficient flatness, floor troweling requires plenty of workers to draw trowels over large surfaces multiple times, which is time-consuming, labour-intensive, and the quality dependent on worker's skills [9]. However, if using a troweling robot, the workload will be greatly reduced, and the surface quality will be easily controlled and consistently ensured [10].

However, the environment at construction sites is often variable and unstructured, posing significant challenges to the automation of construction robots [11]. In order to adapt to different work environments, robots have adopted different designs for high efficiency. Figure 1 shows two different forms of concrete troweling robots. Swing-arm robot is a commonly used concrete troweling robot, and the design of the swing arm enhances the robot's working range while maintaining a compact size. Compared to other types of robots, swing-arm robots exhibit greater flexibility in working modes, enabling them to adapt to a wider range of construction scene. But with an additional degree of freedom for swinging arm, the operation of them becomes more complex. These issues make it difficult to operate troweling robots automatically, and human-robot collaboration [14] or complex pre-defined paths [10] are usually adopted. In addition, the automation of agricultural robotics also faces these issues, but irregular field shapes are often considered as the main constraint of agricultural robots [15]. There usually few obstacles in farmyard but many in construction sites. It will be more challenging when there are many obstacles or holes in the environments. A large number of efforts are needed to improve the automation level of troweling robots.

(a) (b)

Figure 1. (a) Ground troweling robot of Bright Dream Robotics [12]. (b) Crawler troweling robot of FangShi Technology [13].

The essence of troweling work is the coverage path planning (CPP) problem within a certain scene, that is, to find a collision-free trajectory to ensure the robot fully covers an area of interest (AOI) [16]. The most classical method for CPP is cellular decomposition [16]. Firstly, AOI needs to be effectively delimitated and then decomposed into a series of cells. The final coverage path can be solved through simple planning within the cells and connections between the cells. Therefore, the delimitating AOI is a primary and critical part for this method [17], which will affect all subsequent processes. Furthermore, since the troweling and movement of the swing-arm robot are controlled by different components, the passability and workability between obstacles are complex, which poses a huge challenge to the delimitation of AOI.

In order to improve the troweling efficiency, this research focuses on how to delimitate AOI of swing-arm troweling robot (Figure 1 b). By analyzing the characteristic of robot, **AOI** delimitation algorithm for **S**wing-**A**rm **T**roweling robot (**SatAOI** algorithm, a wish for robots working on Sat.) is constructed for. The remainder of this paper is organized as follows. Section 2 introduces methodology of overall research. Section 3 builds the models of obstacle map and swing-arm robot. Section 4 proposes the SatAOI algorithm. Section 5 presents a case study. Section 6 summarizes the research and discusses possible future investigations.

2 Methodology

The objective of this research is to delimitate the AOI of a swing-arm troweling robot. To achieve this objective, it is necessary to fully analyze the working characteristics of the swing-arm robot and establish accurate collision principles. On this basis, AOI is determined based on proposed SatAOI algorithm. The overall methodology is shown in Figure 2.

The first step is to establish the mathematical models of the obstacle map and the troweling robot, of which the most critical part is the definition of collision principles for the swing-arm robot. Then, SatAOI algorithm, composed of collision detection algorithm and search algorithm, is built for AOI delimitation. Finally, a case study is conducted to validate the feasibility of the proposed method. And the AOI results are discussed and visualized for further applying in other downstream tasks such as coverage path planning.

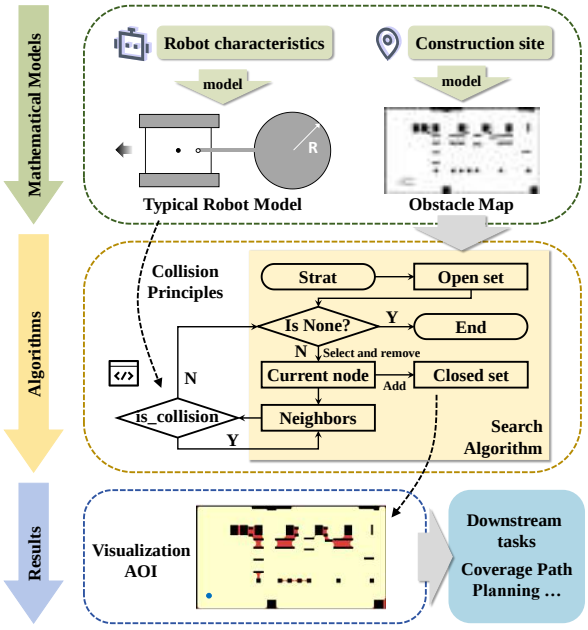

Figure 2. Overall Methodology

3 Model Definition

The challenge of delimitation AOI lies in the complexity of obstacle maps and troweling robots. Therefore, it is necessary to first simplify and define the mathematical model of these two research objects to ensure that the algorithm can accurately judge the robot's accessibility and workability according to certain collision principles.

3.1 Obstacle Map Model

In concrete troweling for building construction, obstacles refer to indoor building components that have already been constructed (such as walls, columns, etc.) or embedded parts and holes reserved on the ground for building function. This information is usually saved at CAD drawings or BIM models. But these structured data is not conducive for path planning. In continuous 2D environments, obstacle and map information is usually discretized into regular grids (such as equilateral polygons) for robot navigation [18]. These grids are easy to construct and clearly represent blocked and unblocked status. For convenience, squares with a side length of 10 mm are used to redraw the obstacle maps from CAD drawings in our research. As shown in Figure 3, the CAD

drawing is converted to a grid-based map. In grid-based map, the cells painted white indicate that areas are accessible. While the cells painted black indicate obstacles, corresponding to areas that robots cannot reach in the real environment, such as walls, columns, pre-embedded parts, holes, etc.

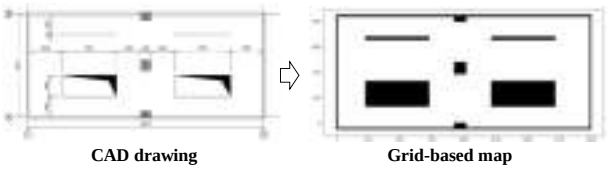

Figure 3. Obstacle map from CAD drawing

3.2 Robot Model

In this research, establishing an accurate and comprehensive mathematical model of swing-arm robot is the chief task. As shown in Figure 4, in our research, swing-arm robot is simplified into three parts: robot body (tracked vehicle), swinging arm and troweling disc. The body of robot is a racked vehicle, which controls the movement of robot. Tracked vehicle relies on the differential speed of its tracks for steering. Commonly, the geometric center of vehicle is used as the vehicle center and as well as control point of whole robot. The troweling disc is the main component for working, which can rotate around the swing-arm center within certain angle range. Notably, vehicle center and swing-arm center may not coincide. In order to ensure that the troweled areas are not disturbed, the robot's heading direction is the orientation of the tracked vehicle.

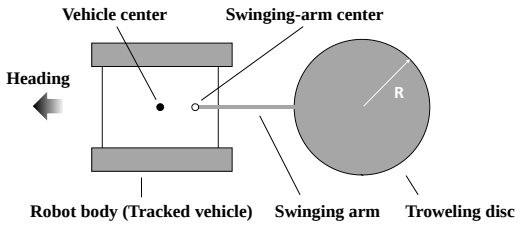

Figure 4. Swinging-arm robot model

As shown in Figure 5, the basic parameters of robot are defined: V_l and V_w represent the length and width of tracked vehicle; L_{vs} represents the offset between vehicle center and swing arm center; L_s represents the length of the swing arm; R represents the radius of troweling disc. Furthermore, if size of robot is determined, accurately defining the position of a swing-arm robot requires 4 parameters: x, y coordinate, yaw, and swing-arm angle (x, y, yaw, s). the x and y coordinates represent the accurate location of vehicle center ($\boldsymbol{V_c}$). The yaw is the angle between robot heading vector and positive x-axis direction, ranging from 0 to 2π (counterclockwise is positive). The swing-arm angle represents the angle deviation of the swing arm from its original position (counterclockwise is positive), and the range depends on the design parameters of robots. For convenience, this angle is specified as $[-\pi/2, \pi/2]$. The above four parameters are sufficient to definite any position of the robot. In a certain position, the effective work area is the coverage area of troweling disc. For convenience, use $\boldsymbol{S_c}: (S_x, S_y)$ and $\boldsymbol{D_c}: (D_x, D_y)$ to represent the center of swinging arm and troweling disc, separately. Then the relationship between $\boldsymbol{V_c}$, $\boldsymbol{S_c}$ and $\boldsymbol{D_c}$ can be expressed as follows:

$$\boldsymbol{V_c} = \boldsymbol{S_c} + L_{vs} \cdot \boldsymbol{h} \quad (1)$$

$$\boldsymbol{S_c} = \boldsymbol{D_c} + L_s \cdot (\cos(yaw + s), \sin(yaw + s)) \quad (2)$$

in which $\boldsymbol{h}$ represent the unit vector of heading direction:

$$\boldsymbol{h} = (\cos(yaw), \sin(yaw)) \quad (3)$$

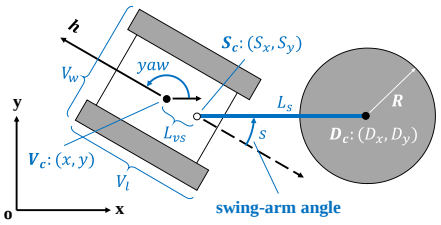

Figure 5. Four parameters for robot positioning: x, y, yaw, and swing-arm angle

On this basis, the collision principles of swing-arm robot are defined. Given that the tracked vehicle part and swinging arm part have different geometric shape, two kinds of collision principles are employed separately. As shown in Figure 6, if the position of an obstacle point is denoted as $\boldsymbol{O_c}: (O_x, O_y)$. In terms of tracked vehicle, collision detection is divided into two rounds. In the first round, the vehicle's circumscribed circle is used to exclude all obstacles outside the circle (obstacle No.1 in Figure 6, Equation 4).

$$\|\boldsymbol{O_c} - \boldsymbol{V_c}\|_2 \geq \frac{\sqrt{V_w^2 + V_l^2}}{2} \quad (4)$$

If any obstacles are inside the circle, proceed to the second round. By calculating the projections of the vector from the vehicle's center to the obstacle in both the heading direction and the perpendicular direction, the collision status can be determined. If the absolute values of these two projections are simultaneously less than half the vehicle's length and width, respectively, the obstacle is judged within the collision range (obstacle No.3 in Figure 6, Equation 5&6). Otherwise, it will not result in a collision (obstacle No.2 in Figure 6).

$$|(\boldsymbol{O_c} - \boldsymbol{V_c}) \cdot \boldsymbol{h}| \leq V_l/2 \quad (5)$$

$$\sqrt{\|\boldsymbol{O_c}-\boldsymbol{V_c}\|^2-|(\boldsymbol{O_c}-\boldsymbol{V_c})\cdot\boldsymbol{h}|^2}\le V_w/2 \quad (6)$$

As for swinging arm and disc, the collision cannot be judged by a simple circle or square. As shown in Figure 6, the avoidance area of this part is a capsule-like shape. This area can be solved by calculating the shortest distance from the obstacles to the line segment **Sc**-**Dc**. This process is also divided into 2 rounds. Firstly, eliminate most irrelevant obstacles through a circle externally connected to the avoidance area (obstacle No.4 in Figure 6, Equation 7).

$$\|\boldsymbol{O_c}-\boldsymbol{C}\|_2 \ge \frac{L_s+R}{2} \quad (7)$$

in where $\boldsymbol{C}$ is the center of avoidance area. As for the remaining obstacles, if they are within the perpendicular range of the endpoints of the line segment $\boldsymbol{D_c'}$-$\boldsymbol{D_c}$ ($\boldsymbol{D_c'}$ is the $\boldsymbol{D_c}$ about the symmetry point of $\boldsymbol{C}$), such as obstacle No.5 in Figure 6 (Equation 8).

$$|(\boldsymbol{O_c}-\boldsymbol{C})\cdot\boldsymbol{h'}| \le \frac{L_s-R}{2} \quad (8)$$

in where $\boldsymbol{h'}$ is the unit vector of $\boldsymbol{S_c}$ to $\boldsymbol{D_c}$.

$$\boldsymbol{h'}=\frac{\boldsymbol{D_c}-\boldsymbol{S_c}}{|\boldsymbol{D_c}-\boldsymbol{S_c}|} \quad (9)$$

In this case, their perpendicular distance to the line $\boldsymbol{D_c'}$-$\boldsymbol{D_c}$ needs to be greater than R to ensure no collision (Equation 10).

$$\sqrt{\|\boldsymbol{O_c}-\boldsymbol{C}\|^2-|(\boldsymbol{O_c}-\boldsymbol{C})\cdot\boldsymbol{h'}|^2} > R \quad (10)$$

If obstacles don't satisfy the Equation 8, such as No.6&7 in Figure 6. No collision means that the minimum distance between obstacle and $\boldsymbol{D_c'}/\boldsymbol{D_c}$ is greater than R (Equation 11).

$$\min(\|\boldsymbol{O_c}-\boldsymbol{D_c'}\|_2, \|\boldsymbol{O_c}-\boldsymbol{D_c}\|_2) > R \quad (11)$$

Notably, in the actual algorithm, all calculations can take redundancy into account to ensure sufficient safety.

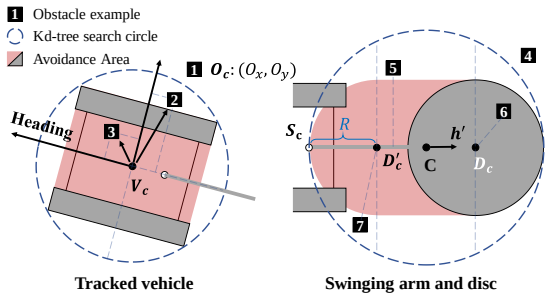

Figure 6. Collision principles of tracked vehicle, swinging arm and disc

4 SatAOI Algorithm for Delimitating AOI

In complex environments with a large number of pre-embedded parts and holes, delimitation of AOI will become more difficult and important. At the same time, since the working range of the troweling disc is separate from the main body of the robot, it further increases the challenges in the delimitation of AOI for the swing-arm robot. So, in this research, using the troweling disc as the main reference, whole map is searched to determine the AOI. The SatAOI algorithm is composed of two core parts: collision detection centered around disc (Algorithm 1: is_collision) and global AOI search (Algorithm 2: troweling_search).

Algorithm 1: is_collision. As shown in Figure 7, if troweling disc is put at certain coordinate, while swing-arm and vehicle are rotated to $angle1$ and $angle2$, separately, the yaw and swinging angle (s) can be calculated by Equation 12&13.

$$yaw = angle1 + angle2 \quad (12)$$

$$s = -angle2 \quad (13)$$

Then based on the robot model and collision principles in 3.2, the collision can be inferred by algorithm 1. If collision occurs, "True" is output. Otherwise, "False" is output.

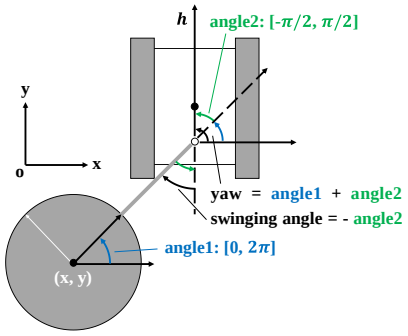

Figure 7. Collision detection algorithm using the troweling disc as the main reference

Algorithm 1: is_collision(D_c, *angle1*, *angle2*)

Input: Coordinate of disc center D_c: (x, y), rotate angles of swing-arm and vehicle *angle1*, *angle2*.
Output: If there is a collision, return True, else False.

```
// kdtree_o is specifically for storing obstacles
kdtree_o ← kd.KDTree(obstacle grids)
If kdtree_o.query_ball_point(D_c,R) then
    Return True
C ← center of capsule-like shape in Figure 6
// R is radius of disc
obstacle1 ← kdtree_o.query_ball_point(C, (L_S+R)/2)
If obstacle1 then
```

```
    h' ← unit vector of S_c to D_c. (Equation 9)
    For p in obstacle1 do
        vec ← p – C
        If |vec · h'| ≤ (L_s − R)/2 then
            If √(||vec||² − |vec · h'|²) ≤ R then
                Return True
        Else
            If min(||p − D'_c||₂, ||p − D_c||₂) ≤ R then
                Return True
    V_c ← Center of tracked vehicle
    r ← √(V_w² + V_l²) / 2
    obstacle2 ← kdtree_o.query_ball_point(V_c, r)
    If not obstacle2 then
        Return False
    Else
        For p in obstacle2 do
            vec ← p − V_c
            yaw ← angle1 + angle2
            h ← (cos(yaw), sin(yaw))
            proj ← vec · h
            proj_v ← ||vec||² − proj²
            If proj < V_l/2 and proj_v < V_w/2 then
                Continue
        Return False
```

Algorithm 2: troweling_search. Inspired by BFS (Breadth-first search) algorithm [19], the search process is a step-by-step exploring that spreads from one point to the surrounding areas. There are two sets: open set is points need to explore, and closed set is points already explored. Starting from a certain point (start node), the center of troweling disc is put at this point. Firstly, add the start node to the open set. Then, loop begins. While the open set is not empty, select the arbitrary node in the open set as the current node (also move it from the open set to the closed set). For each neighbor of the current node (other eight nodes centered around the current node in nine-square grid), if the neighbor is in the closed set, skip it as it has already been evaluated. Otherwise, stepping by $\pi/12$ and considering all discrete angle combinations ($24 \times 13 = 312$ pairs) of angle1&2 at this node, if there a at least a pair of certain angles that frees robot from collision, add this node to open set. Finally, all points that are connected to the start point and can be used to place a troweling disc (robot) are left in the closed set. So, this search algorithm can consider the connectivity of obstacle map.

Algorithm 2: troweling_search(*start_node*)

Input: The starting point of search *start_node*.
Output: area of interest *AOI*

```
// kdtree_v is specifically for storing points excluding obstacles
kdtree_v ← kd.KDTree(all grids excluding obstacle grids)
// Points need to explore open_set, points already explored closed_set
open_set ← {start_node}, closed_set ← {}
While open_set is not empty do
    current_node ← Arbitrary node in open_set
    Remove current_node from open_set
    For node in neighbors of current_node:
        If node in closed_set then
            Continue
        areso ← π/12  // angular resolution
        angle1 ← range(0, 2π, areso)
        angle2 ← range(-π/2, π/2, areso)
        For a1, a2 ← list(zip(angle1, angle2)) do
            If is_collision(node, a1, a2) then
                Continue
            Else
                Add node to open_set
                Break
For node in closed_set do
    For point in kdtree_v.query_ball_point(node, cR) do
        Add point to AOI
Return AOI
```

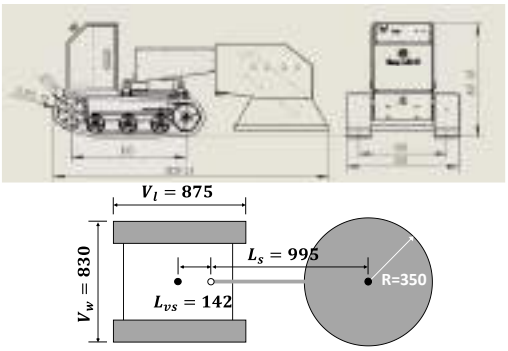
Based on SatAOI algorithm, all possible positions of the troweling disc have been determined, and the envelope region composed of all discs is the final theoretical limit AOI.

5 Case Study

In order to verify the feasibility of the proposed method, taking architectural floor plans of a substation under different complexity as research cases, the robustness of SatAOI algorithm for different scenes and its effectiveness for connected and non-connected areas are tested. Based on this, the importance of AOI delimitation for coverage path planning is discussed.

5.1 Troweling Robot Parameters

The troweling robot from MagicBIM is selected as the robot prototype for simulation. As shown in Figure 8, the tracked vehicle is simplified into a rectangle with a length (V_l) of 875mm and a width (V_w) of 830mm. The center of swing arm deviates from the center of vehicle (L_{vs}) by 142mm, the length of the swing arm (L_s) is 995mm, and the radius of the troweling disc (R) is 350mm. At the same time, the robot can achieve stationary turning by rotating the tracks on both sides in opposite directions. And the maximum swing-arm range is $[-\pi/2, \pi/2]$. These parameters are sufficient to characterize a typical swing-arm troweling robot, including the basic rules for motion, collision and troweling.



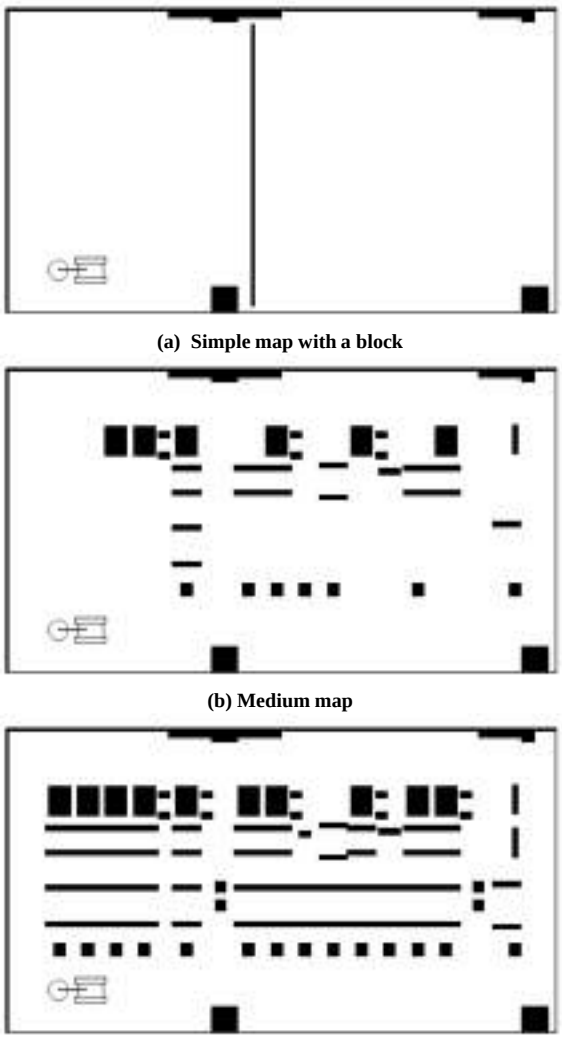


Figure 8. Prototype and key parameters of robot

5.2 Obstacle Maps Generation

The gas insulated switchgear (GIS) room is an important part in substations. However, a large number of electrical equipment requires a large number of embedded parts and holes to be reserved during the construction process, which poses a huge challenge for automation of troweling robots. So, using CAD drawings of different GIS rooms as the data source, obstacle maps under different complexity are generated for testing. As shown in Figure 9, floor plans are converted into grid-based maps using squares with a side length of 10mm. And there are three complexity levels of obstacle maps, denoted as "simple map", "medium map" and "complex map", separately. The overall size of three scenes is same of 10,450mm * 19,190mm. And size of Obstacles (embedded parts and holes) varies from 160mm to 2000mm. Notably, in order to test the ability of SatAOI algorithm to recognize map connectivity, a bottom-to-top block is added to the "simple map" and divides the map into left and right parts. According to statistics, the area proportions of obstacle in each map are shown in Table 1. The area of entire map reached 200.54 m^2, and the highest obstacle area proportion is 12.89%.

Table 1. Statistics of obstacles

Map type	Map area (m^2)	Obstacle area (m^2)	Proportion (%)
Simple		7.00	3.49
Medium	200.54	14.96	7.46
Complex		25.84	12.89

(a) Simple map with a block

(b) Medium map

(c) Complex map

Figure 9. Obstacle maps and robots. (a) (b) (c) represent maps under different complexity

In order to demonstrate challenges of obstacles to the swing-arm troweling robot in a more intuitive way, robots and obstacle maps are simultaneously visualized in Figure 9. It is evident that the complex obstacles in GIS room pose significant challenges to the swing-arm troweling robots, even if manual operations are also extremely difficult in this case. There is no doubt that the delimitation of AOI can assist in the planning and simulation of swing-arm troweling robots.

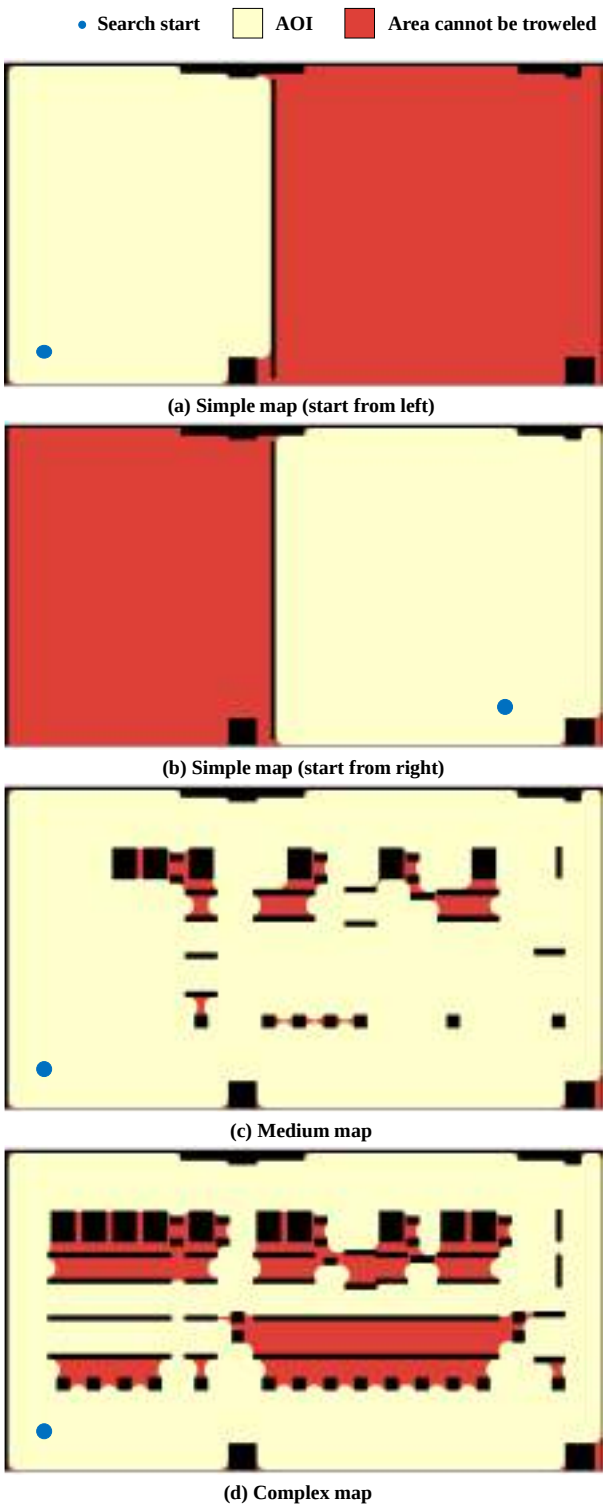

Figure 10. AOI results of different obstacle maps

5.3 AOI Delimitation

The results of SatAOI algorithm are shown in the Figure 10, in which the yellow areas represent the final AOI in all maps. Overall, the all results of AOI are reasonable and effective, only narrow gaps between obstacles and wall corners cannot be troweled by robots. Regardless of the complexity of maps, AOI results effectively represent the maximum troweling areas of the swing-arm robot. In complex maps (Figure 10 d), the algorithm can identify which areas between obstacles can be troweled and which cannot, bringing great convenience to robot simulation. Furthermore, in the simple map (Figure 10 a&b), AOI include left part and right part due to different search starts. This is because the left and right sides of the map are separated by a bottom-to-top block. And in reality, the robot cannot complete the troweling work of both parts at once. The SatAOI algorithm can identify the connectivity between different areas, ensuring that the AOI result can be troweling by the robot in a single task.

These analysis results can be applied to some downstream tasks for construction robots, such as assisting in the path planning and simulation of swing-arm troweling robot in complex construction sites. According to the AOI results, the robot can determine which areas can be reached and troweled, and which areas will not be accessed. On this basis, AOI can be further divided into small cells for CPP task. AOI is the goal of coverage path optimization, and will also participate in the evaluation process of path planning.

6 Conclusion

Although robots have improved the mechanization and automation of construction, swing-arm troweling robot still rely on manual operation in complex construction sites. In this research, the mathematical models of swing-arm robot and obstacle map are built. On this basis, collision detection principle and search method are proposed, together formed the SatAOI algorithm for the AOI delimitation of swing-arm troweling robot. A case study of GIS room from a real substation construction is conducted and the results show that SatAOI algorithm can effectively determine the AOI in maps under different complexity, and meanwhile can distinguish the connected and disconnected areas from a certain start.

The delimitation of AOI is only a first and primary task of troweling robot simulation. Further research is the downstream application of AOI. Cellular decomposition method or other CPP algorithm based on AOI results will greatly enhance the automation level of swing-arm troweling robots. AOI-based coverage path optimization and evaluation can further improve the work efficiency of the troweling robot. In addition, even if the robot cannot be fully automated, AOI can assist workers in achieving more efficient human-robot collaboration and improving construction productivity [20].

Abstract –

Automation using mobile robots at construction sites is gaining attention as a key technology to enhance productivity and safety. However, due to the unstructured nature of construction sites with dynamic elements like construction equipment, robots must perceive their positions and movements in real-time to adapt to workflow changes while performing tasks. To address this issue, this paper proposes a system that enables mobile robots to detect the spatial positions of construction equipment in real time. The system integrates a voxel-based deep learning detection model with a Simultaneous Localization and Mapping (SLAM) algorithm, allowing real-time detection of construction equipment within a consistent reference coordinate system using 3D point cloud data collected by the mobile LiDAR. Experimental results demonstrate that the system achieves an average detection accuracy of 74.51% (AP@R40, IoU 0.25) for excavators, dump trucks, graders, and rollers, demonstrating its capability to accurately recognize the spatial information of construction equipment. This approach highlights the potential for mobile robots to effectively perceive construction equipment in active construction sites, enabling safer and more efficient task execution.

1 Introduction

To address the persistent labor-intensive challenges in the construction industry, construction automation using mobile robots has emerged as a key technology to enhance productivity and safety on construction sites. Various robotic platforms, including drones and quadruped robots, are being explored for applications such as construction automation, 3D reconstruction, material assembly, and safety monitoring [1]. However, the low level of standardization and the dynamic nature of construction environments present significant challenges for robotic automation [2]. In active construction sites, mobile robots share space with dynamic obstacles like construction equipment. Each type of equipment follows distinct operational patterns, often working within a fixed radius or moving along predefined paths. Failure to recognize these machines can increase collision risks and lead to frequent, unnecessary path adjustments, disrupting workflow. To operate efficiently in dynamic construction environments, mobile robots must detect the location and type of construction equipment in real-time and track their movements over time.

Several studies have explored the automation of tasks using mobile robots on outdoor construction sites by employing sensors to identify and respond to obstacles. Kim et al. [3] automated laser scanning tasks with a mobile robot using initial map generated by a UAV (Unmanned Areial Vehicle) and addressed obstacles through a point cloud-based potential field. Asadi et al. [4] developed a mobile manipulator robot capable of grasping and transporting objects using vision-based environmental understanding, employing camera-generated point clouds for obstacle avoidance. Štibinger et al. [5] proposed a mobile manipulator robot for automated structural assembly, leveraging 3D point clouds to detect obstacles and perform navigation. Chung et al. [6] automated laser scanning of scaffold structures on outdoor construction sites without prior information, utilizing point clouds from a mobile LiDAR and IR camera to navigate around obstacles.

While these studies have demonstrated the automation of construction tasks using robots capable of avoiding dynamic obstacles in outdoor environments, there is a lack of research focused on accurately detecting construction entities and continuously recording their locations using point clouds to support robot operations. Studies such as [7] and [8] have explored situational awareness and interaction between mobile robots and construction workers, aiming to implement Human-

Robot Collaboration (HRC) systems. However, research on perception systems for mobile robots specifically designed to interact with construction equipment in 3D space remains significantly underexplored.

This study proposes a system that uses mobile LiDAR to detect the 3D positions of construction equipment in real-time and record them within a global coordinate frame. Figure 1 provides an overview of the proposed system, which integrates a voxel-based 3D object detection model with Simultaneous Localization and Mapping (SLAM). First, the system processes 3D point cloud data collected by the mobile LiDAR to detect various types of construction equipment, such as excavators, dump trucks, graders, and rollers, in real-time. The detected objects are then managed within a global coordinate frame through SLAM, enabling continuous tracking of construction equipment even in dynamic environments. The entire system is implemented on the Robot Operating System (ROS) framework, allowing seamless integration and real-time processing of sensor data acquired by the mobile robot. Using the proposed system, mobile robots can effectively perceive the locations of construction equipment on-site, providing a foundation for applications such as maintaining safe distances, identifying hazardous zones, and understanding work contexts.

Additionally, mobile LiDAR offers a significant advantage by covering a wide area while being less affected by occlusions, enabling the real-time acquisition of high-density 3D data [9]. Due to these characteristics, it is increasingly being integrated with SLAM for 3D reconstruction and safety management in construction sites [10]. The proposed system enables real-time perception of construction equipment movements using mobile LiDAR, which can be utilized to develop a comprehensive progress monitoring system for construction sites, including quality control of individual structures and process monitoring of construction equipment. Based on the potential of mobile LiDAR-based technology, this system supports mobile robot operations on construction sites and lays the foundation for establishing a comprehensive progress monitoring system for large-scale construction projects.

2 Methodology

The proposed system is designed to accurately identify the spatial positions of construction equipment in real time using 3D point cloud data collected by mobile LiDAR mounted on a robot. The mobile LiDAR continuously captures 3D point cloud data as the robot navigates the environment. This data is processed in real time by a voxel-based 3D object detection model, which detects construction equipment and generates bounding boxes. These detection results are then integrated with a SLAM algorithm, transforming them into a consistent global coordinate system, where they are recorded for further use.

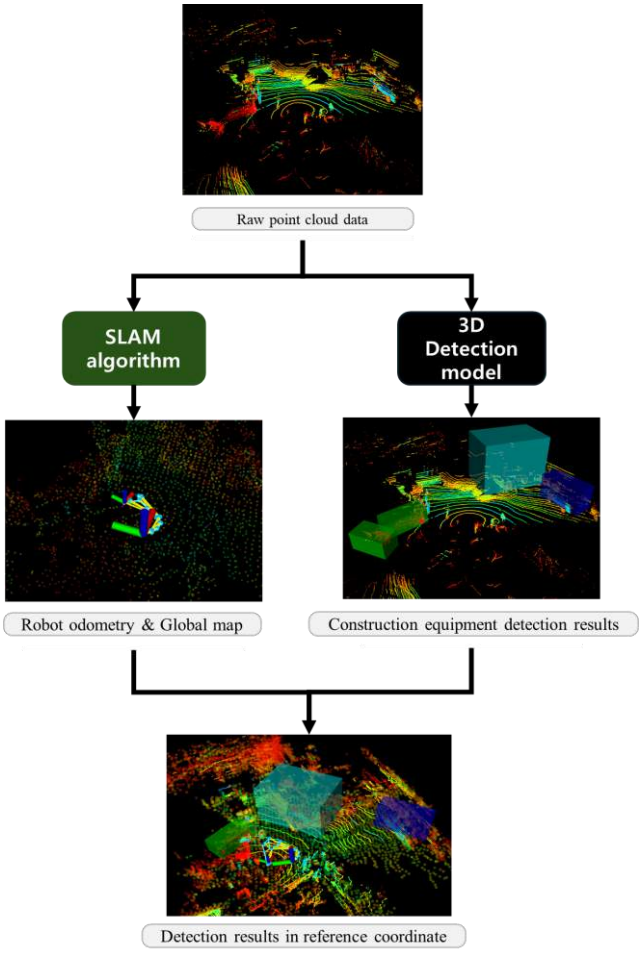

Figure 1. Overview of the proposed system

As shown in Figure 2, the mobile robot system comprises a quadruped robot (Unitree AlienGo), a mobile LiDAR (Velodyne VLP-32), an IMU sensor (Microstrain), and a mini-PC equipped with an NVIDIA GeForce RTX 2060 (Intel NUC 11 PHKi7C). This system was used to acquire the data necessary for model training and experimentation. The mini-PC was directly mounted on the quadruped robot along with a battery, enabling the entire proposed system to operate in a mobile environment. To construct a point cloud dataset for model training, the mobile robot was remotely operated to collect point cloud data at a construction site. During this process, the mobile LiDAR scanned excavators, dump trucks, graders, and rollers from various angles and distances, ensuring diversity in the training data.

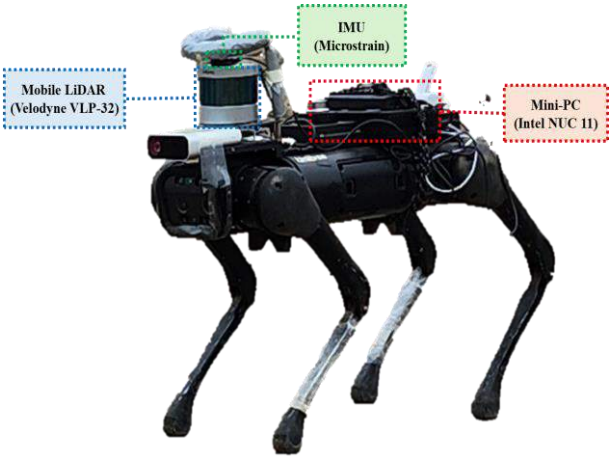

Figure 2. Hardware configuration.

For the mobile robot to understand and respond to the movements of construction equipment, it must rapidly and accurately identify their spatial positions despite limited computational resources. A voxel-based approach efficiently processes 3D point cloud data, significantly reducing computational complexity for large datasets. To achieve real-time detection of construction equipment in 3D point cloud data, we employed the voxel-based 3D object detection model VoxelNeXt [11]. VoxelNeXt utilizes a fully sparse convolutional network to directly predict 3D objects from voxel features, maximizing computational efficiency by eliminating the need for generating dense features after voxel transformation. This makes it particularly well-suited for mobile robot environments with limited computational resources. To train the model efficiently with limited data, VoxelNeXt was pre-trained on the KITTI dataset [12], and transfer learning was performed using this pre-trained model as a starting point. Figure 3 illustrates the architecture of VoxelNeXt. VoxelNeXt utilizes a six-stage Sparse CNN Backbone to process 3D point cloud data. Instead of generating a dense feature map, it applies Sparse Height Compression to create a BEV (Bird's Eye View) feature, preserving only the original data points in sparse format. This approach reduces unnecessary computations and ensures efficient object detection even with limited resources.

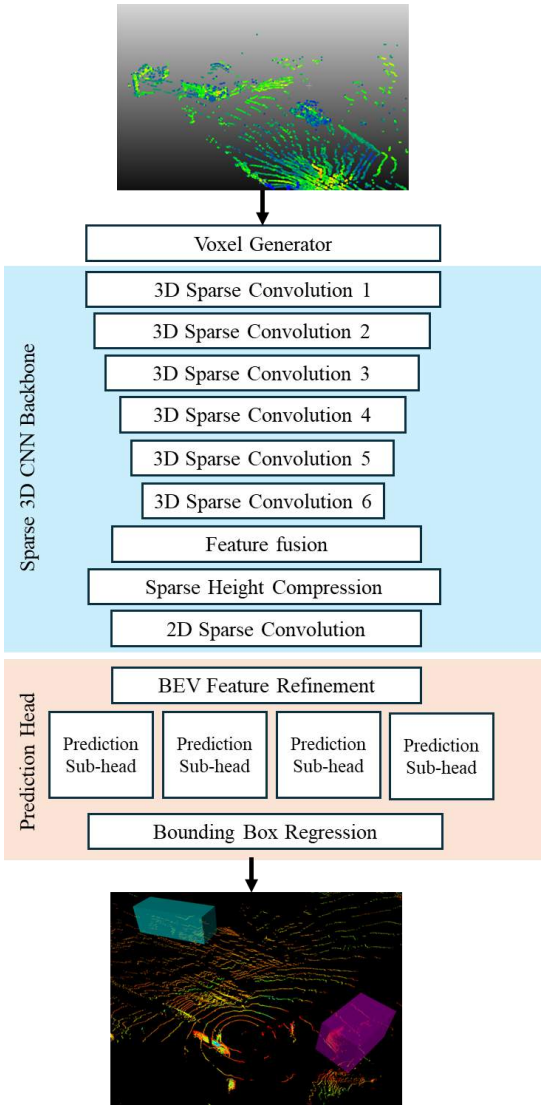

Figure 3. Structure of VoxelNeXt.

In environments where both mobile robots and construction equipment are in motion, integrating detection results into a consistent reference coordinate system is essential for long-term perception of construction equipment positions. To achieve this, the proposed method integrates the SLAM algorithm with VoxelNeXt to process detection results. SLAM is an algorithm that simultaneously maps the environment around a sensor and estimates the sensor's position using the sensor data. The proposed method utilizes the LIO-SAM [13] algorithm, which combines mobile LiDAR and IMU data to generate precise maps. By utilizing odometry information calculated by LIO-SAM, the detected bounding boxes are transformed into the reference coordinate system, enabling accurate localization of construction equipment on the global map

of the construction site. Figure 4 illustrates the process of registering detected equipment in the global coordinate frame of LIO-SAM using VoxelNeXt.

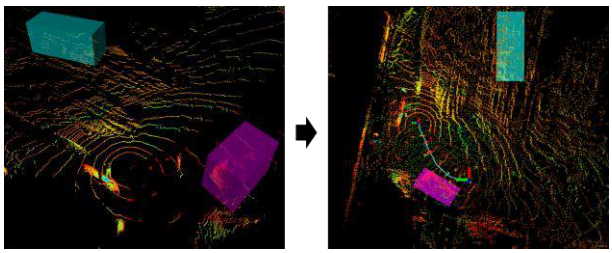

Figure 4. Transformation of detection results: from local coordinates (left) to global map using LIO-SAM (right)

3 Experiments and Results

In this study, a quadruped robot was remotely operated at four large-scale construction sites to collect mobile LiDAR data of construction equipment for VoxelNeXt model training. While navigating active construction sites with moving equipment, the quadruped robot recorded continuous point cloud data. The collected data was captured at one frame per three seconds and converted into PCD file format to construct the dataset.

During the data labelling process, only construction equipment within 40 meters of the robot was selected for annotation. Objects that were visually unidentifiable due to occlusion or motion blur were excluded from labelling. Figure 5 presents examples of the collected data from each site. A total of 1,246 frames of point cloud data were used for training and validation, while 261 frames of point cloud data were reserved for testing. This study focused on training the model to recognize four classes of construction equipment: excavators, dump trucks, graders, and rollers. Detailed class-wise data distribution is provided in Table 1.

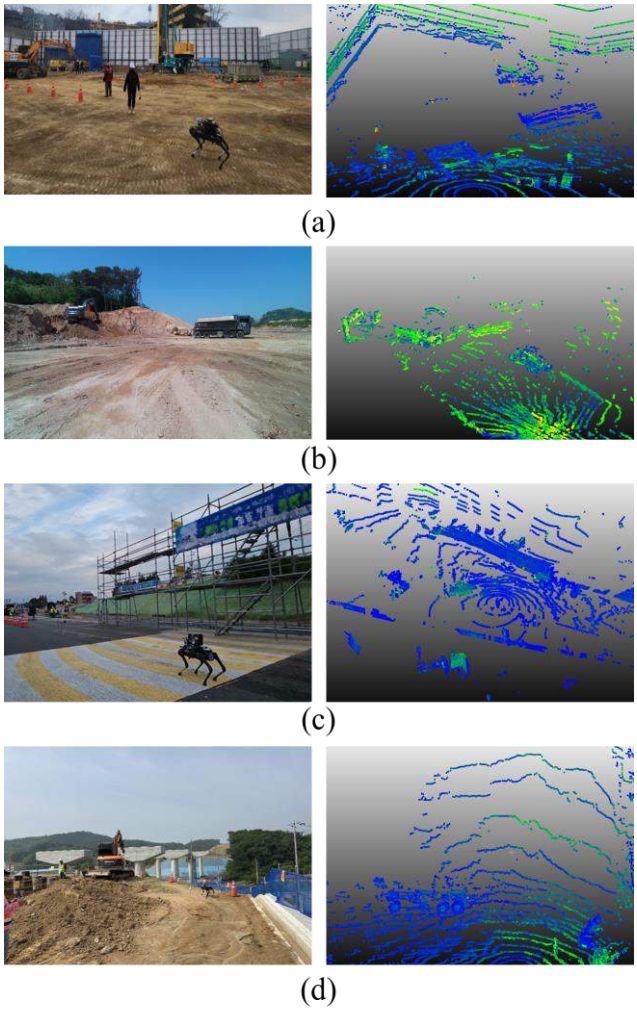

Figure 5. Picture of the site (left) and examples of point cloud data collected at each site(right); Site 1, 2 and 3 were used for training and validation, and Site 4 was used for testing; (a) Site 1, (b) Site 2, (c) Site 3, (d) Site 4.

Table 1. Class-wise dataset distribution

Class	Train	Validation	Test
Excavator	877	175	95
Dump Truck	564	121	71
Grader	199	72	117
Roller	125	32	118
PCD files	1000	246	261

The training of the construction equipment detection model was conducted on an Ubuntu 20.04 environment. Transfer learning was performed using pre-trained

weights from the KITTI dataset, with the model trained for 50 epochs using a batch size of 4. The training process employed an AdamW-based one-cycle learning schedule, where the learning rate increased to a maximum of 0.01 during the first 40% of training and decreased over the remaining 60%. These settings were based on the default VoxelNeXt configuration for training on the KITTI dataset.

During the transfer learning process, fine-tuning was conducted under four different configurations, based on the extent to which the 3D sparse convolution layers in the backbone were frozen. These layers correspond to "3D Sparse Convolution 1–6" in Figure 3. 1) Full fine-tuning was performed, with no layers frozen. 2) Only the first two 3D sparse convolution layers were frozen; the rest of the backbone and the detection head were trained. 3) Only the first four 3D sparse convolution layers were frozen; the remaining layers and the detection head were trained. 4) All 3D sparse convolution layers were frozen, while the detection head and subsequent 2D layers remained trainable. The results showed that full fine-tuning without freezing achieved the highest average class performance, which was used as the basis for selecting the final model configuration.

On the test set, the 3D bounding box accuracy based on AP@R40 IoU 0.25 was recorded as follows: dump truck (79.13%), excavator (70.81%), grader (68.74%), and roller (79.36%). Here, R40 (Recall 40) is an evaluation metric used in the KITTI dataset, where Average Precision (AP) is computed based on 40 recall points. The detailed performance evaluation results are presented in Table 2, while Figure 6 visually illustrates the detection results for each class.

To verify whether the proposed system can reliably perceive construction equipment in real-time environments using data acquired by an actual mobile robot, a live experiment was conducted using sequential point cloud data collected from Site 4. The results demonstrated that VoxelNeXt, implemented within the proposed ROS-based system, detected construction equipment at an average speed of 2.8 Hz on the mini-PC. The detection results were continuously integrated with LIO-SAM in real time, allowing the positions of construction equipment to be sequentially localized on the global map. Figure 7 illustrates the detection results of a continuously moving grader and roller over a 60-second period, recorded on the global map in the test environment. These results demonstrate that the proposed system effectively detects and records the spatial information of construction equipment even in real-time operational conditions.

Table 2. The performance of detection model

Class	AP (IoU > 0.5)		AP (IoU > 0.25)	
	BEV	3D	BEV	3D
All Layers Trainable (No Freezing)				
Excavator	66.59	41.97	70.81	70.81
Dump Truck	78.97	47.90	79.31	79.13
Grader	68.45	50.02	70.14	68.74
Roller	75.62	41.37	80.13	79.36
Freeze 3D Sparse Convolution 1-2				
Excavator	54.05	39.60	55.48	55.48
Dump Truck	82.60	45.21	83.59	81.08
Grader	69.85	53.66	75.99	73.92
Roller	73.14	39.01	77.76	76.41
Freeze 3D Sparse Convolution 1-4				
Excavator	42.38	38.32	54.82	53.12
Dump Truck	83.73	43.20	84.08	82.30
Grader	70.22	51.40	75.45	72.77
Roller	65.67	29.02	74.41	74.41
Freeze All 3D Sparse Convolution				
Excavator	20.63	12.45	28.94	28.27
Dump Truck	85.37	36.93	86.38	81.98
Grader	43.80	33.42	53.65	47.59
Roller	70.97	14.55	82.12	61.19

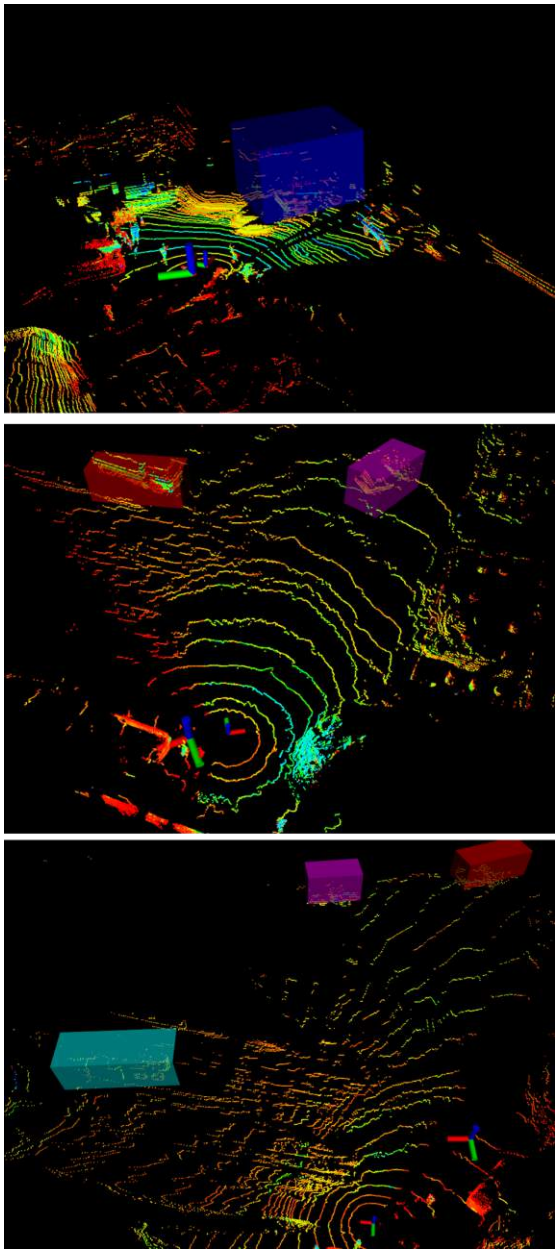

Figure 6. Visual examples of the detection outputs at test dataset: blue boxes represent excavator, red boxes represent truck; cyan boxes represent grader, and pink boxes represent roller.

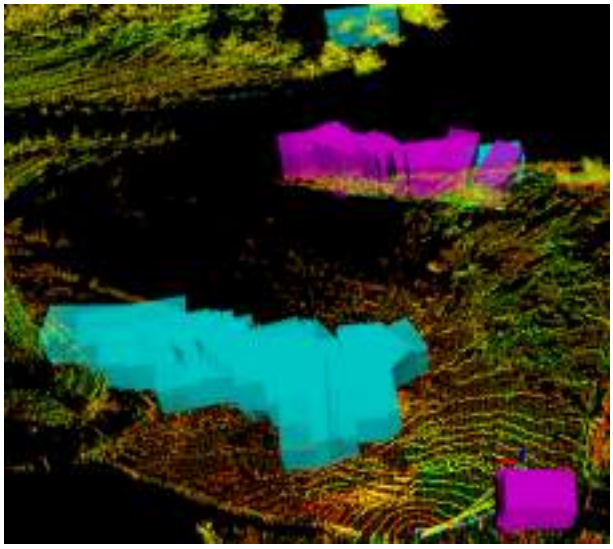

Figure 7. Visualization of grader(cyan) and roller(pink) bounding boxes recorded on the global map at Site 4.

4 Discussion

The experimental results confirmed that the proposed methodology can autonomously perceive construction equipment in real-world construction site data. By leveraging VoxelNeXt, the system demonstrated the ability to detect construction equipment in real time across a wide area and integrate the detection results with LIO-SAM, effectively mapping their positions within a consistent coordinate system. Furthermore, the system successfully recorded equipment positions continuously, enabling long-term perception of their movements and operational ranges. This capability supports mobile robot operations on construction sites and highlights the system's potential as foundational technology for comprehensive progress monitoring in large-scale construction projects.

However, the visually sparse nature of mobile LiDAR point clouds presents challenges in maintaining consistent detection performance, particularly in complex environments. In construction sites where structures and equipment are densely intermingled, achieving robust detection necessitates further research. These sparsity issues become more pronounced when applying technologies originally developed for autonomous driving to complex off-road environments, such as construction sites.

As shown in Table 2, when fine-tuning with more backbone layers frozen from the pretrained model (trained on the KITTI dataset), detection performance remained high for classes similar to those in KITTI, such as dump trucks. In contrast, performance significantly declined for equipment structurally different from KITTI

objects, such as excavators. This demonstrates a clear domain gap between autonomous driving datasets and construction site data, indicating that structural diversity of construction equipment and environmental complexity directly influence detection performance.

Therefore, acquiring construction-specific datasets is essential. Given the current lack of standardized 3D point cloud datasets for construction equipment, generating realistic, variability-inclusive virtual data is an effective alternative for dataset augmentation. This approach can significantly enhance data diversity, improve the generalization capability and robustness of detection models, and ultimately strengthen detection reliability in complex construction environments.

5 Conclusion

This paper proposed a system capable of perceiving the 3D positions of construction equipment in real time using a mobile LiDAR. The system integrates a voxel-based real-time object detection model with a SLAM algorithm to efficiently process 3D point cloud data collected by the mobile LiDAR and consistently map detected results in a global coordinate system. Experimental results demonstrated that the system achieves detection accuracies of 79.13% (dump truck), 70.81% (excavator), 68.74% (grader), and 79.36% (roller) based on AP@R40 with 3D IoU 0.25, proving its capability to reliably recognize the spatial locations of construction equipment. Additionally, experiments confirmed that mobile LiDAR-based detection can effectively identify and track a wide range of construction equipment in dynamic construction environments in real time. Future work will focus on enhancing detection performance and reliability by augmenting the dataset with realistic, simulation-based virtual data, thereby improving the generalization capability and robustness of the detection model. Through these advancements, the proposed system has the potential to support efficient mobile robot operations on construction sites and serve as a foundational technology for automated progress monitoring of large-scale construction projects using mobile LiDAR.

Abstract -

Japan's Public Works Research Institute (PWRI) has developed OPERA (Open Platform for Earthwork with Robotics and Autonomy), an open source-based research and development environment consisting of construction machinery and its physical simulator, to promote the development of automated construction technology. Constructing a dynamic model of construction machinery is key to reproducing its behavior in a physical simulation. However, manufacturers typically treat such information as proprietary, making it difficult for users to access and utilize. This paper shows a Dynamics model based on available information on the user side for a hydraulic excavator implemented in OPERA's physical simulator. The behavior of each joint in the simulator is compared with the actual behavior of each joint under the same joint angle commands. The results show that the actual excavator behavior can be simulated in each joint on the simulator excavator.

1 Introduction

Construction sites, issues of labor shortages due to aging populations and population decline are becoming critical challenges. As a result, reducing the number of required workers has become an urgent priority. Efforts to achieve this through automation are gaining attention, such as replacing excavation and transportation tasks with automated construction machinery or automating entire construction operations.

Japan's Public Works Research Institute has developed OPERA (Open Platform for Earthwork with Robotics and Autonomy) for the development of autonomous construction machinery and automated construction technology [1]. OPERA is an open platform designed to facilitate collaborative development not only with construction machinery manufacturers and construction companies but also with diverse industries such as academic research institutions, software vendors, sensor manufacturers, and system integrators. OPERA comprises three main elements: hardware, including modified construction machinery such as hydraulic excavators and crawler dumpers to allow electronic control; a physical simulator that simulates the behavior of these construction machines; and middleware for controlling them. Developers of automation programs can conduct preliminary verification using the simulator, and if no issues arise, proceed to verification with actual machines. This enables model-based development of automation programs. To replicate the behavior of actual machines in simulations, it is crucial to have accurate dynamic models of the target construction machinery. Examples of model-based development utilizing simulators in construction machinery include works by Kawabata et al. [2] and Shintani et al. [3]

Here, we describe other cases of model-based development of construction machinery. Kawabata et al. [2] describe the use of simulations for dynamic behavior analysis of hydraulic excavators to shorten product development cycles. They evaluated behaviors during flatland and rough terrain traversal using dynamic models, achieving reductions in development time. Shintani et al. [3] proposed model-based development employing 1DCAE technology for performance development of construction machinery. Using 1DCAE technology, they improved design change efficiency and product quality, employing simulations during excavation, among other scenarios.

In model-based development by construction equipment manufacturers, the machine dynamics model is confidential information, so it will not normally be disclosed to all users. Thus, this is a major bottleneck for users such as construction companies. To address such issues, we propose a method for constructing dynamics models based on the following concepts.

1. *Using user-friendly information (e.g., product catalogs for construction machinery):*This study target is to enable users to develop automation systems even if they are unfamiliar with the dynamics model of construction machinery.
2. *Simulating each joint motion in a construction machine operated by hydraulic cylinders, etc., with a simple rotational drive.*This study aims to enable users who are not familiar with hydraulic equipment

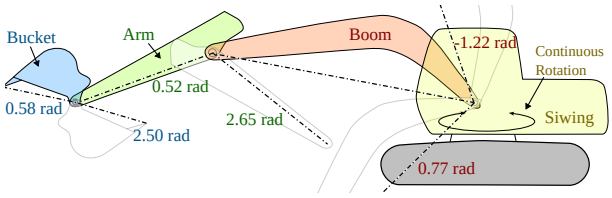

Figure 1. Definition of the joint angles of Boom, Arm, Bucket, and Upper Structure (Swing) in the hydraulic excavator ZX120 (Hitachi Construction Machinery Co.)

to participate in automation development.

This paper describes a method for constructing a dynamics model of a hydraulic excavator based on the above concepts.

2 The physical simulators in OPERA

The physical simulator in OPERA is designed with a focus on the extensibility of functionality on the user side [2]. Other cases of physical simulators have been developed to train construction machinery operators [3, 4]. These are designed for specific applications only, thus providing limited functionality. In contrast, the physical simulators of OPERA provide extensibility so that users can use them in a variety of applications, such as automation and teleoperation.

OPERA provides two physical simulators, OperaSim-AGX [5] and OperaSim-PhysX [6], depending on the user's development objectives and cost requirements. OperaSim-AGX is characterized by its high accuracy in simulating soil deformation. OperaSim-PhysX is inferior to OperaSim-AGX in terms of soil deformation simulation accuracy; however, it has the advantage of not requiring a license fee for using the physics engine, thus reducing the user's development cost. In this paper, we describe a method for simulating the behavior of a hydraulic excavator in OperaSim-PhysX.

3 Dynamics model of the hydraulic excavator

3.1 The system configuration for the hydraulic excavator

Each joint of a hydraulic excavator is controlled by position control. We used the hydraulic excavator ZX120 (Hitachi Construction Machinery Co.). We define the joint angles of Boom, Arm, Bucket, and Upper Structure (hereinafter referred to as Swing) as shown in Figure 1. The system components of the excavator to control the joint angles are shown in Figure 2. The excavator is controlled by repeating the following section 3.1.1 ˜3.2.3

3.1.1 Getting the angle of each joint

The bucket, arm, boom and swing joint angles are measured with absolute encoders. Each joint angle information is sent to the control computer in the excavator.

3.1.2 Controlling valve opening

The Target Angle (command value) and Current Angle (angle obtained from the encoder) are input to each joint controller (Bucket control, Arm control, Boom control, Swing control). Then, the valve openings (valve openings) for the hydraulic valves to control the hydraulic cylinders and motors are calculated.

Each controller consists of a "Dead Time Compensator" and a "PID Controller". The "Dead Time Compensator" compensates for the delay between the time the external computer commands the valve opening degree and when the actuator operates, which is detected as a change in joint angle. We confirmed this delay is 0.35 seconds for each joint through prior measurements. Since the delay causes the controller to be less responsive, we used the Smith method to predict the current angle after the time elapsed.

The PID Controller is provided in a PID [7] package. The valve opening is obtained via the PID Controller from the target angle and the predicted value of the current angle after a time elapse.

3.1.3 Driving each joint

Valve opening information is sent to the main valve system via the solenoid valve system. The oil flow in each drive system ' s hydraulic circuit is controlled according to the valve opening of the main valve system. Then, each joint moves.

3.2 The hydraulic excavator in physical simulation

For simulating the behavior of a hydraulic excavator in a physical simulation, we have constructed the system shown in Figure 3. When a target angle is given to each joint, the torque will be output from each controller (Bucket Control, Arm Control, Boom Control, and Swing Control).

Each controller is composed of a " Dead Time Function " and an " Articulation Body " [8] The Dead Time Function outputs the target angle a certain amount of time ago to simulate the latency of a real excavator. angle a certain amount of time ago to simulate the latency of a real machine. Articulation Body is a Unity component for simulating objects with hierarchical link structures, such as robot arms. It can construct rotating and sliding joints so that angles, angular velocities, and forces can control each joint.

· Articulation Joint Type: Revolute

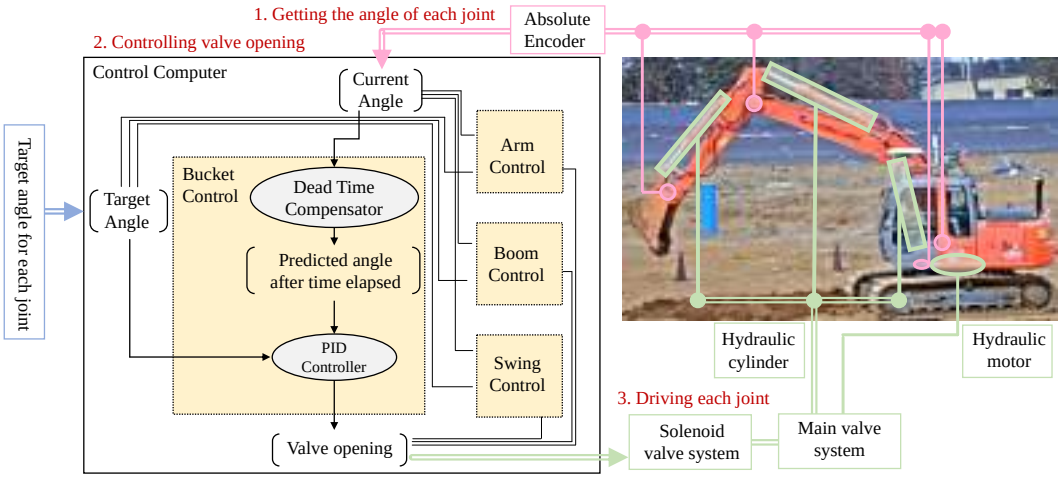

Figure 2. System configuration of the actual autonomous excavator. Each joint is position controlled by repeating the following steps: 1. Getting the angle in each joint, 2. Controlling valve opening, 3. Driving each joint.

Table 1. ZX120 spec about dynamic model

	Boom joint	331.817
	Swing joint	34.3

· Drive Type: Force

Other parameters are described in Sections 3.2.1 ˜3.2.3.

3.2.1 Geometry and weight

The mass of the hydraulic excavator was referenced from the ZX120 model specifications on the catalog [9]. The mass of each component of the excavator is shown in Table 1. The geometry of the hydraulic excavator was scanned using a 3D LiDAR on the excavator shown in Figure 2.

Geometrical data for each link were extracted from the resulting 3D point cloud. The hydraulic excavator is scanned in 3D. The obtained point cloud will be meshed. The mesh is split for each link, and a URDF file is created and imported into the physical simulation. The moment of inertia for each link was derived under the assumption that the mass is uniformly distributed across the obtained geometry. The DH parameters were obtained through measurements of the excavator.

3.2.2 Maximum torque of each joint

We describe how to approximate the maximum output torque for each link, respectively. The maximum torque at the bucket and arm joints is calculated from a value called the ”tool force”. The tool force is the force applied to the blade edge when the bucket or the arm is moved. The method for measuring tool force is defined in ISO 6015:2006 [10]. From those definitions, the maximum torque at each joint of the bucket and arm is obtained to be 121.77 kNm and 236.187 kNm, respectively.

The maximum torque at the boom joint is derived from the force that can be generated by the boom cylinder, as shown in Figure 5. The hydraulic pressure inside the cylinder determines the force exerted by the cylinder. For the ZX120, the maximum pressure applied to the cylinder corresponds to the hydraulic excavator's main relief set pressure. This pressure is regulated by the main relief valve and cannot exceed this limit. According to the specifications of the ZX120, the value is given as $P_b = 34.3$ MPa. The force that can be generated by the cylinder differs during cylinder extension, F_b, and contraction, $\acute{F_b}$. Using the maximum pressure applied to the cylinder P_{bu}, the cylinder's internal diameter D, and the rod's outer diameter d, these forces can be calculated using the following

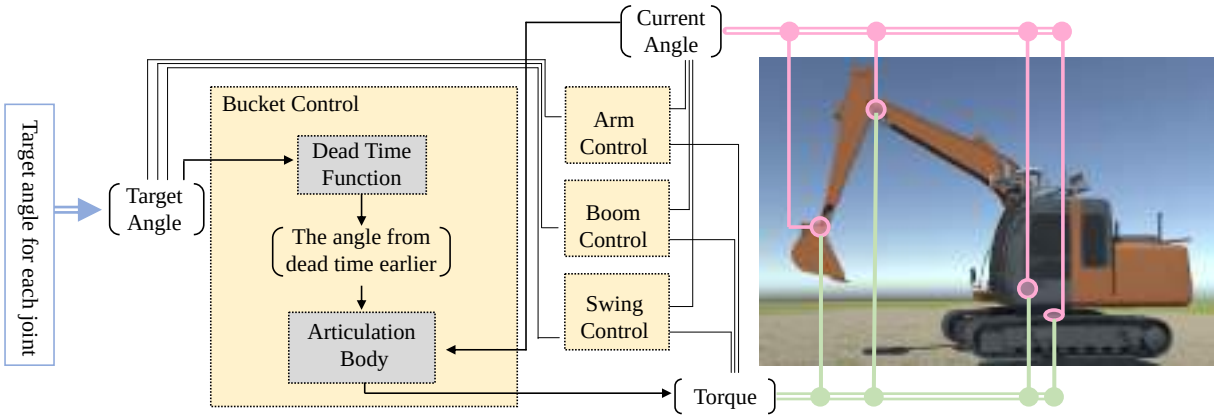

Figure 3. System configuration of the excavator in the physical simulator

Figure 4. Procedure to simulate a excavator in a physical simulator: (a) Obtaining geometry with a 3D scanner, (b) Meshing (c) Constructing and importing a URDF

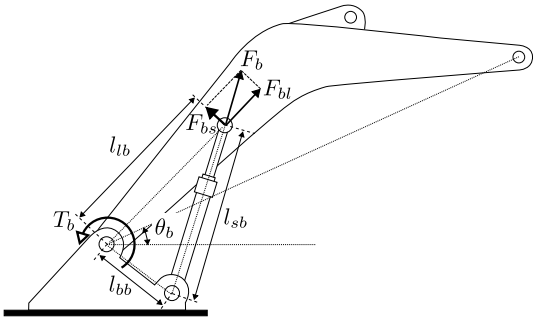

Figure 5. Calculating torque in Boom joint

equations.

$$F_b = 2 * 0.25\pi D^2 * P_{max} \quad (1)$$

$$F_b^{'} = 2 * 0.25\pi (D^2 - d^2) * P_{max} \quad (2)$$

After deriving the force that the cylinder can generate, the rotational torque around the boom link axis is calculated. The rotational torque is generated by the force F_b produced by the cylinder, specifically the component of this force F_{bs} that is perpendicular to the line formed between the boom rotation axis and the rod pin of the boom cylinder, as shown in Figure 5. The relationship between the boom angle θ_b and the rotational torque is shown in Figure 6. The boom's rotation range is from 0.77 [rad] (about 44°) to -1.22 [rad] (about -70°), and the maximum torque occurs at the point where the angle is 0 [rad]. While there are two possible values due to cylinder extension and contraction, the data for the direction in which the boom lifts off the ground (i.e., cylinder extension) is adopted here. The maximum torque is 331.816 kNm.

The maximum torque for the swing axis is taken from the datasheet [9] as 34.3 kNm. The calculation results for the maximum torque are summarized in Table 1.

3.2.3 The gain configuration for torque output

The torque at each joint is calculated as follows.

$$T = K_s(\theta - \theta^*) - K_d(\omega - \omega^*). \quad (3)$$

where, θ and θ^* are the current and target joint angles, respectively, and ω and ω^* are the current and target joint angular velocities, respectively. By adjusting the parameter K_s, which determines the angle gain, and the parameter K_d, which determines the angular velocity gain, the response of the joint to inputs can be modified. The joint torque T is constrained by the Force limit parameter of the Articulation Body. The maximum torque for each joint is applied as the Force limit to ensure that torques exceeding the set values are not output.

4 Estimation of parameters in the excavator dynamics model

We estimate the Stiffness K_s and Damping K_d parameters of the Articulation Body, which compose each joint in a simulation of the excavator. We select values of Stiffness K_s and Damping K_d, which are close to the real machine's response by tuning them. The closeness of the response

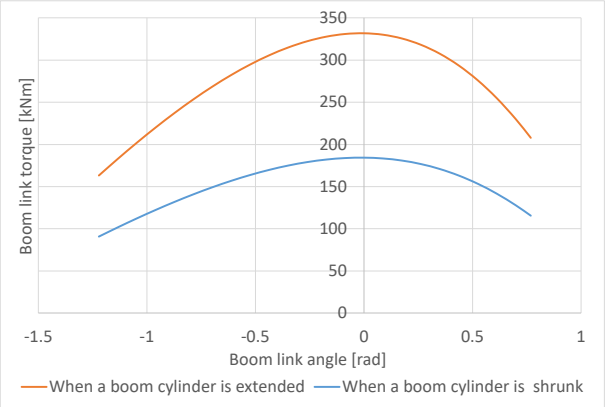

Figure 6. Changes in boom torque with respect to the boom joint angle

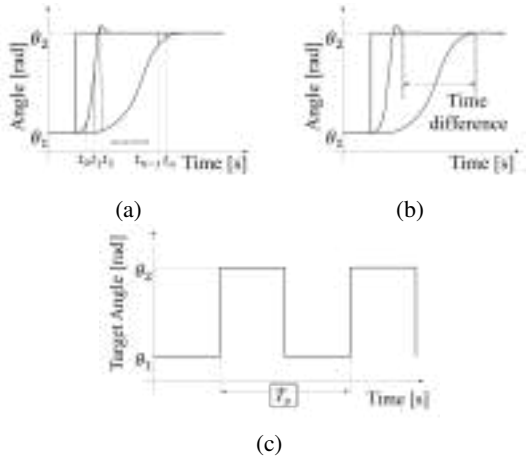

Figure 7. Parameter estimation details

to the actual machine is evaluated in the following two points.

A. **Mean square error of response time change**

Figure 7a shows the mean square of the errors in the response time change. From the Current Angle θ^r of the actual machine and the Current Angle θ^s of the simulator obtained at each sampling time $t_0, t_1, t_2 \ldots t_{n-1}, t_n$, calculate,

$$S = \frac{1}{n}\sum_{i=1}^{n}(\theta^s_{t_i} - \theta^r_{t_i})^2 \tag{4}$$

where n is the number of data samples and S is the mean square error of the time series response. We change the values of K_s and K_d, then select the one for which the mean of squares S is smaller.

B. **Convergence time difference to the target angle**

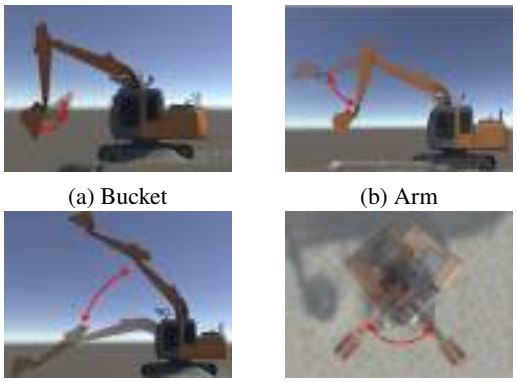

Figure 8. Movement during the parameter estimation at each joint

Table 2. PC specification for simulation

CPU	Intel(R) Core(TM) i9-14900HX 2.20 GHz
GPU	NVIDIA GeForce RTX 4060 Laptop GPU
RAM	32.0 GB
Storage	SSD (NVMe) 1TB

Figure 7b shows the convergence time difference with respect to the target angle. When the convergence time to the target angle in the real machine is T_s^r and the convergence time to the target angle in the simulation is T_s^s, the absolute value of the convergence time difference $|T_s^d|$ is

$$|T_s^d| = |T_s^r - T_s^s|. \tag{5}$$

We select the one with smaller $|T_s^d|$ by tuning the parameters.

For executing the simulation, we used the PC shown in Table 2. Prior to the simulation, we confirmed that the simulation was performed in real time.

4.1 Setting the target angle

The time variation of the target angle is shown in Figure 7c. The θ_1 and θ_2 angles are given alternately at a fixed period T_s.The values of θ_1 and θ_2 and the period T_s at the Bucket, Arm, Boom, and Swing joints are shown in Table 3. The motion of the hydraulic excavator is shown in Figure 8.

4.2 Minimizing the mean square error of response time change

The mean square error S of the time response change when the parameters are changed is shown in Figure 9. In this paper, we describe the results of changing the Arm

Stiffness K_s	2000000	2000000	2E+8	2000000
Damping K_d	2000000	2000000	2E+8	1000000

fixed. The K_d at which $|T_s^d|$ is the smallest is selected. The results are shown in Figure 10 for Arm and Boom. The red box in the figure shows the K_d with the smallest $|T_s^d|$ among the trials. K_d for Bucket and Swing were adjusted similarly, as shown in Table 5.

Table 5. The result of minimizing convergence time difference

	Bucket	Arm	Boom	Swing
Stiffness K_s	2000000	2000000	2E+8	2000000
Damping K_d	1200000	1100000	70000000	900000

4.4 Adjustment result

The response of each joint to the target angle shown in Figure 8 is shown in Figure 11. S was obtained from Figure 4 for bucket, arm, boom, and swing, respectively: 0.179746, 0.009057, 0.034118, and 0.003911 [rad^2].

5 Evaluation of dynamics model by digging operation

We compare the behavior of the excavator during excavation by the actual machine with the behavior of the excavator during excavation within the physical simulation.

5.1 Evaluation requirements

The motion during digging is shown in Figure 12. Excavation is performed in the following order.

1. Turning the Swing to begin excavating the ground
2. Stabbing the bucket into the ground
3. Scooping and lifting

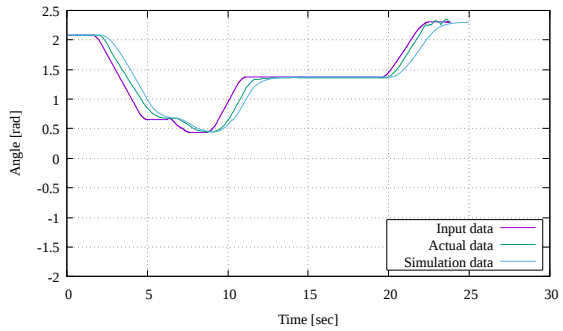
Figure 12. Digging motion

This evaluation was conducted in an experimental field owned by the Public Works Research Institute (PWRI) in Japan. The ground surface consists mainly of clayey soil (loam), which is flat.

5.2 The result

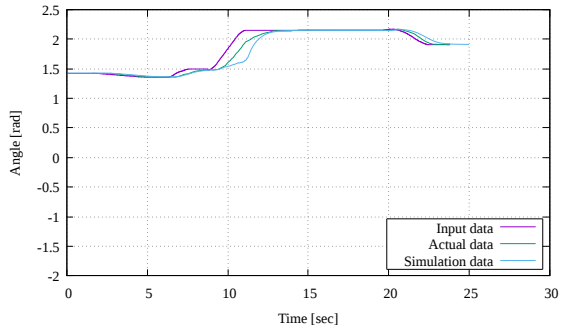
The following figure shows the time variation of the current angle in the actual machine (Actual data) and the angle in the simulation (Simulation data) when the target angle (Input data) is given to Bucket, Arm, Boom, and Swing respectively in Figure 13. data).

The mean square error S of the time response was calculated for each joint according to Formula (4). The results were 6.258×10^{-6}, 6.264×10^{-6}, 6.27×10^{-6} and 6.27×10^{-6} for bucket, arm, boom and swing respectively. The time response is shown in Figure 13.



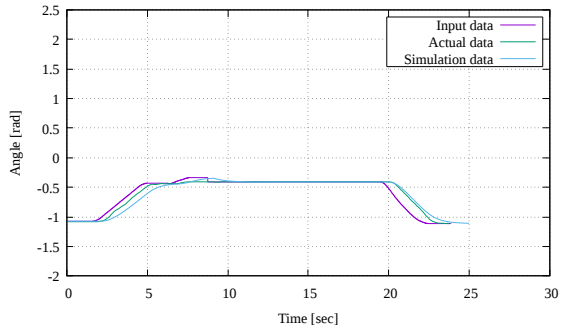
6 Conclution

This paper explained the method for constructing the dynamic model of a hydraulic excavator in the physical simulator of the open platform OPERA, developed for the automation of construction machinery and automated construction technology. Specifically, the dynamic model was configured to ensure that the hydraulic excavator in the simulation operates similarly to the actual machine, focusing on three aspects: digging force, and the response to inputs at each joint of the working mechanism.

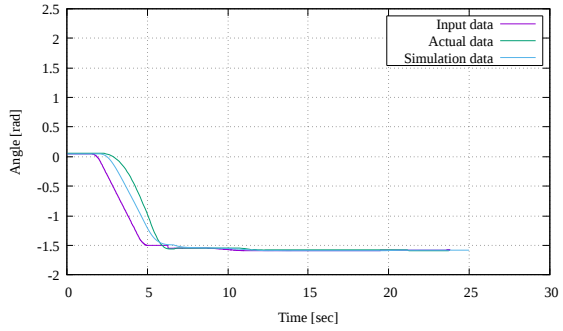


The model was adjusted so that the behaviors of the swing, boom, arm, and bucket rotational axes in OPERA matched those of the actual machine. As a result, it was confirmed that the model could replicate the behavior of the actual machine with an mean squared error of approximately 6.258×10^{-6} to 6.27×10^{-6} [rad^2] for each axis.

The following is the future works. We construct a dynamics model which more closely simulates the behavior of a real excavator.



- We need to confirm the validity of the proposed method on excavators other than ZX120.



(a) Bucket

(b) Arm

(c) Boom

(d) Swing

Figure 13. Evaluation result

- We will experiment whether advanced control methods other than PID control, such as adaptive control, can be applied to excavators and whether their behavior can be simulated.
- We will devise a method of constructing a dynamics model for a machine with aging deterioration. we include in the dynamics model factors such as the decrease in power output of the excavator.

Abstract

While human-robot collaboration (HRC) is anticipated to improve construction productivity and safety, it can become crucial to manage emotional responses of collaborating human workers (co-workers) during HRC due to their critical impacts on co-workers' performance and human-robot cohesion. A potential approach involves controlling robots in ways that can adapt to potentially different emotional responses of co-workers to foster desired responses and productivity in human-robot teams. However, we still lack an effective method as existing robot control strategies tend to prioritize productivity and safety alone or consider co-workers' responses but take standardized actions across different co-workers. In this study, we propose a personalized emotion-adaptive robot control strategy using model-based reinforcement learning (RL), which aims for robots to learn each co-worker's emotional responses over interaction to plan and take actions for fostering desired responses while pursuing high productivity in human-robot teams. The effectiveness of the proposed robot control strategy was demonstrated in a virtual environment by simulating HRC with the emotional responses of 20 co-workers for a construction task. Results showed that a robot with the proposed strategy could promote desired emotional responses like happiness in all 20 co-workers for approximately 37 minutes during a 1-hour bricklaying task. While findings demonstrate the potential of the proposed robot control strategy as a way for robots to adapt to co-workers' emotional responses, further analysis will be anticipated to minimize potential trade-offs in productivity in human-robot teams that may arise from considering co-workers' responses.

Keywords –

Human-Robot Collaboration, Reinforcement Learning, Emotional Response

1 Introduction

The construction industry has suffered from stagnant productivity growth compared to other industries [1]. According to the McKinsey Global Institute, the productivity (real gross value added per labor hour) of the construction industry has grown 1% for the past two decades since 1995, while the average annual growth by the total global economy was 2.8% [2]. Although construction productivity can be considered mainly relying on labor power [3], labor power can be negatively affected by other ongoing issues in the industry, including high safety risks, the aging workforce, and the labor shortage [4-6]. The stagnant growth of productivity has remained a major challenge.

Human-robot collaboration (HRC) has recently gained attention in the construction industry, envisioned as a new paradigm shift toward co-robotic construction [7]. Recent advancements in robotic technology have introduced collaborative robots, an evolved form of conventional industrial robots, enabling collaboration with humans by combining the strengths of humans and robots [8]. For example, robots can take over physically demanding, dangerous, and repetitive tasks for human workers to focus on dexterous, problem-solving, and decision-making tasks [8]. HRC is anticipated to improve construction productivity by reducing the primary dependence on workers' labor power and increasing the level of robotic automation [9].

However, HRC is in its early stages in construction. The extent of its impact on construction productivity has not been thoroughly examined [9]. A potentially crucial factor for productive HRC is emotional response of collaborating human workers (co-workers). Emotions can be defined as mental states, associated with degrees from displeasure to pleasure and from relaxation to excitement, such as excitement, relaxation, boredom, and fear [10]. Studies have demonstrated that emotions can cause critical impacts on worker performance by affecting decision-making, problem-solving, and behaviors [11]. Additionally, studies in some fields, like social robotics, have identified that emotions can be largely influential to the human-robot cohesion by influencing acceptance and trust toward robots [12]. Within the unprecedented co-robotic work environment, the importance of emotions can become more

considerable than before to achieve the anticipated productivity growth by the human-robot teams.

Efforts have identified the potential variations in co-workers' emotional responses during HRC. Our prior work demonstrated through a lab experiment that the emotional responses of co-workers could be significantly influenced during a simulated bricklaying task with a real robot [13]. Major results showed that while every co-worker's emotional response was affected, almost every co-worker exhibited statistically different responses, which were also estimated to affect productivity in human-robot teams. These findings present that considering co-workers' emotional responses, which may vary among individuals, can become essential for fostering desired responses that can enhance both their performance as well as cohesion with robots.

A potential approach can involve controlling robots in a way that can consider each co-worker's emotional responses. However, the consideration of emotional responses has not been a major focus in robot control strategies for HRC, particularly in construction, where performance-oriented factors like productivity and safety remain the primary objectives [14,15]. While a few studies have presented the potential necessity of robot control that considers human responses [16], robots typically take standardized actions for all individuals, which may be ineffective for co-workers with different responses [13]. As such, we still lack an effective robot control strategy for robots to consider co-workers' potentially different emotional responses while pursuing higher productivity in human-robot teams.

In this study, we propose a personalized emotion-adaptive robot control strategy that aims for robots to learn each co-worker's emotional response during interactions, even with whom they encounter for the first time. This strategy allows robots to take actions that can elicit desired emotional responses (e.g., happiness and excitement), which can enhance co-workers' performance and cohesion with robots, while pursuing high productivity in human-robot teams. The proposed robot control strategy is based on reinforcement learning (RL) algorithm, an effective branch of machine learning for adaptive robot control [17]. The effectiveness of the proposed robot control strategy was evaluated through a simulated HRC for a construction task in a virtual environment, where the robot collaborated with virtually simulated 20 co-workers, whose emotional responses were identified in our prior study [13].

This study demonstrates the potential effectiveness of using reinforcement learning (RL) for an adaptive robot control strategy to promote desired emotional responses in each co-worker, including those encountered for the first time. At the same time, the findings present the need for further analysis of robot control to balance emotional responses and productivity in human-robot teams, as trade-offs between these factors may arise.

2 Model-based Reinforcement Learning for Personalized Emotion-Adaptive Robot Control Strategy

The proposed robot control strategy relies on a model-based RL, an effective branch of RL when interacting with complicated environments like human responses [18]. Model-based RL allows the robot to learn the mechanisms of co-workers' emotional responses to its actions through modeling over interactions. This enables the robot to plan and take actions for fostering desired emotional responses in co-workers while pursuing high productivity in human-robot teams. The proposed robot control strategy guides the robot to operate iteratively by 1) taking an action during HRC for a construction task (Figure 1a), 2) learning the co-worker's emotional responses (Figure 1b), and 3) planning the next action to promote desired co-worker's emotional responses and highest possible productivity in human-robot teams (Figure 1c). Notably, it is assumed that the robot can monitor co-workers' emotional responses through wearable sensors, such as brainwave analysis using an EEG headset.

2.1 Desired Emotional Response

Emotional response can be represented using a bipolar dimensional emotion model [19], which reliably and sufficiently captures emotional states (e.g., excited and bored) by estimating emotional status based on two key dimensions (Eq. 1): valence (ranging from displeasure to pleasure) and arousal (ranging from relaxation to excitement). Among various emotional

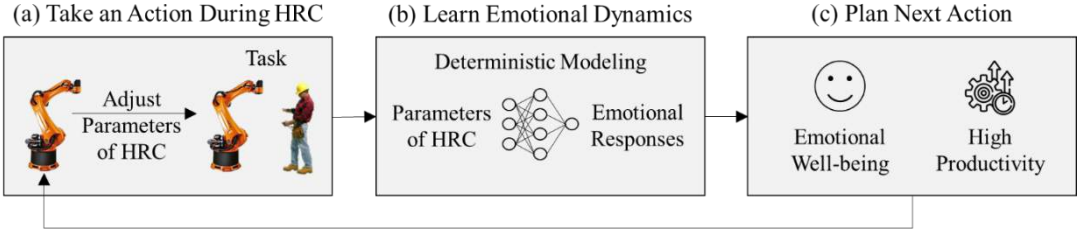

Figure 1. Overview of the proposed robot control strategy.

states, including calmness, anxiety, and boredom, this study considered positive emotions, such as happiness and excitement, as desired. The positive emotions are represented by positive valence and arousal, known to promote cohesive human-robot relationships and help co-workers with better performance while staying alert to potential safety risks in ever-changing, unstructured, and hazardous construction work environments [11,12,20].

$$e = \{valence, arousal\} \quad \text{(Eq. 1)}$$

2.2 Take an Action

In RL, the actions of a robot refer to changes in the state of the environment, which encompasses everything that the robot observes and responds to [17]. In this study, the environment is represented by the states (s_t), consisting of 1) parameters of HRC (p_t), such as robot's movement speed, which can affect co-workers' emotional responses, and 2) the corresponding emotional responses of a co-worker (e_t) at a time t (Eq. 2.1). Actions (a_t) of a robot refer to the adjustments in parameters of HRC (p_{t+1}) during a construction task, such as an updated movement speed after slowing down (Eq. 2.2). The actions directly adjust the parameters of HRC and can cause variations in emotional responses of a co-worker. Over the interaction, the robot can collect the set (D) of observations, consisting of current states (s_t), robot's action (a_t), and corresponding changes in environmental states (s_{t+1}) (Eq. 2.3). It is noteworthy that the size of D expands whenever the robot takes an action.

$$s_t = \{p_t, e_t\} \quad \text{(Eq. 2.1)}$$

$$a_t = p_{t+1} \quad \text{(Eq. 2.2)}$$

$$D = \{(s_t, a_t, s_{t+1})_{t=1\sim T}\} \quad \text{(Eq. 2.3)}$$

$$where\ s_t\ and\ a_t\ represent\ the\ state\ and\ action,\ respectively,\ at\ each\ time\ step\ t,\ ranging\ from\ the\ beginning\ (t=1)\ to\ the\ current\ time\ step\ (t=T)$$

2.3 Learn Co-worker's Emotional Responses

In this study, the proposed strategy is specifically tailored to operate within a deterministic Markov decision process framework, where the environment's transitions are deterministic given the current state and action. The set of observations, D, enables the robot to learn the deterministic state transition model $T(s_{t+1}|s_t, a_t)$ (Eq. 3), which predicts how the state (s_t) evolves based on the robot's action (a_t). As actions (a_t) correspond to the updated parameters of HRC (p_{t+1}), the learning of the transition model solely focuses on $f_{Emotion}$, which represents co-workers' emotional responses to the robot's actions. The structure of $f_{Emotion}$ can be flexibly specified when previously identified relationships exist between the robot's actions and co-workers' emotional responses. For example, in our prior study, we identified multiple linear regression relationships between robot actions, such as movement speed, and co-workers' emotional responses [13]. During interactions, the robot learns coefficients of $f_{Emotion}$ tailored to the specific co-worker using the least square optimization (Eq. 3).

$$T(s_{t+1}|s_t, a_t) = \{a_t, f_{Emotion}(a_t)\} \quad \text{(Eq. 3)}$$
$$where\ s_{t+1} = T(s_t, a_t) = \{p_{t+1}, e_{t+1}\},\ p_{t+1} = a_t, and$$
$$f_{Emotion}(a_t)\ minimizes \sum_t \|e_{t+1} - f_{Emotion}(a_t)\|^2$$

2.4 Plan the Next Action

While the robot's actions can affect co-worker's emotional responses, they also can affect the productivity of human-robot teams. For example, the robot's faster movement speed can enhance productivity in human-robot teams. We assume the robot can estimate the productivity of human-robot teams in terms of the parameters of HRC ($f_{Productivity}$) (Eq. 4). Based on the estimations, $f_{Emotion}$ and $f_{Productivity}$, the robot uses its policy to select the next action a_t^*, aiming to maximize the cumulative reward $r(s_t, a_t)$ (Eq. 4), which can lead to the highest possible productivity in human-robot teams among the candidate actions that can evoke co-workers' emotional well-being. Notably, while traditional RL framework often uses value functions to represent expected cumulative rewards, this study focuses on direct optimization of immediate rewards $r(s_t, a_t)$ using the transition model $f_{Emotion}$. Using a value function to predict cumulative rewards over longer term can be challenging in the context of human response-adaptive robot control, as human responses may change over time even in short periods (e.g., seconds). In this context, we propose the robot focus on immediate rewards, which can allow effective respond to emotional responses. However, for this planning approach to be effective, the robot must first observe co-workers' emotional responses across a wide range of scenarios to accurately learn the transition model. To achieve this, the robot incorporates an exploration strategy, randomly selecting a percentage of its actions to gather diverse data on co-workers' responses. Initially, 100% of the robot's actions are random until collecting 48 observations of co-worker's emotional responses, and this percentage decreased to 20%. This empirically determined strategy balances exploration and exploitation, enabling the robot to refine its transition model and improve action planning over the

interaction.

$$a_t^* = \underset{a}{\operatorname{argmax}} \sum_a r(s_t, a_t) \quad \text{(Eq. 4)}$$

$$where\ r(s_t, a_t) = \begin{cases} f_{Productivity}(p_{t+1} = a_t) & if\ f_{Emotion}(a_t) > 0 \\ 0 & Otherwise \end{cases}$$

3 Simulated HRC for a Construction Task in a Virtual Environment

In our prior study, we analyzed the emotional responses of 20 people, consisting of 13 men and 7 women, while they collaborated with a real robot in a lab environment for a bricklaying task, which can be considered a representative example of distributing tasks between humans and robots in construction [13]; robots take over physically demanding tasks (e.g., lifting bricks) while workers focus on the dexterous tasks like finishing. Participants were recruited from students with various academic backgrounds (mean age: 29; standard deviation of age: 3.5; minimum age: 23; and maximum age: 36), including 12 from civil and environmental engineering, some with construction field experience, 4 from other engineering departments like electrical and mechanical, and 4 from non-engineering departments like music and social science. Their varying levels of construction experience, technical proficiency, and exposure to robotic technologies were expected to exemplify a wide range of emotional responses during HRC, also anticipated among construction workers. As an early attempt to demonstrate the potential effectiveness of the proposed robot control strategy in adapting to wide spectrum of different emotional responses, we adopted the emotional responses of the student participants, instead of exploring and simulating emotional responses of construction workers, whose responses might be affected by occupational biases, such as concerns of job loss and replacement by robots [21].

In this context, we virtually simulated a robot to collaborate with each of the 20 co-workers to conduct a bricklaying task for one hour, a plausible work duration before a break. We replicated the lab environment from the prior study [13] within a virtual environment, where parameters of HRC and emotional responses were computationally simulated. The bricklaying task was conducted by a team of one co-worker and one robot (Figure 2); the robot delivered bricks for the co-worker to lay them in a line. Notably, the simulated bricklaying task conducts some portion of masonry work to demonstrate the effectiveness of the proposed robot control strategy during a representative task distribution between humans and robots, rather than replicating the entire masonry process, including scaffold installation, mortar mixing, and brick cutting.

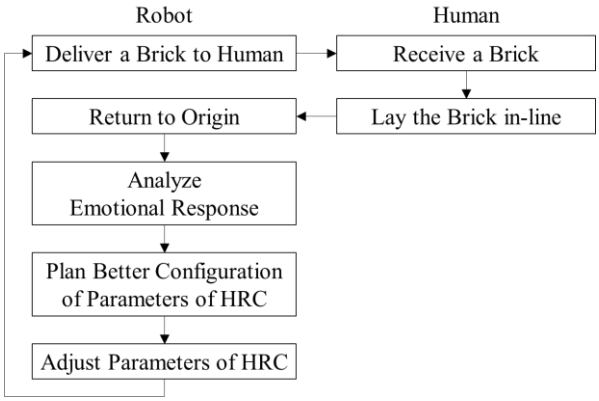

Figure 2. Workflow of the bricklaying task.

The robot was allowed to take actions over five parameters of HRC, which were identified to affect co-workers' emotional responses [13]: 1) robot's movement speed; 2) robot's arm swing speed; 3) proximity between humans and robots; 4) level of autonomy; and 5) leader of collaboration. All the actions were to be made within the specified ranges based on the robot's capability and physical dimension of the lab environment [13]: movement speed from 27.8 cm/s to 143.8 cm/s; arm swing speed from 23.8 cm/s to 109.1 cm/s; proximity as either direct (100 cm) or indirect (200 cm); level of autonomy as either manual or auto; and leader as either human or robot.

In response to the robot's actions, the emotional responses of 20 co-workers were virtually simulated by using two regression models, one for valence and another for arousal, which were obtained from the prior study (Eq. 5.1) [13]. Given robot's actions, these regression models estimate the corresponding valence and arousal of a co-worker at a given time (sec) since the start of HRC. While the robot is aware of these regression models as the $f_{Emotion}$ (Eq. 3), it does not know the coefficients specific to any co-worker but should learn the coefficients tailored to each co-worker through interactions. It is assumed that the robot observes a co-worker's valence and arousal by analyzing EEG signals collected via EEG headset.

Notably, the regression models (Eq. 5.1) were obtained by analyzing EEG signals with noise reduction techniques, including wavelet independent component analysis, which have been demonstrated to be effective in alleviating artifacts—such as eye-blinks, heart rate, and muscle movement—common sources of noise in EEG signals, even in onsite construction settings. However, despite noise reduction, EEG signals can still be affected by noise. In this regard, the estimates for each co-worker were adjusted using means, standard deviations, and noise parameters derived from EEG-based valence and arousal measurements in the prior

study (Eq. 5.2) [13].

$$y_i = c_1 x_1^2 + c_2 x_1 + c_3 x_2^2 + c_4 x_2 + c_5 x_3 + c_6 x_4 + c_7 x_5 + c_8(Time) + \beta \quad \text{(Eq. 5.1)}$$

$$where\ y_i = \begin{cases} Valence \\ Arousal' \end{cases}$$

$$x_j = \begin{cases} Move\ Speed \\ Arm\ Speed \\ Proximity \\ Level\ of\ Autonomy \\ Leader\ of\ Collaboration \end{cases}, \beta = constant,$$

$$and\ Time\ is\ the\ elapsed\ time\ of\ HRC\ (sec)\ since\ the\ start\ of\ HRC$$

$$\tilde{y}_i = \sigma_i y_i + \mu_i + \epsilon_i \quad \text{(Eq. 5.2)}$$

$$where\ \epsilon_i \sim N(0, \delta_i^2),\ and\ \sigma_i, \mu_i, and\ \epsilon_i\ denote\ standard\ deviation, mean, and\ noise\ of\ y_i$$

The robot could estimate productivity in human-robot teams according to its actions during the bricklaying task (i.e., $f_{Productivity}$ in Eq. 4) by following the method used in the prior study [13]. The estimated productivity was represented by the number of bricks laid for one hour by a human-robot team in terms of the five parameters of HRC. Specifically, the bricklaying times for one robot and one human based on five HRC parameters were calculated (Eq. 6.1 and 6.2) and then aggregated into a human-robot team's bricklaying time (Eq. 6.3), which was subsequently converted into the number of bricks for one human-robot team-hour (Eq. 6.4).

$$Time\ (sec)\ for\ a\ robot\ to\ lay\ a\ brick = Body\ Traverse\ Time + Arm\ Traverse\ Time + Delay\ by\ Manual\ Control = \frac{Body\ Travel\ Distance}{Movement\ Speed} + \frac{Arm\ Travel\ Distance}{Arm\ Swing\ Speed} + 1(Manual) * \alpha \quad \text{(Eq. 6.1)}$$

$$where\ Body\ Travel\ Distance\ is\ 6.1m,\ Arm\ Travel\ Distance\ is\ 2.4m,\ and\ \alpha\ is\ delay\ of\ 3\ seconds\ by\ the\ manual\ control$$

$$Time\ (sec)\ for\ a\ human\ to\ lay\ a\ brick = Bricklaying\ Time + Delays\ by\ Indirect\ Proximity\ and\ Human\ Leader = Bricklaying\ Time + 1(Human\ Leader) * \beta + 1(Indirect) * \gamma \quad \text{(Eq. 6.2)}$$

$$where\ Bricklaying\ Time\ is\ 5\ seconds,\ \beta\ is\ delay\ of\ 1\ sec\ by\ human\ leader,\ and\ \gamma\ is\ delay\ of\ 2\ sec\ by\ the\ indirect\ proximity$$

$$Time\ (sec)\ for\ a\ Human–Robot\ team\ to\ lay\ a\ brick = (Eq.\ 5.1) + (Eq.\ 5.2) \quad \text{(Eq. 6.3)}$$

$$Estimated\ Team\ Productivity = \left\{\frac{1\ Brick}{(Eq.\ 6.3)\ Team–sec}\right\} \times \left(\frac{3{,}600\ Team–sec}{Team–hour}\right) = \frac{3{,}600}{Eq.\ 5.3}\ Bricks\ per\ Team–hour \quad \text{(Eq. 6.4)}$$

We compared four types of robot control strategies (Table 1). The first type only prioritized productivity without considering co-workers' emotional responses, representing the currently predominant approach of robot control during HRC. For example, the robot would maximize its movement speed for high productivity. The second type employed a standardized planning approach, which takes uniform actions across different co-workers. Specifically, the robot first identified a set of actions that were effective in evoking positive emotional responses (e.g., positive valence and arousal) and high productivity for a specific co-worker. This co-worker was selected because the emotional responses were the most similar to those of as many other co-workers as possible. The identified actions were then applied uniformly to all other co-workers. The third type is the proposed personalized emotion-adaptive robot control strategy, which would allow the robot to learn the emotional responses of each co-worker, leading it to take actions for fostering positive emotional responses while pursuing high productivity.

Table 1. Four Types of Robot Control Strategies.

Four Types		Consistency	Objectives
1	Productivity-prioritized (Represent Practice)	Same for All People	• Maximum Productivity
2	Standardized Emotion-Adaptive (Represent Other Studies)	Same for All People	• Maximum Productivity • Positive Emotions
3	Personalized Emotion-Adaptive (Proposed Behavior)	Personalized	
4	Fully Emotion-Aware (Ground Truth)	Personalized	

The fourth type represents the theoretical optimum (ground truth) when a robot is fully aware of the emotional responses of co-workers (i.e., regression models of Eq. 4) even before encountering them. This type of robot control may not be practical but can provide insights into how the robot can behave if it is fully aware of co-worker's emotional responses as an ideal case.

We specifically compared the four types of robot control strategies in terms of 1) the number of virtual co-workers who exhibited the desired emotional responses during the 1 team-hour of bricklaying, 2) the average duration of the desired emotional responses across the 20 co-workers, and 3) the average of the number of bricks laid for 1 team-hour. Notably, the robot with the proposed control strategy spent 15 minutes with each co-worker prior to the bricklaying task, as this time was required to initially explore and understand the co-workers' emotional responses.

4 Results and Discussion

The proposed personalized emotion-adaptive robot control strategy could promote the desired positive emotional responses for all 20 virtual co-workers (100%) for around 37 minutes during the 1 hour of simulated bricklaying task (3rd type in Table 2). Every co-worker could experience positive emotions for at least 20 minutes. The results present the potential effectiveness of the proposed robot control strategy in promoting desired emotional responses in co-workers, which can be critical to enhance co-workers' performance and human-robot cohesion for better productivity in human-robot teams.

The comparison of these results with those of the first and second types of robot control strategies is particularly noteworthy. These strategies could only promote positive emotional responses in 5 and 7 virtual co-workers, respectively, and the average durations of positive emotions across 20 co-workers were 15 minutes and 21 minutes, respectively. Although the strategies were effective for some virtual co-workers to exhibit positive emotions during the entire 60 minutes of bricklaying, they were not effective at all for the majority of virtual co-workers. These results present that promoting desired emotional responses in co-workers can require deliberate efforts to consider each co-worker's potentially different emotional responses. Otherwise, prolonged HRC with negative emotional status (e.g., anxiousness and fear) can cause co-workers to have reduced trust in robots, decreased collaboration efficiency, and potentially lead to psychological discomfort or stress, ultimately affecting the overall productivity and cohesiveness of human-robot teams [11,22].

It is noteworthy that the proposed robot control strategy enables the robot to execute personally different actions by considering individuals' emotional responses. As shown in Figure 3, the robot's actions were quite different to different co-workers. While emotional responses can be different among individuals, the proposed robot control strategy holds potential to consider each co-worker's emotional responses for fostering desired responses during HRC.

While promising, however, the proposed robot control strategy still has a room for improvement. The fourth type of robot control strategy shows that all 20 virtual co-workers could theoretically exhibit the positive emotions for around 58 minutes during the bricklaying task, while laying a greater number of bricks. These results present that advancing the proposed robot control strategy to promote desired emotional responses in co-workers for longer duration while maintaining higher productivity can be a direction for improvement.

Meanwhile, although the first type of robot control strategy was not effective in promoting positive emotions in co-workers, it could achieve higher productivity in human-robot teams compared to the proposed and the ideal robot control strategies (types 3 and 4 in Table 2). This can be interpreted that considering and promoting co-workers' desired responses may sacrifice the productivity in human-robot teams.

Such a potential loss in productivity in human-robot

Table 2. Emotional Responses and Productivity by the Four Types of Robot Control Strategies.

Four Types	# of Co-workers w/ Positive Emotions	Avg. Duration of Positive Emotions	Est. Productivity in Human-Robot Teams
1	5 out of 20 (25%)	15 mins (Min: 0, Max: 60)	314 bricks per one team-hour
2	7 out of 20 (35%)	21 mins (Min: 0, Max: 60)	256 bricks per one team-hour
3	20 out of 20 (100%)	37 mins (Min: 20, Max: 60)	244 bricks per one team-hour
4	20 out of 20 (100%)	58 mins (Min: 20, Max: 60)	286 bricks per one team-hour

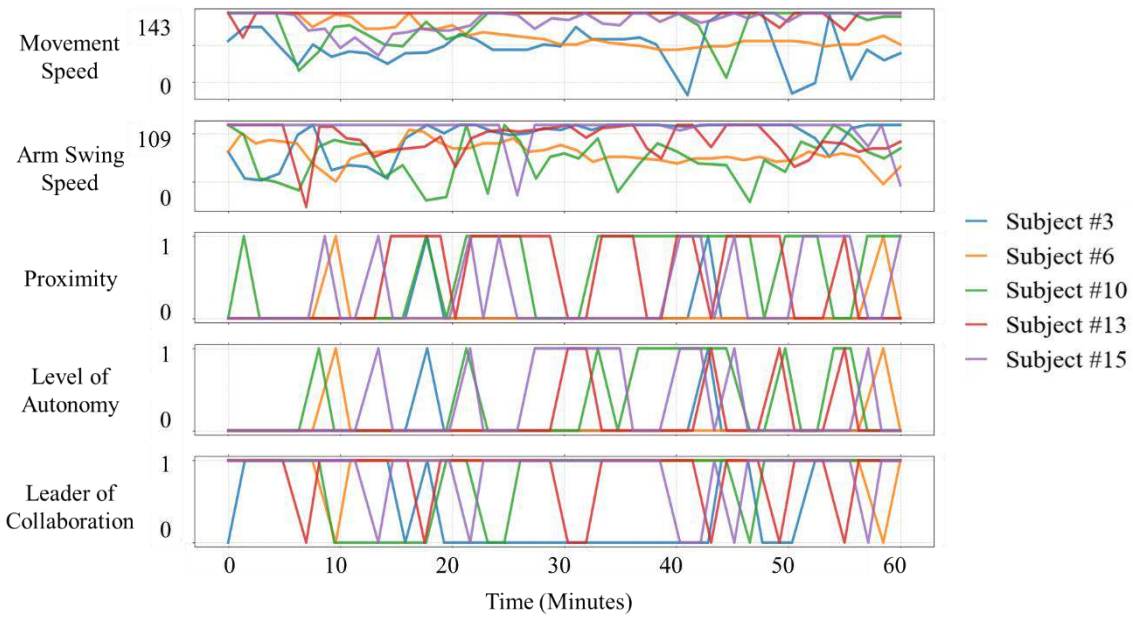

Figure 3. Robot's actions to five different subjects during the bricklaying task.

teams while promoting desired emotional responses in co-workers can raise ethical questions. For example, to what extent is a productivity loss acceptable to ensure co-workers' emotional well-being? Conversely, to what extent can a sacrifice in co-workers' emotional responses be justified to enhance productivity? This presents the clear need for further analysis regarding how we can balance emotional well-being and productivity, particularly in the construction industry, where productivity is crucial.

Grounded on the findings of this study, our future study can be two-fold: 1) demonstrate the effectiveness of the personalized adaptive robot control strategy during the interaction with actual co-workers, as this study simulated the responses of co-workers using the regression models; and 2) examine its effectiveness in other types of HRC in construction, which can involve HRC for different construction tasks, HRC with different construction robots, and HRC without direct physical interactions between humans and robots. The findings of this study are expected to provide a solid foundation for future research, aiming to achieve the emotional well-being of co-workers as well as more productive HRC in construction.

5 Conclusion

Emotions are crucial human responses, affecting human performance and human-robot cohesion, which can be potentially important for the success of HRC in construction. In this study, we propose a robot control strategy that aims to promote desired emotional responses in each co-worker while pursuing the high productivity of human-robot teams. We demonstrated the effectiveness of the proposed robot control strategy by comparing it with predominant strategies of robot control, such as those prioritizing productivity or standardized across people, through a simulated bricklaying task in a virtual environment with 20 people as co-workers. The proposed robot control strategy could lead to the desired positive emotions in all 20 co-workers for around 37 minutes during the 1-hour bricklaying task. Our results present the proposed personalized emotion-adaptive robot control strategy as an effective strategy to aim for promoting desired co-workers' emotional responses, which can contribute to enhancing co-workers' performance and human-robot cohesion. At the same time, the results raise a major question about how we can minimize the potential sacrifice in productivity in human-robot teams, which may arise as we consider co-workers' responses. While future research are expected, aiming to demonstrate the effectiveness of the proposed robot control strategy with actual co-workers for different construction tasks, the findings of this study can serve as a solid foundation to achieve more productive and cohesive human-robot teams in construction.

Abstract –

The Architecture, Engineering, and Construction (AEC) sector faces increasing pressure for higher production rates amidst a growing shortage of skilled labor, driving the demand for advanced robotic applications to enhance precision, efficiency, and adaptability in complex environments.

This paper introduces a software setup designed to ensure collision-free movements for multi-axis robots in AEC scenarios. Our approach leverages the NVIDIA cuRobo framework's robust capabilities, seamlessly integrated with Grasshopper for Rhino 3D software (GH), a tool widely recognized for its versatility in parametric design.

The integration of these technologies allows for the efficient online generation of optimal path movements, avoiding collisions even in highly intricate settings and changing environments. This is achieved in a remarkably short timeframe, enhancing productivity and reducing downtime. NVIDIAs framework's GPU-driven architecture paired with our GH parametric and controlling setup is a significant advancement, validated through a case study involving a complex, tree-like structure constructed from timber sticks. Using a six-axis robotic arm, the study demonstrates the system's capability to navigate and manipulate within congested spaces efficiently. With this enhanced automation workflow, new possibilities emerge for robotic applications, from industrial automation to sophisticated construction projects. Our GH software also allows visualization and exchange with URDF-models and better planning of collision logic, which was previously only possible with ROS and Nvidia Isaac technology.

Keywords –
collision-free path planning, multi-axis robots, AI robotic automation, parametric design

1 Introduction

Collision-free path planning is one of the most complex challenges in robotics, particularly in the AEC industry, where multi-axis robots must navigate dynamic, congested, and constrained environments [1]. We define collision-free in this study as the ability of the system to generate paths that avoid both self-collisions and external obstacles while optimizing for smooth motion and execution speed. Traditional path planning methods, such as manual programming or basic algorithms, are time-consuming and prone to errors, making them unsuitable for the intricate geometries and real-time adaptability required in construction scenarios. While advancements in sampling-based and grid-based algorithms have improved pathfinding capabilities, their integration into widely used design tools remains limited. Most existing solutions in platforms like Grasshopper for Rhino3D (GH) do not support real-time collision avoidance, leaving a critical gap in robotic automation workflows.

This paper addresses this gap between computational robotic planning and architectural workflows, making robotic automation more accessible to AEC professionals by introducing a novel framework that integrates NVIDIA cuRobo [2], a GPU-accelerated motion planning library, with GH. By leveraging cuRobo's advanced capabilities, the system enables real-time, collision-free path planning, even in dynamic environments. This streamlined approach eliminates many of the barriers associated with traditional methods, offering a robust solution for automating complex robotic tasks. The framework's effectiveness is validated through a case study of a robotic timber structure assembly, demonstrating its ability to navigate full cluttered environments with precision and reliability. This advancement represents a significant step toward solving one of the core challenges of robotic automation in the AEC industry.

2 Background & Related Work

The integration of multi-axis robots into the AEC industry has significantly advanced automated fabrication and assembly processes. A critical component of this integration is the development of efficient, collision-free path planning algorithms that can be seamlessly incorporated into architectural design software environments.

Path planning for multi-axis robots involves computing trajectories that avoid obstacles, adhere to the robot's kinematic constraints, and optimize performance metrics like speed and precision. Traditional methods often relied on manual programming, which is time-consuming and susceptible to errors. Recent advancements have focused on automating this process to enhance efficiency and adaptability in complex architectural tasks. One of the most common algorithms comes from the group of **Sampling-Based Algorithms**, such as Rapidly-exploring Random Trees (RRT) and Probabilistic Roadmaps (PRM), that have been widely adopted for robotic path planning in software solutions [3]. These algorithms explore the robot's configuration space by randomly sampling points and connecting them to construct feasible paths. For instance, RRT incrementally builds a tree by randomly sampling the configuration space, effectively handling high-dimensional spaces typical of multi-axis robots. However, their direct application within design environments has been limited, necessitating the development of more accessible tools for architects and designers. In contrary to this, the **Grid-Based Algorithms**, such as the A* algorithm, operate on a discretized representation of the environment [4,5]. They evaluate possible paths based on cost functions to determine the most efficient route. In construction scenarios, an improved A* algorithm with a dynamic weight heuristic has been developed for global path planning, enhancing the robot's ability to navigate complex sites. Our paper describes the implementation of NVIDIA-cuRobo Algorithm that falls into the category of **Optimization-Based Algorithms.** In recent years, optimization-based algorithms have gained prominence in robotic motion planning, particularly for complex tasks requiring smooth and efficient trajectories. These algorithms frame motion planning as an optimization problem, aiming to find the best path according to specific criteria, such as minimizing time, energy, or/and avoiding obstacles.

To bridge the gap between advanced path planning algorithms and architectural design, several plugins have been developed to enable robot programming within design software. For instance, the Software RoboDK [6], which incorporates the PRM motion planner, integrates path planning software interfaces into computational design environments to automatically generate collision-free paths within the robot's workspace. Another example is MoveIt [7], which integrates seamlessly with various computational platforms to facilitate motion planning, collision checking, and trajectory generation. Unlike RoboDK, which focuses on predefined paths within industrial environments, MoveIt is often used for more dynamic and adaptive scenarios, making it suitable for robotics applications that require real-time decision-making or complex manipulations.

Those two software solutions are commonly used in industries such as automotive manufacturing and aerospace, where fabrication setups often rely on highly predefined and controlled processes. Althought RoboDK has a GH plugin and MoveIt can be integrated within Compas-Fab [8| framework the collision-free path planning is not trivial and robust. ROS and its simulation platforms, Gazebo and PyBullet, are excellent for developing robotic systems similar to those presented in this paper. Their integration with NVIDIA Omniverse also makes them potential candidates for automatic collision-free path planning. However, these systems require specialized robotics and programming expertise, posing a barrier to adoption in the AEC industry. While no definitive study exists on the most widely used software in AEC robotic fabrication, the prevalence of Rhino and Grasshopper (GH) plugins across major robotic and software companies suggests its dominant role. GH's visual programming capabilities lower the technical barrier, making it a crucial bridge between design and fabrication, particularly in parametric workflows with evolving design constraints.

For GH, several plugins are available for robotic control and path planning, including HAL, KUKA|prc, Robot Components, Robots (by Visose), FU-Robot, and Machina [9] that makes it a serious tool for robotic control. However, despite their utility, none of these plugins currently support collision-free path planning, primarily due to the complex nature of the task and the substantial computational power required. Real-time, collision-free path planning remains a significant challenge within these design environments. The intricacy of architectural geometries, parametric setups, the presence of dynamic elements such as moving objects and actors, and the high level of customization required, demand more advanced solutions. These solutions must be capable of managing complex design constraints while providing immediate feedback to designers.

3 cuRobo

A notable advancement in the area of automatic collision-free path planning for robots is NVIDIA's cuRobo, a GPU-accelerated library [2]. By leveraging the parallel processing capabilities of GPUs, cuRobo formulates motion planning as a global optimization problem, enabling the simultaneous evaluation of

multiple potential solutions. This parallelism allows cuRobo to solve complex motion generation tasks in approximately 50 milliseconds on average, achieving speeds up to 60 times faster than traditional trajectory optimization methods. It's efficiency stems from combining straightforward optimization techniques with numerous parallel starting points, or "seeds." It utilizes the L-BFGS method—a popular optimization algorithm for estimating step directions—alongside a novel parallel noisy line search strategy and a particle-based optimization solver. Additionally, the algorithm incorporates a parallel geometric planner capable of generating plans within 20 milliseconds and a collision-free inverse kinematics (IK) solver that can process over 7,000 queries per second. These capabilities make cuRobo a powerful tool for real-time robotic applications, including those in the AEC industry, where rapid and reliable motion planning is essential for tasks like automated fabrication and assembly.

The software requires installation on a robust system equipped with a CUDA-capable NVIDIA GPU of Volta or newer architecture, operating on Ubuntu 20.04 or 22.04, although it also works on Debian 11. A Python environment with version 3.10 is recommended, and the software depends on PyTorch version 1.15 or newer. These requirements, including the reliance on a Linux operating system and high-performance hardware, present significant barriers within the architectural and construction industries, where such setups are not commonly available. Additionally, the simulation environment, based on NVIDIA Isaac, a platform designed for developing and deploying robotics applications, further complicates testing different configurations due to its specialized requirements, such as loading Universal Robot Description Format (URDF) files, and the need for high-level technical expertise to adapt it to real-world scenarios. To address these challenges and use the paralleled speed and precision of this framework, we propose a novel setup that integrates high-performance computing with GH for AEC professionals.

4 Grasshopper – cuRobo Setup

The system setup integrates three interconnected software frameworks: cuRobo, Grasshopper and MQTT (Figure 1). **cuRobo's** AI-powered system is equipped with a Python API. It operates by loading a configuration file tailored to a specific robotic setup, such as the Universal Robots UR10e and others, to enable seamless integration and control. It operates headless by just responding with the calculated results (joint values, environment, error messages etc.). **Grasshopper in Rhino3D** (GH) serves for the visual and parametric interaction of the environment (world and robot) with the user as well for the control of the real robotic system. **MQTT**-communication framework stands between the two systems that assures low-level, easy to implement exchange of data. While the MQTT-broker Mosquitto [10] is installed on Debian Workstation, MQTT-clients were implemented inside cuRobo python code and on GH side in form custom build MQTT components, both based on Paho-clients.

Figure 1. Scheme of the system setup: Left – Debian GPU workstation with cuRobo, connected to a GH user computer via an MQTT connection and to the robot via cable.

The backbone of the whole concept is cuRobo API that comprises interconnected modules designed for efficient and precise robotic motion planning. Key components include optimization solvers (curobo.opt) for refining trajectories, kinematics handling (curobo.cuda_robot_model) for forward and inverse computations, and collision detection (curobo.geom) for safe motion planning. Modules like curobo.graph enable geometric pathfinding, while curobo.rollout evaluates motion strategies by mapping actions to costs. High-level wrappers (curobo.wrap) simplify task programming, including collision-free reaching, and curobo.types standardizes data structures. The curobo.wrap.reacher module provides a high-level interface for programming tasks involving collision-free reaching. It simplifies the process of generating safe and efficient motion trajectories, enabling seamless implementation of reaching tasks within various robotics workflows.
Robots are represented in URDF files, along with their collision spheres in an additional YAML file. Another configuration YAML file defines the entire additional setup, as well as the dimensions of the optional end-effector. The world in cuRobo is also represented in this manner but can be programmatically reloaded after the system is initialized. This is important because the elements can change positions in a dynamic environment. Once initialized, the running program waits for a path creation command and returns either a successful path or a message explaining the reason for failure. Other commands update the world or read the collision spheres for improved visualization (Figure 2).

Figure 2. Rhino 3D / GH visualization of 1) Collision spheres of the robot; 2) Collision spheres of the attached stick; 3) World collision object of the cable connection of the robot.

GH handles the visualization and control of the setup. Inside GH, we read the shared robot URDF file and display the output of the resulting joint positions calculated by cuRobo. Additionally, GH is used for world creation, which is reflected back to cuRobo. Visualization and path rehearsal (Figure 4 and 5) are crucial for ensuring safe execution, especially in complex design environments. We enable designers to preview paths, identify potential issues, and refine movements before execution. This prevents costly errors and enhances user confidence. Additionally, we can plan attaching elements to the end-effector and send this configuration back to cuRobo, which incorporates the attached element into collision-free path planning. After detaching, the new world is updated with the element's new position. For this, a unique URDF reader for GH has been developed and incorporated (Figure 3). This makes it much easier to build novel robotic setups as well as collision sphere setups.

The third part is the communication system, whose purpose is to simply incorporate subscription and publisher capabilities on both sides. MQTT can be optimal for secure and rapid communication between subscribers and publishers in the form of topics. It requires an MQTT broker, which most platforms provide, and clients are widely available. For the case study, we incorporated four request topics and five response topics. Depending on the network quality and data size, it will deliver an almost immediate response (see Latency chapter).

The control inside GH consists in these three elements:

Exchange procedures GH with cuRobo. Here we can send the world setup, this means all objects in the real or simulated world, from GH to cuRobo in a form of a list of elements with their dimensions and poses. Vice versa, we can pull the world from cuRobo to cross-check how it sees the world. Furthermore, we can also pull information about the collision spheres for cross-checking the YAML file. This helps a lot also to identify the position of the robot from the cuRobo side.

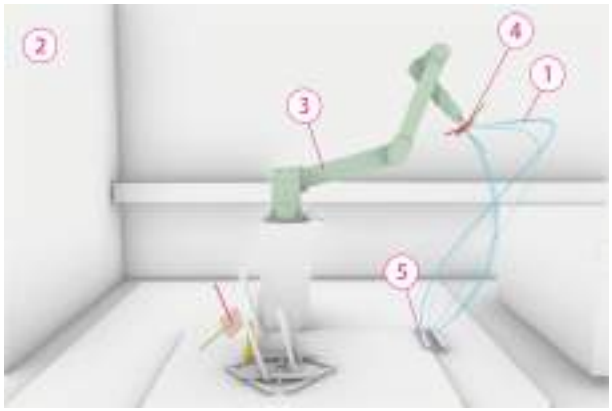

Figure 4. Representation of the real world translated in Curobo and visualized in Rhino3D / GH. 1) automated path options considering the world and self-collision; 2) world perception of Curobo; 3) Robot representation from URDF-file and cuRobo joint positions; 4) start position; 5) goal position

Figure 5. the original scenery

Path queries from GH to cuRobo in form of sending the initial start position (joints) and the desired goal position (plane, position, and pose). This fires back an array of joint positions that can be previewed. Every query will generate a unique new collision-free path. It considers the environment and prevents self-collision. In addition to the path query, we can attach or detach objects to or from the end-effector, in the case of gripping an object or similar. In this case of attaching, the object is removed from the world, and additional collision spheres will be created in the volume of the object as a part of the robot. All subsequent movements of the robot take these new collision spheres into account. In the case of not finding a valid solution for the target pose, start or goal collision states, or other failings, we can provide GH with feedback from cuRobo.

Robot control commands send the calculated new joints to the robot. Here, we can also add other commands, such as gripper control, depending on the robot being used.

5 Latency

The great advantage of cuRobo is its speed. In contrast to other motion planners described in the previous chapter, which often take several seconds to optimize a trajectory, cuRobo requires only 1/5–1/10 of a second. Black Coffee Robotics [11] compared RRTConnect-based MoveIt2 (MI) and cuRobo. In an obstacle-free environment, the results are similar (cuRobo/MI – 100%/96% success rate – 0.19 sec./0.17 sec.). In an environment with obstacles, cuRobo outperformed MI in terms of reliability and trajectory quality (cuRobo/MI – 90.32%/62.50% success rate – 0.69 sec./0.33 sec.).

The response in a system with multiple elements, as described in this paper, is dependent on several factors, such as the computers used and the connection between them. In our setup, cuRobo runs on a Linux workstation with an Nvidia RTX A4000 GPU with 16GB RAM. The computers are connected over a VPN network with a minimum 200 Mb/s download speed using the MQTT framework. GH is running on a MacBook Pro (2021). The average path calculation measured in GH, from activating the toggle until receiving the joint positions, is approximately 200–250 ms (Figure 4). With such speed, an almost continuous flow preview of possible paths for moving elements is possible.

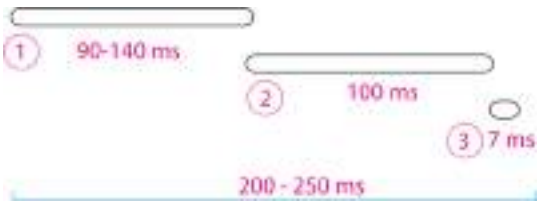

Figure 6. Approximated processing time 1) Path calculation (Python API time measure); 2) MQTT transfer (Mqtt-explorer timestamp); 3) GH path creation (GH profiler).

6 Case Study

To test the automatic collision-free path planning with conventional path planning, we required a sufficiently complex structure that went beyond the typical simple stacking examples. For this purpose, we utilized an ongoing collaborative project with the University of Tokyo. The task involved constructing a wooden structure composed of identical modular elements measuring 18x18x300 mm. In this "classical path planning scenario," two robotic setups were established in Japan and Germany to test remote collaboration scenarios for robotically assembled structures. In each facility, a collaborative robotic arm (cobot - respectively UR10E and UR10) was installed in front of a wooden base on which to perform the assembly. Both setups' gripper end effectors were the OnRobot RG6 finger gripper. The different tool mounting technology caused slight variations in the tool center points. Despite these small differences in the robots' end-effector positions relative to their frames of reference, both setups had very similar reachable workspaces.

In this modular construction system, the sticks are glued together along one of their long faces to form tree-like structures. The simplicity of the assembly rules, paired with the complex architectural results they create, makes it an excellent platform for experimenting with robotic assemblies [11]. The outcome of the original tests was a twin structure in both locations together with the design and fabrication data that was exchanged through a synchronized JSON file stored on a shared Dropbox folder. The JSON file included geometrical information

that was used to build another twin structure [12].

We replicated the experiment of the structure assembly of the first 12 sticks, and instead of manually or parametrically constructing the path, we relied solely on the cuRobo path-planning capabilities. The 3D model was built in GH, and all sticks were positioned at the pick position. The assembly consisted of several parts where all movements and attaching/detaching were made by cuRobo:

1. Movement from home to one of three offset gripping positions of the stick to be picked.
2. Opening the gripper and a movement towards the picking position.
3. Closing the gripper and a movement to the offset position.
4. Virtual attaching the stick to the robot.
5. Movement towards the offset placing position.
6. Movement to the placing position.
7. Opening the gripper and virtual detaching the stick from the robot.
8. Movement to the offset position.
9. Movement back to the home position.

All movements had their preview state in the form of a curve to ensure that the movements were possible and within the desired area. As soon as a preview was validated as valid, it was sent to the robot for execution. The gripper openings and closings were controlled manually through the same GH controller.

The movements were extremely accurate and immediately available. As we had the previews of the movements, we could execute the robot without fear of colliding with other objects, even with the stick in the gripper (Figure 5). Sometimes, it moved very near to objects, which made us nervous.

After the fifth stick, a collision still happened. We forgot to account for the cable connection to the robot that was facing towards the sticks. The joint position of the shoulder squeezed the connector and disconnected it from the power. We had to release the joints manually and rotate the shoulder away. After we integrated the connector into the world (Figure 3), this unusual position never repeated.

As we tested the cuRobo URDF file of a UR10e robot on a real UR10 robot, discrepancies in the calculated positions limited us to only 12 sticks. These discrepancies arose because the base of the UR10e is 15 mm higher than that of the UR10, along with some minor differences in arm length and will be improved in the next tests.

This specific case study demonstrated the technical capabilities of cuRobo in generating fast and precise collision-free paths, seamlessly integrating with Grasshopper for real-time visualization and robotic control. However, limitations emerged, such as discrepancies between simulated and real-world robot models, the need for manual adjustments to account for unmodeled elements like cables, and the lack of real-time dynamic obstacle handling.

7 Conclusion and Discussion

This study successfully integrates advanced AI-based software for collision-free path planning into an architectural workflow, offering significant potential for robotic automation in the AEC industry. By combining the NVIDIA cuRobo framework with Grasshopper in Rhino3D, the system eliminates the need for complex environments like NVIDIA SIM, streamlining the process and lowering adoption barriers. The case study demonstrates the framework's precision and efficiency in generating accurate collision-free paths, enabling complex assembly tasks with minimal intervention. Real-time visualization further empowers users to plan and execute robotic movements confidently.

The system excels in speed, precision, and accessibility. The GPU-accelerated cuRobo framework outperforms traditional motion planners, generating results in near real-time. Its integration into Grasshopper ensures AEC professionals can work within familiar environments, enhancing usability. Additionally, the system's ability to adapt to dynamic changes, such as object attachment and detachment, underscores its flexibility for construction applications.

Despite these strengths, challenges remain. The dual-hardware setup and the need for a CUDA-capable Linux system pose barriers for widespread adoption. Compatibility issues, as seen in the discrepancies between UR10e and UR10 hardware, highlight the need for precise configuration, and oversights in collision modelling, such as the robot's cable connection, demonstrate the importance of comprehensive planning.

Future research will focus on incorporating real-time scanning and dynamic feedback to handle variable environments, as well as developing intuitive control methods like voice or semantic commands. Expanding compatibility to include more robot models and releasing an open-source library is planned.

Abstract –

Architects and construction engineers have long been intrigued by a future where robots become pervasive in the built environment. Recent technological advancement has made this once utopian vision appear more feasible than ever. However, in the discourse of construction robotics, there seems to be insufficient discussion on the relationship between robots and buildings, the two key entities involved. This study delves into the robot-building dyad by taking a historical perspective to examine how their interactive dynamics evolves over time: (a) from an objectified dualism in the past, (b) to an increasingly blurry boundary in the present, and (c) to a prospective symbiosis with mutual benefits. We argue that this shifting dynamic is underpinned by large-scale digitalization and the empowerment of artificial intelligence. Blue-sky prospective scenarios are discussed, where the robots become an inherent part of the building (like the MEP system), or the building itself becomes a robot (like Howl's moving castle). It is our hope to stimulate further discussion on the critical robot-building relationship, gaining a clearer view of which could help overcome the theoretical dilemma hindering wide-spread robotization in the built environment.

Keywords –

Construction robotics; Robot-inclusive built environment; Robot-building dynamics; Robot-oriented design.

1 Introduction

The architecture, engineering, construction and operation (AECO) sector is facing enormous challenges in recent years. Deeply rooted in the complexity and fragmented nature of the industry, its productivity has been stagnant over the past 20 years [1]. The problem is further exacerbated by the lack of skilled labor force, and the increasingly stringent environmental requirements imposed by climate change. To make the situation even worse, many developed economies in the world are experiencing simultaneous deterioration of their building mass and demographic profiles, which is usually referred to as a "double aging" issue [2]. The aging building stock is awaiting proper maintenance or redevelopment on the one hand; and on the other, the shrinking population fails to provide solid workforce for facility upkeep.

Robotization offers a promising solution for the demographic challenge, as well as performance improvement in the AECO sector. For their superiority over humans in terms of consistency, precision, efficiency, and durability, the use of robots is expected to enhance productivity, ensure safety, and reduce wastes [3]. The benefits of robotization have been recognized from early on. In 1980s, pioneering attempts were first made to deploy robots in construction, with Japen as the leading player [4]. These explorations were profit-driven in essence, and thus were largely spearheaded by industrial practitioners. It was not until ten years later that the academia started to follow up. Signified by the establishment of The International Association for Automation and Robotics in Construction (IAARC) in 1990, systematic research efforts have been made to examine construction robotics from a theoretical perspective. The research input has been stagnant afterwards due to technological limitations, but the advancements in AI and automation in recent years re-attract significant attention to this area.

Despite its ups and downs, the discourse on construction robotics seems to be predominantly technology-oriented. Seldom has previous research taken a broader view to examine the relationship between robots and buildings – the two core entities explicitly expressed in the terms "Construction Robotics". Clarification on this somewhat overlooked dyad is essential because of a mutually reliant but also exclusive nature. They are mutually reliant, in a sense that the robots require the physical environment provided by the building to carry out their activities, whereas the building depends on the robots to materialize, inspect, and maintain. At the same time, the distinctive differences between their inherent characteristics also lead to a series

of compatibility problems, whether it is regarding the autonomy level, functional purposes, or just the sheer size of them.

The few attempts to research the topic mainly happened during late 1980s and early 1990s. Back then, the field of construction robotics was still in its infancy. Inspired by the success of robotics in manufacturing, research at that time tried to draw useful experience by separating the building as individual entity from the dyad and comparing it to the production line [5]. Similar to "lean" production in the manufacturing industry, Koskela [5] proposed a process improvement in construction to embrace robotization, but the fragmented and project-based nature of construction makes it more difficult to achieve standardization. Warszawski and Sangrey [6] conducted an in-depth analysis on the respective features of industrial robots and building activities, and proposed possible adaptations of the construction process and building components for efficient applications of robots. Skibniewski and Nof [7] evaluated the readiness of existing construction environment for robotization, and recommended required changes in work organization and construction system. Despite the foundation laid by these pioneering studies, the robot-building relationship has never been formally defined and investigated. Nor has it been examined via a systemic framework in terms of how the relationship evolves over time.

To fill in the gap, this paper aims at examining the dyadic relationship between robots and buildings and its evolvement through a historical perspective. A "Past-Present-Prospect" model is conceptually proposed, which views robots and buildings as dynamically evolving entities that change with the advancement of technologies such as digitalization, industrialization, and AI. The research contributes to the field of construction robotics by theorizing current dilemma faced by construction robotics as a robot-building compatibility problem, and paving the way to its resolution with a clearer view on the robot-building relationship.

2 A conceptual model of the evolving robot-building relationship

A "Past-Present-Prospect" model is proposed to help interpret the evolving robot-building relationship, as shown in Figure 1.

Figure 1. Conceptual model of evolving robot-building relationship.

The study of a subject matter would not have been possible without a clear definition of it. This is also the same when it comes to investigating the robot-building relationship with a historical perspective. The connotations of term "robot" and "building" shift gradually over time, and the scope of objects they refer to does not remain static. For the sake of discussion, we tend to adopt the broadest possible definitions of both. According to the Cambridge Dictionary, a building is a structure with walls and a roof; it can also refer to the process or business of making structures. As for robots, they are generally accepted as machines capable of carrying out a complex series of actions automatically. Despite the varying level of autonomy (e.g., Teleoperation, Supervisory control, Autonomous) [8], an object has to be a machine to become a robot.

As shown in Figure 1, with the risk of over-simplification, both robots and buildings are going through a process of transformation from objects — passive entities that cannot react to external stimulus, to agents — proactive entities with the ability to perceive, plan, and react.

In the past, a robot is nothing more than a deaf-and-dumb machine. Despite being through several revolutionary innovations in terms of their power source (from horse power, to steam and to internal combustion) [9], they were used merely as objective tools to materialize the built environment. The building, on the other hand, is solely made of bricks and mortar [10]. As objects, they can neither sense nor think, let along reacting to a change of the environment. With this objectified nature, the relationship between the machines and buildings is purely utilitarian. Machines are used to construct the building, and the building, as gradually being materialized, offers the physical environment where the robots operate.

At present, with the arrival of the digital era, this relationship gradually changes. A widely accepted but less radical solution is to retrofit existing machines and buildings with an array of digital technologies, in particular the ability to sense intrinsic or environmental changes [11]. As they are being digitalized, the boundary between robots and buildings are becoming vague. The interaction between digital machines and digital buildings not only happens in the physical space, but also in the digital world. This is because the robot can simultaneously sense the built environment and update it to the corresponding digital model as it is being materialized. The other way around, the digital building model, e.g., a building information model (BIM), not only serves as an environment model in the virtual space useful for robot simulation, but also provides a reference map for the robots to perceive their environments.

In the long run, as robots and buildings become gradually intelligentised, they would eventually become

agents. On the one hand, the machines will eventually become robots in the most rigorous sense, meaning that they are able to sense environmental changes, to process and interpret them, and to response independently. On the other hand, the once bricks-and-mortar structures will be turned into smart buildings, which perceive and proactively response to internal (e.g., occupancy) or external changes (e.g., weather, sunlight). This dyad would then eventually become a mutualistic symbiosis, where they are nurtured by each other, and mutually enhanced. However, as a millennium-old profession, construction is deeply rooted in its history, local culture, geographical conditions, etc., and notoriously reluctant to changes. The road to autonomy (and the resulting symbiosis) would be by no means easy. Therefore, researchers [11, 12] have suggested distinct paradigms, which either propose an incremental shift based on existing mature tools and techniques, or strive for a radical change by adopting emerging technologies.

3 Past-to-Present: Blurring boundary between robots and building

The shifting robot-building dynamics from the past to present is underpinned by digitalization. Augmented by an array of digital technologies (e.g., smart sensing, automation, IoT, CAD, simulation), the once deaf-and-dumb machines and buildings are empowered by a sensing ability to understand a change of their environments and their digital representations for simulations. They thus become digital machines and buildings.

The various construction machines used in the building sector evolve as the broader industrial context changes. From an energy source perspective, they have gone through a transformation from being steam-driven to diesel-driven. The latest equipment of computer systems and various sensors elevate them to another level as digital machines, which are able to perceive their own operating status and external environment. When it comes to a digital building, interpretation concerning its definition, and connotation varies. Watson [13] confined the scope to only include a digital model that contains structured information of a physical building, whereas others consider a building augmented by an array of IT infrastructure (e.g., a building control system) as a digital building. This study accepts both interpretations, and defines a digital building as an IT-augmented man-made structure, and its digital representation used in various phases of project cycle.

The digitalization of machines and buildings means they can escape the constraints imposed by their specific physical embodiment. Therefore, interaction between the digital machines and digital buildings no longer remains at a materialism level, but enters the realm of cyber space. This allows the digital models of the machines and buildings talk to each other, and boundary lying in-between becomes blurry. On the one hand, the digital machines not only materialize the buildings, but can also map their surroundings simultaneously along the way; on the other hand, the digital building not only serves as the physical environment indispensable for the machines to operate, but also provide a digital model of the environment to empower the machines (e.g., to understand the environment).

3.1 Mapping buildings with digital machines

A major stream of recent works has been focused on sensifying traditional construction machinery. They are aligned with the incremental approach proposed in [11, 12], which renovates legacy machinery with suite of sensors and computing units. The purpose is to turn the machinery from purely a production tool to instruments with both production and measurement utility. Examples can be drawn from a field called intelligent compaction. In these studies, an array of sensors is installed to a conventional roller used for earthworks/pavement compaction. A typical setup includes an accelerometer mounted on the drum to infer material compactness from vibration, a GNSS unit to track position of the measurement, and some other sensors to collect values deemed necessary, e.g., temperature for asphalt pavement [14]. Thanks to the empowerment of sensors, the rollers can measure whether the materials have reached a desired level of compactness as it carries out the compaction work. Therefore, the moment the compaction finishes, a quality map of the entire working area can be expected. Such sensory augmentation goes beyond compacting machines. Any mechanical-based construction machinery can be given senses to with the help of modern computing instruments. Niskanen et al. [15] developed a 2D profile-augmented excavator, which can dynamically map earthwork surface as it operates. Sun et al. [16] sensified a dozer system with RTK GPS and inertial measurement unit (IMU) to collect machine pose information for construction guidance. The digital machines not only materialize the built environment in a physical sense, but also enrich the digital building/infrastructure model by constantly updating its condition information from the physical world.

The mapping function of digital machines does not stop at the construction phase. They have a critical role to play in facility operation and maintenance as well. These include, but not limit to, flying drones to inspect high-rise façade [17], and quadruped robots or unmanned ground vehicle (UGV) for indoor inspection. In many cases, such robots still rely on humans to remotely control their movements. With high-resolution cameras or LiDAR scanners onboard, they are able to collect first-hand data of the facility condition. These data are then

automatically processed by AI, which can detect defects of various types (cracks, dampness, spalling, etc.). 3D reconstruction and registration techniques are then applied to incorporate defect information (semantics and geometries) into the digital building model such as BIM. Figure 2 summaries a typical workflow.

Figure 2. Workflow of mapping building condition with drones.

3.2 Empowering machines with digital buildings

The other around, a digital building can empower digital machines in various ways. Most notably, a digital building model like BIM can contribute to robot perception of its surrounding by providing a readily available reference map. Two typical problems for robot perception are a) positioning and pose estimation, and b) object recognition/scene understanding.

In terms of robot positioning, several previous studies attempted to explore BIM as an internal world model to estimate the robot's spatial location and orientation. However, there is a cross-domain gap to overcome, which is caused by distinct texture and appearance differences between BIM and its corresponding real-world scene. To address this domain gap, end-to-end training-based approaches have been applied to directly regress robot pose information from BIM renderings [18]. A different approach is to use BIM renderings as a pool of space-aware features that can be compared with real-life photographs for pose estimation. Ha et al. [19] used high-level visual features extracted by CNN as registration targets to avoid the domain gap. Chen et al. [20], on the other hand, proposed a neural rendering approach to turn textureless BIM renderings into photorealistic ones with vivid texture. The synthetic images are not only more plausible to humans, but also more machine-readable (see Figure 3). Rich feature correspondences can be found between robot-collected photos and the synthetic renderings, which then allows pose estimation by solving a typical PnP problem.

By positioning current robot view in BIM, the rich semantic information from the digital building model becomes easily accessible for the robot's perception of the world. This typically involves: (a) Extracting current view from BIM; (b) Overlapping it onto camera view; (c) Retrieving semantics of arbitrary pixel in BIM; (d) Facilitating robot perception with the semantics from BIM. Figure 4 shows the perception of a drone in a building façade scene, where no training has been conducted for object recognition. Instead, it purely relies on semantic information from BIM.

Figure 3. Addressing domain gap between BIM and real scene via neural rendering (with SIFT as an example) [20].

Figure 4. Aligning aerial photograph with BIM rendering to facilitate robot perception.

4 Present-to-Prospect: Towards mutualistic symbiosis as intelligent agents

Looking ahead, both robots and building would eventually become agents with the ability of independent decision-making and autonomy. As agents, they will form a mutualistic symbiosis, where robots and buildings would rely on each other to grow and develop, and benefit from the association. To embrace this future, we need to (a) make robot smart, (b) make building smart, and (c) facilitate robot-building communication. Thanks to the advancing AI, many of these transformations are underway [21].

4.1 Making robot smart

Despite rapid development in the field of robotics, delegating robots fully with independency and autonomy remains risky and challenging. This is even the truth in the built environment with high occupancy dynamics, spatial complexity and affordance diversity.

It is thus imperative to make robots smart, especially regarding spatial intelligence [22], an ability for the robots to process spatial data, make predictions and act upon those predictions. As robots always function in a specific space context (e.g., the built environment), this spatial intelligence is particularly relevant. Connectivism

and symbolism have long been two mainstream schools of thoughts in AI. While the super performance of neural networks in recent years has put connectivism under the limelight, it is believed a convergence of top-down symbolism and bottom-up connectivism is critical when it comes to empowering robots with spatial intelligence.

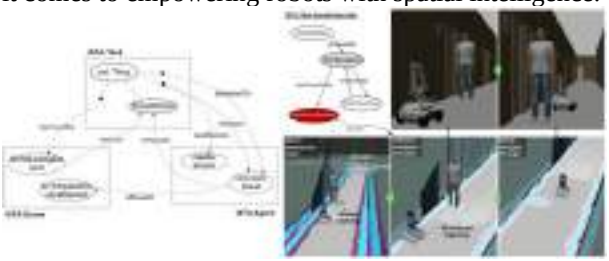

Figure 5. Knowledge graph for smart robot-based facility inspection.

Figure 5 shows a top-down knowledge graph for robot-based facility management (FM). It outlines how the robots should behave when facing different scenarios in the built environment. Combined with bottom-up connectivism neural networks (e.g., for human detection), it can empower robots to carry out advanced actions such as collision avoidance with humans in the corridor. FM robots are just an example. Thanks to the rapid advancement of AI, the entire AECO sector is adopting robots with increasing level of autonomy (LoA). Melenbrink et al. [11] conducted a comprehensive review of existing onsite autonomous construction robots, and rated their LoA according to a categorization system adapted from autonomous vehicle.

4.2 Making building smart

To make building smart, a plethora of studies have been conducted, either from a theoretical perspective or from an implementation standpoint. Ranging from smart home [23], cognitive building [24], to cognitive facility management [25], numerous terms have been proposed to explain and foresee how the once brick-and-mortar buildings would become intelligent with the empowerment of AI.

Different from the current digital buildings that are only able to sense and collect operational data, a smart building evolves to another level where it can react and response to a change of its external environment and internal occupancy situation. Such smart buildings can be built from the bottom up by the empowerment of intelligence to discrete building components (e.g., precast beams, columns, and walls) [26], and even to fine-grain construction materials [27]. As building components are intelligentized, they would eventually become agents that can better co-work with the robots as a material-robot system [28].

Once commissioning, the smart building can comprehensively analyse the data collected by the various sensors scattered in the building, and then independently make decisions given the current conditions. The decision would next be issued, activating actuators around the buildings to implement the decided plans. These smart building reactions can be as trivial as light control responding to room occupancy, or can be much more complicated in scenarios such as window curtain control in response to changing natural lighting. Figure 6 shows a smart living system adopted in the WCH student hostel project at The University of Hong Kong (HKU). It has integrated a smart light control system, an electronic lock system that can be controlled by students on their mobile phones, and a smart camera system to ensure safety of the dormitory area.

Figure 6. Smart building system adopted by HKU WCH project.

4.3 Facilitating robot-building communication

Smooth communication is a premise for taking advantages from each other between robots and buildings, further leading to the formation of the symbiosis. To this end, the robots and buildings need to be able to talk to each other, which entails a common language between the two parties. This, unfortunately, is not the case in current practice, as robotics and AECO industry have developed their own data schemas, i.e., the Unified Robot Description Format (URDF) for robots, and the Industry Foundation Classes (IFC) for buildings.

To mediate the gap, a potential solution is to create a common data environment between the robots and buildings based on IFC. The basic idea is to represent robots and relevant information with IFC, so that they can be compatible with mainstream building software for various applications, such as design, remote control, digital twin and so on. Figure 7 shows a model view definition for robot representation in IFC. Following this data model, a format translator has been developed to convert many of the existing URDF-based robot representations to IFC.

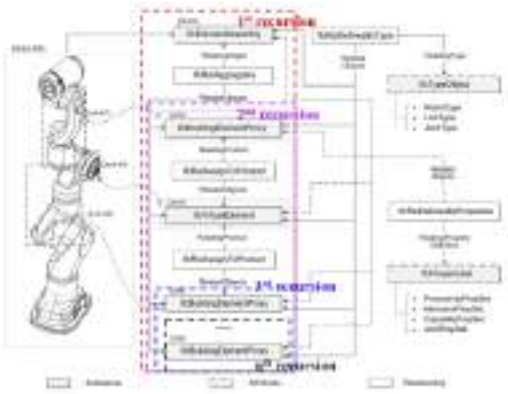

Figure 7. Model view definition for IFC-based robot representation.

Such an IFC-based common language can facilitate robot-building communication, enabling various applications such as robot-inclusive design. Many studies have underscored the need of rethinking building design and process improvement for robot adoption [29-31]. However, software tools are in absence to develop designs catered to the specificity of each project for robotic construction. IFC-based robot-building communication offers a means to resolve the fundamental interoperability problem in developing those design tools. Figure 8 shows an example of robot-inclusive design of a building MEP system. With the common language of IFC, the model of an MEP inspection robot can be directly imported into Revit. Since the robot and building models are in the same design software, one can easily identify clashes between them, and then timely adjust the design.

For construction/operation phase applications, as the IFC robot and building models are integrated in the same environment, the exchangeable information can be leveraged to enable application such as remote control. For example, as shown in Figure 9, by clicking a point in the building model, the robot can automatically navigate to that position. The robot arms and grippers can also be teleoperated by a remote human for more sophisticated tasks such as construction waste sorting.

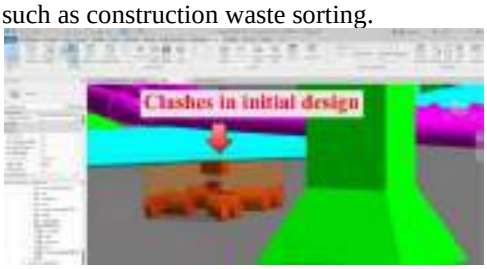

Figure 8. Inclusive design for MEP inspection robots.

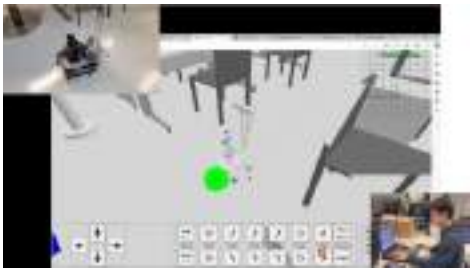

Figure 9. Robot teleoperation enabled by freely exchanged building information.

5 Discussion

Influenced by technological development, societal expectation, and cultural perception, the dyadic relationship between robots and buildings evolves over time. From a purely utilitarian dualism as objects, to increasingly blurry boundaries, and to a prospective mutualistic symbiosis, this shifting interactive dynamics calls for a fundamental rethink of what define a robot and a building, how they should be designed, and where their boundaries lie. Table 1 provides two different models to frame future robot-building relationship, and technological development required for their realization.

5.1 Robot as an inherent part of building

A way to formulate the problem is to consider robots as an inherent part of buildings. This requires a systematic thinking to take robots into account from the outset of building design. A comparable analogy can be drawn from the MEP in a building system, which needs to be considered at the design stage via multi-disciplinary collaboration for clash detection. This is gradually gaining attentions in the field of robotics. For example, in 2022, an office building called 1784 was constructed in Seongnam City, Korea, which claims to be the world's first robot-friendly building. The building was designed to allow a large population of autonomous mobile robots operating within it, and therefore is equipped with robot-friendly infrastructure, which includes world's first elevators exclusively for robots. During the Beijing Winter games in 2022, robots were widely deployed. Among them, there are robotic systems hanging from the ceiling in cafeteria, serving select cuisines individually. This is another example scenario where robots become part of the building system.

Table 1. Models and research required for future robot-building relationship

Model	R&D required

Robots as building parts	Integrated design and engineering, AI-powered generative design, IoT, BMS, Human-robot co-existence
Buildings as robots	Electromechanical building materials, Ambient intelligence, Urban science and design

Further research and development (R&D) are needed to widely deploy robots as parts of the building system. Fundamentally, an integrated mindset is required to design and engineer the building system with robots integrated. The robot design considerations, along with the uncertainty when it interfacing with buildings, is expected to significantly complicate the system design. The complexity can be mitigated by emerging AI-powered design tools. Once the robot-integrated buildings are put in place, the building management systems (BMS) will need to be substantially upgraded to ensure the robot swarms are under control, where the IoT is essential for robot-robot and robot-building communication. In the long run, with more and more robots entering the living environment, the problem of human-robot co-existence would become prominent to research for well-being.

5.2 Building as a robotic system

Taking a more radical step, would the building itself ends up becoming robots? We have been seeing buildings increasingly empowered and computerized by the use of electronics and mechanics. In certain smart home settings, it is already a reality that the furniture and layout of a room can automatically transform to meet occupants' need. In 1970s, when the idea of modular building was still popular in Japen, landmark projects such as the Nakagin Capsule Tower have been designed and developed following the broader context of urban metabolism. The Nakagin building was designed with intentional impermanence, following the principles of growth and transformation over time [32]. With all the mentioned precedents, a robotics building that can move and transform in response to external environment might not be as futuristic as it sounds after all.

R&D is required in the following directions. First, the science of building materials needs a fundamental rethink. For a building to sense and response like robots, its constituent components should be of electromechanical characteristics, so as to be compatible with the current silicon-based artificial intelligence. Second, ambient intelligence is critical to make computing pervasive in the built environment. In doing so, spontaneous response becomes possible. Last but not least, as robotic agents, the dogmatic view of building being places would be challenged. This will then pose new questions about what forms a city, which requires systemic research from a larger scale of the urban system. With continuous research input from the above directions, the Howl's Moving Castle will perhaps become a reality in the foreseeable future.

6 Conclusions

Despite being the most critical dyad in the robotization of the built environment, the relationship between robots and building has seldom been researched systematically. This paper fills in the gap by taking a historical perspective to examine the evolving interactive dynamics between robots and buildings over time: (a) from an objectified dualism in the past, (b) to an increasingly blurred boundary in the present, and (c) to a prospective symbiosis with mutual benefits. The shifting dynamics is argued to be underpinned by large-scale digitalization and the empowerment of artificial intelligence. Blue-sky prospective scenarios have been discussed, where the robots become an inherent part of the building, or the building itself becomes a robot. The paper hopes to stimulate further discussion on the critical relationship between robots and buildings. Its clarification is deemed indispensable to overcome the theoretical dilemma hindering wide-spread robotization in the built environment.

Abstract–
Conventional techniques for installing panels face several problems, such as human errors, time inefficiency, and safety risks. The panel installation robot, outfitted with sophisticated mechanical, electronic, and software technologies, proficiently addresses these challenges. The robot employs omnidirectional motion mechanisms, a telescopic robotic arm, and precision installation tools, including drills and nail guns, to facilitate the accurate and safe execution of installation operations. The robot's positioning system, with advanced cameras and image processing technology, can precisely identify the runners' location and modify the arm's movements accordingly. The semi-automatic control via a web user interface enables operators to remotely monitor and control the installation process. Furthermore, the robot's safety mechanism, utilizing distance sensors and cameras, averts collisions with obstacles, so guaranteeing safer operation. This unique design decreases installation time by 10% to 30%, depending on the length of the panel, while simultaneously enhancing productivity, precision, and addressing environmental concerns.

1 Introduction

The incorporation of Building Information Modeling (BIM) as a holistic tool for design, planning, and project management within the construction sector, alongside significant advancements in robotics, has generated novel prospects for utilizing robots in unstructured settings like construction sites [1]. These developments allow robots to adapt effectively to the intricate and dynamic conditions characteristic of construction environments, ensuring dependable and efficient performance. In the last thirty years, construction robotics has advanced significantly, being utilized in tasks such as painting, welding, exterior cladding installation, major component assembly, precast concrete panel manufacture, and site cleaning [2,3]. Drywall installation, which demands high levels of accuracy and technical expertise, is typically performed by experienced workers. However, installation complexity, and human error make this process challenging. Incorrect measurements, cutting, and drywall misalignment cause uneven surfaces and gaps, increasing repair and rework expenses. Furthermore, the time-consuming nature of drywall installation usually causes delays in large construction projects. To address these challenges, robotic technologies have emerged as an innovative solution, particularly in the installation of interior panels like drywall. The robot studied in this research is specifically designed for the installation of various types of building panels. The robot features a fully automated system for installing drywall panels, which, unlike semi-automated or operator-dependent systems in previous studies, requires no human intervention and offers higher safety and installation speed [4,5]. By automating the installation process, robots not only reduce the dependency on skilled labor but also minimize errors and ensure consistent quality in construction projects. This efficiency is not only about speed but also about the ability to work continuously without the need for breaks, thereby streamlining the construction process. The robot presented in this study (Wall-bot) is designed to operate on various surfaces and install different types of panels, such as drywall. Unlike many previous systems that were limited to specific materials or a particular type of installation, this robot is equipped with two distinct installation tools—an electric drill for metal and a nail gun for concrete [6-8]. These features enhance installation efficiency and align with the evolving requirements of the construction industry. The innovative design of Wall-bot met the requirements of construction tasks. It aims to provide fundamental design

elements while addressing panel installation limitations. Ultimately, this system is market-ready and can reduce installation time, which is a significant advantage compared to systems that are still in the experimental stage or operate slower than manual methods [9]. By decreasing project time and the need for specialized labor, overall costs are significantly reduced. These features enhance installation efficiency and align with the evolving requirements of the construction industry.

2 Design and Implementation

This section details the conceptual design and implementation of various components of the robot, which has been specifically developed for the installation of panels in construction environments. The robot's design incorporates mechanical, electronic, and software systems that operate seamlessly and with high precision to efficiently perform the panel installation process.

2.1 Conceptual design

A robotic system has been designed and developed to overcome the obstacles associated with the installation of panels. The complete process is designed to resolve critical issues and enhance the installation process. Drywall panels are an ideal choice for automation technologies due to their lightweight structure, ease of transportation and installation, and lower execution costs. However, the installation process of these panels faces challenges, such as the need for high precision, ensuring safety in construction environments, and a significant demand for time and labor. In this study, a robotic system that is equipped with advanced technology has been developed to facilitate the installation of panels with superior precision, speed, and efficiency. This section details the conceptual design and implementation of various components of the robot, which has been specifically developed for the installation of panels in construction environments.

One of the most notable features of this robot is its advanced telescopic arm. This arm is specifically designed to provide precise adjustment of the angle and position of panels based on the ceiling-to-floor distance. With five degrees of freedom, the telescopic arm is fully automated for the transportation, positioning, and installation of non-load-bearing building panels. The robotic arm has two linear actuators arranged in parallel along the vertical axis. These actuators are designed to adjust the height of the panel. Additionally, the arm has a linear actuator that enables the forward and backward movement of the entire robotic arm. This actuator, in conjunction with another actuator connected via a metal linkage—one end attached to the robot's body and the other end to the telescopic arm—enables angular adjustments in the robotic arm. Another significant design challenge was the transportation of panels during the installation process. To address this, the robotic arm is equipped with a panel gripper, enabling it to perform all stages of transportation, positioning, and installation fully automatically, without requiring manual labor. For mounting panels onto ceilings, walls, and floors, the telescopic arm is equipped with two types of installation tools designed for attaching panels to both metallic and concrete surfaces. This system operates as an electric drill and a nail gun, guaranteeing accurate and secure panel installation.

The robot is equipped with an advanced positioning and control system specifically designed for panel installation operations in complex construction environments. This system utilizes advanced technologies, such as smart cameras, image processing, and a web user interface (Web UI), to ensure precise movement of the robot and accurate panel installation. Smart cameras are used to ascertain the precise positions of runners (structures onto which panels are affixed). These cameras capture both chromatic pictures and three-dimensional information about the surrounding environment. The collected data is processed to analyze the geometric features of the surfaces, boundaries, and lines. This analysis enables accurate determination of the panel installation positions. The Edge Detection algorithm is used to identify the boundaries and lines of the runners, thereby determining the exact locations for panel installation. The main problem in the installation of building panels is the need for high accuracy and flexibility in complex environmental conditions. This procedure is traditionally performed manually, often resulting in increased installation time, less precision, and possible safety hazards for workers. To address these challenges, an advanced control system has been designed for Wall-bot, automating several tasks, such as guiding the robot to predetermined locations while also allowing manual control by an operator when necessary. The technology employs a web user interface (Web UI) that enables the operator to precisely control the robot in various work conditions and determine the exact locations of the runners. The Web UI, functioning via a local network, synchronizes the robot's wheels and arm, enabling users to control the robot using any device connected to a wireless network. The Web UI includes three primary components:

- **Camera Live View:** It provides live video streams from the cameras mounted at the center of the robot's arm. The strategic positioning of this camera provides the user with a precise view of the working area, enabling more accurate management of operations.
- **Robot Wheel Control:** This section is designed for managing the movement and positioning of the

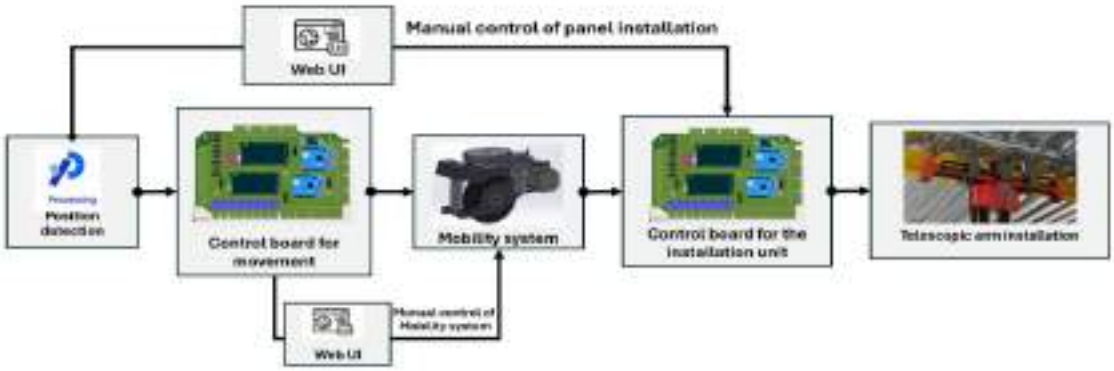

Figure 1. Block diagram illustrating the process of the panel installation. The process begins with position detection using an image processing system and cameras. The mobility system, controlled by an advanced system, enables accurate movement to the target location. Sensors enhance safety and prevent collisions. Finally, the telescopic arm securely installs the panel. Manual control via a Web UI for necessary adjustments.

robot's wheels. Default Modes presents five images, representing the default angles of the wheels. Users can select their preferred image and click the 'Run' button to transmit the angle data to the robot, thereby initiating the movement of the wheels to the desired location. This feature is designed for quick and simple adjustments. The sixth image enables the manual modification of each wheel's angles and robot's linear speed for long-distance straight movements, providing flexibility for users to set the desired speed based on their specific requirements. Furthermore, an emergency 'Stop' button is included to immediately halt the robot in critical situations.

- **Robot Telescopic Arm Control:** This section focuses on the control of the robotic arm and its attached equipment. A set of buttons is designed to restore the motors to their initial positions, which is especially beneficial during startup or while reconfiguring the arm. Additionally, the user can precisely designate the position of each arm motor by inputting numerical values. Once the settings are applied and the execute button is pressed, the arm moves to the specified position. This functionality is ideal for accurate operations. Three toggle buttons are provided for the operation of the auxiliary equipment attached to the robotic arm. These three toggle buttons serve specific functions: they allow precise positioning of the laser pointer, activate the magnet for holding metallic parts, and enable the lighting system to improve visibility in low-light environments. Additionally, the 'Install Runner' button is used to activate the telescopic arm mechanism. At this stage, the arm's motors elevate the runner towards the ceiling, guaranteeing its adherence to the surface and proper positioning. Upon installation, the tools shoot fasteners to affix the runner to the ceiling. After completing the operation, the motors automatically stop for safety and efficiency.

The robot's mobility system is a crucial element of its design. The robot's mobility system, featuring four driven wheels, enables autonomous navigation on construction sites. Each wheel moves linearly and rotates about its vertical axis, providing omnidirectional motion for enhanced maneuverability in complex interior spaces.

A belt and pulley system has been integrated to transfer power from the motors to the wheels. This mechanism guarantees accuracy and increased torque transfer, allowing the robot to function efficiently in various conditions.

A spring-damper system is crucial for enabling smooth and steady robot movement in construction sites with sloped or uneven surfaces, as it absorbs undesirable vibrations during transportation and panel installation. Thus, the robot is equipped with four hydraulic shock absorbers, located next to the wheels due to space limitations for installation.

In addition to the mechanisms that are specifically designed for the working environment, the robot must be equipped with sensors that are capable of detecting obstacles. These sensors measure the distance to obstacles to avoid accidents, ensuring safe and efficient operation in dynamic construction sites. As shown in Figure 1, the panel installation robot follows a designed operation procedure to guarantee the precise and efficient positioning of panels. The procedure begins with the identification of the panel installation position through the use of an image processing system and cameras.

Following the determination of the position, the robot employs its omnidirectional mobility system, which is managed by advanced control systems to guarantee smooth and accurate movement, to navigate to the desired destination. Additionally, sensors are integrated into the system to guarantee safety and prevent collisions during operation. Finally, the telescopic arm, equipped with advanced installation tools, precisely attaches the panels in place. This integrated design optimizes the quality of the project, reduces construction time and costs.

2.2 Implementation of the Robot

Wall Bot is equipped with advanced mechanisms, including mobility systems, a robotic arm, and installation tools, enabling high-speed and precise installation of building panels. Figure 2 illustrates the robot's entire structure and its mechanisms. These mechanisms, enable transportation through difficult pathways, adjust angles and heights, and install panels with accuracy and reliability. The integration of advanced control systems with precise positioning capabilities and an efficient user interface enhances the accuracy and efficiency of the installation process.

A detailed explanation of its main mechanisms is provided below:

2.2.1 Robotic Arm and Motion Mechanism

The Cartesian robotic arm is an essential component of the robot, capable of autonomously positioning, and installing panels at diverse heights and angles. This arm is designed to accurately adjust its position, guaranteeing efficient and precise operation throughout the panel installation procedure. The following information describes the primary mechanics of this arm:

- **Telescopic Mechanism:** The robotic arm is equipped with an advanced telescopic mechanism that enables variable adjustment of height and depth

Figure 3. Detailed View of the Telescopic Mechanism in the Robotic Arm

of motion. To achieve precise and linear movement, a stepper motor with a torque of 85 kg·cm is employed. This motor, in conjunction with a ball screw featuring a 16 mm diameter and a 5 mm pitch, provides highly accurate and controlled linear motion (see figure 3).

- **Motion Mechanisms:** The robotic arm utilizes advanced mechanisms, including stepper motors and ball screws, to achieve accurate vertical and horizontal motions. This mechanism employs a stepper motor with a torque of 45 kg·cm, paired with a ball screw that has a diameter of 16 mm and a pitch of 5 mm. This combination facilitates the accurate and delicate motions, enabling the arm to properly install panels in various positions.
- **Rails and Connections:** Various components of the robotic arm affixed to linear rails and carriages, facilitating the arm's vertical and horizontal motions. These mechanisms enable the arm to transport panels along different paths with accuracy.
- **Panel Gripper:** The robotic arm is equipped with an advanced panel gripper responsible for holding and stabilizing panels during installation operations. This gripper can position panels in various orientations and, with the help of linear actuators and stepper motors, precisely adjust their angles before securely installing them in the desired location. The gripper's design prevents damage to the panels during handling and ensures a safe and highly accurate installation process.
- **Angle Adjustment Mechanisms:** The robotic arm is equipped with an advanced mechanism comprising a linear actuator and a metallic linkage. The linear actuator is responsible for moving the arm forward and backward, while the metallic linkage is connected on one side to the robot's body and on the other side to the telescopic arm structure. These two mechanisms can operate either synchronously or independently. When operating in synchronized mode, the robotic arm moves directly forward and backward without any angular deviation. However, if the two mechanisms operate at different speeds or directions, a positive or negative angle relative to the

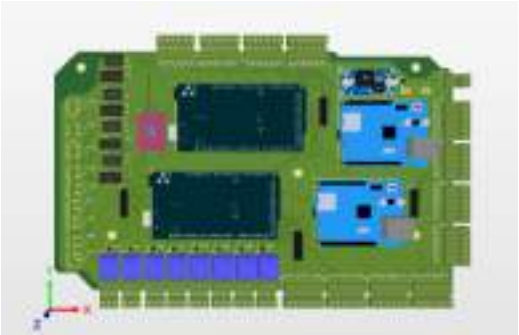
vertical axis is generated, allowing the arm to be adjusted at various angles. This mechanism, by combining horizontal and vertical movements, enables the arm to achieve a wide range of angular adjustments, ensuring precise positioning of the panels. The angular adjustment mechanism of the robot is particularly effective for installing panels in locations where direct installation is not feasible due to obstacles on the ceiling or floor of the building.

2.2.2 Installation Tools

The accurate and efficient operation of installation tools is one of the key features of Wall bot. These tools must operate precisely and impeccably in many construction areas, including uneven surfaces, varying heights. The robot's installation tools are specially designed for various conditions.

- **Electric Drills and Nail Guns:** The robotic arm is equipped with two types of installation tools, enabling the installation of panels on ceilings, walls, and floors.

1. Installation on Metal Surfaces: For metal ceilings, the system employs an electric drill using self-tapping screws. These screws automatically install the runner (the panel support structure) to the metal ceiling without the need for additional pre-drilled holes.
2. Installation on Concrete Surfaces: The robot employs a nail gun system for concrete ceilings. This tool accurately embeds nails into the concrete substrate to firmly fasten the panels. The nail gun technology functions similarly to industrial nailers, facilitating rapid and secure installation of panels on robust and resilient ceilings. Furthermore, each tool is affixed to a linear system that enables positional adjustment according to the unique requirements of the ceiling. This capability allows the robot to do installations with enhanced precision at any location on the ceiling, considering its type and condition.



2.2.3 Cameras for Runner Positioning and Sensors

The runner's location on the ceiling and the robot's movement across obstacles are achieved by two complimentary techniques:

- **Smart Cameras**: Cameras mounted to the robot capture the surrounding environment and transmit this data for image processing. This processed data directs the robot to the precise area for panel installation by determining the runner's position on the ceiling. The robot is equipped with RGB cameras
- and 3D depth cameras, crucial for analyzing the geometric characteristics of the surroundings. The robot's cameras map the area to identify obstacles and determine safe, efficient pathways.
- **Sensors:** The robot's operation in construction environments necessitates the top priority of preventing collisions with obstacles and ensuring safety. The robot's positioning system is designed to autonomously detect obstacles and modify its trajectory using cameras and supplementary sensors. LiDAR (Light Detection and Ranging) sensors provide intricate 3D mapping of the surroundings, allowing the robot to identify obstacles, measure distances, and move securely. These sensors augment the robot's spatial awareness and enable accurate mobility in congested areas. Moreover, the device sends audible and visual alerts to the operator upon the detection of a possible threat. This capability is vital in construction settings, where many impediments and risks may exist. Through the integration of cameras and sensors, the robot has an advanced safety system, guaranteeing secure functionality in dynamic and difficult conditions.

3 Electronic Circuit Board of Wall-Bot

Wall-bot is an advanced machine for drywall installation. The robot must move along the surface and install each panel at the desired positions. This robot has a total of 12 stepper motors, 4 DC motors, 2 drills, and several additional sensors, including two distinct control systems. A Control Board have been designed to make the connections between the microcontroller boards, Ethernet connections, sensors and actuators (see figure 4). The board comprises two distinct Atmega2560 processing boards integrated to facilitate connections. Two boards connect to each other over the Ethernet Cables though a router and then connect to a PC with another Ethernet Cable. The board is required a 12V Main Power supply to run with Maximum current of 10 Amps. A buck switching converter transforms the power into the requisite 5V for the majority of digital components. Given the presence of two control boards within the unit, each board can be reviewed separately.

3.1 Main control for the movement

Four DC motors are coupled to BTS7960B external drivers, each connected with the board via 2x4 IDC connectors. These DC motors are mounted on four stepper motors, which rotate the DC motors to enable the robot to move in any direction across the surface. The stepper motors are controlled with TB66xx series drivers, with each driver connected through a 6-pin, 0.2-inch pitch terminal socket. To accurately measure motor speed, AS5600 Magnetic Angle Encoder are used to precisely measure the motor speed of all tires. The Encoder link to the Arduino processor via 2x3 IDC connectors, with the connection facilitated by the TCA9845 multiplexer. This design guarantees accurate speed measurement and effective motor control. The robot's movements are controlled by a singular ATmega2560 Arduino processor, which implements the control algorithms and manages communication. Commands are sent from the primary PC by a W5100 Ethernet module, facilitating uninterrupted and instantaneous control of the robot's motions. The robot is equipped with advanced communication components, stepper motors, and DC motors, which are incorporated to enhance its adaptability, precision, and mobility for intricate positioning tasks.

3.2 Main control for the installation unit

This unit consists of five actuators driven by eight stepper motors, nine proximity sensors for positioning, and many relays for the control of auxiliary equipment such as drills and fans. The system is controlled by an ATmega2560 Arduino board, which regulates motor function and sensor feedback for accurate operation. The main PC and a router are connected through an Ethernet module in this device, which allows for real-time monitoring and control. Buffer gates and ULN2xxx driver circuits are used to guarantee reliable connection and avert interaction problems among components. These devices provide electrical stability, hence augmenting the system's resilience and reducing possible interference among components. The seamless integration of actuators, sensors, and communication modules guarantees accurate performance, making the unit very efficient for intricate operations. The incorporation of gate ICs in electronic board design offers substantial protection for the primary processor by reducing potential damage. Nevertheless, to attain full electrical isolation and protection against electrostatic discharges (ESDs) and electrical shocks, optocouplers are utilized. These components guarantee strong isolation and improved system reliability, especially in electrically noisy settings. One of the key advantages of this design is the implementation of a dual-processor system. By employing two processors simultaneously, conflicts between movement control and the primary tasks of the robot are effectively prevented, resulting in smoother operation and task execution. A further advantage is the reduction of interference among I²C sensors, since the design has a specialized I²C module. Furthermore, all proximity sensors are completely isolated, guaranteeing precise sensor functionality and reducing the risk of signal disruption. The board is equipped with robust protection mechanisms on the power lines, including safeguards against overvoltage, overcurrent, and polarity mismatches. These protections improve its durability and resilience under challenging operating conditions.

Table 1 Denavit-Hartenberg (D-H) parameters of the robotic arm.

parameter	$\boldsymbol{\alpha_{i-1}}$	$\boldsymbol{a_{i-1}}$	$\boldsymbol{\theta_i}$	$\boldsymbol{d_i}$
i=1	0	0	0	d_1
i=2	0	0	0	$d_2 + l_1$
i=3	0	0	θ_1	l_2
i=4	$-\frac{\pi}{2}$	0	0	$d_3 + l_3$

4 Kinematic Modelling for the Telescopic Arm

For both forward and inverse kinematic analysis, this section models the telescopic arm as a 4-DOF robotic arm with three prismatic joints and one revolute joint, neglecting the fifth degree of freedom, which enables the angle adjustment of the telescopic arm, to simplify the analysis.

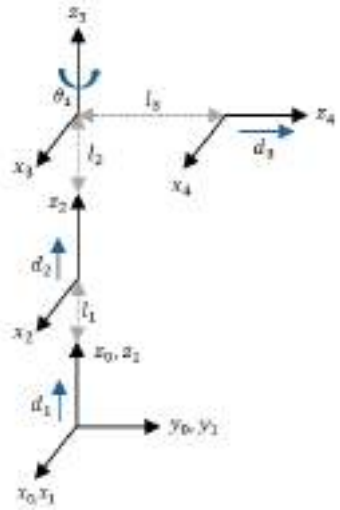


Figure 5 Assigned coordinate frames for each link of the robotic arm

4.1 Forward kinematics model

Forward kinematics calculates the position and orientation of the end-effector in 3D space by using the joint variables, such as joint angles or linear displacements. This calculation is performed by applying homogeneous transformation matrices that describe how the robot's joints and links are connected [10]. The Denavit-Hartenberg (DH) convention is a widely used approach for modeling robotic arms. It defines four parameters to represent the kinematic chains of robotic arms: twist angle, link length, link offset, and joint angle. Fig 5 depicts a coordinate frame attached to each link of the robotic arm. Table 1 lists DH parameters for the telescopic arm. The homogenous transformation matrix (see Equation (2)) that relates the global coordinate system is derived from Equation (1):

$$T_{06} = T_{01}\, T_{12}\, T_{23}\, T_{34}\, T_{45}\, T_{56} \tag{1}$$

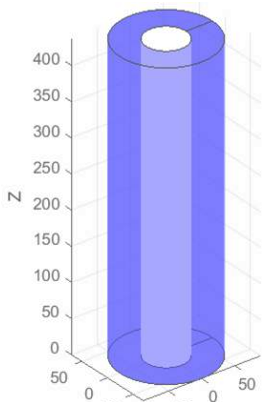
$$T_{04} = \begin{bmatrix} \cos(\theta_1) & 0 & -\sin(\theta_1) & -\sin(\theta_1) * (d_3 + l_3) \\ \sin(\theta_1) & 0 & \cos(\theta_1) & \cos(\theta_1) * (d_3 + l_3) \\ 0 & -1 & 0 & l_1 + l_2 + d_1 + d_2 \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{2}$$

Based on the transformation matrix, five points within the range of motion for each joint, including the initial and final points, were analysed. The position values for the selected points were calculated using MATLAB code and are presented in Table 2.

4.2 Inverse kinematics model

Inverse kinematics is the method of calculating the joint parameters required for a robotic arm to reach a desired position and orientation, functioning as the reverse of forward kinematics. There are two methods for solving inverse kinematics: the geometrical method and the algebraic method. The algebraic method is more complex than the geometrical method, as it involves solving a set of mathematical equations derived from the robot's kinematic chain. The joint values for the telescopic arm are determined from following equations using the geometrical method shown in Figure 1. θ_1 is derived from Equation (3), and d_3 is derived from Equation (4). To determine d_1 and d_2 from the equation, one of the values must be predefined by the operator. It is recommended to initially set d_2 at its maximum displacement (80 cm), and then derive d_1 from Equation (5).

$$\theta_1 = \tan^{-1}(-\frac{x}{y}) \tag{3}$$



$$d_3 = \sqrt{x^2 + y^2} - l_3 \tag{4}$$

$$d_1 + d_2 = z - l_1 - l_2 \tag{5}$$

The telescopic arm has vertical movement along the Z-axis, while the horizontal link rotates along the Z-axis. Additionally, the radius of the installation tools is adjustable. The combination of these movements results in the installation range forming a hollow cylinder, as shown in figure 6.

5 Conclusion

This study demonstrates that the developed robot has the potential to revolutionize the construction industry, particularly in panel installation. The robot enhances efficiency, minimizes human errors and physical strain, and guarantees superior quality and precision in operations by automating the installation procedure. The advanced image processing technology integrated into the robot not only improves accuracy in panel placement but also highlights its high flexibility in installing panels of diverse sizes and weights. The robot's standout features, such as precise environmental analysis, the design of flexible arms, and coordinated movements enable it to effectively perform complex tasks in dynamic and challenging environments. Moreover, its ability to interact and coordinate with other robots facilitates the execution of larger projects with greater efficiency and speed. Future advancements in machine learning algorithms could enhance the robot's decision-making capabilities and adaptability to diverse conditions. Energy sustainability is expected to be incorporated into these systems in the future. Optimizing the robot's energy consumption through advanced energy management technologies, such as intelligent consumption control algorithms, can maximize its operational efficiency. Additionally, integrating the robot with renewable energy sources would enable more

$l_1 = 40\ cm$
$l_2 = 18\ cm$
$l_3 = 30\ cm$
$d_1 < 300\ cm$
$d_2 < 80\ cm$
$d_3 < 40\ cm$

sustainable and environmentally friendly project implementation. Furthermore, it is expected that the integration of robotics with 3D printing technology will be a key focus of future advancements. This integration could provide opportunities for designing and constructing complex building components. With 3D printing, it would become possible to produce parts that are precise, fast, and minimally wasteful, while robots could be equipped to install and assemble these components with high accuracy. This future development is anticipated to reduce costs, expedite project schedules, and align with sustainable construction standards. In terms of social aspects, this technology reduces laborious and repetitive tasks, allowing human workers to focus more on the creative and strategic aspects of projects. This shift not only enhances job satisfaction but also emphasizes the necessity of implementing safety standards and professional ethics to increase human-robot interaction. The Wall-bot, with its distinctive features, provides an innovative shift in civil engineering techniques. Utilizing this innovation may optimize project schedules, improve building quality, and foster robust and sustainable infrastructure, so offering greater prospects for the construction sector. Due to continuous developments, these robots are anticipated to function with enhanced speed, precision, and efficiency, significantly influencing the future of construction.

Abstract –

Construction quality inspection plays a crucial role in ensuring safety and quality at all stages of a project. However, traditional quality inspection has certain limitations, such as time consuming, expensive equipment, and cumbersome processes. Therefore, improving inspection technologies and processes by utilizing Unmanned Ground Vehicle (UGV) equipped with relatively low-cost LiDAR to enhance data collection coverage and efficiency during inspections has become a pressing issue in current construction quality management.

The main objective of this paper is to explore methods for enhancing the data acquisition capabilities of UGV equipped with low-cost LiDAR in construction environments and to experimentally verify the impact of path planning methods on data accuracy. The research focuses on investigating a new algorithm that simulates LiDAR scanning by UGV in point cloud space through 3D modeling and iteratively selects paths using Genetic Algorithm (GA) to preserve the path with the highest point cloud data collection efficiency. The experimental results extract the coordinates of the selected paths based on different scenarios, providing data support for the application of UGV on construction sites and promoting the adoption of intelligent building inspection methods.

Keywords –

Building Inspection; Unmanned Ground Vehicles; Path Planning

1 Introduction

Building inspections are critical to ensuring construction safety and engineering quality within the built environment. This process not only directly affects the structural stability of buildings but also effectively reduces safety hazards during construction, thereby safeguarding lives and property [1]. However, traditional building inspection methods, such as supervisory inspections, third-party testing, self-inspection, and non-destructive testing techniques, still face numerous limitations in practical applications. These limitations include lengthy inspection cycles, cumbersome and complex equipment, and subjective evaluation results that lack consistency and comprehensiveness [2,3]. Furthermore, these methods are constrained by technological means and inspection scope, making it difficult to adequately address potential issues during construction, thereby limiting their applicability in complex construction environments. These shortcomings may adversely impact construction progress to some extent. Therefore, optimizing inspection technologies and processes to improve the efficiency and accuracy of building quality inspections has become an urgent issue in the field of construction quality management [4].

Today, the development of building quality inspection technologies demonstrates a significant trend toward informatization, intelligence, and automation [5]. The use of robots for detecting and monitoring construction environments has gradually become a research hotspot [1]. Their application plays a critical role in reducing human error and improving the efficiency of inspection tasks. Common unmanned platforms include UGV, which exhibit significant payload and functional advantages, enabling them to carry larger-scale inspection equipment [6]. This includes cameras for visual data collection, LiDAR and laser scanners for 3D data acquisition, ground-penetrating radar (GPR) for behind-wall and underground detection, as well as components like inertial measurement units (IMUs) with ultra-wideband (UWB) sensors and global positioning systems (GPS) [7], which play an essential role in positioning and navigation. Among these, LiDAR, with its exceptional ranging accuracy and reliability, has become an essential tool in the architecture, engineering, and construction (AEC) industry, showing promising applications in environmental modeling and mapping [8]. Specifically, comparing the dimensions, positions, and orientations of building components detected on-site with the design parameters in Building Information Modeling (BIM) can effectively identify discrepancies with the BIM model [9].

However, the noisy construction environment significantly interferes with LiDAR scanning, making it a key challenge to achieve high-quality point cloud data acquisition in complex and cluttered environments [10]. Recent research has mainly focused on optimizing trajectory planning for unmanned platforms to enable efficient and high-precision data acquisition. These methods take into account factors such as energy efficiency, planning time, data redundancy reduction, and adaptability. They aim to address challenges such as minimizing energy consumption, reducing travel time, and maximizing data collection efficiency [11]-[13]. However, research focusing on solving path planning problems through path optimization algorithms to enhance data collection coverage remains relatively limited. This limitation constrains the depth and scope of theoretical advancements in this field.

2 Literature review

In order to achieve efficient environmental perception and navigation, path planning algorithms play a crucial role in this process. Traditional path planning algorithms are categorized into cell decomposition methods, roadmap-based methods, graph search-based path planning methods, and sampling-based path planning algorithms [14]. In both cell decomposition and roadmap methods, the shortest path between the starting and target positions is often determined using graph search algorithms. Graph-based path planning methods typically rely on environmental maps as prior input information, making them suitable for static planning scenarios. Among these, Dijkstra's algorithm is one of the most well-known graph traversal search algorithms, designed to find the shortest path between two nodes in a graph [15]. However, when the search space is large, the computation time of Dijkstra algorithm increases significantly. To address this, Peter E. Hart proposed the A* algorithm based on Dijkstra algorithm [16]. As a heuristic search method, A* is widely used in path planning for autonomous driving and robotics. By introducing a heuristic approach to guide the search towards the target node, A* effectively reduces the number of graph nodes explored, thus accelerating the search process. Through comparison with Figure 1, it is evident that the A* algorithm reduces the computational load compared to the Dijkstra algorithm.

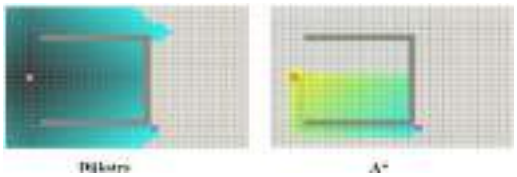

Figure 1. Comparison of A* and Dijkstra [16]

In addition, to adapt path planning algorithms to different application requirements (such as dynamic planning, variable target nodes, and path angles) [17], improving computational efficiency is crucial. The A* algorithm performs exceptionally well in this regard, making it particularly advantageous in static environments [16]. In recent years, researchers have worked on improving the A* algorithm to overcome its limitations.Wang et al. proposed an enhanced version of the A* algorithm that takes into account vehicle contour, speed, and dynamics constraints, thereby providing safer and smoother path planning for self-driving cars [18]. Bao et al. introduced a dynamic weight-adjusted 16-way search method that reduces redundant search nodes, thus improving path planning efficiency. These improvements aim to optimize path lengths, reduce turn times, and improve overall performance [19]. Although the A* algorithm still faces many challenges in practical applications, it is applicable to more and more application scenarios as researchers continue to improve it, and still plays an indispensable role in path planning.

However, most of the research on path planning algorithms is used to perform path navigation, obstacle avoidance, etc. Nguyenet al. proposed a new path planning algorithm, NSPMR (Near-Shortest Path for Mobile Robot), based on the improvement of the traditional local path planning algorithm [20]. It is specifically designed to solve the path optimization and obstacle avoidance problem for mobile robots (MRs) when navigating in known or unknown environments. The algorithm generates an approximate shortest path by integrating sensor data in real time, which effectively avoids the limitations of traditional algorithms in the problems of "local minima" and "infinite loop".Dong et al. proposed a combination of the optimized A* algorithm and the dynamic window algorithm to optimize the path of a mobile robot in a known or unknown environment [21]. A* algorithm and Dynamic Window Algorithm (DWA) to solve the global optimization and dynamic obstacle avoidance problems in path planning for automated guided vehicles (AGVs) [21]. The optimized A* algorithm improves the traditional algorithm's deficiencies in path smoothness and computational efficiency by means of adaptive heuristic functions and redundant point deletion, and is capable of achieving globally optimal path planning in static environments. Baras et al. proposed a Covered Path Planning (CPP) optimization method for UGV to conserve energy with a focus on Reducing the number of UGV turns through area allocation, and significantly improving the energy utilization through path optimization [22]. In the paper, the environment is partitioned and the boundaries are finely adjusted to reduce the region mixing phenomenon, while the node exchange mechanism is introduced to optimize the

generated coverage paths, thus reducing the number of path turns and energy consumption. Experimental results show that the method outperforms traditional algorithms, such as A*-DARP+STC, in different obstacle ratios and complex terrains, and exhibits significant advantages in terms of the number of turns and energy efficiency. The study provides a more efficient solution for path planning of multi-UGV tasks and lays a theoretical foundation for energy-aware path planning in dynamic environments.

These studies typically emphasize minimizing path length and ensuring driving safety, often overlooking the specific requirements for scan coverage and data collection accuracy in construction sites. As a result, the adaptability of existing path optimization algorithms in construction environments remains insufficient. The main difference between this study and previous BIM-based robot path planning methods is that our approach is specifically designed to address the issue of data loss often encountered by unmanned vehicles during point cloud collection due to the noisy construction site environment. The goal is to simulate the collaboration between UGV and LiDAR and optimize the path through algorithmic iterations until the path that allows the UGV to collect the most complete point cloud model is obtained, along with its corresponding path coordinates.

3 Methodology

The method of this study aims to improve the coverage and efficiency of 3D point cloud data collection using unmanned platforms equipped with LiDAR sensors. As shown in Figure 2, the process begins with LiDAR accuracy assessment, where the impact of path planning methods on point cloud accuracy is validated. The next stage is path planning via algorithm, which consists of two parts: algorithm execution and model preprocessing. Preprocessing includes converting the BIM model into a point cloud model and adjusting the coordinate system to ensure data alignment and analysis.

After preprocessing, the feasible path for the UGV is first generated using the A* algorithm. Then, the path points undergo crossover mutation, and the GA is executed to generate the path with the highest number of collected point cloud points, the data processing stage begins, where the path length and point cloud quantity are standardized, unifying the units of path length and point cloud quantity to facilitate scoring and selecting the optimal path required for the experiment. Finally, the path is evaluated using a scoring mechanism to select the final optimized path.

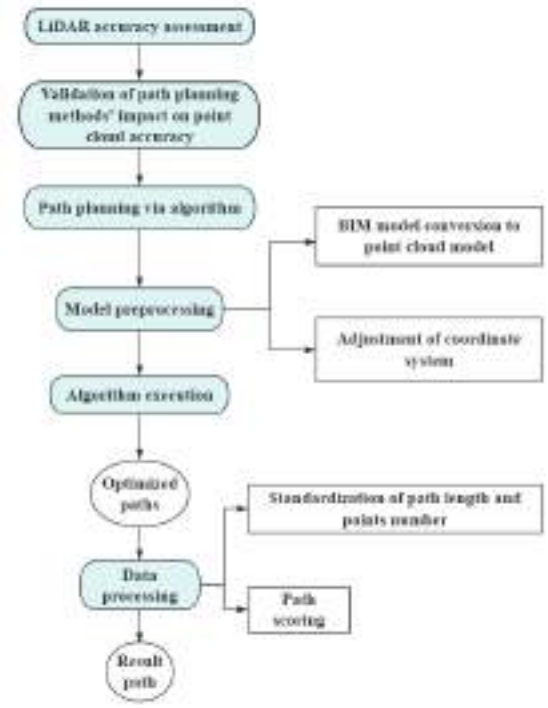

Figure 2. Proposed methodology

To verify the impact of path planning methods on the accuracy of point cloud data, experiments were conducted in both structured and unstructured scenarios (as shown in Figure 3). The experiment in the structured scene was conducted to obtain the accuracy of the UGV when scanning with the mounted LiDAR. Point cloud data was collected along different path types (2 meters, 4 meters, 6 meters, and 8 meters) using both an UGV and a Terrestrial Laser Scanner (TLS), with the high-precision point cloud data collected by the TLS serving as the baseline. After denoising, the dimensions of the target point clouds collected by the two devices were calculated using the C2C (cloud-to-cloud distance) method to ultimately obtain the scanning accuracy results.

Based on the experimental results from the structured scenario, the optimal path for UGV data collection was planned in the unstructured scenario, which simulates the construction site environment where the UGV operates in practical applications, and point cloud data was collected along both the planned path and random paths. Data processing in the unstructured scenario also included noise removal and denoising, but further comparisons of the scanning accuracy for different path types were made to verify the effectiveness of path planning methods in improving UGV scanning accuracy in complex environments.

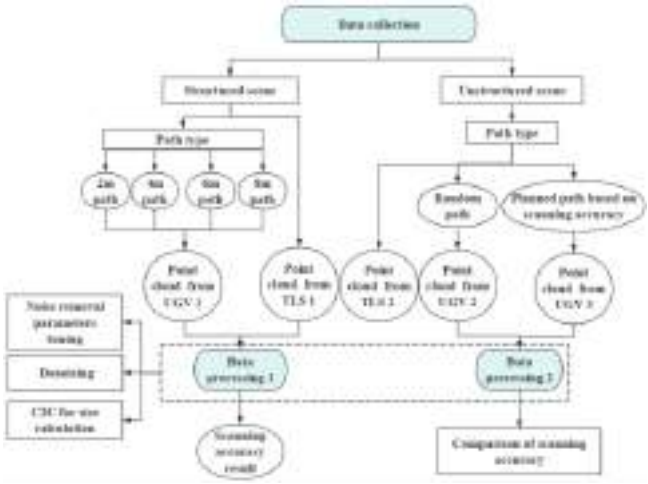

Figure 3. Experimental Workflow for verifying path planning impact on scanning accuracy

4 Case study

4.1 Theoretical verification phase

4.1.1 Mid360 precision exploration

According to existing studies, Lo et al. analyzed the data collection capability of a UGV equipped with the Mid360 in a structured scenario, with the data evaluated using the Level of Accuracy (LoA) rating. The results showed that at a distance of 2 meters, the measurement accuracy was the highest, with errors close to the sub-centimeter level, reaching an LoA30 rating, and the noise was almost negligible. In contrast, when the measurement distance increased to 8 meters, the measurement accuracy significantly decreased, with higher noise intensity and greater measurement errors, approaching 2 centimeters, and the rating dropped to LoA20. This indicates that as the measurement distance increases, the accuracy of LiDAR data is significantly affected. Additionally, at measurement distances of 2 meters and 4 meters, some point cloud data for the cardboard box were lost (as shown in Figure 4) [23].

Figure 4. Point cloud modeling for different distance conditions [23]

4.1.2 Data collection in unstructured scene

In the Civil Engineering Laboratory at university, the researchers selected a structural column as the target to evaluate the effectiveness of using a path planning method to enhance the point cloud data collection capability of an UGV equipped with the Livox Mid360 in an unstructured scenario. As shown in Figure 5, a closed-loop route was laid out with yellow tape in the underground laboratory (at a distance of 4-6 meters from the target column), the path of the UGV shown in

Figure 6. To control variables (data collection time), the UGV in this experiment maintained the same speed (0.6 m/s) and performed multiple data collections along both the planned path and random paths. A set of data files with similar file sizes was selected for accuracy comparison.

Figure 5. Column target in unstructured scene

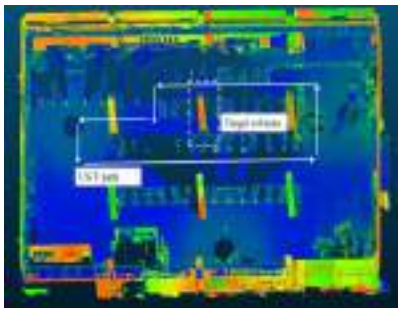

Figure 6. UGV path in unstructured scene

4.1.3 Data analysis in unstructured scenes

Table 1. Point cloud accuracy results for different paths

		TLS	Standard Deviation	UGV(2)	Standard Deviation	Error	UGV(3)	Standard Deviation	Error
Concrete Column	Width	0.608	0.0037	0.651	0.009	0.037	0.574	0.0151	0.032
	Length	0.613		0.627		0.046	0.578		0.035

The denoising process first requires separating the point cloud data of the target column collected by the TLS and UGV (with TLS data serving as the baseline) and measuring its width and length. The measurement results are shown in Table 1. It is worth noting that although the standard deviations are similar, the error range of the Livox Mid360 is slightly larger than the results of the 4m to 6m control distance experiment. This indicates that noisy environments can affect the accuracy of LiDAR data.

The point cloud data collected by the UGV shows slightly higher accuracy in path planning, but both datasets fall within the LoA20 class (Height measurements were not taken into account due to obstructions caused by the mechanical, electrical, and plumbing (MEP) systems on the ceiling). Furthermore, in the point cloud model collected along the random path, the length and width of the near-square target column were recorded as 0.651m and 0.627m, respectively, with an error of 0.24m. In summary, the data error collected by the UGV along the prescribed path was smaller than that collected along the random path.

4.2 Path planning phase

Building on this previous work, this section explores how to optimize path planning through algorithms. The focus of the research is on the global path planning problem for UGV in static environments, aiming to design a path that collects the most point clouds. During the path planning process, it is crucial to consider obstacles and danger zones in the environment, ensuring the path avoids impassable obstacles. At the same time, the kinematic and dynamic constraints of the Bunkerpro unmanned ground vehicle must be satisfied. Unlike traditional path planning methods that simplify the UGV to a particle model, this study takes more key factors into account, such as the platform's size and LiDAR placement height, in order to overcome the shortcomings of traditional methods that overlook motion constraints and environmental factors.

4.2.1 Model preparation

In practical applications, data collection usually relies on existing Building Information Models (BIM) to obtain relevant information about construction sites. Given this, the study selected a classroom and corridor model from the fifth floor of the Engineering Building at university campus for path planning. As shown in

Figure 7, the classroom model contains many obstacles (such as desks, chairs, and podiums), which is similar to the noisy environment of a construction site. The corridor model has a large coordinate range and a high point cloud density, which is similar to the point cloud data scale encountered in real construction sites. Both models are ideal choices for validating path planning and simulating LiDAR scanning effects.

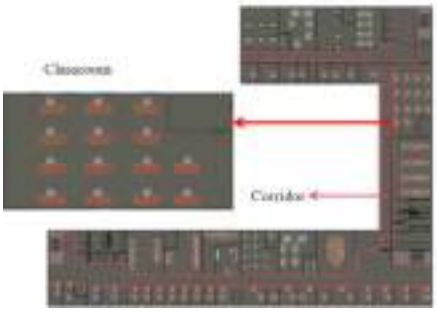

Figure 7. BIM models of classroom and corridor

In this study, the total number of points generated for the corridor and classroom models was set to 100,000, with the point cloud density set to 10 to ensure the preservation of model details. The generated point cloud models required further adjustments to ensure their dimensions and coordinates aligned with the actual building. To achieve this, the researchers imported the models into 3ds Max to adjust their coordinates and dimensions. The final result is shown in Figure 8.

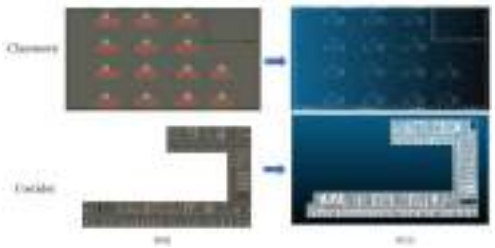

Figure 8. BIM models of classroom and corridor

4.2.2 Algorithm results

This algorithm aims to simulate data collection by an UGV equipped with LiDAR along a planned path. Due to the relatively small passable areas in the two models, the researchers set the grid coordinates to the size of the UGV (0.9m) to ensure smooth passage. The cloud-to-cloud algorithm was used to calculate the ground point cloud thickness of the model as 0.2m. In the algorithm, the parts at an elevation of 0.2m were designated as the ground for the UGV, and a feasible path map was generated (as shown in Figure 9). In addition, to ensure that the path does not collide with obstacles and that the start and end points are within valid areas, the constraint equations are used as follows:

$$g_1(x) = valid_path(x) = Ture \quad (1)$$

$$g_2(x) = start_point_valid(x) = Ture \quad (2)$$

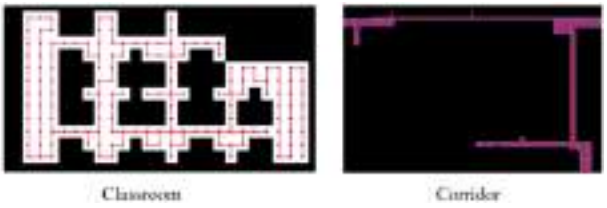

Figure 9. Feasible path map of classroom and corridor

It is important to note that during this process, the LiDAR simulates emitting rays within a specific angular range and checks where each ray intersects with the point cloud. In this study, the parameters of the Livox Mid-360 were used to set the LiDAR's field of view (fov=360°), scanning angle range (up_angle=52°, down_angle=7°), mounting height (h=0.7m), and measurement range (range_min=0.1m, range_max=70m). The rays are traced in each direction until they hit the nearest point in the point cloud. This setup ensures that the system does not detect point clouds behind obstacles, thus reducing noise interference.

In this algorithm, the objective function can be the number of point clouds covered by the path, that is, the number of valid point clouds scanned in the area traversed by the path. This reflects the optimization effect of the path and is defined as:

$$f_{objective}(\mathrm{x}) = \mathrm{coverage}(\mathrm{x}) \quad (3)$$

The researchers recorded the number of point clouds corresponding to the optimal path in each generation (as shown in Figure 10). During the simulation scanning process in the tenth generation of GA, the maximum number of point clouds was obtained, with values of 6115 and 30606, respectively. As shown in Line charts, the point cloud collection gradually stabilized in the later generations for both models. This indicates that the GA converged after several generations of optimization, and the model's performance became consistent. The number of point clouds collected reached the optimal state during the optimization process, confirming the success of the framework in this study. Furthermore, it is important to note that in GA's iterative process, it is possible for two generations to produce identical results. This happens because the fitness function of the offspring, after crossover and mutation, is lower than the optimal result of the parent generation.

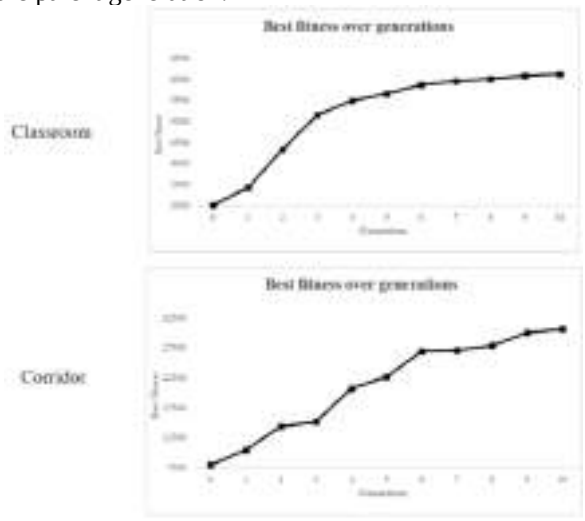

Figure 10. Convergence trends of GA

Figure 11 shows the coordinate information of the paths for the two models and the preview of the point cloud. The coordinate information of the path reflects the specific distribution of the optimal solution after optimization by GA in the coordinate space, while the point cloud preview displays the distribution of the point cloud data collected along the optimized path, providing a clear and intuitive reference.

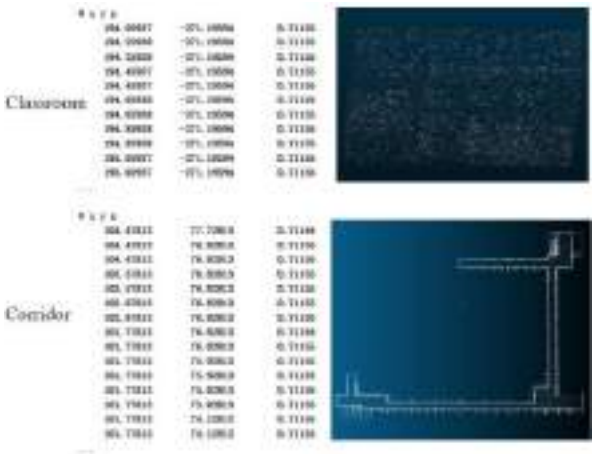

Figure 11. Path coordinate set and simulation models

Through approximate calculation, the longest path is 1417.09m and the shortest is 1203.32m. From the Figure 12, it can be seen that the path length does not show an obvious pattern of change and does not exhibit a significant convergence trend. Among them, the third-generation path, due to random variations, shows a significantly longer result compared to other generations. It can be attributed to the exploratory nature of the algorithm in the early stages of evolution, which is a common occurrence in the initial phase of GA optimization.

Figure 12. Changes in path length per generation

4.2.3 Data normalization

For point cloud path planning and scanning coverage optimization, the goal of data normalization is to bring different evaluation metrics to a unified dimension, allowing researchers to derive an optimal path based on the scoring rules they formulated.

Since the classroom model is relatively small, path length is not considered as a scoring factor for its optimal path. For the corridor model, researchers selected point cloud quantity and path length as scoring metrics, assigning weights of 80% and 20%, respectively. Path length, being a common optimization objective, means that shorter paths result in lower task costs (such as collection time, battery consumption of the autonomous vehicle, etc.).

The normalized calculation results and final scores are shown in Table 2, with the tenth generation path receiving the highest score. This indicates that the path in the tenth generation achieved the best balance during the optimization process, representing the optimal trade-off between path length and point cloud coverage. Therefore, the path from the tenth generation was selected as the optimal result for this experiment and output as the final recommended path.

Table 2. Scoring results for all paths

Generation	Best Fitness	Path length	Score
1	0.111	0.914	0.272
2	0.284	0.820	0.391
3	0.319	0.000	0.255
4	0.563	0.956	0.642
5	0.648	0.951	0.709
6	0.837	0.831	0.836
7	0.844	0.888	0.853
8	0.877	0.947	0.891
9	0.973	0.914	0.961
10	1.000	1.000	1.000

5 Discussion

This study first converted the BIM model of the fifth-floor corridor and classroom of the Engineering Building into a point cloud model. During this process, software limitations caused coordinate system confusion, requiring researchers to adjust coordinates and obstacle dimensions comprehensively using professional 3D modeling software.

Next, a path optimization algorithm (combining GA and A* algorithm) was developed in Python to maximize data collection by UGVs in three-dimensional space. The algorithm iteratively searched for the optimal path over multiple generations, eventually converging to the best path planning scheme, ensuring that the LiDAR covered all target areas as comprehensively as possible. Notably, the algorithm allows researchers to select the most suitable path based on specific needs. In the tenth generation of GA, path optimization reached its optimal state according to the weighted scoring system.

The experimental results indicate that during the path optimization process, the number of scanned point clouds increases continuously and eventually stabilizes. Researchers can flexibly choose the path from the stable results based on different experimental requirements.

Moreover, It is worth noting that the algorithm has certain CPU performance requirements and relatively low precision requirements for imported point cloud data, retaining only the essential key details. In practical applications, to improve efficiency and save time, it is recommended to limit the size of point cloud data to within 100 MB to meet practical needs while ensuring the high efficiency of the algorithm.

6 Conclusion

This study proposes an innovative path planning method that ensures UGVs can capture point cloud data more comprehensively in noisy construction environments, thereby improving model completeness. Additionally, by overcoming the limitations of existing tools, we elevate radar scanning simulation from the traditional 2D (such as the MATLAB Driving Scenario Designer) to 3D, and accurately track and record the spatial areas that can be captured within the scan range.

Experimental results show that this path planning method exhibits high adaptability, allowing adjustments based on different laser radar performance characteristics (such as scanning range and installation position). Moreover, the algorithm iteratively optimizes the path to minimize scanning blind spots, enhancing the coverage of the laser radar and consequently obtaining denser point cloud data, providing a more comprehensive data foundation for building inspections.

Abstract -

In response to the challenges in the assembly process of prefabricated buildings and the pursuit of sustainable construction, this paper proposes an industrial robot arm teleoperation method based on mixed reality (MR) technology. Traditional assembly processes that rely on manual installation face challenges such as operator safety issues, and high energy consumption. Our proposed method utilizes MR technology to achieve immersive and remote control and uses Optimal Resolved Acceleration (ORA) and Resolved Acceleration Control (RAC) to complement the shortcomings of Resolved-Rate Motion Controller (RRMC) by introducing compliance control to enhance environmental adaptability and telemanipulation accuracy. The aluminum profile assembly and precision testing experiments have shown the feasibility and accuracy of this method. The MR teleoperation framework allows for compliance control, and despite some noise, the robotic arm exhibits good accuracy. Future work will focus on expanding task complexity, improving system accuracy, integrating intelligent functions, and exploring scalability for large-scale construction projects.

Mixed Reality; Teleoperation; Robotic arm; Prefabricated Building; Sustainable Construction

1 Introduction

In recent years, with the increasing global industry attention to sustainability, integrating low-carbon and environmental practices into the construction industry has become a focus. For example, the European Union continuously updates its Building Energy Efficiency Directive, requiring building projects to standardize carbon emission management from design to construction to operation and maintenance, and transform them into environmentally friendly projects. Industry and market demand are also driving the construction industry to transition towards low-carbon operations.

Prefabricated construction refers to transferring a large amount of on-site work from traditional construction methods to factories, where building components and accessories (such as floor slabs, wall panels, stairs, balconies, etc.) are processed and manufactured, transported to the construction site, and assembled and installed on site through reliable connection methods. Compared to traditional buildings, buildings using prefabricated components can reduce greenhouse gas emissions by 8.06%. In addition, using alternative green concrete materials in the prefabrication process of prefabricated buildings can reduce the total greenhouse gas emissions by 2.83-12.05% [1]. Xiang [2] also pointed out that the construction industry has caused a significant amount of carbon emissions worldwide. The adoption of prefabricated buildings has reduced the industry's environmental pressure. The comparison between prefabrication methods (such as assembly) and traditional in-situ casting methods shows that in all categories of influence, prefabrication methods have greater environmental advantages than traditional methods [3].

Although prefabricated structures have many advantages compared to traditional construction techniques, there are still many disadvantages in the assembly process. Due to differences in operational proficiency and on-site conditions, prefabricated buildings often and energy. In order to solve the above problems, this article proposes a teleoperation method for industrial robot arms based on mixed reality technology, which is used for assembly work in prefabricated buildings. This method enables us to detect hand displacement and angle deflection through MR devices while wearing them, and accurately control the robot arm to make responsive actions to complete assembly work. Compared to using cranes and manual assembly methods. This method can complete assembly work more accurately and quickly while maintaining low carbon emissions. In order to solve the challenge of realizing slosh-free assembly in the assembly process of prefabricated buildings and improve the efficiency and accuracy of the assembly work and the computational efficiency of the slosh-free assembly trajectory under the condition of real-time feedback, ORA and RAC with compliance control algorithm is proposed. This algorithm introduced the compliance matrix into the existing motion controller to make the robot arm perform the assembly task more

smoothly and naturally[4]. Ensure that the robot arm can not only meet the accuracy of assembly without shaking in the condition of human-computer interaction, but also reduce the vibration and impact caused by rigid movement, further improving the response ability to external forces. This method supports remote assembly by experienced workers, avoiding the cost increase and additional carbon emissions associated with personnel mobility. In addition, it can replace operators in some extremely dangerous situations and still accurately and effectively complete assembly work, ensuring the safety of construction personnel.

This article mainly consists of six parts: we begin by discussing introduction, followed by related work of this study. The methodology for implementing the article will be presented in the third section. The experimental verification of the technology and the analysis of the results are presented in the fourth and fifth parts, respectively. The final section includes a summary of this study and plans for future research work.

2 Related work

The integration of mixed reality (MR) technology enriches and enhances collaborative experiences by seamlessly merging digital and physical elements. For instance, MR systems empower operators to engage with both digital and physical environments, thereby reducing redundant hardware and maximizing workspace efficiency [5]. MR technology amalgamates the strengths of AR and VR, augmenting user immersion and facilitating interaction with holographic physical devices within the real environment. This enables humans to remotely operate robotic arms, significantly mitigating the environmental footprint associated with substantial human resource deployment. Moreover, immersive systems diminish the necessity for construction industry operators to travel, consequently reducing the carbon footprint linked to transportation. Case in point, the Australian company GRAINTECH has implemented Microsoft's HoloLens mixed reality technology to enhance remote assistance and collaboration, reportedly slashing travel expenses and carbon emissions by 68% [6]. This showcases the potential of MR technology in reducing the need for physical travel and lowering the carbon footprint. The MR remote control method can also prevent humans from working in extremely dangerous situations, improving worker safety and work efficiency [7].

MR remote-controlled robots have achieved considerable success in assembly tasks. Takahashi [8]proposed a virtual reality-based robot teaching interface, offering a user-friendly environment where novice operators can effortlessly instruct robots. Robots in the workplace replicate the actions of operators within a virtual workspace to perform assembly tasks. Jarecki and Lee [9] introduced a mixed reality (MR) user interface (UI)-based system device that supports the remote operation of mobile robotic arms. Their findings suggest that MR-based UIs may be perceived as more intuitive by operators compared to conventional control interfaces. Zhang et al. [10] integrated collaborative robots with mixed reality technology to achieve human-machine collaborative assembly, enhancing assembly efficiency and presenting a novel and viable assembly model for the intelligent collaborative assembly of large-scale and complex spatial products.

In the operation scenario of an industrial assembly line, the robot arm must be able to accurately control its motion trajectory and speed. Although the current research on gesture-based building robot control has been relatively abundant. However, in this dynamic environment, it is difficult to ensure that the assembly slosh-free when moving rapidly due to inertia. Humans need special skills to perform tasks efficiently without shaking. Therefore, how to balance the agility of the robot arm and the maneuverability in slosh-free, and improve the assembly accuracy and efficiency is an important challenge. We can improve the agility of the robot system by designing advanced control methods, so that the robot arm can achieve superhuman slosh-free motion. In addition, in the case of real-time feedback, the calculation of slosh-free trajectory requires a lot of computational resources, so the design of an efficient optimized solver is also crucial. To solve these problems, this paper proposes a solution based on conformance control algorithm ORA (Optimization trajectory algorithm) and RAC (real-time adjustment algorithm). The algorithm is improved on the basis of ORA and RAC, and the compliance matrix is introduced to ensure the high precision and efficiency of the robot arm during assembly. The tolerance of the robot arm to the rigid external force is enhanced, so that the worker's operation is safer and smoother. This approach greatly facilitates remote assembly by experienced workers, significantly reducing safety risks and the additional carbon emissions associated with too many workers.

3 Methodology

The methodology integrates Mixed Reality (MR) technology with advanced motion control algorithms to enhance robotic arm manipulation. It employs Transmission Control Protocol/Internet Protocol (TCP/IP) [11] for Unity [12]and xArm 6 communication [13], ensuring synchronized movements. Data transmission aligns position and rotation data, minimizing operational gaps. The system was first introduced by the Resolved-Rate Motion Controller (RRMC), improved with the Optimal Resolved Acceleration (ORA) algorithm for precision control in the context of assembly, and finally combined with compliance control for adaptability. The framework (as shown

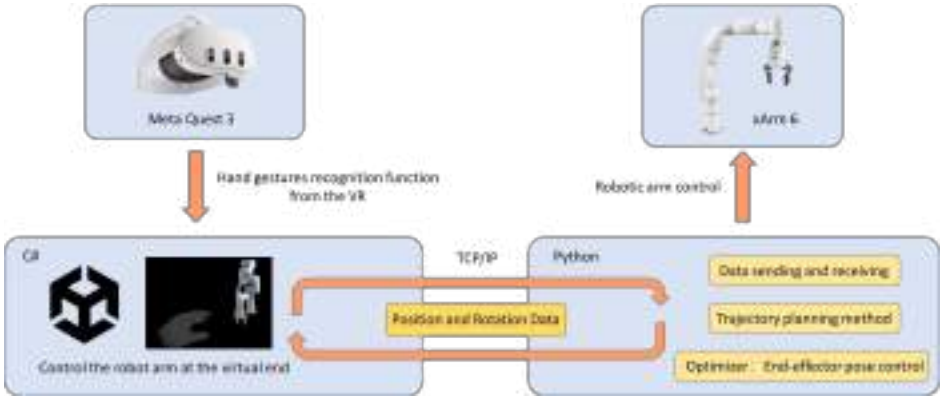

Figure 1. The workflow of the communication between Unity and xArm-6

in Figure 1) aims to improve assembly accuracy and efficiency while maintaining low carbon emissions, in line with sustainable building goals.

3.1 TCP/IP Connection

As depicted in Figure 1, the TCP/IP connection method was used in this study primarily to fulfil the communication function between Unity based on C # and xArm 6. Python implemented both the sending and receiving of control information, as well as the optimization functions of xArm 6. The objective was to transmit the data of hand recognition coordinates and attitude angles (position x, y, z, and rotation x, y, z) data provided by Meta Quest 3's SDK function in the VR headset and Unity scene to the xArm 6, with which a control connection had already been established, through the specified IP address and port, thus achieving the control of the real end (xArm 6) by the virtual end (Unity and VR). Meanwhile, the target angles of each link of the robotic arm could also be reversely transmitted to Unity through the PyCharm end to control the movement of the virtual xArm 6 model, thus realizing the control of the virtual end by the real end.

3.2 Data Transmission

The hand gesture recognition technology (i.e. pinch interaction) in VR equipment captures the spatial coordinates of the five fingers and the palm's center point. The palm's center point data is used to map the end-effector of the robotic arm, enabling precise control of its position and rotation. The pinching distance (spatial separation between fingertips) is directly mapped to the gripper aperture, where a smaller distance corresponds to a narrower gripper closure, providing intuitive control.

In the data transfer module, a calibration coefficient of 1000 is applied to position data in Python to align Unity's meter (m) units with Python's millimeter (mm) units. This ensures that the actual displacement values remain aligned between the two systems. For large industrial robotic arms, this coefficient can be adjusted to handle tasks like automobile assembly, where precise positioning of large components is required. The robotic arm's motion is controlled using coordinate and attitude rotation differences between consecutive frames, enabling accurate trajectory tracking based on real-time hand position and orientation changes.

3.3 Manipulator motion control and trajectory optimization

3.3.1 Resolved-Rate Motion Controller (RRMC)

For attitude control at the end of a robotic arm, we first introduce Resolved-Rate Motion Controller (RRMC) [14]. This is a closed-loop attitude controller that is applied directly to the robotic arm as a first-order differential equation to generate the motion trajectory of the end-effector with velocity-level commands.

$$\mathbf{T} = \begin{bmatrix} r_{11} & r_{12} & r_{13} & t_1 \\ r_{21} & r_{22} & r_{23} & t_2 \\ r_{31} & r_{32} & r_{33} & t_3 \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{1a}$$

$$\rho(\mathbf{T}) = \begin{bmatrix} r_{11} & r_{12} & r_{13} \\ r_{21} & r_{22} & r_{23} \\ r_{31} & r_{32} & r_{33} \end{bmatrix} \tag{1b}$$

$$\tau(\mathbf{T}) = \begin{bmatrix} t_1 \\ t_2 \\ t_3 \end{bmatrix} \tag{1c}$$

where $\rho(\mathbf{T}) \in \mathbb{R}^3$ constitutes the rotation component, $\tau(\mathbf{T}) \in \mathbb{R}^3$ constitutes the translation component.

The translation and rotation of the end effector with respect to the difference between the current attitude and the desired attitude is represented by the error vector e:

$$e = \frac{\tau\left({}^0T_{e^U}\right) - \tau\left({}^0T_{e^R}\right)}{\alpha\left(\rho\left({}^0T_{e^U}\right)\rho\left({}^0T_{e^R}\right)^T\right)} \in \mathbb{R}^6 \tag{2}$$

Figure 2. Hand gesture recognition points for the teleoperation

where ${}^0T_{e^R}$ is the end effect pose in the base frame, ${}^0T_{e^U}$ is the desired end effect pose in the base frame. $\alpha(\cdot)$: **SO**(Special Orthogonal Group) $\in \mathbb{R}^3$ turns rotation matrix into an equivalent Euler vector.The Euler vector specifies the rotation axis and rotation angle.

The v in the RRMC equation is determined by the error e, when $v = ke$ and k is the proportional gain term. We limit v to some value v_m by modifying the magnitude of the proportional gain term k until the error e drops below some value e_m:

$$v = \begin{cases} k_e \frac{v_m}{||k_e||} & \text{if } ||k_e|| > v_m \\ k_e & \text{if } v_m \geq ||k_e|| > ||e||_m \\ 0 & \text{otherwise} \end{cases} \tag{3}$$

The RRMC ensures that the error decreases at the same rate until the speed gradually decreases to a smooth stopping of the arm.

3.3.2 Optimal Resolved Acceleration (ORA) with Resolved Acceleration Control (RAC)

RRMC relies more on the computation of Jacobi matrices and pseudo-inverses to deal with external forces and constraints indirectly through pliability matrices and avoids dealing directly with constraints arising in the system, leading to controller degradation. To solve this problem, we introduce quadratic programming techniques to achieve the desired results. Quadratic programming (QP) can transform the RRMC into an optimization problem and quickly generate the optimal control strategy in a short time. As a general optimization algorithm, it can provide additional functions directly in the formulation of RRMC and show good results when dealing with equality, inequality and cost constraints. Therefore, QP applied to the control of a robotic arm is a quadratic planning process that includes the physical constraints of the whole system, and does not encounter the problem of generating very high control speeds due to the presence of non-square and rank-loss Jacobi matrices.

In addition, RRMC, as a first-order differential equation, generates motion trajectories only at the velocity-level command. Precise positioning and trajectory tracking of the robotic arm is achieved by accurately controlling the acceleration in response to rapidly changing task demands and environmental conditions. For the required accuracy in the context of assembled buildings, we can introduce Optimal Resolved Acceleration (ORA) for optimization. ORA is primarily concerned with optimizing the acceleration of the robot, and is usually formulated through a quadratic programming problem with formulas that contain the cost terms for acceleration and velocity, as well as velocity and acceleration constraints in the task space. At the acceleration-level command, optimal joint accelerations and velocities are found by minimizing the cost functions of acceleration and velocity.

We use the resolved acceleration control (RAC) method, which maps the acceleration command $u_a(t)$ in the task space to the joint space [15]:

$$u_j(t) = [q(t),\ \dot{q(t)}, \ddot{q(t)}] \tag{4}$$

By direct application of second-order differential equations at the acceleration-level command, an optimal control problem under constraints is solved in each iteration to ensure the feasibility of the joint configurations. For an intial joint space configuration $u_j(t) = [q(t),\ \dot{q(t)}, \ddot{q(t)}]$, in each iteration of the QP solution, acceleration command $\ddot{x_d}$ and kinematics contraints of robotic arm can be showed:

$$\min_{q,\dot{q},\ddot{q},\delta} [q, \dot{q}, \ddot{q}, \delta] P [q, \dot{q}, \ddot{q}, \delta]^T \tag{5a}$$

Contraints:

$$q = q_0 + \dot{q}_0 \Delta t \tag{1}$$

$$\dot{q} = \dot{q}_0 + \ddot{q} \Delta t \tag{2}$$

$$\ddot{x_d} + \delta = J_0 \ddot{q} + \dot{q_0} \bigotimes H_0 \dot{q_0} \tag{5b}$$

where $P \in \mathbb{R}^{27\times27}$, Δt is time-step, $J_0 = J(q_0)$, $H_0 = H(q_0)$.

The introduction of slack variables $\delta \in \mathbb{R}^6$ to the task-space controller in the minimization of the acceleration command $\ddot{x_d}$, when the variables include $q, \dot{q}, \ddot{q}, \delta$, ensures that the optimal control problem is reachable to an optimal solution. The slack variable δ is in the cost function and is activated only if the acceleration command u_a does not satisfy the kinematic constraints. For ease of understanding and computation, we rewrite the objective function:

$$\min V(\ddot{q}) = \ddot{q}^T P \ddot{q} + \dot{q}^T Q \dot{q} \tag{6a}$$

Constraints:

$$\ddot{x_d} = J(q)\ddot{q} + \dot{J(q)}\dot{q} \quad (6b)$$

$$\dot{x_d} = J(q)\dot{q} \quad (6c)$$

where $\dot{x_d}, \ddot{x_d}$ are desired mission space velocity and acceleration.

Both P and Q are positive definite matrices used to weight the cost of joint acceleration and velocity.

For the first part of the optimization objective of the objective function $\ddot{q}^T P\ddot{q}$, minimizing joint acceleration $\ddot{q}$ and controlling acceleration amplitude.

For the second part of the optimization objective of the objective function $\dot{q}^T Q\dot{q}$, minimizing joint velocity $\dot{q}$ and controlling velocity smooth.

3.3.3 Compliance Control and Environmental Adaptability

Since we need to meet accuracy not only in the context of assembly-type building installation, but also in applications where humans collaborate with robotic arms, or operate in uncertain environments, we introduced suppleness control to robotic arm operation to avoid collisions and injuries.

In order to enhance the compliance, a compliance matrix S is introduced into the objective function $V(\ddot{q})$. This compliance matrix S, weighs the relationship between joint acceleration $\ddot{q}$ and end-actuator acceleration $\dot{x_d}$ while enhancing the collaborative capability of the robotic arm. The objective function $V(\ddot{q})$ can be modified as:

$$\min V(\ddot{q}) = \ddot{q}^T P\ddot{q} + \dot{q}^T Q\dot{q} + (\ddot{x} - \ddot{x_d})^T S(\ddot{x} - \ddot{x_d}) \quad (7a)$$

Constraints:

$$\ddot{x_d} = J(q)\ddot{q} + \dot{J(q)}\dot{q} \quad (7b)$$

$$\dot{x_d} = J(q)\dot{q} \quad (7c)$$

where $\dot{x_d}, \ddot{x_d}$ are desired mission space velocity and acceleration. For the compliance matrix S, which reflects the weight of the system on the end-effector acceleration error. S as a symmetric positive definite matrix for tuning the sensitivity of the system to different directional pliability:

$$S = \mathrm{diag}(\lambda_x, \lambda_y, \lambda_z) \quad (8)$$

where $\lambda_x, \lambda_y, \lambda_z$ denote the weights on the acceleration errors in Cartesian space for the three directions, respectively. When $\lambda_x, \lambda_y, \lambda_z$ is small, the system is less sensitive to errors and exhibits a higher degree of suppleness; conversely, it exhibits rigidity.

In human-robot collaboration, the compliance matrix S can be dynamically adjusted to enhance the compliance and adaptability of the robotic arm according to environmental demands. The compliance matrix S can also be combined with an impedance control strategy to further improve the responsiveness of the robotic arm to external forces.

3.4 Apparatus

3.4.1 Manipulator

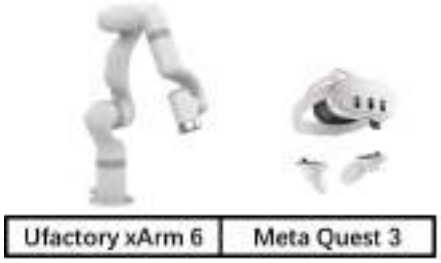

Figure 3. Hardware required for the teleoperation

In order to verify the feasibility of our approach to this control, we chose a robotic arm of the xArm 6 model from Ufactory as shown in Figure 3 . It has high load and accuracy, with a maximum load of 5kg and repeatability of ±0.1mm. xArm-Python-SDK provides a complete Python interface, which makes it easy for researchers to quickly get started and perform new algorithms. Compared with other industrial robots, xArm 6 is less expensive and more cost-effective. Therefore, this approach was used to validate the feasibility of the control method proposed in the paper.

3.4.2 Teleoperator

Meta Quest 3 (Figure 3) supports 6 Degree of Freedom (DoF) tracking function with excellent motion tracking performance. It is capable of accurately capturing the user's movements with an average latency of only 12 milliseconds, which enables natural and smooth interactions, allowing us to manipulate the virtual objects and carry out experimental simulations in a more precise way, improving the accuracy and efficiency of scientific research.

4 Experiment

The experimental section provides a detailed introduction to two key experiments: aluminum profile assembly based on MR teleoperation framework and robot arm trajectory accuracy testing. The aluminum profile assembly experiment demonstrated the effectiveness of the remote control framework in controlling the construction of assembly tasks for the robotic arm. The trajectory accuracy test of the robot arm evaluates its accuracy by comparing its trajectory with the trajectory of the hand. The results indicate that although there are some errors in the accuracy of the robotic arm trajectory, the overall control accuracy

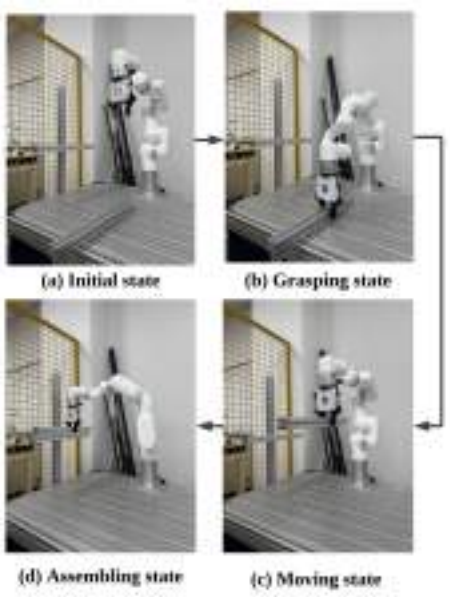

Figure 4. The teleoperation of assembling aluminum profiles. Subfigure (a) represents the initial position of the robotic arm, at which point there is no movement of the robotic arm. (b) illustrates that robotic arm received instructions to clamp the aluminum profile. Subfigure (c) shows arm moves according to the trajectory of the hand. And (d) presents the state that robotic arm completes the assembly process.

is considerably high. Both experiments emphasize the potential of remote operating systems in sustainable building practices.

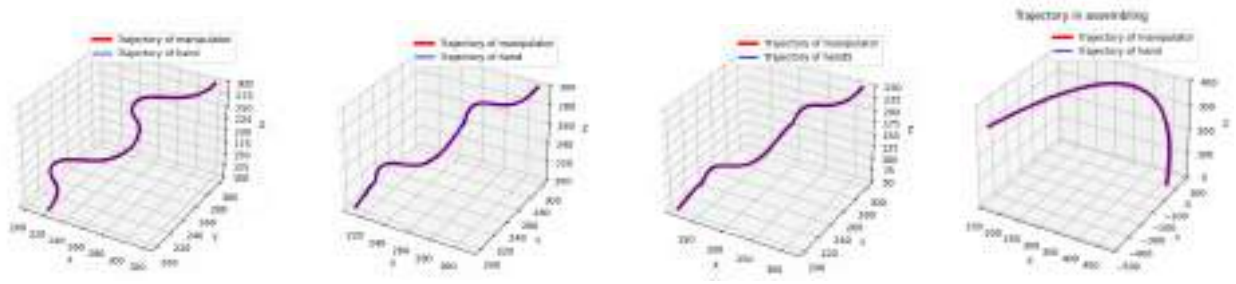
4.1 Aluminum Profile Assembly

To explore whether a robotic arm can replace human labor to perform various assembly tasks, it is necessary to test its flexibility. When the robotic arm is operated using the MR telecontrol frame, it is tested whether the robotic arm can assemble the components as flexibly as the traditional assembly method. For this purpose, a small experiment was designed to use the MR device to manipulate the robotic arm to pick up aluminum profiles on the workbench and place them on a shelf built from aluminum profiles. The experimental process is shown in the Figure 4 .

The key to this experiment is to observe whether the robot arm can complete the task quickly and flexibly. If the robotic arm is able to complete the task successfully, then the framework is feasible and the assembly task will not be affected by remote control or MR interaction. This manipulation method can be further tested to manipulate larger industrial robotic arms to accomplish some assembly tasks.

(a) (b) (c)

Figure 5. Movement of the manipulator and hand during the assembly process: (a) The robotic arm is controlled via hand interaction using MR-based gesture recognition to clamp aluminum profiles. (b) The robotic arm follows the trajectory of the hand interaction to move to the designated location. (c) Completion of the assembly task by the robotic arm.



4.2 Accuracy test

Another measure of teleoperation of robotic arms to replace humans in completing assembly work is accuracy, as robots need to fully follow the operator's hand movements to complete task responses. The higher the precision, the higher the success rate of the robot arm in completing assembly work. In this experiment, MR equipment will be used to detect three different human-demonstrated paths (experiment $\boldsymbol{a}$, $\boldsymbol{b}$ and $\boldsymbol{c}$ shown in Figure 5). In experiments, the operator's hand will operate the robotic arm within a reasonable range to draw different trajectories. Then observe whether the trajectory generated by the robot arm is consistent with the trajectory of the hand. The degree of overlap between two trajectories is the precision of control.

5 Result and Analysis

5.1 Result of Aluminum Profile Assembly

As shown in the Figure 5 , the operator finally controlled the robotic arm to successfully complete the assembly work of the aluminum profile. This indicates that the MR teleoperation framework can flexibly control robot arms to complete simple assembly tasks. In addition, setting aside various physical controllers, the control method of directly detecting the position and state of the hand is also more convenient for operators to understand its control mode. We extracted 200 points from the hand trajectory and robotic arm trajectory of each group of experiments, and then calculated the offsets of adjacent two points on the X, Y, and Z axes in turn. Then, the distance threshold is set, and the offset error between the trajectory of the manipulator and the trajectory of the hand is smaller than the threshold, which Indicates that the two trajectories are aligned In this study, the distance threshold was set

(a) (b) (c) (d)

Figure 6. Trajectory comparison of human-demonstrated paths and robotic manipulator replication under various conditions. Subfigures (a), (b), and (c) illustrate three distinct trajectories demonstrated by hand movements using MR-based remote control of a robotic manipulator. The trajectories executed by the manipulator (red lines) are compared against the original human-demonstrated trajectories (blue lines) to evaluate precision and alignment accuracy. (d) presents the trajectory comparison during an assembly task, where the manipulator replicates the trajectory of grasping aluminum profiles.

at 0.5mm. The experimental results also show that the remote control scheme has a delay of less than 400 ms, and the main reason for the delay is the network delay, and the coincidence between the hand trajectory and the robot arm trajectory reaches 96%. However, the assembly work in the experiment was too simple and unitary, so more experiments are needed to explore whether the robotic arm controlled by the scheme can help workers complete the assembly work in high-risk or extreme environments.

5.2 Result of Accuracy test

As can be seen in the Figure 6 , the trajectory of the robotic arm essentially coincides with the trajectory of the hand. The table 1 also shows the overlap of the two trajectories in each set of experiments.The higher overlap among the three groups indicates that the robot arm has a certain degree of accuracy. In Experiment ***a***, the overlap between the two trajectories reached 97%, and in Experiments ***b*** and ***c***, the overlap between the two trajectories also reached 92% and 94%, respectively. This means that the manipulator can use this control method for more precise control. From the figure, it can be seen that there is some noise in the hand trajectory, which may be introduced by the MR device when detecting the position and posture of the hand. However, after optimizing the motion control algorithm of the robot arm, the trajectory of the arm became smoother. This indicates that using this control framework, the robot arm also has a certain degree of noise resistance, which can avoid shaking caused by noise.

Experiments	Accuracy
a	97%
b	92%
c	94%
Trajectory in assembling	96%

Table 1. Accuracy of manipulator

6 Conclusion and Future work

In this study, we propose an industrial robot arm teleoperation method based on mixed reality technology for assembly work in prefabricated buildings. Through the integration of TCP connection, data transmission and advanced motion control algorithm, xArm 6 robot arm and Meta Quest 3 are used to carry out the feasibility analysis of this control method, and the aluminum profile assembly experiment and accuracy test are carried out.

The experimental results show that the MR teleoperation frame can effectively and flexibly control the robot arm to complete simple assembly tasks. This direct detection of the position and status of the hand control mode, for the operator to understand and operate the system provides convenience. However, current assembly tasks do not fully demonstrate the complexity of assembly tasks, so further experiments are needed to explore the full potential of robotic arms in supporting and assisting humans with difficult assembly tasks.

In the accuracy test, the robotic arm has a certain accuracy, and its trajectory is very consistent with the trajectory of the hand. Although there is some noise in the hand trajectory, which may be introduced by the MR Device during the hand position and attitude detection process, the motion control algorithm optimization of the robot arm effectively smooths its trajectory. This shows that the control frame makes the manipulator have the ability to resist noise and avoid jitter.

Future work will focus on several key areas. Firstly, our goal is to increase the complexity and diversity of assembly tasks to more comprehensively evaluate whether robotic arms have the potential to help humans in assembly

tasks. This will involve testing a wider range of building components and assembly scenarios. Secondly, in order to improve the accuracy and efficiency of assembly work, efforts will be made to enhance the accuracy and stability of the system. This will require further optimization of motion control algorithms and calibration of MR devices to minimize errors and noise. Finally, we plan to explore the integration of more intelligent features, such as real-time obstacle detection and avoidance, to improve the safety and reliability of robotic arms in building environments [16].

Abstract –

The introduction of innovative robotics to the traditional construction processes involves complex and multi-dimensional interfaces that could hinder effective technology implementation. This paper aims to identify potential interface problems between construction robots and traditional construction processes, and propose effective strategies for interface management. Drawing on a case study of the implementation of an overhead drilling robot in Macao, the findings indicate various issues related to physical, contractual and organizational interfaces and their causes associated with the integration of construction robots. In particular, contractual interface problems were identified as the most critical factors affecting the real-world application of robots in construction. This highlights the importance of developing new business models and fostering collaboration among stakeholders through innovative contract forms. The developed innovative interface management framework for construction robots provides valuable insights for future research and practice to understand and manage complex interfaces between robots and traditional construction processes. The paper should contribute to the better implementation of robots in construction.

Keywords –

Construction robot; Interface management; Drilling robot; Engineering management

1 Introduction

Construction robots, often refer to sophisticated and intelligent machinery designed for construction processes with robotic features, are emerging as a cutting-edge solution that could address many challenges confronting the industry [1]. The first on-site construction robot was developed by the Japanese Shimizu company for spraying surface materials in the 1980s [2], followed by diverse construction robots springing up during the 1990s. Consequently, many prototypes of single-task robots have been developed in the construction industry, such as those for concrete finishing, wall painting, and ceiling board installation, providing evidence of the potential of robots to assist in performing dangerous, dirty, and difficult construction jobs [3]. Recently, research has also embarked on more general-purpose or human-assisted robotics in construction, such as aerial robots, robotic exoskeletons, collaborative robots and humanoid robots [4, 5].

Previous works have contributed to the development of construction robots and demonstrated technological and economic feasibility in specific cases [6]. However, robots have yet to experience large-scale, real-world implementations in construction. There are still doubts regarding how robots will outperform humans in construction and what new problems they might introduce [4, 7]. One major barrier hindering the effective implementation of robots in construction is the complex interfaces between robots and traditional construction processes. However, there is still limited exploration of these interfaces and how they can be effectively managed.

This paper fills the above knowledge gap by achieving three objectives: 1) identifying the potential challenges related to the complex interfaces between robots and traditional construction processes; 2) examining causes of interface problems; and 3) proposing strategies for effective interface management. The research is based on a case study of a pilot trial of an overhead drilling robot in Macao, drawing on the classification of the interfaces into physical, contractual and organizational (PCO) dimensions [9].

2 Background

2.1 Interface Management in Construction

The term ‘interface’ generally refers to the soft or/and hard interaction of entities (e.g., products, people) with boundary limits [8]. In construction, Pavitt and Gibb (2003) [9] argued that interfaces between different elements and components cause most problems and highlighted the importance of interface management.

Interface management is critical to project success, as it could directly or indirectly affect the time, cost and quality performance of a construction project [10]. Wideman [11] defined it as '*managing the problems that often occur among people, departments, and disciplines rather than within the project team itself.*' Construction Industry Institute (CII) [12] defined it as '*management of communications, relationships, and deliverables among two or more interface stakeholders*'. The effective implementation of interface management could enhance construction processes, reduce the occurrence of rework, and shorten the overall construction period [10].

Earlier research has identified interface problems that emerge in traditional construction projects due to the complex and fragmented nature of the construction industry [13]. In particular, poor communication and coordination among project stakeholders have been widely recognized as key issues leading to interface problems like design errors and construction conflicts [14]. Recent studies examined the problematic interfaces in modern construction methods, like prefabricated and modular construction [15, 16].

However, limited empirical research has investigated interface problems from the adoption of construction robots. The introduction of robots as a disruptive technology to the traditional construction processes often involves complex interfaces and triggers new interface problems. To unleash the full potential of robots in construction, it is essential to understand the potential interface problems and develop effective interface management strategies.

2.2 Physical, Contractual and Organizational Interfaces of Robots in Construction

There are different ways to understand interfaces and interface management. From a systems perspective, interface management can be categorized into four types: time, relational, information, and environmental [17]. Additionally, Pavitt and Gibb [9] classified three types of interface management within construction as physical, contractual and organizational. Specifically, physical interfaces refer to the actual physical linkage between two or more building elements or components; contractual interfaces relate to how the work packages involving processes and people have been formed from a contractual basis; organizational interfaces indicate managerial interactions related to individual and/or group relationships. Building upon Pavitt and Gibb's categorization [9], this research examines the complex interfaces from the three dimensions, with a specific focus on the integration of construction robots.

Physically, the implementation of robots on construction sites necessitates careful consideration of spatial constraints, adaptability to diverse and complex work environments, and the potential impact on construction personnel and existing infrastructure.

Contractually, the introduction of robots could affect traditional contracting and subcontracting practices and result in new issues related to obligations, liabilities, and profitability.

Organizationally, the integration of robots will change the existing workflows, roles, and responsibilities of various parties on construction sites, which require organizational adjustments, such as redefining job roles and fostering an innovative culture to embrace change.

3 Methodology

The research design is illustrated in Figure 1. Initially, a critical literature review was conducted using databases including Web of Science, Scopus, and Google Scholar, with keywords related to "construction robotics" and "interface management". The review aims to examine the application challenges of construction robots and explore the potential interface problems, which enables the preliminary analysis of physical, contractual and organizational (PCO) interfaces of robots.

Then, a case study of the implementation of an overhead drilling robot in Macao was carried out to further analyze the PCO interface problems between the drilling robot and traditional construction processes. The case study utilized multiple sources of evidence, including documents, researchers' observations of the actual application of the robot through site visits, and 7 semi-structured interviews with key stakeholder groups covering principal contractor and mechanical, electrical and pumping (MEP) subcontractors. The interviewees were purposefully selected considering their direct involvement in the case of the drilling robot and work experience in the industry, including 1 project director, 2 project managers, 1 site manager and 3 technical staff. The interview questions were semi-structured, combining both open and closed-ended questions to gather comprehensive insights into the interface problems associated with robot integration. In particular, the interviewees were asked to provide their perspectives on what specific interface problems they encountered, why these problems occurred, and their suggestions for addressing these challenges. Each interview lasted for approximately 20-30 minutes. The data collected from the case study were analyzed using the NVivo 15 software.

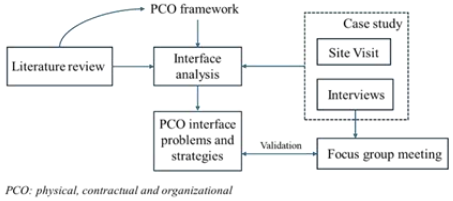

Figure 1. Research design

Finally, the initial findings identified from the case

study were further validated through a focus group meeting with the previous interviewees.

4 Case Study Results and Analysis

4.1 Case Background

The case study was conducted with a pilot trial of an overhead drilling robot applied on the construction site of a residential building project comprising 1,566 residential units. The project is in the form of an Engineering Procurement Construction (EPC) contract in which the MEP work is carried out by various subcontractors. The pilot trial was initiated by the principal contractor, while the robot was responsible for the drilling tasks involving MEP engineering.

The overhead drilling robot utilized in the case study project is a semi-automatic construction robot (Figure 2), with a flexible robotic arm for drilling tasks mounted on a mobile vehicle. It is specifically designed for MEP and interior installation work, which is often strenuous, challenging, and time-consuming for construction workers. In the studied case, the operator was an electrician with one hour of training.

During the construction process, the operator needs to move the robot to the designated work area via a controller and utilize a total station for positioning purposes. Then, within the achievable area, the robotic arm can automatically drill holes for one or multiple MEP subcontractors based on the design data from AutoCAD or Revit.

Figure 2. The overhead drilling robot

Compared with traditional manual-based methods, the drilling robot can offer several distinct advantages. For instance, it can eliminate potential risks associated with overhead installation and conduct vacuuming operations during drilling for improved occupational health and safety. Moreover, the robot can enhance productivity and efficiency by autonomously marking and drilling holes according to digital plans.

4.2 Interface Analysis

Drawing on the case project, the identified PCO interface problems, potential causes, and key stakeholders are shown in Tables 1 to 3, and elaborated in the following subsections.

4.2.1 Physical Interfaces

The implementation of the drilling robot may lead to physical interface problems between robot and operator/worker, site environment, and built structure.

Between robot and operator/worker: During the drilling process, human errors by robot operator (e.g., accidentally touching and displacing the total station) may result in construction deviations. Additionally, cross-work and collaboration between the robot and construction workers from multiple trades are inevitable, potentially leading to physical contact and associated problems.

Between robot and site environment: The dynamic and complex construction site presents significant challenges for the robot performance, particularly regarding their interfaces with site environment. For example, as one interviewee noted, "*due to the high reliance on the total station, when facing a space/room with many obstructions, operators must perform multiple positioning operations for the robot, which greatly reduces its efficiency.*"

Between robot and built structure: The robot's primary function is to drill holes in the built structure to meet the installation requirements of MEP engineering. Consequently, it will inevitably encounter the built structure. The robot may face physical interface problems with the rebar or pre-built piping inside the structure and with the finished paint on the surface.

To summarize, potential causes for physical interface problems mainly include the lack of technological maturity of the robot (such as limited mobility, flexibility, and adaptability) and poor engineering management.

4.2.2 Contractual Interfaces

When work elements are grouped into different work packages to meet the needs of the principal contractor, new contractual interfaces may arise between work packages, typically involving specialist contractors [10]. The introduction of the drilling robot may create contractual interface problems in terms of work package reassignment and liability attribution among stakeholders.

Work package reassignment: The drilling robot is designed for a single task with the aim of integrating all MEP drilling tasks, while in the case project, these tasks were undertaken by separate subcontractors. This necessitates the adjustment of relevant tasks at the contract level, which led to contractual interface problems among the principal contractors and MEP subcontractors. Furthermore, due to the limited coverage, areas that the robot cannot reach need to be drilled by workers, which also requires contractual reassignment of work packages.

Table 1. Identified physical interface problems and potential causes

Category	Physical interface problems	Potential causes	Key stakeholders						
			PC	MEP	P	A	S	O	W
Between robot and operator/ worker	• The robot operator or worker may accidentally touch and displace the total station, which could result in localization errors for the robot, potentially leading to subsequent drilling errors	• The localization of the drilling robot highly relies on the total station; no mechanism to avoid or alarm its displacement	√	√				√	√
	• The drilling robot might introduce new risks (e.g., injury) to co-workers	• Workers' unfamiliarity and incompetence in working with the robot	√				√		√
Between robot and site environment	• The drilling robot requires relocalization for different rooms/spaces with obstacles (e.g., columns, walls), resulting in a long setup time	• There should be no obstructions between the drilling robot and the total station	√	√			√	√	
	• Special arrangements are required for the drilling robot to move in a dynamic site environment with steps	• The drilling robot has limited mobility	√	√			√		
	• The drilling robot is incapable of adjusting drilling to construction errors (e.g., discrepancies between actual construction and drawings)	• The robot can't recognize and address construction errors and uncertainties; poor construction management	√			√	√		
	• Uneven ground can affect the drilling quality and accuracy of the robot	• The drilling robot has limited adaptability	√	√			√		
Between robot and built structure	• The robot is unable to make flexible adjustments of drilling when encountering rebar in the structure to meet subsequent MEP installation requirements	• The drilling robot has limited flexibility	√	√			√		
	• The robot may damage the surface of the structure or pre-built piping during drilling	• The drilling robot has a low intelligence level	√	√			√		
	• The drilling robot may cause damage or pollution to the completed ceiling and floor paint	• Lack of measures to protect finished painting for the previous process	√		√			√	

Note: PC = principal contractor; MEP = MEP subcontractor; P = painting subcontractor; A = architect; S = robot supplier; O = robot operator; and W = Worker.

Table 2. Identified contractual interface problems and potential causes

Category	Contractual interface problems	Potential causes	Key stakeholders						
			PC	MEP	P	A	S	O	W
Work package reassignment	• The drilling robot will integrate all drilling requirements of MEP works that are assigned to different subcontractors under separate contracts, with unclear responsibility	• There is no large subcontractor that can provide an integrated MEP engineering solution in Macao	√	√			√		
	• The drilling robot may have limited coverage and require supplementary work by MEP workers	• The robot is unable to access narrow spaces and corners for drilling	√	√			√		√
Liability attribution	• The drilling robot may cause delays (e.g., robot breakdown, maintenance) in project schedule and result in claims	• Improper planning and scheduling with the use of robots	√	√		√			
	• The liabilities are unclear among stakeholders for the drilling errors of the robot due to improper construction works (e.g., uneven ground, construction deviations, problems with drawings), operator mistakes or robot performance that may incur rework and additional cost	• Immature business models	√	√	√	√	√	√	
	• The introduction of the drilling robot necessitates the implementation of additional measures and agreements (e.g., reserve dedicated channels, coordinate working areas) to guarantee robot operating performance	• The drilling robot is integrated into traditional construction as a new element and role	√	√	√		√		

Note: PC = principal contractor; MEP = MEP subcontractor; P = painting subcontractor; A = architect; S = robot supplier; O = robot operator; and W = Worker.

Liability attribution: As a new role introduced in construction sites, the drilling robot requires additional measures and attention to ensure its functional operation. Moreover, factors such as limited robot performance, poor project management, immature business models and improper construction works could result in the misuse of robot that cause project delays, rework, and even additional costs and contract breaches. These circumstances often involve multiple stakeholders in the attribution of contractual liability.

Based on the case study, many respondents considered contractual interface issues as the most critical factors affecting the practical application of robots. Specifically, these issues involve the complex reassignment of tasks and liability attribution resulting from the integration of robots. This could lead to contractual misunderstandings and disputes, and affect the profitability of stakeholders and the overall efficiency of the construction process. Consequently, these challenges could hinder the widespread adoption of robots in the construction sector.

4.2.3 Organizational Interfaces

The implementation of the drilling robot on construction sites involves multiple stakeholders, with various organizational interfaces forming during the communication and collaboration process at project, government and industry levels.

At the project level, with the introduction of the robot and the integration of drilling requirements, the original workflows and responsibilities within the project have been altered, potentially leading to organizational interface issues, such as difficulties in coordination and communication between organizations. Additionally, poor management may result in worker idleness with the introduction of robots on site.

At the government level, the early stages of robot development are characterized by funding shortages and a lack of relevant regulations and standards. Moreover, respondents have argued that the absence of government support in economic and policy aspects significantly hinders the widespread adoption of robots in construction.

At the industry level, organizational interface problems usually involve all stakeholders. These challenges are primarily reflected in industry resistance to adopting robots, which may be driven by a lack of innovative culture. Potential risks posed by robots, such as employment concerns, present additional challenges in the industry.

Table 3. Identified organizational interface problems and potential causes

Category	Organizational interface problems	Potential causes	Related key stakeholders						
			PC	MEP	P	A	S	O	W	G
Project level	• Robotic integration of MEP drilling involves multiple stakeholders, which has more coordination difficulties and is vulnerable to communication problems	• Lack of management and coordination between multiple stakeholders	√	√	√	√	√			
	• There could be worker idling issues during the operation of the drilling robot	• Inexperience of the management team in work arrangements involving robots	√	√					√	
Government level	• There are new legislation and regulation related issues (e.g., additional time for permit approval) with the introduction of the drilling robot	• The development of robots is still in its early stages and lacks standards and practice	√				√			√
	• The drilling robot involves high initial costs, while its development and adoption lack government support and incentives	• The development of robots is still in its early stages and lacks economic justification	√				√			√
Industry level	• The drilling robot may pose a threat to employment opportunities and salaries of workers	• The introduction of the drilling robot will increase efficiency and reduce the need for manual labor	√	√					√	√
	• Multiple stakeholders may have resistance to the adoption of the drilling robot	• Lack of innovative culture and acceptance of new technology	√	√	√	√	√	√	√	√

Note: PC = principal contractor; MEP = MEP subcontractor; P = painting subcontractor; A = architect; S = robot supplier; O = robot operator; W = Worker; and G = government.

4.3 Strategies for Interface Management

Based on the identified interface issues and their causes associated with the integration of construction robots, several strategies are proposed on the technical, contractual and organizational aspects for different stakeholders.

Technical strategies are mainly focused on the design and development of robots to avoid or address technical interface problems, which are particularly important for robot suppliers, including:

- Improve the adaptability and mobility of robots to better interact with unstructured, dynamic and complex construction site environments.
- Enhance the flexibility of robots to handle uncertainties and a variety of construction tasks.
- Design more user-friendly and collaboration-enabled interfaces to allow robots to effectively work with people in a conflict-free manner.

Contractual strategies primarily concern the need to adjust existing contractual arrangements among principal contractors and subcontractors, including:

- Adjust and optimize contracts to reasonably allocate work packages and improve liability attribution. This includes clarifying the new roles and responsibilities of stakeholders considering the introduction of robots and ensuring that contractual terms align with their work requirements.
- Develop new business models to address the potential conflicts and claims arising from robot-related performance issues, foster collaboration among stakeholders with pain/gain mechanisms and better integration.

Organizational strategies primarily consider the requirement of the government and principal contractors' efforts in project management, policy implementation and innovation culture creation to address organizational interface problems, including:

- Principal contractors should embrace potential robot-incurred issues into existing project management practice and enhance the coordination among various stakeholders.
- The government should accelerate the formulation of relevant legislation, regulations and standards to clarify the roles and responsibilities with the introduction of robots in construction. Government support and incentives should be provided during the initial phases of robot development to encourage research and trial projects.
- The industry should cultivate a culture of innovation to increase the acceptance of robots, and take measures to address the potential risks (e.g., worker unemployment) associated with robot integration.

5 Discussion

This paper conducted a case study on the interfaces between the overhead drilling robot and traditional construction processes from PCO perspectives. By analyzing and summarizing the interface problems, their corresponding causes, and preventive strategies, a PCO interface management framework for construction robots is proposed, as shown in Figure 3.

The research has identified potential interface problems when introducing robots in construction environments. Firstly, limitations in the robot's adaptability, intelligence level and collaborative ability impact its performance in the construction process. This results in numerous physical interface problems, primarily occurring between robots and operators/workers, construction site environments, and existing built structures. Secondly, the contractual interface problems, which are identified as the most critical factors affecting the practical application of robots, mainly involve the reassignment of work packages and the attribution of contractual liabilities. On the one hand, the introduction of the robot integrates traditional tasks in a different way, which incurs changes in work processes and requires the reassignment of subcontractors' work packages. On the other hand, potential issues (e.g., rework, project delays) caused by robots require a determination of contractual liability attribution. Finally, organizational interfaces mainly occur among different organizations or individuals. Factors such as poor communication and collaboration, as well as the lack of clear regulations and standards, may lead to interface problems at the project, government, and industry levels. These findings echo with previous studies to highlight the importance of developing new business strategies and stakeholder networks to promote the implementation of construction robots [18].

The findings further indicate the complex interactions among PCO interfaces. Firstly, physical interface problems can affect the contractual interface. For instance, the mobility limitations of the drilling robot in the studied case necessitated the establishment of a dedicated working channel, requiring supplementary contract clauses. Conversely, modifications to the contractual interface can lead to the regrouping of certain work elements into new work packages, which may involve different subcontractors and result in changes in physical interfaces. For example, integrating the drilling tasks using the robot could create additional physical interfaces between the robot and MEP subcontractors. Secondly, both physical and contractual interfaces can influence organizational interfaces. Physical interface problems (e.g. worker idling) can intuitively reflect issues in communication and collaboration between organizations. Meanwhile, contractual interface issues, such as conflicts and liability attribution, can negatively

affect inter-organizational collaboration and organizational profitability. Finally, effective coordination of organizational interfaces can address problems related to physical and contractual interfaces, such as coordinating work areas and adjusting contract terms.

This study adapts the PCO classification for interface management in the construction field [9, 20] and pioneers the research of interface management for construction robots. While previous studies mainly focus on technical challenges of construction robots in the implementation [19], this research emphasizes the underlying interface problems in the contractual alignment and division of work that could hinder the real-world application of robots in construction. The developed framework enriches the previous studies by specifying the interface elements and illustrating the complex interrelationship among multi-dimensional interfaces, which contributes to both knowledge fields of interface management and construction robots.

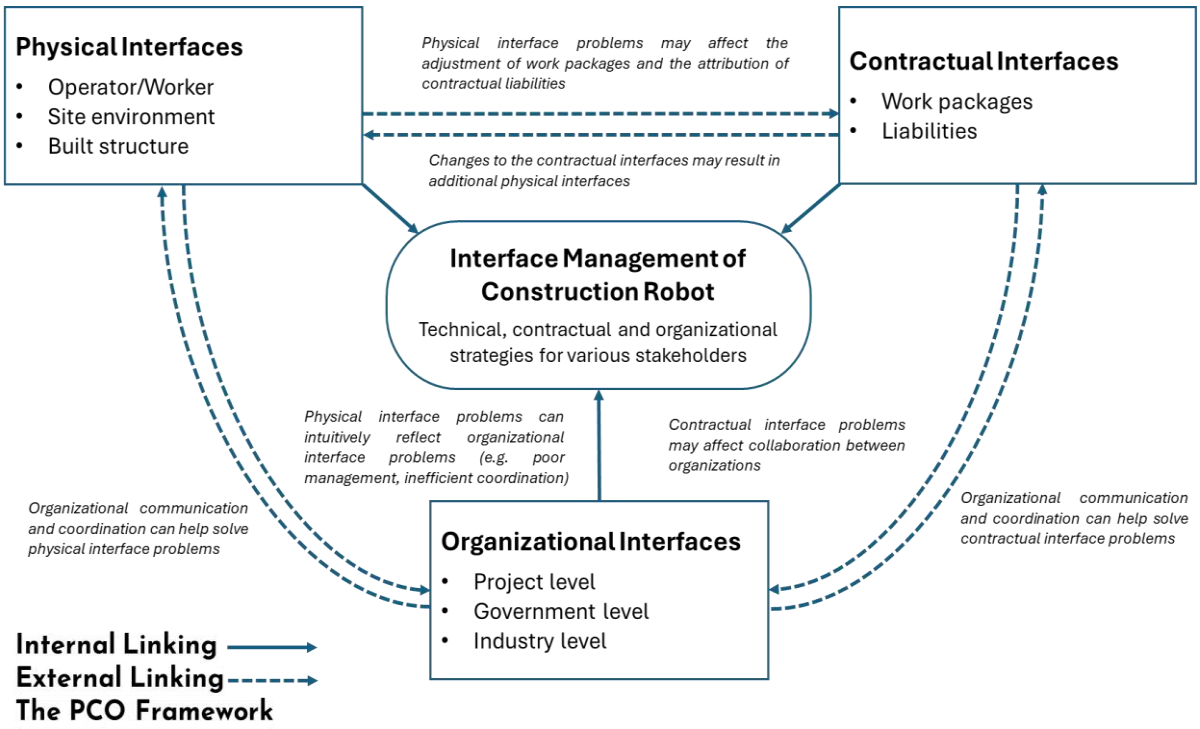

Figure 3. PCO interface management framework for construction robots

6 Conclusion

This paper investigates the interface management of construction robots through a case study of an overhead drilling robot by examining the interface problems, potential causes and preventive strategies. The findings reveal complex interface issues emerging between robots and traditional construction processes, leading to an innovative PCO interface management framework for construction robots. In particular, contractual interface issues are highlighted as the most critical factors hindering the implementation of robots, including work package reassignment and liability attribution. The findings further highlight the importance of developing new business models and stakeholder collaboration schemes with innovative contract forms to address the interface problems involved in construction robot implementation and support effective technology uptake.

This research contributes to the literature on interface management in the construction industry by proposing an innovative framework for interface management specific to construction robots. The PCO framework offers a new theoretical foundation for understanding the complex interfaces with the integration of robots in construction, and provides valuable insights for the industry and academia to address the interface problems derived from the implementation of construction robots. Future research can extend the research by incorporating a broader range of construction robots. Further research can also apply the framework in different institutional contexts to improve its generalizability.

Acknowledgments

We acknowledge funding support from the University of Macau (File no. SRG2023-00006-FST). We also would like to express our sincere gratitude to China Construction Engineering (Macau) Company Limited for their support in the case study.

Abstract –
The Canadian construction industry faces challenges in accessing remote sites, resulting in logistical and environmental issues. Robotic construction, especially in situ or on-site assembly with industrial robots, offers a promising solution. This paper explores the feasibility and impact of on-site fabrication and construction (OSF&C) by performing a scaled down simulation with two UR5e Universal Robots. The study utilizes additive manufacturing (AM) for key construction elements to achieve increased performance. The case study involves the fabrication of a complex pentagonal-cross section bridge structure consisting of foam beams and 3D-printed brackets. The methodology includes detailed description of the fabrication and stacking procedures, material handling optimization, and human-robot interaction. The study proposes a scaled-down robotic simulation approach, which is then used to evaluate production consistency and time, demonstrating the benefits of utilizing additive manufacturing into OSF&C.

Keywords –
On-site robotic construction, additive manufacturing, industrial robots, human-robot collaboration, construction simulation, sustainability.

1 Introduction

In the Canadian construction industry, a key challenge extends beyond just a labour shortage to difficulties in accessing remote construction sites. The conventional construction approach often entails transporting workers and materials to remote or difficult-to-reach locations, resulting in greenhouse gas emissions (GHG), logistical challenges, and potential project delays. Addressing this predicament necessitates innovative solutions.

The realm of robotic construction has undergone significant exploration and adoption in recent decades. A rapidly expanding literature field of robotics in construction has made significant progress in automating field equipment and adopting robots from other industrial sectors for construction purposes (e.g., drones), and robots customised for the construction industry [2].

While robotic construction has been utilised for constructing modular building components off-site, the transportation of these pieces to the construction site contributes to high GHG emissions. An alternative approach involves on-site construction with the assistance of robotic arms, offering the potential to reduce transportation costs and environmental impact. Industrial robots, known for their flexibility, precision, speed, and cost-effectiveness, can navigate challenging areas. This has spurred increased research into novel applications of robots in construction methods, such as TIM proposed by ETH Zurich, wherein a dual robotic arm platform was used to manufacture modular wooden panels on-site, which were then assembled into the elaborate BUGA Wood Pavilion [3].

Robotic construction emerges as a promising alternative to traditional methods, particularly in situations where on-site assembly poses challenges. Off-site construction, involving the assembly of modular components in a factory, can decrease transportation frequency and distance to challenging sites, thus lowering GHG emissions during the construction phase of the project. However, substantial transportation costs and environmental impact persist when moving modules to construction sites [4].

On-site robotic construction, as opposed to off-site construction, employs mobile robotic fabrication platforms to assemble raw construction materials into modules in close proximity to the construction site. This approach circumvents the need to transport prefabricated modules and large teams of workers to remote sites, cutting down on associated GHG emissions and total project time and cost. Industrial robots, known for their flexibility, precision, speed, and cost-effectiveness, can operate in challenging environments, especially in areas with difficult access. This approach aims to facilitate the on-site assembly of modular components using a robotic

arm, which will be assembled to create a larger, complex structure. On-site robotic construction can be even further improved with AM utilization. AM is a collection of manufacturing technologies which deposit materials layer by layer to build parts based on a digital solid model in an entirely computer-controlled manner [1]. AM broadly enables more design flexibility and complexity while reducing material waste, providing two invaluable advantages in a remote construction environment.

This paper presents a method for rapidly evaluating the feasibility and performance of novel on-site robotic construction methods by using a scaled down simulation with two robotic arms. The potential for an AM enabled on-site robotic construction approach is explored, and the advantages and limitations of the scaled down simulation are discussed.

2 Literature Review

The construction industry has changed significantly with the advent of robot-automated construction, and while robotic construction automation is not yet ubiquitous in the field, many high-level studies have predicted that it has significant potential to expand the capabilities of the industry where traditional methods have stagnated [5], [6]. The McKinsey Global Institute survey found that globally, labour productivity growth in construction lagged far behind similar sectors and the overall economy [7]. Robot arms and autonomous vehicles are being employed to perform tasks traditionally carried out by human labour, enhancing precision, efficiency, and safety.

An interesting approach within this paradigm is the exploration of on-site robotic construction, which leverages robotics and automation directly at the construction site. While off-site fabrication is the conventional approach when applying robotic automation to the construction industry, it comes with many challenges such as transportation costs, logistical complexities, and limitations in design flexibility. The need for assembly and installation post-delivery can introduce delays and offset project timelines. Recent comprehensive review studies highlight the benefits of on-site robotic construction, including reduced construction time, lower transportation costs, and the ability to adapt to site-specific challenges such as irregular terrain or constrained spaces [8], [9].

Distributed In-Situ robotics, a rapidly evolving area in construction technology, has been explored through several notable projects at institutions like MIT Cambridge and ETH Zürich [3], [10]. This work demonstrates the advantage of on-site construction, emphasising the elimination of transportation-related issues, reduction in project lead times, and the ability to address site-specific constraints more effectively compared to off-site methods. Its design allows for flexibility and mobility on construction sites, enabling it to perform tasks in various locations without being confined to a fixed setup. This robotic system has been used effectively for tasks like stacking timber elements, demonstrating its capability in handling construction materials with precision [11]. Similarly, the "Digital Construction Platform" from MIT Cambridge is another transportable robotic platform. It's not just mobile but also versatile in its functions. This platform has been used for stacking bricks, among other tasks, showcasing its adaptability in different construction scenarios. The ability of these platforms to move around and perform tasks autonomously marks a significant advancement in construction methodologies, allowing for more efficient, precise, and cost-effective building processes [12].

The incorporation of AM (commonly referred to as 3D printing) technologies in on-site robotic construction presents a novel avenue of research. AM enables rapid fabrication of and design iteration of high complexity structures both in traditional off-site fabrication, as well as directly at the construction site. When applied to the on-site construction automation framework, it can further reduce the need for traditional prefabrication and assembly and improve the flexibility of the automation workflow by allowing for rapid design iterations. Recent work by Paolini et al. [13] highlights the benefits of integrating 3D printing/additive manufacturing in on-site robotic construction, including enhanced design freedom, reduced material waste, and the ability to create complex geometries with ease. A variety of AM technologies including selective laser sintering (SLS), wire arc additive manufacturing (WAAM) and material extrusion, have been applied in case studies to manufacture structural components, with steel and concrete being the most common materials [14].

One compelling reason to integrate 3D printing in on-site construction is the unparalleled design flexibility it offers. Many studies on the adoption of AM in the construction industry [15]–[18] emphasise how AM allows for the creation of bespoke structures, tailored to meet specific project requirements, surpassing the limitations of traditional construction methods. The utilization of AM also aligns with sustainability goals by minimising material waste. Studies by Javid et al. [19] and Ghaffar et al. [20] showcase how 3D printing enables precise material usage, reducing environmental impact and contributing to sustainable construction practices.

Altogether, the benefits of on-site construction compared to off-site fabrication, along with the unique advantages offered by 3D printing, provide a compelling case for combining both technologies in the constructions industry.

3 Research Objectives

Our research designed and executed a scaled down robotic simulation as a case study to evaluate the following aspects of an OSF&C scenario:

- How can a scaled down simulation of an on-site construction environment be used to explore how robots will perform modular fabrication tasks with restricted motion and human collaboration?
- How does utilization of AM affect the OSF&C workflow (complexity, speed, flexibility, etc.)?

4 Methodology

A case study is often essential for examining methods of robotic construction. The simulation employs digital twin software for path planning and utilizes two Universal Robots (UR5e) to construct a complex geometric structure incorporating additively manufactured parts. For this research project, a case study involving a complex geometric structure was developed as a key component. The fabrication and construction processes are iterated multiple times to facilitate further analysis of robotic adaptability, production performance, and human-robot interactions as part of the research effort.

The design structure, as illustrated in Figure 1 below, consists of several pentagon frames connected by lateral beams. The pentagon pattern is specifically chosen to increase the difficulty of the fabrication process. The overall structure shape can be conceptualised as a bridge or a tower. The following sections provide an overview of the simulation sequence, materials used, fabrication platform and details about the fabrication and construction procedures.

4.1 Simulation Sequence

The sequence of the simulation involved fabrication and construction, and each was taken care of mainly by each robot. The overall sequence involves the following five steps as listed below, and as shown in Figure 2 steps:

- Steps I and II are carried out exclusively by the fabrication robot. These two steps assemble a module of the structure. Minor human labour is involved with these two steps.
- Step III is completed through collaboration of two robots. In this step, the fabrication robot will indirectly lift and position the assembled module to be transported by the construction robot.
- Step IV is completed solely by the construction robot. Immediately after completion of Step III, the construction robot will stack the assembled module to another at the designated location. Human labourers will aid the stacking processes. If the stacked module is not the third, then the process will repeat from Step I again.
- Step V is the end of the process where three modules are stacked successfully by the construction robot. Both robots then move back to home position.

4.2 Materials Used

4.2.1 Brackets

The main functional component of the scaled-down bridge structure was a set of 3D printed brackets which were designed to hold together the members at each vertex. The brackets use AM because it enables them to be produced on-site with great design flexibility and efficiency. The bridge was held together by 20 of these brackets. Figure 3D Shows various batch sizes which were considered for printing – printing a large batch on the 60x60cm build area Modix Big 60 was avoided because if the batch of 19 failed, it would set the project back significantly. Instead, the brackets were printed out of PLA on an Ender 3 printer and an Ender 5 Plus FDM printer in batches of 2 and 5, respectively. Notable print settings for the brackets included the use of a 0.6mm nozzle and a relatively large layer height of 0.32 mm. The prints took roughly 8.5 hrs for a batch of 2, and about 28 hrs for a batch of 5. The full collection of 20 brackets was printed and post-processed over the course of two weeks. While desktop FDM printing was a suitable stand-in for this relatively small-scale project, more expensive AM

methods could be used in the field to obtain industry grade print performance.

Detailed views of the bracket design are shown in Figure 3A-C. The parts were modelled in Fusion 360 and are easily modified for various beam sizes. The brackets adhered to common principles of Design for Additive Manufacturing (DFAM), which minimised use for support structures, reduced print time, and improved quality control. The brackets have a large first layer with no excessively sharp corners in order to provide a stable first layer that will not delaminate. The brackets have no overhangs above 50-degrees, resulting in no support structures. This reduces both print time and waste. Notches were introduced to the brackets to securely grip the structural members, enhancing the connection. These notches added complexity to the part but did not add any manufacturing time to the print, taking advantage of the unique design benefits of AM. The parts were designed to fit onto an assembly platform in a pentagonal shape before inserting and joining the members. Connections on the bracket were designed so that during this stage, the robot could use force sensing to find the inner surface with the member before inserting it. This utilization of 3D printed brackets into the bridge structure increased design flexibility and reduced material waste.

4.2.2 Beams

For our simulation, all structural members were fabricated from FOAMULAR NGX F-150 2.54cm thickness foam insulation due to their combined price point, strength, and ease of cutting and shaping. The horizontal beams that made up the pentagonal cross sections (Figure 4G) had dimensions of 2.54cm x 9cm x 24cm, while the vertical beams that connected the pentagonal cross sections to each other (Figure 4F) had dimensions of 2.54cm x 10cm x 30cm. Notably, the corners of the beams were chamfered to increase the clearance during insertion, improving the ease of assembly for the robot arm.

4.3 Fabrication Platform

The base robot workspace consisted of one Universal Robots UR5E robot arm and a flat acrylic panel acting as a workbench. A key modification to this setup was the addition of a customised fabrication platform, which fit into the upper right side of the workbench as illustrated in Figure 4.

The assembly process takes place on the assembly base, which was integrated into the assembly platform for the following objectives:

1. Facilitate the assembly by incorporating guides on the surface to assist in placing fabrication materials and securing them once in place (Figure 4d). The 3D printed brackets are designed to fit snugly onto these guides (Figure 4A), improving consistency during assembly.
2. Minimise movement of materials during the assembly. The dimensions of the assembly base were designed to fit one side of the workstation well, restricting movement in three directions during assembly. This, combined with the guides, significantly reduces the potential movement of materials (Figure 4C).
3. Facilitate assembled module transfer. The design allows freedom of movement once the base (Figure 4E) is lifted by the assembly robot (Figure 4B). With an assembled module on top, the base can be lifted and tilted by the assembly robot to a designated transport position (Figure 4H). After transporting the module out of the base, the base can be de-elevated to the assembly position, ready for the next assembly process.

The assembly base represents a scaled-down version of an assembly table with customisable guides, which can be rapidly reconfigured to meet assembly requirements for a diverse range of projects. In practical terms, this assembly base can be mechanised and programmed to optimise the assembly procedure, resulting in higher degree of automation and time savings.

Figure 4: Above) the robotic workstation setup showing the pentagonal fabrication stage and the stacking stage. Below) a closeup of the assembly platform.

4.4 Fabrication Procedure

Fabrication of each module involves Stages I and II: pentagonal cross section assembly and lateral beam insertion. To begin the assembly, the fabrication robot will pick each bracket at the time and place it to the designated location. Once all brackets are placed on the platform, placement of ring beams between each pair of brackets commences, forming the pentagon ring shown in Figure 5A. Lastly, lateral beams are inserted into the designated slot of each bracket. A finished module model is shown in Figure 5C.

The material placement is facilitated by having the guide placed on the assembly base and deploying the universal robot advanced functions Insertion and Finding Surface. These combinations were optimised through iterations to minimise collision potential and trim fabrication time. Section 8 will further discuss this topic.

4.5 Construction Procedure

The on-site construction task is simulated by the second robot. The robot transports the assembled module from the assembly base at the transport position for modular stacking process (Stage III).

The stacking procedure (Stage IV) varies depending on the order of the module. For the first module, the robot places it at the ground of the designated area, and then returns to its neutral position. For the second and third, the robot firstly positions the module directly on top of the other module already placed, at approximately 2 to 3 cm. This is followed by a momentary pause to allow human labour to physically examine whether the precision toleration is met. Once clearance is granted, the robot proceeds to lower the module to a final contact position, while the lateral beams of the module slide into the designated slots of the previous module. Once the final position is reached, the robot pauses while human labour inspects the connection between modules and enhances if necessary. Once connection is verified secure, the robot releases the module and returns to its home position ready for stacking the next module.

Figure 5: Fabrication and construction procedure. a) First robotic arm lifts the assembly platform for easier access. b) the second robot pick the pentagon structure off of the platform. c) the second robot completes a cycle by stacking the pentagonal unit

5 Material Handling Optimization

In assembling the pentagon, beams of two different sizes, crafted from identical materials, are employed. These are paired with 3D-printed joints, their number matching the pentagon's edges, ensuring each beam connects to a joint. The specific spots for situating the pentagon are marked out on a foam base. Accompanying this, a 3D model is crafted, featuring an added female plug to match a corresponding male plug on the foam base, based on these markings. Additionally, for ease of assembly, the longer beam, which is oriented vertically, is shaped to fit more seamlessly into the pentagon structure, aiding the second robot arm in its assembly task. The secure contact between modules is achieved by:

- Engineered connection design: The 3D printed brackets have special features within the slot where the beams slide into making the connections. Notches are designed into the brackets, which bite into the foam material of the beams, securing them in place. This eliminated the need for adhesives or fasteners and reduced prototyping time.
- Additional reinforcement by human labour: a human labourer can choose to insert a thin shim (approximately 5 mm thick) between the bracket slot and the beam upon detection of a loose connection.

6 Path Planning and Collision Avoidance

Collision avoidance is one of the biggest challenges in the on-site construction environment due to the limited working area available and complexity of managing moving equipment, vehicles, and workers in close proximity. For this study, digital twin simulation software RoBIM was explored to plan waypoints and simulate robot maneuverer to achieve collision avoidance. RoBIM uses the modified A* algorithm to find a collision-free path between consecutive waypoints [21]. Manual waypoints were entered into the software to assist the path finding calculations. The planned pathways were examined both in simulation and in real life. Manual adjustments were made to improve overall placement efficiency. During simulation, high collision potentials were found to be associated with the lateral beam placement. Placement sequencing was optimised to avoid collision by prioritising the beams furthest from the material loading area and therefore effectively reducing the number of obstructions for the subsequent beams.

In addition to RoBIM, manual programming was utilised for the module transport phase and stacking phase, because RoBIM was unable to simulate collaboration between two robots and moving part groups. Manual programming involved examination of pick and place pathways, material placement sequencing optimization, addition of intermediate waypoints along the pathway if necessary. Each material pick-and-place manoeuvre was carefully examined to analyse collision potential with the placed material on the assembly as well as the robot body. The stacking process was also found to have high collision potential, and the collision avoidance is mainly achieved by incorporating additional waypoints along the path to maintain sufficient clearance.

7 Human Robot Collaboration (HRC)

The fabrication and construction processes of this study attempted to limit HRC required, because control of the HRC timing can optimise productivity and reduce health and safety risks to human labour. It is also because the scaled-down environment cannot properly simulate full-scaled HRC. The forces exerted by workers in the scaled-down environment cannot be proportionally adjusted for a real-world scenario. Additionally, the inspection time and reinforcement used to connect components do not scale appropriately, as the actual time required in a full-scale setting depends on the workers' skills and the size of the workforce. Moreover, in a real-world environment, additional health and safety protocols would be necessary to ensure worker protection.
